Marine Metabolites and Metal Ion Chelation: The Facts and the Fantasies

By Joseph P. Michael and Gerald Pattenden*

The marine environment is a seemingly inexhaustible treasury of organisms whose secondary metabolites bear witness to the lavishness and inventiveness with which nature is able to manipulate molecular architecture. But to what purpose are these diverse and often grotesque compounds produced? This review is founded on the premise that some of them may be involved in the uptake and transport of metal ions present in the aquatic milieu. Many metabolites produced by terrestrial organisms are known to act as ionophores, but the case for similar behavior by their marine counterparts is far hazier. Notwithstanding the relative abundance of certain metal ions in the oceans, and of metabolite structures possessing features that should facilitate the chelation of metal ions, few attempts to establish a connection between these two phenomena have been reported. We have whittled down the voluminous literature of natural products derived from marine sources to expose a core of observations and speculations germane to our premise. These facts and fantasies are evaluated in this review. A mere handful of metal-containing complexes has actually been isolated; furthermore, attempts to prepare such complexes in vitro are rare, and spectroscopic evidence for metal–metabolite interactions, whether in vivo or in vitro, is not common. Only with the vanadium-sequestering tunichromes does a logical (but by no means complete) picture begin to emerge. In several other cases, the plausibility of metal chelation, though mooted by authors, remains unsupported by experimental evidence. However, continuing efforts to obtain structural, and particularly conformational, information on the metabolites by means of X-ray crystallography, nuclear magnetic resonance spectroscopy, and molecular mechanics calculations would seem to provide the key to a rational approach to this neglected topic. On the basis of recent studies dealing with such structural aspects, we present a selection of candidate compounds, some of which are the targets of our own synthetic attentions, whose potential for binding to metal cations merits further research.

1. Introduction

To the chemist familiar with terrestrial secondary metabolites having structures that tend to conform to securely established biogenetic postulates, many natural products from marine sources must seem quite freakish. Unexpected and bizarre molecular architecture, unusual functional groups, stereochemical quirks—these all challenge one's perception of nature as a machinist working to cunning but time-honored patterns. Yet why should marine metabolism mimic terrestrial metabolism? Indeed, a recent review lists several cogent reasons why we should expect significant differences in the biosynthetic pathways that operate on land and in the

sea.[1] For example, the marine environment, though teeming with life forms, is a biosynthetically bleak one. The oceans may be comparatively rich in carbon, buffered as they are to pH 8.2–8.5 with carbonate and bicarbonate, but few organisms other than algae can exploit this carbon source photosynthetically. Other customary nutrients such as amino acids and sugars occur only at the parts-per-billion level; and nitrogen, available principally as the ammonium or nitrate ion, tends to be a limiting nutrient. It comes as no surprise, therefore, that metabolites of marine plants and animals may be formed very slowly, and in only trace amounts. The metabolites that the organisms are capable of manufacturing despite these handicaps are thus all the more awesome in their variety.

On the other hand, the oceans, while inhomogeneous, contain substantial quantities of dissolved inorganic salts; indeed the salinity may reach levels as high as 40%.[2] Chloride, bromide, bicarbonate, and sulphate ions account for the larger part of the anionic species. Common metal cations, e.g. sodium, potassium, magnesium, and calcium, reach concentrations above 10^{-3} M, while most other metal ions, including important trace elements such as vanadium, manganese, iron, cobalt, copper, zinc, and molybdenum, occur in concentrations below 10^{-6} M. Some consequences of the ionic constituents, such as the occurrence of chloro and bromo groups in certain marine metabolites, are therefore readily comprehended. Altogether more subtle, however, is the effect of the metal ions. Their interaction with marine organisms in the external milieu (uptake and accumulation) has been reviewed,[3] and is not at issue here. Furthermore, the indisputable physiological role of certain metals in the intracellular medium, a phenomenon of immense biochemical importance,[4] is also not an issue. For us as chemists, the most intriguing feature is the possible relationship between metal ions and the secondary metabolites. Many marine natural products seem to have structural features that make them ideal for interacting with metals, for example, polar functional groups in potentially chelating arrangements, macrocyclic cavities and geometries apparently tailor-made for wrapping around metal ions. Yet the grounds for supposing that such interactions really exist are by and large so tenuous that few researchers who publish in the field of marine natural products venture so much as a sentence on likely roles for metal ions in either the chemistry or the biochemistry of these compounds.

Can marine metabolites sequester and transport metal ions in vivo? Do metal ions provide a convenient template for biological assembly of the metabolites? Could metal–ligand complexation play a part in the pronounced biological activity of many of the compounds? Might in vitro studies of interactions still provide revealing results even if mutual in vivo effects prove elusive? These are some of the perhaps ingenuous but nonetheless provocative questions that provided the inspiration for this review. We entered this arena as practising synthetic organic chemists, interested in two specific families of structurally novel and biologically important marine metabolites: 1) the ulapualide group of trisoxazole-containing macrolides, for example **82**, found in nudibranchs (sea slugs) and sponges (see Section 7.6),[5] and 2) the thiazole/dihydrothiazole/dihydrooxazole-containing lissoclinamide family of cyclic peptides (**76**–**78**), produced by tunicates (sea squirts) of the genus *Lissoclinum* (see Section 7.5).[6] In our research, and in this review, we have explored an intuitive hypothesis of congruence between metals and marine metabolites. Structural analogies with well-explored terrestrial metabolites, especially polyether antibiotics and siderophores, for which the phenomenon has often been convincingly documented,[7] led us to hope that we could uncover similar information for their marine counterparts.

We began by first compiling a short-list of potentially ligating species from the thousands of known marine metabo-

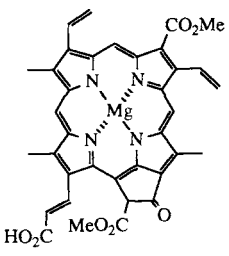
Gerald Pattenden is Sir Jesse Boot Professor of Organic Chemistry at the University of Nottingham. He recieved his PhD from Queen Mary College, London University, in 1966, and in the same year he was appointed to a lectureship at University College, Cardiff. In 1972 he moved to Nottingham and was made Professor in 1980. His research concentrated on total synthesis of natural products and the discovery and design of new synthetic methods in Organic Chemistry. He has recently initiated studies of molecular recognition and metal transport phenomena with natural macroheterocycles, cyclic peptides, and siderophores.

Born and educated in South Africa, Jo Michael received his PhD degree in 1975 from the University of the Witwatersrand, Johannesburg. He spent two years as a post-doctoral research fellow with Dr Ian Fleming at Cambridge University before returning to his alma mater as a lecturer in 1978. He is currently Associate Professor in the Department of Chemistry. His interests in the synthesis of natural products and in synthetic methodology have taken him on sabbatical leave to the University of California, Berkeley, where he collaborated with Professor Paul A Bartlett (1984), and more recently to the University of Nottingham (1991–92).

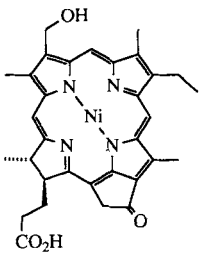
lites described in the literature.[8] We excluded those examples in which the metal ion is present merely as a counterion for anionic residues such as carboxylate and sulfate. The more than 300 publications dealing with the compounds on our short-list were then scrutinized for even the slightest comment relating to interactions between the marine metabolites and metals, or to structural studies that might have a bearing on the topic. A slim core of facts emerged, accompanied by an equally insubstantial collection of fantasies that a handful of authors had been brave enough to voice. Our interpretation of our readings reflects the perspectives of two somewhat naive organic chemists who sense that an opportunity for significant research is being overlooked. We air these impressions in the hope that researchers in the field may find in them the incentives to start remedying what we perceive as a deficiency in contemporary chemistry.

2. The Isolation of Complexes of Marine Metabolites with Metals

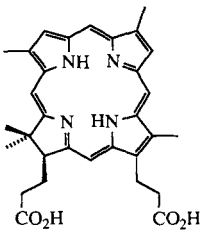
The least disputable evidence for the interaction of marine metabolites with metals must come, of course, from the direct isolation of metal-containing complexes. Such complexes, other than the ubiquitous magnesium-containing chlorophylls *a* and *b*, are rare indeed. The new chlorophyll c_3 (**1**), from the alga *Emiliana huxleyi*,[9] is hardly a startling addition to the catalog. Far more exciting is tunichlorin (**2**), a nickel-containing blue-green pigment from the tunicate *Trididemnum solidum*.[10] The function of the nickel, which can be replaced under laboratory conditions by copper(II), is as yet unknown. A cautionary note must be sounded, however: metal-containing porphyrinoid pigments from marine sources may be the exception rather than the rule, since the number of related compounds isolated in metal-free form is significantly large. In addition to the well-known pigment bonellin (**3**), associated with defence and larval masculinization of the echurian worm *Bonellia viridis*,[11] recent isolations of metal-free tetrapyrrole marine metabolites include



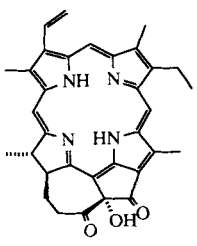
1



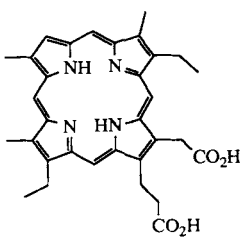
2



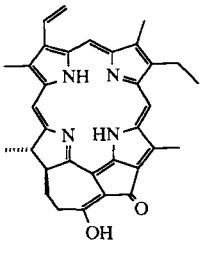
3



4



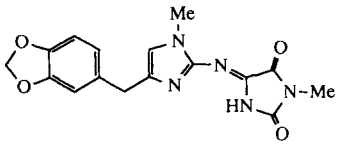
5



6

chlorophyllone-A (**4**) from the mollusc *Ruditapes philippinarum*,[12] corallistin A (**5**) from the demosponge *Corallistes* sp.,[13] and cyclopheophorbide enol (**6**) from the sponge *Darwinella oxeata*.[14] These compounds are certainly capable of forming metal complexes; as long ago as 1939, zinc, copper, and iron complexes of bonellin were prepared,[15] and more recently a zinc complex of corallistin A has been characterized.[13]

The unusual guanidine alkaloid clathridine **7** has been isolated together with its 2:1 zinc complex from the sponge *Clathrina clathrus*.[16] The latter compound is a genuine



7

metabolite. The solid-state structure, determined by X-ray crystallography,[17] shows a distorted tetrahedral arrangement of the ligands around the metal (Fig. 1[18]). Zinc is an

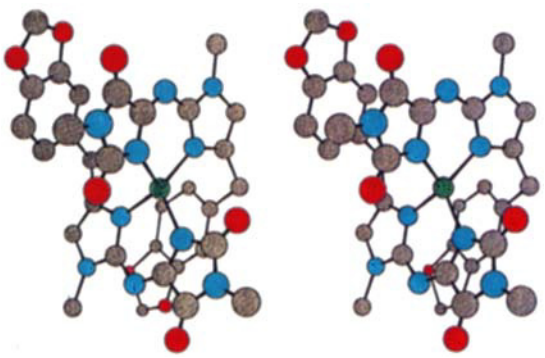


Fig. 1. Stereoscopic view of the crystallographically determined structure of the zinc complex of clathridine **7**. The metal is shown in green.

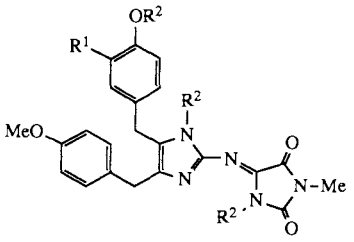
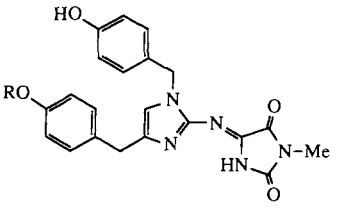
extremely important constituent of metalloenzymes, but its function in the clathridine chelate is unclear. The structure of clathridine is by no means unique; a small family of similar alkaloids, including naamidines A–D (**8**), and isonaamidines A and B (**9**),[19] pyronaamidine (**10**),[20] and corallistine (**11**),[21] has now been isolated from a variety of sponges. Is it possible that they, too, are coordinated to metals in nature, and that these complexes have so far escaped detection?

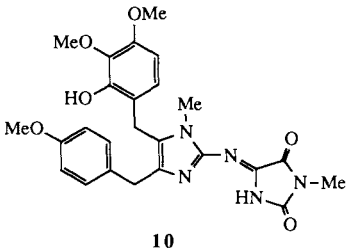
The most interesting examples of metal-containing marine natural products are provided by the aplasmomycins, for example aplasmomycin A (**12a**), boron-containing antibacterial metabolites from the cultured marine microorganism *Streptomyces griseus*.[22] Boron can hardly be regarded as a metal, but its encapsulation in the macrocyclic cavity of the aplasmomycins as tetracoordinate borate confers the same sort of rigidity on the structure that a chelated metal ion would. Has this factor a bearing on the observation[23] that deboroaplasmomycin A is devoid of biological activity? A further dimension comes from the fact that the negatively charged borate–macrocycle complex necessitates ion pairing with a monovalent cation. As isolated, the aplasmomycins



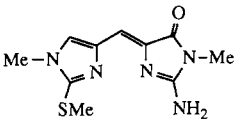
8 R^1 = H, OH ; R^2 = H, Me



9 R = H, Me

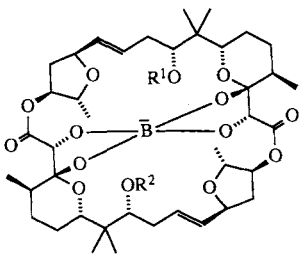


10



11

are sodium salts,[23, 24] but the initial X-ray structural studies on aplasmomycin A were on the silver salt.[25] The metal cation turned out to be located in the macrocyclic cavity, five-coordinated to two of the oxygens of the borate, two OH groups, and water (Fig. 2a). Even more noteworthy are some recent structural studies on the sodium salt of aplasmomycin C (**12c**), various conformers and polymorphs of which were separated and examined by single-crystal diffraction methods.[26] The cation was located within the cavity as expected, but the different conformers (Fig. 2b, c) were stabilized by either six- or four-coordination of sodium! The ability of aplasmomycins to envelop metal cations is thus in no doubt. In fact, one of the few semiquantitative studies of metal affinity for marine metabolites[23] shows that all three aplasmomycins bind alkali metal cations according to the trend Rb > K > Cs ~ Na > Li. There was no demonstrable affinity for Mg or Ca dications. Aplasmomycins A (**12a**) and B (**12b**) were able to transport K^+ ions across a bulk phase; deboroaplasmomycin A and the more heavily derivatized aplasmomycin C were not.



12a $R^1 = R^2 = H$
12b R^1 = Ac, R^2 = H
12c $R^1 = R^2$ = Ac

Finally, two peptidic isolated of marine animals, neither of which has been fully characterized, are worthy of mention here. The violet Fe^{3+}-binding pigment adenochrome, from the branchial heart of *Octopus vulgaris*, has been known for most of this century, and was the first known non-porphyrin iron-chelating metabolite from the animal kingdom. The last attempt to unravel its structure, published in 1979,[27] was based on analysis of the iron-free analogue, also a natural

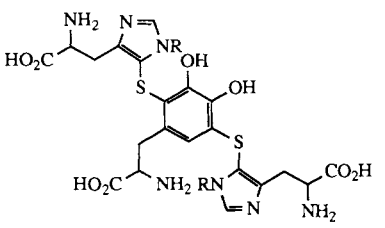
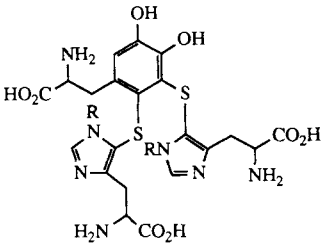
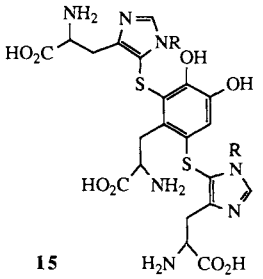
product. This was shown to be a mixture of several closely related peptides constructed from glycine and the novel DOPA-derived amino acids **13**–**15**, called adenochromines (DOPA = 3-(3,4-dihydroxyphenyl)alanine). The pigment could be reconstituted as a blue precipitate from desferriadenochrome and iron(III) chloride at pH 4.5. In view of intense current interest in the metal-binding properties of naturally occurring catechols (see **16** and **17** in Section 3), it is important that the structure of adenochrome components be solved and their biological function probed. Also worthy of further investigation are the geodiastatins A and B, which are silicon-containing chromoproteins from the sponge *Geodia mesotriaena*, a rare example of an animal that deposits a silica rather than a limestone skeleton.[28] Do these



13



14



15

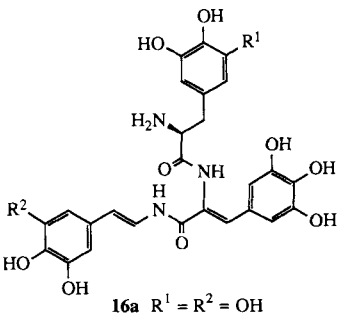
metabolites play a role in the formation of these siliceous structures and the protection of the sponge surface from predators?

3. Lessons from the Tunichromes

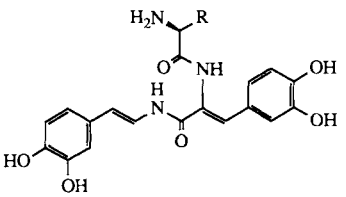
The saga of the tunichromes, air-sensitive yellow pigments present in specialized blood cells of sea squirts (tunicates), has been summarized in a recent review[29] that tellingly illustrates the frustrating uncertainties clouding the issue of the importance and function of metal–metabolite association in vivo. It has been known for decades that sea squirts are capable of assimilating metals such as vanadium, manganese, iron, niobium, and tantalum from sea water, often concentrating them to an extraordinary degree.[30] *Ascidia nigra*, for instance, is a vanadium-sequestering tunicate having intracellular levels of the metal as high as 0.15 M, ten million times the level in sea water, while a related species, *A. ceratodes*, can concentrate the element to an incredible 1 M.[31] About 90% of the vanadium is in the air-sensitive V^{III} state and the remainder is V^{IV}, observations all the more startling in the light of the element's presence as stable V^{V}-containing vanadates in the oceans. If the reduced form of vanadium is stabilized as a simple hydrated complex in the organism, it would require an acidic intracellular environment corresponding to about 0.01 M sulfuric acid, since insoluble V_2O_3 would precipitate above pH 3. Evidence for such an extraordinary milieu is not lacking, but the current view is that acidic "compartments" in cells, though credible, can be responsible for the stabilization of only a small fraction of the V^{III}. Far more compelling evidence exists for the presence in tunicate blood cells of endogenous organic ligands that can stabilize the reduced form of the metal by chelation. This is where the tunichromes come into the story.

Early studies with an unpurified "tunichrome" pigment showed that it behaved as a powerful reducing agent towards V^{V} and Fe^{III}. These observations spearheaded protracted research efforts to isolate the pure constituents of the pigment. After considerable experimental heartache, the inordinately unstable tunichromes, which decompose by oxidation, hydrolysis, and polymerization, were isolated by some unusual chromatographic procedures and then characterized by chemical and spectroscopic methods.[31] A more recent functional group protection–deprotection strategy has made the individual compounds somewhat more accessible.[32] To date, five tunichromes have been identified: An-1 (**16a**), An-2 (**16b**), and An-3 (**16c**) from *Ascidia nigra*; Mm-1 (**17a**) and Mm-2 (**17b**) from the iron-sequestering tunicate *Molgula manhattensis*. The compounds are hydroquinoid peptides that incorporate DOPA and hydroxy-DOPA units. The catechol and pyrogallol components of these compounds are, in principle, splendid chelating partners for Fe^{II}, Fe^{III}, V^{III}, and $V^{IV}O$, for which complex constants for the parent ligands are of the order of 10^{10} to 10^{28}. The auguries for tunichrome–metal binding are thus promising. What, then, are the facts?

The evidence collected to date, almost all qualitative, is that tunichromes An-1, An-2, and An-3 (**16**) react with V^{IV} and V^{V} to produce insoluble green or green-black polynuclear complexes with a binding stoichiometry of 2:1–3:1. Some spectroscopic data (UV and ESR) have been recorded on the complexes, but the heterogeneous nature of the species clearly frustrates the kinds of studies that one would dearly love to see. The formation of precipitates is in itself interesting, however, since vanadium is often associated with the formation of granules or intracellular membranes in blood cells. Another approach to the problem, the attempted isolation of an intact vanadium–tunichrome complex from ascidian blood, was largely unsuccessful; nevertheless, a green fraction, designated An-C, was isolated. While it has up to now eluded purification and characterization, it contains about 1% vanadium and has the spectroscopic hallmarks of an An–V complex. There might well be greater promise for qualitative studies with Mm-1 (**17a**), which appears to form soluble chelates with V^{III}, V^{IV}, and Fe^{II}. Recent syntheses[33] of An-1 (**16a**), Mm-1 (**17a**), and Mm-2 (**17b**) should ensure that in future sufficient quantities of these labile compounds will be available to extend our understanding of their fascinating bioinorganic chemistry.



16a $R^1 = R^2 = OH$
16b $R^1 = H, R^2 = OH$
16c $R^1 = R^2 = H$



17a R = H
17b R = *i*Bu

It is very important to highlight a caveat that the principal researchers of tunichrome stress repeatedly: despite the attractions of the tunichrome–metal hypothesis, there is in fact no direct definitive evidence linking *any* marine metabolite, let alone tunichrome, to metal ion assimilation in tunicates. The indirect evidence, however, is extremely alluring. For

example, spectroscopic signals similar to those obtained for reconstituted tunichrome–vanadium complexes have been detected in the signet ring cells.[31] Analytical data on ascidian blood are also intriguing. An important assay for free (that is, unoxidized and uncomplexed) tunichrome, by acetylation and HPLC analysis, has shown that the dried blood of *A. nigra* contains about 0.3–0.4 μmol of free tunichrome per mg. The level of vanadium is about 0.16 μmol per mg. Furthermore, cell sorting of fluorescence-activated intact cells showed which of the several types of blood cells held most of the free tunichrome and which the vanadium, thereby providing the first unambiguous demonstration of the coexistence of tunichrome and vanadium in the same intracellular compartments.[34] The two species are admirably matched to constitute a redox couple, the biological implications of which, persuasively outlined in two reviews,[29, 35] now surely enters the realm of fantasy. For instance, the mechanistic key for regulating vanadium influx into vanadium-containing cells (vanadocytes) may well be provided by excess tunichrome, which undergoes concomitant oxidation. The quinoid products of tunichrome oxidation, effectively also styrenes by virtue of unsaturation in the peptide backbone, plausibly can undergo polymerization and crosslinking to protein and cellulose, in the process perhaps generating the tough "tunic" that is so characteristic a feature of the animals. Furthermore, now that an earlier proposal that vandium might serve to transport oxygen in the blood is clearly untenable, an alternative hypothesis[35] postulates a role for the redox couple in anaerobic respiration. By ascribing to the metallic species the same sort of electron-scavenger function that molecular oxygen would normally fulfill, it is surmized that tunicates should be able to survive the periods of oxygen deprivation that may occur in their customary habitat.

The tunichrome story should provide useful analogies for exploring the chemistry of other DOPA-derived metabolites, for instance the long-unresolved problem of adenochrome's structure or the biological function of clionamide (**18**)[36] and the celenamides (**19**),[37] unstable metabolites of the burrowing sponge *Cliona celata*. Celenamide D (**20**), in particular, bears a remarkable similarity to the An-tunichromes (**16**), in its peptide backbone and the styrene-like disposition of its catechol and pyrogallol units, while compounds **18** and **19** have 6-bromotryptophan replacing a DOPA unit. A single fantasy concerning this group of compounds has found its way into print: the phenolic portion of **18** might well function as a chelating agent for calcium, since *Cliona celata* is often found boring into the calcium carbonate shells of other marine animals.[36] The recently described halocyamines **21** and **22**[38] from the ascidian *Halocynthia roretzi* are more distant relatives of the tunichromes, in which both 6-bromotryptophan and histidine join DOPA as formal constituents, but similar considerations might underlie a potentially exciting coordination chemistry.

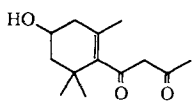
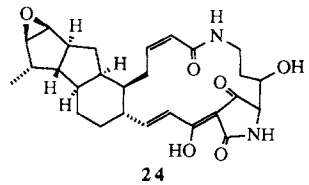
4. "Obvious" Ligands

For the overwhelming majority of marine natural products there is no evidence whatsoever for interaction with metal ions in vivo. In the quest for such interactions under laboratory conditions, the informed chemist can be expected to follow the leads provided by classical coordination chemistry, which teaches us to associate good metal-chelating properties with certain structural features. A case in point is the 1,3-diketone unit, celebrated for its ability to form stable complexes with many metal ions by way of its enol tautomer. Metabolites possessing this structural unit are thus "obvious" contenders in the coordination stakes. However, the scarcity of examples based on such clear-cut analogies is noteworthy; even qualitative evidence, such as colorimetric tests for metal complexation, is uncommon. For the simple dinoflagellate metabolite **23**, for instance, the evidence for interaction with metals was a spot test, reported in a simple phrase stating that the compound was "strongly ferric chloride positive", on which was built a minor fantasy concerning the potential of the compound as an excellent trace-metal chelator.[39] Even with a more complex natural product such as the acyl tetramic acid discodermide (**24**) from the sponge



23



24

Discodermia dissoluta,[40] complexation studies were confined to the observation of an orange-red coloration with iron(III) chloride and the formation of a greenish-yellow complex with copper(III) acetate; both features were used as supporting evidence for the enolized 1,3,5-tricarbonyl grouping.

Yet the lure of the "obvious" can be dangerous for the unwary. A cautionary tale is tucked away in the literature pertaining to a group of condensed polycyclic alkaloids found in certain tunicates. In attempts to elucidate the structure of 2-bromoleptoclinidinone, an antileukemic metabolite isolated from *Lissoclinides* sp., the range of likely structures was narrowed down to several candidates, including **25a** and **26**, on the basis of long-range NMR coupling data.[41] Structure **25a**, which incorporates a 1,10-phenanthroline substructure, was ruled out partly because the alkaloid failed to give a red complex with the iron(II) ion, a simple colorimetric test that is usually very sensitive to this tricyclic ligand. The correct structure was later shown, in fact, to be **25a**;[42] for whatever reason, the intuitively expected interaction with the metal ion was not manifested. This is not an isolated observation: related alkaloids such as ascididemin **25b**,[43] eilatin **27**,[44] and calliactine[45] also failed to give complexes with Fe^{II}. (The structure of calliactine, incidentally, is still unsolved, but formerly discarded structures based on 1,10-phenanthroline should now be reconsidered.) In point of fact, the ability to form complexes depends very much on the metal used. Eilatin (**27**) associates with Ni^{II}, as evidenced by shifts in its UV spectrum on the addition of salts of the metal.[44] To come full circle, 2-bromoleptoclinidinone (**25a**) has recently been converted into an octahedral Ru^{II} complex that can intercalate into double-stranded DNA and serve as the initial site for photochemical cleavage.[46] The message

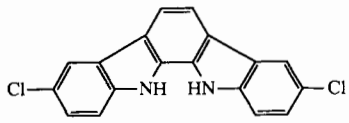
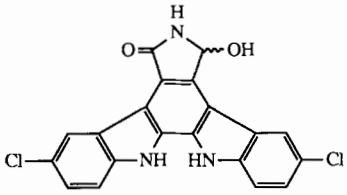
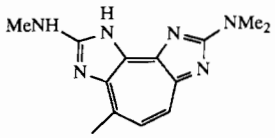
31



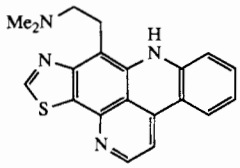
32



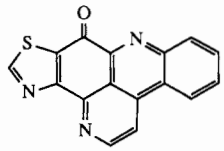
33



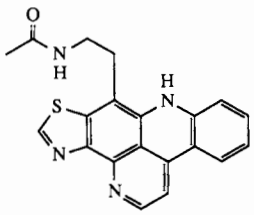
34



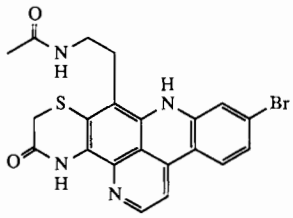
35



36



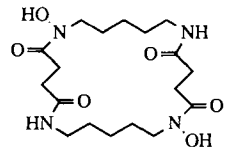
37



38

of the story is that the mere expectation of metal–metabolite interaction is not enough; the acute researcher needs to probe relationships between ligand structure and metal selectivity as well. A small group of marine alkaloids having 2,2′-linked azacyclic rings would thus appear to contain interesting candidates for chelation studies, since not only are the nitrogen atoms suitably placed for bidentate coordination to metal ions, but subtle electronic influences and spatial effects arising from small structural differences in the rest of the polycyclic skeletons should guarantee a measure of selectivity. Compounds deserving attention include other 1,10-phenanthrolines or reduced analogues such as eudistone B (**28**),[47] and plakinidine A (**29**),[48] several β-carbolines bearing pyrrol-2-yl or dihydropyrrol-2-yl substituents at C1 such as the eudistomins **30**[49] and eudistomidin A (**31**),[50] indolo[2,3-*a*]carbazoles like tjipanazoles D (**32**) and J (**33**),[51] bisimidazoles like paragracine (**34**) and related alkaloids,[52] and finally an interesting group of alkaloids in which one of the pyridine rings of the phenanthroline system is replaced by thiazole or 1,4-thiazine as in nordercitin (**35**)[53] and kuanoniamines A (**36**) and D (**37**),[54] and shermilamine A (**38**).[55]

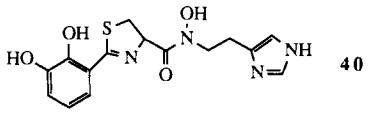
Perhaps the most important examples of "obvious" ligands are hydroxamates and catechols, which have the potential to bind and transport iron(III) ions. Natural siderophores have profound biological significance,[56] since they can assimilate iron from a variety of sources and transport it across membranes to sites where it is needed for functions such as respiration. Few siderophores have been isolated from marine sources, however. One of them is bisucaberin (**39**), a 22-membered hydroxamate-based macrocycle from the bacterium *Alteromonas haloplanktis*.[57, 58] Its ability to sensitize tumor cells to macrophage-mediated cytolysis was suspected to arise from its trapping of iron within the cells, thereby



39

preventing the metal from participating in mitochondrial respiration.[57] The evidence stemmed from the failure of a preformed bisucaberin complex to stimulate tumor lysis. The bisucaberin–iron complex could be formed as a red water-soluble species with iron(III) chloride. So far there have been no quantitative studies on the bisucaberin–metal interaction, but researchers who have synthesized the metabolite report that they are currently measuring binding constants with Fe^{III} and Cu^{II}.[59]

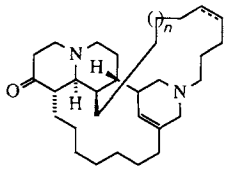
Despite the profusion of phenolic natural products from marine sources, very few are proven siderophores. Anguibactin (**40**), a somewhat exotic metabolite possessing catechol, hydroxamate, imidazole, and thiazoline units, was isolated[60] from the virulent fish pathogen *Vibrio anguillarum* 775. The full structure was deduced only after crystallographic investigation of a derivative.[61] The compound has



40

such an affinity for the iron(III) (but not iron(II)) ion that the microorganism source had to be cultured in an iron-starved medium, and the metabolite purified with deionized chromatographic materials.[60, 61] The bonus was that anguibactin (**40**) could easily be assayed spectrophotometrically with iron(III) perchlorate. Indeed, metal chelation was exploited as an aid in structure elucidation: evidence for the catechol unit was deduced from colorimetric tests with Fe^{III}, and from characteristic features in the IR, UV/VIS, and resonance Raman spectra of the complex.[60] As a token of the compound's high affinity for iron(III) ions, a complex was prepared in solution by ligand exchange with the (ethylenediaminetetraacetate)iron complex. Electrophoretic mobility showed that the binding with Fe^{III} had displaced three protons, and FAB mass spectrometry provided evidence for a 1:1 complex by showing an ion for $[M + Fe + 2H]^+$. The most conclusive evidence for anguibactin's ability to function as a ligand, however, has so far been revealed only as a note added in proof:[61] the racemic metabolite and Ga^{III} form a crystalline 1:1 complex, the structure of which has been elucidated by single-crystal X-ray diffraction. The ligand coordinates to the metal through the deprotonated imidazole ring, the hydroxy group of hydroxamate, the nitrogen atom of the thiazoline ring, and the catechol unit's *ortho*-hydroxy group.

Conspicuously rare in the foregoing pages are examples of a ligand type that has become a modern classic: the macrocycle. There is no dearth of macrocyclic marine metabolites containing suitable donor atoms for chelation; aspirant ionophores, which include macrolides, macrolactams, cyclic peptides, and polyethers, flaunt structural features that should make a coordination chemist drool. It is surprising, therefore, that the metal-binding properties of so few of these have been examined, and that even their potential for coordination has largely been passed over without comment. Apart from the comparatively predictable porphyrins and the more interesting aplasmomycins (**12**) and bisucaberin (**39**), ionophore activity has been reported only for the sarains (**41**),[62] sponge alkaloids in which the macrocycle can scarcely be regarded as a donor of "obvious" type. These alkaloids are effective phase-transfer catalysts, facilitating the esterification of potassium acetate with benzyl chloride almost as well as [18]crown-6 does.



41, $n = 1, 2$

Opportunities for substantial research effort are clearly being missed with macrocyclic marine natural products in general. However, this is an appropriate moment at which to stress a fundamental feature that needs to be properly evaluated before one embarks on wild speculations. For effective ligand function, it is essential that likely donor atoms or groups be directed towards a focal position at which a metal ion can be located. Structural features such as the folding of the molecular backbone, the directionality of polar functional groups, intramolecular separations, and (for macrocyclic substances) approximate cavity size and shape, are all fundamental to the proper understanding of metal complexation. The three-dimensional shapes of the molecules are thus critically important factors in the quest for metal–metabolite interaction, and a knowledge of molecular conformation can prevent the waste of time and effort. Since genuine examples of metal–metabolite interactions involving compounds of marine origin are exceedingly rare, researchers keen to take up the challenge presented by the phenomenon should be guided not only by the gross structural features of the candidate ligands but also by any available conformational data. It is also important to realize that the most highly populated conformer may not actually be suitable for complexation; molecular reorganization may be necessary to get the donor atoms into appropriate orientations for metal chalation. A great deal of the remaining material in this review will be concerned with speculations constructed on the basis of conformational data from a variety of sources.

5. Chelation and Spectroscopy

Spectroscopic methods figure prominently in the coordination chemist's examination of both qualitative and quantitative aspects of metal–ligand interactions.[63] These methods are generally sensitive, seldom requiring large quantities of materials, and therefore suited to the study of compounds that may be available in only limited amounts, as most

marine metabolites are. It is consequently most surprising that despite the inevitable use of spectroscopic techniques for elucidating the structures of marine natural products, applications in studying interactions with metal ions have almost never been considered. The sole examples we have come across reporting the use of optical spectroscopies (IR, UV, and Raman) were pointed out in previous sections of this review.

Fast-atom bombardment (FAB) mass spectrometry has frequently been used as an indicator for metal ion interaction with marine metabolites. Molecular ions of low intensity can be enhanced by complexation with metal cations sputtered from solution by fast atom impact, because fragmentation of the resulting $[M + \text{metal}]^+$ species is often suppressed. Alkali metal iodides are commonly used with complex natural products, although Ag^+ and Tl^+ have also found application.[64] It is doubtful, however, whether the technique necessarily indicates the sort of chelation effect that we are discussing in this review. Association of species in the gas phase is intrinsically unlikely to be a good analogy for interactions (if any) in the solution phase or in the solid state, and will in any case seldom be a reliable guide to the site-specificity of metal binding unless a metal-enhanced fragment ion is present as well. Those who have applied the method in studying marine metabolites have never looked for effects other than the obvious one of molecular ion enhancement. Some researchers have even pointed out the dangers of interpretating the interaction: for example bryostatins 1–3 (see Section 7.1) were observed to complex strongly with Ag^+ in the FAB mass spectrum, but, as acknowledged in a footnote, complexation with the diene side chain might be the factor responsible for the association.[65] The interested reader may care to draw his or her own conclusions about the nature of the metal–metabolite interaction for the following marine natural products: bengamides (for example, **42** with Na^+);[66] various bryostatins (**52** with Li^+, Na^+, K^+, Cs^+, or Ag^+);[65,67] discodermins (**43** with Na^+);[68] iejimalides (**44** with K^+);[69] janolusimide (**45** with Na^+);[70] laulimide and isolaulimide (**46** and **47** with K^+ or Cs^+);[71] neristatin 1 (**54** with Li^+);[72] oscillariolide (**48** with Na^+);[73] and patellazole C (**49** with K^+).[74]

The almost total neglect of NMR methods for detecting metal–metabolite interactions is all the more disappointing in view of the prominence of one- and two-dimensional NMR methods in the elucidation of the structures of marine natural products. As far as we are able to determine, only two publications, both very recent, report such metal complexation. A study of the conformation in solution of okadaic acid (**50a**), isolated for the dinoflagellate *Prorocentrum lima* as an unspecified "metal complex", revealed diagnostically useful, though minor, chemical shift differences between the free and the complexed metabolite.[75] Far more significant, however, and perhaps the most important in vitro study on the complexation of the marine natural product to date, is the thorough series of investigations on jasplakinolide[76] (**51**, also known as jaspamide[77]), a sponge metabolite of considerable interest because of its anthelminthic, insecticidal, ichthyotoxic, cytotoxic, and antifungal properties.

Compound **51** was the first mixed macrocyclic polyketide–depsipeptide to be isolated from a marine organism. In an extension of a comprehensive investigation of conformational effects in solution,[78] the titration of the macrolide with various alkali metal salts ($LiClO_4$, LiBr, NaSCN, KSCN; in CD_3CN) was monitored by ^1H and ^{13}C NMR spectroscopy.[79] Significant differences in the chemical shifts

were found only with lithium as cation. Moreover, the signals most affected suggested that only the carbonyl oxygen atoms at C1, C4, and C8 were involved in forming a 1:1 chelate. The values of the observed proton coupling constants at the endpoint of the titration suggested a conformation for the macrocycle corresponding to just one of two

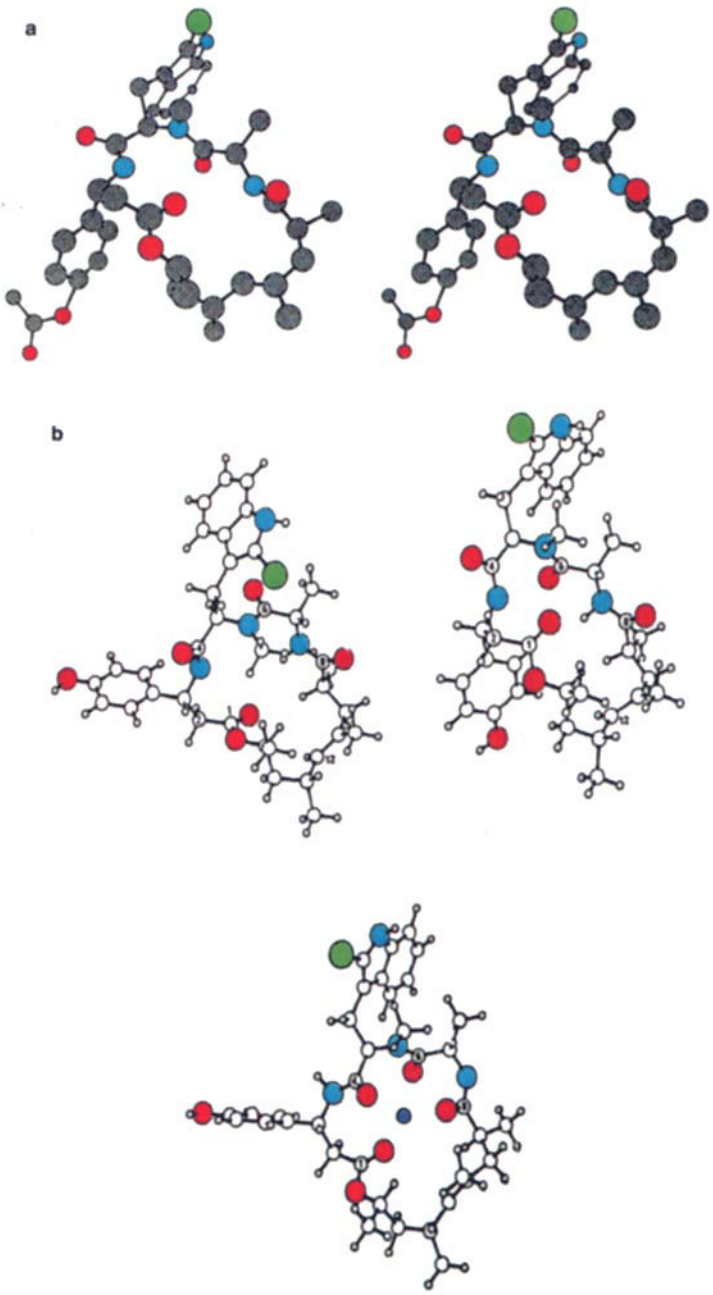

Fig. 3. a) Stereoscopic view of the X-ray crystal structure of the acetate of jasplakinolide **51**. b) Top: structures derived from molecular mechanics calculations for the two major conformers, $1g^+$ and $1g^-$, of jasplakinolide. Bottom: corresponding structure for the lithium complex of jasplakinolide. (Adapted and reprinted with permission from ref. [79].)

major conformations deduced from a similar interpretation of J values for the uncomplexed ligand and also from constrained minimization and dynamics calculations (Fig. 3).[78] A weak binding constant of about 60 M^{-1} and a ΔG value of -10 kJ/mol^{-1} were calculated. These are the only quantitative data we have uncovered that relate to metal-binding to marine natural products!

The jasplakinolide studies break new ground for a further reason: they contain the only example of the molecular modeling of a marine metabolite in the presence of metal ions. When the interactions of sodium and lithium cations with likely backbone conformations of the macrocycle were modeled with a constant dielectric term similar to the dielectric constant of acetonitrile, the conformation most suited to metal binding proved to be essentially the same as that deduced from the NMR studies (Fig. 3b). Calculated coupling constants agreed well with experimentally determined ones. The computed metal–ligand affinity was reasonable only for lithium, which lay in the plane of the macrocycle at an acceptable bonding distance of about 2.0–2.1 Å from the same three carbonyl groups that were indicated in the spectroscopic study, and considerably further from other donor sites. A footnote contains the intriguing mention of a higher order (2:1?) jasplakinolide–LiBr complex that precipitated from solution.

At this point it is perhaps appropriate to highlight the importance of NMR methods in studying molecular conformation in solution. The difficulties of extracting this information, however, can be immense. The Karplus equation (and its many successors) quantifying the relationship between vicinal coupling constants ($^3J_{H,H}$ in particular) and dihedral angles allows one, in principle, to construct, albeit piecemeal, a three-dimensional model of a given molecule as long as certain provisos are borne in mind. Firstly, if conformers interconvert at rates equal to or faster than the timescale of the NMR experiment, observed J values may translate into misleading torsional relationships. Secondly, because of the nature of the terms in the Karplus equation, a given coupling constant will, more often than not, correspond to several alternative values of the dihedral angle. It may thus not be possible to fit the data to a unique conformation. It is not surprising, therefore, that detailed conformational analyses of complicated marine natural products are rather rare. One must also bear in mind that the most abundant conformation in solution will not necessarily be the best for embracing a metal cation. In the more speculative sections of this review that follow, NMR conformational studies that might have implications for metal–metabolite interaction will be presented alongside studies that employ crystallographic and computational techniques.

6. Crystallographic and Computational Signposts for Chelation

X-Ray crystallography is a powerful and much-used tool in the structural elucidation of uncomplexed marine metabolites, often providing the only unambiguous evidence for structural features, stereochemistry, and even absolute configuration. By contrast, diffraction studies involving metal complexes of marine metabolites are woefully few (see the previously described aplasmomycins (**12**) and the zinc complex of clathridine **7**), especially when compared with the ever-growing number of similar studies on metal complexes of terrestrial natural products. However, a significant bonus

of crystallographic methods is that topological information, generally difficult to obtain by other means, can be extracted relatively easily. Admittedly, electrostatic forces, hydrogen bonds, and packing considerations may all conspire to produce a solid-state conformation that might be misleading for studies of complexation equilibria and kinetics in solution. On the other hand, crystallographic data should be seen as a signpost: not an infallible guide to the complexation phenomenon, but a useful aid to those of us seeking direction. It is regrettable that the accumulation of X-ray diffraction data relating to marine metabolites is still a largely untapped resource, since as long as one has access to atomic coordinates (e.g., from the Cambridge Structural Database, see reference [18]), the manipulation of data is relatively straightforward. As will be indicated in subsequent sections, several authors have explicitly extracted conformational information from their crystallographic data, and a few have even gone as far as expressing tentative opinions on implications for the binding of cations by marine metabolites.

Molecular mechanics calculations, once securely in the domain of theoretical chemists, have now become a tool that is widely available to all chemists, thanks largely to the commercial availablility of computer software packages in varying degrees of sophistication. At their best, they offer the average user comparatively painless access to a variety of alternative methods of modeling structures, computing energy minima, and obtaining information (including graphical information) on molecular topology. It is possible to be too naive in using these methods, however, and one needs to be aware of their inherent limitations. The force fields themselves may be designed for specific molecular types; the parameters contained therein, though representing workable averages, are invariably subjective to some extent (they can usually be modified, at one's peril); parameters for unusual bond types or atoms in unusual environments may simply not be present; and the time taken to perform calculations may vary considerably according to the available equipment. The time can often be shortened if one commences from atomic coordinates derived from sources such as X-ray crystallographic data, but unless well versed in the methods, one might compute a local energy minimum that is biased towards the starting coordinates. The best packages will have a conformational search option allowing the location of all stable conformations within a specified energy range as well as the global energy minimum. This can be especially important for predicting suitable conformations for metal chelation, as the lowest energy conformation need not have an appropriate geometry for metal binding. One must also realize that the species modeled is generally an isolated molecule, the conformation of which may not be typical of the state of affairs in a molecular ensemble present in solution. Molecular dynamics calculations, which can simulate a solvent environment, are preferable in many cases, but require much more computer time. In the light of these problems it is little wonder that very few marine metabolites have been modeled by computational methods. Modeling of metal–metabolite interactions is, in consequence, unknown with this group of natural products, except for jasplakinolide,[78] as previously mentioned. A major contributory factor to this unsatisfactory state of affairs is the paucity of properly parametrized data for metal ions.[80]

7. Hypotheses and Hunches

In the absence of other information relating to metal complexes of marine natural products, conformational studies by spectroscopic, crystallographic, and computational methods should be seen as providing useful grounds on which to base hypotheses. The subjective manipulation of conformational data thus provides a necessary bridge between the worlds of fact and fantasy. In the following section, we cross over into the realm of fantasy, highlighting published speculations that have been based on conformational premises. We also present additional examples of candidate structures that we consider to be worthy of the attention of interested chemists.

7.1. The Bryostatins

The growing family of bryostatins (**52**–**54**), macrolides from the marine bryozoan *Bugula neritina*, is of considerable interest because of the antineoplastic, cytostatic, and immunomodulatory activity of certain members. To date, bryostatins 1–15 have been reported, and several related compounds have also been described.[65,67] Most are characterized by the "bryopyran" core **55**, a 20-membered tetraoxamacrolide in which three of the four oxygen atoms are constituents of tetrahydropyran rings and the fourth is in the acyloxy group of the lactone. The best studied and most

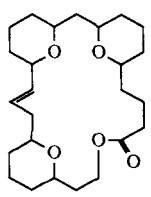
54



55

abundant compound, bryostatin 1 (**52a**) has been the subject of much spectroscopic and biological study, and an X-ray crystallographic investigation at low temperature has revealed its full structure (Fig. 4).[81] The authors of this study

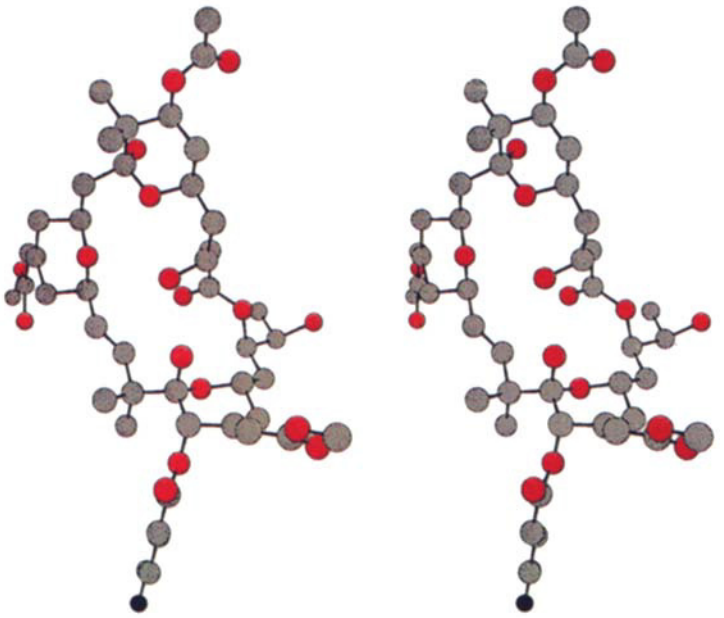


Fig. 4. Stereoscopic view of one of two molecules in the asymmetric unit of bryostatin 1 (**52a**). The disordered alkyl side chain is represented by the black circle.

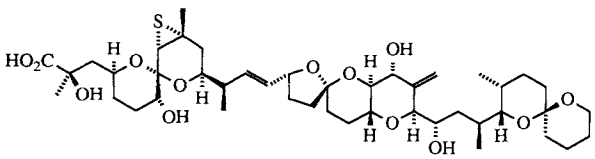
highlighted the "scoop shape" of the molecule in the solid state, pointing out the location of the tetrahydropyran oxygen atoms, the carbonyl group of the lactone, and two other hydroxy groups on the interior surface of the oxygen-rich cavity. These are the bare facts. The minor fantasy derived therefrom is typical of the bland and inoffensive statement that one encounters in the literature of potential marine ionophores: "The size and shape of this cavity and the arrangement of oxygen atoms suggest that the molecule may have cation-binding capabilities, similar to the polyether antibiotics."[81] The lipid chain, it was felt, might swing over the cavity and seal one side. A later publication developed the theme, adding a speculation relating to some biological explorations: "The bryostatins may prove to be important ionophores for altering membrane permeability."[82] In these few tentative words and the previously mentioned FAB-MS results resides the *entire case* for bryostatins as metal chelators, at least as presented in the chemical literature. Now that an improved isolation procedure has ensured the availability of gram quantities of bryostatin 1 for important clinical purposes,[83] it is to be hoped that material can be spared for enterprising workers to take up the challenge of its coordination chemistry.

7.2. Other Macrolides and Polyethers

The scoop shape, an attractive vehicle for encapsulating a cation, is not limited to macrocycles. X-ray structure analysis has shown that the sponge metabolite acanthifolicin (**56**), a linear polyether containing spirofused tetrahydrofuran and tetrahydropyran rings, forms a cavity of diameter 5–7 Å, which is held in place by a hydrogen bond (Fig. 5a).[84]



56

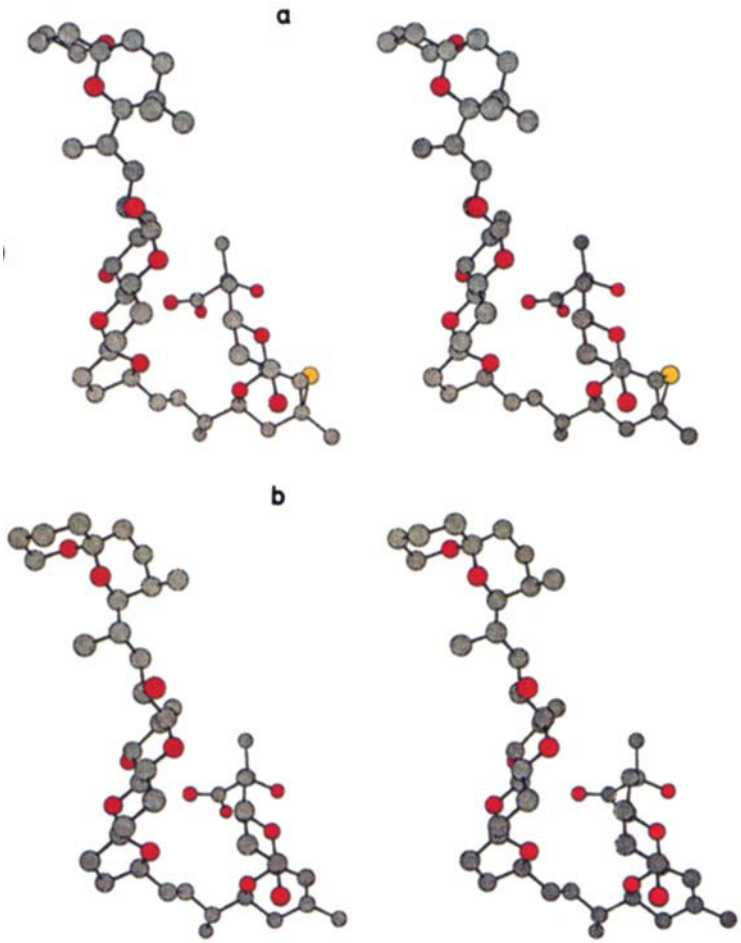


Fig. 5. Stereoscopic views of the X-ray crystal structures of a) acanthifolicin (**56**) and b) a derivative of okadaic acid **50a**. The *o*-bromobenzyl ester group of the latter has been omitted for clarity.

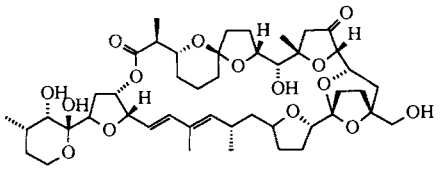
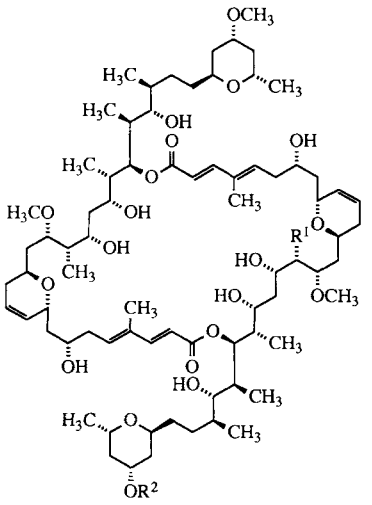
Ten oxygen atoms cluster around this cavity, seven of them within 4 Å of a central point. "A situation quite suitable for complexation of a cation" was the sole comment on this highly suggestive arrangement. The X-ray crystal structure (Fig. 5b) of the closely related dinoflagellate product okadaic acid (**50a**), determined for the *o*-bromobenzyl ester,[85] is similar to that of acanthifolicin (**56**), but the conformation and its implications have passed without comment. The previously mentioned NMR study of okadaic acid's solution conformation,[75] incidentally, correlated well with the solid-state conformation. Some relatives of okadaic acid, the dinophysistoxins **50b**, are thought to be produced by dinoflagellates ingested by edible molluscs that then cause severe diarrhoea on human consumption;[86] it would be fascinating to explore a possible connection between toxicity and ionophore activity.

Linear, bridged, and spirocyclic tetrahydrofuran and tetrahydropyran units are components of several other marine metabolites whose structures have been disclosed by X-ray diffraction techniques. The macrolide ring of pectenotoxin 1

(**57**), another diarrhetic shellfish toxin produced by a dinoflagellate present in the digestive gland of scallops, is a "large oxygen-rich cavity ... grossly similar to the cavities found in the polyether ionophores from terrestrial microorganisms".[86] Most of the polyether macrolides produced by sponges of the genus *Theonella* have slipped by without comments relevant to our present purpose, other than in the case of the antifungal and cytotoxic compounds swinholide A (**58a**). Initially formulated as a 22-membered macrolide,[87]



57



58a $R^1=R^2=Me$
58b $R^1=H$, $R^2=Me$
58c $R^1=Me$, $R^2=H$

it was later shown by FAB-MS to have twice the expected molecular mass.[88] X-ray crystallography on a diketoester derivative[89,90] subsequently revealed a 44-membered macrodiolide having a twisted saddle shape with turns at the dihydropyran rings, and slightly distorted from the expected C_2 symmetry. This derivative structure was extrapolated to the parent metabolite,[90] for which the authors deduced a conformation in which "oxygen atoms ... are all directed into the interior of the ring structure". The argument was taken no further; perhaps nothing more than imagination makes us sensitive to the reverberations of this unadorned statement and the published stereoscopic views of the molecule (Fig. 6). The relatives of swinholide A (**58a**) are numerous: swinholides B (**58b**) and C (**58c**),[91] isoswinholide A (**59**),[91] bistheonellides A, B, and C (**60**)[92,93] (the first of which has also been named as misakinolide A[94]), and isobistheonellide A (**61**)[93] are all macrodiolide isomers or lower homologues of swinholide A that might reasonably be expected to behave towards metal ions in a related fashion. Norhalichondrin A (**62**), an antitumor agent from the sponge *Halichondria okadai*, appears to be the only other complex polyether marine metabolite to have been the subject of crystallographic investigation,[95] but in this case the comparative rigidity imposed by the arrays of fused tetrahydrofuran and tetrahydropyran rings makes the macrocycle an unpromising receptacle for metal ions.

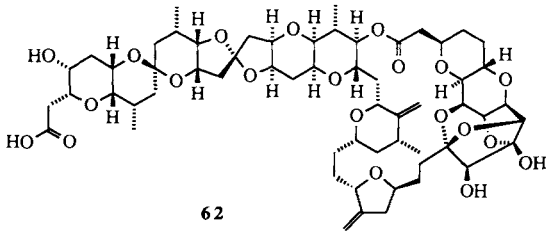
61



62

Solid-state conformations revealed by diffraction methods may prove a less useful guide when molecules are floppy, since steric effects and electrostatic repulsions may promote accessible conformations remote from those needed for a comparatively ordered metal-centered chelate. Thus, while several polyethers from red algae of the genus *Laurencia* have been studied by crystallography, the disposition of the donor oxygen atoms in the resulting solid-state structures is not suitable for multidentate interaction with cations unless substantial molecular reorganization occurs. The potential ability of compounds like chilenones A (**63**)[96] and B (**64**),[97] thyrsiferol (**65a**),[98,99] and venustratriol (**65b**)[99] to wrap themselves around metal ions is not apparent from the published structural models. Teurilene (**66**),[100] an elegantly symmetrical linear tristetrahydrofuran, though tantalizingly reminiscent of a cleaved crown ether, would also need flexing of its solid-state conformation to enfold a cation. There is not even a hint of a possible ionophoric role in any of the publications dealing with these compounds.

66

7.3. The Didemnins

Caribbean tunicates of the genus *Trididemnum* are the source of a small family of cyclic peptides called the didemnins, which are powerful antitumor and antiviral agents.[101] Didemnins A (**67a**), B (**67b**), and C (**67c**) in particular have been the subjects of numerous structural, synthetic, and biological studies.[11a,102] Furthermore, conformations of didemnins A and B in solution have been elucidated by NMR methods,[103,104] and rationalized further with the aid of restrained molecular dynamics calculations.[104] The structure of **67b**, the most potent metabolite of the group, has also been determined crystallographically.[105] The spectroscopic, crystallographic, and calculational approaches agree substantially on the conformation adopted by the essentially rigid macrocyclic ring. Minor differences (and alternative conformations) tend to arise from variations in the orientation of side-chain substituents rather than the basic ring structure. However, the commentary provided by the authors on the crystallographic analysis introduces, for the first time in this review, a note of genuine doubt about the feasibility of interaction with cations. The conformation of the cyclic moiety, it is pointed out, "resembles the cavity formation of many large polypeptides that form complexes". It is a "twisted figure 8", stabilized by a transannular hydrogen bond. A closer look at the oxygen atoms shows that "most of them are pointed away from the interior of the cavity" (see Fig. 7). What significance does one attach to this

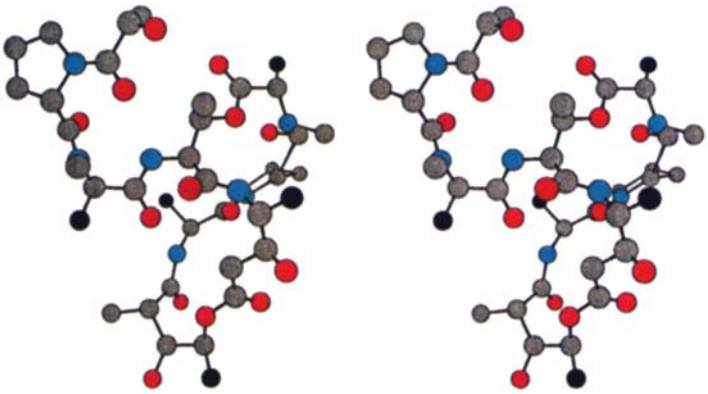

Fig. 7. Stereoscopic view of the crystallographically determined structure of the backbone of didemnin B (**67b**). Various side chains, omitted for clarity, are represented by the black circles.

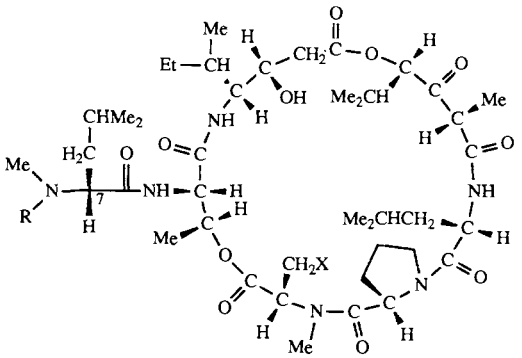
observation? An isolated study in the biological literature has demonstrated that didemnins A and B fail to complex or transport sodium and potassium cations.[106] The temptation to link this observation and the conformational findings



X = 4-OMeC$_6$H$_4$

67a R = H

67b R = MeCHOHC(=O)–N<

67c R = MeCHOHC(=O)–

is irresistible; the likely connection is indeed explicitly mentioned in the crystallographic study. To our knowledge, these results, considered in combination, constitute the only serious evidence *against* a metal–metabolite association to be found in the whole canon of researches dealing with marine natural products. It is interesting that while a synthetic analogue of didemnin B (**67b**) with a methyl-L-leucine substituent replacing the natural methyl-D-leucine at position 7 has considerably reduced biological activity, NMR and molecular dynamics calculations on the major conformer showed only minor differences in conformation for the macrocyclic backbone compared with **67b**.[107]

7.4. The Dolastatins

The dolastatins, for example **68**–**73**,[108] form a heterogeneous group of potent antineoplastic and cytostatic peptides isolated from the sea hare *Dolabella auricularia*, though the primary source may be a dietary cyanobacterium. Of the fifteen numbered dolastatins, seven have been fully or partially characterized,[101] sometimes only after intense efforts that have included the total synthesis of alternative structures. The only link between these compounds is their name and their source; otherwise, points of structural similarity are few. Some are linear and some cyclic, and all contain unusual components that include highly modified amino acid residues, lactone units, polyketide fragments, and thiazole rings. Furthermore, none of these compounds has been characterized crystallographically, and the literature contains no speculations whatsoever on possible ionophoric roles. Unpromising subjects for metal complexation though these compounds appear to be, an important conformational study affords a glimmer of hope. The cyclic, thiazole-containing metabolite, dolastatin 3 (**68**), the most intensively investigated member of the group, has been synthesized and thoroughly characterized by NMR in $CDCl_3$ and $(CD_3)_2SO$ solution.[109] Circular dichroism measurements have indicated conformational homogeneity in solution, a fact confirmed by the detection of just one conformer by NMR. A self-consistent set of torsion angles was deduced from J values, and the resulting conformation was refined further by means of force-field calculations. The final model (Fig. 8) shows a saddle-shaped macrocycle with turning points between the two thiazole units and at the center of the loop centered on leucine. An intriguing observation, not explored further, was that all but one of the N–H bonds point into the middle of the ring. This is the sort of orientation that should

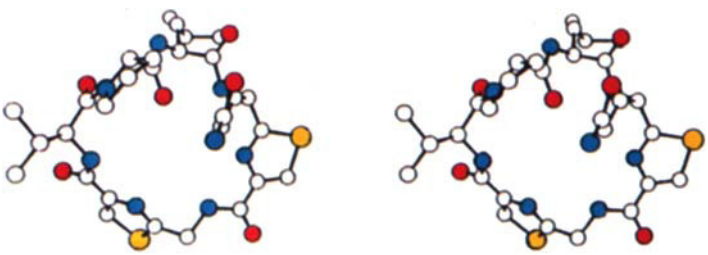


Fig. 8. Stereoscopic view of the probable conformation of dolastatin 3 (**68**) in solution, as determined from NMR data and force-field calculations. (Adapted and reprinted with permission from ref. [109].)

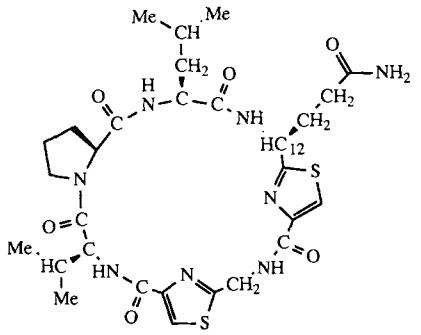
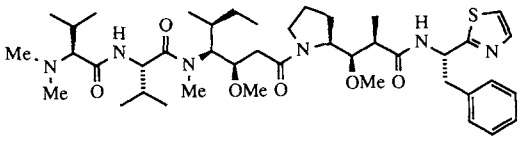


68



69

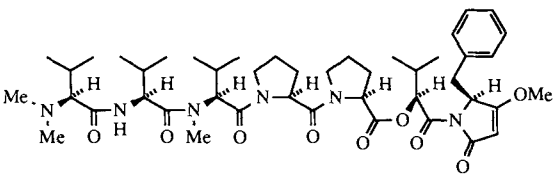
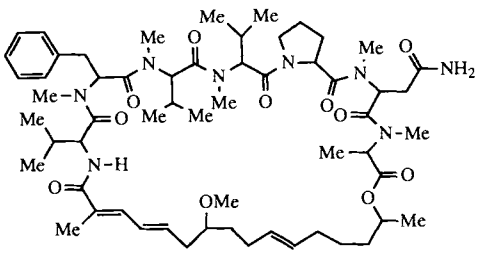
71a R^1 = OH, R^2 = H
71b R^1-R^2 = $\Delta^{14,15}$



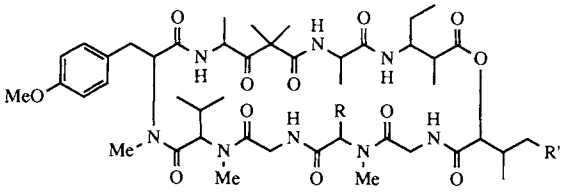
72



73

facilitate metal ion encapsulation. An analogous study on a biologically inactive synthetic diastereomer of dolastatin 3, differing only in absolute configuration at position 12 (12*R* rather than 12*S*), showed the only major conformational difference of the macrocycle to be the orientation of the (Gln)Thz unit.[110]

It should be pointed out that other marine organisms also produce natural products related to some of the dolastatins. The blue-green alga *Lyngbya majuscula*, responsible for an irritating condition known as "contact dermatitis" or "swimmer's itch", produces cyclic peptides, majusculamide C (**74a**) and 57-normajusculamide C (**74b**),[111] that differ in minor structural details from dolastatins 11 (**70a**) and 12 (**70b**). Any investigation of the metal-binding properties of the structurally diverse dolastatins should thus also give attention to similar metabolites from other sources.



74a R = CH(Me)CH_2Me, R' = Me
74b R = CH(Me)CH_2Me, R' = H

7.5. *Lissoclinum* Peptides

Tunicates of the genus *Lissoclinum* produce several different classes of natural products, perhaps in cooperation with algal symbionts.[101] The best investigated animal is *L. patella*, the metabolites of which differ with geographical location. The largest group of compounds consits of a range of cyclic hepta- and octapeptides distinguished by the presence of thiazole (or dihydrothiazole) and dihydrooxazole rings in the macrocyclic periphery. This rather closely allied group of cytotoxins comprises ascidiacyclamide (**75a**),[112] lissoclinamides 1–8 (**76b–g**, **77**),[113–117] patellamides A–D (**75b–e**),[116,118] ulicyclamide (**76a**),[113,119] ulithiacyclamide (**75f**),[119,120] and ulithiacyclamide B (**78**),[121] as well as a number of related compounds in which the dihydrooxazole ring has been opened.[114] Spectroscopic methods have played a crucial role in the assignment of these structures, and abundant conformational data from NMR studies are available in consequence. Several X-ray crystallographic structure determinations also provide a good basis for speculations derived from conformational considerations.

There are interesting topological similarities between ulithiacyclamide (**75f**) and ascidiacyclamide (**75a**). Peptide **75f**,[119,120,122] the most potent cytotoxin in the group, has been the subject of a detailed conformational study by NMR spectroscopy. The data was used as input for energy minimization calculations,[123] which revealed an unambiguous dependence of the conformation on solvent. In a relatively nonpolar medium ($CDCl_3$ or C_6D_6), the molecule is saddle-shaped, has twofold symmetry, and a radius of curvature of about 3.4 Å. The disulfide bond is an integral stabilizing element in the structure, forming a 'strap' across the slightly

convex surface of the cavity, which is an approximate rectangle of dimensions 6 by 8 Å (Fig. 9). All four N–H bonds

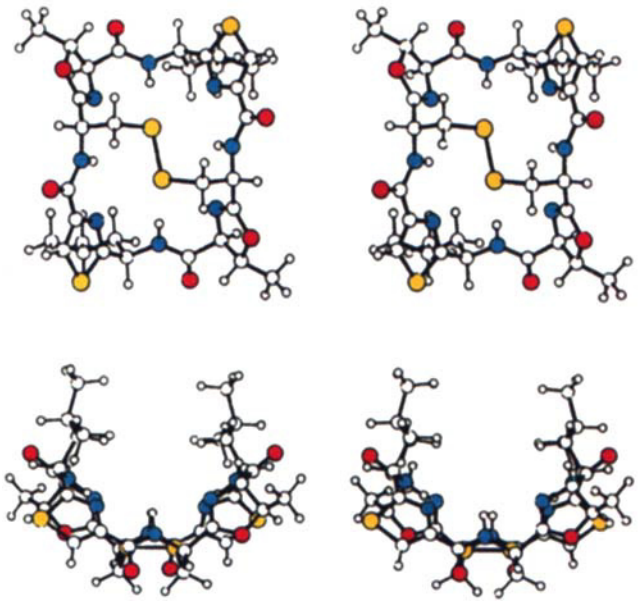

Fig. 9. Stereoscopic view of a likely conformation of ulithiacyclamide (**75f**) in chloroform solution, as viewed alog the C_2 axis (top), and perpendicular to this axis (bottom). (Adapted and reprinted with permission from ref. [123].)

point into the cavity, as do the nitrogen atoms of the azole units. The saddle shape is maintained in $(CD_3)_2SO$ solution, but the cavity is shallower and wider and the N–H bonds adjacent to the thiazole rings point away from the cavity. The molecular topology revealed in a crystallographical study of **75a**[124, 125] is remarkably similar to the nonpolar conformation of **75f**: the macrocyclic backbone is saddle-shaped with the heterocycles at the corners, and cylindrically curved (radius approximately 4 Å) about a line between the isoleucine units. The roughly rectangular cavity measures about 7.5 by 6.1 Å. Most importantly for our purposes, the N–H bonds and nitrogen lone pairs are directed towards the interior of the molecule (Fig. 10). The hollows are not empty, but occupied by benzene molecules of crystallization. Thoughts of metal chelation obviously occurred to the authors, who commented:[125] "There is no direct evidence of the interaction of these peptides with metal ions." However,

Fig. 10. Stereoscopic view of X-ray crystal structure of ascidiacyclamide (**75a**) showing encapsulation of a molecule of benzene. A second highly disordered benzene molecule has been omitted for clarity.

an intriguing suggestion about possible interactions with biomolecules was put forward on the basis of differential scanning calorimetric results obtained with a model phospholipid and nucleic acid. A conformational study of **75a** by NMR methods gave results essentially in agreement with the solid-state conformation.[125]

A comparison of coupling constants for patellamides B (**75c**) and D (**75e**)[115] suggested a structural analogy with ascidiacyclamide (**75a**), and it was postulated that these two metabolites should thus also have N–H bonds and nitrogen lone pairs pointing into the cavity, "orientations ideal for chelation to metal ions". However, an X-ray crystallographic study of **75e**[116] has shown that the solid-state conformation is quite different from that of **75a**. The molecule is severely folded into a "twisted figure 8" that deviates significantly from its potential twofold symmetry. Four transannular NH···O hydrogen bonds hold the molecule in the observed conformation. Most interestingly, an unexpected new feature emerges: the thiazole rings are aligned nearly parallel; the distance between them is a remarkably small 4.1 Å (Fig. 11). This evidence for transannular π stacking,

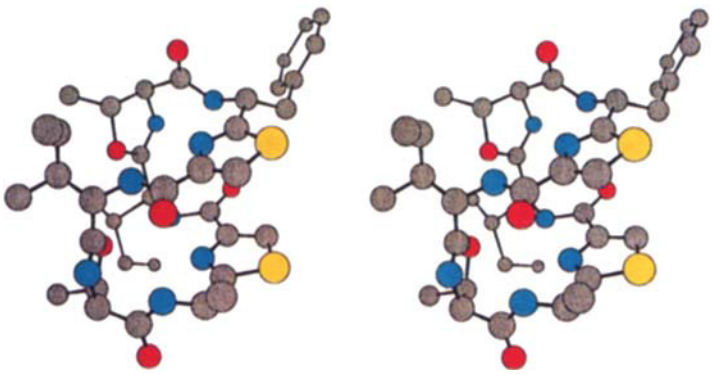

Fig. 11. Stereoscopic view of the X-ray crystal structure of patellamide D (**75e**).

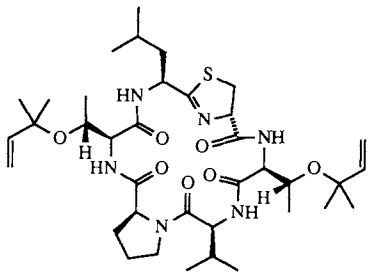
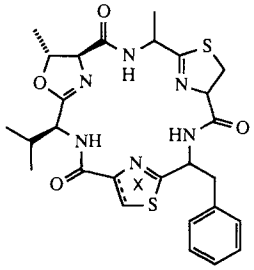
unique for a marine metabolite, might well have implications for an electron-transport function for the compound in nature, as befits a charge-transfer complex, though this is not mentioned by the authors. Could it also possibly indicate interaction with metal ions by π coordination—even sandwiching—rather than by simple chelation? As a tailpiece to this interesting study, energy minimizations were performed on the structure revealed by crystallography and on a different conformation constrained to fit the ascidiacyclamide saddle. The former was calculated to be about 10 kcal mol^{-1} more stable than the latter.

Patellin 2 (**79**), a dihydrothiazole-containing cyclic hexapeptide, is strucutrally quite distinct from the compounds in the previous group.[126] Any hypothesis relating to interaction with metal ions would have to take into account a number of conformational ambiguities that have shown up in both solution and solid-state studies. For instance, *cis*/*trans* isomerization about the Val-Pro bond was responsible for a temperature- and solvent-dependent doubling up of NMR signals, the *trans* conformer dominating in polar solvents. The rotational barrier, calculated by minimization of dynamics data, was a comparatively modest 21 kcal mol^{-1}.

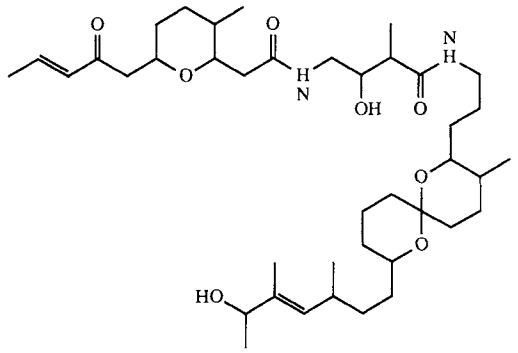


79



80a X = dihydrothiazole
80b X = thiazole

The *trans*-amide conformer occurred in the crystallographically determined structure (Fig. 12), but the dihydrothiazole ring was disordered, and had to be modeled with two conformations. Molecular mechanics calculations also located two distinct minima, corresponding to forms in which the torsion angles approximate those found in the solid-state structure. From the viewpoint of potential cation binding, the most significant feature of the crystallographic study is that all the nonpolar residues lie on one face of the somewhat bowed ring, while the dihydrothiazole and most of the carbonyl groups lie on the other, slightly concave, face.



81

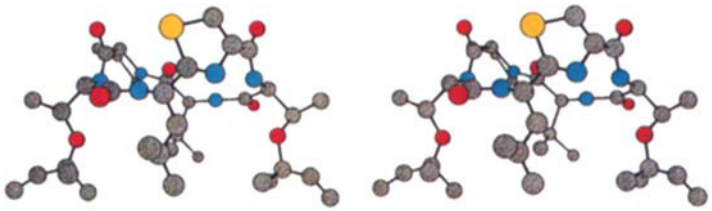


Fig. 12. Stereoscopic view of the X-ray crystal structure of patellin-2 (**79**).

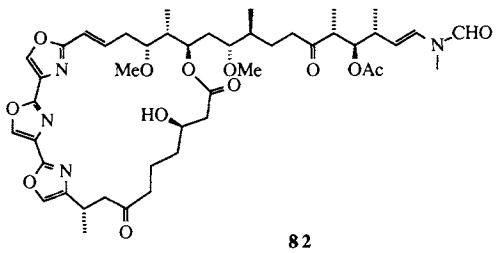
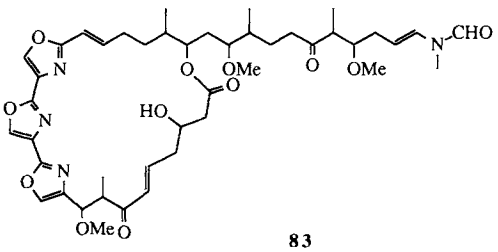
A different tunicate, *Lissoclinum bistratum*, produces a further two cyclic hexapeptides, bistratamides A (**80a**) and B (**80b**), containing a dihydrooxazole ring and either two dihydrothiazole rings or one thiazole and one dihydrothiazole ring.[127] Conformational analysis of bistratamide B by NMR gave two alternative sets of dihedral angles. The larger angles corresponded to a conformation in which all nitrogen atoms pointed towards the center of the ring, the smaller to a conformation in which only the heterocyclic nitrogens do. Both might conceivably be suitable for metal attachment. The same animal also produces[127] two exceedingly potent cytotoxins of quite different constitution, bistratene A (**81**, also known as bistramide A[128]) and its acetate, bistratene B, which, as peptide derivatives having additional oxygen functionalities, should also function as ionophores.

7.6. Oxazole Metabolites

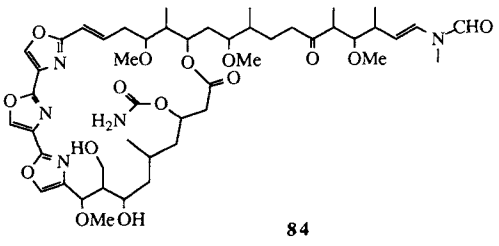
Amongst the most fascinating macrolides from marine sources are a number of compounds in which three contiguous oxazole rings, linked between positions 2 and 4, form part of the macrocyclic ring. They also possess a functionalized lipid-like side chain that terminates in an *N*-methyl-*N*-



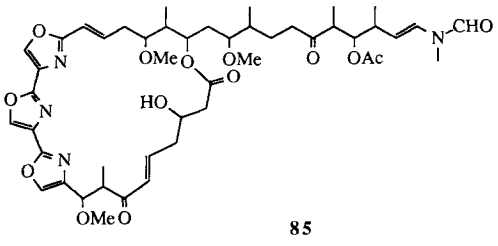
82



83

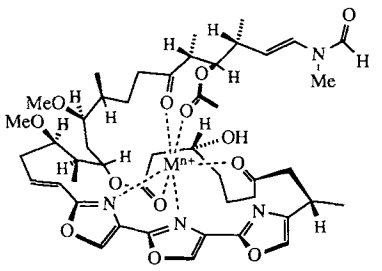


84

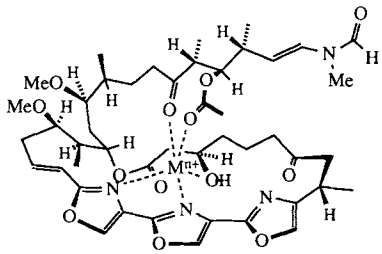


85

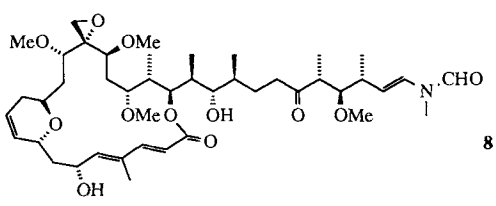
alkenylformamide group. These compounds, though forming a structurally homogeneous set, come from two distinct classes of marine organism: nudibranchs (principally *Hexabranchus sanguineus*), and sponges (including *Halichondria* sp. and *Mycale* sp.). The sponges might possibly form part of the diet of the animals. The nudibranch metabolites were isolated from the egg masses, which in their natural environment are remarkable for remaining untouched by predators. In fact, this unusual property provided the initial incentive for searching for deterrent chemical principles in the egg masses. The metabolites of interest from both nudibranches and sponge sources include, amongst others, ulapualide A (**82**),[129] halichondramide (**83**),[130] kabiramide A (**84**),[131] and mycalolide A (**85**).[132] Although gross structural features for these compounds are secure, their relative stereochemistry has not been established. In the absence of crystallographic information, the resolution of these problems will probably have to await total synthesis. However, the structures are so patently plausible as ligands for metal chelation that our research group in Nottingham has been enticed into carrying out a molecular mechanics study on 'dummy' metal-chelated ulapualide A (**82**) using varying combinations of its oxygen and nitrogen atoms as ligating sites. Perhaps somewhat whimsically, by using the chelated models shown in **86** and **87**, this study has permitted us to predict the relative stereochemistry shown in formula **82** for ulapualide A. This is more significant than it may appear at first sight, since the stereochemistry revealed for the polyol side chain in **82** correlates with the corresponding chiral centers in scytophycin B (**88**), a related metabolite whose structure has been secured by X-ray measurements.[133] We now look forward to the outcome of the synthetic endeavors with these fascinating and unusual trisoxazole-containing macrolides.[134]



86

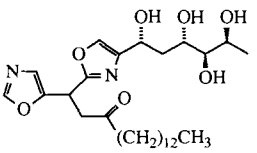


87

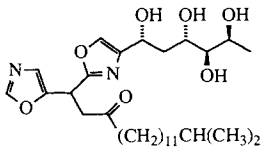


88

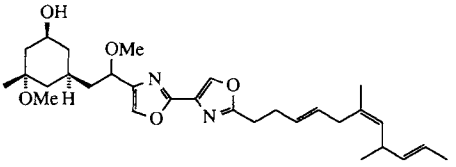
We also draw attention to several marine bisoxazoles that merit consideration as potential ligands: bengazoles A (**89**) and B (**90**) from a sponge of the family Jaspidae;[135] hennoxazoles, for example **91**, from the sponge *Polyfibrospongia* sp.;[136] and diazonamides A (**92a**) and B (**92b**), unique macrobicyclic bisoxazoles from the ascidian *Diazona chinensis*.[137] The macrocyclic cavities of **92** may lack sufficient functionality for holding cations, but an X-ray structure determination of a acetal/amide derivative of **92b** has shown that the oxazole rings are twisted at 29° to each other, which places both nitrogen atoms orientated away from the cavity but in principle still able to cooperate as a bidentate ligand.



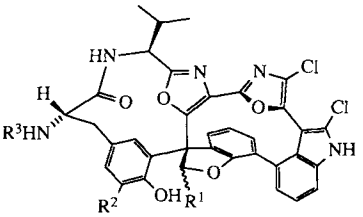
89



90



91



92a R^1 = OH, R^2 = H, R^3 = $COCH(NH_2)CH(CH_3)_2$
92b R^1 = OH, R^2 = Br, R^3 = H

7.7. Bastadins

Many sponge metabolites derived from bromotyrosine moieties[101] are characterized by the presence of free oxime groups, which should encourage chelation by metal ions. For our purposes the most interesting are the bastadins (e.g., **93**–**95**), antimicrobial compounds in which four bromotyrosine-derived segments are linked into chains or, further, into macrocycles by amide and ether bonds.[138, 139] Crystal structures have been obtained[139] of bastadin-4 (**95a**) as the trispyridine solvate, and of the tetramethyl ether of bastadin-5 (**95b**) (Fig. 13). Of the latter the authors remarked that "there appeared to be a sizable 'hole' inside the macrocyclic ring, which might accommodate small mono- or divalent metal cations". Though the hole was partially blocked by one of the methoxyimino protecting groups, the hope was expressed that "one or more of the unmethylated natural products could behave as an ionophore". The conformation of the elongated rectangular ring in **95a** is probably atypical, since hydrogen bonding to the solvent of crystallization on the outside of the macrocyclic cavity is likely to distort the structure.

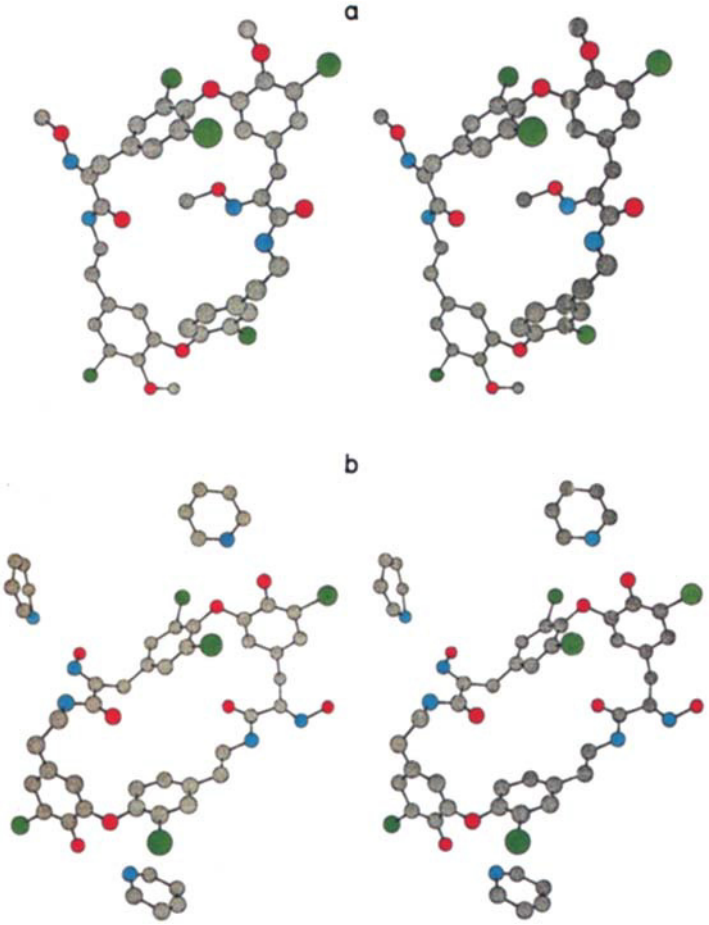


Fig. 13. Stereoscopic views of the X-ray crystal structures of a) the tetramethyl ether derivative of bastadin-5 **95b**; and b) the pyridine solvate of bastadin-4 **95a**.

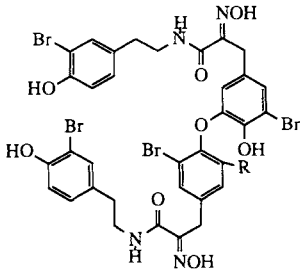
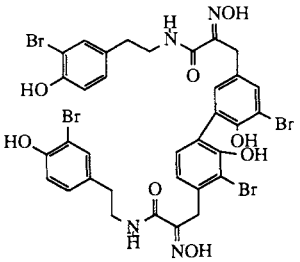


93 R = H, Br



94

95b C5-C6 = CH_2-CH_2, X = Br, Y = H

8. Summary and Outlook

The preceding pages present the case for potential and known interactions of marine natural products with metal ions. The progression has been from solid facts to nebulous fantasies. So tenuous does the link become in the end that additional natural product examples would have to be chosen on no better grounds that the aesthetic appeal of their structures (or intuitive guesswork, which might amount to the same thing). Many other marine polyethers, macrolides, cyclic peptides, alkaloids, and the like no doubt deserve a mention, but the reader whose interest has been quickened by our survey will be at least as able as we are to compile a short-list of personal favorites for further attention.

What are the major problems in undertaking metal-chelation studies of marine matabolites? The limiting factor is often the availability of materials. Marine organisms are seldom prodigal in the production of secondary metabolites. The fact that sub-centrigram quantities of componds are routinely isolated and analyzed is a tribute both to the painstaking efforts of dedicated researchers and to the sensitivity of modern analytical and spectroscopic techniques. The scaling up of isolation procedures (assuming that the source organism is sufficiently prolific for large-scale collection) poses enormous logistic problems. Worthy of highlighting in this regard is the recent extraction of 18 g of pure bryostatin 1 (**52a**) from 28000 pounds of damp *Bugula neritina*, processed in 15 batches over 10 months.[83] Many organisms can, of course, be grown in culture, though we are some way off from large-scale microbiological production of desirable metabolites at will. Bioengineering of suitable genetic material for the controlled production of important products is also not practicable at this stage. As we see it, organic synthesis will continue to serve as the most important alternative source of interesting metabolites well into the next century. Far from being a passé discipline, the art of organic synthesis plays a more vital role than ever before in ensuring access to valuable compounds that are otherwise nearly impossible to come by. However, we should be disingenuous if we failed to acknowledge the frequently inefficient and uneconomical nature of synthetic processes. The fearsome structural complexity of many marine natural products, while certain to succumb to persistent and imaginative assault by creative synthesists, will always militate against rapid and plentiful access. In the short term, dreams of studying metal chelation will probably remain unfulfilled for many important marine metabolites. Another problem arises from the still incompletely characterized, stereochemical features of many interesting compounds. Obviously, the task of the synthetic chemist is impeded by imprecise definition of the target. However, stereoselective routes to some of the alternative structures can, and do, result in analogues that in themselves are worthy of study. The synthesis of model compounds, too, is not to be despised, because the first tentative phase of chelation studies on them may provide valuable indications of the behavior of the natural metabolites.

Significantly, most new marine natural products have been isolated after biological screening of crude plant and animal extracts for desirable activity. Whether the biological activity involves metal chelation has seldom been discussed, and we are not qualified to pass comment. The questions we posed in the introduction concerning possible in vivo relationships between metabolites and metal ions have scarcely been illuminated by the facts we have managed to uncover.

We must make it clear that the biological and medical literature has, in general, not been examined in the compilation of this review; important references to the phenomenon under consideration may well be lurking in this unexplored body of information.

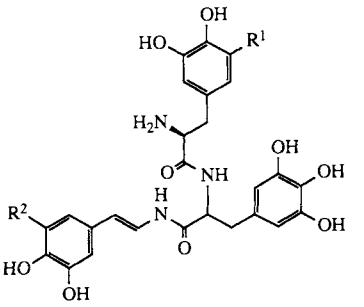
What sort of studies might we wish to see in the future? Firstly, simple qualitative evidence for metal–metabolite interaction should be relatively easy to obtain, and should provide a broad foundation for more detailed investigations. Spectroscopic changes on the addition of metal ions to solutions of natural products are certainly within the ambit of virtually all researchers. The preparation and isolation of characterizable complexes would be even more convincing. Because conformational aspects of the interaction are important to study, it is imperative to add to the catalogue of crystallographic structures of metal complexes of marine natural products. In terms of physical properties, the lack of thermodynamic data on the binding and stability of metal–metabolite complexes is a serious omission that could be remedied. Studies on the kinetics of complexation would follow naturally once the thermodynamic aspects are clarified. Finally, molecular mechanics studies, which have the advantage of not even requiring the isolated compound, must assume a greater importance once reliable parameters for metal ions become more widely available.

It is understandable but unfortunate that few daydreams on the topic of metal–metabolite interaction have appeared in print. The natural caution of authors, and the conservatism of many referees and editors who excise speculative statements, no doubt play a part in suppressing the fantasies that may excite less timorous researchers into action. By throwing the spotlight on a topic that has hitherto lain dormant in the dark recesses of the literature, we hope that we have focused attention on the latent possibilities that await exploration.

9. Addendum

The following material, published after the completion of the manuscript, casts more light on some of the major issues addressed in this review.

1. The vanadium-sequestering tunicate *Phallusia mammillata* is the source of three new tunichromes, Pm-1 (the major metabolite), Pm-2, and Pm-3 (**96a–c**).[140] The compounds lack one of the double bonds of the An-tunichromes **16** (Section 3), and it may be significant that **16** appeared as artifacts when the Pm-tunichromes were purified by chromatography on silica gel rather than on the polystyrene phases recommended in this later paper (80–90% recovery of compounds). A highly relevant point is that ^{13}C CP-MAS NMR spectra of lyophilized blood cells of *P. mammillata* corresponded closely with the solution spectra of Pm-1: the native tunichrome is thus present in the blood cells as free pigment and not as a vanadium-bound species. Semiquantitative comparison of tunichrome content with sulfate and vanadium content has revealed approximately equivalent amounts of sulfate in the morula cells and vanadium (aquasulfatovanadium complex?) in blood cells. A new mechanism for the uptake, reduction, and concentration of vanadium has been proposed, the reduction stage being mediated by a



96a $R^1 = R^2 = OH$
96b $R^1 = H, R^2 = OH$
96c $R^1 = OH, R^2 = H$

tripeptide sulfoconjugate that itself undergoes oxidative decarboxylation to give the observed styrylamide residue of the tunichromes.

2. Faulkner et al. have shown that the structures proposed for the dercitamine family of alkaloids (nordercitin (**35**), Section 4) are incorrect.[141] The positions of nitrogen and sulfur in the thiazole must be interchanged; the compounds are, in fact, members of the same series as the kuanoniamines. More importantly, however, these researchers have used NMR and fluorescence measurements to show that kuanoniamine D (**37**) forms ML_2 complexes with divalent metal cations such as Co^{2+}, Cu^{2+}, Fe^{2+}, and Zn^{2+}. Stability constants for the binding of **37** to $CoCl_2$ and $Cu(OAc)_2$ were determined from fluorescence studies to be $2.5 \times 10^{10}\ M^{-2}$ and $1.3 \times 10^{10}\ M^{-2}$, respectively.

3. The zinc complex of clathridine **7** has been isolated from another sponge, *Leucetta microrhaphis*.[142]

J. P. M. wishes to thank the University of the Witwatersrand, Johannesburg, and the Foundation for Research Development, Pretoria, for financing his sabbatical leave at the University of Nottingham.

Mercury, a Structural Building Block and Source of Localized Reactivity in Extended Metal–Metal Bonded Systems

By Lutz H. Gade*

Transition metal–mercury complexes were among the first compounds of study for the concept of direct metal–metal bonding which was established more than three decades ago. Since then, a large number of such systems have been synthesized and studied. The fact that mercury is readily attached to a large variety of main group or transition metals has stimulated its use as a general building block in the systematic synthesis of mixed-metal clusters. The past decade has witnessed a rapid expansion of bimetallic cluster chemistry in which species containing mercury have played a prominent role, and which has led to the discovery of many unprecedented cluster structures and reactions. In particular, the ability of mercury to form multicenter metal–metal bonds with polynuclear cluster fragments has substantially extended its coordination chemistry which was thus far dominated by simple linear structural arrangements. Although certain structural motifs are found to be common to many of the transition metal–mercury clusters investigated to date and thus enable a relatively systematic synthetic approach, the multitude of surprising discoveries has kept the interest in the chemistry of the element itself alive. The recent discovery of the redox and photochemical reactivity of some of these systems has opened up an exciting and promising area of cluster research. Its significance for the synthetic methodology lies in the fact that the increasing redox activity of molecular carbonyl clusters on going to higher nuclearities appears to set a limit on the size of metal frameworks attainable by the standard preparative methods. On the other hand, their potential use as photochromes or redox mediaters in coupled electron-transfer reactions provides an additional stimulus for future studies in this field.

1. Introduction

Nowadays, the study of the properties of clusters is a vast and highly structured area of research, which draws its experimental and theoretical methods and techniques from virtually every scientific discipline.[1] A special class of systems studied in this field is that of molecular cluster complexes, in particular, polynuclear metal carbonyl clusters and their derivatives.[2] These have received considerable attention with regard to both their structural chemistry and reactivity. The ever growing number of high-nuclearity clusters containing up to a few dozen metal atoms has led to an increased interest in their chemical and physicochemical properties.[3, 4] While the fascinating structures of many of these molecules are well established by X-ray crystallography, our knowledge of their chemical transformations is rather limited. This is largely due to the delicate energy balance between the metal–metal and metal–ligand bond relationships of the species formed in the cluster aggregation, a situation which prohibits the selective and localized manipulation of their ligand shells or metal frameworks. Most standard synthetic approaches (e.g., thermally or chemically induced ligand substitutions or additions), which have successfully served in the chemistry of low-nuclearity systems, lead if performed on large clusters to more or less complete breakdown of the metal framework. Alternatively, complex cascades of cluster degradation and aggregation reactions generate products that are structurally unrelated to the initial substrate. These standard techniques are therefore of limited value for the development of a general synthetic strategy and have fuelled the widespread perception of the "hit-and-run" nature of cluster synthesis.

On the other hand, mixed-metal frameworks containing metal atoms or cluster subunits with significantly different electronic properties offer the potential to direct chemical changes towards the interfaces between these components. This anticipated reactive behavior originates from the introduction of metal–metal bond polarity in the framework. The idea itself is reminiscent of the synthetic strategies employed in organic chemistry for the construction of complicated functionalized hydrocarbons that are based on the exploitation of specifically introduced bond polarities (e.g. the generation of nucleophilic or electrophilic centers of reactivity) for the regio- or even stereoselective formation or cleavage of C–C bonds.

The potential of mercury to form heterobimetallic complexes with transition metal complex fragments was recognized long before the direct metal–metal bonding between transition metals became a generally accepted concept in inorganic chemistry. Compounds containing mercury atoms directly bonded to a complex fragment have long since entered standard textbooks of inorganic chemistry.[5] The fact that the metal is readily attached to a large variety of other main group or transition metals has made it an attractive candidate for a "universal glue" in the systematic synthesis of high-nuclearity clusters. This may involve the addition of Hg–ligand fragments to cluster frameworks or the incorporation of naked Hg atoms or aggregates into an extended framework.

The past decade has witnessed a rapid expansion of the chemistry of bimetallic clusters containing mercury, such that it now rivals that of gold, its precious neighbor in the

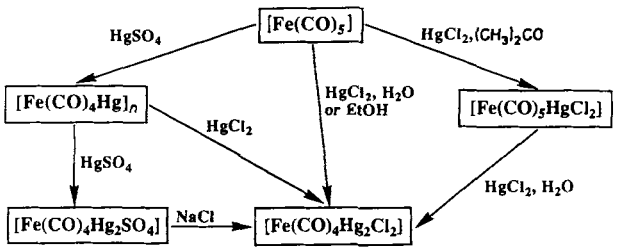
periodic table. This has entailed the discovery of many unprecedented cluster structures and reactions. The ability of mercury to form multicenter metal–metal bonds, and thus bridge metal–metal edges, or cap triangular faces of cluster cores, has substantially extended the coordination chemistry of the element, which was peviously dominated by linear structural arrangements in its molecular species. Developments in this area that have generated a multitude of new data therefore warrant a reassessment of the structural chemistry of mercury. This is one of the aims of this article; the other is to provide a critical survey of the progress made in the development of generalized synthetic concepts in the chemistry of high-nuclearity mixed-metal clusters.

2. Historical Milestones in the Chemistry of Molecular Transition Metal–Mercury Compounds

The publication by Hock and Stuhlmann in 1928 "*Über die Einwirkung von Quecksilbersalzen auf Eisenpentacarbonyl*" must be regarded as the birth of transition metal–mercury complex chemistry.[6] In this and a series of subsequent papers[7] they reported the results of reactivity studies of $[Fe(CO)_5]$ towards mercuric salts, and the characterization of the products obtained from these reactions (Scheme 1). They provided the archetypal examples for



Scheme 1. The reactions of $[Fe(CO)_5]$ with Hg salts reported by Hock and Stuhlmann.

much of the chemistry reported in this area in later years. Reacting $[Fe(CO)_5]$ with one equivalent of $HgCl_2$ while cooling the reaction mixture yielded the product $[Fe(CO)_5(HgCl_2)]$, a Lewis acid–base adduct of the mercuric salt with the carbonyl complex. Nowadays several structurally characterized examples for this kind of complex confirm the authors' interpretation of their results, which at the time were based solely on a complete elemental analysis. In the presence of an excess of $HgCl_2$, the reaction went further to the dimercurated complex $[Fe(CO)_4Hg_2Cl_2]$. While this formulation was correct, its structure remained obscure. The fact that this complex could also be obtained by the reaction of the oligomeric $[Fe(CO)_4Hg]_n$ with $HgCl_2$ led to its original formulation as $[Fe(CO)_4Hg(HgCl_2)]$, that is, an $HgCl_2$ adduct of the iron carbonyl derivative $[Fe(CO)_4Hg]$. The latter was first isolated from the reaction of $[Fe(CO)_5]$ with an aqueous solution of $HgSO_4$. The structure of this completely insoluble material remained speculative and for a long time was thought to be polymeric.[8] More recently the crystal structure of the analogous Cd compound has been reported, and this shows the species to be a cyclic tetramer,[9] a geometry which may therefore also be assumed for $[Fe(CO)_4Hg]_n$.

While the work on iron carbonyl derivatives was conducted with the specific aim of exploring the chemical reactivity of $[Fe(CO)_5]$ towards mercury(II) salts, the next mercury–carbonyl complex to be reported was a by-product of research aimed in a totally different direction. In an early example of bioinorganic chemistry, Schubert studied the interaction of a Co^{II}–cysteine complex with carbon monoxide.[10] Instead of the desired mixed carbonyl-cysteine complex he observed the disproportionation of the complex, which yielded $[Co^{III}(cys)_3]^{3-}$ (cys = $[SCH_2CH(NH_2)Co_2]^{2-}$) and $[Co(CO)_4]^-$. The latter component could not be isolated, but on reaction with $HgCl_2$ a novel compound precipitated, which was correctly formulated as $[\{(CO)_4Co\}_2Hg]$. This work was followed up by Hieber et al. who developed several high-yield syntheses for this complex and its Zn and Cd analogues.[11] At the same time Hein and Pobloth reported the synthesis of the first carbonyl–organomercury compound $[Fe(CO)_4(HgCH_3)_2]$, as well as a detailed investigation of the thermal symmetrization (dismutation) to $[Fe(CO)_4Hg]_n$ and $[(CH_3)_2Hg]$ [Eq. (a)].[12] Equilibria of this

$$[Fe(CO)_4(HgCH_3)_2] \rightleftharpoons 1/n[Fe(CO)_4Hg]_n + [(CH_3)_2Hg] \quad (a)$$

kind were later found to dominate the chemistry of this class of mercury compounds and play an equally important role in the reactions of transition metal clusters containing mercury.

By the mid-1940s, the most important synthetic routes leading to these mixed-metal compounds had been well established. However, the molecular structures of most of the products remained poorly understood. Both the Fe–Hg and

Lutz H. Gade was born in 1963 in Bonn and raised in Johannesburg (South Africa). From 1983–1988 he studied chemistry at Bonn University and at the Technical University Munich, where he wrote his diploma thesis under F. H. Köhler. Thereafter he took up short-term employment in the pharmaceutical industry. He worked on his Ph.D. from 1989–1991 with Jack Lewis at Cambridge University, and since 1991 has been a Liebig fellow at Würzburg University. His research interests include polar metal–metal bonds in polynuclear coordination compounds, the coordination chemistry of early transition metals, and the photochemistry of organometallic compounds.

Co–Hg compounds were generally regarded as salts of the carbonyl metalates, a notion which was irreconcilable with the absence of any saltlike behavior. This confusion about their molecular structures seems to have temporarily inhibited further development of transition metal–mercury chemistry until about 1960. Within this period, the concepts of chemical bonding, particularly with regard to polynuclear transition metal compounds, developed rapidly. This fundamentally changed the inorganic chemist's approach to the theoretical understanding of such compounds. The crucial step in this "revolution" was the report of the crystal structure analysis of $[Fe_2(CO)_9]$ by Powell and Ewens in 1939, which led the authors to invoke a metal–metal bond between the two Fe centers.[13] This view was immediately endorsed by Pauling,[14] but initially met with fierce opposition from other researchers.[15] However, the amount of experimental data supporting the presence of covalent metal–metal bonds and the solution they offered to many problems arising from the apparently contradictory experimental results obtained earlier, along with the application of new physicochemical methods for the characterization of polynuclear compounds, won wide acceptance for this new concept.[16] Apart from the polynuclear metal carbonyls and low-valent halides of the early transition metals, the Hg-containing compounds discussed above, as well as the mercurous ion Hg_2^{2+} were prime targets for reinvestigation within this conceptual framework.

From 1960 onwards there was a rapid succession of publications on new syntheses and properties of transition metal–mercury complexes, beginning with the report of the Co–Hg vibrational band in the Raman spectrum of $[\{(CO)_4Co\}_2Hg]$.[17] Nyholm and Vrieze synthesized the complexes $[(Ph_3As)_3RhCl_2(HgCl)]$[18] and $[(Ph_3P)_2Ir(CO)Cl_2(HgCl)]$,[19] and Stiddard et al. prepared the septacoordinate complex $[W(CO)_3(bipy)(HgCl)_2]$.[20] At the same time the *cis* geometry of the two Fe–Hg bonds in $[Fe(CO)_4(HgCl)_2]$[21] was derived from its IR spectrum and confirmed by X-ray crystallography a few years later.[22]

Up to the late 1970s, an enormous amount of work concerning various aspects to Hg–transition metal bonding was published. This has been comprehensively reviewed by Hsieh and Mays[23] and later by Burlitch.[24] The latest development in this area is the application of Hg reagents in the synthesis of mixed-metal carbonyl clusters initiated by the work of Rosenberg et al. in 1980. This area will be highlighted in this article.

3. Structural Principles Determining the Buildup of Molecular Clusters Containing Isolated Hg Atoms or Hg_n Subclusters

3.1. Building Chains, Rings, and Cages with Mononuclear Transition Metal Complex Fragments

The preferred linear coordination of the mercury atoms involved in two-center two-electron (2c2e) bonding to a transition metal sets relatively narrow limits on the possible types of cluster structures incorporating mercury. On the other hand, it makes their analysis, at least superficially, straightforward and lends a certain predictability to their geometries. These will be mainly governed by the functionality of the transition metal complex fragments, that is, the number of M–Hg bonds (M, M′ = transition metal complex fragment) a single fragment can form as well as the relative configuration of the Hg groups coordinated to the transition metal. Three possible structural types have been observed so far:[25, 26]

a) simple trimetallic complexes of the type M-Hg-M′ for monofunctional fragments M and M′;

b) chain and ring structures $(\text{-Hg-M-})_n$ requiring difunctionality of M;

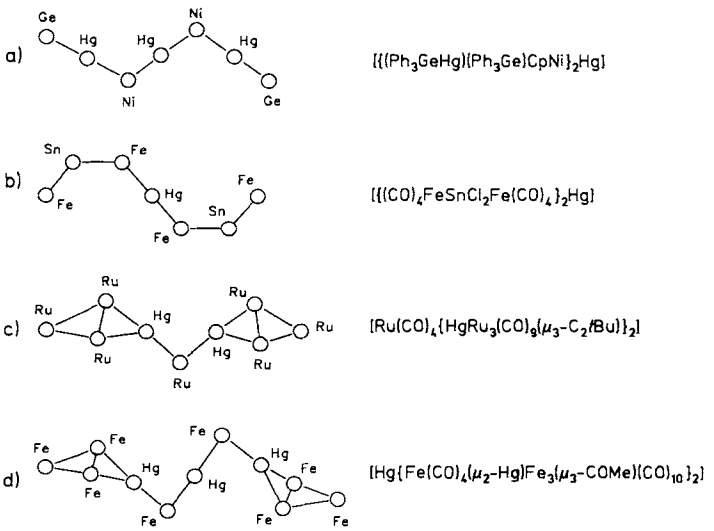
c) three-dimensional cluster structures for trifunctional complex fragments.

The chemistry of the first type of compounds M-Hg-M′ has been reviewed elsewhere and is not within the scope of the article.[23, 24] A representative example would be $[\{Cp(CO)_3Mo\}_2Hg]$, a compound which has been studied extensively with regard to its physicochemical properties as well as its reactivity.[27]

Structurally characterized examples of open, metallic-chain structures containing more than one mercury unit linking only mononuclear complex fragments have not been reported to date. The only such species identified so far involve triangular cluster units.[28] However, mercury atoms have generally proved to be ideal "linkers" in metal chain structures, as was first observed in $[\{(Ph_3GeHg)(Ph_3Ge)CpNi\}_2Hg]$, which was isolated from the reaction of $[Cp_2Ni]$ with $[(Ph_3Ge)_2Hg]$ (Scheme 2a).[29] A heptametallic chain structure containing Fe, Hg, and Sn atoms was obtained and structurally characterized from the symmetrization of $[(CO)_3CpMoHgFe(CO)_4SnCl_2Fe(CO)_4]^-$ (Scheme 2b, [Eq. (b)]).[30]

$$2[Et_4N][(CO)_3CpMoHgFe(CO)_4SnCl_2Fe(CO)_4] \rightleftharpoons [Et_4N]_2[\{Fe(CO)_4SnCl_2Fe(CO)_4\}_2Hg] + [\{(CO)_3CpMo\}_2Hg] \quad (b)$$

In this compound, the Hg and Sn atoms are coordinated in a *cis* arrangement to the central $[Fe(CO)_4]$ units, and therefore generate a folded-chain structure. The *cis* coordination of two Hg atoms to the transition metal complex



Scheme 2. Examples of metal chain structures containing mercury atoms as linking units.

fragments may also lead to the formation of closed-ring structures, as was proposed for $[Fe(CO)_4Hg]_n$ ($n = 4$) in the previous section.

The structure of such a cyclic mercury compound was substantiated by replacing the $[Fe(CO)_4]$ complex fragment by its isolobal analogue $[(MeCp)Mn(CO)_2]$; thus Gäde and Weiss obtained the tetrameric complex $[\{(MeCp)Mn(CO)_2Hg\}_4]$ by reacting $K[(MeCp)Mn(CO)_2GeH_3]$ with $HgCl_2$ (Fig. 1).[31] This fascinating compound, along with its

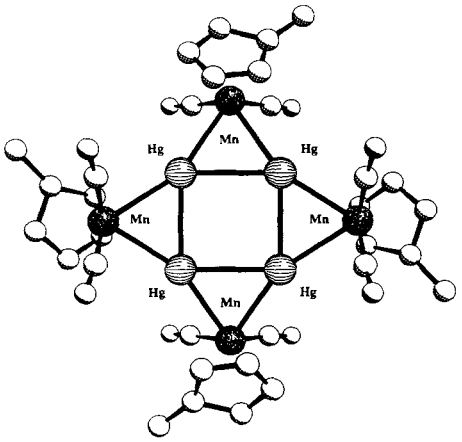


Fig. 1. The molecular structure of $[\{(MeCp)Mn(CO)_2Hg\}_4]$.

Re analogue,[32] remains the only structurally characterized example of its kind to date. In contrast to the $(FeCd)_4$ ring which is distorted by the coordination of acetone molecules to two of the Cd atoms, the $(MnHg)_4$ cluster has a highly symmetrical metal core, in which there are very short distances between the Hg atoms (2.89 Å). This structural feature, along with the nonlinearity of the Mn-Hg-Mn subunits, suggests a significant degree of secondary bonding interaction between the Hg centers. In this complex the mercury atoms may be assigned a formal oxidation state of II and thus possess closed 5d valence shells, which should imply a repulsive interaction between the Hg atoms for the Hg–Hg distances found. However, Hoffmann and other theoreticians have shown that in such compounds with closed-shells, an admixture of s and p wave functions into the molecular orbitals primarily composed of d functions partially converts bonding and antibonding interactions into more bonding and nonbonding ones, respectively.[33] This disruption of the closed d valence shells in heavy atoms has also been invoked for the explanation of the ubiquitous d^{10}–d^{10} attraction in Au^I compounds.[34] To summarize, in polymetallic compounds containing two or more mercury atoms in close proximity, there may be attractive secondary bonding interactions between the Hg atoms in addition to the primary σ-type bonding to the transition metal centers.

A remarkable cluster geometry is found for the metathesis product of $[HOs_3(CO)_{11}]^-$ with Hg^{II} salts. In contrast to the Ru analogue which fragments under the same reaction conditions (see Section 3.5), condensation and subsequent deprotonation occurs, yielding the dodecanuclear, extremely photolabile, "raft" cluster $[\{Os_3(CO)_{11}Hg\}_3]$ (Fig. 2).[35] The $Os(CO)_3$ vertex of each $Os_3(CO)_{11}$ triangle is therefore the difunctional metal complex fragment. In addition to the

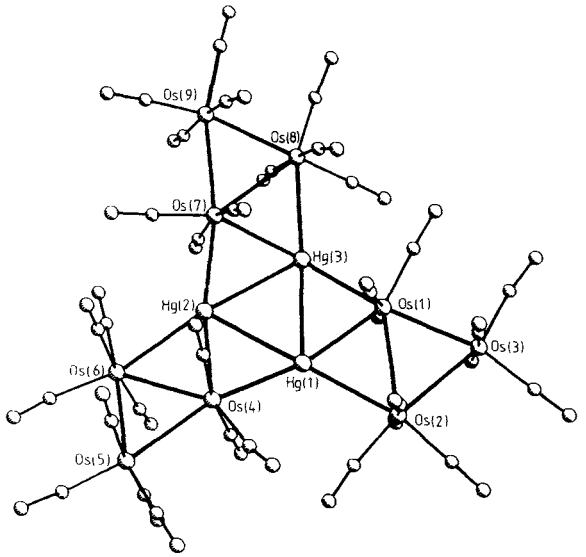

Fig. 2. The structure of the Os–Hg cluster $[\{Os_3(CO)_{11}Hg\}_3]$.

Os–Hg bonds (d(Os–Hg) = 2.71–2.76 Å) in the central Os_3 macrotriangular structure, there are donor/acceptor interactions between an $Os(CO)_4$ vertex and each mercury atom (d(Os–Hg) = 2.98–3.05 Å). The fact that the Hg–Hg distances in the central Hg_3 triangle are significantly greater than those in the Hg_4 square of $[\{(MeCp)Mn(CO)_2Hg\}_4]$ is attributed by King to the *trans* influence of these Os–Hg dative bonds.[26]

Transition metal–mercury compounds containing trifunctional metal complex fragments may form three-dimensional cluster structures ("cages"), as found in $[Hg_6Rh_4(PMe_3)_{12}]$ (Fig. 3 top)[36] and $[Hg_9Co_6(CO)_{18}]$ (Fig. 3 bottom).[37] As King has pointed out,[26] these clusters contain mercury polyhedra within transition metal macropolyhedra, the number of Hg atoms being equal to the number of edges in the respective macropolyhedron. For the macropolyhedra whose vertices have a connectivity of 3 this would constitute a series of clusters with the general formula $[\{Hg_3(ML_3)_2\}_{n+1}]$ ($n = 1,2,3,\ldots$). Thus, $[Hg_6Rh_4(PMe_3)_{12}]$ is the first member of this series containing a mercury octahedron inside a rhodium macrotetrahedron, while $[Hg_9Co_6(CO)_{18}]$ is built up from a tricapped trigonal prism of nine Hg atoms inside a cobalt trigonal macroprism of six Co atoms. The cobalt compound has an interesting chemistry in solution: fragmentation to $[(XHg)_3Co(CO)_3]$ occurs on reaction with HgX_2 (X = I, Cl, O_2CCF_3), a process which can be reversed for $[(ClHg)_3Co(CO)_3]$ upon addition of PPh_3. The Hg_9Co_6 cluster may therefore be seen as the (three-dimensional!) symmetrization product of the trimercurated Co complex.

More recently Strähle and Wurst have reported the synthesis and structure of the Pt–Hg cluster $[Hg_6Pt_4(dippb)_4]$ (dippb = 1,4-bis(diisopropylphosphinobutane)), which has a similar metal framework to $[Hg_6Rh_4(PMe_3)_{12}]$.[38] In contrast to the rhodium cluster, which has a skeletal electron count of 132 and thus conforms to the effective atomic number (EAN) rule, the Pt–Hg cluster lacks four skeletal electrons, and metal–metal bonding within the system is explained by invoking the presence of two three-center two-electron (Pt-Hg-Pt) bonds. The presence of the three-

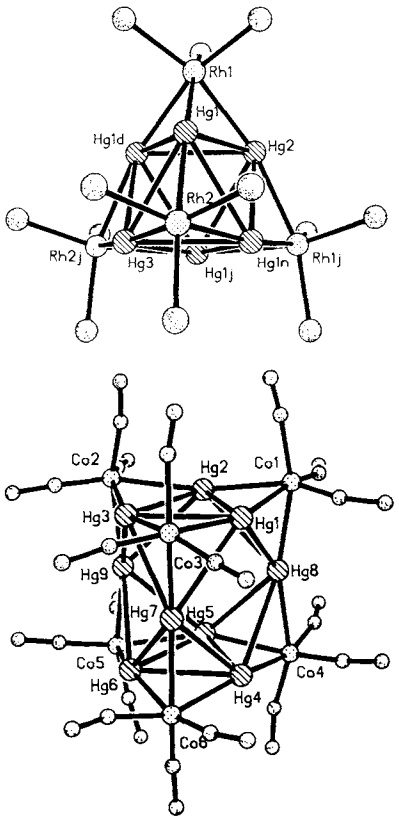

Fig. 3. The molecular structures of $[Hg_6Rh_4(PMe_3)_{12}]$ (top) and $[Hg_9Co_6(CO)_{18}]$ (bottom).

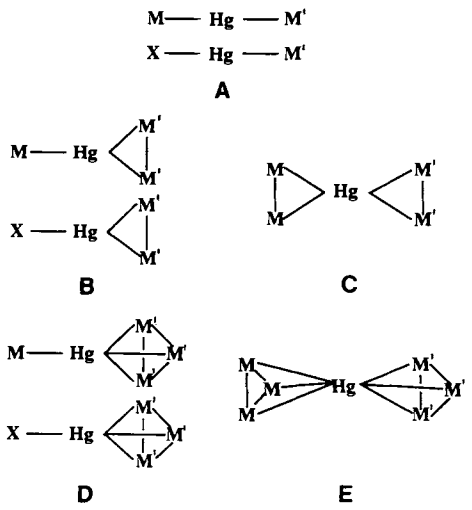
center two-electron (3c2e) bonds is thought to be reflected in the local distortion within the Hg_6Pt_4 macrotetrahedron found in the solid-state structure.

A unique Mo_4Hg_4 metallacubane forms the central unit of $[\{CpMo(CO)_3HgMo\}_4]$ obtained by Ziegler et al. as a by-product of the reaction of $[CpMo(CO)_3]^-$ (generated in situ by reduction of $[CpMo(CO)_3]_2$ with Na/Hg) with 2-butenylchloride.[39] Both the naked molybdenum and mercury atoms within the cube have an unusual coordination environment, and in spite of numerous attempts to synthesize further compounds of this type by varying the metals, it remains the only example of its kind to date.

3.2. The Structural Environment of the Linking Hg Atom in Mixed-Metal Clusters

The basic structural motif in transition metal–mercury compounds is the linear M-Hg-M' unit, as was discussed in Section 3.1 for mononuclear transition metal complex fragments, and its metal–mercury bonding can be described as 2c2e bonding of an sp-hybridized Hg atom. However, for a mercury atom linking cluster fragments there is the additional possibility of primary metal–metal bonding through multicenter bonds. The most frequently encountered structural arrays **A**–**E** observed in mixed-metal Hg clusters are summarized in Scheme 3.

In the substructures **A**–**E** the metal–mercury bonding may be viewed simplistically as arising from the bonding interaction of an Hg 6sp hybrid orbital with a frontier orbital of suitable (σ!) symmetry of the metal fragment. Such a bonding situation would electronically allow unhindered internal rotation of the molecule around an axis through the mercury atom and the midpoint of the bridged M–M vectors or capped M_3 triangles. The variation of the dihedral angle between the M_2Hg and M'_2Hg planes in compounds of type **C** is therefore most probably a consequence of steric interactions between the sets of ligands on the two bridged cluster fragments (see Section 3.3). Examples of structural types **A**–**E** have been synthesized and structurally characterized over the past decade and many aspects of the M–Hg bonding in these compounds has been studied in detail. Since structures of type **A** have already been discussed in Section 3.1, the next two sections will focus on types **B** and **C** as well as **D** and **E**.



Scheme 3. The principal structural environments of a linking Hg atom in metal clusters. M, M' = cluster fragment.

3.3. Clusters with Hg Atoms in Edge-Bridging Positions (Type B and C)

The systematic application of the synthetic techniques developed for Hg-bound mononuclear complexes to cluster chemistry was pioneered by Rosenberg et al. who synthesized the first metal cluster in which an HgX fragment occupies an edge-bridging position (type **B**).[40] The preparation of $[Ru_3(\mu_3\text{-}C_2t\text{Bu})(CO)_9(HgX)]$ (X = Br, I) could be achieved either by reaction of a phenylmercury halide with the hydrido cluster $[Ru_3(\mu_3\text{-}C_2t\text{Bu})(CO)_9H]$ or metathetical condensation of the deprotonated anion with HgX_2 (X = Br, I) (Fig. 4 top). Essentially the same coordination geometry of the mercury atom is obtained if the halide is replaced by a mononuclear organometallic fragment, as in $[M_3(\mu_3\text{-}C_2t\text{Bu})(CO)_9(Hg\text{-}m)]$ (m = $CpRu(CO)_2$, $CpFe(CO)_2$ for M = Ru; m = $(CO)_4Co$, $CpMo(CO)_3$ for M = Os), although these clusters are monomeric in the crystal.[41, 42]

The XHg-bridged clusters themselves may be employed as Hg fragments in further cluster buildup, as was again first achieved in Rosenberg's group with the synthesis of $[\{Ru_3(\mu_3\text{-}C_2t\text{Bu})(CO)_9\}_2Hg]$ (Fig. 4 bottom).[43] As in the case of the simple bridged species, the bonding in this cluster can be described in terms of the interaction of Hg 6sp orbitals with suitable cluster fragment orbitals. The wide variation of the dihedral angle ($\measuredangle_{dih}$) between the M_2Hg and the

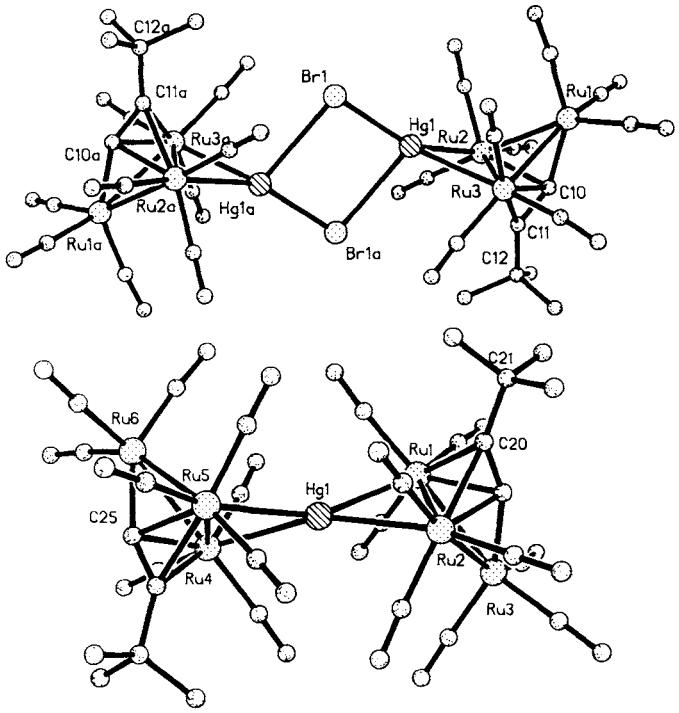


Fig. 4. The solid-state structures of $[Ru_3(\mu_3\text{-}C_2t\text{Bu})(CO)_9(HgBr)]$ (top) and $[\{Ru_3(\mu_3\text{-}C_2t\text{Bu})(CO)_9\}_2Hg]$ (bottom).

M'_2Hg planes in compounds of this type is to be interpreted as a manifestation of the system's steric constaints and is consistent with the simple bonding model assumed here (Table 1).[41-49] The linking of triangular clusters through transition metal–mercury chains of the kind encountered in Section 3.1 may be understood as an extension of the building principles discussed so far. In the simplest reported example, $[cis\text{-}Ru(CO)_4\{HgRu_3(CO)_9(\mu_3\text{-}C_2t\text{Bu})\}_2]$,[61] the two Ru_3 triangles are connected through a $RuHg_2$ bridge (Scheme 2c), whereas the linking unit in $[Hg\{Fe(CO)_4(\mu\text{-}Hg)Fe_3(\mu_3\text{-}COCH_3)(CO)_{10}\}_2]$ is an Hg_3Fe_2 zigzag chain (see Scheme 2d).[28]

Table 1. Transition metal cluster containing μ_4-linking Hg atoms.

Compound	$\measuredangle_{dih}$ [a]	ref.
$[\{(\mu\text{-}C_2t\text{Bu})Ru_3(CO)_9\}_2Hg]$	44.6	43
$[\{(\mu\text{-}H)(\mu_3\text{-}S)Os_3(CO)_9\}_2Hg]$	65.0	41
$[\{Cp(\mu_3\text{-}COCH_3)Fe_2Co(CO)_7\}_2Hg]$	46.2	44
$[\{Cp(\mu_3\text{-}COCH_3)Fe_2Rh(CO)_7\}_2Hg]$	71.9	44

$[\{(\mu_3\text{-ampy})Ru_3(CO)_9\}_2Hg]$ [b]	35.8	47
$[\{(CH_3CN)_3Ni_3(dppm)\}_2Hg]$ [c]	9.7	48
$[\{Os_{10}C(CO)_{24}\}_2Hg]^{2-}$	38.4	49

[a] $\measuredangle_{dih}$ = torsion angle. [b] ampy = 2-aminopyridine. [c] dppm = bis(diphenylphosphino)methane.

A characteristic feature of the behavior of these systems in solution is the high degree of fluxionality of the cluster fragments linked through the Hg bridge. This fluxional behavior can be observed on the NMR timescale and includes both the rotation of the molecules around the internal axis through the Hg atom and the midpoints of the bridged M–M vectors as well as the migration of the Hg fragment around the edge of the M_3 triangles. In view of the importance of this intramolecular dynamic behavior for the properties of virtually all Hg-containing clusters in solution, this topic will be discussed in detail in Section 4.

The method of metathetical condensation (or, as normally called in cluster chemistry, redox condensation) of anionic clusters with Hg^{II} salts has been successfully applied in the selective buildup of high-nuclearity clusters with a mercury atom in a type **B** or **C** environment, such as $[Os_5(CO)_{15}(HgX)]^-$ (X = Cl, CF_3),[50] $[\{Ru_6C(CO)_{16}\}_2Hg]^{2-}$,[46] and in particular, $[\{Os_{10}C(CO)_{24}\}_2Hg]^{2-}$,[49] the largest reported species of its kind (Fig. 5). On going to anionic clusters of higher nuclearity, the choice of the appropriate mercury salt gains in importance, due to the weaker nucleophilicity of the polynuclear metal carbonyl fragment as well as its propensity to follow competing reaction pathways leading to the partial degradation or rearrangement of the metal framework structures (Section 5). The use of $[Hg(O_3SCF_3)_2]$ instead of the more conventional halides has proved to be crucial in the selective synthesis of these compounds.[51]

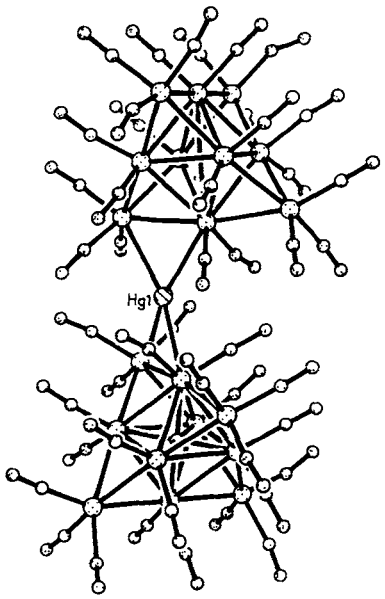

Fig. 5. The molecular structure of the dianion $[\{Os_{10}C(CO)_{24}\}_2Hg]^{2-}$.

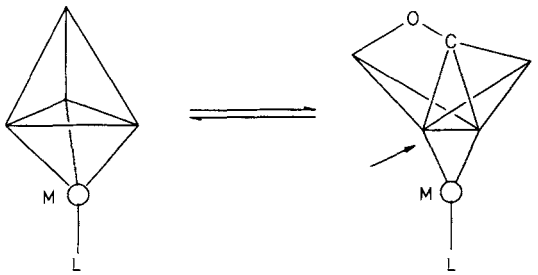
3.4. Clusters with Hg Atoms in Face-Capping Positions (Type D und E)

The first example of a d^{10}-metal complex fragment capping a triangular face of a cluster was reported by Lauher and Wald in 1981 for $[FeCo_3(CO)_{12}(AuPPh_3)]$ in the successful attempt to demonstrate the isolobal relationship between $[R_3PAu]$ and [H].[52] The complex fragments [R–Hg] are isoelectronic (and isolobal) with [L–Au] and should therefore exhibit a similar structural chemistry. This was realized by Braunstein et al. who synthesized and structurally characterized $[RuCo_3(CO)_{12}(Hg\text{-}m)]$ (m = $Co(CO)_4$, $Mo(CO)_3Cp$) (Type **D**)[53] and the μ_6-Hg-linked cluster $[\{RuCo_3(CO)_{12}\}_2Hg]$ (Type **E**).[54]

Detailed comparative studies of the structural changes in the $[RuCo_3(CO)_{12}]^-$ unit on capping the Co_3 triangle with various d^{10} complex fragments such as $(Ph_3P)Cu$, $(Ph_3P)Au$, and R–Hg, revealed that while the overall geometry is similar for all these systems, specific geometrical distortions in the $RuCo_3$ tetrahedron seem to depend on the capping metal complex fragment.[55, 56] This has shown that while these isolobal fragments should formally lead to similar structures, their influence on the electronic (and thus geometrical) structure of the principal cluster core differs significantly. The influence of different electrophilic metal capping groups as well as steric effects on the core geometry of a cluster has been reported by Shriver et al. They studied the effect of [H] and [L–M] groups (M = Cu, Au, Hg) on the equilibrium between the tetrahedral and butterfly structures in $[Fe_4(CO)_{13}]^{2-}$ (Scheme 4).[57, 58] While $[Fe_4(CO)_{13}(AuPEt_3)]^-$ and $[Fe_4(CO)_{13}(HgCH_3)]^-$ have a lower butterfly/tetrahedron ratio in solution than was found for the protonated compound $[HFe_4(CO)_{13}]^-$, the introduction of a sterically demanding complex fragment such as $\{Mo(CO)_3Cp\}$ at the mercury atom favors the butterfly structure in which the mercury atom bridges the "hinge" in a type **B** fashion.



Scheme 4. The equilibrium between the tetrahedral and butterfly structures of metalated derivatives of $[Fe_4(CO)_{13}]^{2-}$; M = Hg, Au, Cu, L = ligand. The arrow indicates the hinge position in the butterfly structure.

The addition of capping Hg units to cluster cores has recently been reported for hexa- and heptanuclear clusters, for examples $[Os_6(CO)_{18}(HgY)]^-$ (Y = Cl, Br, CF_3),[50] $[Ir_6(CO)_{15}(HgCl)]^-$,[59a] (Fig. 6) and $[Re_7C(CO)_{21}(HgY)]^{2-}$ (Y = Cl, Br, CN, Ph, CH_3).[59b] The structures of the Re_7 clusters, however, could not be confirmed by X-ray structure analysis. The largest structurally characterized clusters with Hg atoms in a μ_3 position are yet again derived from $[Os_{10}C(CO)_{24}]^{2-}$: $[Os_{10}C(CO)_{24}(HgBr)]^-$ and $[Os_{10}C(CO)_{24}(HgCF_3)]^-$ (Fig. 7).[49, 60] While the (HgBr) cluster is thermally unstable with respect to symmetrization and cluster degradation, the introduction of the strongly electron-withdrawing CF_3 group significantly stabilizes the $(HgCF_3)$ cluster with respect to subsequent conversions.

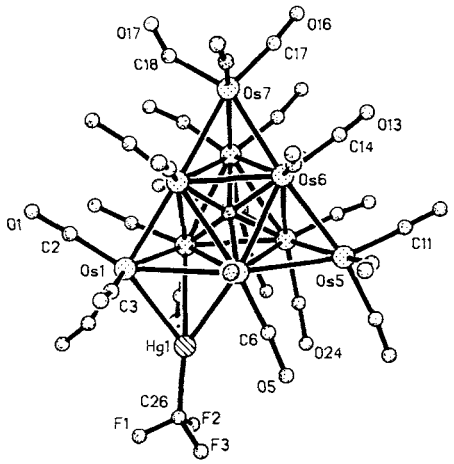

Fig. 7. The solid-state structure of $[Os_{10}C(CO)_{24}(HgCF_3)]^-$.

3.5. The Oxidative Addition of Hg^{II} Salts to Clusters: Fragmentation, Core Rearrangement, or Subsequent Demercuration

Oxidative addition reactions play an important role in the synthesis of di- and trinuclear transition metal–mercury bonded systems but have not found wide application in cluster chemistry. The main reason is the nonspecific degradation of the cluster metal cores, which normally accompanies this reaction. For example, on reacting $[HRu_3(CO)_{11}]^-$ with HgI_2, successive degradation of the triangular Ru cluster occurs, ultimately leading to $[Ru(CO)_4Hg]_n$, the ruthenium analogue of the well-known iron carbonyl derivative.[61] On the other hand, a μ_3-bridging ligand may sufficiently stabilize the Ru_3 framework to allow simple metathetical condensation, such as that leading to $[Ru_3(\mu_3\text{-}C_2tBu)(CO)_9(HgI)]$.[40]

Oxidative addition to a cluster core invariably leads to the fission of metal–metal bonds. Stable products are generated only if the metal framework of the cluster is structurally reinforced so as to accommodate the necessary rearrangement. This consideration provided the basis for Saharan's investigations into the reactivity of the neutral cluster $[Ru_5C(CO)_{15}]$ towards Hg^{II} salts.[50] The square-pyramidal carbido cluster has been known to undergo rearrangement to a more open, bridged wingtip, butterfly structure on oxidative addition of various reagents (Fig. 8 top).[62] Addition of $HgCl_2$ to the cluster led to the formation of the bridged butterfly structure with an HgCl fragment in a μ_2 position across the two Ru atoms on the hinge (Fig. 8 bottom). In the solid state, the cluster is dimeric with an Hg_2Cl_2 unit linking the two Ru_5 cluster fragments. A similar, though monomer-

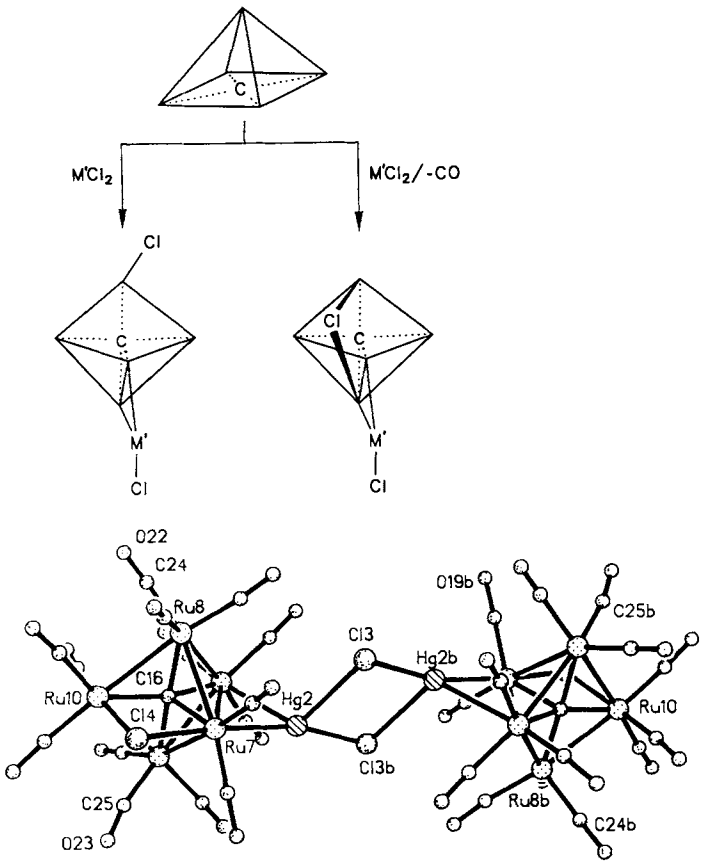

Fig. 8. Top: the oxidative addition of $M'X_2$ (M' = transition metal, X = halide) to the core of $[M_5C(CO)_{15}]$ (M = Ru, Os) and its subsequent rearrangement from a square pyramid to a wingtip-bridged butterfly structure. Bottom: the structure of $[\{Ru_5C(CO)_{15}Cl(HgCl)\}_2]$ as determined by X-ray crystallography.

ic, structure has been estabilished for the product of the reaction with $[F_3CHg(O_2CCF_3)]$.[63]

An oxidative addition is most probably the first reaction step in the formation of a range of osmium clusters isolated from the reaction of $[Os_6(CO)_{18}]$ with $[Hg(O_2CCF_3)_2]$.[64] The only product containing mercury which was characterized is the dimercury pentaosmium cluster $[HOs_5Hg_2(CO)_{15}(O_2CCF_3)_3]$, which consists of a bridged tetrahedral Os_5 core, to which two μ_2-$Hg(O_2CCF_3)$ units are attached (Fig. 9). The third trifluoroacetate ligand is coordinated to

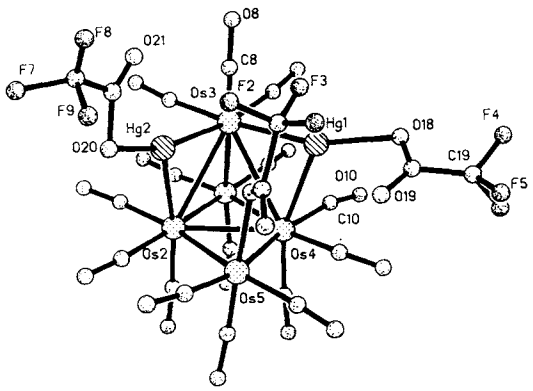

Fig. 9. The molecular structure of $[HOs_5Hg_2(CO)_{15}(O_2CCF_3)_3]$, a model for the oxidative addition of Hg salts to clusters containing metal atoms in tetrahedrally capping positions.

the bridging Os atom in close proximity to the two adjacent Hg groups. The osmium core is derived from the capped trigonal-bipyramidal structure of $[Os_6(CO)_{18}]$ by removal of the cap and opening up of the trigonal bipyramid. It may be regarded as a model for an intermediate in the partial degradation of $[M_{10}C(CO)_{24}]^{2-}$ by $[Hg(O_2CCF_3)_2]$ to yield $[M_{18}Hg_3C_2(CO)_{42}]^{2-}$ (M = Ru, Os). This reaction will be discussed in more detail in Section 5.

3.6. "Tinkering" with Platinum Clusters

Triangular platinum carbonyl clusters and their derivatives are ideal building blocks for the construction of high-nuclearity clusters. This concept has been dubbed by Hoffmann's group as the "tinkertoy approach".[65] The experimental foundation was laid by Chini's group in the

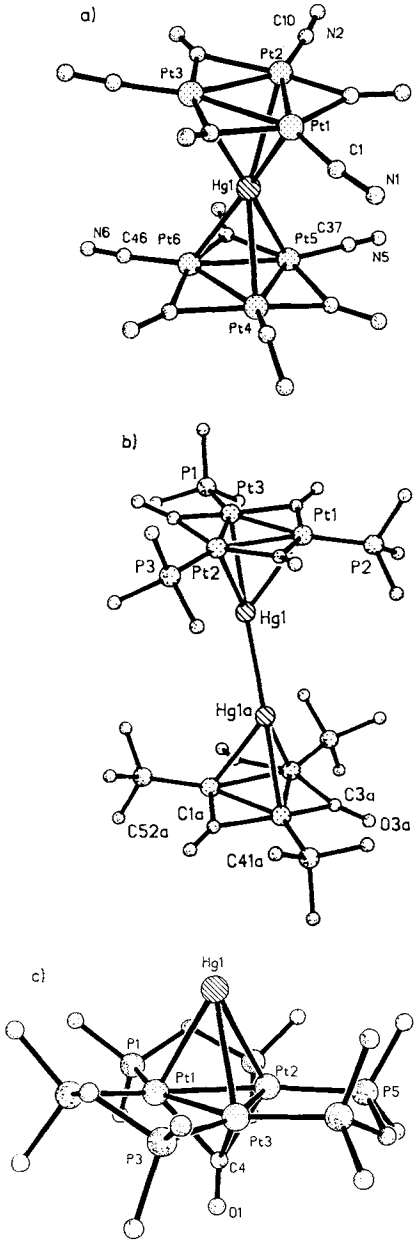

Fig. 10. The molecular structure of $[Hg\{Pt_3[(2,6\text{-}Me_2C_6H_3NC)_6\}_2]$ (a), $[Hg_2\{Pt_3(CO)_3(PPhiPr)_2)_3\}_2]$ (b), and $[Hg\{Pt(\mu_3\text{-}CO)(dppm)_3\}]$ (c).

1970s, who characterized a whole series of platinum clusters $[Pt_3(\mu_2\text{-}CO)_3(CO)_3]_n$ ($n = 2-6, 10$.) containing stacked $[Pt_3(CO)_6]$ units.[3a] By reacting the derivatives of the Pt_3 clusters containing 42 CVEs (*c*luster *v*alence *e*lectron) with metallic mercury, it has been possible to intercalate Hg_n fragments ($n = 1$, 2) between the platinum Pt_3 disks in a sandwich-type fashion.

Three varieties of this structural type have been found to date: $[Hg\{Pt_3(2,6\text{-}Me_2C_6H_3NC)_6\}_2]$, in which a mercury atom is intercalated between two Pt_3 triangles (Fig. 10a);[66] $[Hg_2\{Pt_3(CO)_3(PPhiPr_2)_3\}_2]$, which contains a dimercury fragment almost linearly linking two parallel Pt cluster units (Fig. 10b);[67] and $[HgPt_3(CO)(dppm)_3]$ (dppm = bis(diphenylphosphino)methane), which has a mercury atom capping a single Pt_3 fragment (Fig. 10c).[68]

The first of these compounds was obtained by Yamamoto et al. on reduction of dichloro-bis(2,6-xylylisocyanide)-platinum(II) with sodium amalgam, a process which has been studied in some detail with electrochemical techniques.[69] It is thought that a two-electron reduction generates—via a series of postulated intermediates—the unsaturated fragment $[Pt(2,6\text{-}Me_2C_6H_3NC)_2]$, which trimerizes and reacts with the mercury present in the reaction medium (either from the amalgam or the Hg pool electrode used in the investigations) to generate the Pt_6Hg cluster. ESCA (*e*lectron *s*pectroscopy for *c*hemical *a*nalysis) studies of the compound suggest that the system is most appropriately described by the interaction of a neutral Hg atom with two 42 CVE Pt clusters.[70] This electronic situation has also been assumed in an EHMO (extended Hückel molecular orbital) fragment orbital analysis of the Hg–Pt bonding in the system (Fig. 11).[65, 71] This is dominated by the interaction of the filled 6s orbital of the mercury atom with two a_1' orbitals of the $(Pt_3)_2$ fragment. The degree of stabilization of the bound

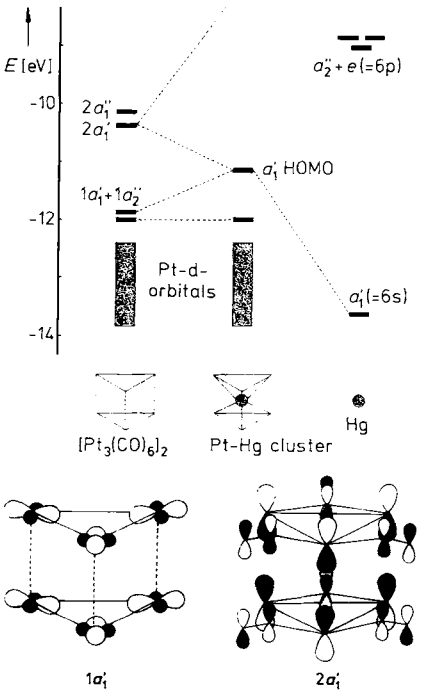

Fig. 11. Top: simplified diagram of the interaction between $[Pt_3(CO)_6]_2$ and the 6s orbital of Hg (adapted from ref. [65]). Bottom: the $1a_1'$- and $2a_1'$ frontier orbitals of the Pt cluster fragment, drawn separately for clarity.

mercury atom appears to depend primarily on the energy of the $2a_1'$ LUMO of the $(Pt_3)_2$ unit, which mixes into the $1a_1'$ HOMO of the cluster, and is primarily of ligand π^* character. The Pt–Hg bonding should therefore be enhanced by π-acceptor ligands such as isocyanides coordinated to the Pt complex fragments. From the point of view of its reactivity, the cluster was found to be a useful precursor for the (L_2Pt) fragment in the synthesis of a (L_2Pt)-bridged diplatinum A-frame complex.[72]

The dimercury cluster $[Hg_2\{Pt_3(CO)_3(PPhiPr_2)_3\}_2]$ was synthesized simply by exposing a solution of the triplatinum cluster to metallic mercury.[67] The two triangular $[Pt_3(CO)_3(PPhiPr_2)_3]$ units are each capped by a mercury atom and then joined through what the authors call a Hg–Hg interaction in the solid state (see Fig. 10b). The mercury–mercury distance of 3.225 Å suggests that this interaction is at best weak, and there seems to be no direct evidence for the dimeric structure in solution.

That monomeric units with a capping Hg atom are feasible entities has recently been shown by Puddephatt et al., who prepared $[HgPt_3(CO)_3(dppm)_3]^{2+}$ and $[Hg_2Pt_3(CO)_3(dppm)_3]^{2+}$.[68] The monomercury complex has been characterized by a single-crystal X-ray structure analysis (Fig. 10c). An EHMO analysis of the compound indicated a very small stabilization energy for the mercury bound to the Pt core, a result which is experimentally reflected in the facile displacement of the Hg by weak nucleophiles such as CO.

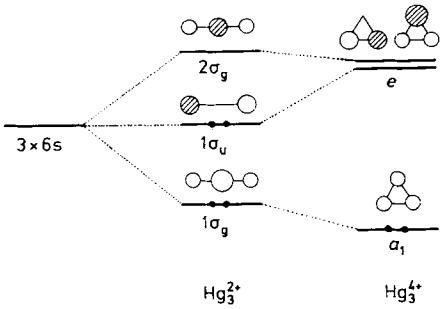
Both these compounds are examples for clusters containing unligated Hg atoms on the surface of their metal frameworks. Other examples for the formal addition of a naked Hg atom to a cluster framework are the mixed-metal systems $[Pt\{AuPPh_3\}_8Hg_2]^{2+}$[73] and $[Ni_8Hg(PPh)_6(PPh_3)_4]$,[74] in which the mercury is screened by neighboring ligands.

3.7. Mercury Subclusters within Larger Metal Arrays

A characteristic feature of mercury chemistry is the formation of compounds with Hg–Hg bonds in solids, coordination compounds, amalgams, and in subunits of mixed-metal high-nuclearity clusters. The location of several mercury atoms at very close proximity in large clusters is a fairly recent discovery, and the chemical consequences of the emergence of a domain structure within the metal core are only beginning to be understood (see Section 6). We will therefore at first briefly recapitulate the structural chemistry of Hg_n units not bound to other metal complex fragments, and discuss the mercury substructures in the light of these results.

The existence of the dimercury(I) Hg_2^{2+} ion is an equally intriguing and puzzling fact of heavy metal chemistry, and has given rise to countless theoretical and experimental investigations over the past two centuries.[75, 76] The stability of the dimer made mercury a promising element for the formation of further subvalent metal ions. The syntheses of these poly-mercury cations were developed primarily in Gillespie's group and culminated in the characterization of $Hg_{3-\delta}(AsF_6)$ ($0 < \delta < 0.15$), a compound with a unique solid-state structure containing AsF_6^- anions and infinite cationic Hg_n chains, whose lattice parameters are mutually incommensurate.[77] As for the simplest member of this series, the Hg_3^{2+} ion, the metal–metal bonding in this species is

predominatly of σ_{6s} character. The preference of a linear arrangement of the Hg atoms over, for example, a conceivable triangular geometry can be easily rationalized in terms of a simple MO scheme which only involves the 6s orbitals (Scheme 5).[78] For the dication a linear geometry will clearly



Scheme 5. A qualitative MO scheme for a linear and a triangular $[\{M(ns)\}_3]^{y+}$ ($y = 2, 4$) system.

be preferred since the population of antibonding orbitals is thus avoided. On the other hand, a tetracationic species Hg_3^{4+} would adopt a triangular arrangement due to the decreased energy of the bonding σ orbital for this configuration. This is indeed observed for the formal Hg_3^{4+} clusters in the mineral terlinguaite, $Hg_4Cl_2O_2$,[79] and the trinuclear coordination complex $[Hg_3(dppm)_3(SO_4)_2]$ (Fig. 12).[80]

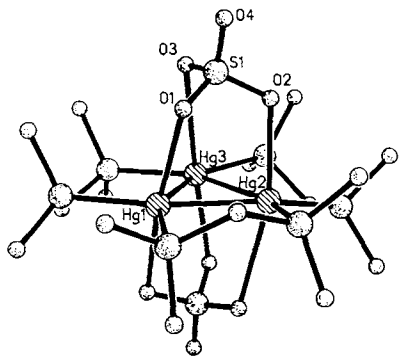


Fig. 12. Structure of the trimercury cluster $[Hg_3(dppm)_3(SO_4)_2]$.

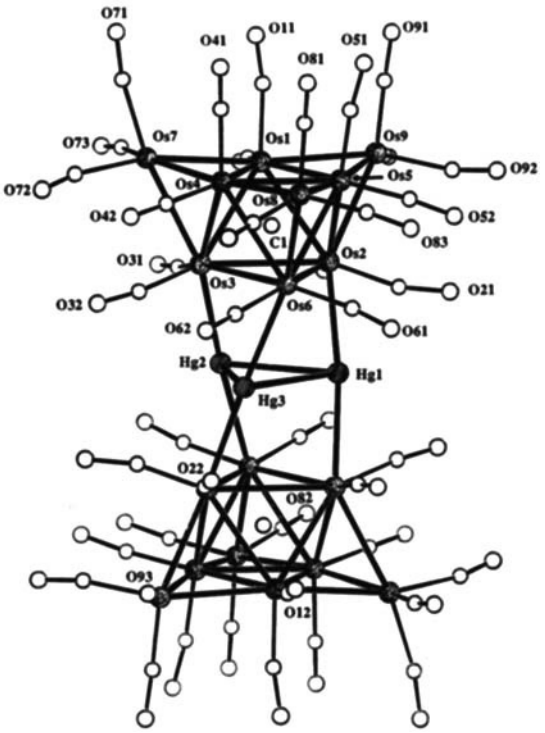
In addition to these multinuclear cationic clusters, the structures of anionic Hg_n clusters in alkali metal amalgams have recently received considerable attention due to the work of Deiseroth et al., who developed a new preparative technique for the synthesis and isolation of crystalline phases of varying composition.[81] The most spectacular result has been the discovery of Hg_8 cubes along with Hg_4 square-planar clusters in $Rb_{15}Hg_{16}$.[82] The Hg-Hg-Hg angles of approximately 90° found for these clusters indicate the predominance of σ_{6p} type bonding between the Hg atoms. The bonding electrons are provided by the alkali metals, which are formulated as monocations.

In view of the tendency of mercury in various oxidation states between +1 and −1 to form aggregates with metal–metal bonds, it might be anticipated that Hg subclusters should be readily incorporated into larger cluster frameworks, as has been found for gold, the neighbor of mercury in the periodic table.[83, 84] However, thus far there are only a few examples of transition metal–mercury clusters which qualify for this category. The cage structures of the type $[Hg_3(ML_3)_2]_{n+1}$ ($n = 1, 2, \ldots$) mentioned in Section 3.1 appear to be constructed around Hg_n subunits. However, the large intramolecular Hg–Hg distances found in their solid-state structures (d(Hg–Hg) > 3.0 Å) and, consequently, weak bonding interactions between the mercury atoms make such an interpretation questionable.

A series of high-nuclearity Ru–Hg and Os–Hg clusters derived from $[M_{10}C(CO)_{24}]^{2-}$ (M = Ru, Os) may be interpreted along the lines of the concept of metal domains referred to in the heading of this subsection. This is justified not only on the basis of their structural data, but also in the light of their chemical behavior with respect to transformations involving their metal cores.

The formation of a trinuclear Hg subunit within the framework of a large carbonyl cluster was the unexpected result of the reaction of $[Ru_{10}C(CO)_{24}]^{2-}$ with $Hg(O_2CCF_3)_2$, which yielded the cluster dianion $[Ru_{18}Hg_3C_2(CO)_{42}]^{2-}$.[85] The subsequent reinvestigation of the corresponding reaction with the osmium analogue led to the isola-



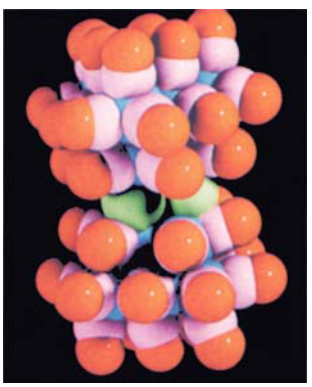


Fig. 13. Top: plot of the molecular structure of $[Os_{18}Hg_3C_2(CO)_{42}]^{2-}$. Bottom: computed space-filling model (CHEM-RAY) of the cluster, showing the exposed situation of the central Hg_3 unit. Red spheres = O, pink = C, green = Hg, blue = Os.

tion and characterization of $[Os_{18}Hg_3C_2(CO)_{42}]^{2-}$ (Fig. 13 top).[49] Both compounds contain the Hg_3 subcluster sandwiched between two tricapped octahedral $[M_9C(CO)_{21}]$ units, which are derived from the framework of the tetracapped, octahedral starting materials, $[M_{10}C(CO)_{24}]^{2-}$, by removal of a capping $Os(CO)_3$ vertex. Although the ligand-free central Hg_3 unit of the cluster is shielded very little by the neighboring carbonyl groups, as seen in the space-filling model (Fig. 13 bottom), the compound is surprisingly stable with respect to nucleophilic attack. The osmium cluster, in particular, has been the object of extensive studies into the reactivity at the interfaces between the different metal domains within these so far unique mixed-metal clusters.[86-89] The reversible photochemical and redox extrusion and reinsertion of mercury atoms has yielded the complete series $[Os_{18}Hg_xC_2(CO)_{42}]^{y-}$ ($x = 1-3$, $y = 1-4$). While the bonding interaction between the Hg atoms in the Hg_3 species is thought to be rather weak (d(Hg–Hg) = 2.927 Å), the significant shortening of the Hg–Hg distance in its photolysis product $[Os_{18}Hg_2C_2(CO)_{42}]^{2-}$ (2.745 Å; Fig. 14) is indicative of a significant degree of bonding between both Hg atoms. Its electronic nature remains poorly understood because the simple electron counting rules and the concept of formal oxidation states of individual metal atoms, used so successfully in the analysis of metal–metal bonded systems, break down for mixed-metal clusters of this size.

To exemplify this, let us consider $[Os_{18}Hg_2C_2(CO)_{42}]^{2-}$ (Fig. 14). Assuming that the polyhedral skeletal electron pair theory is applicable to the two nonaosmium moieties $[Os_9C(CO)_{21}]$, which require an electron count of 122 and thus a formally tetraanionic charge,[90] we are faced with the unreasonable oxidation state of III for the mercury atoms. If this extreme, but in simpler cases useful, approach does not hold, how then is the structure of the dimercury fragment embedded in the osmium core to be analyzed? The answer to this problem is most likely related to the fact that large metal clusters may accommodate a whole range of oxidation states (and therefore a certain degree of electron deficiency) without the accompanying bond breaking or formation associated with redox processes in low-nuclearity species. In other words, the bonding within the metal core of such systems cannot be reduced to a mere series of localized interactions.

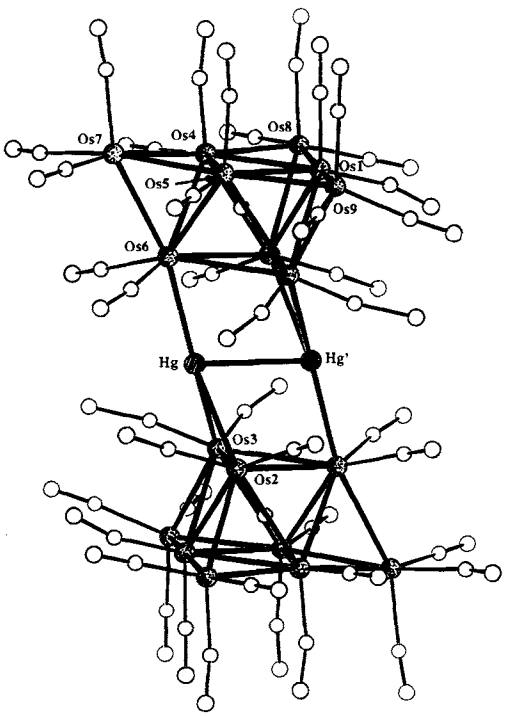

Fig. 14. Molecular structure of the photolysis product, the dianion $[Os_{18}Hg_2C_2(CO)_{42}]^{2-}$.

4. Mercury as a Ligand? The Dynamic Properties of Mercury-Containing Carbonyl Clusters

Mercury as a ligand?[91] This may seem rather paradoxical in view of the approach chosen so far, which has considered Hg-containing units in clusters as an intergral part of their metal frameworks. Nevertheless, this is a fairly common approach whenever the transition metal atom to which the mercury atom is bonded is in the focus of interest rather than the metal–metal bonding itself. To a certain extent this was the case in some of the early work. Thus Nyholm and Vrieze deduced a spectrochemical ligand-field sequence for various Hg–Y groups coordinated to $[(Ph_2MeAs)_2X_2Rh]$ complex fragments,[18b, 19b] and Lewis and Wild related the frequency of the υ(CO) bands in the infrared spectra of $[Fe(CO)_4(HgY)_2]$ to the group electronegativity of the mercury units.[21b]

If there is a property of Hg fragments in clusters that justifies their comparison to other ligands coordinated to the respective principal metal core, it is the dynamic behavior observed in solution. The plots of the molecular structures shown here may convey the impression of rigid metal cores embedded in their equally static ligand shells. While in many cases this is an adequate view of the molecules packed in a single crystal, spectroscopic studies performed on their solutions have revealed the existence of dynamic processes effecting the permutation of nuclear positions in these systems. For transition metal carbonyl clusters containing Group Ib or IIb metal complex fragments in their framework core, fluxionality[92] involving these subunits has been widely observed.[83] This typical behavior may be exemplified by the results obtained for two types of clusters. Type **I** are triangular M_3 clusters, which are linked by a μ_4-Hg bridge, and type **II** are the mercurated derivatives of $[Os_{10}C(CO)_{24}]^{2-}$.

Systematic variable temperature NMR studies of clusters of the type $[\{M_3\}_2Hg]$ (**I**), as discussed in Section 3.3, have been carried out in the groups of Rosenberg[41, 93] and Farrugia.[28, 44] The observed fluxionality may be essentially broken down into two elementary processes (Fig. 15), the rotation around an internal axis through the Hg atom and

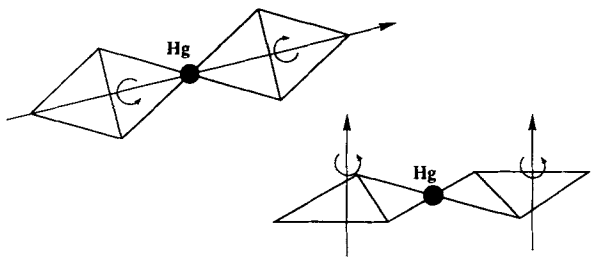

Fig. 15. The two elementary processes which are proposed to account for the dynamic behavior of a series of $[\{M_3\}_2Hg]$ clusters in solution.

the midpoints of the bridged M–M vectors, and at least the partial migration of the Hg complex fragment around the M_3 triangles. The remarkable conclusion drawn from these studies is that a μ_2-Hg moiety has about the same mobility on these clusters as a μ_2-hydrido ligand.[41]

The interpretation of the ^{13}C NMR spectra obtained for $[Os_{10}C(CO)_{24}(HgY)]^-$ (Y = Cl, Br, I, CF_3, $Mo(CO)_3Cp$) (**IIa**) and $[\{Os_{10}C(CO)_{24}\}_2Hg]^{2-}$ (**IIb**) has been slightly more involved.[94] At the high-temperature limit of (**IIa**) the exchange between all positions on the tetrahedral Os_{10} core is a fast process resulting in the effective T_d symmetry of the compound. On cooling the samples, an intermediate dynamic regime is reached in which the chemical exchange of the Hg–Y fragment is restricted to a rotation around a single vertex of the tetrahedron (Fig. 16). Only for the

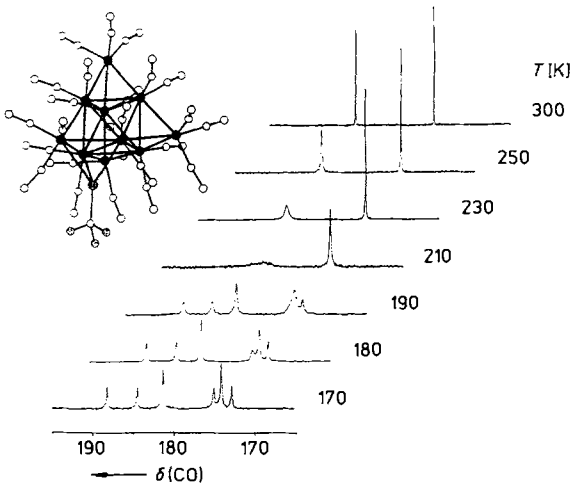

Fig. 16. Variable low-temperature ^{13}C NMR spectra of $[Os_{10}C(CO)_{24}(HgCF_3)]^-$.

$[\{Os_{10}C(CO)_{24}\}_2Hg]^{2-}$ cluster with a linking Hg has it been possible to freeze out the static metal core structure. On heating samples of this compound, a rapid migration of the Hg "linker" around a single vertex in both Os_{10} subclusters is observed, a motion which implies a fast rotation of the two halves relative to each other, as is depicted in Figure 17.

A comparison of the variable-temperature NMR spectra recorded for the Hg–Y-capped Os_{10} clusters with that of the monohydrido species $[HOs_{10}C(CO)_{24}]^-$ has revealed that in these Hg compounds the mobility of the Hg–Y fragment even exceeds that of the isolobal hydrido ligand.[95] Thus, in

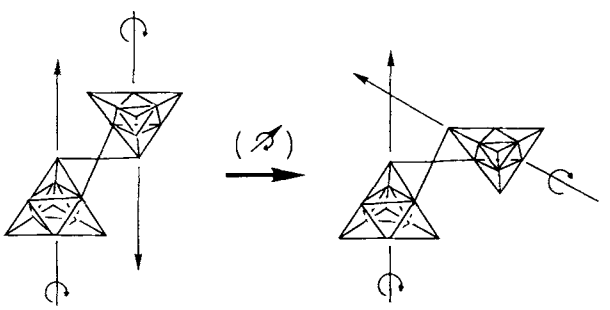

Fig. 17. The proposed intramolecular motion of the Os_{10} cluster fragments in $[\{Os_{10}C(CO)_{24}\}_2Hg]^{2-}$ relative to the Hg bridge, to explain the high-temperature ^{13}C NMR spectral patterns (from ref. [94]).

this context the Hg group displays a behavior that is otherwise typical of ligands in clusters.

5. Characteristics of the Chemical Reactivity of the Hg Complex Fragment Attached to Cluster Cores

Redistributions, that is, symmetrizations or asymmetrizations, of the kind introduced in Section 2 dominate the chemical reactivity of Hg fragments attached to both low- and high-nuclearity metal frameworks [Eq. (c)]. The rela-

$$2\,[M_m(CO)_n(HgY)] \rightleftharpoons [\{M_m(CO)_n\}_2Hg] + HgY_2 \qquad (c)$$

tive stability of the asymmetric over the symmetric components in these equilibria depends on the properties of both the cluster fragment $[M_m(CO)_n]$ (for instance its charge) and the ligand Y coordinated to the mercury center. It has been found that an increased electronegativity of Y stabilizes the asymmetric product M_m-Hg-Y. Another criterion is the strength of the Hg–Y bond. While the factors determining the redistribution reactions of Hg-linked mononuclear complexes have been known for a long time, these studies now include systems with μ_2-Hg-bridged $[M_m(CO)_n]$ units (Scheme 6).

$$2\,[Mn_2(\mu\text{-}HgY)(\mu\text{-}PPh_2)(CO)_8] \rightleftharpoons [\{Mn_2(\mu\text{-}PPh_2)(CO)_8\}_2Hg] + HgY_2$$

$$2\,[Fe_2(CO)_8(\mu\text{-}Hg\text{-}M)]^- \rightleftharpoons [\{Fe_2(CO)_8\}_2Hg]^{2-} + M_2Hg$$

$$2\,[Fe_2(CO)_7(\mu\text{-}PPh_2)(\mu\text{-}Hg\text{-}M)] \rightleftharpoons [\{Fe_2(CO)_7(\mu\text{-}PPh_2)\}_2Hg] + M_2Hg$$

$$2\,[Ru_3(CO)_9(\mu_3\text{-}C_2\,t\text{Bu})(\mu\text{-}HgX)] \rightleftharpoons [\{Ru_3(CO)_9(\mu_3\text{-}C_2\,t\text{Bu})\}_2Hg] + HgX_2$$

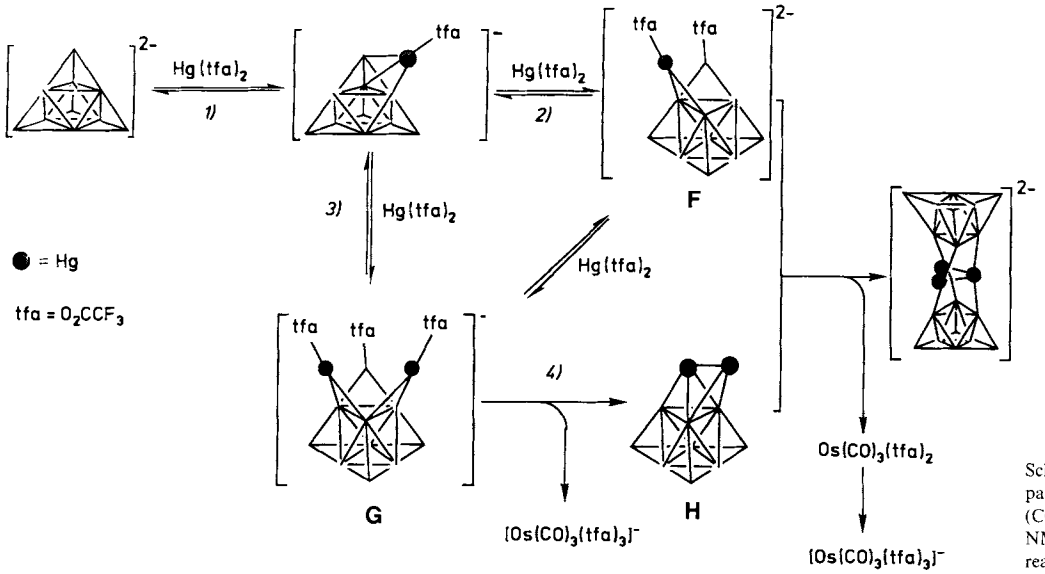
Y = Ph, Cl, CN X = Br, I

M = $Mo(CO)_3Cp$, $W(CO)_3Cp$, $Mn(CO)_5$, $Co(CO)_4$, $Fe(CO)_2Cp$

Scheme 6. Redistribution equilibria of transition metal–mercury compounds containing μ_2-Hg fragments.

For $[Mn(\mu\text{-}HgY)(\mu\text{-}PPh_2)(CO)_8]$ it was found, that while the phenyl derivative (i.e., Y = Ph) symmetrized immediately under the reaction conditions of its synthesis, the equilibrium for the more electronegative chloride (Y = Cl) was almost completely on the side of the asymmetric reactant.[96] On the other hand, the negative charge on $[Fe_2(CO)_8(\mu_2\text{-}Hg\text{-}m)]^-$ appears to stabilize the asymmetric species, while in the case of the neutral μ_2-PPh_2-bridged complex immediate symmetrization occurs.[97] The greater bond energy of the Hg–Br bond in $HgBr_2$ is thought to be the reason for the more strongly favored symmetrization of the bromomercury–ruthenium cluster $[Ru_3(CO)_9(\mu_3\text{-}C_2t\text{Bu})(HgBr)]$ in comparison to its iodo analogue.[43b] Thus, to suppress the symmetrization of an asymmetric transition metal–mercury cluster the ligand Y coordinated to the mercury atom should be a highly electronegative fragment as well as a bad leaving group.

The ideal ligand at the Hg atom in this respect is probably the CF_3 group, which effectively stabilizes the monomer-



Scheme 7. A proposed mechanistic pathway leading to $[Os_{18}Hg_3C_2(CO)_{42}]^{2-}$ based on IR and ^{13}C NMR spectroscopic studies of the reaction mixture.

cury-capped or -bridged cluster even in cases where a whole range of other ligands have failed. This has been shown in the synthesis of $[Os_{10}C(CO)_{24}(HgCF_3)]^-$ and $[Os_{10}H_4(CO)_{24}(HgCF_3)]^-$, the only thermally stable Hg-capped derivatives of the decanuclear parent cluster dianions.[49, 60] The effective blocking of one coordination site at the mercury atom has therefore enabled the characterization of model compounds for the proposed primary intermediate in the more complicated reaction cascades that result from the treatment of the parent cluster dianions $[Os_{10}Z(CO)_{24}]^{2-}$ ($Z = H_4$, C) with Hg^{II} salts.

While the Hg–Y bond is the focus of the discussion of the redistribution chemistry of mercury bound by transition metals, its effect on the principal cluster core may open up additional reaction pathways. The effect an electrophilic attack of a cationic Hg fragment may have on the subsequent conversions of the cluster has been pointed out in Section 3.5 in the discussion of the oxidative addition reactions of Hg salts. The attached Hg fragment activates (i.e. polarizes) the metal framework towards an attack by nucleophiles, such as the displaced anion of the mercury salt or the oxidative addition of a second HgY_2 molecule. Another conceivable secondary reaction is the rearrangement of the ligand Y in the Hg–Y group bound to a neighboring metal center in the cluster. This is expected to be particularly facilitated for labile, potentially bidentate anions such as carboxylates, which may explain their efficiency in cluster degradation reactions, for example $[Os_6(CO)_{18}]$ with $Hg(O_2CCF_3)_2$ (see Section 3.5).[64]

One of the most thoroughly studied reactions, in which these considerations play a role, is the conversion of $[Os_{10}C(CO)_{24}]^{2-}$ to $[Os_{18}Hg_3C_2(CO)_{24}]^{2-}$ with $Hg(O_2CCF_3)_2$. IR and ^{13}C NMR spectroscopic investigations of this reaction as well as the knowledge of the results reviewed in Section 3.5 have led to the proposal of a mechanistic model for this multiple-step transformation (Scheme 7).[51] This comprises the three fundamental reaction types cited above: electrophilic addition of the $Hg–Y^+$ fragment to the cluster (step 1), nucleophilic attack of the displaced anion of the Hg salt on the polarized metal core (steps 2 and 3), and internal rearrangement of the Hg-bound ligands (step 4) yielding the proposed intermediate (**H**) as well as the isolated second reaction product $[Os(CO)_3(O_2CCF_3)_3]^-$. Condensation of (**F**) and (**H**) leads to the final reaction product. The proposed intermediate (**G**) is adequately modeled by $[HOs_5Hg_2(CO)_{15}(O_2CCF_3)_3]$, the only structurally characterized Hg-containing degradation product of $[Os_6(CO)_{18}]$ with $Hg(O_2CCF_3)_2$ (see Section 3.5).

A frequently observed secondary reaction of electrophilic mercurations, which also defines the limits of the synthetic approach discussed in this and the previous section, is the thermal demercuration of the cluster. Anionic carbonyl clusters that have low oxidation potentials are simply oxidized by the attacking Hg reagent with the concomitant precipitation of metallic mercury. The increasing redox activity of clusters on going to high nuclearities has so far prohibited the synthesis of transition metal–mercury clusters containing significantly more than twenty metal atoms. This is illustrated by the completely different behavior of the tetrahydridodecaosmium cluster $[Os_{10}H_4(CO)_{24}]^{2-}$ towards Hg^{II} salts in comparison to its carbido analogue.[60] While the carbido cluster may be regarded as the ideal substrate for redox condensation reactions with Hg electrophiles, $[Os_{10}H_4(CO)_{24}]^{2-}$ is readily oxidized to the radical monoanion by most mercury salts. The same applies to even larger osmium cluster dianions such as $[Os_{17}(CO)_{36}]^{2-}$[98] and $[Os_{20}(CO)_{40}]^{2-}$.[99] These species are known to have a high density of reversibly coupled redox states, a situation which has so far inhibited their use in cluster condensation reactions.[100] The competition between redox reactions and redox condensation reactions is thus an important factor to be considered in cluster synthesis!

6. The Redox and Photochemistry of the Transition Metal–Mercury Bond: Site-Specific Core Manipulation in High-Nuclearity Clusters

The photosensitivity of carbonyl complexes with one or more Hg units bound to the transition metal atoms was

noticed and reported in the early studies on these compounds. Ever since Schubert warned that $[\{Co(CO)_4\}_2Hg]$ had to be manipulated and stored under exclusion of light to avoid photoinduced precipitation of metallic mercury,[10] this characteristic reactivity of a whole range of similar species has only been of interest with regard to the protective measures necessary for their synthesis. It was not until 1988 that the first systematic photochemical investigation of the reaction (d) was reported by Vogler and Kunkeley.[101] The

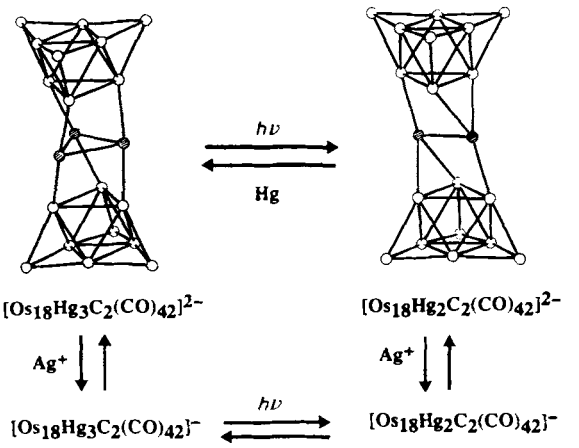
$$[\{(CO)_4Co\}_2Hg] \overset{h\nu}{\rightleftharpoons} [Co_2(CO)_8] + Hg \qquad (d)$$

fragmentation may be understood as being triggered by a metal-to-metal charge transfer (MMCT) transition from the primarily cobalt-centered HOMO to a low-lying primarily mercury-centered unoccupied orbital. This transition effectively amounts to a photochemically driven intramolecular redox reaction, a point of view which is of great heuristic value in the study of high-nuclearity mixed-metal clusters.

The main reason for the paucity of systematic photochemical studies of this kind is probably the lack of interest that the chemical transformations associated with the Hg extrusion have created so far. In addition, the frequently encountered thermal instability of the primary photochemical products may be another aspect which has discouraged the development of this area. The situation should be somewhat different for mixed-metal clusters for which photochemical reactions of this kind might open up new routes to synthetic targets unattainable by the standard preparative techniques.

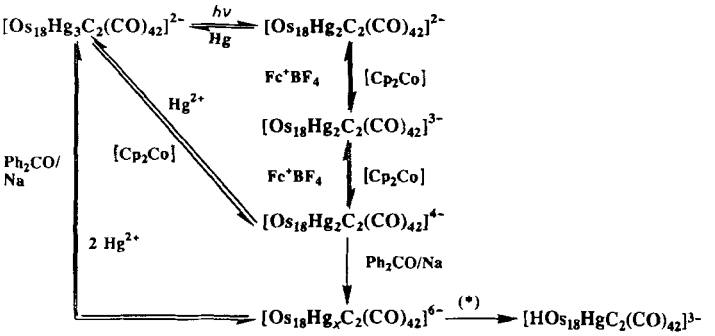
The example par excellence for these conceptual considerations is the octadecaosmium–trimercury cluster $[Os_{18}Hg_3C_2(CO)_{42}]^{2-}$. Its photochemical behavior may well herald a range of comparable metal core manipulations in other mixed-metal clusters. The structure (see Fig. 13) with its clearcut borderlines between the osmium and mercury subunits appeared predestined for core transformations following a photoinduced Hg-extrusion step. Indeed, on irradiation of the deep purple solutions of its $[(Ph_3P)_2N]^+$ salt, a single mercury atom is ejected generating the dimercury species $[Os_{18}Hg_2C_2(CO)_{42}]^{2-}$, which if stirred in the dark in the presence of the precipitated Hg metal, reincorporates an Hg atom to regenerate the starting material completely. Since the Hg-extrusion and Hg-reinsertion steps are accompanied by a change in color of the solution studied, the $Os_{18}Hg_3$-cluster dianion is an example of a photochromic system. The same behavior was found for the corresponding monoanionic species, which are reversibly generated from the dianions by a one-electron oxidation. The tri- and dimercury clusters $[Os_{18}Hg_3C_2(CO)_{42}]^{n-}$ and $[Os_{18}Hg_2C_2(CO)_{42}]^{n-}$ ($n = 1, 2$) are therefore linked by a reversible photochemical and redox cycle as depicted in Scheme 8. The low quantum yields of the two photochemical reactions of approximately 0.5% are probably a consequence of the large number of nonreactive deactivation pathways in these systems.[86, 87, 102]

It was pointed out that the MMCT transition, which induces the loss of one mercury atom, may be viewed as an intramolecular redox reaction in which the population of an Os–Hg/Hg–Hg antibonding orbital leads to the destabilization of the central Hg_3 unit. If this simplistic view holds, the population of the same antibonding orbital from an external electron source, that is reduction of the cluster, should lead



Scheme 8. The reversible photochemical and redox cycle linking $[Os_{18}Hg_3C_2(CO)_{42}]^{n-}$ and $[Os_{18}Hg_2C_2(CO)_{42}]^{n-}$; $n = 1,2$.

to essentially the same structural transformation. This consideration was the starting point of a rich redox chemistry and electrochemistry of the osmium–mercury clusters as summarized in Scheme 9. Particularly notable is the struc-



Scheme 9. The network of reversible photochemical redox transformations of $[Os_{18}Hg_mC_2(CO)_{42}]^{n-}$ ($n = 1-3$, $m = 2-6$). Fc = ferrocene; (*) = workup.

tural relationship between the electron deficient cluster which has fewer electrons than required by the Wade–Mingos rules, $[Os_{18}Hg_2C_2(CO)_{42}]^{2-}$, and the corresponding "electron-precise" tetraanion $[Os_{18}Hg_2C_2(CO)_{42}]^{4-}$ (Fig. 18, see Section 3.7).[88] While the dianion has a distorted core geometry with an Hg–Hg distance of 2.745 Å, the tetraanion shows a significant straightening of the metal core and increase of the Hg–Hg bond length to 2.827 Å. The ejection of a second Hg atom was feasible with a strong reducing agent such as Na/Ph_2CO or $Na/C_{10}H_8$, yielding μ_6-Hg linked clusters in various oxidation states, of which the protonated species $[HOs_{18}HgC_2(CO)_{42}]^{3-}$ has been structurally characterized by X-ray crystallography.[89]

The reductive extrusion of Hg atoms from compounds with metal–mercury bonds is a well established route to mononuclear anionic metal carbonyls, the Hg-bonded species functioning as stable precursors to these materials. A prominent example is the formation of $[Co(CO)_4]^-$ by reduction of $[\{(CO)_4Co\}_2Hg]$ with Na/Hg.[103] On the other hand, the oxidative cleavage of Hg–transition metal bonds is a less well understood process. Reactions of this type may proceed along complex multistep pathways as has been shown recently in a study of the redox chemistry of

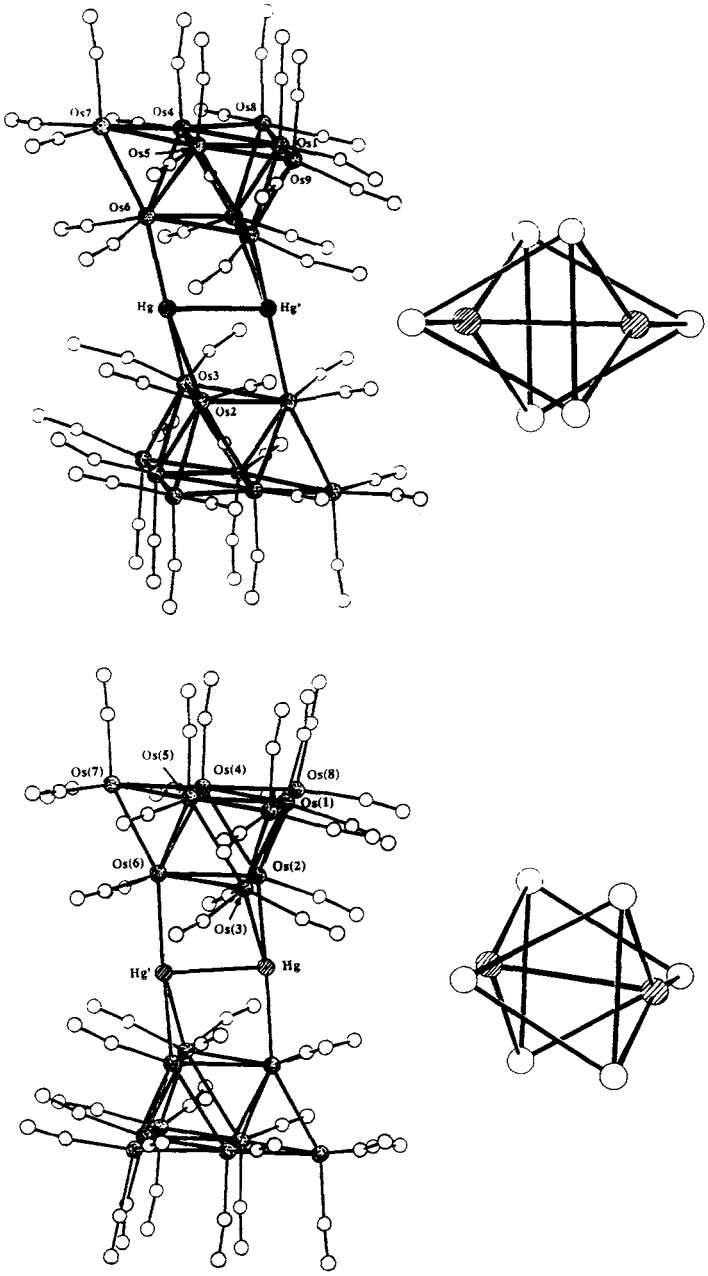


Fig. 18. Left: comparison of the molecular structures of $[Os_{18}Hg_2C_2(CO)_{42}]^{2-}$ (top) and $[Os_{18}Hg_2C_2(CO)_{42}]^{4-}$ (bottom). Right: the structural changes accompanying the two-electron reduction on viewing the molecule along an axis perpendicular to the Os_3 triangles adjacent to the dimercury unit.

$[\{CpMo(CO)_2(PPh_3)\}_2Hg]$.[104] The oxidation of high-nuclearity clusters in the presence of mercury metal may be even more complicated. Chemical and electrochemical oxidation of $[Os_{10}C(CO)_{24}]^{2-}$ in the presence of Hg leads to cluster aggregation, although neither the possible reaction pathways nor the exact nature of the products have been established beyond doubt.[105]

7. Conclusion and Outlook

The wealth of data accumulated over the past decade has impressively demonstrated the potential of mercury reagents in the construction of metal cluster frameworks. While certain structural motifs are found to be common to many of the systems known so far, which enables a relatively systematic synthetic approach to mercury–transition metal clusters, surprises have been plentiful and have kept the interest in the chemistry of the element itself alive.

The step into the regime of high-nuclearity species has only recently been made and has yielded unprecedented structures and reactive transformations. One of the lessons learnt in the investigation of such systems is a consequence of the large variety of potential reactive interactions with mercury salts. To avoid complicated product mixtures arising from redistribution reactions, subsequent demercurations, partial cluster degradation, etc., it is necessary to focus as much attention on the solution properties of the Hg reagent as on the cluster itself. The most important properties of mercury compounds in this respect are their solubility in polar aprotic solvents, the degree of dissociation of the relevant salt in these media, and the strength of the Hg–ligand bond in comparison to the Hg–metal bonds to be formed. Through careful control of these properties, by choice of the appropriate reagent, it should be possible to generate certain cluster types selectively, and in this area considerable progress is to be expected in the near future. In other words, transition metal–mercury cluster chemistry should be viewed as being rooted as much in the chemistry of the element Hg as in mixed-metal cluster chemistry.

The systematic application of photo- and electrochemical techniques to large mixed-metal clusters with their preformed breakage points or "sticky ends" is an exciting and promising area of cluster research.[106] This is so particularly since the increased redox activity of molecular carbonyl clusters on going to higher nuclearities appears to set a limit to the size of metal frameworks attainable by the standard preparative methods. Few examples that fall into this category have been studied to date, and it is therefore too early to draw general conclusions about their reactivity. However, in the same way as mercury has played a prominent role at various stages in the development of organotransition metal chemistry and the concept of direct bonding between metal atoms in molecular structures (Section 2), it may open up new entries into the buildup of extended metal–metal bonded systems.

The author would like to thank particularly Prof. Lord Lewis (Cambridge) and Prof Brian Johnson (Edinburgh) for introducing him to the fascinating field of high-nuclearity cluster chemistry and inspiring the writing of this article; likewise Dr. Phil Bailey (Munich) for his stimulating proposals or vehement opposition to some of the thoughts expressed here. Prof. Mary McPartlin (London), Prof. Alistair Lees (Binghamton), Prof. Joe Lauher (Stony Brook) as well as Dr. Paul Raithby, Dr. Martin Mays, and Dr. Catherine Housecroft (Cambridge) have pointed out many important aspects of the chemistry of Hg–transition metal clusters, and they as well as Prof. J. Strähle (Tübingen) communicated experimental data prior to publication. I am grateful to Dr. Paul Raithby for his help with the production of the figures and to Prof. Helmut Werner (Würzburg) for providing the facilities for the writing of this review. The author's own contributions to the area were financially supported by the British Council, the Kurt Hahn Trust, the Studienstiftung des deutschen Volkes as well as ICI PLC.

Colloidal Semiconductor Q-Particles: Chemistry in the Transition Region Between Solid State and Molecules

By Horst Weller*

In semiconductor particles of nanometer size, a gradual transition from solid-state to molecular structure occurs as the particle size decreases. Consequently, a splitting of the energy bands into discrete, quantized levels occurs. Particles that exhibit these quantization effects are often called "Q-particles" or, generally, quantized material. The optical, electronic and catalytic properties of Q-particles drastically differ from those of the corresponding macrocrystalline substance. The band gap, a substance-specific quantity in macrocrystalline materials, increases by several electron volts in Q-particles with decreasing particle size. In Q-particles there are approximately as many molecules on the surface as in the interior of the particle. Therefore, the nature of the surface as well as the particle size is also largely responsible for the physico-chemical properties of the particle. Q-particles of many materials can be prepared in the form of colloidal solutions or embedded in porous matrices and are stable over a long period of time. In sandwich colloids, in which Q-particles of different materials are coupled, as well as in porous semiconductor electrodes containing Q-particles in the pores, very efficient primary charge separation is observed. As a result, sandwich colloids have greatly enhanced photocatalytic activity relative to the individual particles, while electrodes modified with Q-particles show high photocurrents. This article deals with the size quantization effect, the synthesis and characterization of Q-particles, as well as with the spectroscopic, electrochemical, and electron-miroscopic investigation of these particles.

1. Introduction: The World of Neglected Dimensions

In 1915, Ostwald[1] entitled his famous book on colloid chemistry "The World of Neglected Dimensions", implying that this was a science in its own right. This opinion is certainly correct as the physical and chemical properties of colloids largely depend on their size and shape, two parameters that are of only secondary importance in classical chemistry.

In spite of the tremendous development in colloid chemistry in the subsequent decades, the world of extremely small particles with sizes in the nanometer range was neglected for a long time. As Ostwald stated, it concerns a size range in which a continuous transition occurs from condensed materials to molecular structures.

Only recently has research in many fields of chemistry and physics commenced providing a basis for nanometer technology, such as, for example, the synthesis of ligand-stabilized clusters,[2, 3] the spectroscopic examination of clusters in the gas phase,[4] the examination of ceramics and metals having crystalline regions of only a few nanometers in size,[5] attempts to miniaturize semiconductor structures into the nanometer region (quantum wells, quantum wires, quantum dots),[6] and the study of the photochemistry and optical and catalytic properties of metal and semiconductor particles with sizes in the nanometer range, both in solution and in thin layers (see [5–9] and references therein). Of special interest are those properties that differ greatly from those of the corresponding macrocrystalline material.

The size quantization effects in colloidal semiconductors, the subject of this article, has led to great interest in these systems. The charge carriers generated by light absorption, which are free to move in a macrocrystalline material, "feel" the particle walls in nanometer large particles. As a result of this situation, described in quantum mechanics as a particle-in-a-box, the band gap increases the smaller the particles become. The onset of the absorption of light and the position of the fluorescence bands are shifted to shorter wavelengths. This can be clearly seen in Figure 1 from the color of the cadmium phosphide powders. Cadmium phosphide is a semiconductor which has a band gap of only 0.5 eV in the macrocrystalline state and is consequently black (bottom left). The powders were prepared by the careful drying of colloidal solutions under vacuum. The powders can be redissoved in water. The average particle size decreases in the opposite direction to the arrows, the color of the material changes to brown (about 30 Å particles) through red, orange, yellow to white (about 15 Å), and the band gap increases to 4 eV.

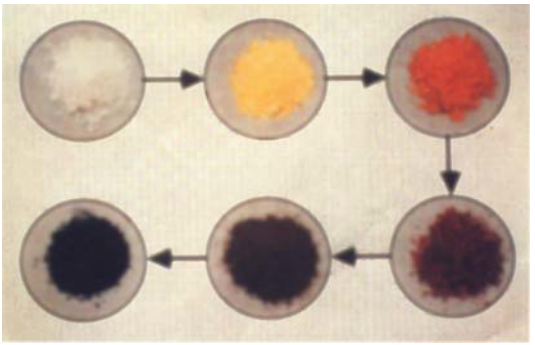

Fig. 1. Q-Cd_3P_2 powder. The particle size increases in the direction of the arrows. The size quantization effect can be clearly seen from the color of the particles.

[*] Dr. H. Weller
Hahn-Meitner-Institut, Abteilung Photochemie
Glienicker Strasse 100, 1000 Berlin 39 (FRG)

Work on colloidal semiconductors started at the beginning of the 1980s with the aim of splitting water photocatalytically.[10, 11] The basic idea of these experiments was to reduce the water to hydrogen by means of the light-induced conduction-band electrons and to oxidize it to oxygen by the holes. Hydrogen production with high quantum yields was achieved when electron donors, such as amines, alcohols or sulfur containing substances were added to the solution.[12, 13] The simultaneous production of hydrogen and oxygen was, however, not achieved. All the photoreactions of colloidal semiconductors described to date for the production of hydrogen in the presence of a donor have been exothermic and are only catalyzed by light. In other words, the end products, hydrogen and oxidized donor, have a lower energy content than the starting materials. There is therefore no point in using these systems for solar energy conversion.

As well as the reports on the attempts to split water, there are also many papers[14] on the use of semiconductor particles in the photocatalytic synthesis of organic compounds and in the photocatalytic destruction of halogenated hydrocarbons. These will not be discussed further here.

Surface boundary processes, such as photocatalytic reactions on semiconductors, are not largely understood even today. One problem arising during the examination of surface processes on macroscopic samples is the very small ratio of the surface to the bulk material. Very sensitive and complicated measurements must be used to separate surface from bulk properties. This problem is readily overcome when colloidal systems in the nanometer range are used. The dispersity (the ratio of surface to bulk) is so big in such particles that a similar number of atoms are located on the surface as in the crystal lattice structure of the bulk. Also, because the particles are so small, the colloidal solutions are completely transparent, so established stationary and time-resolved optical spectroscopy methods, as used in homogeneous systems, can be employed to study the reaction processes.

The main subject of this article is the influence of the particle size and surface properties on the energies of the electronic levels and on the reactivity and kinetics of the charge carriers in Q-particles. The chemical and photochemical aspects of Q-particles will be especially discussed. In another report,[15] more emphasis will be placed on the physical properties of these particles and properties relevant to materials science.

After an initial brief description of the energy levels in macrocrystalline semiconductors, the results of a few theoretical models of the size quantization effect will be discussed and compared to experimentally obtained data. The present state of the preparation and characterizaton of small particles will be described by means of examples in a further section. This will be followed by a section in which methods will be presented which enable mainly monodisperse samples with uniform surface characteristics to be obtained. The effect of surface modifications on the photochemical properties will be dealt with in Section 5 by using fluorescence measurements and photocorrosion experiments as a basis for discussion. The last part of this article considers the examination of charge separation in sandwich colloids (particles in which two different semiconductor materials are coupled) and in semiconductor layers (where the small particles are deposited on a very rough polycrystalline electrode). In particular, ultrafast electron transfer reactions that result in a higher photocatalytic activity in sandwich colloids and in increased photocurrents in the modified layers will be discussed.

2. From Semiconductor to Molecules

2.1. The Energy Levels of a Semiconductor

The semiconductor properties observed in many inorganic substances are not properties of individual molecules or atoms but are a result of the arrangement of the constitutive elements in an ordered crystal lattice. The overlapping of the atomic orbitals in the crystal leads to the formation of a continuum of the position-independent electronic energy levels, the energy bands. A typical energy scheme of a semiconductor is shown in Figure 2. The valence band in an undoped semiconductor is completely filled at 0 K, whereas the conduction band is empty. The energy differene between the valence and conduction band is called the band gap. An electron can be excited from the valence band into the conduction band by the absorption of a quantum of light. A positive charge (a hole) remains in the valence band. The electron and hole can move independantly of one another in the crystal, which results in electrical conductivity. The electron and hole also experience coulombic forces and can form a Wannier exciton, a state that is very similar to a hydrogen atom. In molecular terminology an exciton would be called the first excited state. However, from solid state physics one knows that, because of the interaction of the electron and

Horst Weller, born in 1954 in Siegen, Westphalia, began to study chemistry at the University of Göttingen in 1974. He obtained his PhD in 1982 at the Max Planck Institute for Biophysical Chemistry under the supervision of his namesake A. Weller. Since 1983 he has been employed as a scientist in the group of A. Henglein at the Hahn–Meitner Institute in Berlin where he became deputy leader of the photochemistry department in 1989. In 1991 he received the Bodenstein Prize of the German Bunsengesellschaft and in 1992 completed his habilitation and became a lecturer in Physical Chemistry at the Technical University of Berlin. His sphere of work concentrates on small particle research.

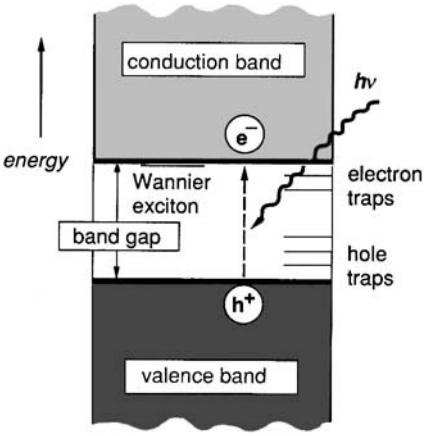

Fig. 2. Energy scheme of a semiconductor.

hole with the core levels of the atoms in the crystal, the masses of the electrons and holes must be replaced by the so-called effective masses (m*). This is the ratio of the masses of the electrons and holes in a semiconductor to the masses of the electrons in vacuum. As the effective masses are usually small and, additionally, because the crystal with its electrons screens the charge carriers in the exciton (expressed by the high frequency dielectric constant), the binding energy of the exciton is small and its radius large. For example, the binding energy of the excitons in CdS is only 0.05 eV and its radius approximately 25 Å (for comparison, the binding energy of a hydrogen atom is 13.51 eV and its radius 0.53 Å). The small binding energy results in the very rapid dissociation of the excitons into free charge carriers at room temperature. Usually, excitons are observed by their sharp absorption and emision lines in optical spectra only at temperatures close to absolute zero.

Beside bands and excitonic energy levels, semiconductors contain traps for electrons and holes. These are interstitial atoms, impurities, dislocations, and defects. Traps are frequently located on the surface as a result of the disturbed bonding forces there. The charge carriers can recombine from traps, either radiatively or nonradiatively, or undergo transfer to electron donors or acceptors. They can also recombine from the bands and excitonic state. The traps in nanometer large particles are found mainly on the surface as a result of the large surface to bulk ratio.

2.2. The Size Quantization Effect

In the case of nanometer large particles, the unusual situation exists that the particle size is the same as or actually smaller than the size of the excitons in macrocrystalline material. The electron–hole pair can only "fit" into such a particle when the charge carriers assume a state of higher kinetic energy. In solid state terminology this results in the energy bands splitting into discrete quantized levels and the "band gap" increasing with decreasing particle size. Particles that show this size quantization effect are frequently called Q-particles or quantum dots. Whether one can speak of bands or excitons at all in this situation is a purely semantic question. On one hand, the electron and hole, because of their increased kinetic energy, move practically freely within the particle, a situation similar to that in the energy bands. On the other hand they experience a coulombic attraction, which is why this state is frequently called "excitonic" (I shall use this terminology in this article). When one comes into a size range of 1–2 nm, in which each particle consists of a few dozen molecules, it is better to talk about molecular orbitals. From the difficulties experienced in the terminology, one can already see that the properties of such particles lie between those of the solid state and their molecules.

The shift of the electronic levels with decreasing particle size, easily seen in Figure 1 from the color of the particles, can also be seen in Figure 3 which shows the absorption spectra of three CdS samples of different particle size. The

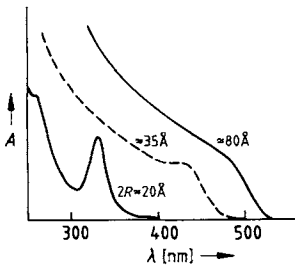

Fig. 3. Absorption spectra of three colloidal CdS solutions containing CdS particles of different size.

spectra are labeled with the appropriate average particle diameters (80 Å, 35 Å, and 20 Å). Macrocrystalline CdS has an absorption edge at approximately 515 nm, which is close to the beginning of absorption of the 80 Å particles. As well as a strong blue shift of the absorption edge, a clear maximum is formed near the start of absorption with decreasing particle size. This maximum is assigned to the optical transition of the first excitonic state.

Many model calculations concerning the size quantization effect have been published in the past few years.[16–32] The majority of these calculations start from the macroscopic solid state and determine the increase of the band gap with decreasing particle size on the basis of a particle-in-a-box assumption. The differences in the models lie in the complexity of the calculation and the boundary conditions. Efros et al.[16] described the first calculation. They used spherical, infinite potential wells and ignored the coulombic interaction between the charge carriers. Brus et al.[18, 19] developed the energy levels of the first excited state by considering the coulombic interactions and polarization terms. They showed[18] that the coulombic interaction could not be ignored. In some papers[21, 22] the coulombic interaction was introduced into the wave functions of the electron and hole as a perturbation parameter. Like the increase in the energy of the first excited state, the splitting of the bands into discrete excitonic levels is a direct consequence of the size quantization effect. Weller et al.[22] made a quantum mechanical calculation of the energy values of higher excited states as a function of particle size for the first time. The expansion of the quantum mechanical models by including Hylleraas functions, which led to very exact results for the description of the helium atom,[35] brought no significant improvements in the calculation of the first excited state in Q-particles. Similar results were described recently.[23, 24, 28] However, comparison of the experimental results with different calcu-

lations[21, 33] showed that, as suggested by Brus,[17] it is necessary to include finite barrier heights in the description of the experimental results (see below). The most universal particle-in-a-box calculation has recently been presented by Nosaka.[30] In this calculation the barrier height and effective masses (m^*) of the charge carriers of any semiconductor can be introduced into an analytical formula and the first excited state calculated as a function of particle size. All the previously presented calculations assume the validity of the effective mass approximation. The appropriate values for the effective masses as well as the high frequency dielectric constants are taken from macrocrystalline solids, which results in the greatest uncertainty of these calculations.

On the basis of work by Burdett,[34] Wang[26] described the first molecular orbital calculations (tight binding) for Q-particles for PbS, while Lippens et al.[29] did the same for CdS and ZnS. These calculations are not better per se than the particle-in-a-box calculations. Although they avoid the problem of the effective mass approximation, they do not include the altered bonding forces of the surface atoms as compared to the bulk atoms.

The first pseudopotential calculations have recently been presented by Rama Krischna and Friesner,[31] as well as by Einevoll.[32] In the former paper even the different crystal structures and particle shapes are considered.

The results of some calculations and their comparison with experimental values will be shown in the next section. The wavelength of the excitonic absorption (shoulder on maximum in the spectra) is shown in Figure 4 as a function of the particle size for different CdS samples. In this case

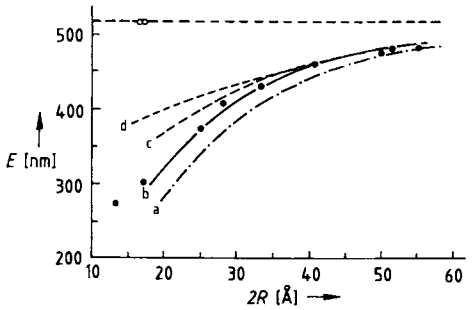

Fig. 4. Energy (converted to light wavelength) of the first excitonic transition in CdS particles as a function of the particle size; —oo—: energy in the macrocrystal. The curves a–d show the results of different quantum mechanical calculations (see text). •: values determined with the electron microscope.

the size was determined exclusively by electron microscopy.[21, 33, 36, 37] Other authors[27, 38] calculated the average particle size from the line width in X-ray powder diffractograms using the Scherrer formula.[39] This method usually gives smaller particle sizes than electron microscopy for the same optical absorption. This discrepancy probably arises because in X-ray diffraction measurements the particle size does not determine the line width directly. Instead the width depends on the size of the crystalline regions within a particle. This leads to false results when the particles are not perfectly crystalline (as the ones shown in the lower part of Figure 5).

Figure 4 shows the results of different calculations in curves a–d. Good agreement with the experimental values is obtained with curve b (particle-in-a-box with finite barrier height[21]) and, with some restrictions, with curve c (tight-binding calculation[29]). Curve a (infinite potential well[18]) and curve d (pseudopotential calculation[31]), on the other hand, show large deviations from the experimental points. (Rama Krishna and Freiser[31] obtain good agreement for their calculated values with the values obtained from X-ray measurements.[27])

Similar results to CdS are obtained when the experimental values are compared with the calculations for PbS[26, 30] and ZnO.[40] Also in these cases the particle-in-a-box calculation with finite barrier heights and the tight-binding (PbS) calculation agree quite well with the experimental values.

In spite of certain deviations the relatively good agreement of the theoretical models with the experimental results is astonishing, especially as the models start from very different assumptions and questionable simplifications must be introduced in the calculations.

Because of the large percentage of surface in Q-particles, the question of the effect of surface characteristics and the chemical environment of the particle on the optical absorption arises. Recently the absorption behavior of approximately 40 Å diameter CdS particles stabilized by sulfonic acid has been examined.[41] These colloids were dried and redissolved in organic solvents of very different polarity (between *n*-hexane and *n*-propanol) without any significant change occurring in the absorption spectra. In this work the subsequent exchange of the stabilizer, 4-dodecylbenzenesulfonic acid, by polyphosphate, polysilicate, and thiols was also described. Again only minor changes were registered in the absorption spectra.

3. Preparation and Characterization of Small Particles

Most of the research on Q-particles has been performed on colloidal samples of CdS, CdSe, and PbS. Reports on the synthesis of other Q-particles include ZnS, ZnO, TiO_2, AgI, AgBr, HgI_2, PbSe, ZnTe, CdTe, In_2S_3, In_2Se_3, Cd_3P_2, Cd_3As_2,[7–9, 14, 42] and recently also GaAs.[43, 44] The sulfides, selenides, tellurides, and phosphides are usually prepared by precipitation by H_2S, H_2Se, H_2Te, or PH_3, or their alkali metal salts from a solution containing the metal ion. Either AsH_3 or $As(CH_3)_3$ is used for the preparation of the arsenides. The oxides are prepared, for example, by the hydrolysis of the alkoxy compounds. Stable colloidal solutions are obtained by the addition of stabilizers (tensides, organic or inorganic polymers).

A much used method for the preparation of Q-particles is precipitation in the presence of sodium polyphosphate as stabilizer (average chain length about 15 PO_3^- units). Polyphosphate is well suited for the stabilization of nanometer large particles, because the chain is strongly bound by metal ions onto the particle surface. It causes electrostatic repulsion between particles because of its charge, and also keeps them apart sterically because of its chain length. Other frequently used stabilizers for the chalkogenides are thiols. In the following, the preparation of Q-CdS with different particles sizes will be described as an example.

In an aqueous solution cadmium ions are complexed with polyphosphate chains (PP^{2n-}) [Eq. (1)].

$$n\,Cd^{2+} + PP^{2n-} \rightleftharpoons Cd_nPP \quad (1)$$

From the concentration ratio of Cd^{2+} to PP^{2n-} (approximately one Cd^{2+} ion per two to six PO_3^- units) and the absolute concentration (of the order of 10^{-4} M), conditions are chosen under which most of the Cd^{2+} ions are bound to the polyphosphate. After the addition of H_2S, seed formation occurs by the reaction of the sulfide with free Cd^{2+} ions [Eq. (2)].

$$m\,Cd^{2+} + m\,S^{2-} \rightleftharpoons (CdS)_m \quad (2)$$

The formation of the seeds is accelerated by high pH values because of the dissociation equilibrium of H_2S [Eq. (3)].

$$H_2S \rightleftharpoons 2H^+ + S^{2-} \quad (3)$$

The growth of the seeds occurs either because the Cd^{2+} ions are liberated in the equilibrium described in (1) and CdS grows on the seeds (growth from a supersaturated solution [Eq. (5)], or by the process of Ostwald ripening whereby larger seeds grow at the expense of smaller ones [Eq. (4) and (5)].

$$(CdS)_n \longrightarrow (CdS)_{n-1} + Cd^{2+} + S^{2-} \quad (4)$$

$$Cd^{2+} + S^{2-} + (CdS)_m \longrightarrow (CdS)_{m+1}\ (m > n) \quad (5)$$

A requirement for the preparation of especially small particles is rapid formation of crystal seeds but slow growth of these seeds. This can be realized by keeping the pH slightly alkaline during the preparation and when an excess of Cd^{2+} ions is present.[20] Also, vigorous shaking is necessary to ensure thorough mixing. Very good, reproducible mixing can also be realized when two chromatography pumps are used.[45] The resulting colloid contains particles of between 13 Å and 20 Å. Figure 5a shows an electron microscope photograph of a sample containing 13 Å particles. In the lower part of the figure a single particle is shown. The lattice planes of cubic CdS (zinc blende structure) can be seen even with these very small particles.

The main difference in the preparation of the larger particles in samples b and c lies in the relative amounts of Cd^{2+} and S^{2-} ions; the preparation occurs under stoichiometric conditions, that is, more H_2S is used than in a. The seed formation also occurs under slightly alkaline conditions, but during the precipitation the pH drops to about 4 as a consequence of the released protons.[33] Under these conditions the growth of the particles by the reactions (4) and (5) is accelerated. The growth can be stopped by increasing the pH once more to between 9 and 10. Sample b was kept at pH 4 for about 10 minutes and sample c for a few hours. The particles in sample c are, therefore, bigger than in sample b. Even larger particles are obtained when the precipitation occurs under weakly acidic conditions. The ratio of the rate of seed formation to particle growth is displaced in the direction of growth. Sample d from Figure 5 (average size of 250 Å) was prepared under such conditions. The electron microscope photographs of individual particles from these samples are shown in the lower part of Figure 5. The crystal lattice planes with distances typical for a zinc blende structure can be clearly seen. The particles shown, which are typical for each sample, have a perfect crystal structure.

It is still unknown why nearly all the existing methods for the preparation of colloidal CdS particles with nanometer dimensions result in the cubic zinc blende structure, whereas macrocrystalline CdS nearly always has the hexagonal wurzite structure. Hexagonal Q-CdS particles are only formed during the cathodic deposition from a dimethyl sulfoxide solution of sulfur containing Cd^{2+} ions.[46]

For very small CdS particles less than 20 Å across, it has been observed that when the stabilizer is polyphosphate the growth does not occur continuously but that certain particle sizes are preferred.[20, 63] This behavior is known from clusters in the gas phase. The occurrence of such "magic numbers" was first observed by Weller et al.[20] There are two reasons why particles with preferred agglomeration numbers

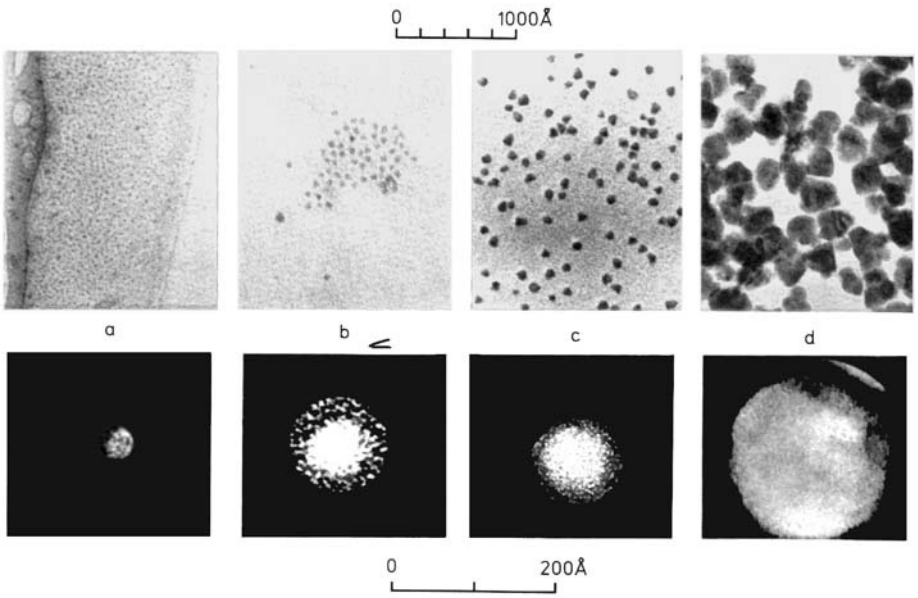

Fig. 5. Electron microscope photographs of polyphosphate-stabilized CdS particles of different sizes (a–d). Single particles of each sample at higher magnification are shown in the lower part of the figure.

can be formed: certain structures are thermodynamically especially stable, or the growth of the initially formed, smallest particles with agglomeration number k occurs not by Ostwald ripening but by the combination of the particles. The particles so formed would then have agglomeration numbers of $2k$, $3k$, and so on. Which of the two mechanisms is operative with CdS is unclear, as well as the exact "magic numbers".

In many laboratories attempts to synthesize and characterize defined semiconductor clusters are in progress.[2, 3] The largest CdS cluster with a defined structure has the formula $Cd_{10}S_4(C_6H_5S)_{16}^{4-}$ and is pyramidal.[47] This cluster does not show an excitonic absorption band. Dance[47] suggested that the next larger, especially stable cluster would have the structure $Cd_{20}S_{13}(C_6H_5S)_{22}^{8-}$. Wang and Herron[42] have recently claimed that they have synthesized this cluster but have not yet been able to isolate it.

In the past few years further methods for the preparation of semiconductor particles have been developed. Just a few are listed here: preparation in inverse micelles,[48-50] vesicles,[51] Langmuir–Blodgett films,[52] glasses,[53-55] polymer films,[56, 57] clay minerals,[54] zeolites,[54, 58] and on porous TiO_2 layers.[59, 60]

The basic idea behind many of these preparative methods, that of controlling the particle size by the size of the reaction space (e.g. in micelles or zeolites), is, in principle, an attractive idea. These methods are doomed, however, because the individual reaction steps of the seed formation, the growth, and stabiliztion of the small particles are not well enough understood and hence, cannot be sufficiently controlled. Generally, the preparation of stable colloidal samples of Q-particles is a very empirical field. Beause of the complexity of the individual coupled reaction steps, minimal variations in the preparative conditions can lead to very different results. I therefore recommend that an interested reader who would like to prepare Q-particles in his own laboratory (which is neither difficult nor time-consuming) follow exactly the recipes given in the original literature.

4. On the Road to Monodispersity

4.1. Size Fractionation

Many of the interesting properties of Q-particles can only be observed when the examined samples are nearly monodisperse. Thus, a separation of the bands into discrete excitonic levels, as predicted by theory, (see Section 2.2), should only be observed in nearly monodisperse samples. Also, the very pronounced nonlinear optical properties that should be observed in Q-particles require narrow size distributions.[42]

Recently, methods for the size fractionation of colloidal samples have been developed. The best results have been obtained by size exclusion chromatography and gel electrophoresis, methods that have for a long time been successfully applied in biochemistry and polymer science.[37, 61-63]

In size exclusion chromatography, the colloidal solution of the semiconductor particles forms the mobile phase which flows through a stationary phase consisting of porous SiO_2 spheres. Small particles penetrate deeper into the pores than the bigger ones. The elution time for the smaller particles is, therefore, longer than for the larger ones. Hence, the elution time is a measure of the particle size. The exact relation between the particle radius (R) and the retention time (t_r) is given by Equation (6),[63, 64] where k_1 and k_2 are experimental constants.

$$k_1 + k_2 \lg R = t_r \tag{6}$$

Conventional low-pressure column chromatography and high-pressure gel chromatography (HPGC) have both been successfully applied for the size fractionation of Q-particles. HPGC can also be used as a very convenient method for the determination of the average particle size as well as the size distribution, after the calibration of analytical columns.[63]

In the case of gel electrophoresis, the particles are introduced on to the top of a column containing weakly crosslinked polyacrylamide. The upper and lower ends of the column are dipped into buffer solution. After the establishment of an electrical field the particles move through the gel as a result of their surface charge. Two parameters, the charge on the particle and its size, determine their rate of movement and, thus, their separation. The bigger the charge and the smaller the diameter, the faster the particles move through the gel. When using polyacrylamide gels the particle size has the greater effect (molecular sieve effect).[65] When the leading particle front has moved approximately two thirds through the gel, the gel is cut into thin slices and the particles dissolved out of the slices. The gel residues are filtered from the resulting colloidal solution with membrane filters, and the soluble impurities removed by washing with dilute sodium hydroxide in an ultrafiltration apparatus.

Very monodisperse samples, with a standard deviation from the average size of about 7–8%, are obtained by using both HPGC and gel electrophoresis. Without size fractionation, the best preparation methods result in about two times larger standard deviations.

4.2. Discrete Optical Transitions in Samples with Narrow Size Distributions

Figure 6 shows the absorption spectra of a CdS sample after separation by electrophoresis at room temperature and at 77 K. The particle size was 55 ± 4 Å. The second derivative spectra are shown in the lower part of the figure. A 1:1

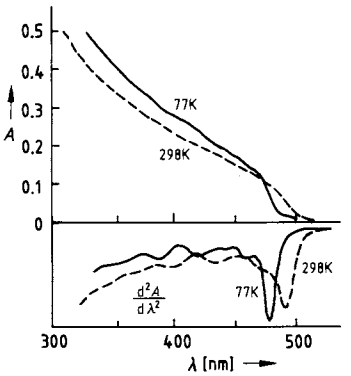

Fig. 6. Upper part: Absorption spectra of a Q-CdS sample separated by gel electrophoresis, at 298 K (broken) and 77 K (solid line). The particle size is 55 ± 4 Å. Lower part: The second derivative spectra.

ethanol/methanol mixture containing about 2% of water, which forms an optically transparent glass at low temperatures, was used as the solvent.

The absorption spectrum at room temperature has a steep increase in absorption at about 500 nm with several weak shoulders at shorter wavelengths. At 77 K the spectrum is shifted to shorter wavelengths, and the shoulders are better visible. Both these observations result from the decreased coupling of the electron with the optical (LO) phonons. The structure of the spectra can be seen more clearly from the second derivative spectra. The position of the minima in the second derivative gives a good approximation of the position of the shoulders of the absorption spectra. These shoulders arise from transitions to discrete higher excitonic levels. The structuration can only be observed after gel electrophoretic separation. The starting material with a wide size distribution (about 20% standard deviation from the average size) has an unstructured spectrum, since the line widening due to inhomogeneities is so big that it covers the discrete optical transitions in the spectrum. Koch obtained similar results[66] for the simulated absorption spectra of Q-particles.

In order to prove the existence of discrete optical transitions in samples with somewhat worse size distributions, Brus applied the technique of optical hole burning and fluorescence excitation spectroscopy (both at 15 K).[9] In the second technique the fluorescence with the longest wavelength resulting from the largest particles was observed while varying the excitation wavelength. The smaller particles in the sample had, therefore, no influence on the resulting excitation spectrum.

The energetic positions of the first five excitonic transitions can be obtained from the derivative absorption spectra of Q-CdS samples fractionated by gel electrophoresis (as in Fig. 6). Figure 7 shows the energies of the first five excitonic transitions in Q-CdS as a function of the particle size.[36] All the transitions move to higher energy with decreasing particle size and the energy difference between the transitions becomes ever larger.

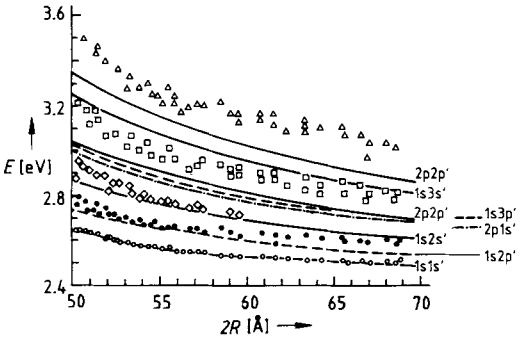

Fig. 7. Energy of the first five excitonic transitions in Q-CdS as a function of particle size. The points are taken from the absorption spectra of CdS samples separated by gel electrophoresis.

The curves resulting from a particle-in-a-box calculation (according to ref. [22]) are also shown. These curves were calculated from the product of the wave functions of the electron and hole in the indicated quantum states (the prime gives the state of the positive hole). Two different sets of curves are shown. In the first set the states have a total magnetic moment of $L = 0$ (solid lines: 1s1s', 1s2s', 2p2p', 1s3s', 2p3p'), and in the second $L = 1$ (broken lines: 1s2p', 2p1s', 1s3p'). To what extent these transitions are allowed is difficult to know: the classical selection rules for atoms are certainly not strictly valid.

The comparison between the experimentally determined points and the calculated curves is not very satisfactory. Only the curves for 1s1s' and 1s2p' agree with the experimental points in the examined size range. Definite deviations can be seen for the higher transitions. The reason for this is probably some of the simplifications used in the calculations. These are mainly the use of an infinite barrier height, the assumption that the effective masses approximation is also valid for higher states, and the use of the hexagonal CdS solid state values for the effective masses, as well as the dielectric constants[67] for Q-particles with cubic structure.

To explain the experimental data on the electronic states of Q-particles, new efforts in the area of theoretical physics and chemistry are necessary.

5. Fluorescence, Photochemical Reactivity, and Surface Modification of Q-Particles

The wave functions of the exciton fill the whole volume of the Q-particles. Already at the moment of their formation the electrons and holes have a large probability that they will be resident on the surface of the particle. Diffusion processes of the charge carriers from the interior of the particle to the surface or to the traps, which are of importance in macrocrystalline semiconductors, are therefore of no significance in Q-particles. Consequently, the time for the charge carriers to be caught in the traps is very short. Measurements of the two-photon ionization of Q-ZnS and Q-CdS[68,69], as well as measurements by Bawendi et al.,[70] have shown that the time required to trap at least one of the two charge carriers lies in the range of 100 femtoseconds or shorter. All chemical reactions and recombination processes are thus very dependent on the surface traps. The recombination of the charge carriers can be easily measured by stationary or time-resolved fluorescence spectroscopy, which is therefore a convenient method for the study of changes of the particle surface, for example, by the exchange of the solvent and stabilizer in already prepared colloidal CdS.[41] As already described in Section 2.2, the absorption spectra of the CdS remain practically constant. On the other hand, very great differences in the fluorescence spectra result, both in the intensity as well as in the spectral distribution.

5.1. Blocking of the Traps on the Particle Surface

An impressive example of how the fluorescence properties can be altered by surface reactions is the modification of the surface of Q-CdS particles with $Cd(OH)_2$.[33] After preparation from equimolar amounts of the ions, the CdS solution is slightly acidic and exhibits the typical weak red fluorescene of colloidal CdS with a quantum yield of the order of 10^{-4}. After increasing the pH to 11 and adding Cd^{2+} ions in excess, the fluorescence quantum yield increases to about 0.2. The absorption and fluorescence spectrum of such an fluo-

rescence-activated colloid is shown in Figure 8. The sharp excitonic fluorescence band near the beginning of the absorption can be clearly seen. When the spectrum is magnified 40 times weak red fluorescence at the same spectral position as before activation, originating from the recombination of trapped charge carriers, can be seen. Before the activation the intensity of this band is about ten times smaller.

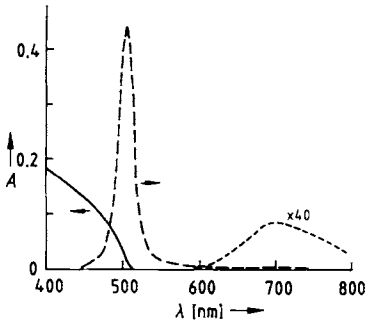

Fig. 8. Absorption and fluorescence spectrum of a fluorescence-activated, colloidal CdS sample (2×10^{-4} M solution). The long-wavelength fluorescence is magnified 40 times.

The centers for the otherwise dominant radiationless recombination are mostly blocked by the fluorescence activation. Pulse radiolytic measurements by Kumar et al. show that these radiationless recombination centers arise from trapped holes.[71] These are S^- or HS^- radicals on the surface of the particles, which are also responsible for the photocorrosion.[72] It is probable that the fluorescence activation chemically involves first the deprotonation of the HS^- groups followed by the binding of the excess Cd^{2+} ions on the deprotonated surface sulfide groups. The free valencies of the surface sulfide groups present in the nonactivated colloid are saturated with Cd^{2+} ions and the hole traps are, therefore, blocked. As the activation occurs in alkaline media, $Cd(OH)_2$ should also be present on the particle surface, as well as polyphosphate.

Henglein, in one of the first papers about colloidal CdS particles, described similar results for fluorscence activation obtained by the addition of Cd^{2+} ions to a SiO_2-stabilized CdS colloid,[73] as did Dannhauser et al. by the addition of amines to Q-Cd_3As_2,[48] Wang et al. by the treatment of Q-CdS in Nafion films with ammonia,[74] and Kortan et al. by the precipitation deposition of ZnS on CdSe.[75]

The exact fluorescence mechanism in Q-prticles is very complex. From careful and comprehensive examinations by different groups[76-78] of the excitonic fluorescence, it can be said that at least one of the charge carriers involved in the recombination process is trapped in very shallow traps. O'Neil et al.[76] and Eychmüller et al.[77] assume that the electrons are at first trapped and that, after thermally returning to the conduction band, they recombine with free holes. On the other hand, Bawendi et al.[78] postulate a model in which there is a strong resonance between free holes and holes in shallow traps.

The fluorescence, which is strongly red shifted from the absorption, is usually assigned to the recombination of trapped holes. The fluorescence decay (as well as that of excitonic fluorescence) follows a multiexponential decay law, and decay times of up to the microsecond range are observed.[77] An analysis of the decay kinetics, which are mainly determined by the depth of the traps and the distance between the charge carriers located in the traps, is very complicated and results in physically unreliable conclusions.[76]

To understand the photocatalytic properties of Q-particles it is very important to know, at least approximately, the depth of the electron and hole traps. In this connection, the discussion at present centers around whether the electrons are trapped in flat traps and the holes in deep ones or vice versa.[77, 78] The latest fluorescence quenching experiments with electron acceptors with different redox potentials show that the electron traps lie energetically only slightly under the edge of the conduction band in CdS Q-particles.[79]

5.2. Photostability of Fluorescence-Activated CdS Particles

The modification of the surface of CdS particles with cadmium hydroxide leads not only to the drastic changes in the fluorescence behavior already described, but also to an enormous increase in the stability of the particles towards photocorrosion.[33] The optical absorption of CdS particles at $\lambda = 400$ nm as a function of irradiation time (irradiation wavelength 366 nm) is shown in Figure 9. With a nonactivated colloid the absorption decreases by a factor of 2 within three minutes. The CdS dissolves with the formation of Cd^{2+} and SO_4^{2-} ions [Eq. (7)].

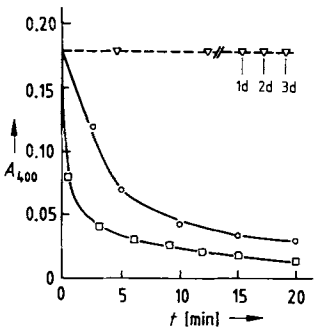

Fig. 9. Photochemical decomposition of colloidal CdS (2×10^{-4} M). Solid line: without (○) and with (□) a 1×10^{-4} M solution of Tl^+ ions. Broken line: fluorescence-activated CdS.

$$CdS \xrightarrow[O_2]{h\nu} Cd^{2+} + SO_4^{2-} \quad (7)$$

The first step in this process is again the formation of S^- or HS radicals which subsequently react with oxygen.[72] The quantum yield for this process is 0.001 decomposed CdS molecules per absorbed photon. The rate of decomposition can be increased by the addition of Tl^+ ions, an effective scavenger of the photoinduced electrons in CdS colloids (see also ref. [73]). For comparison, no decomposition occurs in a fluorescence-activated colloid even after three days of irradiation. From the measured photon flux it can be easily calculated that after this time each CdS particle has absorbed 1.7×10^8 photons (every molecule 1.7×10^5). Rhodamine B,

one of the most frequently used laser dyes, would have decomposed 20% under the same irradiation conditions.

The extraordinary photostability of surface-modified CdS colloids arises from the fact that the first stage of this corrosion, namely the formation of HS and/or S^- radicals by the reaction of the positive hole on the surface, is largely repressed after the reaction of Cd^{2+} ions with the surface sulfur groups. In addition, the layer of $Cd(OH)_2$ and polyphosphate could prevent the attack by oxygen on the trapped holes.

5.3. Formation of New Traps on the Particle Surface

An elegant method to alter the traps on the particle surface is the partial precipitation of the particle into a more insoluble compound. So, for example, the addition of Ag^+ [80] or Hg^{2+} ions to a CdS colloid results in the production of a few molecules or larger aggregates (depending on the amounts added) of Ag_2S or HgS directly on the particle surface [Eq. (8)].

$$(CdS)_n + m\,Hg^{2+} \longrightarrow [(CdS)_{n-m}(HgS)_m] + m\,Cd^{2+} \quad (8)$$

Under these conditions a homogeneous mixed crystal does not result. HgS and Ag_2S are semiconductors whose band gaps lie within the band gap of CdS, as can be easily seen from Figure 10. As a consequence, the photogenerated elec-

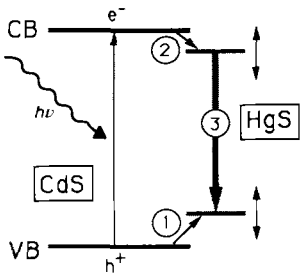

Fig. 10. Energy scheme of CdS particles with HgS (or Ag_2S) regions on the surface. CB: conduction band edge, VB: valence band edge.

trons and holes in the CdS are transferred to the HgS or Ag_2S regions in the modified particles. This can clearly be seen from the fluorescence of the particles. Figure 11 shows the fluorescence spectra of CdS samples prepared in the same manner as the fluorescence-activated colloids in Section 5.1 but to which small amounts of Hg^{2+} ions were added. Apart from the excitonic CdS fluorescence band, a broad band can be seen at longer wavelengths, which results from the recombination of the charge carriers in the HgS part of particles (step 3 in Fig. 10). The HgS areas on the CdS particles grow with more added Hg^{2+} ions and the fluorescence maximum is shifted to longer wavelengths. This can be understood in terms of the size quantization effect and results from the variable positions of the band edges in Figure 10. Time-resolved fluorescene measurements and fluorescence-quenching experiments with CdS–HgS colloids show that practically immediately after the excitation of the CdS the holes are transferred to the HgS (step 1 in Fig. 10), whereas the electrons require about 100 ps for this process (step 2, Fig. 10).[81]

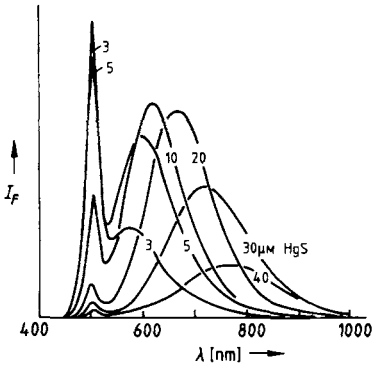

Fig. 11. Fluorescence spectra of a CdS sample (2×10^{-4} M) after the addition of different amounts of Hg^{2+} ions.

The modification of the CdS particle surface with HgS is evident from the color of the fluorescence. Figure 12 shows the fluorescence of five samples with different quantities of HgS. The turquoise blue/green fluorescence arises from pure fluorescence-activated CdS. In the other samples the quantity of HgS and therefore the size of the HgS regions increases from the sample with the yellow/green to that with the red fluorescence.

Fig. 12. Fluorescence of CdS colloids with small areas of HgS. The size of the HgS areas increases from left to right.

6. Sandwich Colloids

In the examples given in the previous section the applied term "surface modifiation" is certainly no longer correct, especially for the samples with higher amounts of HgS. One should really speak here of two strongly coupled Q-particles of different materials. During the past years such sandwich colloids have been examined in many laboratories.[80–88] Of special interest are those systems in which, because of the coupling of two particles, efficient charge separation results.[83, 84] The energy scheme of such a sandwich colloid is shown in Figure 13. Excitation with visible light occurs in the particle with the smaller band gap (CdS or Cd_3P_2) and results in the formation of electron–hole pairs. The TiO_2 or ZnO particles have a larger band gap and an energetically lower lying conduction band. Consequently, the electrons excited by light are transferred from the CdS (or Cd_3P_2) particles to the TiO_2 (or ZnO) particles, whereas the holes remain in the CdS (or Cd_3P_2). Such sandwich colloids are prepared by mixing two separately prepared colloidal solu-

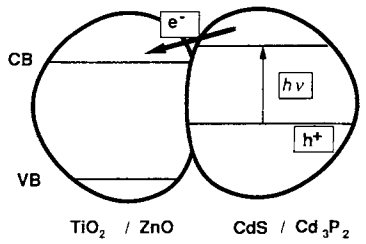

Fig. 13. Schematic representation of a sandwich colloid. CB: conduction band edge, VB: valence band edge.

tions. The trick is that a small quantity of a weakly acidic, concentrated solution of positively charged TiO_2 (or ZnO) particles is added under vigorous stirring to a dilute, alkaline solution of negatively charged CdS (or Cd_3P_2) particles. The solution must remain alkaline. Under such conditions a coagulation of the positively and negatively charged particles begins but is stopped when the original positive charge on the oxide particles becomes negative in the alkaline medium. With this method transparent colloidal solutions can be prepared in which every CdS (or Cd_3P_2) particle is coupled with at least one TiO_2 (or ZnO) particle. The formation of the sandwich colloids can be followed especially well by fluorescence-quenching experiments. Figure 14 shows the excitonic fluorescence intensity of fluorescence-activated CdS particles as a function of the added amount of TiO_2. When the

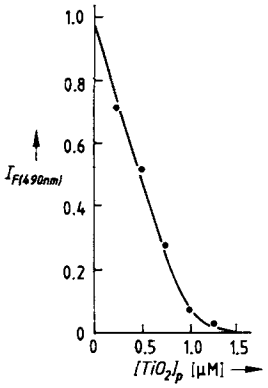

Fig. 14. Intensity of the excitonic CdS fluorescence as a function of the quantity of added TiO_2 (given as particle concentration). The particle concentration of CdS was 0.2 μM.

particle concentration reaches 0.6 μM TiO_2, the fluorescence has dropped to 1/e of the original value. Under these conditions there are about three TiO_2 particles for every CdS particle present in the solution. With these concentrations and a CdS fluorescence decay time of 10 ns the fluorescence quenching cannot arise from the diffusion of the TiO_2 particles to the CdS particles followed by an electron transfer in the encounter complex. The diffusion process is at least five orders of magnitude too slow to compete with the fluorescence decay. Sandwich colloids in which a fast electron transfer can occur from CdS to TiO_2 must be formed. In order to gain some information about the rate of these processes, the decay time for the Cd_3P_2 fluorescence in Cd_3P_2–TiO_2 sandwich colloids was measured and amounted to less than one picosecond (for comparison: in Cd_3P_2 colloids without TiO_2 it was a few 100 ns).[88]

This extremely fast and efficient primary charge separation results in the CdS–TiO_2 sandwich colloids exhibiting a much higher photocatalytic activity than the individual colloids.[83] Methyl viologen (MV^{2+}) is reduced to the blue MV^+ radical by irradiating CdS with visible light in the presence of methanol as a hole scavenger. From the known extinction coefficient of MV^+ ($\varepsilon_{605nm} = 11000\ M^{-1}cm^{-1}$) and the measured photon flux, a quantum yield for the reduction of MV^{2+} of $\Phi = 0.13$ is obtained when fluorescence-activated CdS is used. As shown in Figure 15, after the addition of TiO_2 (i.e., after the formation of sandwich colloids) the quantum yield increases drastically. The quantum yield approaches 1 when the TiO_2 particle concentration is higher than 1.5 μM. Evidently, in this concentration range all the CdS particles are coupled with at least one TiO_2 particle. As expected, the increase in the quantum yield (Fig. 15) follows the decrease in the fluorescene intensity in Figure 14.

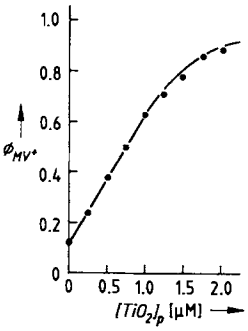

Fig. 15. Quantum yield of MV^+ formation by irradiation of a fluorescence activated CdS as a function of the added quantity of TiO_2 (particle concentration as in Fig. 14). Irradiation wavelength: 436 nm; the solution contained 0.1 M methanol as hole scavenger.

In sandwich colloids of CdS (or Cd_3P_2) with ZnO, the transferred electron in the ZnO can be substantiated by spectroscopy.[84] In this case a stored electron leads (as incidentally also with CdS particles) to bleaching of the optical absorption near the band edge.[40, 89, 90] This effect, which forms the basis of the nonlinear optical behavior of Q-particles, is considered in another report.[15]

Gopidas et al. have reported electron microscope photographs of sandwich colloids.[86] However, it is never clear whether the particles were already coupled in solution or whether the coupling resulted when the sample was dried for the microscope.

7. Q-Particles in Modified Semiconductor Layers

In order to utilize the fascinating properties of Q-particles for typical semiconductor applications the particles must be in electrical contact.

Recently, Hodes reported that when CdSe is electrochemically deposited on electrically conducting glass, agglomerated Q-particles are formed and not a compact film.[46, 91, 92] Such electrodes in photoelectrochemical cells exhibit photocurrents arising from the Q-particles. In order to absorb significant quantities of incident light, ten to twenty coatings of the Q-particles must be deposited one over the other, and thus the released electrons must be transported over many particles to the back contact. Energy is lost with every jump of the electrons from one particle to another, so the photocurrents and voltage attainable with such systems are relatively low.

This problem can be overcome by depositing the Q-particles on a very porous TiO_2 electrode, to which the electrons are transferred after light absorption.[59, 60, 93] Less than a monolayer of particles is necessary for practically all the incident light to be absorbed, because of the large surface area of the electrodes. For several years such porous TiO_2 electrodes have been used with great success by Grätzel et al. as substrate electrodes for dye sensitization.[94–97]

An electron microscope picture of such a TiO_2 electrode shows clearly the raw surface (Fig. 16). The surface is

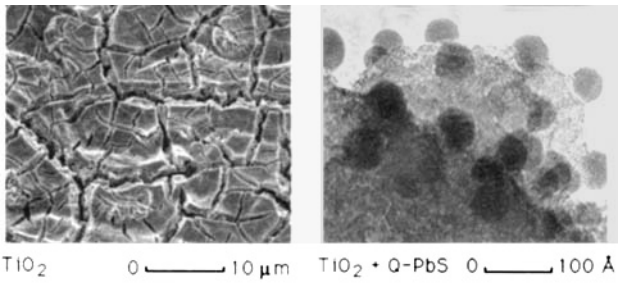

Fig. 16. Electron microscope photographs of a porous TiO_2 electrode. In the right hand photograph at greater magnification, the Q-PbS particles can be seen.

400 times larger than the geometric area of the electrode as determined by BET (BET = Brunauer, Emmett, Teller) measurements. The thickness of the TiO_2 layer was about 20 µm. The electrode, after the deposition of Q-PbS, is shown at a higher magnification on the right hand side of Figure 16. It can be clearly seen that individual particles, approximately 60 Å big, are stuck on to the crystalline background of TiO_2. The characteristic reflections of cubic PbS (galena) are found adjacent to the anatase reflections of TiO_2 in X-ray diffraction diagrams of such electrodes.[93]

The procedure for depositig the particles is very simple. The porous electrode is dipped into a concentrated solution of a cadmium (or lead) salt. It is washed with water and subsequently dipped into a Na_2S solution. The metal ions adsorbed on the oxidic surface react with the initial formation of CdS (or PbS) particles of approximately 30 Å. When this submergence procedure is repeated (each cycle forms one coating), new CdS (or PbS) is formed mainly on the small particles formed during the first coating. Hence, the particle size increases with the number of coatings.

This can be easily seen from the optical reflection spectra of a TiO_2 electrode after different numbers of coatings (Fig. 17). The absorption of the particles is shifted to longer wavelengths with increasing number of coatings, as a result of the size quantization effect. The average particle size increases from 34 to 104 Å. The simultaneous increase over the whole absorption spectrum results from the increased quantity of PbS deposited on the electrode.

The corresponding photocurrent spectra are shown in Figure 18. The photocurrent yield (number of electrons detected in the exterior current circuit per number of photons arriving at the electrode) is shown as a function of the incident light wavelength. As in the reflection spectra, the red shift can be seen with increasing particle size. The quantum yield attains values of 70%. If we compensate for the reflection losses, this implies that the primary electron transfer from the Q-

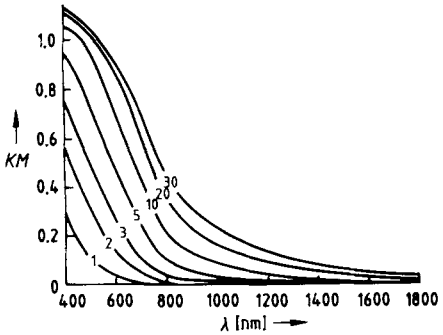

Fig. 17. Spectra of the diffuse reflections of a TiO_2 electrode after different numbers of coatings (number given for on each curve) of PbS. The Kubelka Munk values [98], which correspond to optical densities in transparent systems, are shown on the ordinate. The particles grow with increasing number of coatings from 34 to 39, 42, 50, 71, 82, and 104 Å.

particles into the TiO_2 layer must occur with a quantum efficiency of almost 1. This is in agreement with the very high rate of electron transfer observed in sandwich colloids.[86, 88]

It can be seen from the photocurrent spectra in Figure 18 that the photocurrent quantum yield decreases when the particle sizes reach 50 Å or more. The reason for this lies in the

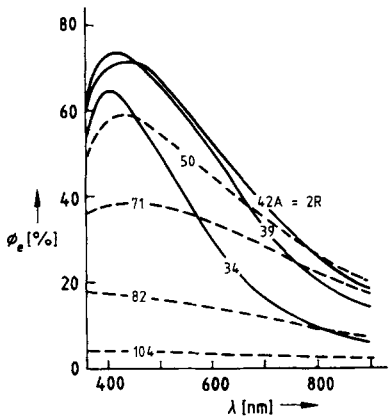

Fig. 18. Photocurrent spectra of porous titanium dioxide electrodes with different size Q-PbS particles. The electrochemical cell was purged with nitrogen and contained a solution of 0.1 M Na_2S and 1 M KCl as electrolyte, a Pt counter electrode, and a Ag/AgCl reference electrode. The measurements occurred under potentiostatic conditions.

relative positions of the bands of PbS and TiO_2. The energy of the conduction band edge of macrocrystalline PbS lies below that of TiO_2; a sensitization is thus impossible. Only by increasing the energy level of the PbS conduction band as a result of the size quantization effect is electron transfer possible. The critical size of PbS particles above which no efficient electron transfer occurs, lies between 40 and 50 Å (corresponding to a band gap of about 1.3 eV).[60, 93]

At present the biggest obstacle for potential applications is the stability of the electrodes. In the case of electrodes sensitized with Q-CdS, the photocurrent decreases to about half the original value after a few months and for those sensitized with PbS already after a few days. It remains to be seen if surface modification or embedding in pure solid state systems can overcome these problems.

8. Conclusions and Prospects

Q-Particles represent a novel state of matter in chemistry and materials science. The chemical and physical properties of the particles can be greatly varied by changing the particle size without changing the chemical composition. In the areas of catalysis, electronics, and optics, a wide variety of applications are conceivable. Also, it is much easier to prepare Q-particles in gram quantities than cluster compounds in the gas phase. Developments in preparation are moving in the direction of soluble powders of Q-particles with narrow size distributions, enabling Q-particles to be handled more like "normal" chemicals.

Surface processes on Q-particles can be very readily examined because of the very large surface to volume ratios. In solution or in transparent solid matrices the methods of optical spectroscopy, either stationary or time-resolved, can be easily employed, which is not the case in a molecular beam or on single-crystal surfaces. It is therefore conceivable that molecular beam and surface physics on the one hand, and Q-particle colloid chemistry on the other, will increasingly supplement one another in the examination of nanometer large clusters or particles and in surface science.

In the area of "nanostructuration" new physical and chemical properties can be expected from the combination of different materials each a few nanometers big. Here also colloid chemistry offers an interesting alternative to the gas-phase processes usually used in materials science.

By embedding the Q-particles in porous semiconductor electrodes the possibility of utilizing the fascinating electronic properties of the particles for optoelectronic and photovoltaic applications can be attempted for the first time. As in the whole of this research area, however, one is at the very beginning and in the phase of fundamental research.

Finally it should be said that similar effects to those that occur when going from molecules to compact materials can also be observed in the case of colloid metals.[7, 8, 99, 100]

Transmembrane Signaling of T Lymphocytes by Ligand-Induced Receptor Complex Assembly

By Klaus Eichmann*

T lymphocytes (T cells) are the central cell type initiating all immune responses. They are able to recognize other cells in the body that have been invaded by foreign living or nonliving matter. In such cells, foreign peptides generated by intracellular breakdown are complexed with molecules of the major histocompatibility complex (MHC) specially designed for peptide binding. Peptide-loaded MHC molecules appear on the surface of these cells and alert the immune system. The molecular complex which T cells use for recognition of peptide-loaded MHC molecules is among the most sophisticated and versatile receptor systems in biology. It consists of specific and nonspecific transmembrane components which assemble to a functional signal transduction unit as the result of ligand binding. Correct assembly leads to activation and relocation of enzymes including membrane-associated, tyrosin-specific protein kinases and phosphatases. Transmembrane signaling in T cells depends on the correct assembly and cooperation among multiple molecular components. This may be related to a multitude of different cellular responses of T cells at different stages of differentiation, all elicited through the T cell receptor complex.

1. Introduction

A major task of the immune system is to protect the vertebrate macroorganism against a myriad of microorganisms. To this end, the immune system is able to generate a series of effector cells and molecules appropriate to the elimination of most microbial invaders. These include antibodies for the neutralization of extracellular infectious agents, various cells and molecules with cytolytic properties mainly to eliminate cells harboring infectious agents or tumor cells, molecular systems for the stimulation of phagocytic cells with antimicrobial principles such as the generation of reactive nitrogen or oxygen intermediates, etc. The diversity of effector systems is a direct corollary to the heterogeneity of infectious agents. Nevertheless all immune responses are initiated by the same basic events, which are summarized in a highly simplified schematic drawing in Scheme 1: Upon entering the body, an antigen is first encountered by macrophages, cells with a "sticky" surface which are present in the blood stream as well as in all tissues. Macrophages as well as a few other cell types are able to engulf the antigen then destroy the engulfed material by the phagolysosomal pathway. This is the end of most microorganisms which are thus eliminated in a nonspecific manner without involving the components of the specific immune system. However, a number of infectious agents including viruses, bacteria, and parasites are more or less resistent to destruction by this mechanism. Nevertheless some of their antigens are processed by macrophages, in other words, proteins are broken down into peptides, which are complexed with the gene products of the major histocompatibility complex (MHC) and presented on the cell surface.[1] Two classes of MHC molecules are responsible for two distinct processing pathways: Proteins derived from phagocytized extracellular antigens are processed in such a way that their peptides are presented with MHC class II molecules. In contrast, peptides derived from proteins which were synthetized within the cell, for example by viruses, are presented with MHC class I molecules.[1] Peptides presented with MHC molecules are recognized by T lymphocytes, which as a corollary to the two types of processing pathways and MHC molecules can be categorized in two distinct subsets, CD4 T cells and CD8 T cells.[2] CD4 T cells have a recognition system for peptides presented by MHC class II and are therefore activated mainly by extracellular infectious agents. Activated CD4 cells produce cytokines involved in the recruitment of inflammatory cells and in the activation ("helper cells") of B lymphocytes that produce antibodies. CD8 T cells have a recognition system for peptides presented by MHC class I molecules; as a consequence, they are activated mainly by intracellular infectious agents.[3] Activated CD8 cells are cytotoxic ("killer cells") and able to destroy cells harboring infectious agents.

As indicated in Scheme 1, the activation of lymphocytes by antigens is a highly integrated process of cellular cooperation involving direct interactions between cells as well as intercell communication by soluble mediators (lymphokines). In addition to CD8 and CD4 T cells, macrophages and B lymphocytes are activated in this process. The major task of activated macrophages is eliminating intracellular pathogens, the major task of activated B cells is secreting antibodies. An attempt to give a full account of all known cellular and molecular events which constitute an immune response would be beyond the scope of this review.[*] Rather, I will restrict myself to describing the multimolecular membrane complex that mediates recognition by and activation of CD4 and CD8 T cells.

2. The Ontogeny of T Lymphocytes

The stem cells for all hemopoetic (blood-cell producing) cells of vertebrates are found during embryonic development

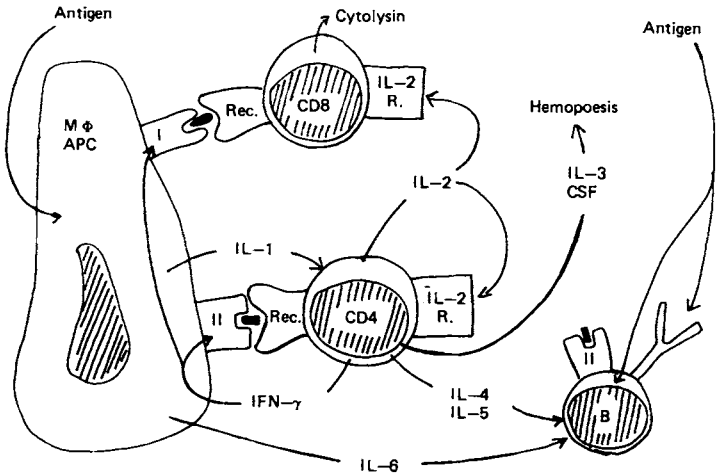


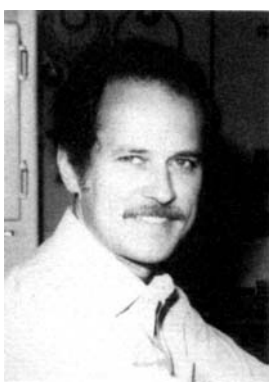
Scheme 1. A very simplified schematic representation of cell types, receptor molecules, soluble mediators, and reaction pathways in a specific immune response. Abbreviations: MΦ = macrophage, APC = antigen-presenting cell, I/II = class I and class II molecules of the major histocompatibility complex, CD8/CD4 = T cells belonging to CD8 and CD4 subsets, Rec. = MHC/antigen-specific αβCD3 T cell receptor, IFN-γ = interferon-γ, IL = interleukin, IL-2R = interleukin-2 receptor, CSF = colony stimulating factor, B = B lymphocyte. This review focuses on the events in the molecular recognition that takes place between CD4 and CD8 T cells and macrophages.

mainly in the yolk sak, during fetal life mainly in the liver, and during adult life in the bone marrow.[4] These stem cells become committed to producing distinct types of cells including T cells, B cells, macrophage-granulocyte cells, etc. Precursor cells committed to T cell lineage leave their tissue of origin and seek the thymus, an epithelial organ that has developed from the fifth pharyngeal pouch and is the primary site for the generation of mature T lymphocytes and the selection of T cell receptors (TCRs) that distinguish "self" from "non-self".[5, 6] Mature T lymphocytes leave the thymus and repopulate the peripheral lymphoid organs as naive, resting, peripheral T cells. Maturation of T lymphocytes is first observed in fetal life, peaks at adolescence, continues throughout adult life, and decreases then with age. Mature naive T lymphocytes die in the periphery within days to weeks unless they encounter and are activated by antigen-presenting cells (APCs) presenting a suitable peptide on their MHC molecules. The MHC/peptide complex is registered by the specific T cell recognition system. Activated T cells divide several times, giving rise to clones of effector cells which, after elimination of the antigen, return to the resting state and become long-lived memory T cells, all having the same recognition system. Memory T cells can be reactivated by the same MHC/peptide combination any time later, giving rise to a new effector and memory cell population with the same specificity.[7]

Thus, during its lifetime, a clone of T lymphocytes comprises T cells with the same recognition system in quite distinct stages of differentiation. Recognition of the MHC/peptide complex leads to quite distinct cellular responses at each differentiation stage. In the thymus, recognition of the MHC/peptide complex (both "self") results in one of two responses: Thymic T cells with efficient recognition (high affinity?) are actively deleted to ensure tolerance of "self", a phenomenon termed negative selection. In contrast, positive selection induces other thymic T cells to mature and is generated by yet poorly understood (low affinity?) means of recognition of the MHC/peptide complex.[5] Positively selected T cells repopulate the periphery, and their receptors recognize self MHC molecules loaded with foreign peptides that were not present during thymic selection. Cells that were neither positively nor negatively selected, that is, those that do not recognize self MHC, also die within the thymus. Recognition of the MHC/peptide complex is again required for activation of naive peripheral T cells to generate clones of functionally competent effector cells. Activated effector cells use their recognition system once again to synthesize and excrete effector molecules. Memory cells are reactivated by their recognition system to develop into secondary effector and memory cells. Taken together, a number of distinct cellular responses are induced through the specific recognition system of T cells, a phenomenon unique to T lymphocytes and worthy of a detailed molecular analysis.

3. The Molecules Involved in T Cell Recognition

In this review the nature and properties of the recognition complex on T lymphocytes will be discussed, with particular emphasis on how its members interact with each other and regulate each other's function. This requires some degree of knowledge on their structure, which I will describe only briefly; the interested reader is referred to many excellent review articles in this field.[8–13] Moreover, an understanding of T cell recognition is not possible without a brief discussion of the physiological ligand, the MHC/peptide complexes on APC. This subject is discussed further in more detailed reviews.[1, 8]



Klaus Eichmann was born in 1939 in Kassel, Germany. He studied medicine from 1959 to 1965 at the Universities of Marburg and Munich and received his doctorate in 1966 in Marburg. He then spent three years at the Rockefeller University in New York in the department led by Prof. Richard M. Krause, first as a research associate and later as an assistant professor. Upon his return to Germany, he became a group leader at the Institut für Genetik at the University of Cologne and later department head at the Deutsche Krebsforschungszentrum in Heidelberg. Since 1981 he has been Director of the Max-Planck-Institut für Immunbiologie in Freiburg and a member of the Max-Planck-Gesellschaft. Since the mid-1980s his research group has been studying the molecular processes on the T cell membrane that lead to signal transduction and activation.

3.1. MHC Molecules and Peptide Presentation

The MHC is a gene complex which is highly conserved in all vertebrate species studied.[14] It contains several types of genes which are more or less closely related to immune functions. For the present purpose it suffices to discuss two types of MHC genes, the class I and class II genes, both occurring in several different functional copies per haploid genome (haplotype).[15] Their most unusual property is an unusual degree of polymorphism, resulting in the practical consequence that each individual haplotype represents a unique combination of alleles, and no two phenotypes are identical. This fact accounts for most of the problems connected with tissue transplantation.[14, 15]

The proteins encoded by MHC class I and class II genes belong to the immunoglobulin (Ig) superfamily, whose common unit is the Ig-like domain consisting of approximately 110 amino acids folded in two parallel layers of three to four antiparallel strands of β sheet, connected by a disulfide bond.[16] MHC class I proteins consist of three domains in tandem; the amino-terminal domains (α1 and α2) are atypical in that they form α-helical regions sitting on a single monolayer of a β sheet (Fig. 1). The α-helical portions of the α1 and α2 domains are arranged in parallel forming a groove between them whose bottom is provided by the combined β sheets of both domains. The α3 domain is typically Ig-like and is attached to the cell surface by a transmembrane region followed by a cytoplasmic tail. Noncovalently attached to the α3 domain is the non-MHC encoded β2 microglobulin (β2M), a single Ig domain structure.[8] The MHC class II proteins are heterodimers; each chain consists of an N-terminal atypical domain (α1 and β1) followed by a typical Ig domain (α2 and β2) and transmembrane and cytoplasmic regions. The α1 and β1 domains together form a structure similar to that described above for the α1 and α2 domains of MHC class I (Fig. 1).

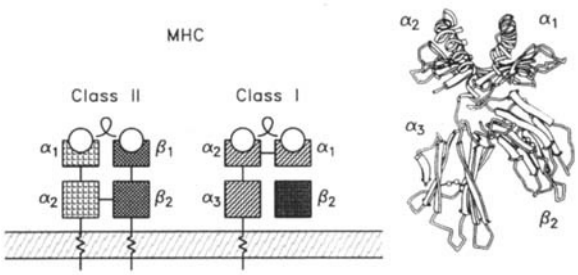


Fig. 1. Schematic representation of MHC class II and class I molecules and the three-dimensional crystal structure of a human MHC class I molecule. The typical Ig domains are represented by squares. The α-helical regions of the atypical domains are indicated by open circles. The position of the peptide in the cleft between the α-helical regions is indicated; in the crystal structure the cleft between the α-helical regions is empty. The crystal structure does not include the transmembrane portion, since the protein used for crystallization was obtained by papain digestion of MHC class I molecules from cell surfaces (cf. [1, 8]).

The grooves of both types of MHC molecules are receptacles for peptides with eight to ten amino acids for MHC class I and somewhat longer for MHC class II.[17, 18] Several algorithms have been developed to predict peptide sequences that fit into MHC grooves, but to date none is entirely reliable.[1] Most data suggest that the MHC fit is determined by no more than one or two amino acid positions at one or both ends of the peptide, whereas the rest of the sequence may vary widely.[17–20][*] Hence, a single MHC molecule can bind and present many different peptides. There is no indication that any difference is made at this stage between self and foreign peptides. However, due to selection of T cell receptors in the thymus (thymic selection), only foreign peptides alert the T cell system to the presence of foreign invaders within the antigen-presenting cell.

3.2. The T Cell Receptor

The T cell receptor (TCR) also termed $\alpha\beta$ CD3 complex, consists of seven transmembrane polypeptides (Fig. 2). Two

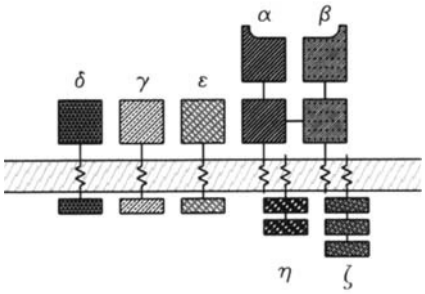

Fig. 2. Schematic representation of the components of the $\alpha\beta$ CD3 T cell receptor. The α and β chains form disulfide-linked heterodimers. The distal domains of both chains contain the binding sites for MHC peptide complexes. These two chains as well as the γ, δ, and ε chains belong to the Ig superfamily. η and ζ chains consist predominantly of cytoplasmic regions. Ig domains are indicated by squares, domains containing intracellular signal sequences, by rectangles. The ζ chain occurs as a homodimer or as a heterodimer with η. The exact composition of the CD3 complex is unknown, and there is no three-dimensional information on any of its components.

of these, the α and β chains, form a heterodimer that shows molecular diversity similar to antibody molecules and confers specific recognition properties to the TCR and to the T cells expressing it.[21, 22] Similar to antibody-producing B cells, T cells rearrange the genes for the α and β chains from a number of V (variable), D (diversifying), J (joining), and C (constant) gene segments in such a way that a very large number of different α and β chains are made. Yet one T cell expresses only a single pair ($\alpha\beta$) with one defined combining site structure. This pair of rearranged receptor genes is transmitted to all progeny of a T cell, accounting for the fact that all members of a clone of T cells have the same recognition specificity. The gene structure of the T cell receptor and its rearrangement have been described in detail.[8, 13] Both α and β chains have two extracellular Ig domains; the distal domains carry the variable portions and form the combining site for the MHC/peptide complex, the proximal domains are invariant. The α and β chains are linked by a disulfide bridge and anchored in the cell membrane by transmembrane regions with very short cytoplasmic tails. There is no information to date on the three-dimensional structure of TCR $\alpha\beta$ heterodimers.

[*] Editorial note: New insights on MHC/peptide complexes from X-ray crystal structures were reported recently: D. H. Fremont, M. Matsumura, E. Stura, P. A. Peterson, I. A. Wilson, *Science* **1992**, *257*, 919; M. Matsumura, D. H. Fremont, P. A. Peterson, I. A. Wilson, *ibid.* **1992**, *257*, 927; see also M. Barinagu, *ibid.* **1992**, *257*, 880.

The five additional polypeptides of the CD3 complex (γ, δ, ε, η, ζ) are noncovalently associated with αβ. They have larger cytoplasmic regions and are strongly suspected to play a role in transmembrane signaling. The η and ζ subunits have extracellular portions consisting of only nine amino acids but have large intracellular tails carrying characteristic sequence motifs which are suspected to play a role in coupling the CD3 complex to intracellular protein tyrosine kinases.[23-25] They occur as ζ–ζ homodimers and ζ–η heterodimers. The η and ζ subunits are highly homologous to one another and to the γ chain of the high-affinity IgE receptor (FcεRI);[26] together they form a new protein family of signal transducers with apparently similar function. The γ, δ, and ε subunits have extracellular Ig domains and are expressed as noncovalently associated δε and γε pairs.[27-29] Because of their relationship to the Ig superfamily[30] these chains have been suspected to be involved in coupling the CD3 complex to other surface receptors (see below). Their cytoplasmic parts contain sequence motifs similar to those which characterize the η and ζ subunits, but with fewer repeats.[31]

3.3. The Accessory Molecules CD4 and CD8

These molecules were first known as *markers* by which the two major subsets of T cells, helper and killer T cells, can be distinguished by using appropriate monoclonal antibodies.[2, 32, 33] The molecules became of interest with the discovery that, without exception, CD4 T cells carry αβ TCR that recognizes MHC class II and CD8 T cells carry αβ TCR that recognizes MHC class I.[2] Since in principle there is no differences between the αβ TCR of the two types of cells, it became clear that CD4 and CD8 themselves are involved as receptors in MHC recognition.

Both CD4 and CD8 are members of the Ig superfamily.[11, 12, 34, 35] CD4 is a monomeric transmembrane polypeptide with four extracellular Ig-like domains (Fig. 3). In a crystallographic study on a fragment comprising the two distal domains, both were shown to be tightly and rigidly connected by a continuous strand of a β sheet.[36, 37] CD8 is a disulfide-linked heterodimer of α and β chains, each carrying a single Ig-like domain which is linked by a hinge region to its transmembrane part (Fig. 3). There is no information on the three-dimensional structure of CD8,[*] but functional considerations suggest that the Ig domains of the α and β chains of CD8 are at the same distance from the cell surface as the most distal domain of CD4. The hinge regions of both chains must thus have highly extended linear structures. The cytoplasmic tails of both CD4 and of the α chain of CD8 are associated with the cytoplasmic protein tyrosine kinase $p56^{lck}$ (lck).[38-40]

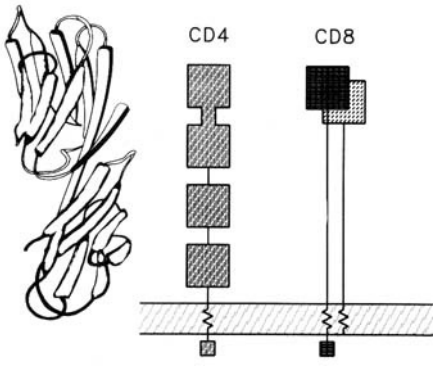

Fig. 3. Schematic representation of the accessory molecules CD4 and CD8. Ig-like domains are indicated by patterned squares. The crystal structure of a fragment corresponding to the two distal Ig domains of CD4 is shown on the left (cf. ref. [36, 37]). The rigid connection of the two domains by a β strand suggests that they form a functional unit. The two Ig domains of CD8 (α and β) may form a similar structure as the two distal domains of CD4 as an alternative to the configuration shown. The cytoplasmic tails of CD4 and of the CD8 α chain contain a sequence which serves as contact site for $p56^{lck}$.

When overexpressed in COS cells,[**] CD4 mediates adhesion to cells expressing MHC class II,[41] and the CD8 α chain mediates adhesion to cells expressing MHC class I.[42, 43] The binding site of CD4 for MHC class II has been broadly defined by mutagenesis experiments; it extends across one side of the two distal Ig domains and overlaps with the smaller and more concise region involved in HIV-GP120 binding.[44, 45] The binding site of MHC class II for CD4 is unknown but is expected to reside within nonpolymorphic regions, that is, in the α2 and/or β2 domains.

The binding site of CD8 for MHC class I has been shown by mutagenesis experiments to involve the Ig domain of the α chain.[46] The binding site for CD8 on MHC class I has been mapped by mutagenesis experiments and by the study of natural variants to a defined region within the α3 domain, also a conserved portion of the molecule.[43, 47-49]

3.4. Molecules Involved in Tyrosine Phosphorylation

3.4.1. Tyrosine Kinases

T cell receptors appear to activate two signal transduction pathways.[50] One involves phospholipase Cγ1 (PLCγ1) which cleaves phosphatidyl inositol into inositol phosphates and diacylglycerol, resulting in a rise in intracellular Ca^{2+} levels, on the one hand, and in activation of protein kinase C on the other. This leads to the phosphorylation of serin in numerous components including the CD3γ chain[51] and to rapid activation of secondary messengers such as p21 ras and c-raf kinase.[52, 53] It is not known how the CD3 complex is coupled to PLCγ1 or to further messenger systems that reach the cell nucleus.[50] The second perhaps more relevant signal transduction pathway appears to involve tyrosine phosphorylation of several substrates including CD3ζ and PLCγ1.[54-56] None of the CD3 subunits possess intrinsic protein tyrosine kinase (PTK) activity but cytoplasmic PTKs appear to be associated with components of CD3 as well as with CD4 and CD8: fyn[50] and lck,[38-40] both members of the src family. Little is known about fyn, except that it can be coprecipitated with the CD3 complex; lck forms a coimmunoprecipitate with both CD4 and CD8.[38-40] It binds to a distinct cystein-rich sequence in their cytoplasmic tails, as shown by deletional and mutational analyses.[57-59] lck was first described as a tyrosine kinase that was overexpressed in a lymphocytic leukemia.[38] Whereas the carboxyl terminal

[*] The crystal structure of a CD8α homodimer was in the meantime reported: D. J. Kahy, R. Axel, W. A. Hendrickson, *Cell*, **1992**, *68*, 1145.

[**] COS cells: Denotation for one of the cell lines derived from the established simian kidney cell line CV1 by treatment of the cells with a mutant of the simian virus SV40.

part of the molecule is highly homologous to members of the src family, unique features of the amino terminus include the binding motif for CD4/CD8 and the myristilation site that mediates association with the inner face of the T cell membrane (Fig. 4). Two tyrosine residues, 394 and 505, appear to regulate lck activity: phosphorylation of Tyr 394 enhances lck activity, whereas phosphorylation of Tyr 505 results in loss of kinase activity. Indeed, mutation of Tyr 505 to phenylalanine converts lck to a constitutively active form.[60]

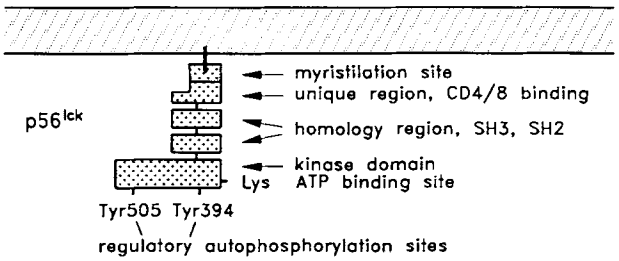

Fig. 4. Schematic representation of $p56^{lck}$ pointing out the typical structural properties of all members of the src tyrosin kinase family (taken from ref. [60]). The CD4/CD8 binding region is unique to $p56^{lck}$. Homologous regions SH3 and SH2 may interact with components of the cytoskeleton. Autophosphorylation of the regulatory tyrosine residues has been suggested to alter the angle of attachment of the kinase domain to the rest of the molecule, thereby regulating kinase activity [60].

3.4.2. CD45, a Tyrosine Phosphatase

Originally termed "leucocyte common antigen", CD45 is expressed on all cells of hemopoetic origin.[61] It consists of an extracellular domain, a transmembrane region, and a cytoplasmic tail with two tyrosine phosphatase domains in tandem (Fig. 5).[62, 63] Isolated CD45 has tyrosine-specific phosphatase activity.[63]

The extracellular domain of CD45 is of special interest because it occurs in multiple molecular versions due to differential RNA splicing.[61] This part of the molecule is encoded by seven exons, three of which, termed A, B, and C, may be differentially spliced, accounting for a total of eight possible isoforms[64] (Fig. 5). The complete molecule containing exons A, B, and C is expressed on all white blood cells.[61] In contrast, the incomplete versions are expressed in a restricted fashion (CD45R) and mark T cells at distinct stages of differentiation: naive peripheral T cells express incomplete isoforms containing one or two of the three variable exons mostly including A (CD45RA) or B (CD45RB), whereas memory T cells express a short version lacking all three exons (CD45RO).[64-76] The latter form may also be expressed on immature thymocytes.[68, 69]

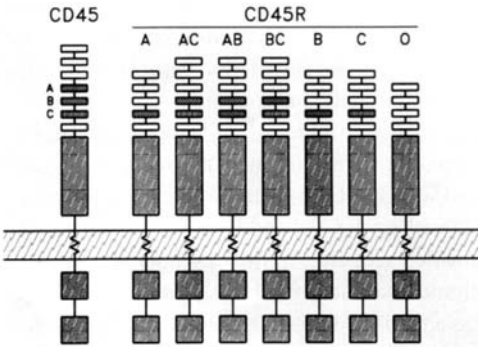

Fig. 5. Schematic representation of the complete CD45 molecule (left) and the family of splicing isoforms. The isoforms containing exon A (CD45RA) and B (CD45RB) can be distinguished from complete CD45 and from CD45RO by monoclonal antibodies. Not all possible isoforms have been clearly demonstrated to be expressed on T cells. The molecule does not belong to the Ig superfamily. The intracellular portion has been shown by structural and functional analyses to be a protein tyrosine phosphatase (see ref. [61]).

The expression of different versions of the CD45 extracellular domain at defined stages of T cell differentiation strongly suggests that CD45 plays a regulatory role in recognition-related signal transduction. It is likely that the various isoforms interact with other cell surface molecules either on the same or on a different cell. For example, low molecular weight isoforms on memory T cells have been shown to associate with components of the CD3 complex or with CD4,[77, 78] whereas high molecular weight isoforms seem to behave independently of the TCR in the membrane of naive T cells.[77]

The PTK lck can act as a substrate of CD45.[79, 80] This was studied in crosslinking experiments[80] and in transfected cell lines expressing lck with CD4 or CD8 in the presence and absence of CD45.[79] The degree of autophosphorylation of lck upon surface crosslinking of CD4/CD8 was reduced in the presence of CD45. Moreover, crosslinking of CD45 to CD4/CD8 led to dephosphorylation of lck. In these experiments, dephosphorylation of lck was accompanied by an increase in kinase activity of lck, suggesting that CD45 regulates lck activity through dephosphorylation of Tyr 394. Antibodies to CD45 had inhibitory or stimulatory effects on several cellular functions.[81-84]

4. Experimental Approaches to Studying T Cell Activation Molecules

Two genetic methods are being used to assess the functional role of T cell activation molecules. The first involves the selection of loss variants of T cell lines or clones growing in vitro and/or their transfection with the appropriate normal or mutated genes to reexpress molecules under study. This approach is restricted to T cells growing in vitro, which are by definition activated T cells, that is, they are at a late stage of differentiation. The second method is the study of genetically manipulated mice in which relevant genes are introduced as transgenes or are inactivated by homologous recombination in embryonic stem cells. Transgenic expression or deletion ("knockout") of the molecules discussed in this review mostly leads to perturbation of the maturation of T cells in the thymus; this restricts the information of this approach to the early stages of T cell development. Naive peripheral T cells are per definition resting and thus cannot be continually cultured in vitro. Nevertheless, this cell type must be the primary target of studies on T cell activation. These studies, therefore, often utilize primary T cells recovered ex vivo from blood or lymphoid organs which are analyzed in short-term culture. Since this type of experiment does not allow genetic manipulation of clonal cells, results are often not as unambigious. In contrast, the interpretation of results from genetic experiment is limited by the fact that

the studies apply to the very early and very late stages of T cell differentiation.

4.1. Transmembrane Signaling of Resting Peripheral T Lymphocytes

In this section the molecular events at the membrane of naive peripheral T cells during T cell activation will be described. This is only the beginning of a complicated cascade of molecular processes extending through the cytoplasm into the nucleus, eventually resulting in the induction of gene transcription. Restricting myself to the initial steps, I refer the reader to a competent recent review[50] of the intracellular events following activation.

Physiological T cell activation involves the interaction of a T cell with an antigen-presenting cell (APC) and includes the specific recognition by the αβ heterodimer on the T cell membrane of the MHC molecule presenting a peptide on the APC. The interaction between two cells is difficult to study on the molecular level. Attempts to reduce the complexity include using truncated soluble receptor molecules, an approach which has thus far not been fully successful. Alternatively, ligands on the surface of the APC have been replaced by soluble reagents such as mitogenic lectins or antibodies. Lectins have proven useful to some extent, but their ligand specificity is often broad and undefined. Monoclonal antibodies (mAbs) of defined specificity for individual T cell surface molecules have been successfully used in these studies, and some key experiments will be discussed here.

4.1.1. The Importance of Crosslinking

Addition of a mAb to any component of the αβ CD3 complex to a culture of peripheral lymphocytes from blood or spleen leads to the activation of the T cells in the culture. Various parameters can be used to monitor this T cell activation such as increase in cell size, mobilization of Ca^{2+}, activation of several enzymes, transcription of genes for lymphokines and lymphokine receptors, cell division etc.[85–88] mAbs to a handful of other T cell surface components also can cause activation, but the significance of this observation is not clear.[89] I will restrict this discussion to signaling events involving the αβ CD3 complex that reflect T cell activation by a specific antigenic challenge.

Activation of T cells by anti-TCR mAbs requires the presence of non-T cells having Fc receptors, for example macrophages. After depletion of Fc receptor positive cells from the culture, anti-TCR mAb is unable to activate T cells. However, T cells depleted of Fc receptor positive cells can be activated efficiently by anti-TCR mAb coupled to a solid-phase carrier.[88, 90, 91] This demonstrates that individual ligation (or even dimerization) of the TCR is insufficient to activate a T cell. Cell surface aggregation of the TCR is required for successful transmembrane signaling.

4.1.2. The Role of CD4 and CD8 in Resting T Cells

Soluble mAbs to CD4 and CD8 inhibit the activation of the corresponding T cell regardless of whether the activation is induced by APC, lectins, or anti-TCR mABs bound to a solid support.[90, 92–99] Since the latter two activation protocols do not involve MHC molecules as ligands for CD4 or CD8, inhibition by anti-CD8/4 mAbs could not be due to blocking of MHC binding. This has raised a long discussion on the possibility that the accessory molecules are receptors of negative or inactivating signals to T cells. Although this is still maintained by some investigators,[100] negative signaling is in my opinion excluded by the following findings: The efficiency of the activation of T cells by crosslinking the TCR by anti-TCR mAbs is enhanced by at least two orders of magnitude when antibodies to CD8/CD4 are included, that is when the TCR is coaggregated with CD8/CD4.[90, 92, 93, 101–105] When heterozygous T cells expressing two different CD8 alleles were used, activation was achieved by coaggregation of only one of the CD8 alleles to the TCR. This activation could be inhibited by antibodies to the coaggregated CD8 allele but not by antibodies to the free CD8 allele.[92] This experiment shows that inhibition of T cell activation by anti-CD8/4 mAbs occurs by blocking of the association of the accessory molecule with the TCR. Aggregation of the TCR alone—by whatever ligand—induces a sufficient degree of association with CD4/CD8 for low-level activation to occur, which is blocked by anti-CD4/CD8 mAbs. The spontaneous association due to TCR crosslinking is greatly enhanced when the accessory molecule is forcefully coaggregated with the TCR, either experimentally by solid-phase antibodies, or physiologically by MHC molecules on APC, to which both the TCR and the accessory molecule bind at the same time. This model predicts that the accessory molecules must have two combining regions, one for the MHC molecule on the APC and the other for the TCR on the same T cell (see next section).

It is generally accepted that the close proximity between the TCR and CD4/CD8 required in the activation of resting T cells is related to the necessity of relocating the protein tyrosine kinase (PTK) lck next to the CD3 complex. As mentioned in Section 3.4.1., lck is associated with CD8/CD4 on the inner face of the T cell membrane. Moreover, CD3 phosphorylation and TCR-CD4 association is induced in parallel by the same antibodies.[100] The sole purpose of the formation of the TCR–CD4/CD8 complex may thus be to achieve tyrosine phosphorylation of the CD3 ζ chain.

4.1.3. Relationship between CD4/CD8 and the T Cell Receptor in the Resting State

The studies of transmembrane signaling in resting peripheral T cells described in the previous section suggest the formation of a complex between the TCR and CD4/CD8. This opens the question on the configuration of both molecular components in the resting state itself. The simplest assumption would be that the two components on the T cell membrane are completely independent and that proximity between the two is induced only upon binding with the appropriate ligand (Fig. 6 top). Some experimental evidence has been reported in favor of this model.[106–109] However, a number of previous indirect experiments have suggested that some form of association exists continually.[110–113] This has been confirmed recently by direct immunoprecipita-

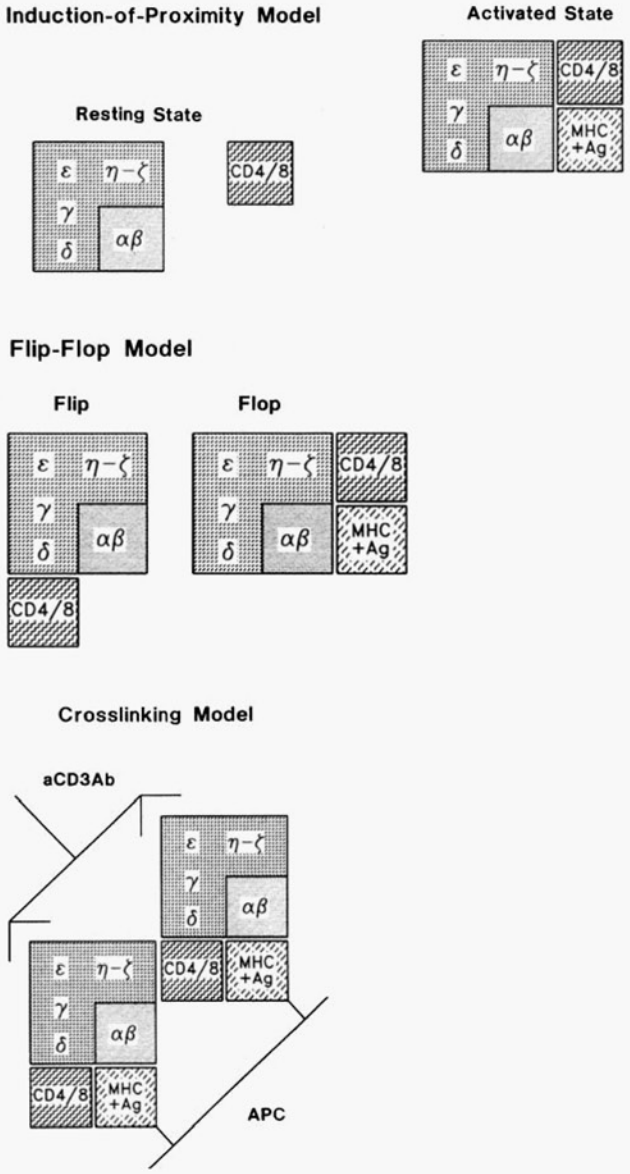

Fig. 6. Three models for complex assembly between αβ CD3, the accessory molecules CD4/CD8, and the MHC/peptide complex during T cell activation. Top: The "induction-of-proximity" model predicts that the accessory molecules and αβ CD3 on the T cell membrane are independent of each other in the absence of the MHC/peptide complex. Mutual binding of both components to the MHC/peptide complex induces proximity between CD4/CD8 and αβ CD3 on the outer cell surface, as a consequence leading to proximity between lck and cytoplasmic tails of CD3 components on the inner face of the T cell membrane. Middle: The "flip-flop" model takes the association of the accessory molecules CD4/CD8 with the CD3 δ chain on resting T cells into account. It predicts two different configurations of the complex, one in which the association between CD4/CD8 and CD3 δ maintains the resting state, and another in which MHC-binding induces the flipover of CD4/CD8 to CD3 ζ, thus leading to ζ chain phosphorylation and T cell activation. Bottom: The "crosslinking model" does not require alterations within the complex during activation. It can explain activation of T cells by MHC on APC as well as by antiCD3 antibody-mediated crosslinking. However, it is possible that antibody-induced T cell activation occurs according to the crosslinking model, whereas T cell activation by MHC/peptide binding occurs according to the flip-flop model.

tion experiments, which clearly demonstrate that CD4/CD8 are associated with the CD3 δ chain on resting T cells.[114] Virtually every CD3 δ is associated with an accessory molecule. In contrast, after activation this association is no longer found. This suggests that the TCR–CD4/CD8 complex is highly dynamic and oscillates between several different conformations, each relating to a functional status of the T cell.

4.1.4. Models for the Formation of the Activation Complex

A Flip-Flop Model

In the resting state (flip state), CD4/CD8 is associated with the CD3 δ chain.[114] For activation, lck must be relocated next to the CD3 ζ chain. It is thus possible that CD4/CD8 flips over from CD3 δ to CD3 ζ (flop state), carrying lck along (Fig. 6 middle). In this model, lck would be kept at a distance from CD3 ζ in the resting state, thus preventing an accidental encounter followed by activation, unless the proper MHC peptide complex induces the flop state. This model requires the induction of conformational changes within at least one member of the complex.

A Crosslinking Model

This mechanism may indeed coexist with a flip-flop mechanism. It simply proposes that aggregation of the complex which exists in the resting state may result in accidental proximity between CD3 ζ and CD4/CD8-lck, which induces activation (Fig. 6 bottom). In contrast to the flip-flop model, there is no mechanism that prevents accidental activation in this model. There is also no requirement for conformational changes.

Figure 7 shows a currently accepted schematic representation of a possible configuration of the activation complex during transmembrane signaling. It is obvious that this is a

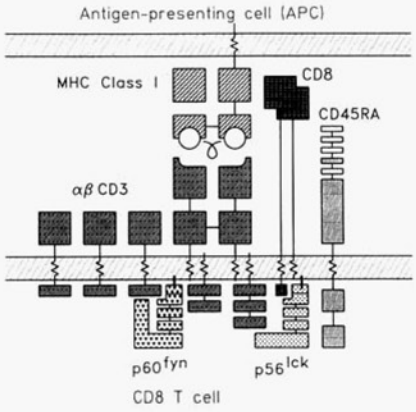

Fig. 7. Possible configuration of the T cell recognition complex during activation. The precise molecular association of $p60^{fyn}$ with components of the CD3 complex is unknown. The molecules interacting with CD45 or CD45R isoforms are also unknown. A similar picture may be drawn for MHC class II and CD4.

minimal model. There is insufficient information on CD45, for example, to make reasonable predictions on its involvement in the activation complex. More sophisticated techniques must be developed to elucidate multimolecular functional complexes within cellular membranes.

4.2. Transmembrane Signaling in Activated T Cells

Upon further encounter with the antigen-presenting cells (APCs), activated T cells respond either with or without the induction of transcriptional activity. For example, the induction of the release of cytolytic molecules from activated $CD8^+$ cytotoxic T cells (CTL) requires no transcription. In

contrast, production of cytokines by activated $CD4^+$ or $CD8^+$ T cells in most cases requires induction of transcription of the corresponding genes. Tissue culture lines or hybridomas representing most types of activated T cells have been established, so that their study have most successfully employed a genetic approach. In the first place, transfection of the genes for the α and β chains of individual TCR into hybridomas have established that the $\alpha\beta$ heterodimer of the CD3 complex alone is responsible for the specificity of a T cell to a certain MHC/peptide complex.[21, 22] Nevertheless, these experiments also revealed that the recognition process itself was inefficient without the proper accessory molecule: TCRs recognizing MHC class I molecules required CD8,[115–118] whereas TCRs recognizing MHC class II molecules required CD4 for optimal recognition;[119] the improper heterologous accessory molecules also had some improving effect.[119–123] These experiments formed the basis for the hypothesis on the affinity-enhancing role of accessory molecules: The binding of both the TCR and the accessory molecule to the same MHC target efficiently enhanced a per se low-affinity TCR–MHC interaction; much less enhancement was observed when the accessory molecule bound to a different MHC molecule on the APC.

More ambigious results were obtained when the signaling role of accessory molecules was assessed in activated T cells. One type of experiment employed transfection of the genes deleted of their cytoplasmic tail, in other words their products were not able to associate with lck. These truncated accessory molecules nevertheless enhanced activation by APC, albeit less efficiently than the complete accessory molecules.[124–127] Another type of experiment employed CD8-deficient variants of CTL and their CD8 transfectants. Whereas the activation of these cells by APCs was essentially dependent on CD8, their activation by anti-TCR mAbs was fully maintained in CD8 loss variants, both for transcriptional and nontranscriptional responses.[117, 118, 128] Together, these results suggest that activated T cells are to some degree independent of the transmembrane signaling function of the accessory molecules. This is brought out in situations in which the TCR is engaged with a high-affinity ligand, for example anti-TCR mAb. These interpretations are also in line with previous observations on single activated $CD8^+$ and $CD4^+$ T cell lines and clones which cannot be inhibited by anti-CD8/4 mAb.[129–131] Variants selected from T cell clones for low expression of CD4 have been shown to be even more sensitive to activation by APC than the cells expressing CD4 at a normal level.[132] Experiments using hybridoma cells transfected with CD3 $\gamma\delta\varepsilon$ without functional CD3 ζ have revealed efficient induction of transcriptional responses, also suggesting a partial independence of activated T cells of the CD4/CD8–lck–CD3 ζ signaling pathway. It was proposed that the CD3 $\gamma\delta\varepsilon$ components provide an alternative transmembrane signaling route.[31] It is possible that this pathway is relatively inactive in naive T cells and takes over in activated T cells.

4.3. The Bifunctional Nature of Accessory Molecules

The activation of resting naive T cells depends primarily on transmembrane signaling by TCR–CD4/CD8 association. In contrast, transmembrane signaling in activated T cells is partly independent of CD4/CD8. Nevertheless, most activated T cells depend on CD4/CD8 for MHC/peptide recognition, undoubtedly through their MHC-binding function. This situation was utilized in a recent study in which, using monoclonal anti-CD8 mAbs, epitopes related to the binding of MHC to CD8 could be distinguished from epitopes related to TCR association.[133] The study showed that distinct regions on the CD8 molecule are involved in either function. Moreover, both functions involved epitopes on the α and the β chain of CD8. Whereas the MHC-binding region is undoubtedly associated with the V domain of the α and perhaps also the β chain, there is no structural information as yet on the location of the TCR-binding region. Logically this region should be somewhere between the V region and the cell surface, that is, within the hinge region of CD8 (Fig. 7).

5. The Recognition Complex in Thymic Selection

Thymic selection requires the intact thymus either in vivo or in organ culture. It has therefore not been possible to analyze events inducing selection of T cell receptors in the thymus at the level of single cells, not to speak of single molecules. Biochemical signaling pathways leading to positive and negative selection responses have thus, with some exception,[134] not been studied conclusively to date. Nevertheless, highly sophisticated experimental protocols, utilizing transgenic mice or mice in which individual genes have been deleted, have allowed the functional roles of several members of the T cells recognition complex in thymic selection to be assessed.

The role of the TCR $\alpha\beta$ heterodimer was studied in mice transgenic for rearranged α and β genes isolated from individual CD8 or CD4 T cell clones with known MHC/peptide recognition.[5, 6] Encounter of the TCR $\alpha\beta$ heterodimer with the homologous MHC/peptide complex during the development of T cells in the thymus induced deletion by apoptotic cell death, thus preventing self-reactive cells to emerge from the thymus. If the T cells failed to encounter the correct MHC molecule in the thymus they did not mature. Successful maturation and generation of mature T cells leaving the thymus depends on the presence of the correct MHC molecule during thymic development. These results proved that the TCR $\alpha\beta$ heterodimer was instrumental in thymic selection: Encounter with the self-MHC/self-peptide complex induces a deletional response, encounter of self MHC alone induces a maturational response, failure to encounter a fitting structure results in developmental arrest.

T cells carrying transgenes for a TCR with MHC class I recognition emerge from the thymus only as $CD8^+$ cells, whereas T cells carrying transgenes for a TCR with MHC class II recognition emerge from the thymus only as $CD4^+$ cells. These results suggest that only those T cells in which the specificity of the $\alpha\beta$ TCR correlates to the accessory molecule are allowed to become positively selected and mature. This has been shown to be the result of an instructional process which occurs at the stage at which immature T cells in the thymus express both CD4 and CD8 and which ends with the shutdown of the expression of the noncorresponding accessory molecule.[135, 136] A reasonable assumption is

that thymocytes are positively selected when the αβ TCR and the accessory molecule bind to the same MHC molecule.[137] Mice carrying mutated transgenic MHC molecules that are unable to bind CD8 or CD4 can neither positively nor negatively select T cells that recognize such MHC molecules.[138] Thus, some form of cooperation between the TCR and the accessory molecules appears to be required for both positive and negative selection. The differences between transmembrane signaling events leading to positive and negative selection responses are the subject of current intense investigation. These experiments with transgenic mice have been recently complemented by research with mouse strains in which the corresponding genes are deleted. As expected, mice that fail to express MHC class I[139] or class II[140] molecules fail to develop CD8 and CD4 T cells, respectively. In addition, mice that fail to express CD8 or CD4 molecules fail to develop T cells whose TCRs recognize MHC class I and class II molecules, respectively.[141]

Taken together, there is little doubt that the same recognition system that allows for T cell activation in the periphery is also involved in thymic selection. Nevertheless, the responses elicited in thymocytes differ distinctly from those in peripheral T cells. These differences may result from the way in which the recognition complex is assembled or which individual members of the complex are coupled to second and subsequent messenger systems in the cytoplasm. There is little doubt that the T cell recognition complex is one of the most sophisticated and versatile signaling structures in biology.

6. Conclusion

T lymphocytes are capable of recognizing other cells containing foreign living or nonliving matter (antigen presenting cells, APCs). These foreign structures are broken down within the APC, and resulting peptides are complexed with newly synthesized MHC molecules which are then exposed on the cell membrane. Complexes of MHC molecules with foreign peptides are recognized and bound by a recognition complex composed of specific and nonspecific components on the T cell membrane. As a consequence of recognition and binding, specific and nonspecific members of the recognition complex assemble in the T cell membrane in such a way that transmembrane signaling results, most likely through relocation and activation of membrane-associated protein tyrosine kinases and phosphatases and tyrosine phosphorylation/dephosphorylation. The cellular responses elicited by this complex are diverse and differ according to the stage of T cell development and differentiation. Factors determining the nature of the response may reside in the numerous ways of complex assembly or in differential coupling to intracellular messengers.

Further analyses leading to a more detailed understanding of the T cell activation complex would be highly desirable, both for the development of better theoretical models and for applications in medicine. Methods could be designed for medical interference with immune disorders such as autoimmune diseases, allergies, and immunodeficiencies. This would require new technologies for the analysis of complexes of macromolecules as they exist in cell membranes, including their dynamic changes. In the past, immunology has greatly benefitted from basic analytical technology developed in many other scientific disciplines, including chemistry. The task of developing methods for the analysis of macromolecular complexes and their dynamics may provide a new challenge for chemists, particularly protein and membrane chemists. Such an effort, if successful, would result in a much deeper insight than is presently possible into functional events at cell membranes, including transmembrane signaling of T lymphocytes.

X-ray Structure Analysis of FeMo Nitrogenase—Is the Problem of N_2 Fixation Solved?

By *Dieter Sellmann**

Metalloenzymes rank among the most active and efficient catalysts, and the elucidation of the structure–function relationships in these metalloenzymes not only presents a fascinating challenge for research, but also can potentially show ways to new industrial catalysts with previously unattainable activity. Many of these metalloenzymes, for example, ferredoxins, hydrogenases, nitrate reductases, and last but not least nitrogenases,[1] contain transition metals in sulfur-dominated coordination spheres in their active centers. Nitrogenase research recently took a big step forwards: in the summer of last year the scientific community was galvanized by reports describing the X-ray crystal structure analysis of crystalline nitrogenase, which for the first time led to a concrete model for the active centers of iron–molybdenum nitrogenase.[2]

Like photosynthesis, enzymatic N_2 fixation is one of the fundamental synthetic processes of nature. It is catalyzed by nitrogenases, which catalyze the reduction of the usually inert N_2 molecule to ammonia. The nitrogenases known today can be classified according to the metals they contain as FeMo, FeV, and FeFe nitrogenases. The nitrogenases that have been most thoroughly studied are the FeMo nitrogenases, and for a long time molybdenum was considered an essential metal for nitrogenases.[1b] The discovery of FeV nitrogenases, however, showed that the role of molybdenum possibly can be fulfilled by other metals,[3a, b] and the isolation of nitrogenases containing exclusively iron finally ended the belief that two different metals are necessary for the activation and reduction of N_2.[3c]

The FeMo nitrogenases consist of two proteins, the Fe protein and the FeMo protein, which can be purified separately. The Fe protein ($M_r \approx 60000$) is a dimer of two identical subunits, which are bridged by one $[Fe_4S_4]$ cluster. It functions as a *specific* one-electron donor for the FeMo protein, and as yet no other protein or reducing agent has been able to assume the function of the Fe protein. The FeMo protein is a $\alpha_2\beta_2$ tetramer with $M_r \approx 220000$, containing two Mo centers, 32 ± 3 Fe centers, and 32 ± 3 S^{2-} units (Fig. 1).

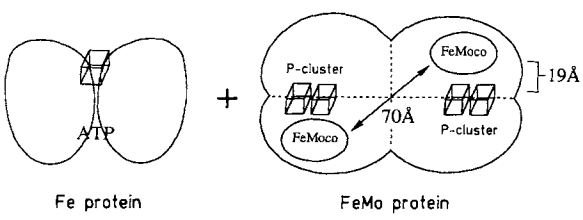

Fig. 1. Schematic representation of FeMo nitrogenase. Fe and FeMo protein form the complete enzyme. The spatial arrangement of the metal–sulfur clusters and a proposal for the binding site of the adenosine triphosphate (ATP) in the Fe protein result from the X-ray structure analyses of the two proteins according to [2] and [8]. Cube = Fe_4S_4; FeMoco = FeMo cofactor.

Institut für Anorganische Chemie der Universität
Egerlandstrasse 1, D-W-8520 Erlangen (FRG)

Only the combined effect of the Fe *and* the FeMo protein in the presence of a reducing agent such as $Na_2S_2O_4$ makes possible the reduction of N_2. As Equation (a) shows, during this process 2 mol H^+ ions are always reduced to give H_2,

$$N_2 + 8\,H^+ + 8\,e^-\ (\text{e.g. from } Na_2S_2O_4) + 16\,\text{MgATP} \xrightarrow{N_2\text{-ase}} 2\,NH_3 + H_2 + 16\,\text{MgADP} + 16\,PO_4^{3-} \quad (a)$$

and 16 mol magnesium adenosine triphosphate (MgATP) are required. The role of the MgATP is not yet understood. The reduction potential of $Na_2S_2O_4$ alone would be sufficient for the reduction of N_2 to NH_3, which thermodynamically requires $E^0 = -280$ mV at pH 7. In this respect, the hydrolysis of MgATP is a waste of energy.[4]

The FeMo protein contains the FeMo cofactors; these are the active centers at which bonding, activation, and reduction of the N_2 molecule occur. The interest was focussed on these cofactors, since a solution to the "nitrogenase problem" was expected from the elucidation of the composition and structure of these cofactors. The separation of the cofactors from the protein was achieved for the first time in 1977.[5] They have a surprisingly low molecular mass of $M_r \approx 1500$, and were characterized as clusters with the composition [1 Mo; 6–8 Fe; 8–9 S^{2-}; 1 homocitrate]. Hence it followed that two such FeMo cofactors must be present in the FeMo protein, although the data, 6–8 Fe and 8–9 S^{2-}, show that the exact composition could not be determined unambiguously. Only in 1988 was it finally confirmed that homocitrate is an endogenous ligand of the FeMo cofactor and essential for their biosynthesis.[6a] The structure of the isolated cofactor remains unknown to the present day despite many efforts. Despite its relatively small molecular mass it could not be obtained in a crystalline form, such that an X-ray structure analysis was impossible. Spectroscopic investigations such as EXAFS (*e*xtended *X*-ray *a*bsorption *f*ine *s*tructure) provided accurate MoS, MoO/MoN, and FeS distances, however, they did not allow conclusive proposals for the structure. The numerous model complexes, whose syntheses was initiated by the determination of the composition of the cofactor, all showed deviating Mo:Fe:S^{2-} ratios.[6b]

In the same way, the structure of the other [FeS] centers in the FeMo protein remained unresolved. Extrusion experiments yielded evidence that these [FeS] centers contain $[Fe_4S_4]$ units,[7] their spectroscopic properties, however, differed so clearly from those of other $[Fe_4S_4]$ proteins that they were only described as "unusual P clusters".

For the first time, light was shed upon this darkness by the X-ray structure analysis of crystalline FeMo protein whose results were published in 1990 by J. T. Bolin et al.[8] (Fig. 1). They showed that the two FeMo cofactors are located approximately 70 Å apart in two different subunits of the protein. At a distance of approximately 19 Å from the FeMo cofactors, one "P cluster" each is situated, which, according

to the analytically determined metal content of the FeMo protein, must consist of approximately 8 Fe and 8 S^{2-} groups. Thus, the long-discussed hypothesis that the two Mo centers of the FeMo protein jointly participate in the activation of the N_2 molecule was invalidated. An ellipsoid form of the FeMo cofactors could also be deduced from the electron densities, due to the low resolution (5 Å), however, the arrangement of the individual atoms in these cofactors remained open to question.

For this arrangement, D. C. Rees et al. have now proposed a model.[2b] This model is based on the X-ray structure analyses of three crystal forms of the FeMo protein, which was isolated from *Azobacter vinelandii* and *Clostridium pasteurianum*. Even this X-ray structure analysis with the best resolution achieved so far (2.7 Å; $R = 0.20$) does not allow the identification of single atoms in the [MS] clusters. However, the combination of electron densities determined by experiment, with peptide sequences established by biochemistry, the results of mutagenesis studies, EXAFS, and other spectroscopic results, the composition of the isolated FeMo cofactor determined by chemical analysis, and X-ray structural data of model complexes has resulted in such a convincing picture of the FeMo cofactors and P clusters that the solution of the nitrogenase structure has probably reached a preliminary end for the present. The proposed structure of these clusters is depicted in Figure 2.

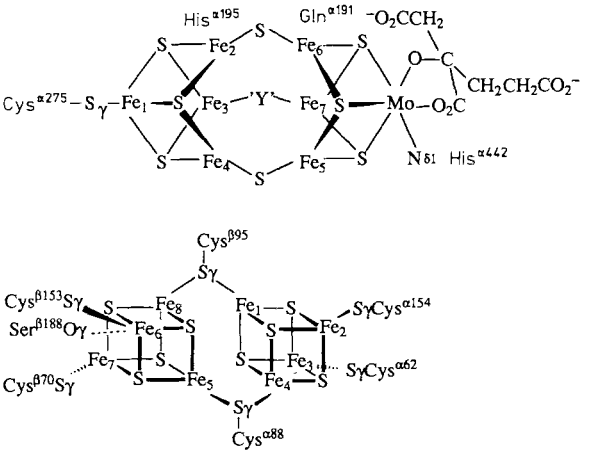

Fig. 2. Structure of the FeMo cofactors (top) and of the unusual P clusters in the FeMo protein of nitrogenase (bottom) (according to [2]). Distances in the FeMo cofactor [Å]: Fe1–Mo = 7.5, Fe2–Fe6 = 2.8, Fe2–Fe5 ≈ 3.8, Fe–S ≈ 2.3, Mo–S ≈ 2.4

The FeMo cofactor consists of $[Fe_4S_3]$ and $[Fe_3MoS_3]$ cubane fragments, which are linked by two S^{2-} and one "Y" bridge. The nature of the Y bridge could not yet be determined unambiguously; it has a lower electron density than the two S^{2-} bridges, and possibly is a NH or O donor. The cluster is bound to the cysteine α275 residue and the histidine α442 side group of the protein at the Fe1 and the Mo atom, respectively. The coordination sphere of the hexacoordinated molybdenum is completed by homocitrate. Two other side chains of the protein, histidine α195 and glycine α191, are approximately 5 Å away from Fe2 and Fe6, respectively, and do not appear to directly bind to the metals. (Cysteine α275, histidine α442, histidine α195, and glycine α191 are conserved in all known FeMo protein sequences, additionally, mutagenesis studies have showed that cysteine α275 and histidine α195 are necessary for the binding of the FeMo cofactor to the FeMo protein.) With the exception of the tetrahedrally coordinated Fe 1, in a remarkable way all the other six Fe atoms are surrounded by only three donors resulting in a coordination geometry which is approximately trigonal planar.

The P clusters contain $[Fe_4S_4]$ cubane units; this had been concluded previously from extrusion experiments.[7] The close bridging of two such clusters via thiolate residues of the protein (cysteine β95 and cysteine α88) as well as the pentacoordination of the Fe6 atom may be responsible for the fact that the spectroscopic properties of the $[Fe_4S_4]$ units in the P clusters so distinctly differ from those of typical $[Fe_4S_4]$ proteins.

The structure of the FeMo cofactor proposed now by Rees et al. explains for the first time and in a plausible way most of the previous analytical, spectroscopic, and chemical findings.[6b] Due to the threefold linkage of the two cubane fragments by S^{2-} and "Y" bridges, it differs significantly from all complexes, which had been proposed previously as structural models. Figure 3 shows a selection of such complexes.[9] These compounds are called structural—in contrast to functional—models because they contain the essential components of the cofactor (Fe, Mo, S^{2-}), but do not show any reactivity towards N_2.

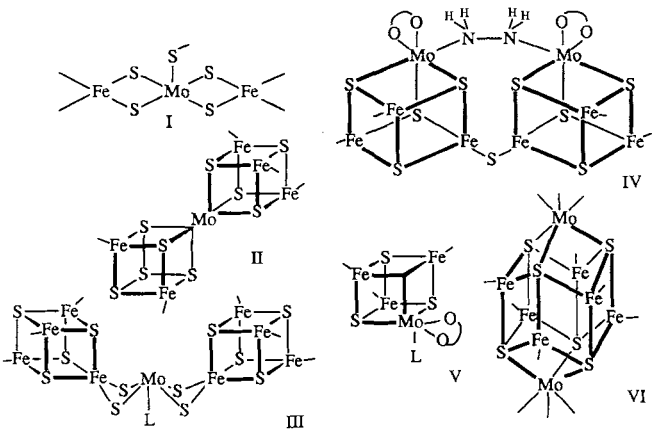

Fig. 3. Previously proposed structural models for the FeMo cofactor [9a]: linear model I, double cubane models II, III, and IV, monocubane model V, prismane model VI. Only the cores of IV [9b], V [9c], and VI [9d] could so far be characterized in isolable complexes by X-ray structure analysis.

The bonding of the FeMo cofactor to the protein by cysteine and histidine only, and the absence of protein-bound bridging ligands within the cluster explain why the cofactor can be extracted from the protein as an intact entity. The cofactor, in a first approximation, contains five magnetically inequivalent kinds of Fe [(Fe 1, Fe 3, Fe 7, (Fe 2 + Fe 4), and (Fe 5 + Fe 6)], which were detected by ENDOR (*e*lectron *n*uclear double *r*esonance) studies with ^{57}Fe.[6b] The distances within the cofactor agree with those obtained from Fe and Mo EXAFS studies. The structure also explains why the cofactor in the protein-bound state is resistant to water, whereas it is decomposed by water with a half life of approximately 2 h in the isolated state. The coordinatively unsatu-

rated Fe atoms in trigonal-planar environments can be expected to allow a facile attack of H_2O, and a subsequent hydrolytic cleavage of the [Fe-S-Mo] bridges.

Is the problem of N_2 fixation now solved, and is the further quest for other model compounds a waste of time? Apart from the fact that important details of the N_2 fixation such as the interaction between the Fe protein and the FeMo protein, the flux of electrons from the reducing agent via the Fe protein to the MoFe protein and from there to the cofactor, or the role of the MgATP for the reduction according to Equation (a) remain as unsolved as before, also the question which directly interests the chemist is still unanswered. At which site on the FeMo cofactor does the N_2 molecule attack to become coordinated, activated, and reduced? All these questions are concerned with the problem of how nitrogenase functions. In answering these questions one is only at the beginning, one can now proceed, however, on structurally safer grounds.

At which site on the FeMo cofactor could the N_2 molecule bind? This question particularly stimulates the imagination of the chemist. One proposal is that the N_2 molecule coordinates side-on to the two Fe atoms, which are linked to one another by the as yet unidentified Y bridge (Fig. 4a).[10a]

In the same manner one can speculate that the N_2 molecule binds end-on between these two Fe atoms, whereby the cluster "breathes" (Fig. 4b). The two [FeSFe] bridges between the cubane fragments should be flexible and thus guarantee variable distances between the Fe atoms (linked via the Y bridge). End-on coordination of the N_2 molecule to two metals has been established for many binuclear N_2 complexes.[10b] In both cases the formation of N–H···X bridges between the reduction intermediates diazene and hydrazine, and the protein environment could facilitate the reduction of N_2.[10c] Finally it has to be discussed whether the N_2 molecule completely slips into the cagelike center of the cofactor and binds to six Fe centers (Fig. 4c). However, if this is so, how can the reduction of other, sometimes considerably larger nitrogenase substrates such as ethylisocyanide be explained? And also the reduction of numerous other nitrogenase substrates, starting from H^+ via C_2H_2 to azide and cyanide, [10d] still remains to be explained.

Beyond all that one has to take into account that the FeMo protein characterized by X-ray structure analysis was in the "resting state" (no substrate binding). What happens to the cofactor in the "turnover state" of the enzyme? It is almost certain that the embedding protein changes its conformation when going from the resting state to the turnover state, as is also the case for hemoglobin. Do side chains move so close to the Fe centers, that these become four or fivefold coordinated and can only thus bind the N_2 molecule?

And what about the Mo atom which for many years was propagated as the binding site for the N_2 molecule? It seems to play no role anymore in the present discussions between the experts. The Mo atom in the resting state of the enzyme probably has the oxidation state + IV, [6b] appears to be coordinatively saturated, and is thus indeed not predestined for the binding of N_2. However, there is a difference between the results of the X-ray structure analysis and the EXAFS studies. The EXAFS studies indicate an $[S_4O_2]$ donor set for the molybdenum in the protein, but an $[S_3O_3]$ or $[S_3O_2N]$ set for the molybdenum in the isolated FeMo cofactor,[6b] as is

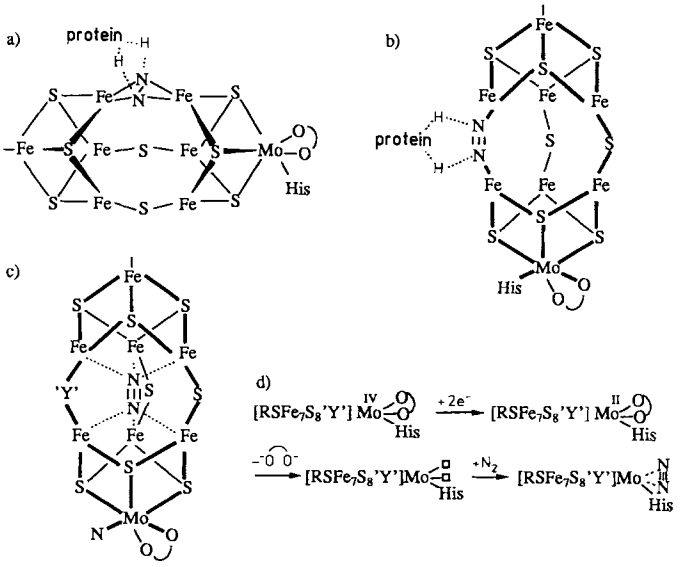

Fig. 4. Proposals for the bonding of N_2 to the FeMo cofactor. a) Side-on and b) end-on coordination of N_2 at the two Fe centers, which are linked by the Y bridge. The H atoms indicate H bonds to the protein, which stabilize the potential intermediates diazene and hydrazine in the course of N_2 reduction. c) Coordination of N_2 within the cage. d) Proposal for a reaction sequence when N_2 coordinates to the Mo center of the cofactor.

shown in the model in Figure 2 (top). (The EXAFS investigations allow no differentiation between N and O donors.) It has recently been proven that at least CO, which is isoelectronic to N_2, can coordinate to $[Mo^{IV}S_4]$ centers.[10e] What happens if, in the turnover state, the $[Fe_7S_9]$ unit of the cofactor serves as electron relay only? Then, after electron transfer to the molybdenum, the hard Mo^{IV} could become a soft Mo center, for example, of the oxidation state + II. Consequently, the hard homocitrate ligand could dissociate, the Mo center would gain free coordination sites for the binding of N_2, and the N_2 reduction could begin (Fig. 4d).

There are thus still many questions, which may be answered—if perhaps not conclusively, then at least approximately—by studies with model compounds. These model compounds must be oriented on the cluster shown in Figure 2 (top), and this will provide a challenge for synthetic chemists. If compounds can be obtained with the characteristic features of the FeMo cofactor, it should also be possible to use them for those cross-linking experiments with apoproteins, which so far could be carried out with the isolated FeMo cofactor only. Also attempts to crystallize the natural FeMo cofactor are now by no means redundant. On the contrary, they have become even more urgent in order to finally confirm the present model of the FeMo centers of nitrogenase by an X-ray structure analysis of the low molecular weight isolated FeMo cofactor.

What can be derived from all these results for the development and synthesis of new catalysts? It is difficult to envisage a compound such as the FeMo cofactor as catalyst for an ammonia synthesis which can compete with the Haber–Bosch process. This cofactor needs numerous auxiliaries—protein environments, specific reduction proteins, MgATP etc.—in order to display its activity. To sum up: here too nature could be the teacher, not in the sense that details, but rather principles of construction should be adhered to. One

of these principles appears to be: in order to catalyze the most difficult reactions under the mildest conditions, use catalysts which consist of transition metals and sulfur ligands. And this is to quote Fontane[11]—a wide field.[12]

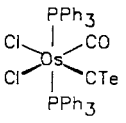
Tellurium—An Interesting Bonding Partner for Transition Metals: New Results from Molecular Chemistry

By *Ulrich Siemeling**

In transition metal chemistry, ligands containing oxygen and sulfur are extremely important; the abundant complex chemistry of oxo, sulfido, alkoxido, and thiolato ligands, to name only the simplest, has consequently been well-studied. Considerably less is known about the complex chemistry of the heavier elements of Group 16, selenium and tellurium.[1] The molecular chemistry of transition metal–tellurium compounds, in particular, is for many an area bordering inorganic and organometallic chemistry, which rarely attracts attention, and when, only because of a chemical oddity, such as the tellurocarbonyl complex **1** synthesized by Roper et al.[2]



1

However, recently this has changed. The great interest in II/VI semiconductors has helped transition metal–tellurium chemistry to take off: defined precursor compounds for these materials[3] make possible a whole range of different preparations, including particularly interesting high-tech variations such as nanoclusters[4] and thin layers.[5]

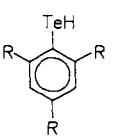
In 1987 Steigerwald et al. showed that phenyltellurolates of cadmium and mercury gave the corresponding semiconducting metal tellurides in a polycrystalline form on heating to typically 120–200 °C.[6] This thermolysis reaction basically known for a long time for transition metal chalcogenates[7] occurs according to Scheme 1.

$$[M(TeR)_2]_n \xrightarrow[\Delta]{} (MTe)_n + n\ TeR_2$$

Scheme 1. M = Cd, Hg; R = Ph.

In the meantime, a growing interest in tellurolate chemistry has been observed. Bochmann et al.[8] and Arnold et al.[9] described, at the same time and independently from one another, tellurolysis as preparatively the most important method for the synthesis of transition metal tellurolates. The starting materials for this method, the tellurols R'TeH **2**, are generally photo- and especially thermolabile (Scheme 2). These compounds can, however, be isolated as solids with suitable choice of the group R'. Whereas the crystalline tellurophenols **2a–c** described by Bochmann et al. decompose above approximately −30 °C, the tellurol **2d** prepared by Arnold et al. survives undamaged with exclusion of light even at much higher temperatures: it melts at 130 °C without decomposition!

The cadmium tellurolate **3a** was prepared starting from **2a** (ArTeH). Subsequent heating of **3a** in mesitylene afforded cadmium telluride as expected; analoguously, the corre-



2a – c

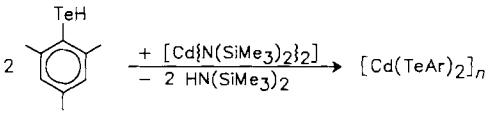
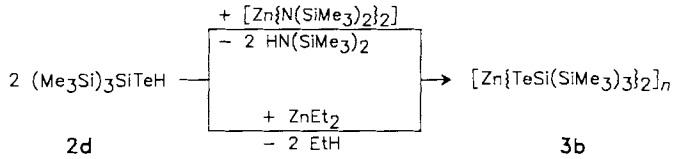
sponding homoleptic zinc tellurolate **3b** is formed by the tellurolysis of diethyl zinc or bis(trimethylsilyl)amide zinc with **2d**.

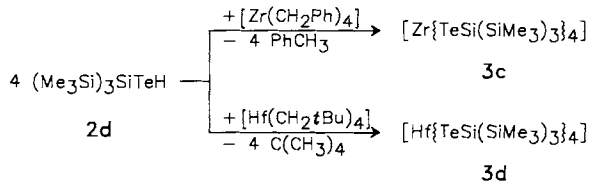


2a **3a**

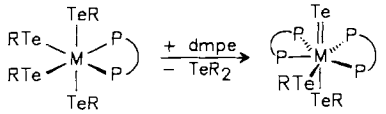


2d **3b**

The tellurolates of the early transition metals, which were previously extremely rare, for example **3c,d**, are easily accessible starting from **2d**.[10] According to X-ray crystal structure analyses, the homoleptic tellurolates **3c** and **3d** are both



monomeric, in contrast to **3a** and **3b**, and are therefore clearly Lewis acidic. The reaction of **3c,d** with the chelating phosphane 1,2-bis(dimethylphosphino)ethane (dmpe) leads to the octahedrally coordinated adducts **4a** and **4b**, respectively, which each react with an additional equivalent of dmpe, accompanied by the loss of $Te[Si(SiMe_3)_3]_2$, to give the very interesting compounds **5a** and **5b** (Scheme 3).

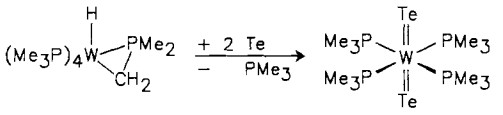


4a – b **5a – b**

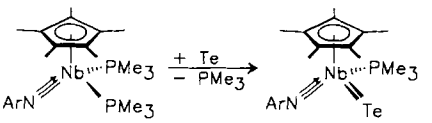
Scheme 3. R = $Si(SiMe_3)_3$; a: M = Zr; b: M = Hf.

These complexes are stabilized intermediates (and can therefore be isolated) in the decomposition of metal tellurolates to the corresponding metal tellurides (cf. Scheme 1). At the same time they belong to a class of compounds, namely the terminal tellurido complexes, for which only one year ago not one example existed in transition metal chemistry.

The first complex of this kind, **7**, was synthesized by Rabinovich and Parkin by the reaction of the tungsten compound **6** (itself already remarkable) with elemental tellurium.[11] Also Gibson et al. have reported the preparation of a terminal tellurido complex **9**, which was synthesized from **8** by a similar method.[12] That the synthesis of terminal tellurido complexes was imminent in the last few months is supported by the fact that the compounds **5a,b**, and **9** were introduced at the same time, namely, at this year's Gordon Research Conference on organometallic chemistry.



6 **7**



8 **9**

In a time when transition metal compounds, which contain multiple-bonded main group elements or main group complex fragments are intensely researched,[13] these compounds presented here are without doubt highly attractive, and it will be interesting to see how transition metal–tellurium chemistry develops in the future.

Multicomponent Self-Assembly: Spontaneous Formation of a Cylindrical Complex from Five Ligands and Six Metal Ions**

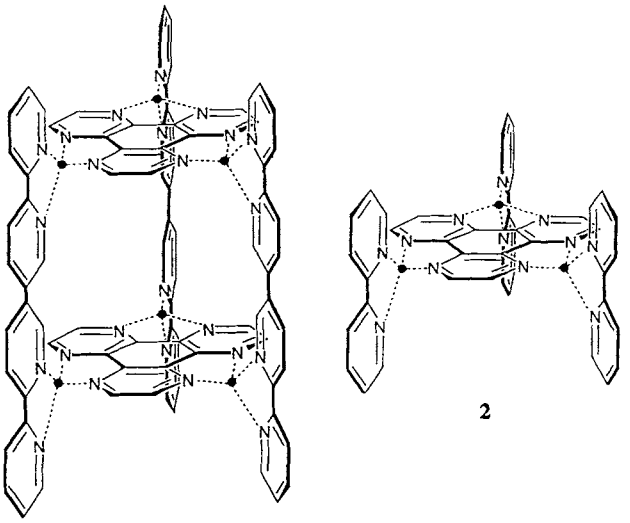
By *Paul Baxter*, *Jean-Marie Lehn*,* *André DeCian*, and *Jean Fischer*

Self-assembly consists of the spontaneous generation of a well-defined, discrete supramolecular architecture from a given set of components under specific conditions. Such processes require the design of "programmed" supramolecular systems that rely on the information stored in the components and on the interaction algorithm that operates through molecular recognition events.[1, 2] Depending on the nature of the molecules involved, the self-assembly can be organic or inorganic. In the assembly of supermolecules from metal ions and ligands, the latter must contain the steric program that is "read" by the metal ions following the algorithm represented by their coordination geometry. The self-assembly of a given superstructure involves three stages: *recognition* between the components, correct *orientation* so as to allow growth, and *termination* of the process leading to a discrete, finite supramolecular species.[1-3]

The formation of double-helical metal complexes, the helicates,[3-6] results from the self-organization of oligobipyridine (bpy) strands and Cu^+ or Ag^+ ions that possess tetrahedral coordination geometry.[3-5] The interaction of appropriately substituted oligo-bpy strands or related ligands with metal ions prefering octahedral coordination may yield triple-helical complexes.[7, 8] Closed inorganic structures have been obtained, for instance, from the self-assembly of Ni^{2+}[9a] or Cu^{2+}[9b] ions and bis-β-diketone type ligands, of four Pt^{II} metal complex fragments and four 4,4'-bpy groups,[10] and of four Cu^+ ions and four bispyridylpyridazine ligands.[11]

The self-assembly of the helicates and related structures involves just one type of ligand and metal ion. Further progress in the understanding and the control of the self-assembly and self-organization of inorganic (as well as of purely organic) superstructures requires the conception of systems capable of spontaneously generating well-defined inorganic complexes from a larger set of components, comprising at least two types of ligands and/or metal ions. The design and choice of these components must fulfill criteria at all three levels of molecular programming and information input that determine the output of the desired final species—recognition, orientation, and termination.

We report here on two such multiligand, multimetal, self-assembly processes involving two types of ligands and several Cu^+ ions: the generation of a cylindrical complex **1** and the related component species **2** (Scheme 1). The formation of a capped complex will be described elsewhere.[12]



2

Scheme 1. Schematic representation of the structures of **1** and **2**. Phenyl and methyl substituents are omitted for clarity. ● = Cu.

Hexaazatriphenylene (HAT) and its derivatives are ligands with three metal coordination sites, which yield, for instance, a trinuclear complex by complexation of three $[Ru(bpy)_2]^{2+}$ units.[13, 14] It appeared that a similar complex might be formed with three $[Cu(bpy)]^+$ units or related groups.

Hexaphenylhexaazatriphenylene Ph_6-HAT **3** was synthesized by condensation of benzil with hexaaminobenzene,[15, 16] which was obtained by reduction of 1,3,5-triamino-2,4,6-trinitrobenzene with sodium in liquid ammonia.[16, 17] When 3 equiv dimethyl-bpy **4** and 1 equiv **3** in CH_2Cl_2 were treated with $[Cu(CH_3CN)_4]BF_4$ in CH_3CN, the reaction mixture showed first the reddish color ($\lambda_{max} = 457$ nm, $\varepsilon = 6550\ M^{-1}cm^{-1}$) characteristic of bis-bpy Cu^I complexes (for $Cu^I(\mathbf{4})_2]^+$: $\lambda_{max} = 454$ nm, $\varepsilon = 6700\ M^{-1}cm^{-1}$[18]). After 1.5 equiv $[Cu(CH_3CN)_4]BF_4$ the solution turned brown and after the addition of 2.5 equiv, intensely purple ($\lambda_{max} = 568$ nm, $\varepsilon = 15\,700\ M^{-1}cm^{-1}$; shoulder at 700 nm, $\varepsilon = 6570\ M^{-1}cm^{-1}$), an unusual color for a Cu^I complex. These observations may be interpreted as follows: initially the $[Cu(\mathbf{4})_2]^+$ complex is formed exclusively until at 1.5 equiv the free ligand **4** is consumed. Upon further addition of $[Cu(CH_3CN)_4]BF_4$, the weaker ligand Ph_6-HAT **3** (whose pyrazine-type N atoms are poorer binding sites than the bpy N atoms) participates; the $[Cu(bpy)_2]^+$ species opens up and $[Cu(bpy)]^+$ units bind to the coordination sites of ligand **3**. Finally at 3 equiv $[Cu(CH_3CN)_4]BF_4$, a single

3 R =

4

species is present, the trinuclear circular complex **2** (as the **2**-$(BF_4)_3$ salt).

This proposed sequence is supported by mass spectrometry performed on the solutions containing different amounts of the Cu^I salt, which reveals the formation of $[Cu(\mathbf{4})_2]BF_4$ and $[Cu_3(\mathbf{3})(\mathbf{4})_3](BF_4)_3$.[19] The ^1H NMR spectrum of the **2**-$(BF_4)_3$ in CD_2Cl_2 also corresponds to the postulated structure.

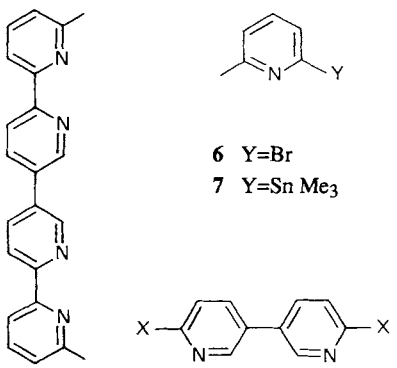
Treatment of **3** itself with 3 equiv $[Cu(CH_3CN)_4]BF_4$ in CH_3CN also afforded an orange-red solution which may correspond to the formation of branched oligomeric and polymeric Cu^I complexes. This would amount to the spontaneous growth through self-assembly of coordination compounds resembling dendrimer-[20] and arborol-type[21] structures. Such a process may allow an entry into the self-assembly of oligomeric and polymeric coordination architectures from branching multinucleating ligands and suitable metal ions.[22]

The results above were taken as sufficient evidence for the generation of complex **2**. They also suggested that it might be possible to achieve the self-assembly of a cylindrical, cagelike structure **1** if **4** were replaced by ligand **5**, in which two bpy subunits are linked in the 5,5′ positions. The quaterpyridine (qpy) **5** was synthesized as follows: lithiation of **6** with BuLi followed by treatment with $SnMe_3Cl$ (1.2 equiv) gave **7** (63%; b.p. 200–205 °C). The regioselective monolithiation of 2,5-dibromopyridine at position 5 with 1 equiv *n*BuLi and subsequent treatment with $CuCl_2$ (0.5 equiv) was followed by oxidative dimerization with O_2 to provide **8** (30%; m.p. 248–249.5 °C). Finally reaction of **8** with 2 equiv **7** in the presence of $[Pd(PPh_3)_4]$ gave **5** (68%; m.p. 249.5–250 °C).

During the slow addition of a solution of $[Cu(MeCN)_4]BF_4$ (6 equiv in CH_3CN) to a stirred mixture of **3** (2 equiv) and **5** (3 equiv) in CH_2Cl_2 under argon, the color of the reaction mixture changed from initially reddish brown through dark brown to finally deep purple. The suspension of **5** went into solution, and after about 20 h of stirring the solvent was evaporated under vacuum leaving a dark-purple, air-stable, solid. This was redissolved in CH_3NO_2, filtered, and benzene was added dropwise to the filtrate. The solid was removed by filtration and then dried under vacuum at room temperature to give deep-purple, microcystalline powder in quantitative yield (λ_{max} = 546 nm, ε = 27 600 $M^{-1}cm^{-1}$; 699 nm, ε = 13 500 $M^{-1}cm^{-1}$; CH_2Cl_2).

The ^1H NMR spectrum, the FAB (fast atom bombardment) mass spectrum, and the microanalytical data agree with the formulation of this compound as $[Cu_6(\mathbf{3})_2(\mathbf{5})_3](BF_4)_6$, that is, **1**-$(BF_4)_6$. This complex was found to be markedly more stable than the trinuclear complex **2**; repeated recrystallizations of the latter, for example, from CH_2Cl_2/hexane invariably resulted in some decomposition, whereas the hexanuclear complex **1** was stable under the same conditions; **1** also underwent slow oxidation upon exposure to air for several months. The ^1H (500 MHz) and ^{13}C (50.3 MHz) NMR spectra of **1**-$(BF_4)_6$ indicate that all three qpy ligands as well as the two Ph_6-HAT ligands are equivalent in solution on the NMR timescale.

The construction of complex **1** was confirmed by its X-ray crystal structure determination (Fig. 1).[23] It is indeed an



5

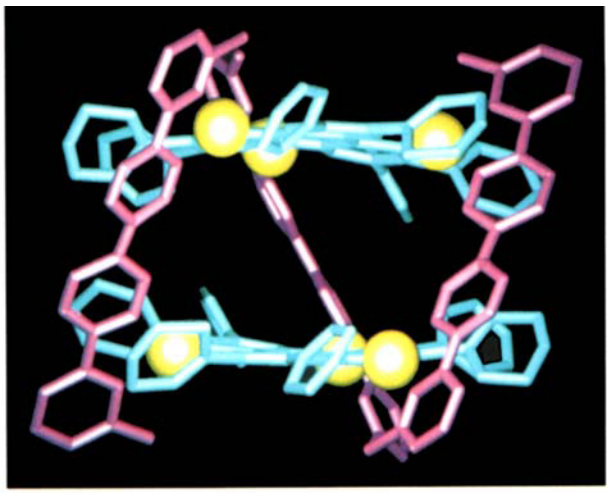
7 Y=Sn Me$_3$

8 X=Br



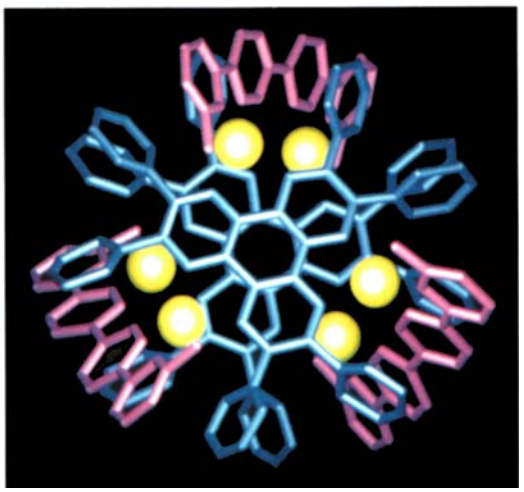


Fig. 1. Model of the crystal structure of the self-assembled cylindrical inorganic complex **1**. Top: Side view. Bottom: View along the vertical axis.

inorganic cagelike compound resulting from the self-assembly of two flat circular HAT ligands **3** that form the top and bottom, three bridging quaterpyridine groups **5**, and six Cu^{I} ions that hold the five organic components together.

Complex **1** possesses a C_2 axis passing through the middle of the central C–C bond of one of the qpy units; this distorsion from the threefold symmetry may be due to crystal packing. The top and bottom HAT units are close to planar (maximum deviation from mean plane 0.19 Å) and almost parallel to each other (13.3° angle between the normals to their mean planes); they are not eclipsed as shown in Scheme 1, but rotated with respect to each other by about 27° (Fig. 1 bottom). Every bpy group in the three qpy units is approximately planar (maximum deviation of 0.32 Å), and the two bpy groups of the two equivalent qpy groups are twisted with respect to each other by an angle of 36°; those of the qpy located on the binary axis are twisted by 25°. The vertical qpy bridges are inclined by an angle of 66° with respect to the axis passing through the center of the two HAT units. The Cu^{+} sites are distorted from tetrahedral coordination, with a dihedral angle of 72° between the N-Cu-N planes corresponding to the bpy and HAT units. The three Cu^{+} ions lie in the HAT plane and form approximately an equilateral triangle with a mean edge length of 6.85 Å. The planes of the phenyl rings form a 60° angle with the plane of the respective HAT unit. The overall twist of the structure results in a triple-helical shape of the complex. Bond lengths and angles do not show any peculiarity.

Complex **1** has a cylindrical internal cavity with a height of 7.4 Å (mean distance between the HAT planes) and a radius of about 5.5 Å (based on the nitrogen atoms of the three qpy groups). Taking the van der Waals radii into account the cylindrical void has a height of approximately 4 Å and a radius of 4 Å; one may envisage binding substrate molecules in this cavity, in particular flat, aromatic units of suitable dimensions. Thus **1** would be a self-assembled molecular receptor for appropriate substrate species.[*]

An investigation into the precise structural requirements of the ligands **3** and **5** which control the self-assembly of the cage complex **1** is in progress. We are also working on the extension of the process described here to related ligands.

The formation of structure **1** demonstrates the remarkable self-organization of a closed inorganic architecture by the spontaneous and correct assembly of altogether eleven particles consisting of two types of ligands and one type of metal ion. The operation of this instructed supramolecular system fulfills the three levels of molecular programming and of information input: recognition, orientation, and termination.

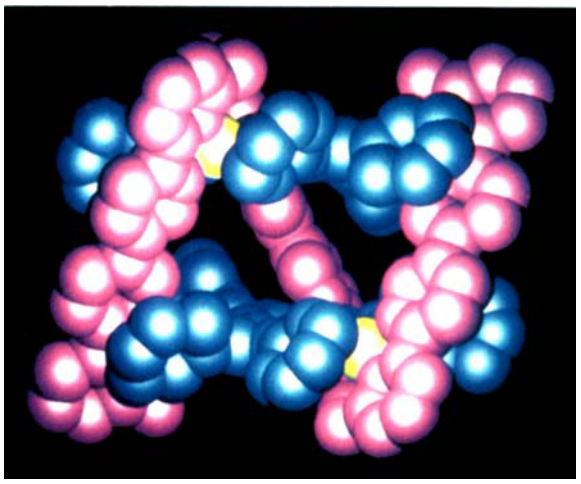

Fig. 2. CPK representation of **1**. The side view corresponds to Figure 1 top.

[*] If a suitable substrate were to be spontaneously and selectively included into **1** in the course of the self-assembly, this would represent an assembly of twelve (!) partners into an elective community (EC), a very timely process.

[23] a) Crystal data: Suitable single crystal of **1**-$(BF_4)_4F_2 \cdot 4C_2H_2Cl_4 \cdot 5H_2O$ were obtained by slow diffusion of pentane into a solution of **1**-$(BF_4)_6$ in 1,1,2,2-tetrachloroethane (initially cooled in air to liquid N_2 temperature) at room temperature. A single crystal was cut out from a cluster of crystals and mounted on a rotation-free goniometer head (Philips PW1100/16 automatic diffractometer). $M = 4104.9$, monoclinic, space group $C2/c$, $a = 33.978(10)$, $b = 30.141(9)$, $c = 20.840(6)$ Å, $V = 19846.8$ Å^3, $\varrho_{calcd} = 1.374$, $Z = 4$, $\mu(Cu_{K\alpha}) = 33.755$ cm^{-1} (graphite monochromator). A total of 9377 reflections were collected at −100 °C; the temperature was held constant with a gas flow device of our own construction. For all calculations the Enraf-Nonius Mole/VAX package [23b] was used, with the exception of data reduction program which was our own. The raw step-scan data were converted to intensities by the Lehmann–Larsen method [23c]. The intensities of three reflections measured every hour during the entire data collection period showed a decay of 46%; therefore a second data collection was started using two crystals. With the first one, data with $3° < \theta < 35°$ were collected, with the second remaining data. For each crystal, a linear decay of 16% was corrected. After application of separate Lorentz, polarization, and absorption corrections, the latter based on psi scans, the scale between the two sets was determined from 120 common reflections using a least-squares procedure. The structure was solved using MULTAN [23d]. After refinement of the heavy atoms, the hydrogen

atoms of the core were introduced in structure factor calculations by their computed coordinates (C–H = 0.95 Å) and isotropic temperature factors such as $B(H) = 1.3$ Beqv(C) Å^2, but not refined. The overall temperature factor of the structure is high (5.4 Å^2) indicating some disorder and low diffraction power, therefore the accuracy obtained is lower than normally expected. Full least-squares refinements; $\sigma^2(F^2) = \sigma^2_{counts} + (pI)^2$. $R(F) = 0.103$, $Rw(F) = 0.147$. The scattering factor coefficients and anomalous dispersion coefficients come from ref. [23c]. b) B. A. Frenz, *The Enraf-Nonius CAD4-SDP* in *Computing in Crystallography*, (Eds.: H. Schenk, R. Olthof-Hazekamp, H. Van Koningveld, G. C. Cavities for Binding Two Metal Atoms: A Novel Pentanuclear Copper(I) Complex with an Anionic, Pentadentate Aryl Ligand with Two *ortho*-Chelating Diamine Substituents**

By *G. Marc Kapteijn, Ingrid C. M. Wehman-Ooyevaar, David M. Grove, Wilberth J. J. Smeets, Anthony L. Spek*, and *Gerard van Koten**

The design and use of multidentate ligands is of great interest in organometallic chemistry.[1] We are studying the construction of cavities formed by organic ligands, in which a metal ion is bound by a metal–carbon σ bond and the metal center is coordinatively saturated as a result of additional intramolecular coordination of heteroatoms present in the surface enclosing the cavity. A simple representative of this class of ligands is the anionic aryldiamine ncn which coordinates through the two N and one C atoms and exhibits

$[2,6\text{-}(CH_2NMe_2)_2C_6H_3]^-$ ncn

versatile bonding modes ranging from monodentate (σ-C) and bidentate (C,N) to tridentate (*mer*- or *fac*-N,C,N),[2] depending on the metal (structure **A** in Scheme 1). Interestingly, several examples are known in which ncn formally binds two metal atoms by either a two-electron three-center (2e-3c) bond, whereby C_{ipso} bridges two metal atoms, as in **1**[3] and **2**,[4] or by a (2e + 2e)-3c bond, whereby C_{ipso} bridges two unlike metal atoms as in **3** (structure **B** in Scheme 1).[5] The structures of **1** and **2** in the solid state and in solution

$[Li_2(ncn)_2]$ **1** $[Cu_4Br_2(ncn)_2]$ **2**

$[TaCl_2(\mu\text{-ncn})(\mu\text{-C-}t\text{Bu})(ZnCl)]$ **3**

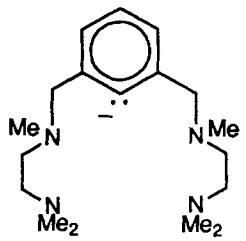
A B

Scheme 1. Bonding modes of ncn. In structures of type A ncn may function as a two-, four-, or six-electron donor ligand.

clearly show that completion of the Li and Cu coordination spheres requires formation of larger aggregates. In the case of **1** this is achieved by dimerization; in the case of **2** by linkage of two Cu(ncn) units with two CuBr units. We have now expanded the simple cavity of ncn by replacing one methyl group of each NMe_2 unit by $CH_2CH_2NMe_2$ to form a potentially pentacoordinate, anionic N,N,C,N,N ligand **4**. We report here on our investigation of the bonding properties of **4** to copper(I) centers, specifically on an arylcopper copper bromide compound in which aryldicopper cations are stabilized by intramolecular coordination and a $CuBr_3$ dianion.



4

The precursor to **4**, compound **5**, was synthesized from the reaction of 1 equivalent of $2,6\text{-}(CH_2Br)_2C_6H_3Br$ with 2 equivalents of $HN(Me)CH_2CH_2NMe_2$ in the presence of NEt_3 as a base.[6] Treatment of **5** with two equivalents of

$2,6\text{-}[CH_2N(Me)CH_2CH_2NMe_2]_2C_6H_3Br$ **5**

n-butyllithium afforded the lithium salt of **4** which was isolated as the unique adduct **6** of aryllithium and lithiumbromide.[6] When **6** was treated with two equivalents of CuBr in benzene a novel type of pentanuclear Cu^I complex **7** was

$[Li_2Br(\mathbf{4})]$ **6** $[Cu_5Br_3(\mathbf{4})_2]$ **7**

isolated in 73% yield.[7] In the X-ray crystal structure of **7** the monoclinic unit cell contains two molecules of **7** and two molecules of diethyl ether. **7** is a pentanuclear Cu^I complex most readily described as two cationic organocopper moieties $[Cu_2(\mathbf{4})]^+$ linked by a $CuBr_3^{2-}$ dianion (Fig. 1).[8] The two aryl ligands **4** bridge a pair of Cu atoms (Cu2, Cu3 or Cu4, Cu5) at the anionic C_{ipso} center, the Cu-C_{ipso}-Cu angles are very acute (Cu2-C1-Cu3 73.8(2); Cu4-C19-Cu5 73.6(2)°). In combination with the short Cu ··· Cu distances (Cu ··· Cu 2.456(1) Å) and the four similar Cu–C distances (Cu–C 2.049(6) Å) these geometric parameters are indicative

of a 2e-3c Cu_2C_{ipso} bond (for a discussion of this bonding see ref. [9]).

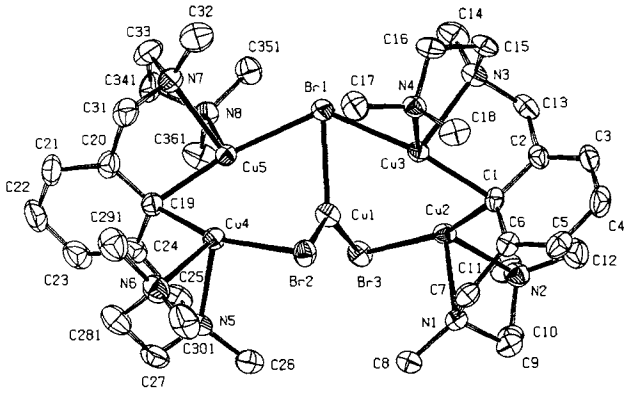


Fig. 1. Crystal structure of **7** (ORTEP, thermal ellipsoids at 30% probability). Only one of the configurations giving rise to the disorder is shown. Selected distances [Å] and angles [°]: Cu1-Br1 2.459(1), Cu1-Br2 2.389(2), Cu1-Br3 2.398(2), Cu2-C1 2.020(6), Cu3-C1 2.076(6), Cu4-C19 2.038(7), Cu5-C19 2.062(6), Cu2-Br3 2.448(1), Cu2-N1 2.288(6), Cu2-N2 2.316(6), Cu2···Cu3 2.458(1), Cu4···Cu5 2.454(1), Cu1···Cu (mean) 2.77(8); Br1-Cu1-Br2 114.97(6), Br1-Cu1-Br3 109.48(5), Br2-Cu1-Br3 135.47(5), Cu2-C1-Cu3 73.8(2), Cu4-C19-Cu5 73.6(2), Cu3-Br1-Cu5 130.35(4).

In each $[Cu_2(\mathbf{4})]^+$ unit the two copper atoms are held in a polyamine cavity and the C_{ipso} bridged Cu atoms are tetracoordinate through $Cu-N_2$ chelate coordination of the $N(Me)CH_2CH_2NMe_2$ substituents and an additional interaction with a Br atom of the central $CuBr_3^{2-}$ unit. The Cu–N distances (2.203(6)–2.334(6) Å) fall in the range for Cu–$N(sp^3)$ bond lengths observed in *ortho*-chelated organocopper compounds.[10] The central Cu atom (Cu1) is bonded to all three Br atoms and has a distorted trigonal geometry in which the Cu–Br bond lengths are 2.389(2)–2.459(1) Å and the Br–Cu–Br angles are 114.97(6) (Br1-Cu1-Br2), 109.48(5) (Br1-Cu1-Br3), and 135.47(5)° (Br2-Cu1-Br3). To our knowledge only three complexes characterized by X-ray crystallography have been reported to contain a $CuBr_3^{2-}$ ion and these all concern the free dianion which has substantially shorter Cu–Br bond lengths than **7** (typically 2.37 to 2.39 Å).[11] The Br atoms in **7** have additional interactions with the $[Cu_2(\mathbf{4})]^+$ ions; Br1 with both cations (bonds to Cu3 and Cu5) and Br2 and Br3 each to one cation (bonds to Cu4 and Cu2, respectively). We believe the correct way to view complex **7** is as a pentanuclear Cu^I aggregate $[\{Cu_2(\mathbf{4})^+\}_2(CuBr_3^{2-})]$ in which the central dianionic unit bridges the two cationic units. The formation of aggregates is normal in organocopper chemistry, and it has been argued that these may be thought of as assemblies of either neutral RCu, CuX, CuSR, CuH, RLi units or anionic R_2Cu^-, R_2Li^- units, depending on the solution equilibria. However, the combination of Cu_2R^+ units and a $CuBr_3^{2-}$ unit present in **7** is without precedent in copper chemistry. ^1H and ^{13}C NMR studies have shown that the structure of **7** in solution is similar to that in the solid state, but fluxional processes are operative and still under investigation.

These results in Cu^I chemistry show that the monoanionic pentadentate ligand **4** is capable of binding two metal atoms in a unique manner. In **7** the Cu_2C_{ipso} bond can be considered as arising from the interaction of a Cu^+ ion with a neutral 2e-2c Cu–C_{ipso} bond at C_{ipso}, and the whole is then stabilized by appropriate chelate coordination. It is this idea that we are currently exploring for the synthesis of polynuclear organometallic species in which the coordination of a C_{ipso}–$(M_{n+1})^{n+}$ unit with a relatively stable metal–carbon bond is completed by additional inter- and intramolecular coordination. In this way the cavity formed by a polyamine encloses metal atoms so that they are close to each other, while leaving one side open for binding of either anions or small neutral molecules.

Experimental Procedure

7: To a suspension of CuBr (0.55 g, 3.83 mmol) in benzene (15 mL) was added a solution of **6** (0.77 g, 1.92 mmol) in benzene (15 mL). After 1 h of stirring the yellow solution was evaporated to dryness and the residue dissolved in diethyl ether. After 2d at −20 °C yellow crystals were isolated; 0.82 g, yield 73%.

This paper describes the synthesis, properties, and X-ray crystal structure of **6**. Compound **6** is the first example of a monomeric organolithium compound containing one additional equivalent of lithium bromide.

[7] **7**: ^1H NMR (200.13 MHz, C_6D_6, 24 °C): δ = 6.9–6.8 (m, 3, Ar-*H*), 2.75 (brs, NCH_3), 2.2 (brm, CH_2-CH_2), 1.9 (brs, $N(CH_3)_2$), Ar-CH_2-N protons not observed. ^{13}C NMR (50.32 MHz, C_6D_6, 24 °C): δ = 151.7 (Ar-C2 and 6), 128.4 (Ar-C4), 127.1 (Ar-C3 and 5), 69.4 (Ar-CH_2-N), 59.2 (-CH_2-), 52.4 (br, -CH_2-), 47.6 (-$N(CH_3)_2$), 46.4 (NCH_3), C_{ipso} not observed.

[8] Crystal data for **7**: $C_{36}H_{66}Br_3Cu_5N_8 \cdot C_4H_{10}O$, M_r = 1242.54, brownish plate-shaped crystals (0.86 × 0.43 × 0.08 mm), monoclinic, space group $P2_1$, with a = 11.132(1), b = 14.969(1), c = 15.232(2) Å, β = 90.33(1)°, V = 2537.9(4) Å^3, Z = 2, $\rho_{calcd.}$ = 1.626 g cm^{-3}, $F(000)$ = 1260, $\mu(Mo_{K\alpha})$ = 44.5 cm^{-1}, 6055 independent reflections ($1.34 < \theta < 27.5$ °; $\omega/2\theta$ scan; T = 295 K) were measured on an Enraf–Nonius CAD-4T/rotating anode diffractometer using graphite-monochromated $Mo_{K\alpha}$ radiation (λ = 0.71073 Å). Data were corrected for Lorentz-polarization effects, linear decay (19.5%) of the intensity control reflections, and absorption (DIFABS; correction range 0.759–1.237). The structure was solved by Patterson (SHELXS86) and difference Fourier techniques. Six carbon atoms [C28, C29, C30, C34, C35, and C36] were found disordered over two positions (52:48 ratio). Hydrogen atoms were introduced at calculated positions and refined riding on their carrier atoms [C–H = 0.98 Å]. All non-hydrogen atoms were refined with anisotropic thermal parameters, convergence was reached at R = 0.0312, wR = 0.0326, $w = 1/[\sigma^2(F) + 0.000343F^2]$ for 4322 reflections with $I > 2.5\sigma(I)$ and 577 parameters. The absolute structure was checked by refinement with opposite anomalous dispersion factors ($-if''$) resulting in R = 0.0362, wR = 0.0408. A final difference Fourier map shows no residual density outside −0.36 and 0.43 e A^{-3}. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

Detection of Trimethylenemethane by IR Spectroscopy: The Result of an Unexpected Photoisomerization of Methylenecyclopropane in a Halogen-Doped Xe Matrix**

By *Günther Maier,* Hans Peter Reisenauer, Klaus Lanz, Ralf Tross, Dorothée Jürgen, B. Andes Hess, Jr.*, and *Lawrence J. Schaad*

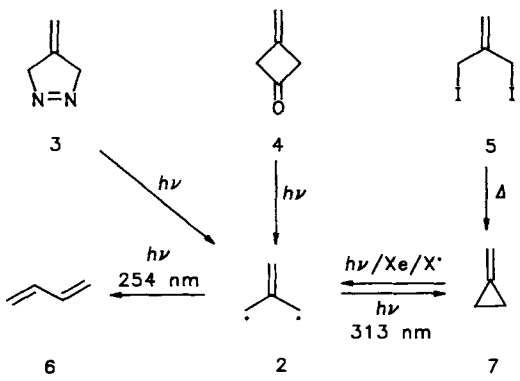
Dedicated to Professor Rudolf Hoppe on the occasion of his 70th birthday

Cyclobutadiene (**1**) and trimethylenemethane (**2**) are the parent molecules of two fundamentally different families of conjugated hydrocarbons. Cyclobutadiene is the first member of the series of cyclic conjugated hydrocarbons (Kekulé compounds); trimethylenemethane, of the non-Kekulé hydrocarbons.[1]

1 **2**

Following simple Hückel theory, in **1** and **2** four π electrons are distributed over four C atoms, and one electron is placed in each of the two degenerate nonbonding molecular orbitals. Accordingly, both the square form of **1** (D_{4h}) and **2** (D_{3h}) should have triplet ground states. This is indeed true for **2** but not for **1**. The distinct arrangements of the individual centers account for this difference.[2]

During our studies of cyclobutadiene[3] we wondered even years ago[4] if matrix-isolation spectroscopy would be a good tool for the study of trimethylenemethane. Compound **2** was first prepared in 1966 by Dowd[5a] by irradiation of 4-methylenedihydropyrazole **3** in an organic matrix at −185 °C, and its existence was proven by ESR spectroscopy. Despite great efforts[6] our current understanding of **2** is still quite limited. The only certainty is that the irradiation of suitable precursors, for example **3**, **4**, or **7** (γ radiation), gives rise to triplet **2** in such low concentrations that it can be detected only with ESR spectroscopy.[5, 7] Species **2** is capable of existence at temperatures up to −150 °C.[5a] We report here for the first time the IR spectrum of **2**.



Our previous attempts[4] at isolating **2** in an argon matrix gave the following results: After irradiation (313 nm) of **3** in argon at 10 K a well-resolved ESR spectrum of **2** could be recorded, but in the IR spectrum only the bands of methylenecyclopropane **7** were recognizable.[8] When **3** was subjected to flash pyrolysis (400–600 °C) and the fragments were then isolated in argon at 10 K, **2** could not be detected even by ESR spectroscopy. The IR spectrum again showed only the bands of **7**. Diiodide **5**[9] was inert to irradiation (Ar, 10 K, 254 nm), and the combination of flash pyrolysis (500–800 °C)/matrix isolation[10] again provided exclusively **7**.

Despite these disappointing results we recently reopened our investigations, and our efforts have been rewarded: When ketone **4** was irradiated (Ar, 10 K, 300 nm) the ESR spectrum of **2** was observed. In the IR spectrum besides the bands of **7**, two miniscule absorptions are seen at 758 and 500 cm^{-1}[11] with an intensity ratio of roughly 4:1. These correspond to the two most intense bands in the predicted IR spectrum of **2**[12, 13] (Fig. 1).

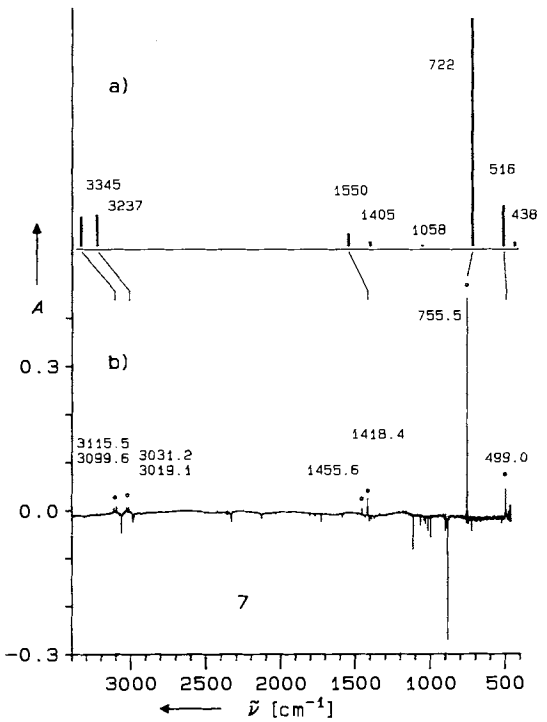


Fig. 1. IR spectrum of **2**: a) calculated (ab initio UMP2/6-31G*), b) measured (Xe matrix, 12 K, difference of the spectra after irradiation of **7**/Br_2 with light with a wavelength of 254 nm followed by irradiation with light with a wavelength of 313 nm). The bands with negative values of A arise from compound **7**.

Even more importantly, we found that these same bands (756, 499 cm^{-1}) arose when **5** was subjected to flash pyrolysis at 600 °C with xenon, the product mixture condensed at 10 K, and the matrix finally irradiated (254 nm). This observation was initially confusing, since **5** and methylenecyclopropane **7** formed in the thermolysis are photostable in xenon when irradiated separately. We conducted a long list of experiments to solve this mystery. The results: a) The source of **2** in these reactions is not **5** but **7**. b) The photoconversion **7** → **2** takes place in a xenon or a xenon/argon matrix (limiting ratio 1:4), but not in a pure argon matrix. c) Halo-

gen atoms (I$^{\bullet}$, Br$^{\bullet}$, or Cl$^{\bullet}$) must be present in the irradiation. d) The same IR spectrum is recorded regardless of which halogen is used.

Based on these results we devised two methods for the production of **2**. The halogen, that is, bromine or iodine, is pyrolyzed with xenon at 750 °C. The halogen atoms that arise are frozen onto a window cooled to 10 K along with a gaseous mixture of **7**/xenon, which is introduced separately. A Hg low-pressure lamp (254 nm) is then used for the irradiation. The formation of **2** by this procedure is faster and more effective than by the direct irradiation of halogen molecules (Cl_2, Br_2, or I_2) in a xenon matrix in the presence of **7**.

The identification of trimethylenemethane (**2**) formed in the xenon matrix is based primarily on the comparison of the measured with the calculated (ab initio UMP2/6-31G*; Table 1) IR spectrum (Fig. 1). Because of the D_{3h} symmetry

Table 1. Calculated vibrational spectrum of **2**; symmetry of the vibrations, wavenumbers in cm^{-1}, intensity in $km\,mol^{-1}$.

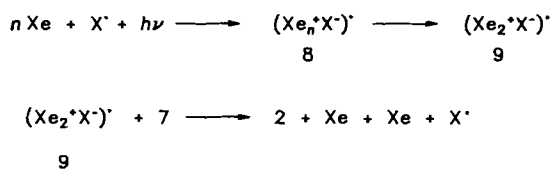
Sym.	$\tilde{\nu}$	Int.	Sym.	$\tilde{\nu}$	Int.
E'	438	1.58	E'	1058	0.02
A_1''	492		E'	1405	2.00
E''	498		E'	1550	6.78
A_2''	516	23.39	A_1'	1572	
E''	687		E'	3237	18.00
A_2''	722	133.72	A_1'	3243	
A_1'	982		A_2'	3342	
A_2'	992		E'	3345	16.88

of **2**, only 14 of the 24 fundamental vibrations are IR active and should result in 8 IR bands ($6E'$, $2A_2''$; calculated spectrum Fig. 1 top). The five most intense bands correlate well with the observed bands. The two strongest absorptions are assigned to the out-of-plane deformations (A_2'') of the hydrogen atoms (756 cm^{-1}) and C atoms of the framework (499 cm^{-1}) according to the calculations. The asymmetric C–C stretching frequency (E') calculated at 1550 cm^{-1} may correlate to the band observed at 1418 cm^{-1}. The IR band registered at 1456 cm^{-1} does not have an equivalent in the calculated spectrum and probably results from a combination vibration. Two weak "doublets" are observed in the region typical for C–H stretching frequencies; these correlate well with the two calculated E' type IR absorptions at 3345 and 3237 cm^{-1}. Matrix effects probably cause the splitting of these bands.

Besides the IR spectrum discussed, the typical ESR spectrum of **2** should also be measureable. This was achieved only with difficulty, as only very broad signals can be obtained in xenon matrices. A series of experiments with ketone **4** as the precursor and various argon/xenon ratios showed that the ESR bands were less resolved with an increasing proportion of xenon in the matrix.

A chemical structural proof of trimethylenemethane was found in the isomerization of **2** back to **7** upon irradiation (313 nm). This photoreaction is evident in the difference spectrum (Fig. 1 bottom). The bands of the product **7** appear as negative peaks, those of the starting material **2** as positive peaks. Light with a wavelength of 254 nm transforms **2** into *s-trans*-butadiene (**6**). Because of this photolability, a certain stationary concentration of **2** cannot be exceeded (maximum 25%[14]).

How does one explain the photoexcitation of **7**, a compound that does not absorb in the UV range? We assume that the photochemically or thermally generated halogen atoms X$^{\bullet}$ form exciplexes with xenon when irradiated, which then immediately relax to form the triatomic charge-transfer complexes **9**.[15] The exciplexes can be detected by UV absorption spectroscopy (Xe/I$^{\bullet}$: $\lambda_{max} = 280$ nm, Xe/Br$^{\bullet}$: $\lambda_{max} = 310$ nm, Xe/Cl$^{\bullet}$: $\lambda_{max} = 354$ nm), **9** with emission spectroscopy ($\mathbf{9} \rightarrow Xe + Xe + X^{\bullet} + h\nu$).[15] We presume that the energy stored in **9** is transferred to **7** across a long distance (ratio 7:Xe and X$^{\bullet}$:Xe < 1:1000). Exactly how the energy is relayed and how the ring cleavage of **7** is induced remains open. In any case the energy stored in **9** (50–



75 kcal mol^{-1}) is enough for the conversion of **7** into the excited singlet state of **2**,[16, 17] which then undergoes intersystem crossing to the triplet ground state. At 10 K the kinetic energy is too low to allow the back reaction to **7**, once **2** is formed.

If this description is true, irradiation in the presence of halogen atoms may be a fundamentally new method for the generation of highly reactive species in a xenon matrix. This could be applied to cases for which the previous methods (matrix photolysis of absorbing starting materials or the combination flash pyrolysis/matrix isolation) cannot be applied.

Didodecylsexithiophene—A Model Compound for the Formation and Characterization of Charge Carriers in Conjugated Chains**

By *Peter Bäuerle,* Uwe Segelbacher, Kai-Uwe Gaudl, Dieter Huttenlocher,* and *Michael Mehring*

Oligothiophenes are among the best investigated model compounds for electrically conducting polymers.[1] The excellent properties, which in some respects surpass those of the related polymers,[2] are attained by stepwise chemical assembly leading to compounds with well-defined structures and controlled chain and conjugation length. The stability of the oligothiophenes in both their neutral and oxidized forms allows the precise characterization of the electronic structure and the charge carrier responsible for the conductivity along the conjugated chains.[3] The characterization of oligothiophenes in solution, in which the cooperative interactions characteristic of the solid state are eliminated, is more difficult because of their inherent reactivity in the oxidized state ($n \leq 5$) and their poor solubility with increasing chain length ($n \geq 6$). However, when the reactive terminal positions[4] are blocked or solubilizing alkyl groups are introduced to the oligomer,[5] the precise characterization of the oligomers in solution is possible.

In this context we have synthesized 3‴″-4′-didodecyl-2,2′:5′,2″:5″,2‴:5‴,2⁗:5⁗,2⁗′-sexithiophene (**1**), whose alkyl substituents in contrast to the compounds in previous studies are fixed at defined positions, and whose structure is established unambiguously by NMR spectroscopy and X-ray structure analysis.[6, 7] Sexithiophene **1** is the first compound of this type that can be oxidized to form a stable dication and also reduced to form a stable dianion. We report here on the preparation and characterization of the

[**] Thiophenes, Part 9. This research was supported by the Deutsche Forschungsgemeinschaft (SFB 329) and the Bundesminister für Forschung und Technologie (TK 0325). We thank Dr. A. Grupp and Dr. S. Sariciftci for helpful discussions. – Part 8 [6].

redox states of **1**; a dimerization of the radical cation $\mathbf{1}^{\bullet+}$ to $(\mathbf{1})_2^{2+}$ was also observed.

Controlled electrochemical and chemical oxidation (with iron trichloride), and reduction (with potassium) led to the different redox states of **1**, which were characterized by cyclic voltammetry, and absorption (Table 1) and ESR spectroscopy. The cyclic voltammogram exhibits two reversible waves in the oxidation part ($E_1^\circ = 0.34$ V and $E_2^\circ = 0.54$ V[8]) which correspond to a one-electron transfer in each step leading to the radical cation $\mathbf{1}^{\bullet+}$ and the dication $\mathbf{1}^{2+}$, respectively (Fig. 1). The first oxidation potential of **1** is close to that of polythiophene ($E^\circ = 0.30$ V[9]), which shows only one extremely broad redox wave because of the chain-length distribution in the polymer. Since the alkyl side chains improve the solubility, the reduction of **1** could also be examined. Two further reversible one-electron transfer steps were evident in the reduction cycle of the cyclic voltammogram ($E_3^\circ = -2.27$ V and $E_4^\circ = -2.40$ V) providing the radical anion $\mathbf{1}^{\bullet-}$ and the dianion $\mathbf{1}^{2-}$ (Fig. 1).

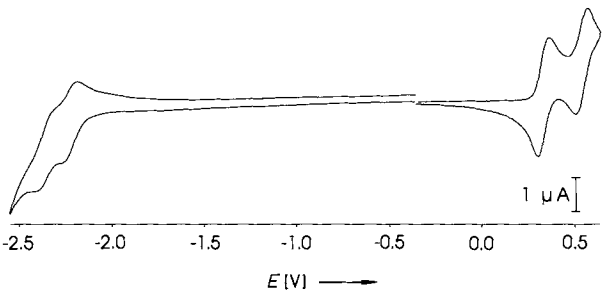

Fig. 1. Cyclic voltammogram of **1** recorded with a scan rate of 100 mVs^{-1}. The oxidation was measured in dichloromethane, the reduction in THF. The potentials are referenced to ferrocene (Fc)/Fc$^+$.

The stability of all the redox states allowed their characterization by absorption spectroscopy. In comparison to the unsubstituted sexithiophene **2** ($\lambda_{max} = 432$ nm, $E = 2.87$ eV),[3] the neutral dialkylsexithiophene **1** absorbs as expected at a somewhat shorter wavelength ($\lambda_{max} = 416$ nm, $E = 2.97$ eV), due to the steric interaction of the alkyl chains with the conjugated π system. This interaction is also reflected in the crystal structure of **1** by the twisting of the relevant thiophene rings by 10.8°.[7] Two bands are observed in the absorption spectrum of cation radical $\mathbf{1}^{\bullet+}$, each with shoulders [sh] at higher energies ($E = 0.87$, 1.14[sh], 1.60, 1.81[sh] eV) (Fig. 2 top); the structure and position of these bands are almost identical to those of $\mathbf{2}^{+}$ [3] (Table 1), indicating that the conjugated system becomes more planar during the transition from **1** to $\mathbf{1}^{\bullet+}$. Variable-temperature measurements show that the absorption spectrum changes with decreasing temperature; only two of the transitions ($E = 1.60$ and 0.87 eV) can be attributed to $\mathbf{1}^{\bullet+}$. These tran-

sitions almost disappear at lower temperatures, whereas the bands at $E = 1.81$ and 1.14 eV become more pronounced (Fig. 3). This observation can be easily explained by the re

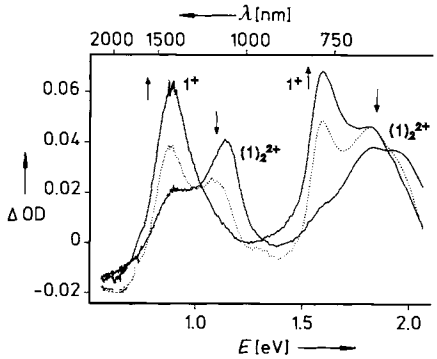

Fig. 3. Temperature-dependent absorption spectra of the dimer equilibrium $\mathbf{1}^{\bullet+} \rightleftharpoons (\mathbf{1})_2^{2+}$ starting at 244 K(--↓), 274 (···), and 294 K (–↑).

versible equilibrium between monocation $\mathbf{1}^{\bullet+}$ and a dimeric radical cation $(\mathbf{1})_2^{2+}$. Stable dimers of this type, also called pimers, have been described for other large aromatic cations of porphyrins,[10] phthalocyanines,[11], perylenes,[12] and viologens.[13] In every case the formation of the π dimer is accompanied by a blue-shift of the absorption band(s) of the monocation and the simultaneous emergence of a long-wavelength charge-transfer transition.[14] The π dimerization of cation radicals is also discussed in the context of the formation of conducting radical ion salts.[15]

At higher concentrations the dimerization of $\mathbf{1}^{\bullet+}$ to $(\mathbf{1})_2^{2+}$ is favored. ESR measurements also prove that spin pairing occurs as the temperature is lowered, causing the intensity of the ESR signal of $\mathbf{1}^{\bullet+}$ to decrease. Based on the temperature-dependence of the equilibrium constant, a value for the dimerization enthalpy, $\Delta H = -21$ kcal mol^{-1}, was found and determined from the intensity of the ESR signals. Although known for many years, the dimerization process has been neglected in the discussion of the properties of conducting polymers. The first report of the dimerization of a terthiophene cation radical was published only recently. In that case the dimerization tendency ($\Delta H = -10$ kcal mol^{-1}) is only half the value found for $(\mathbf{1})_2^{2+}$, correspoonding to the size of the molecule.[16] The variable-temperature studies of a series of oligothiophenes (trimer to pentamer) with combined in situ UV/VIS/NIR and ESR spectroscopy clearly demonstrates the dependence of the dimerization of the cation radicals on the chain length.[17]

Further oxidation of $\mathbf{1}^{\bullet+}$ leads to dication $\mathbf{1}^{2+}$, whose absorption spectrum exhibits a band with two maxima ($E = 1.47$ and 1.31 eV) (Fig. 2 top). In comparison to the absorptions of $\mathbf{2}^{2+}$ these bands are again shifted to higher energies. In this case, measurements at various temperatures do not show changes in the absorption spectrum, and an equilibrium with the dimer can thus be ruled out.

Successive chemical reductions of **1** provide monoanion $\mathbf{1}^{\bullet-}$ and dianion $\mathbf{1}^{2-}$. The π–π^* transitions of the anions are generally shifted to lower energies in comparison to those of the cations $\mathbf{1}^{\bullet+}$ and $\mathbf{1}^{2+}$ (Table 1). The absorption spectrum of anion radical $\mathbf{1}^{\bullet-}$ shows a band with fine structure and a maximum at $\lambda_{max} = 781$ nm ($E = 1.59$ eV). An absorption at unusually low energy in the near-IR regime is found ($\lambda_{max} = 1725$ nm, $E = 0.72$ eV; Fig. 2 bottom), which is very similar to that observed for the anion radicals of oligo-*p*-phenylenevinylenes.[18] The ESR spectrum of $\mathbf{1}^-$ proves its paramagnetic nature. In analogy to $\mathbf{1}^{2+}$, $\mathbf{1}^{2-}$ has an absorption band at $\lambda_{max} = 912$ nm ($E = 1.35$ eV; Fig. 2 bottom). Although dimerizations of anion radicals are known,[19] none is observed for the anionic species of **1**.

ESR measurements conducted for the unequivocal identification of the paramagnetic radical ions $\mathbf{1}^{\bullet+}$ and $\mathbf{1}^{\bullet-}$ also allowed the determination of the spin density distributions. The *g*-factors ($g = 2.0023$ and 2.0046, respectively) are in agreement with those of the radical ions of unsubstituted oligothiophenes[20] and doped poly(3-methylthiophene).[21] The *g*-factor of $\mathbf{1}^{\bullet-}$ is substantially greater than that of $\mathbf{1}^{\bullet+}$, indicating that the orbitals of the sulfur atoms are significantly involved in the SOMO of $\mathbf{1}^{\bullet-}$. In contrast, the electronic structure of cation radical $\mathbf{1}^{\bullet+}$ more closely resembles that of a *cis*-polyene system due to the limited involvement of the sulfur atoms in the SOMO. A preliminary determination and assignment of the spin densities was possible by simulation of the ESR spectra and accompanying calculations.[22] The spin density distributions obtained are represented in Figure 4. Besides the expected localization of spin density at the terminal α C atoms, it is worth noting that in both paramagnetic species the largest hyperfine coupling constants and the highest spin densities are localized on β carbon atoms. This is in agreement with the fact that in the course of the oxidative polymerization of heterocycles such as thiophenes and pyrroles even at short chain lengths incorrect linkages and cross-couplings occur due to α,β-couplings and β,β-couplings, respectively, which interfere and interrupt the conjugated chain. Similar charge distributions were calculated for pyrrole oligomers.[23]

The enhanced stability and solubility of **1** allow the precise characterization of the electronic structure of the different redox states. The temperature-dependent formation of the diamagnetic dimeric cation radical $(\mathbf{1})_2^{2+}$ in solution pro-

vides a new alternative to the description of the doping behavior of polythiophenes and conducting polymers in general. Thus, the formation of corresponding dimeric species complementary to polarons and bipolarons, can now be considered as the first mechanistic step during doping. This fact easily explains the observation that the ESR activity of polarons in conducting polymers[21] and cation radicals in longer oligomers[5a] is detected only at unexpectedly low levels of doping, in the first case, or not at all, in the second. Nevertheless, the findings described here do not necessarily disagree with the existence of polaronic and bipolaronic bands in highly doped conjugated polymers. In addition, the anionic redox states of **1** are the first models for negatively charged defects in thiophene chains. The n-doping of polythiophene is possible otherwise only under extreme conditions.[24]

[7] P. Bäuerle, K.-U. Gaudl, F. Pfau, S. Henkel, unpublished results. In the X-ray structures of sexithiophene **1** and the related precursor 3′-dodecyl-2,2′:5′,2″-terthiophene both have the same torsion angle with a value of 10.8 and 11.0°, respectively, for the thiophene rings which are sterically hindered by the alkyl side chains. In the case of **1** not all of the bond lengths and angles have yet been obtained with satisfactory precision because of the small size of the crystals examined and the resulting weak reflections. For this reason the X-ray structure is not discussed further here.
[8] Oxidations of **1** were measured in dichloromethane, reductions in tetrahydrofuran at a concentration of 5×10^{-4} mol L^{-1} with tetrabutylammonium hexafluorophosphate (0.1 M) as the supporting electrolyte. The working electrode was a platinum disk 1 mm in diameter, the counterelectrode a platinum wire, and the reference electrode a Ag/AgCl electrode which was calibrated with ferrocene after each measurement.
[9] We measured the oxidation potential of polythiophene under identical conditions.

Reaction of Buckminsterfullerene with *ortho*-Quinodimethane: a New Access to Stable C_{60} Derivatives**

By *Pavel Belik, Andreas Gügel, Jochen Spickermann*, and *Klaus Müllen**

The fullerene synthesis reported by Krätschmer et al. in 1990,[1] the discovery of fascinating material properties of fullerenes and their derivatives,[2] and the development of efficient processes to separate fullerene mixtures[3] have led to a burgeoning number of publications on this class of material in the last two years. These papers are primarily concerned with the physico-chemical aspects of fullerenes and less with their functionalization.[4] This one-sidedness has the following causes: 1) C_{60} is an exceptionally stable molecule that adds most reaction partners reversibly only,[5] 2) fullerene and fullerene adducts are only slightly soluble, 3) the determination of the structure of fullerene adducts is extremely complex because of the large number of possible products and isomers, and 4) high-performance chromatographic methods are necessary to separate the fullerene adducts. Nevertheless, there are already some papers which report successful syntheses and isolations of fullerene derivatives.[6] Here we present a new access to stable C_{60} derivatives.

For addition to the electron-poor "superalkene" C_{60} (**1**), which easily adds radicals, *o*-quinodimethane[7] seemed particularly suitable. It can be prepared in situ containing differ-

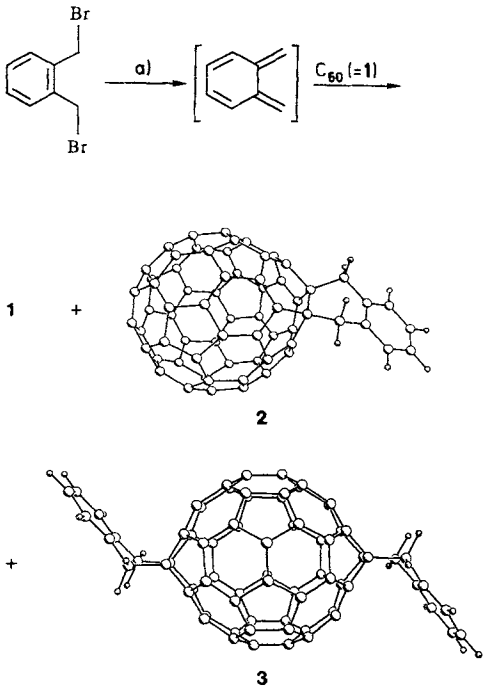
[**] We thank Dipl.-Chem. U. Koch for preparing the structural formulas. This work was supported by the Bundesministerium für Forschung und Technologie (project 13 N 6076).

ent functional groups[8] and forms very reactive dienes that can form [4 + 2] cycloadducts even with the least reactive dienophiles.

A simple method to generate *o*-quinodimethane is the iodine-induced 1,4-elimination at 1,2-bis(bromomethyl)-benzene, which is usually performed in dimethylformamide (DMF).[9] Because C_{60} (**1**) is almost insoluble in DMF, the synthesis must be transferred to toluene through the phase transfer catalyst, [18]crown-6. C_{60} (**1**) reacts with 1 equivalent of 1,2-bis(bromomethyl)benzene, 2.2 equivalents of KI, and 8.1 equivalents of [18]crown-6 within 6 h in boiling toluene to form the monoadduct **2** (88%, based on converted C_{60}) and the bisadduct **3** (7%). Unchanged C_{60} (37.8% based on employed amount of C_{60}) was recovered (Scheme 1).



Scheme 1. Reaction of C_{60} with *o*-quinodimethane (for **3** only one of the possible isomers is given) [15]. a) KI, [18]crown-6, toluene, reflux.

The separation of **1**, **2**, and **3** was achieved by gel permeation chromatography (GPC) on polystyrene gel with toluene as eluent[10] (Fig. 1). Since the products are sufficiently soluble in toluene (solubility of the monoadduct: about 30 mg mL^{-1}), 10 gram amounts of crude product can be separated on a 20 × 600 mm column per day.[3]

The reversibility of addition reactions has often proved to be the central problem in C_{60} chemistry.[5] The elugram of the crude product, as well as the mass spectrum of fractions 1 and 2,[11] show that adducts **2** and **3** do not fragment during the reaction or in the mass spectrometer. The monoadduct sublimes above about 400°C without decomposition. Only traces of a trisadduct can be detected.

NMR spectroscopy yields important information about structure. Addition at a double bond between two annelated six-membered rings is proved by the number of ^{13}C NMR signals in the region for aromatic carbon atoms. Seventeen such signals indicate a C_{2v} symmetry for the molecule (a result of rapid ring inversion of the cyclohexene unit). Addition at a double bond between a five- and a six-membered ring would lower the symmetry because of the absence of a

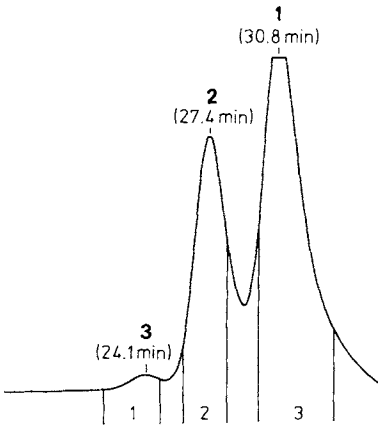


Fig. 1. Separation of **1**, **2**, and **3**, indicating cuts for fractions 1, 2, and 3. Column: 20 × 600 mm; stationary phase: Shodex K-2001 polystyrene gel, 5 μm, 50 Å; mobile phase: 5 mL min^{-1} toluene; detection: UV at 340 nm; injection of 1 mL of toluene solution.

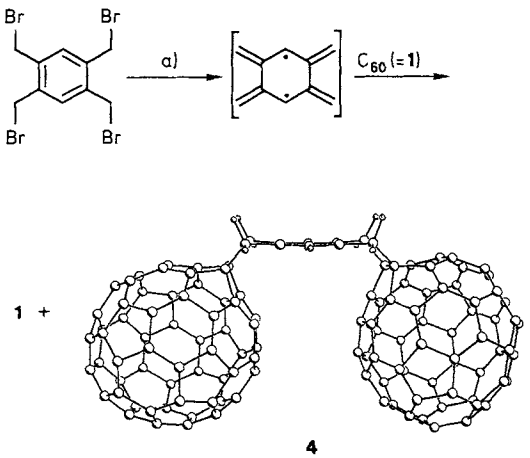
mirror plane. The ^{13}C chemical shift (δ = 66.09) for the two C_{60} carbon atoms that participated in the addition, as well as the number of signals in the region for aromatic carbon atoms, rule out a 1,6-substituted [10]annulene[12] as structural unit, since 18 signals would be expected. The ring inversion of the cyclohexene ring is slow on the NMR time scale at room temperature. This is easy to recognize by the splitting of the signals for the methylene protons.

This synthesis is a valuable addition to preparative fullerene chemistry because of its selectivity and the high stability of the adducts. Its versatility was tested through an analogous reaction of C_{60} with bis-*o*-quinodimethane (Scheme 2). The bisadduct of this reaction was isolated by



Scheme 2. Reaction of C_{60} with bis(*o*-quinodimethane) (for **4** only the *cis* isomer is represented) [15]. a) KI, [18]crown-6, toluene, reflux.

GPC and characterized by ^{1}H NMR spectroscopy and mass spectrometry. Typical for compound **4**, a dumbbell-shaped molecule, is a distinctly lower solubility than C_{60} and a slightly longer elution time on the GPC column (all the compounds we studied thus far eluted before C_{60}). This makes the isolation of larger amounts of **4** considerably more difficult.

We are now trying to prepare adducts that are suitable for polymerization, for example by transformation with *o*-quinodimethanes functionalized with carboxyl and hydroxyl groups.

Experimental Procedure

Preparation: C_{60} (**1**, 100 mg, 0.139 mmol) [13], 1,2-bis(bromomethyl)benzene (37 mg, 0.139 mmol), KI (50 mg, 0.3 mmol), and [18]crown-6 (300 mg, 1.13 mmol) in toluene (50 mL) were heated under reflux under an inert atmosphere (argon) in the dark for 6 h. The solution became dark brown. The reaction mixture was allowed to cool to room temperature, washed with NaOH (5%) and then H_2O, and evaporated to dryness under vacuum. The brown solid was taken up in toluene (10 mL), and the solution filtered through a 0.25 μm Teflon membrane filter. After the chromatographic separation described next, methanol was added to fraction 2 to precipitate the brown solid, which was dried for 4 h at 100 °C and 10^{-2} Torr.

Chromatography [3,14]: Elution pump: Master pump M 305 with pump head 25SC; injection pump M 306 with pump head 25SC. Detector: UV detector M 115 with 0.3 μL flow-through cell (light path 0.1 mm). Fraction collector: 201 C. Column: 20 × 600 mm filled with polystyrene gel (5 μm, 50 Å). Amount injected: 1 mL of the toluene solution. Mobile phase: toluene, 5 mL min^{-1}.

Fraction 1: **3** (7%, based on converted C_{60}); MS(FD): *m/z* 822 ([*M* of **2**−2H]$^+$, 8%), 824 (M^+ of **2**, 7%), 928 (M^+, 100%), 944 ([*M* + O]$^+$, 9%), 1032 (M^+ of trisadduct, 4%); UV/VIS (CH_3Cl): unstructured.

Fraction 2: **2** (88%, based on converted C_{60}); MS(FD): *m/z* 824([*M*]$^+$, 100%), 840 ([M^+ + O]$^+$, 2%), 928 (M^+ of **3**, 2%); UV/VIS (CH_3Cl): similar to C_{60}, but less structured; ^{1}H NMR (500 MHz, $C_2Cl_4D_2$, 28 °C): δ = 4.46 (d broadened, 2 H; CH_2); 4.82 (d broadened, 2 H; CH_2); 7.57–7.59, 7.69–7.71 (m, AA'BB' system of the arene); measurement at 125 °C: δ = 4.70 (s, 4 H; CH_2); ^{13}C NMR (125 MHz, $C_2Cl_4D_2$, 80 °C, *J*-modulated spin echo for ^{13}C): δ = 45.28 (benzyl-C); 66.09 (aliphat. quaternary C_{60} C atoms); 128.02, 128.09 (H-subst. aromat. C atoms), 135.76, 138.21, 140.20, 141.66, 142.13, 142.30, 142.62, 143.17, 144.78, 145.42, 145.49, 145.51, 145.85, 146.30, 146.52, 147.76, 156.93 (17 arene signals).

Fraction 3: **1** (37.8%, based on initial C_{60}).
4: ^{1}H NMR (500 MHz, CS_2, 28 °C): δ = 4.79 (d broadened, 4H; CH_2); 5.27 (d broadened, 4 H; CH_2); 8.18 (s, 2H; arene).

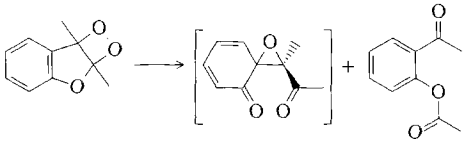
[15] The structures were optimized with the force-field program MOMO (H. Beck, M. Dyrbusch, E. Egert, MOMO, version 1.0, University of Frankfurt, **1991**), and the cartesian coordinates transferred to XP for manipulation (XP-Interactive Molecular Graphics, Version 4.1, Siemens Analytical X-Ray Inst. Inc., **1990**).

Photosensitized Oxygenation of an Acyl Furan: Isolation of the First Furan Dioxetane by Rearrangement of its Endoperoxide and Selected Chemical Transformations**

By *Waldemar Adam,* Michael Ahrweiler,* and *Markus Sauter*

Recently we reported the novel thermal rearrangement of benzofuran dioxetanes to the 1-oxaspiro[2,5]octadienone derivative,[1] which are formed in addition to the usually expected dioxetane cleavage products [Eq. (a)]. Analogous



(a)

cis-diacyl-substituted epoxides have been observed for the thermolysis of furan endoperoxides,[2, 3] but the mechanistic details of this isomerization still need to be convincingly defined. We suspected that furan dioxetanes are immediate precursors to such *cis*-diacyloxiranes, which constitute photooxygenation products of furans.[2b] Indeed, the isomerization of a furan endoperoxide to its dioxetane has been followed by spectroscopy,[2d] but the subsequent rearrangement to the epoxide not mentioned. In Scheme 1 we present the first example of such a sequence of transformations in the photooxygenation of the acyl furan **1**. Remarkable is the fact that the furan dioxetane **3** is sufficiently persistent (actually less labile than its endoperoxide **2**) to permit isolation and full characterization.

2,3,6,6-Tetramethyl-4,5,6,7-tetrahydrobenzo[*b*]furan-4-one (**1**), prepared according to the literature,[4] gave with singlet oxygen at −35 °C the endoperoxide **2** in quantitative yield (Scheme 1, step a). The endoperoxide **2** rearranged in solution at −20 °C within two days (step b) and instantly on silica gel (step c) into the dioxetane **3**. The spectroscopic data in Table 1 and iodometric titration support the structural assignment of the peroxides **2** and **3**. At elevated temperature (step d), the endoperoxide **2** decomposed directly into the dioxetane cleavage product **4** and the spiroepoxide **5** in a ratio of 42:58. Under the same conditions (step d), the dioxetane **3** gave the expected cleavage product **4** and the spiroepoxide **5** in ratio of 40:60. Most surprising was the quan-

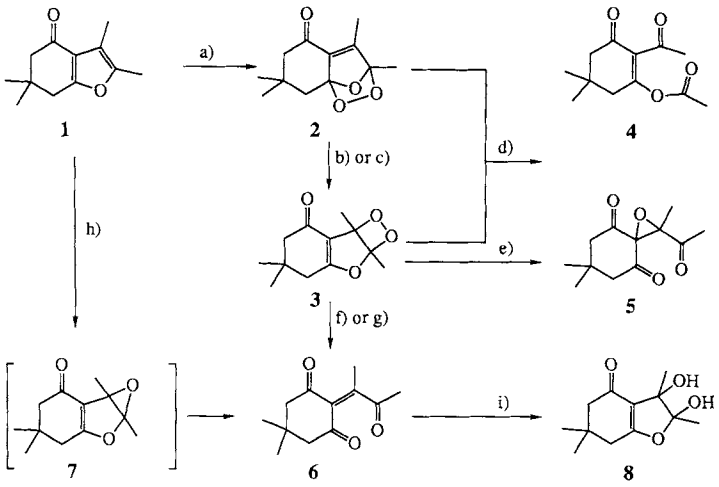

Scheme 1. a) O_2, tetraphenylporphyrin (TPP), *hv*, CH_2Cl_2, −35 °C, 1.5 h, ca. 100%; b) $CDCl_3$, −20 °C, 48 h, ca. 75%; c) silica gel, pentane, −40 °C, 74%; d) $CDCl_3$, 20 °C, 12 h, ca. 85%, **4**:**5** = 40:60; e) 1 mol% Et_4NBr_4, $CDCl_3$, 0 °C, 4 h, > 95% **5**; f) Ph_2S, CD_2Cl_2, −100 °C, 1 min, > 95%; g) PPh_3, $CDCl_3$, −80 °C, > 95%; h) [D_6]dimethyldioxirane, [D_6]acetone, −40 °C, 1.5 h, > 95%; i) 1.1 equiv H_2O, [D_6]acetone, −20 °C, 1 h, > 90%.

titative rearrangement (step e) of the dioxetane **3** to the spiroepoxide **5** with catalytic amounts (1 mol%) of Et_4NBr. A control experiment revealed that the endoperoxide **2** was stable towards Et_4NBr under these conditions. The structure of the unusual spiroepoxide **5** was assigned on the basis of spectroscopic data and elemental analysis. Characteristic are the epoxide ^{13}C resonances at $\delta = 73.1$ and 73.9 (Table 1).

Deoxygenation of the dioxetane **3** by Ph_2S (step f) or Ph_3P (step g) gave the enedione **6** quantitatively. Not even traces of the expected epoxide **7** could be detected by ^1H or ^{13}C NMR monitoring of the deoxygenation product mixture at temperatures as low as −100 °C. No persistent furan epoxides are known to date;[5] for example, epoxidation of furanes by *meta*-chloroperoxobenzoic acid[6a] and dimethyldioxirane[6b] afforded enediones quantitatively as oxidation products.

Table 1. Physical and spectroscopic data of **2**–**6** and **8** [a].

2: Colorless oil; ^1H NMR [b]: $\delta = 1.05$, 1.06 (s, 6 H), 1.76 (s, 3 H), 2.15 (s, 2 H), 2.23 (s, 3 H), 2.30 (s, 2H); ^{13}C NMR [c]: $\delta = 10.7$ (q), 11.4 (q), 28.6 (q), 28.9 (q), 32.3 (s), 35.9 (t), 53.6 (t), 112.5 (s) [d], 132.0 (s), 152.8 (s), 194.9 (s).

3: Yellow prisms, m.p. 63–64 °C (CH_2Cl_2/pentane); ^1H NMR [b]: $\delta = 1.08$, 1.19 (s, 6 H), 1.76 (s, 3 H), 1.86 (s, 3 H), AB system ($\delta_A = 2.22$, $\delta_B = 2.38$, $J = 13.0$ Hz, 2 H), AB system ($\delta_A = 2.40$, $\delta_B = 2.60$, $J = 20.0$ Hz, 2 H); ^{13}C NMR [c]: $\delta = 16.9$ (q), 17.3 (q), 28.2 (q), 28.9 (q), 33.8 (s), 37.6 (t), 51.3 (t), 94.1 (s), 116.0 (s), 119.8 (s), 181.5 (s) 194.0 (s); IR (CCl_4): ν[cm^{-1}] = 2970, 2870, 1670, 1625, 1465, 1385, 1300, 1230, 1150.

4: ^1H NMR [e]: $\delta = 1.20$ (s, 6 H, CH_3), 2.02 (s, 2 H), 2.15 (s, 2 H), 2.23 (s, 3 H, CH_3), 2.47 (s, 3 H, CH_3); ^{13}C NMR [f]: $\delta = 21.2$ (q), 26.9 (q), 27.7 (q), 32.5 (s), 43.1 (t), 51.3 (t), 129.9 (s), 165.8 (s), 167.4 (s), 194.5 (s), 196.8 (s).

5: Colorless oil; ^1H NMR [e]: $\delta = 0.93$ (s, 3 H), 1.04 (s, 3 H), 1.33 (s, 3 H), 2.24 (s, 3 H), 2.62 (m, 4 H); ^{13}C NMR [f]: $\delta = 13.4$ (q), 26.9 (q), 27.7 (q), 30.3 (q), 31.2 (s), 54.8 (t) 55.1 (t), 73.1 (s), 73.9 (s), 199.5 (s), 200.4 (s), 205.1 (s); IR (CCl_4): ν[cm^{-1}] = 2980, 2960, 1750, 1740, 1510, 1420, 1380, 1130.

6: Colorless powder, m.p. 135–137 °C (acetone); ^1H NMR [e]: $\delta = 1.10$ (s, 6 H), 2.33 (s, 3 H), 2.36 (s, 3 H), 2.52 (s, 2 H), 2.59 (s, 2 H); ^{13}C NMR [f]: $\delta = 19.9$ (q), 27.5 (q), 28.3 (q), 30.2 (s), 52.2 (t), 54.1 (t), 129.0 (s), 167.1 (s), 197.6 (s), 198.7 (s), 205.2 (s); IR (CCl_4): ν[cm^{-1}] = 2980, 1705, 1670, 1610, 1365, 1240.

8: ^1H NMR [b]: $\delta = 1.07$ (s, 6 H, CH_3), 1.42 (s, 3 H, CH_3), 1.49 (s, 3 H, CH_3) 2.18 (s, 2 H), 2.24 (s, 2 H); ^{13}C NMR [c]: $\delta = 20.2$ (q), 20.6 (q), 27.6 (q), 33.3 (s), 37.6 (t), 51.4 (t), 76.2 (s), 103.5 (s), 131.7 (s), 177.1 (s), 194.7 (s).

[a] For all new compounds consistent elemental analyses were obtained except for **2**, **4** and **8**, which were too labile for purification; the purity of the peroxides **2** and **3** was > 98% as determined by iodometry. [b] 200 MHz, −20 °C. [c] 50 MHz, −20 °C. [d] Two carbons with identical resonances, established by the inverse gated technique. [e] 250 MHz, 20 °C. [f] 100 MHz, 20 °C.

It appeared to us important, therefore, to attempt the direct epoxidation of the tetrahydrobenzofuran **1**. Indeed, treatment with [D_6]dimethyldioxirane in an NMR tube at −40 °C (step h) resulted in the enedione **6** quantitatively. Unfortunately, the tetrahydrobenzofuran **1** was not sufficiently reactive towards this dioxirane to conduct the epoxidation below −40 °C; however, in view of our deoxygenation results for dioxetane **3** (steps f and g), the expected furan epoxide **7** probably rearranges to the enedione **6** already at −100 °C.

When enedione **6** was treated with water (step i), the labile diol **8** was obtained essentially quantitatively. The ^{13}C NMR signals at $\delta = 76.2$ and 103.5 for the tertiary alcohol and the acetal carbons are in the expected region; these results cast doubt on the existence of the recently proposed epoxide **9**, for which a nearly identical chemical shift is obtained.[5a] Within 4 h at −20 °C or upon warming to room temperature, the diol **8** decomposed completely to a complex mixture. The lability of diol **8** precluded attempts to purify it by low-temperature chromatography (silica gel, −30 °C).

Thus, we succeeded in isolating and fully characterizing the first furan dioxetane through thermal or silica gel catalyzed isomerization of its furan endoperoxide. The subsequent rearrangement of the furan dioxetane to the corresponding spiroepoxide seems to be quite general and was hitherto not recognized. It occurs selectively on treatment with catalytic amounts of Et_4NBr, an unprecedented process in dioxetane chemistry. The mechanism of this novel Br^--catalyzed rearrangement of furan dioxetanes to *cis*-diacyloxirane apparently involves a S_N2 attack on the dioxetane peroxide bond.[7]

[5] S. Oishi, S. D. Nelson, *J. Org. Chem.* **1992**, *57*, 2744–2747. In this paper the furan epoxide **9a** is proposed on the basis of ^{13}C NMR spectroscopic data; however, not only are the reaction conditions rather unusual for the formation of such labile epoxides, and contrary to our experience with the more persistent benzofuran epoxides **10a** [1], but the reported data are more consistent with the structure of the diol **9b**. This becomes evident if the spectroscopic data of the epoxide-diol pairs is compared with that of **10a**,**b** [1] and **11a**,**b** [6c]. Presumably diol **9b** results from the hydrolysis of the enedione, the rearrangement product of the epoxide **9a**, because it is difficult to prepare anhydrous solutions of dimethyldioxirane in acetone.

$[(Me_3Sn^{IV})_2Mo^{VI}O_4]$: An Organometallic Quasi-AB_2 System with a Layered Structure**

By *Ulrich Behrens, Abdul K. Brimah, Kenan Yünlü,* and *R. Dieter Fischer**

Organometallic esters, for example of the type $[(R_3E^{IV}O)_2Cr^{VI}O_2]$ (R = alkyl, aryl; E = Si, Ge, Sn, Pb), are found relatively often in patent literature; however, up to now hardly any basic research has been conducted on the compound class $[(R_3E^{IV})_2M^{VI}O_4]$ (M = Cr, Mo, W).[1] So far, only one compound (R = Ph, E = Si, M = Cr[2]) has been characterized by X-ray diffraction, while the higher homologues with M = Mo and W have remained unknown.

Through our work on novel three-dimensional coordination polymers of the general composition $[(R_3E)_nM(\mu\text{-}X)_m]_\infty$ (X is e.g. CN, SCN, O[3]), we have found that compounds of the type $[(R_3E)_2MO_4]$ (**1**) with E = Sn and Pb; M = Mo and W, but not Cr, are accessible by precipitation from aqueous solution [Eq.(a)].

$$2\,R_3ECl + Na_2[MO_4] \xrightarrow[(Me_2CO)]{H_2O} [(R_3E)_2MO_4]\downarrow + 2\,NaCl \qquad (a)$$

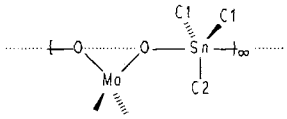
1a, R = Me, E = Sn, M = Mo
1b, R = Me, E = Pb, M = Mo
1c, R = Me, E = Sn, M = W

In contrast to the chemically more labile, yellow Cr homologues,[1] the colorless molybdates and tungstates **1**[4] are sparingly soluble in H_2O (pH range 3–10) and stable up to 350 °C. So far we have only obtained optimal single crystals of **1a** as an unexpected by-product during attempts to crystallize coordination polymers **2**[5] in air [Eq.(b)][24].

$$4\,Me_3SnCl + K_4[Mo(CN)_8]\cdot 2\,H_2O \xrightarrow[(O_2)]{H_2O} \underset{\mathbf{2}}{[(Me_3Sn)_4Mo(CN)_8]_\infty} + 4\,KCl \quad (+\,\mathbf{1a}) \qquad (b)$$

The less abundant, colorless crystals of **1a** grew, nevertheless, faster than the yellow crystals of **2** from the initially saturated, clear solution of the starting materials. Formation of **1a** from Me_3SnCl and $K_4[Mo^{IV}(CN)_8]\cdot 2H_2O$ did not occur when air was strictly excluded; the question concerning the true origin of the $[Mo^{VI}O_4]^{2-}$ ions still needs to be addressed.[6, 7, 17] The identity of product obtained according to Equations (a) and (b), **1a**, was confirmed by the good correlation of the experimental Debye–Scherrer photograph of **1a** from reaction (a) with the powder diagram calculated[8] from single-crystal data of **1a** from reaction (b).

Although the structural framework of **1a** (Fig. 1) contains tetrahedral MoO_4 and trigonal-bipyramidal (tbp) Me_3SnO_2 units (with shared O atoms),[9] principally conceivable *three*-dimensional networks (e.g. of the cristobalite type[10]) are not formed. The actual, relatively compact,[11] *layered* structure resembles that of the genuine AB_2 system HgI_2 (red modification[12]). Replacement of the Hg atoms with Mo atoms and of the iodide bridges with the practically linear {O–Sn–O} bridges would provide **1a**. Layers result from the interlinkage of quasi-linear strands (Scheme 1) parallel to the *a* and *b* axes. Only van der Waals forces may be acting between adjacent layers with the sequence ABCDA···. The uniform Mo–O distance of 1.770(8) Å corresponds roughly to those observed in $K_2[MoO_4]$ and $[MoO_3(tren)]$ (tren = diethylenetriamine[13]). The ν and δ (Mo–O) vibrational frequencies are weakly shifted in comparison to those of the "free" $[MoO_4]^{2-}$ ions.[14] The uniform Sn–O distance of 2.268(9) Å in **1a** correlates well with the corresponding distances in the tbp-configured R_3SnO_2 building unit of the polymeric esters $[(R_3Sn)_2CO_3]_\infty$ (R = Me, Et, *i*Bu[16]).



Scheme 1.

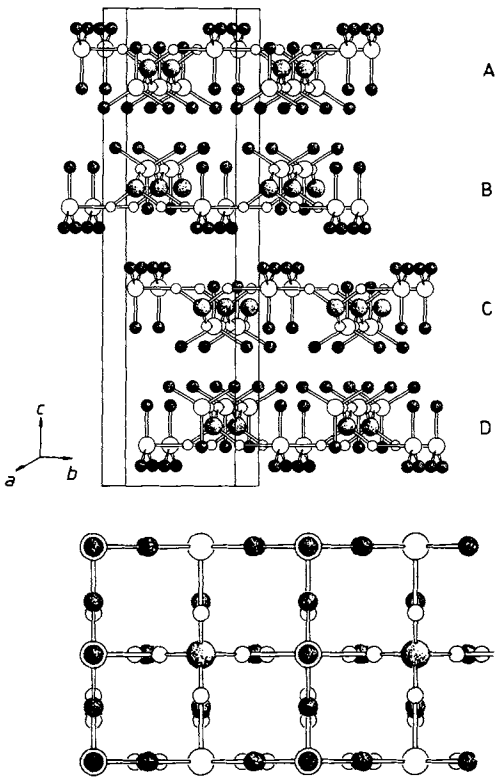


Fig. 1. Top: The layered structure and unit cell of **1a** (SCHAKAL plot: H atoms are omitted). Open circles: large, Sn; small, O; dotted circles: large, Mo; small, C. Bond lengths [Å]: Sn–O, 2.268(9), Mo–O, 1.770(8), Sn–C1, 2.095(18), Sn–C2, 2.147(18); bond angles [°]: O-Mo-O', 107.4(5), 110.5(3), O-Sn-O', 179.8(4), Mo-O-Sn, 143.6(4), O-Sn-C1, 90.0(1), O-Sn-C2, 90.1(2). Bottom: The framework of **1a** as viewed along the *c* axis.

The Pb homologue of **1a**, $[(Me_3Pb)_2MoO_4]$ (**1b**), which can even be crystallized according to Equation (a) (but not (b)[17]), is isostructural with **1a**. The poorer quality of the single crystal of **1b** and its strong X-ray absorption led, however, to less satisfactory results for the structure analysis.[18] $[(Me_3Sn)_2WO_4]$ (**1c**) is also isostructural with **1a** according to its X-ray powder diagram. Corresponding "alloyed" polymers with variable Mo/W or Mo/Cr content (and E = Sn) are also accessible by Equation (a). The CP-MAS ^{13}C solid-state NMR spectra of both **1a** and **1b** show only *one* symmetric signal between + 20 and −40 °C, despite the fact that there are two nonequivalent methyl C atoms in the asymmetric unit.[19] Obviously the Me_3Sn groups rotate "freely" about the O-Sn-O axes on the NMR timescale.[20]

Martin-Luther-King-Platz 6, D-W-2000 Hamburg 13 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank T. M. Soliman (deceased), K. Saliminia, and J.-U. Schütze for carrying out certain experiments.

Because of their polymeric layered structures, **1a** and **1b** differ fundamentally from the monomeric molecular compounds $[(Ph_3SiO)_2CrO_2]$[2] and $[(Me_3SiO)_2SO_2]$.[21] In contrast, the anionic sublattice $[(Et_3Sn^{IV})_2Cu^{I}(CN)_4^-]_\infty$ in the new host–guest system $[(nBu_4N)(Et_3Sn)_2Cu(CN)_4]_\infty$ [22] has a noncubic, *three*-dimensional framework comprised of bent [-Cu-CN-Sn-NC-]$_\infty$ chains. The new polymers **1** appear destined to open the way to genuine intercalation compounds; on the other hand, it cannot be ruled out that the incorporation of appropriately sized guest molecules may occasionally result in the formation of, for example, cristobalite-like *three*-dimensional host systems. Attempts to incorporate cobaltocene into **1a** according to Equation (c)[23] (with $0 < n \leq 1$) showed that even under relatively mild conditions light-brown to gray products form slowly from the colorless starting material **1a**; the IR spectra of the products show metallocene absorption bands in addition to the otherwise unchanged vibrational spectra of the starting material.

$$[(Me_3Sn^{IV})_2Mo^{VI}O_4] + n[Cp_2Co^{II}] \rightarrow [(Cp_2Co^{III})_n(Me_3Sn^{IV})_2Mo^{V}_nMo^{VI}_{1-n}O_4] \quad (c)$$

Experimental Procedure

Typical preparation of **1**, R = Me, M = Mo: A saturated aqueous solution of 1.2 g (5 mmol) $Na_2[MoO_4]\cdot 2H_2O$ was added dropwise with stirring to a saturated aqueous solution of 1.0 g (5 mmol) Me_3SnCl. The air-stable, colorless precipitate which occurred spontaneously was filtered, washed on the frit thoroughly with H_2O, and dried at 100 °C in a drying oven. Yield: 1.0 g (80%). Decomposition temp.: 360 °C (discolored to ocher-yellow). The organotin compounds with R ≠ Me which are less soluble in H_2O were fully dissolved by adding some acetone.

[24] Note added in proof (Dec. 15, 1992): Experiments with analytically pure $K_4[Mo(CN)_8]\cdot 2H_2O$ prepared from MoO_3 [6] (ν(Mo–O) IR and Raman bands are completely absent) did not afford any **1a**.

A Diastereoselective Synthesis of β-(*N*-Acylamino)aldehydes by Rearrangement of *O*-Vinyl-*N*,*O*-Acetals**

By *Herbert Frauenrath,* Thomas Arenz, Gerhard Raabe,* and *Martin Zorn*

Dedicated to Professor Hermann Stetter on the occasion of his 75th birthday

Chiral carbonyl compounds with a nitrogen-containing substitutent in the β position are important building blocks or intermediates in the synthesis of pharmaceuticals such as β-lactams. The stereoselective construction usually required is achieved by the Mannich reaction, the conjugated addition of amines to α,β-unsaturated carbonyl compounds, and the addition of enolates or allyl metal compounds to imines.[1–6] These methods, however, do not allow access to a great number of target structures. We report here on a new synthe-

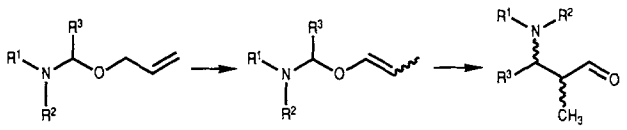
[a] All new compounds gave correct elemental analyses and suitable IR spectra (for ^1H NMR and ^{13}C NMR spectroscopic data of **3a** see Table 2). [b] Reaction temperature 70 °C; data in parentheses from reaction at 0 °C. [c] Data in parentheses: yields determined by NMR spectroscopy.

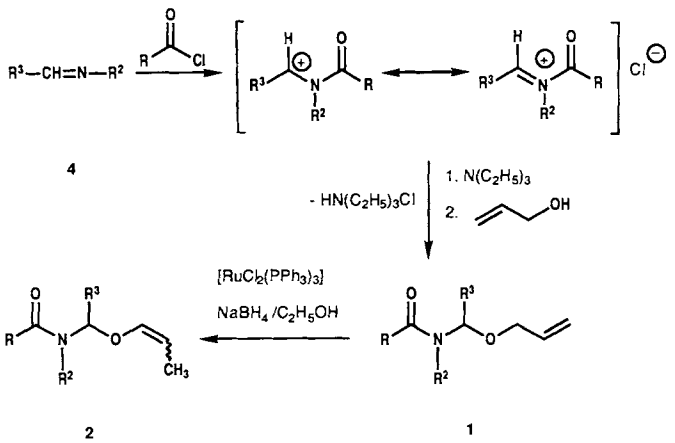
sis of chiral β-(*N*-acylamino)aldehydes which proceeds with high *syn* selectivity and requires few steps.

In recent work on the acid-catalyzed rearrangement of *N*,*O*-acetals **2** we showed that *N*,*N*-dialkyl *O*-allyl-*N*,*O*-acetals **1** (R^1,R^2 = alkyl) form aminomethylbutadienes even under the conditions for the isomerization of **1**; the Mannich products **3** are most likely the intermediates.[7] In contrast, *N*,*N*-diacylated *N*,*O*-acetals **2** (R^1,R^2 = RCO) do not undergo acid-catalyzed rearrangement.[8] Thus, monoacylated compounds **2** (R^1 = RCO, R^2 = alkyl) should be suitable starting materials with intermediate reactivity for the stereoselective synthesis of β-(*N*-acylamino)aldehydes.



1 **2** **3**

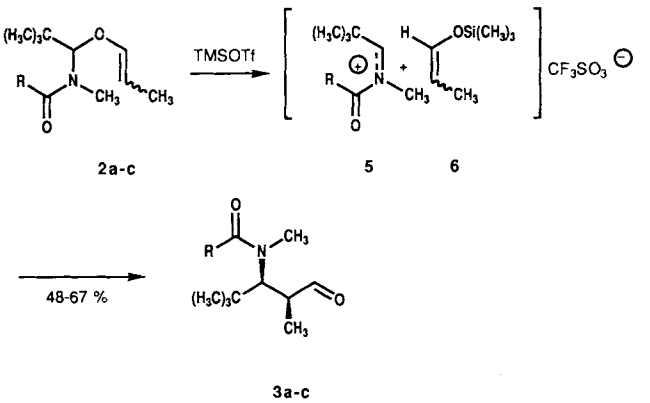
Compounds **1a**–**e** (Table 1) were prepared in a one-pot reaction by acylation of Schiff bases **4** followed by alcoholysis with allyl alcohol according to the procedure of Böhme et al.[9] Compounds **1a**–**e** were isomerized to **2a**–**e** with ruthenium hydrides generated in situ from $[RuCl_2(PPh_3)_3]$ and $NaBH_4$.[10] We observed here that in the isomerization the configuration of the double bond could be influenced by temperature (Table 1). This indicates that the catalyst induces a further *cis*–*trans* isomerization.



4

2 **1**

In the rearrangements of **2a**–**c** in the presence of trimethylsilyl trifluoromethanesulfonate TMSOTf, β-(*N*-acylamino)aldehydes **3a**–**c** were formed in 48–67% yield with high diastereoselectivity (Table 1).[11]



2a-c **5** **6**

3a-c

The relative configurations of the stereocenters formed were determined by X-ray structure analysis; compounds **3a** and **3b** are *syn* configurated (Fig. 1).[12]

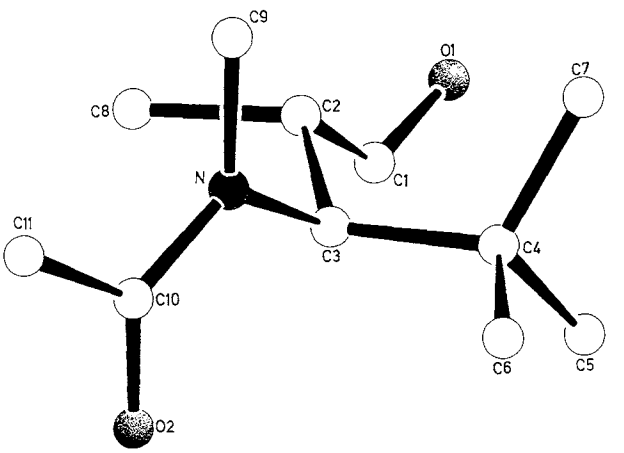


Fig. 1. Crystal structure of *syn*-**3a** (Schakal plot)[16].

The rearrangements of **2d** and **2e**, *N*,*O*-acetals of enolizable aldehydes, proceed analogously to the rearrangements of **2a**–**c** and give *syn*/*anti* mixtures of **3d** and **3e**, respectively (Table 1). Compounds **3d**,**e** were assigned to the *syn* and *anti* series, respectively, by comparison of their NMR data with that of **3a**,**b** (Table 2). In the *E* form of **3a**,**b** the protons β to the carbonyl groups and the protons of the acyl group showed large NOEs. The NMR spectra of freshly prepared solutions of **3a**, whose amide bond was proven by X-ray

3a: B.p. 74–75 °C/0.04 Torr, m.p. 55 °C. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 0.96 (s, 9H; $C(CH_3)_3$, *Z*), 0.97 (d, *J* = 6.7 Hz, 3H; $CHCH_3$, *Z*), 0.98 (s, 9H; $C(CH_3)_3$, *E*), 1.00 (d, *J* = 6.7 Hz, 3H; $CHCH_3$, *E*), 2.13 (s, 3H; H_3CC=O, *Z*), 2.21 (s, 3H; H_3CC=O, *E*), 2.65–2.78 (br, m, 1H; *CH*CHO, *Z*), 2.86–2.97 (m, 1H; *CH*CHO, *E*), 2.81 (s, 3H; NCH_3, *E*), 2.90 (s, 3H; NCH_3, *E*), 3.86 (d, *J* = 10 Hz, 1H; NCH, *E*), 4.94 (br d, *J* = 11 Hz, 1H; NCH, *Z*), 9.56 (d, *J* = 5 Hz, 1H; CHO, *Z*), 9.71 (d, *J* = 7 Hz, 1H; CHO, *E*); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 12.8 ($CHCH_3$, *Z*), 13.1 ($CHCH_3$, *E*), 21.9 (H_3CC=O, *Z*), 22.4 (H_3CC=O, *E*), 28.4 ($C(CH_3)_3$, *Z*), 28.7 ($C(CH_3)_3$, *E*), 31.0 (NCH_3, *Z*), 33.2 (NCH_3, *E*), 35.8 ($C(CH_3)_3$, *Z*), 36.6 ($C(CH_3)_3$, *E*), 46.7 (CHCHO, *E*,*Z*), 59.0 (br, NCH, *Z*), 65.4 (N-CH, *E*), 171.6 (C=O, *E*), 171.9 (C=O, *Z*), 201.4 (CHO, *E*), 202.4 (CHO, *Z*)

structure analysis to have a *Z* configuration, showed almost exclusively the *Z* form. With time, however, the rotamers attained equilibrium, at which the *E* rotamer is the minor form.

In contrast to the rearrangement of *O*-vinyl-*O*,*O*-acetals, the diastereoselectivity of the formation of **3** does not depend on the configuration of the double bond in **2**. For example, both 40:60 and 83:17 mixtures of *cis*/*trans* **2d** yielded **3d** with the same *syn*/*anti* ratio of 85:15. Pure *cis* **2b** (prepared by isomerization of **1a** with $KOC(CH_3)_3$/DMSO, 37% yield) provided the *syn* diastereomer **3b** with the same selectivity (*de* = 88%) as that obtained from 28:72 mixture of *cis* and *trans* **2b**. We presume that the rearrangement **2** → **3** proceeds intermolecularly; the mechanism is currently under investigation.

Experimental Procedure

To a solution of 30 mmol of **2** in 15 mL of CH_2Cl_2 at 0 °C under nitrogen was added dropwise the appropriate amount (Table 1) of TMSOTf. The reaction mixture was stirred for 24 h at 0 °C then poured into a cooled, saturated solution of K_2CO_3. The organic phase was removed and the aqueous phase extracted with CH_2Cl_2 (3 × 15 mL). The combined organic layers were dried over $MgSO_4$. After the solvent was removed, products **3** were isolated by distillation under reduced pressure or by recrystallization (ether/pentane = 3/1) (Table 2).

New Half-Sandwich Polysulfidorhenium Complexes

By *Max Herberhold*,* *Guo-Xin Jin*, and *Wolfgang Milius*

Many oligo- and polysulfido complexes have been synthesized during the last two decades.[1, 2] From this work it became apparent that rhenium complexes with sulfur-rich coordination spheres—similar to the molybdenum and tungsten complexes[3, 4] previously studied in more detail—could be interesting structure-chemical models for metal sulfide catalysts, for example, for hydrodesulfurization.[5] Thus, in the mononuclear Re^V ion $[ReS(S_4)_2]^-$, the monosulfido ligand is the apex and the two tetrasulfido chelate ligands are the base of a tetragonal pyramid.[5, 6] In the binuclear Re^V ion $[Re_2(S)_2(S_3)_2(S_4)_2]^{2-}$, a tetrasulfido chelate ring is coordinated to each Re atom; the formal Re–Re double bond (2.636 Å) is spanned by two monosulfido and two trisulfido bridges.[7] The highly symmetrical, tetranuclear Re^{IV} ion $[Re_4S_4(S_3)_6]^{2-}$ consists of a distorted $Re_4(\mu_3\text{-}S)_4$ cube, whose six faces are bridged with S_3 units.[6, 8] Complexes of the type $[Re_4(\mu_3\text{-}S)_4(S_3)_n(S_4)_{6-n}]^{4-}$ are also known,[9] containing both S_3 and S_4 bridges between the Re^{IV} centers.

The structural diversity of the complexes is reduced if part of the coordination sphere is blocked by the voluminous Cp* ligand (Cp* = C_5Me_5). In the following, the first two Cp*Re complexes are described, which contain exclusively sulfido ligands in the remainder of the coordination sphere.[10]

Starting from $[Cp^*Re(O)Cl_2]$ (**1**)[11, 12] two products (**2** and **3**) can be obtained by the reaction with Na_2S_4 in THF. An equimolar ratio of **1** and Na_2S_4 gives almost only the

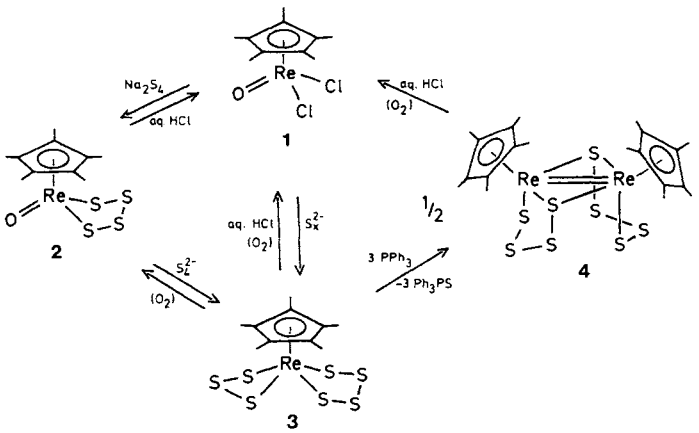
black oxo complex **2**, which had been previously prepared from **1** and $[Cp_2TiS_5]$ as the source of sulfur.[13] With increasing excess of Na_2S_4, mixtures of **2** and **3** are obtained with a rising share of **3**. The green complex **3** is formed almost quantitatively if an excess of a solution of $(NH_4)_2S_x$ ($x \approx 10$) in methanol is added. Desulfurization of **3** with triphenylphosphane leads to the black binuclear complex **4**.



X-ray structure analyses were carried out for complexes **3** and **4** (Figs 1 and 2, respectively).[25] In the mononuclear complex **3** Re^V is the center of a tetragonal pyramid; complex **3**, like **1** and **2**, is a 16-electron complex. The Re–S distances to the S_3^{2-} chelate ligands (2.301(2), 2.336(3) Å) are significantly shorter than those to the S_4^{2-} chelate ring (2.350(2), 2.395(3) Å), but still longer than those in **2** (2.244(2) and 2.264(1) Å).[13] The Cp* ring is unsymmetrically π-coordinated (Re–C distances 2.257(9)–2.443(8) Å), however, this is not unusual for mononuclear Cp*Re complexes with unsymmetrical tripodal structure.[11, 14–16]

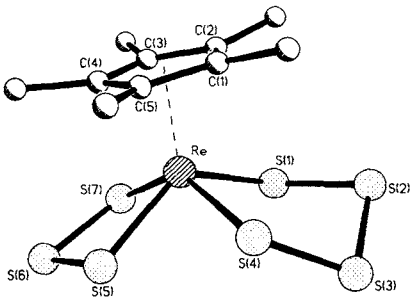


Fig. 1. Crystal structure of **3**. Selected distances [Å] and angles [°]: Re-S(1) 2.350(2), Re-S(4) 2.395(3), Re-S(5) 2.301(2), Re-S(7), 2.336(3), Re-Cp* (center) 1.993, Re-C(1) 2.406(7), Re-C(2) 2.443(8), Re-C(3) 2.330(9), Re-C(4) 2.257(9), Re-C(5) 2.276(8), S(1)-S(2) 2.090(4), S(2)-S(3) 2.010(4), S(3)-S(4) 2.083(4); S(5)-S(6) 2.042(4); S(6)-S(7) 2.054(3); S(1)-Re-S(4) 89.6(1), S(5)-Re-S(7) 75.6(1), S(1)-Re-S(7) 82.7(1); S(4)-Re-S(5) 76.5(1).

The binuclear Re^{III} complex **4** contains two S_4^{2-} chelate ligands, which are arranged so that one S atom of each ligand bridges the Re atoms (Fig. 2). In contrast to the oligosulfido chelate ligands in **2** and **3**, which are formally two-electron ligands, the S_4^{2-} ligands in **4** function as four-electron ligands. The Re–Re distance (2.618(1) Å) lies in the range for a double bond (2.38–2.65 Å);[17] thus **4** is formally an 18-electron complex. The cisoid arrangement of the two S_4^{2-} ligands in **4** causes the sulfur atoms S2 and S8 as well as S4 and S6 to approach each other to a distance of 3.369 and 3.438 Å, respectively. The corresponding rhodium compound $[Cp_2^*Rh_2S_8]$[18] is less symmetrical.

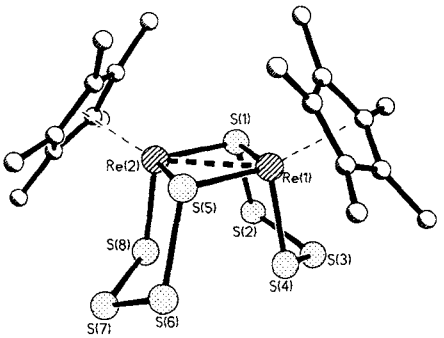

Fig. 2. Crystal structure of **4**. Selected distances [Å] and angles [°]: Re(1)-S(1) 2.283(3), Re(1)-S(4) 2.294(3), Re(1)-S(5) 2.290(2); Re(2)-S(1) 2.291(2), Re(2)-S(5) 2.266(3), Re(2)-S(8) 2.287(3); Re(1)-Re(2) 2.618(1); Re(1)-Cp* (center) 1.961, Re(2)-Cp* (center) 1.958, S(1)-S(2) 2.315(4), S(2)-S(3) 2.022(5), S(3)-S(4) 2.080(4), S(5)-S(6) 2.302(4), S(6)-S(7) 2.027(4), S(7)-S(8) 2.082(4); S(1)-Re(1)-S(5) 109.7(1), S(1)-Re(2)-S(5) 110.3(1), Re(1)-S(1)-Re(2) 69.9(1), Re(1)-S(5)-Re(2) 70.2(1).

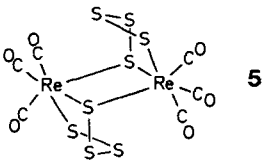
Surprisingly, there are clear differences between the structures of **4** and the formally analogous 18-electron complex $[Re_2(CO)_6(\mu\text{-}S_4)_2]^{2-}$ (**5**), formed by the action of sulfur on $[Re(CO)_5]^-$.[19] Both complex **4** with approximate C_2 symmetry and complex **5** with C_i symmetry have a planar Re_2S_2



5

center, but only in **4** exists a binding Re–Re interaction (Re=Re 2.618(1) Å in **4**, Re···Re 4.07 Å in **5**). Consequently only **5** has acute angles at the rhenium atoms (73.7(3)°).

The simultaneous coordination of a S_3^{2-} and a S_4^{2-} chelate ligand in **3** is remarkable; indications for the formation of $[Cp^*Re(S_4)_2]$ have so far not been found. Complexes with S_7^{2-} chelate ligands such as $[(PMe_3)_3M(S_7)]$ (M = Ru, Os)[20] and $[(S_7)_2Bi(\mu\text{-}S_6)Bi(S_7)_2]^{4-}$[21] are known, but are rare. The selenium analogues of the complexes **2**, **4**[22] and **5**[23] were also characterized by X-ray crystallography; they are isostructural with the corresponding sulfur complexes.

Experimental Procedure

3: A green solution of **1** (0.18 g, 0.44 mmol) [11,12] in THF (80 mL) was treated with a solution of $(NH_4)_2S_x$ ($x \approx 10$) in MeOH [24] and stirred for 4 h. After removal of the solvent, the green residue was purified by chromatography on silica gel (Merck, Kieselgel 60). S_8 was eluted with toluene/pentane (2:1), and **3** was eluted with CH_2Cl_2. Recrystallization from $CHCl_3$/hexane at −25 °C gave dark green crystals of **3** (0.23 g, 95.8%, m.p. 194 °C). IR (CsI): $\tilde{\nu}$[cm^{-1}] = 499 (μ – S_3); ^{1}H NMR ($CDCl_3$): δ = 1.90 (s, C_5Me_5); ^{13}C NMR ($CDCl_3$): δ = 11.3 ($C_5\mathit{Me}_5$), 104.4 (C_5Me_5); EI-MS (70 eV): m/z = 546 (M^+, 4%), 514 (M^+ – S, 3%), 482 (M^+ – 2S, 70%), 450 (M^+ – 3S, 14%), 418 (M^+ – 4S, 100%).

4: A solution of **3** (0.15 g, 0.27 mmol) and PPh_3 (0.29 g, 1.10 mmol) in $CHCl_3$ or CH_2Cl_2 (ca. 30 mL) was stirred for 10 h. Upon chromatography on silica gel

Ph_3PS was eluted with CH_2Cl_2, followed by **4** with CH_2Cl_2/THF (5:1). Compound **4** was slowly crystallized from CH_2Cl_2 (black prisms, 0.03 g, 24.5%, m.p. 225 C). ^1H NMR ($CDCl_3$): $\delta = 2.02$ (s, C_5Me_5); ^{13}C NMR ($CDCl_3$): $\delta = 11.5$ ($C_5\mathit{Me}_5$), 100.6 (C_5Me_5); EI-MS (70 eV): $m/z = 836$ ($M^+ - 2S$, 7%), 804 ($M^+ - 3S$, 9%), 772 ($M^+ - 4S$, 100%), 740 ($M^+ - 5S$, 30%), 708 ($M^+ - 6S$, 28%).

$[(\eta^5\text{-}CH_3C_5H_4)Mn(CO)(dppfe)]$: Two Isomers Distinguished by their Characteristic CO Stretching Frequencies, which Differ Only in Rotation of the Methylcyclopentadienyl Ligand: Evidence for an Intramolecular M–CO ··· H–C Interaction

By *Satoru Onaka,* Hiroyuki Furuta*, and *Shigeru Takagi*

The importance of C–H ··· O interactions in determining the molecular and solid-state properties of organic compounds is well known.[1–4] Hirota and Nishio recently reported that the intramolecular interaction of C–H groups with π-electron system is another important factor for the conformation of organic molecules.[5, 6] For organometallic compounds, however, we know of few papers that have suggested a C–H ··· OC–M interaction in the form of either a C–H ··· O hydrogen bond or an interaction between C–H and the π system of CO,[7] although there are a significant number of compounds in which a particular conformation is supposed to be induced by intramolecular C–H ··· OC–M interactions. Here we report a serendipitious example in which such a C–H ··· OC–M interaction is responsible for one of the conformations of a carbonyl (methylcyclopentadienyl)manganese derivative.

$[(\eta^5\text{-}CH_3C_5H_4)Mn(CO)\{[\eta^5\text{-}C_5H_4P(C_6H_5)_2]_2Fe\}]$ **1**

When we allowed crystals of the title compound **1**[8, 9] to grow from CH_2Cl_2/hexane, we found that **1** crystallizes in two different crystal forms with slightly different colors, an orange-yellow isomer (**1a**) and an orange-red isomer (**1b**). The two isomers were obtained in approximately 1:1 ratio and separated under a microscope with a needle. The orange-yellow isomer **1a** (Nujol mull) exhibits a strong ν(CO) band at 1835 m^{-1}, while the orange-red isomer **1b** (Nujol mull) exhibits a strong ν(CO) peak at 1810 cm^{-1}. The molecular structures for **1a** and **1b** are shown in Figure 1, projec-

tions of the $(\eta^5\text{-}CH_3C_5H_4)Mn(CO)P_2$ unit for these molecules along the axis through the manganese atom and the center of the methylcyclopentadiene ring in Figure 2, and a side view of this group in **1b** in Figure 3.[10] Isomer **1a** has a

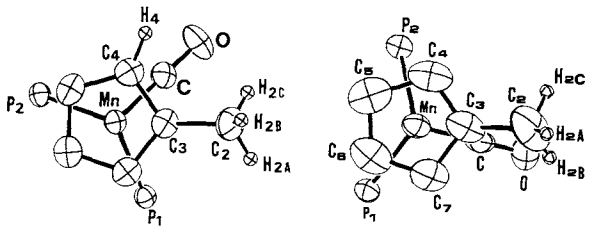

Fig. 2. Conformations of **1a** (left) and **1b** (right) in the crystal. Selected bond lengths [Å]: $C\cdots H_{2C}$ 3.06(3), $O\cdots H_{2C}$ 3.22(3), $O\cdots H4$ 3.18(3) (**1a**) and $C\cdots H_{2B}$ 2.75(9), $O\cdots H_{2B}$ 2.78(9) (**1b**).

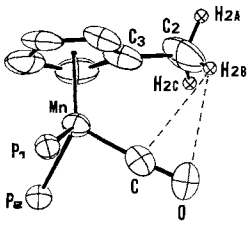

Fig. 3. Side view of the $(\eta^5\text{-}CH_3C_5H_4)Mn(CO)P_2$ unit in **1b**.

staggered conformation, while isomer **1b** is found in an eclipsed conformation.[10, 11] The distances between the CO group and the closest hydrogen atoms of the methyl substituent in **1b** are $H_{2B}\cdots C = 2.75(9)$ Å and $H_{2B}\cdots O = 2.78(9)$ Å, whereas the corresponding distance in **1a** is much longer, $H_{2C}\cdots C = 3.06(3)$ Å. The methyl hydrogen atom H_{2B} in **1b** is almost equidistant from the C and the O atoms of the CO group, consistent with the interaction of H_{2B} with the π electrons of the C≡O bond (the distance between H_{2B} and the midpoint of the C≡O bond is 2.70(9) Å). The Mn-C-O group is bent slightly toward the methyl group (∢ Mn-C-O in **1b** is 175.3(6)°). The contacts between the Cl atoms of the solvent molecule, (CH_2Cl_2) and **1** are greater than 3.0 Å in these crystals. Thus, it is unlikely that the solvent molecules and/or crystal packing forces induce the eclipsed conformation and overcome the repulsive forces normally associated.[11] Rather, the eclipsed conformation is favored over the staggered because of the C-H···OC interaction. The π-electron density of the CO group should be reduced by this largely electrostatic interaction, thus accounting for the significantly lower CO stretching frequency for the eclipsed isomer.

It is worthwhile to compare these results to those obtained for $[In\{CpMo(CO)_3\}_3]$ by Norman et al.[7] Here the canting of the CO groups in each $CpMo(CO)_3$ unit may arise from the interaction between one of the C–H bonds in the C_5H_5 group of the adjacent $CpMo(CO)_3$ unit with the CO group concerned. The C–H···CO distances reported (2.52–2.72 Å) are somewhat shorter than the range in **1b** (2.75–2.78 Å) and consistent with a similar type of interaction. However, this report lacks spectral evidence to verify the proposed interaction.

Figure 4 shows a typical IR spectrum ($\tilde{\nu}_{CO}$ region) of compounds **1** in $CHCl_3$; **1a** and **1b** afford the same $\tilde{\nu}_{CO}$ spectrum. The spectrum shows an asymmetric absorption band, which

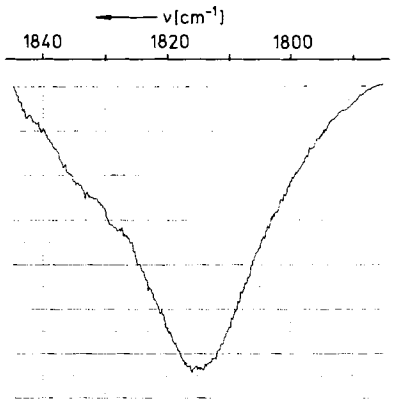

Fig. 4. IR spectrum of **1b** in $CHCl_3$ solution (ν_{CO} region).

is apparently composed of at least two bands, one around 1830 cm^{-1} and one at 1815 cm^{-1}. The former peak should arise from the staggered isomer and the latter peak from the eclipsed isomer. The existence of two conformers in solution was also demonstrated previously by temperature-dependent ^1H NMR spectroscopy.[8] Thus, the C–H···OC–M interaction is effective not only for solids but also for solutions.

Intramolecular C–H···OC–M interactions should not be overlooked in organometallic compounds when conformations of a molecule in the solid state and/or in solution or that of a reactive intermediate are analyzed. Similar interactions are quite likely to occur in the surface processes between the adsorped CO and alkanes on the catalyst.

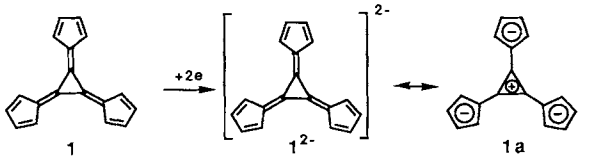
The independent reflections ($3° < 2\theta < 55°$ for **1a**; $3° < 2\theta < 45°$ for **1b**) were measured on a MAC MXC^3 diffractometer using $Mo_{K\alpha}$ radiation with $\omega - 2\theta$ scans. The structures were solved by direct methods (MULTAN 78), and all non-hydrogen atoms were refined anisotropically. The positions of all hydrogen atoms were determined from the difference Fourier map and were refined isotropically. The structural refinements were made by full-matrix least-squares method on a SUN SPARC2 workstation. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Center, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB21EW (UK), on quoting the full journal citation.
[11] It was shown previously that when compound **1** is recrystallized from $CHCl_3$/hexane, orange-red crystals (**1c**) are obtained, which contain chloroform as a solvent of crystallization [8,9]. These crystals are isomorphous with those of **1b**, and the isomer present is isostructural with that in **1b** and has the same CO stretching frequency ($\tilde{\nu}(CO) = 1810$ cm^{-1}).

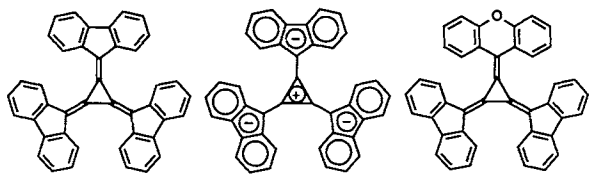
Synthesis of the Tris(9-fluorenylidene)cyclopropane Dianion and Related Dianions: [3]Radialenes with Novel Electronic Properties**

By *Masahiko Iyoda,* Hiroyuki Kurata, Masaji Oda, Chiaki Okubo*, and *Kichisuke Nishimoto**

Dedicated to Professor Emanuel Vogel on the occasion of his 65th birthday

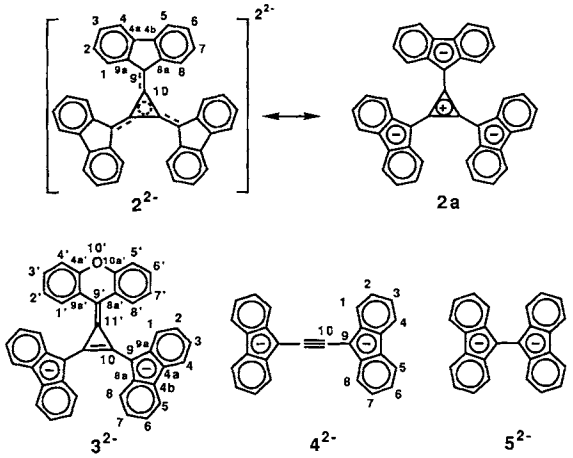
According to Hückel MO theory for cyclic polyenes, five-membered rings act as electron acceptors, while three-membered rings act as electron donors. Thus, the cyclopropenium resonance structure (**1a**) with three anionic cyclopentadienyl units can be expected to contribute to the stabilization of the dianion $\mathbf{1}^{2-}$ derived from **1**. We recently reported the synthesis of tris(9-fluorenylidene)cyclopropane (**2**)[1,2] and bis(9-fluorenylidene)-9′-xanthenylidenecyclopropane (**3**).[2] Since the [3]radialene **2** shows remarkably positive reduction potentials by cyclic voltammetry, the resonance structure **2a** can be expected to contribute considerably to the stabilization of the dianion $\mathbf{2}^{2-}$.[1]





We now describe the preparation and spectroscopic characterization of the stable dianions $\mathbf{2}^{2-}$ and $\mathbf{3}^{2-}$, together with the dianions of bis(9-fluorenylidene)ethene (**4**)[3] and 9,9′-bifluorenylidene (**5**),[4] as well as the novel electronic properties of the [3]radialenes **2** and **3** and their dianions in their ground and excited states.[5]

The sodium salts of the dianions $\mathbf{2}^{2-}$–$\mathbf{5}^{2-}$ were prepared by reduction of **2**–**5** with sodium in THF. Qualitative electronic spectra of the salts could be measured satisfactorily with degassed solutions; however, no ^{1}H and ^{13}C NMR spectra of the sodium salts of the dianions $\mathbf{2}^{2-}$–$\mathbf{4}^{2-}$ could be obtained because of their extremely poor solubility in THF. Therefore, a series of lithium salts were prepared by reduction of the corresponding hydrocarbons with lithium in [D$_8$]THF. The dianions $\mathbf{2}^{2-}$–$\mathbf{5}^{2-}$ with lithium counterions are very stable and moderately soluble in THF. They can be stored at room temperature in NMR tubes for a year without any detectable decomposition.



The ^{1}H and ^{13}C NMR data for the dianions $\mathbf{2}^{2-}$ and $\mathbf{3}^{2-}$ as well as the neutral compound **2** are summarized in Table 1.[6] The ^{1}H and ^{13}C NMR spectra of the dianions $\mathbf{4}^{2-}$ and $\mathbf{5}^{2-}$ are similar and reveal the formation of charged diatropic species. In the case of the dianion of **4**, the contribution of the resonance structure shown as $\mathbf{4}^{2-}$ is dominant. Thus, the ^{13}C NMR resonance signals of the sp hybridized carbon atoms (C10) were observed at high field (δ = 111.64) owing to their increased acetylenic character.

Table 1. ^{1}H and ^{13}C NMR data [a] of **2** and the dianions $\mathbf{2}^{2-}$ and $\mathbf{3}^{2-}$.

2: ^{1}H NMR (400 MHz): δ = 7.88 (d, ^3J(H,H) = 7.3 Hz, H-1,8), 7.42 (t, ^3J(H,H) = 7.3 Hz, H-2,7), 7.28 (d, ^3J(H,H) = 7.3 Hz, H-4,5), 7.22 (t, ^3J(H,H) = 7.3 Hz, H-3,6); ^{13}C NMR (100 MHz): δ = 140.84 (C-8a, 9a), 138.44 (*C*-4a,4b), 126.88 (*C*-3,6), 128.76 (C-2,7), 128.33 (C-4,5), 124.45 (C-10), 120.39 (C-1,8), 118.11 (C-9)

Li_2-**2**: ^{1}H NMR (400 MHz): δ = 8.24 (d, ^3J(H,H) = 7.5 Hz, H-1,8), 7.84 (d, ^3J(H,H) = 7.1 Hz, H-4,5), 6.67 (t, ^3J(H,H) = 7.0 Hz, H-2,7), 6.62 (t, ^3J(H,H) = 7.0 Hz, H-3,6); ^{13}C NMR (100 MHz): δ = 141.07 (C-8a,9a), 129.31 (C-4a,4b), 126.07 (C-10), 121.41 (C-2), 121.03 (C-1), 118.53 (C-4), 114.46 (C-3), 89.59 (C-9)

Li_2-**3**: ^{1}H NMR (400 MHz): δ = 8.00 (d, ^3J(H,H) = 7.9 Hz, H-1,8), 7.79 (d, ^3J(H,H) = 7.5 Hz, H-4,5), 7.37 (dd, ^3J(H,H) = 7.8, ^4J(H,H) = 1.5 Hz, H-4′,5′), 6.62 (t, ^3J(H,H) = 7.3 Hz, H-2,7), 6.55 (t, ^3J(H,H) = 7.1 Hz, H-3,6), 6.02 (dd, ^3J(H,H) = 7.7, ^4J(H,H) = 1.5 Hz, H-1′,8′), 5.92 (dt, ^3J(H,H) = 7.4, ^4J(H,H) = 1.5 Hz, H-2′,7′), 5.83 (dt, ^3J(H,H) = 7.4, ^4J(H,H) = 1.5 Hz, H-3′,6′); ^{13}C NMR (100 MHz): δ = 151.17 (C-4a′, 10a′), 140.79 (C-8a,9a), 134.88 (C-8a′,9a′), 128.37 (C-4a,4b), 123.45 (C-10), 123.15 (C-2′,7′), 123.07 (C-1′,8′), 120.79 (C-2,7), 120.68 (C-1,8), 119.18 (C-11′), 118.33 (C-4,5), 117.03 (C-3′,6′), 113.76 (C-3,6), 112.76 (C-4′,5′), 89.91 (C-9), 75.30 (C-9′)

[a] In [D$_8$]THF.

The ^{1}H and ^{13}C NMR data of the dianion $\mathbf{2}^{2-}$ reflect its highly symmetrical structure. Since the ^{1}H NMR signals of $\mathbf{2}^{2-}$ at δ = 6.6–8.2 are temperature independent in the range −80 to +30 °C, $\mathbf{2}^{2-}$ exists most probably in a stable, symmetric conformation with twisted bonds between the cyclopropane and fluorenylidene units (twist angle is calculated to be 30° by geometric optimization with the AM-1 program). The ^{13}C NMR chemical shifts of the fluorenylidene carbon

atoms C9 and the cyclopropane carbon atoms C10 of 2^{2-} were observed at very high and very low fields, respectively. The ^{1}H NMR spectrum of 3^{2-} is temperature dependent, as expected from the unsymmetrical charge density in the fluorene units. Thus, the spectrum at room temperature shows sets of signals for two four-spin systems, one of which is assigned to the fluorene unit and the other to the xanthene unit. However, the spectrum at $-25\,^{\circ}C$ gave very broad signals, and the spectra at lower temperatures ($< -50\,^{\circ}C$) showed well-resolved, complex sets of signals corresponding to three four-spin systems, two for the unsymmetrical fluorene unit and one for the symmetrical xanthene unit. The activation energy $\Delta G^{\neq}$ of the rotation of the fluorene units in 3^{2-} was estimated to be 12.0 kcal mol^{-1} ($-50\,^{\circ}C$).

The electronic spectra of Na_2-**2** and Na_2-**3** show a marked hypsochromic shift (150–250 nm) compared with the neutral compounds **2** and **3**. Thus, blue solutions of **2** and **3** change to red on reduction with sodium.[8] In contrast, the electronic spectra of Na_2-**4** show a remarkable bathochromic shift (300–400 nm).[8] Therefore, electronic properties of [3]radialene dianions are obviously different from those of other dianions.

In order to estimate the charge distribution in **2**–**5** and 2^{2-}–5^{2-}, MO calculations were carried out on these molecules.[9] A relatively good correlation between the calculated charge densities of **2**–**5** and 2^{2-}–5^{2-} and their ^{13}C NMR data can be derived, although ^{13}C chemical shifts are sometimes affected by other factors such as bond orders, ring current, hybridization, and steric effects.

As shown in Table 2, the calculated charge densities of **2** and 2^{2-} reflect the novel electronic properties of the [3]radialene system. The neutral **2** in the ground state (S_0) shows a marked charge separation, and positive charges at the central cyclopropane carbon atoms C10. Interestingly, these calculated positive charges in 2^{2-} remain almost unchanged in the ground state, in spite of the increase of negative charge density in the three fluorene units when **2** is converted into 2^{2-}. The distance between the carbon atoms C9 and C10 in **2** is 1.385 (observed)[10] and 1.382 Å (calculated) and in 2^{2-} 1.428 Å (calculated). Therefore, the symmetric resonance structure **2a** with charge separation makes a relatively large contribution to the stabilization of 2^{2-}.

Table 2. Calculated charge densities of **2** and 2^{2-} in the ground state (S_0) and the excited states (S_1).

Compound	Charge density [a]
2 (S_0)	+ 0.031 (1,8); + 0.012 (2,7); + 0.014 (3,6); + 0.039 (4,5); − 0.070 (4a,4b); − 0.073 (8a,9a); − 0.099 (9); + 0.192 (10)
2 (S_1)	+ 0.042 (1,8); + 0.007 (2,7); + 0.021 (3,6); + 0.047 (4,5); − 0.082 (4a,4b); − 0.074 (8a,9a); − 0.118 (9); + 0.294 (10)
2^{2-} (S_0)	− 0.030 (1,8); − 0.054 (2,7); − 0.093 (3,6); − 0.031 (4,5); − 0.073 (4a,4b); − 0.023 (8a,9a); − 0.205 (9); + 0.146 (10)
2^{2-} (S_1)	− 0.012 (1,8); − 0.075 (2,7); − 0.071 (3,6); − 0.038 (4,5); − 0.063 (4a,4b); − 0.034 (8a,9a); − 0.081 (9); + 0.002 (10)

[a] Numbers of the appropriate C atoms in parentheses.

In the excited state S_1, the calculated positive charges at the C10 carbon atoms are considerably higher in **2**. This charge transfer causes a bathochromic shift and the deep blue color of **2** in solution. The amount of charge transfer from the three-membered ring to the fluorenyl groups in **2** are calculated to be 0.58 electron for the ground state and 0.88 for the excited state. On the other hand, the calculated positive charges on the C10 carbon atoms in 2^{2-} are apparently smaller than in **2** (back charge transfer). This effect causes a hypsochromic shift and the deep red color of 2^{2-} in solution. The amount of back charge transfer from the fluorenyl groups to the three-membered ring is calculated to be 0.56 for the ground state and 0.99 for the excited state. From analogous calculations similar electronic properties can be expected for the ground and excited states of **3** and 3^{2-}.

Two Modifications of a Cyclopentadienylthallium(I) Complex Linking the Chemistry of the Cp and Arene Complexes of Main Group Elements**

By *Walter Frank*,* *Dietmar Kuhn*, *Stefan Müller-Becker*, and *Abbas Razavi*

The interactions between main group metals and aromatic π-systems have been studied primarily with cyclopentadienyl compounds; in the last few years, however, arene complexes have also received much attention.[1, 2] Are mixed π-arene-π-Cp complexes (Cp = cyclopentadienyl) also capable of existence? Coordinatively unsaturated monomeric units such as CpTl, CpSnCl, and $CpSbCl_2$ should be able to bind arenes. These building blocks are accessible only when their competing aggregation producing oligomers or polymers with bridging Cp or halide ligands is prohibited. The sole report

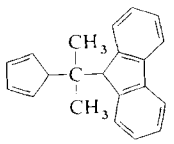
of the addition of such a compound to arenes described the reactions of the extremely thermolabile pentachlorocyclopentadienylthallium,[3] but closer examination of the bonding relationships in the adducts was not possible. In studies of (dimethylphenylsilyl)- and (benzyldimethylsilyl)-tetramethylcyclopentadienylthallium with NMR spectroscopy, the $^{203,205}Tl-^{13}C$ and $^{203,205}Tl-^{1}H$ couplings for the arene–carbon and arene–hydrogen interactions, respectively, were interpreted as indicative of an intramolecular Tl–arene interaction in solution.[4] By using the 9-(1-cyclopentadienyl-1-methylethyl)fluorenyl ligand **1**, we have succeeded in synthesizing two modifications of the Tl^{I} complex **3**, whose solid-state structures show each thallium atom to be coordinated to three aromatic systems.



1

We prepared **3** by the metathesis of the lithium derivative **2**[5] and thallium(I) chloride [Eq.(a)] and by the direct metalation of **1**-H with thallium ethoxide [Eq.(b)].[5] Method (a) provided modification **3a**, while (b) yielded modification **3b**. Single crystals of both modifications were examined by X-ray diffraction.

$$\underset{\mathbf{2}}{[C_{13}H_9C(CH_3)_2C_5H_4]Li} + TlCl \xrightarrow[LiCl]{\text{hexane}} \underset{\mathbf{3a}}{[C_{13}H_9C(CH_3)_2C_5H_4]Tl\text{-}I} \quad (a)$$

$$\underset{\mathbf{1}}{C_{13}H_9C(CH_3)_2C_5H_5} + TlOC_2H_5 \xrightarrow[C_2H_5OH]{C_6H_5CH_3} \underset{\mathbf{3b}}{[C_{13}H_9C(CH_3)_2C_5H_4]Tl\text{-}II} \quad (b)$$

The primary interaction in both modifications is a slightly distorted η^5 Tl–Cp coordination (Fig. 1) which takes up most of the binding potential of the thallium atoms according to the analysis of the Tl–C distances. In addition, two secondary contacts between thallium and the aromatic systems in both structures lead to the formation of chains (**3a**) or layers (**3b**) of coordination polymers (Fig. 2). The structure of **3a** is reminiscent of the zigzag chain arrangement found for many Tl–Cp derivatives with bridging Cp ligands.[7] In this case, however, the Cp bridge is very unsymmetrical. The coordination sphere of the Tl atoms is completed by an "intramolecular", η^3-like π-arene contact to the fluorenyl system perpendicular to the direction of the chain. No bridging Cp ligands are found in **3b**. The two layer-forming contacts here are of the Tl–arene type (η^2- and η^3-like). For the η^2-like variation a comparison to the η^5-Cp complexes having additional intramolecular η^2-Cp coordination[8] is instructive. The metal–arene distances indicate that the strength of the metal–arene interactions in both modifications lies in the middle of the known spectrum.[9] Nonclassical Tl–Tl interactions[10] can be discounted in both modifications because of the observed distances.

Both **3a** and **3b** are readily soluble in aromatic solvents. Solutions in the same solvent show the same properties. Complex **3** is monomeric in benzene, and its ^1H NMR spectrum is temperature-dependent: at low temperatures the spectrum is in accord with the atomic arrangement shown in Figure 1 (left) (point group symmetry C_1). As the temperature is increased a dynamic intramolecular process raises the observed symmetry of the molecule (C_s), and finally the

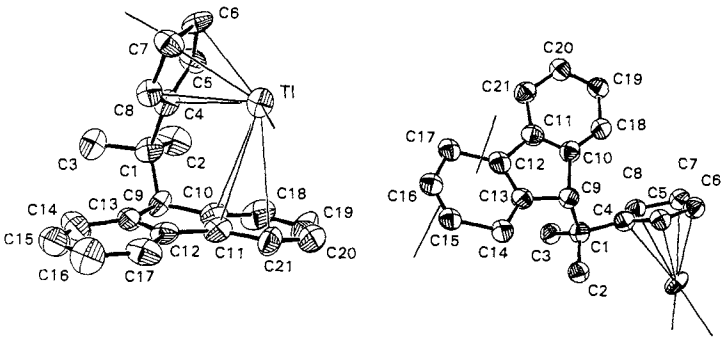


Fig. 1. Quasi-molecular units of **3a** (left) and **3b** (right). The thermal ellipsoids are drawn at the 50% level; hydrogen atoms are omitted for clarity; the directions of the subsequent linkages in the solid state are indicated. Selected distances [pm] in **3a**: Tl-C4 296.4(9), Tl-C5 295.0(8), Tl-C6 280.0(9), Tl-C7 273(1), Tl-C8 286(1), Tl-C10 350.5(8), Tl-C11 337.4(8), Tl-C21 349.2(9), Tl-C20 373(1), Tl-C19 390(1), Tl-C18 380.3(9); in **3b**: Tl-C4 284(2), Tl-C5 281(2), Tl-C6 271(2), Tl-C7 272(2), Tl-C8 275(2). The distances and angles in the $C_{21}H_{19}$ ligands have the anticipated values.

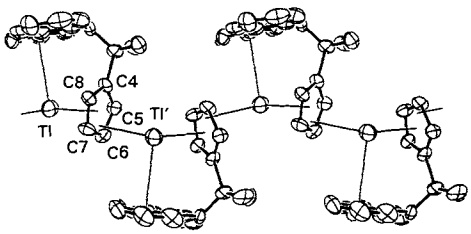

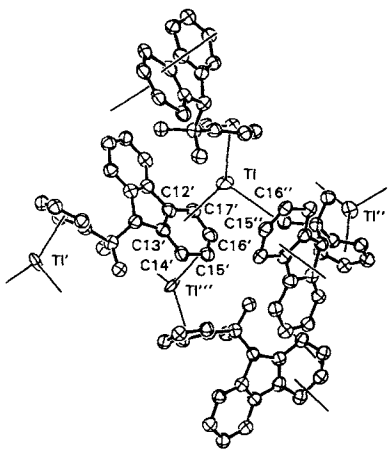

Fig. 2. The linkage of the quasi-molecular units in the crystal; a section of a polymeric chain of **3a** (top; ': 0.5−x, −0.5 + y, 0.5 + z) and of the three-dimensional network of **3b** (bottom; the four quasi-molecular units were chosen so that the complete surroundings of one Tl atom and one (fluorenyl)isopropyl-Cp fragment are visible for each compound; ': 0.5 − x, 1.5 + y, 1.5 + z, '': − x, 1 − y, 0.5 + z). Distances [pm] relevant for the linkage in **3a**: Tl-C4' 361.9(9), Tl-C5' 342(1), Tl-C6' 313(1), Tl-C7' 312.3(9), Tl-C8' 340.2(8), E(= plane)1(C4-C8)-Tl 256(1), E2(C4'-C8')-Tl 306(1), E3(C10, C11, C18-C21)-Tl 329(1); in **3b**: Tl-C12' 336(2), Tl-C13' 367(2), Tl-C14' 388(2), Tl-C15' 375(2), Tl-C16' 357(2), Tl-C17' 346(2), Tl-C15'' 345(2), Tl-C16'' 341(2), E1(C4–C8)-Tl 250(2), E2(C12'-C17')-Tl 326(2), E3(C12''-C17'')-Tl 336(2).

$^{203,205}Tl$ couplings collapse indicating metal–ligand dissociation.

In the mass spectrum (electron impact) the highest mass observed is that of the M^+ peak. The fragmentation patterns indicate that the Tl atoms do not bind exclusively to Cp in the fragmentation; fragments in which thallium is bound to

the fluorenyl system are also evident and are possibly an indication of the considerable strength of the intramolecular Tl–arene interaction in the gas phase.

Experimental Procedure

3a: A suspension of **2** (0.28 g, 1.0 mmol)[5] and TlCl (0.24 g, 1.0 mmol) in hexane (15 mL) was stirred for 24 h at room temperature. The clear, yellowish solution was filtered away from a brown precipitate. The filtrate was concentrated under high vacuum giving a solid or oily residue which was then taken up in benzene (4 mL) and stored at room temperature. Within 24 h colorless crystals of **3a** (0.220, 46%) had formed, which melt at 123 °C (decomp) and are soluble in benzene and other arenes, minimally soluble in dichloromethane, and insoluble in hexane. Correct elemental analysis. MS (EI, 70 eV): *m/z* 476 ($M^{\oplus}$, 3%), 370 ($M^{\oplus} - C_8H_{10}$, 10), 311 ($M^{\oplus} - C_{13}H_9$, 14), 205 ($Tl^{\oplus}$, 60), 165 ($C_{13}H_9^{\oplus}$, 100), 106 ($C_8H_{10}^{\oplus}$, 9), 91 ($C_7H_7^{\oplus}$, 14); molecular mass (cryoscopic, C_6H_6) 465.

3b: A solution of **1** (0.27 g, 1.0 mmol)[5] in toluene (20 mL) was added dropwise to a solution of thallium ethoxide (0.25 g, 1.0 mmol) in toluene (20 mL) at 0 °C over 1 h. The reaction mixture was then stirred for 24 h at approximately 60 °C to give a pale yellow solution above an oily sediment. When the solution was concentrated colorless crystals of **3b** formed which were washed with hexane (0.40 g, 85%). In several experiments the crystallization lasted days. The elongated crystals, readily soluble in aromatic solvents and insoluble in hexane, have an apparently metastable melting point of 97 °C (second heating 105–107 °C). Correct elemental analysis.

3a, b: ^{1}H NMR (400 MHz, [D$_8$]toluene, 193 K, TMS, all signals broad): δ = 0.66 (s, 3H; CH_3), 1.48 (s, 3H; CH_3), 4.17 (s, 1H; CH), 5.62, 5.83, 5.99, 6.74 (m, 4H; C_5H_4), 7.11–7.66 (m, 8H; arom. H); ^{1}H NMR (400 MHz, [D$_6$]toluene, 298 K, TMS): δ = 0.88 (s, 6H; $C(CH_3)_2$), 3.88 (s, 1H; CH), 5.72, 5.93 (m, 4H, J(H,Tl) ca. 28 and 21 Hz; C_5H_4), 6.80–7.33 (m, 8H; arom. H); ^{13}C{^{1}H} NMR (100.6 MHz, [D$_6$]benzene, 300 K): δ = 23.0 (C2, C3), 39.2 (C1), 60.8 (C9), 105.3 (br. s), 107.5 (C5, C8 and C6, C7), 119.7, 120.3 (br. s) (C17, C21 and C14, C18), 125.9, 126.0 (C15, C19 and C16, C20), 127.1 (br. s) (C4), 142.9, 147.0 (C10, C13 and C11, C12).

Functional Modeling of CO Dehydrogenase: Catalytic Reduction of Methylviologen by CO/H_2O with an N, O, S-Ligated Nickel Catalyst**

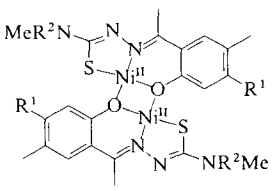
By *Zheng Lu,* Corbet White, Arnold L. Rheingold,* and *Robert H. Crabtree**

An important class of CO dehydrogenases,[1] of which that from *Clostridium thermoaceticum* (*Ct*) is the best characterized, catalyzes reaction (a), the reduction of the electron acceptor methylviologen (MV^{2+}) with CO. Essential to the

$$CO + H_2O + 2\,MV^{2+} \rightleftharpoons CO_2 + 2\,MV^{\bullet+} + 2H^+ \qquad (a)$$

enzyme is nickel, which is believed to be the site of CO binding.[2] Of the two Ni centers, one is close to and probably linked to a Fe_4S_4 cluster. CO reduces the Ni^{II} form of the protein to an EPR-active Ni^{I} form. The EPR signal for this form (g = 2.028 and 2.074) shows coupling to ^{61}Ni, ^{57}Fe, and ^{13}C (of the CO) in the isotopically labeled protein, indicating that the unpaired electron resides on the Ni, CO carbon, and Fe atoms. EXAFS data suggests the presence of a N- (or O-) and S-donor coordination sphere around Ni.[3] We have therefore been looking for Ni complexes with an N,O,S ligand environment which show catalytic activity in CO dehydrogenase (CODH) reactions. Active catalysts must bind the substrate to the metal, yet thiolato ligands tend to reduce the number of open sites and catalytic activity by forming μ-SR bridges. Thioamides are more convenient S-donors than thiolates, because they seem to be less apt to form such bridges, yet they bind in the iminothiolate ($R_2N^+{=}C{-}S^-$) form.[4]

We found that the new complex [{Ni(tmtss)}$_2$] (**1a**)



1a, R^1 = Me, R^2 = H
1b, R^1 = H, R^2 = Me

(tmtssH_2 = 2′-hydroxy-4′,5′-dimethylacetophenone-4-methylthiosemicarbazone) catalyzes the CODH reaction shown in Equation (a) with MV^{2+} as the electron acceptor. The unusual O-bridged structure **1** was assigned on the basis of a crystal structure[5] (Fig. 1) of the closely related species **1b**, which is a less active catalyst but crystallizes well.

The $MV^{\bullet+}$ formed in Eq. (a) was detected by its characteristic dark blue color (λ_{max} = 610 nm). The protons released were detected from the change in the pH of the medium during the reaction. Finally, the CO_2 formed was precipitated as $CaCO_3$ after passing the gas mixture through aqueous $Ca(OH)_2$. When the reaction was conducted with CO/$H_2{}^{18}O$/MV^{2+}/**1a**, the ν_4 and ν_5 bands (CO_3^{2-}) of the $CaCO_3$ precipitated were shifted from 872 and 710 cm^{-1} to 863 and 664 cm^{-1} resulting from ^{18}O–^{16}O substitution of the carbonate. The complex is selective for CO and does not give $MV^{\bullet+}$ with RNC or H_2. Recrystallization of **1a** caused no

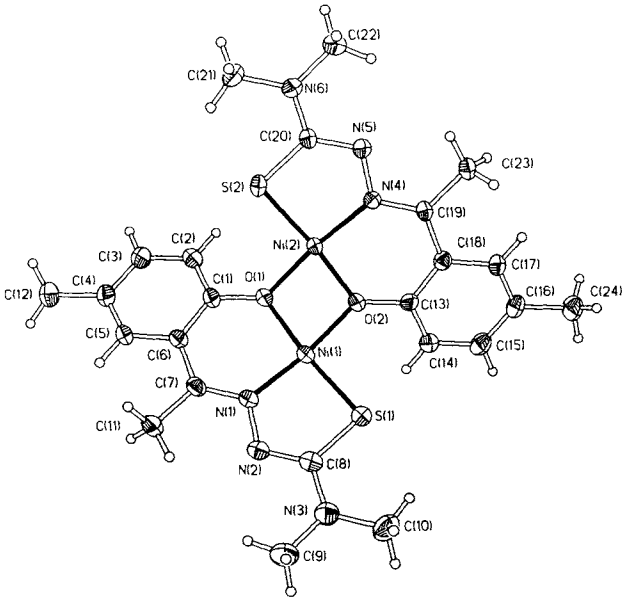

Fig. 1. Molecular structure of **1b** (ORTEP). Selected bond lengths [Å] and angles [°]: Ni(1)-Ni(2) 2.729(1), Ni(1)-O(1) 1.851(3), Ni(1)-O(2) 1.912(4), Ni(1)-N(1) 1.855(5), Ni(2)-O(1) 1.898(4), Ni(1)-S(1) 2.129(1), C(8)-S(1) 1.744(6), C(8)-N(2) 1.298(5); Ni(1)-O(2)-Ni(1) 93.0(2), O(1)-Ni(1)-O(2) 76.4. Dihedral angle Ni(1)O(1)O(2)-Ni(2)O(1)O(2), 136.9(2)°.

change in rate, and neither $NiCl_2$ nor Ni metal mediated the reaction.

The system was active even in neutral solution, but the buildup of protons stopped the process under these conditions. The enzyme was also inhibited at low pH.[1] When sodium acetate (20 mM) was used as a proton acceptor, the reaction proceeded faster. The formation of the methylviologen radical and changes in pH (Fig. 2)[6] indicated that the reaction proceeds steadily at 1.0 turnovers per hour at 25 °C.

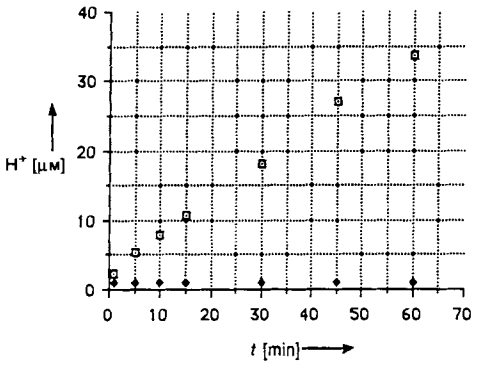

Fig. 2. Release of H^+ in the reduction of MV^{2+} by CO/H_2O with (□) and without (●) catalyst **1a**. [6].

The rate is first order with respect to Ni. Like the enzyme,[1] this system was inhibited both by CN^- (inhibited rate: $3.0 \times 10^{-2}\ h^{-1}$ with 2.5 mM CN^-) and by MeI ($0.78\ h^{-1}$ with 50 mM MeI). This appears to be the first complex to mediate the CODH reaction of Equation (a); stoichiometric model reactions related to the acetylCoA synthase activity of the enzyme have been studied by Holm et al.[7] The water-gas shift reaction, in which CO/H_2O gives CO_2 and H_2, is well known, but not with Ni^{II} as catalyst.[8]

CO reacted with **1a** in CH_2Cl_2 to give a paramagnetic complex **2**, which has an EPR spectrum (Fig. 3, $g_{x,y} = 2.29$, $g_z = 2.05$) consistent with a Ni^I metal center. In the absence of MV^{2+}, Ni^{II} therefore acts as electron acceptor. Complex **2** has so far proved too unstable for a crystal structure to be obtained.

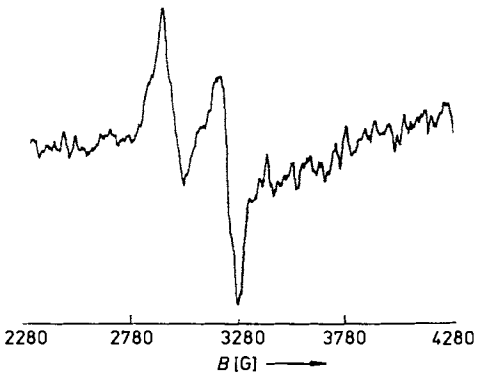

Fig. 3. X band EPR spectrum ($\nu = 9.0519$ GHz) of a frozen solution (5.6 K) of **2**.

The reaction of CN^- and **1a** gave **3**, which has an IR band at 2118 cm^{-1} (νCN) appropriate[9] for a terminal cyanide ligand. CN^- is more resistant to nucleophilic attack than CO, and this may be what allowed us to isolate **3**. The carbonyl analogue of **3**, [Ni^{II}(CO)(tmtss)], could not be prepared or observed spectroscopically, but may be a reactive intermediate in the CO reaction.

$Na[Ni^{II}(CN)(tmtss)]$ **3**

The characteristic blue color of $MV^{\bullet+}$ makes the system a selective sensor for CO when the reaction is conducted under anaerobic conditions as above. Since $MV^{\bullet+}$ is rapidly reoxidized by air to MV^{2+} and the catalyst is not air-sensitive, the acetate-buffered system can be run aerobically for catalytic air oxidation of CO to CO_2 (0.94 turnovers h^{-1}).

Experimental Procedure

$tmtssH_2$: 2'-Hydroxy-4',5'-dimethylacetophenone (1.64 g, 0.01 mol) readily condensed with 4-methylthiosemicarbazide (1.05 g, 0.01 mol) in ethanol (25 mL). Yield 69%, correct C,H,N analysis. ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 10.50$ (s, 1H; OH), 8.59 (s, 1H; NH), 7.18 (s, 1H; C_6H_2), 6.78 (s, 2H; NH, C_6H_2), 3.25 (d, 3H; CH_3), 2.36 (s, 3H; CH_3), 2.24 (s, 3H; CH_3), 2.21 (s, 3H; CH_3).

1a: To a stirred suspension of $tmtssH_2$ (0.5 g, 2 mmol) in ethanol (20 mL) was slowly added a solution of nickel acetate (0.496 g, 2 mmol) in ethanol (20 mL). After 2 h at reflux, a brownish precipitate was filtered off, washed with cold ethanol, and dried in vacuo. Yield 0.549 g, 89%, correct C,H, analysis. The complex can be recrystallized from CH_2Cl_2/Et_2O. ^{1}H NMR (250 MHz, [D_6]DMSO): $\delta = 7.21$ (s, 1H; C_6H_2), 6.55 (s, 2H; NH, C_6H_2), 2.59 (d, 3H; CH_3), 2.40 (s, 3H; CH_3), 2.11 (s, 3H; CH_3), 2.07 (s, 3H; CH_3). **1b** was prepared analogously.

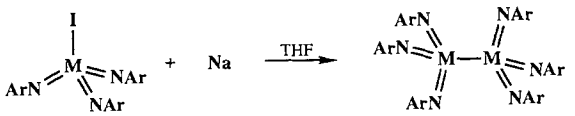
Synthesis and Structure of the First Homoleptic Imidotechnetium Complex: $[Tc_2(NAr)_6]$ (Ar = 2,6-diisopropylphenyl)**

By *Anthony K. Burrell* and *Jeffrey C. Bryan**

Transition metal complexes containing only imido ligands are currently known for niobium, rhenium, osmium, and the Group 6 metals.[1-3] An example especially pertinent to this work is the complex $[Re_2(NtBu)_4(\mu\text{-}NtBu)_2]$, which is formed by reduction of $[Re(NtBu)_3(OSiMe_3)]$ with sodium amalgam.[2] $[Re_2(NtBu)_4(\mu\text{-}NtBu)_2]$ is an edge-bridged tetrahedral dimer, similar to all other structurally characterized M_2E_6 complexes (where E stands for dianionic ligands such as N*t*Bu, S, Se, which form multiple bonds to the metal center).[2-4] We report here the first homoleptic imidotechnetium complex $[Tc_2(NAr)_6]$ (**1**, Ar = 2,6-diisopropylphenyl), which adopts an unprecedented "ethanelike" structure.

Tetrahydrofuran solutions of $[Tc(NAr)_3I]$[5] react quickly at room temperature with sodium metal to form $[Tc_2(NAr)_6]$ (**1**) in high yield (Scheme 1, M = Tc). Complex **1** does not



M = Tc, Re
Ar = 2,6-*i*Pr$_2$C$_6$H$_3$

1, M = Tc

Scheme 1. Synthesis of **1**. The analogous Re complex appears to be accessible by the same route.

react with iodine at room temperature to re-form $[Tc(NAr)_3I]$; **1** is air-stable in solution and can be purified on a silica gel column. The ^{1}H NMR spectrum of **1** shows only one set of resonances for the aryl groups, suggesting that all the imido ligands in **1** are chemically equivalent.

X-ray structure analysis of a single crystal of **1**, grown by slow evaporation of a THF/$(Me_3Si)_2O$ solution, reveals an ethanelike structure (Fig. 1).[6] The two Tc atoms are joined

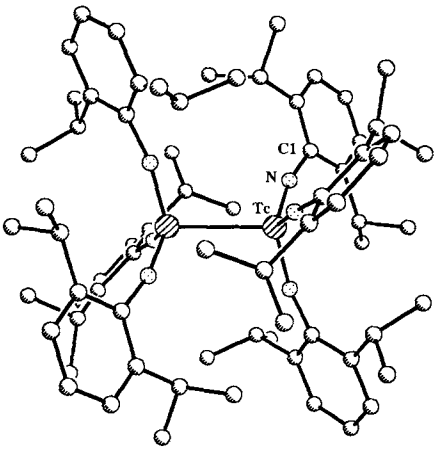


Fig. 1. Crystal structure of $[Tc_2(NAr)_6]$ (**1**). Selected bond angles [°] for **1**, not already mentioned in the text: N–Tc–Tc(A) = 103.6(1), N–Tc–N(A) = 114.6(1).

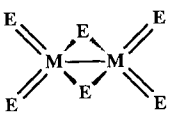
by an unbridged metal–metal bond, and all six imido ligands are terminally bound, three to each technetium. The Tc–Tc bond lies on a crystallographic S_6 axis making all six imido ligands symmetry equivalent, and requiring a staggered arrangement. If the imido ligands in **1** are counted as dianionic,[7] the Tc atoms can be considered formally to be in the oxidation state +VI. The Tc–Tc bond length of 2.744(1) Å could then only be considered a single bond, consistent with the formulation of **1** as a d^1–d^1 dimer and the diamagnetic behavior of the complex. The Tc–Tc bond is longer than known single bond lengths for Tc^{VI}–Tc^{VI} dimers;[8] this may be due to the sterically demanding Ar groups of the imido ligands. The short Tc–N distances of 1.758(2) Å, and the nearly linear Tc–N–C angles of [167.6(3)°] are consistent with strong multiple bonding between the Tc atom and the imido ligands.[7]

All previous examples of structurally characterized M_2E_6 complexes are edge-bridged tetrahedral dimers with sterically less demanding ligands such as S, Se, and N*t*Bu (Scheme 2).[2-4] Simple molecular mechanics calculations[9] on $[Tc_2(NAr)_6]$ clearly indicate that the observed ethanelike structure is strongly preferred over the dimeric configuration of edge-bridged tetrahedra.



Scheme 2. M_2E_6 complexes which can be considered edge-bridged tetrahedral dimers.

This preference has been extensively demonstrated for M_2X_6 complexes, where X is a *mono*anionic ligand; they adopt a dimeric structure of edge-bridged tetrahedra for nonbulky X ligands and an ethanelike structure for bulky X ligands.[10] Since $[Re_2(NtBu)_4(\mu\text{-}NtBu)_2]$ adopts an edge-bridged tetrahedral dimer structure, we attempted to prepare $[Tc_2(NtBu)_4(\mu\text{-}NtBu)_2]$, without immediate success. However, preliminary work indicates that reduction of [Re-

$(NAr)_3I]$[11] with sodium gives ethanelike $[Re_2(NAr)_6]$ in good yield (Scheme 1, M = Re).[12] These results suggest that steric factors determine the structure of the M_2E_6 complexes.

Experimental Procedure

Caution: The isotope ^{99}Tc used in the synthesis is a low-energy β emitter (E_{max} = 0.29 MeV) with a very long half life (2.1×10^5 years) and without nuclide-specific γ radiation. All preparative procedures were carried out in a glove box.

$[TcI(NAr)_3]$: Iodotrimethylsilane (0.6 mL, 0.42 mmol) was added to a solution of $[Tc(OSiMe_3)(NAr)_3]$ (100 mg, 0.14 mmol) in toluene (15 mL). The mixture was stirred for approximately 1 h, after which the solvent was removed in vacuo. The residue was then extracted with hot $(Me_3Si)_2O$ (15 mL) and filtered through Celite. The solution was cooled at -40 °C for 12 h and then filtered to give the product as a dark green solid (97 mg, 92%). ^{1}H NMR (250 MHz, C_6D_6, 25 °C): δ = 6.97 (m, 9H; ArH), 3.72 (hep, ^3J(H,H) = 6.8 Hz, 6H; CH), 1.09 (d, ^3J(H,H) = 6.8 Hz, 36H; CH_3). Correct elemental analyses (C,H,N).

1: Na (3 mg, 0.13 mmol) was added to a solution of $[TcI(NAr)_3]$ (100 mg, 0.13 mmol) in THF (15 mL). The mixture was stirred for approximately 3 h, after which the solvent was removed in vacuo. The residue was then extracted with $(Me_3Si)_2O$ (15 mL) and filtered through Celite. Evaporation of the $(Me_3Si)_2O$ gave the product as a green solid. Compound **1** was then purified by column chromatography with silica gel by using hexane:toluene (9:1) as eluent. ^{1}H NMR (250 MHz, C_6D_6, 25 °C): δ = 6.97 (m, 18H; ArH), 3.94 (hep, ^3J(H,H) = 7.5 Hz, 12H; CH), 1.08 (d, ^3J(H,H) = 7.5 Hz, 72H; CH_3); ^{13}C NMR (62.8 MHz, CD_2Cl_2, 25 °C): δ = 144.3 (NC), 128.1 (Ar), 126.8 (Ar), 123.5 (Ar), 28.3 (CH), 24.0 (CH_3). Correct elemental analysis (C,H,N).

[12] The fact that NAr is "less prone to bridge between metals than, for example, a *tert*-butylimido ligand" has been previously observed [1a].

Synthesis and Reactivity of $Me_2P(ZrCp_2Cl)$=NAr, the First Iminozirconiophosphorane, a Masked Iminophosphide**

By *Alain Igau, Nathalie Dufour, Armelle Mahieu,* and *Jean-Pierre Majoral**

Little is known about the interactions of derivatives of unsaturated main group elements and Group 4 metallocenes.[1, 2] We recently investigated the reactivity of phosphaalkenes and iminophosphanes towards the Schwartz reagents $[Cp_2ZrHCl]$,[3, 4] $[Cp_2ZrH_2]$,[4] and $[Cp_2ZrMe_2]$.[4] We now report the surprising synthesis of the first linear *P*-metalated iminophosphorane **3** by carbometalation of the chloroiminophosphane ClP=NAr (**1**, Ar = 2,4,5-*t*Bu$_3$-C_6H_2).[5, 6] Up to now only *N*-metalated iminophosphoranes were prepared because of the strong polarization of the phosphorus–nitrogen double bond of compounds of type R_3P=NR'. From the preliminary studies on the reactivity of **3** we found an unprecedented insertion reaction of nitriles into the phosphorus–zirconium bond.

The chloroiminophosphane **1**, and $[Cp_2ZrMe_2]$, (**2**) were allowed to react in pentane at -40 °C. After workup of the reaction mixture, **3** was isolated as a white powder in 85% yield (Scheme 1). Compound **3** was identified by NMR spectroscopy (Table 1). The ^{1}H NMR signal of Cp protons appeared as a doublet with a coupling constant $^3J_{P,H}$ = 1.4 Hz, consistent with a Cp-Zr-P skeleton. The two methyl groups are bonded to the phosphorus atom, as illustrated by the ^{1}H (only one doublet for the two methyl groups, $^2J_{H,P}$ = 6.3 Hz), ^{13}C (also one doublet, $^1J_{C,P}$ = 11.1 Hz), and ^{31}P NMR spectra (doublet of septet, $^2J_{P,H}$ = 6.3 Hz, $^3J_{P,Cp(H)}$ = 1.4 Hz). The formation of **3** might involve the transient intermediate **4**, which rearranges by migration of the chlorine atom and the methyl group at the zirconium.[7] In solution at room temperature **3** afforded the phosphane **5** quantitatively (the migration of $ZrCp_2Cl$ moieties from the phosphorus to the nitrogen atom gives the thermodynamically favored product **5**, Scheme 1). Compound **5** was characterized by NMR spectroscopy: the ^{31}P NMR chemical shift of **5** was in the expected range; the Cp protons appeared as a singlet, and no coupling with the phosphorus atom was observed. Addition of pyridine or PMe_3 to **3** gave **5** instantaneously. In the presence of proton donors (solvent, traces of water), the Zr–N bond in **5** was cleaved to form **6** quantitatively (Scheme 1).

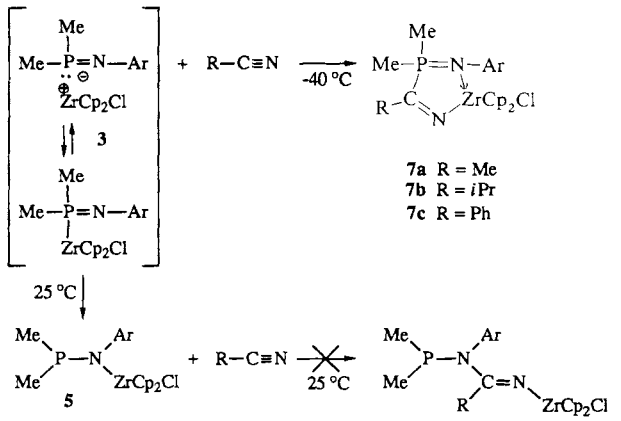
[a] All NMR spectra were recorded on a Bruker AC 200. Standards: $\delta(^{31}P)$: 85% H_3PO_4 external; $\delta(^1H, ^{13}C)$: $(CH_3)_4Si$ external.

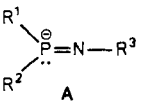
The *P*-metalated iminophosphorane **3** was allowed to react with 1.1 equivalents of acetonitrile in CH_2Cl_2 at −40 °C. The iminophosphorane **7a** was formed instantaneously (Scheme 2) by the insertion of MeC≡N into the P–Zr bond. The presence of a third methyl group in **7a** was clearly evident from the ^1H and ^{13}C NMR spectra. In the ^1H NMR spectrum the C–Me group appeared as a doublet at $\delta = 1.70$ ($^3J_{H,P} = 0.9$ Hz) and in the $^{13}C\{^1H\}$ NMR spectrum as a singlet at $\delta = 28.3$. The signal of the imino C atom can also be observed at characteristically low field ($\delta = 165.0$, $^2J_{C,P} = 14.4$ Hz).

The formation of **7a** favored a linear rather than a cyclic structure for **3**, since the azaphosphazirconacyclopropane $[Cp_2Zr(Cl)N(SiMe_3)P(H)N(SiMe_3)_2]$[3] is inert toward nitriles. Other nitriles were treated with **3** under the same conditions. Addition of *i*PrC≡N or PhC≡N to **3** gave the expected insertion products **7b** and **7c**, respectively (Scheme 2). The iminophosphorane **3** reacted formally like an iminophosphide of type **A**, a species never observed until now.[8]

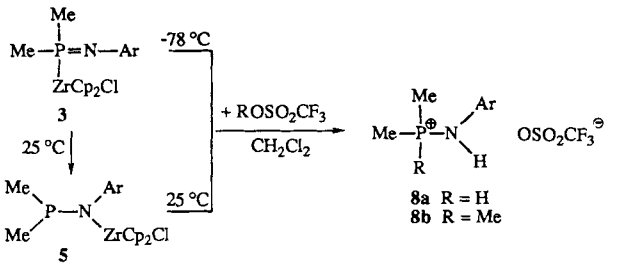


Scheme 2. Reactivity of **3** and **5** toward nitriles.

In marked contrast **5** did not react even with an excess of acetonitrile at room temperature. If **3** is treated with trifluoromethanesulfonic acid or its methylester at −78 °C, the



phosphonium compounds **8a** and **8b**, respectively, were obtained in quantitative yield (Scheme 3).



Scheme 3. Reactivity of **3** and **5** toward trifluoromethanesulfonic acid and its methyl ester.

Compounds **8a** and **8b** were also formed by treating **5** with the same reagents (Scheme 3). Like PMe_3 and pyridine ligands, the trifluoromethanesulfonic anion may act as a catalyst for the rearrangement of **3** to **5**. Electrophilic attack of R^+ (H^+, Me^+) at the phosphorus center of **5** followed by cleavage of the Zr–N bond might give rise to the quantitative formation of **8**.

We are currently attempting to determine the scope of the reactions in which **3** reacts as a *P*-metalated iminophosphorane and **5** as a aminozirconiophosphane.

Experimental Procedure

All manipulations were performed in an inert argon atmosphere.

Isolation of **3**: To a solution of **1** (0.326 g, 1.0 mmol) in pentane (10 mL) cooled to −40 °C was added **2** (0.251 g, 1.00 mmol) in pentane (10 ml) at −40 °C. The mixture was stirred for 30 min, after which a white precipitate separated from the solution. The white powder was washed twice with pentane (10 mL, −40 °C), and dried under vacuum. This afforded **3** (0.491 g, 0.850 mmol) in 85% yield.

Decomposition of **3**: A solution of **3** (0.200 g, 0.346 mmol) in CH_2Cl_2 (15 mL) was stirred at room temperature for 4 h, which after removal of the solvent gave a white powder **5** (0.200 g, 0.346 mmol) in quantitative yield. Attempts to iso-

late **5** by treatment of the residue with pentane and THF, gave a mixture of **5** and the phosphane **6**.

Reaction of **3** with nitriles (typical experiment for the isolation of **7a** and **7b**): CH_3CN (10 mL) cooled to −30 °C was added to **3** (0.288 g, 0.50 mmol) through a canula. The reaction mixture was stirred at −40 °C for 1 h, after which a white precipitate separated from the solution. The white powder was washed twice with CH_3CN (10 mL, −30 °C) and pentane (2 × 10 mL), then dried to afford **7a** (0.263 g, 0.425 mmol) in 85% yield.

Typical reaction of **3** with trifluoromethanesulfonic acid: To a solution of **3** (0.577 g, 1.00 mmol) in CH_2Cl_2 (10 mL) cooled to −78 °C was added $HO-SO_2CF_3$ (0.150 mL, 1.00 mmol). The reaction mixture was allowed to warm to room temperature over 30 min. Removal of the solvent gave a white paste. Extraction with pentane (3 × 10 mL) afforded **8a** (0.319 g, 0.98 mmol) as a white powder in nearly quantitative yield.

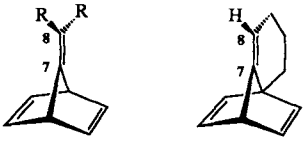
1,7-Cyclopentenonorbornadiene: Synthesis and Crystal structure**

By *Axel G. Griesbeck,* Thomas Deufel, Karl Peters, Eva-Maria Peters,* and *Hans Georg von Schnering*

Homoconjugative effects[1] are regarded as the reason for the considerable differences in the shifts $\Delta\delta$ of C7 and C8 in the ^{13}C NMR spectra of 7-alkylidenenorbornadienes.[2] Thus, the parent compound 7-methylenenorbornadiene (**1**) shows a resonance signal at $\delta = 177.1$ for C7 and at $\delta = 78.5$ for C8 ($\Delta\delta = 98.6$).[3] In addition, photoelectron spectroscopic results[4] and the peculiar reactivity[5] of analogous compounds indicate an additional interaction between the endocyclic double bonds and the exocyclic double bond.

Paquette and Racheria prepared the 1,7-cyclohexeno-annelated derivative **2**, which also exhibits a considerable low-field shift $\delta(C7) = 170.9$ ($\Delta\delta = 81.8$).[6] We have now synthesized lower homologues by cycloaddition to a 1,3-disubstituted 1,2-dihydropentalene.



1 (R=H) **3** (R=Me) **2**

Compound **4**, prepared in a one-step reaction from benzylideneacetone,[7] behaves nonuniformly towards dienophiles, in contrast to the 1,5-dihydro- and tetrahydropentalenes[8] derived from it. Like 1,2-dihydropentalene itself,[9] alkene–dienophiles react with **4** to give mixtures of [2 + 2] and [4 + 2] adducts.[10] A markedly higher periselectivity was observed with alkyne–dienophiles. Thus, the reaction of **4** with dimethylacetylenedicarboxylate (after 24 h at 65 °C), followed by chromatographic purification, gave the desired [4 + 2] adduct **5** in 62% yield (Scheme 1).

Scheme 1. E = COOMe

In **5**, as for the known 7-alkylidenenorbornadienes, the ^{13}C NMR signal of C7 is also shifted to low field $\delta = 161.8$; the resonance signal of C8 occurs at $\delta = 103.3$ ($\Delta\delta = 58.5$). In comparison with the cyclohexeno-annelated norbornadiene **2**, the higher homologue, this shift effect is, however, markedly reduced. This is due to the higher degree of substitution at C8, and the electronic effects of the ester groups at C1 and C2. The crystal structure of **5**[11] is shown in Figure 1.

For all cycloadditions to **4** only one diastereomer was formed. Apparently, the phenyl substituent at C1 directs the attack of the dienophile in all cases so that it occurs highly selectively from the opposite side of the molecule, as revealed by the crystal structure analysis of **5**.

The structural parameters are particularly interesting since they can indicate homoconjugative stabilization. However, neither the endocyclic double bonds C2–C3 and C5–C6 (134 and 133 pm, respectively) nor the C7–C8 double bond (131.5 pm) show notable deviations from the corresponding values in norbornene skeletons. According to NMR spectroscopic data, the highly polarized double bond C7–C8 is slightly compressed and not stretched, as expected for a high degree of polarization. The side bonds of the norbornadiene framework are relatively long (average length 155.5 pm)[12] and indicate a high strain within the molecule. This is also evident from the significant distortion of the angle at C7: $\sphericalangle$ C1-C7-C4 = 97.4 and $\sphericalangle$ C4-C7-C8 = 148.2°.

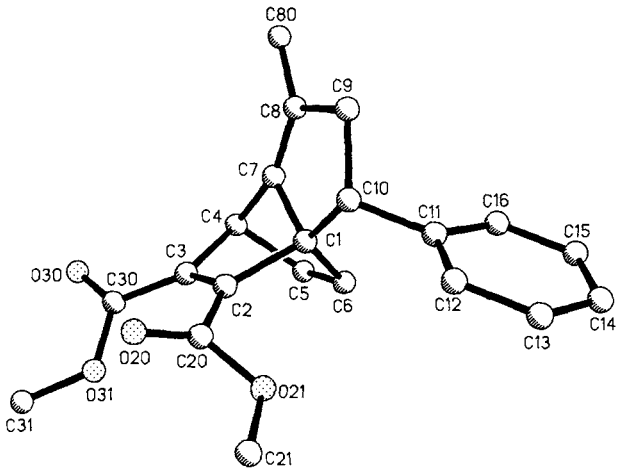

Fig. 1. Crystal structure of **5**. Selected distances [pm] and angles [ ]: C1-C2 155.9(4), C2-C3 134.2(4), C3-C4 155.9(4), C4-C5 155.5(4), C5-C6 132.9(5), C1-C6 155.0(5), C1-C7 151.6(4), C4-C7 151.8(5), C7-C8 131.5(4), C8-C9 151.7(4); C2-C1-C6 104.7(2), C3-C4-C6 104.8(2), C1-C7-C4 97.4(2), C1-C7-C8 114.1(3), C4-C7-C8 148.2(3).

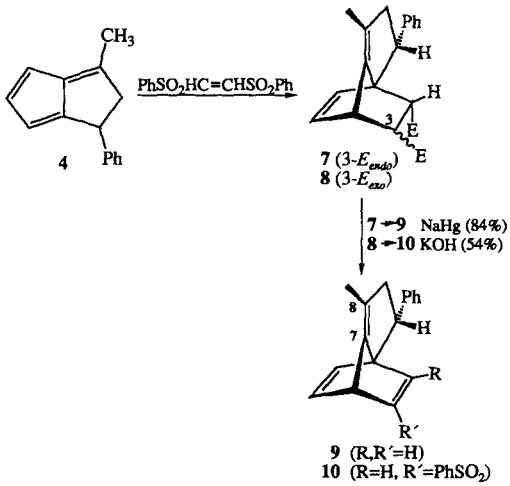
The acetophenone-sensitized irradiation of **5** in pentane affords quantitatively the quadricyclane **6**. The above-mentioned peculiarities for the C7–C8 double bond in the ^{13}C NMR spectrum have disappeared in **6** as expected; the shifts of C7 ($\delta = 144.1$) and C8 ($\delta = 127.3$) are within the range of the values for normal endocyclic double bonds. Since ester

functions at C2 and C3 of 7-alkylidenenorbornadienes reduce the extent of the homoconjugation (again interpreted from the NMR values),[13] we prepared the derivative **9**, which is unsubstituted at the C atoms 2, 3, 5, and 6. For this, **4** was treated with both (*Z*)- and (*E*)-1,2-bis(phenylsulfonyl)ethylene.[14] The cycloaddition with the (*E*)-dienophile was complete after 6 h, in contrast, with the (*Z*)-dienophile this required 48 h. Both cycloadducts were obtained in the diastereomeric pure form, that is, the addition of (*Z*)-1,2-bis(phenylsulfonyl)ethylene led exclusively to the *endo* product **7**, whereas from the reaction with (E)-1,2-bis(phenylsulfonyl)ethylene **8** is formed, in which the phenylsulfonyl group in the neighborhood of the annelated five-membered ring is directed selectively into the *endo* position (Scheme 2).



Scheme 2. E = $PhSO_2$

From the adduct **7**, reductive elimination with sodium amalgam led to the norbornadiene **9** in 84% yield. In the ^{13}C NMR spectrum, the signals for C7 ($\delta = 165.7$) and C8 ($\delta = 96.8$) are now even more clearly separated ($\Delta\delta = 68.9$), the bridgehead atom C1 is again markedly shifted to high field $\delta = 78.3$. However, if these values are compared with those of 7-isopropylidenenorbornadiene (**3**) (δ(C7) = 165.6, δ(C8) = 94.2, $\Delta\delta = 71.4$[13]), the additional annelation seems to have only a marginal effect on the polarization of this bond.

The 3-phenylsulfonyl-substituted norbornadiene **10** could (in addition to ca. 40% of the 2-isomer) be synthesized from **8** by KOH-assisted elimination. The resonance signals for C7 and C8 in this case are approximately the same as for compound **5**: $\delta = 161.8$ for C7 and $\delta = 102.9$ for C8 ($\Delta\delta = 58.9$).

1,7-cyclopentenonorbornadienes can be easily constructed according to the synthetic method described here. These compounds exhibit, analogous to the previously described homologous 1,7-cyclohexeno-annelated derivatives,[6] a strongly polarized C7–C8 double bond. However, no indications of homoconjugative effects can be derived from the structural parameters (compound **5**) given here for the first time.

Pentafluorophenylxenon(II) Pentafluorobenzoate: the First Preparative Synthesis and Structural Characterization of an Acyloxy Compound of Xenon(II)**

By *Hermann Josef Frohn,* Angela Klose*, and *Gerald Henkel*

Covalent xenon(II)–oxygen compounds of the type XO–Xe–OX and F–Xe–OX have been described previously.[1] These compounds are stable up to 130 °C when X = TeF_5 and SeF_5, while for X = SO_2F, ClO_3, IOF_4,[2] POF_2, and SO_2CF_3, the upper limit of their thermal stability generally lies below room temperature, and the compounds are explosive. All previous attempts to isolate xenon(II) carboxylates of the type RCO_2–Xe–O_2CR or F–Xe–O_2CR and to characterize them unequivocally by spectroscopy were unsuccessful.[3, 4] We report here the first spectroscopically and structurally characterized xenon(II) carboxylate, C_6F_5–Xe–$O_2CC_6F_5$ (**3**); this compound decomposes exothermically at 85 ± 3 °C.

It has often been suggested both in textbooks and in the literature that only the most electronegative ligands can bond to xenon.[3d, 5] However, we have observed that the xenon(II) carboxylate of the type R–Xe–O_2CR, which we have now prepared, is more stable than the known compounds of the type F–Xe–O_2CR. Thus, F–Xe–O_2CCF_3 is a kinetically unstable compound which detonates readily[3e] and has a half-life of only 10–12 h at room temperature,[3c, 3d] while **3** does not decompose even after 5 days at room temperature.

Our isolation[6] of arylxenon salts with $[C_6F_5Xe]^+$ as the cation[7] and weakly polarizable complex fluorides $[EF_n]^-$ as counterions has provided the basis for a route to new arylxenon compounds with a polar covalent bond, which proceeds by ligand exchange in water(!). Using this principle, **1** was treated with the cesium salt **2** to give the title compound **3** in 80% yield [Eq. (a)]. The compound **3** is insoluble in water but soluble in CH_2Cl_2 and MeCN; as a solid it has an almost unlimited stability at room temperature. In CH_2Cl_2 **3** shows no sign of decomposition after seven days at −45 °C, while at room temperature decomposition takes place within a few hours ($T_{1/2} \approx 3$ h at 35 °C). A CIDNP (chemically induced dynamic nuclear polarization) effect is observed during its slow decomposition at 35 °C in MeCN: the ^{19}F NMR signal of a decomposition product (*o*-F of a C_6F_5 group) is detected at $\delta = -139.4$ as an emission signal (negative peak with increased intensity). The occurrence of this CIDNP effect demonstrates that a radical intermediate of fluoroaromatic nature is formed during the decomposition. The main decomposition product is the ester $C_6F_5CO_2C_6F_5$.

$$[C_6F_5Xe][AsF_6] + Cs[O_2CC_6F_5] \longrightarrow C_6F_5XeO_2CC_6F_5 \quad (a)$$
1 **2** **3**

The xenon compound **3** exists in a covalent form with a strongly polarized Xe–O bond in solution and in the solid state. Both the solubility of **3** in the noncoordinating solvent CH_2Cl_2 (**1** and all previously known salts with an arylxenon cation are completely insoluble in this solvent) and the results from NMR spectroscopy (in particular ^{19}F NMR data) indicate that it cannot be described by the ionic form $[C_6F_5Xe]^+[O_2CC_6F_5]^-$. While in MeCN the cation of **1** exists in the solvated form $[MeCN\cdots XeC_6F_5]^+_{solv}$, that is, coordinated in a manner analogous to that observed in the crystal,[6b] and has a coupling constant $^3J_{Xe,F}$ of 67.2 ± 0.5 Hz, the value of this coupling for **3** in MeCN is 84.0 ± 0.5 Hz. In addition the $^3J_{Xe,F}$ coupling constant for **3** is almost identical in MeCN and CH_2Cl_2, thus **3** must exist in the molecular form in both solvents. The signal due to the *p*-F atom in the C_6F_5Xe moiety is shifted to lower frequency on going from **1** to **3** (in MeCN from $\delta = -141.27$ to $\delta = -146.21$), thus indicating a decrease in the mesomeric interaction between the C_6F_5 group and Xe^{II}, that is, a decrease in the effective charge at Xe^{II} due to replacement of the neutral base MeCN by the anionic base $[C_6F_5CO_2]^-$.

The ^{129}Xe chemical shift for **3** of $\delta = -2029.7$ (with respect to XeF_2) is as far as we are aware the lowest frequency value so far measured (Table 1). As expected, the transition from the base-coordinated cation $[MeCN\cdots XeC_6F_5]^+$ ($\delta = -1956.0$) to the covalent neutral species **3** leads to a shift to lower frequency.

Table 1. ^{129}Xe, ^{19}F, and ^{13}C NMR data for **3** in CD_2Cl_2 at −10 °C [a].

C_6F_5Xe moiety	
^{129}Xe	−2029.7 (t, 84 ± 6 Hz, $\nu_{1/2} = 49$ Hz) [b]
^{19}F	−128.26 (dm, $^3J(F,Xe) = 86.3 \pm 0.5$ Hz, 2; *o*-F), −144.71 (tt, $^3J(F,F) = 20.5$, $^4J(F,F) = 3.7$ Hz, 1; *p*-F), −154.81 (m, 2; *m*-F)
$^{13}C\{^{19}F\}$	144.32 (C4), 143.99 (C2,6), 138.14 (C3,5), 91.25 (C1)
$C_6F_5CO_2$ moiety	
^{19}F	−141.59 (m, 2; *o*-F), −154.39 (t, $^3J(F,F) = 21.0$ Hz, 1; *p*-F), −162.43 (m, 2; *m*-F)
$^{13}C\{^{19}F\}$	163.08 ($-CO_2-$), 144.32 (C2,6), 141.62 (C4), 137.57 (C3,5), 111.63 (C1).

[a] Measured with a Bruker WP 80 SY (^{13}C, Bruker WM 300), $\delta(Xe)$ relative to $\delta(XeF_2)$ in CD_2Cl_2, $\delta(F)$ relative to $\delta(CCl_3F)$. Values in parentheses after the δ values refer to the signal multiplicity, the magnitude of the coupling constant *J*, the signal intensity, and the signal assignment. [b] $\delta = 1327.8$ relative to $\delta(Xe(0))$ in MeCN at −30 °C.

The IR spectrum of the solid also lends no support to the description of **3** as an ionic carboxylate. Asymmetric and symmetric C–O stretching vibrations, as in sodium pentafluorobenzoate (1600 and 1395 cm^{-1}) are not observed. Ab-

sorptions at 1652 (m), 1626 (s), and 1619 (vs) cm^{-1} are assigned to the C–O stretching vibrations; these values are comparable with those found for the compounds $(C_6F_5)_2IO_2CC_6F_5$[8] (1650 (m) and 1600 (vs) cm^{-1}) and **4**[9] (1707

$C_6F_5I(O_2CC_6F_5)_2$ **4**

(m) and 1658 (vs) cm^{-1}) containing hypervalent iodine. In contrast, the C=O stretching frequency in the ester $C_6F_5CO_2C_6F_5$ lies at 1780 cm^{-1}.[10]

Low-temperature recrystallization from CH_2Cl_2 yielded single crystals of **3**, which according to the results of the X-ray structure analysis[11] consist of neutral molecules (Fig. 1). The xenon atom is linearly coordinated (178.1(1)°) by a carbon atom of the pentafluorophenyl substituent and one of the two oxygen atoms of the pentafluorobenzoyloxy substituent (hypervalent compound[14]). The other oxygen atom of the carboxyl group shows both a weak intramolecular Xe···O interaction (3.142 Å) and an even weaker Xe···O bridge (3.237 Å) to a neighboring molecule. These bridges lead to a pairing of the molecules with an almost square Xe_2O_2 four-membered ring in the crystal (Fig. 1).

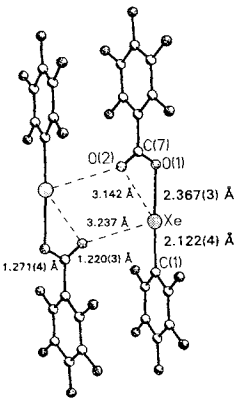

Fig. 1. Crystal structure of **3** with Xe–ligand bond lengths and the relevant intra- and intermolecular Xe–O contact distances. The C–Xe–O bond angle is 178.1(1)°.

According to Alcock[15] these are, however, not secondary bonds, since the intermolecular Xe–F distances *trans* to them do not deviate significantly from the sum of the van der Waals radii (3.47 Å). The length of the Xe–C bond in **3** is 2.122(4) Å; the corresponding bond length in the cation $[MeCN\cdots XeC_6F_5]^+$ is 2.092(8) Å, so that in **3** the Xe–C bond is apparently weakened in favor of the Xe–O bond. However, the Xe–O bond length of 2.367(3) Å in **3** is still considerably longer than that in the other known Xe–O compounds (F_5SeO–Xe–$OSeF_5$ 2.12,[12] F–Xe–$OS(O)_2F$ 2.16,[5] and F–Xe–OS(O)(F)O–Xe–F 2.21 Å[13]). In contrast to purely ionic carboxylate groups with two equal C–O bond lengths of 1.26 Å,[16] the pentafluorobenzoyloxy group in **3** has a longer (O(1), 1.271(4) Å) and a shorter C–O bond (0(2), 1.220(3) Å). A structural comparison with the iodo compound **4**, which exists in solution as discrete molecules and can also be transported in the molecular form in the gas phase,[9] appears appropriate; crystals of **4** contain two primary and two secondary I–O bonds, while the mean C=O and C–O bond lengths are 1.198 and 1.312 Å, respectively.

If we consider the available information on **3** in the solid phase and in solution and in addition take into account that **3** cannot be vaporized in the mass spectrometer without decomposition (decomposition occurs with pressure when the probe is heated), **3** can be described as a covalent compound with a polar, but relatively weak Xe–O bond, which is stabilized more effectively in the solid phase by the intra- and intermolecular contacts than in solution by solvation. The surprisingly high thermal stability of **3** in comparison with F–Xe–O_2CCF_3 cannot at present be explained satisfactorily. Ab initio calculations, as well as further experimental studies, for example by photoelectron spectroscopy, are planned.

Experimental Procedure

1 (81 mg, 166 μmol) was dissolved in D_2O (2 mL) and treated with **2** (60 mg, 174 μmol). After the mixture had been vigorously stirred, **2** dissolved and a voluminous colorless solid was immediately precipitated; the latter was isolated after centrifugation, decantation, and washing three times with D_2O (0.5 mL). The mother liquor contained the by-product $Cs[AsF_6]$. The solid **3** was dried for 3 hours under high vacuum at room temperature and subsequently dissolved in CD_2Cl_2 (≥ 500 μL); **3** crystallized out at −78 °C. Yield: 68 mg (133 μmol, 80%). NMR data are given in Table 1. Single crystals were obtained from CD_2Cl_2 at −45 °C (solubility at room temperature approximately 0.24 M). Differential thermal analysis (stainless steel autoclave): $T_{max} = 85 \pm 3$ °C (exothermic); main decomposition product: $C_6F_5CO_2C_6F_5$. IR(AgCl): $\tilde{\nu}$[cm^{-1}]: 1652 (m, sh), 1635 (m, sh), 1626 (s), 1619 (vs), 1577 (w), 1521 (m, sh), 1505 (vs), 1487 (vs), 1407 (w), 1349 (vs), 1286 (m), 1102 (m), 1082 (s), 1006 (m, sh), 990 (vs), 975 (s), 923 (m), 826 (w), 754 (s), 506 (m) 475 (w), 381 (m).

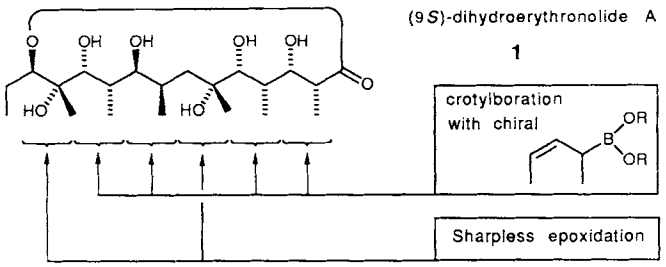
A Short, Linear Synthesis of (9*S*)-Dihydroerythronolide A**

By *Rainer Stürmer,* Kerstin Ritter,* and *Reinhard W. Hoffmann**

Recently Mulzer[1] characterized the efforts directed toward the synthesis of erythronolides as a "never-ending story", which is even more amazing as there is no direct need for such syntheses. The motivation is found elsewhere: Since 1956 when Woodward gave his famous appraisal of erythromycin,[2] erythronolide syntheses have become the yardstick for measuring progress in the efficiency of stereoselective synthesis. Almost all of the published syntheses or attempted syntheses of erythronolides A and B were designed to demonstrate the reliability or superiority of a certain methodology or strategy. Thus the history of the development of methods in stereoselective synthesis can be traced from the syntheses of erythronolides.[3]

We present here a stereoselective synthesis of (9*S*)-dihydroerythronolide A (**1**), whose subsequent conversion into erythronolide A is known.[3i,k] In our synthesis, in contrast to that of Woodward et al.,[4] all the stereocenters are generated by external asymmetric induction, for which allylboration and the Sharpless epoxidation were employed (Scheme 1). Although our synthesis is linear with 23 steps (and 16 isolated intermediates) it is the hitherto shortest synthesis of this type of compound.



Scheme 1. Strategy for the generation of the stereocenters in (9*S*)-dihydroerythronolide A.

The course of the synthesis is easy to describe. The C11–C15 building block **2** was obtained by Sharpless epoxidation.[5] Reaction with (*S,S,S*)-1-methyl-2-butenylboronic ester **3** led to alcohol **4** in 81% yield (*ds* > 96%).[6]

The hydroxyl group was protected as the *p*-methoxybenzyl ether. Ozonolysis provided aldehyde **5**, which was treated with (*R,R,R*)-1-methyl-2-butenylboronic ester *ent*-**3** to give homoallyl alcohol **6** with > 95% *ds*. The hydroxyl group in **6** was protected as the *p*-methoxylbenzylidene acetal **7** by oxidation with DDQ, and the C–C double bond was subsequently cleaved by ozonolysis. The resulting aldehyde was converted into allyl alcohol **8**, and the next stereocenter was generated by Sharpless epoxidation (Scheme 3). The reaction proceeded with 90% diastereoselectivity in favor of the desired epoxide **9**. The other diastereomer, 6,7-di-*epi*-**9**, was crystalline; its X-ray structure analysis established the correct relative configurations of all of the stereocenters generated up to this point. Epoxy alcohol **9** was oxidized to the

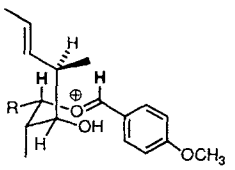
aldehyde, which when treated with (*S*,*S*,*S*)-**3** furnished homoallyl alcohol **10** (*ds* > 95%). The 6,7 epimer was removed at this step.

In our attempts to reductively cleave the C7–oxygen bond at the stage of epoxides **9** or **10**, eighteen standard reagents failed. Eventually a solution to this problem was found based on work of Marshall et al.:[7] the epoxide was activated as a magnesium chelate and then cleaved by $LiAlH_4$. The secondary hydroxyl group of the resulting diol was then selectively protected as a *p*-methoxybenzyl ether. Finally, bishydroxylation of the C–C double bond and cleavage with periodate furnished aldehyde **11**. In the next chain extension this aldehyde favors the formation of the *anti*-Cram product (not shown),[8] although the Cram product is desired. Nevertheless, the asymmetric induction of the chiral reagent (*S*,*S*,*S*)-**3** sufficed to provide the Cram product **12** with a diastereoselectivity of 89%. The second diastereomer formed had an *Z*-configurated double bond and should therfore possess the opposite configuration at C2 and C3. The hydroxyl group at C3 of **12** was protected as the *p*-methoxybenzylidene acetal (→**13**) by treatment with DDQ. The subsequent oxidative cleavage of the C–C double bond resulted in the unusually labile derivative **15** of erythronolide A seco acid.

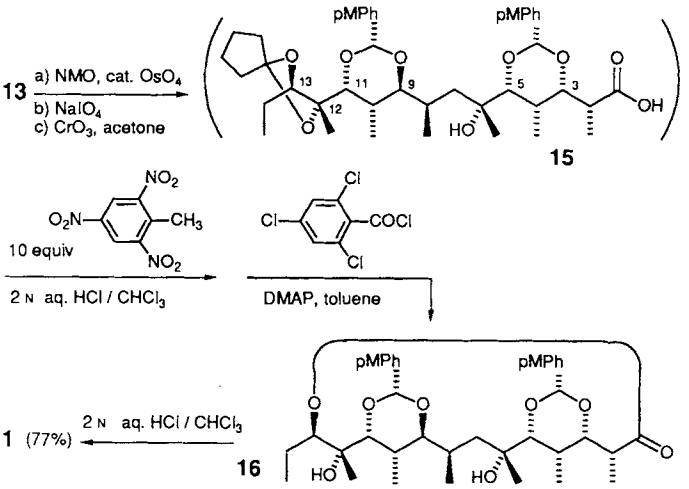
This synthesis, which appears so well-planned and unproblematic, was actually close to failure at a number of stages. The last-resort measures that finally led to success constitute the novelty in this communication. The first critical point was the oxidation of **6** to provide **7**, because for the later macrolactonization the *para*-methoxyphenyl group on the dioxane **7** must be in the α position.[3e, p, 4] This can be achieved with freshly recrystallized DDQ by kinetic control,[9] since the oxonium ion **14** is generated in the conformation with *syn* H atoms as a result of allylic strain.[10] As



14

soon as equilibration becomes possible acetal **7** isomerizes to the thermodynamically more stable isomer with the aryl substituent in the β position, a compound that is worthless for our synthesis. This happened frequently during the second DDQ oxidation **12**→**13**, because the weakly acidic dichlorodicyanohydroquinone triggered the epimerization of the strained[11] C9/C11 dioxane. We ultimately found that by oxidation with DDQ on molecular sieves (but not on alumina or silica gel) compound **12** could be converted into **13** without epimerization of the other dioxane ring.

The most difficult step was still to come. The seco acid **15** decomposed upon attempted isolation; specifically, the labile C9/C11 and C3/C5 dioxane rings were cleaved. This also occurred in the attempts to hydrolyze the C12/C13 cyclopentylidene moiety selectively in the presence of the *p*-methoxybenzylidene acetals, although this transformation had been successful on model compounds. At this point it was out of the question to start the synthesis over with another protecting group at C12/C13. Therefore a way had to be found to slow down the hydrolysis of the *p*-methoxybenzylidene acetals selectively. While the inclusion of these groups in cyclodextrin did not bring the desired result, a charge-transfer deactivation of the methoxyphenyl groups by trinitrotoluene (10 equiv) in a two-phase system permitted a selective hydrolysis of the cyclopentylidene group of compound **15**.



Scheme 4. Final steps in the synthesis of **1**. DMAP = 4-dimethylaminopyridine.

At this stage Yamaguchi lactonization[12] provided macrocycle **16**, whose spectral data are in accord with those of related compounds.[3p] The acetal groups were then hydrolyzed readily under standard conditions. This sequence allowed the generation of (9*S*)-dihydroerythronolide A (**1**) from **13** in 77% yield without isolation of the intermediates (total yield for all steps 10%). The melting point of **1** (201–203 °C)[3l] and its optical rotation (+9.2, $c = 0.7$ in methanol)[3k] are in agreement with the literature values. The ^1H and ^{13}C NMR spectra of **1** are identical to the spectra kindly provided by Dr. I. Paterson (Cambridge, England) and Prof. O. Yonemitsu (Sapporo, Japan).

This does not bring the story of erythronolide synthesis to an end. Inasmuch as our synthesis reflects the present state of the art in the methodology of stereoselective synthesis, more efficient syntheses of erythronolides should become possible with improved methods in the future.

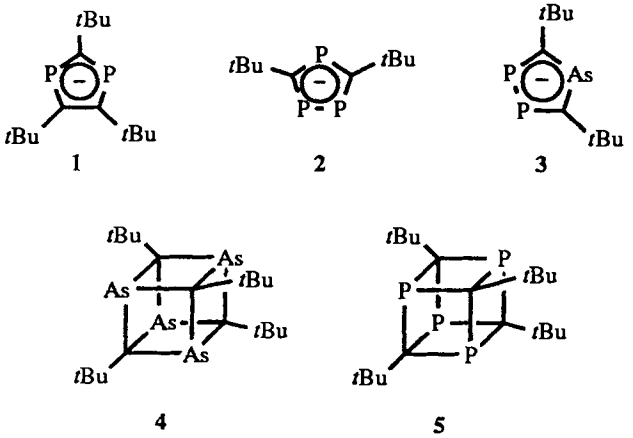
Synthesis and Structure of the Arsaalkyne Tetramer $(AsC\mathit{t}Bu)_4$ and its $Fe(CO)_4$ Derivative**

By *Peter B. Hitchcock, Julian A. Johnson*, and *John F. Nixon**

Current interest in the chemistry of phosphorus–carbon multiple bonds has arisen, because such compounds were once thought, on theoretical grounds, not to exist.[1–3] In particular, the substitution of CR units by phosphorus in many organic compounds, leading to the formation of novel ring and cage molecules has been widely explored in recent years.[4–8] These molecules include the di- and triphosphacyclopentadienyl anions $(P_2C_3\mathit{t}Bu_3)^-$ (**1**) and $(P_3C_2\mathit{t}Bu_2)^-$(**2**), which have been complexed to several transition metals.[9]

Recently we reported the synthesis of the arsadiphosphacyclopentadienyl anion $(AsP_2C_2\mathit{t}Bu_2)^-$ (**3**) and its η^5-complexation to Mn, Ru, and Co centers.[10] Attempts to prepare similar anions containing more than one As atom resulted in the unexpected formation of an arsaalkyne tetramer $As_4C_4\mathit{t}Bu_4$ (**4**). This has a cubane structure, similar to the analogous phosphaalkyne tetramer **5** reported by Regitz et al.[8]

The yellow, air-stable, sublimable (115 °C, 5×10^{-2} Torr) tetraarsacubane $As_4C_4\mathit{t}Bu_4$ (**4**) is isolated in 35% yield from the reaction of $LiP(SiMe_3)_2$, the arsaalkene (**6**),[11] and $CoCl_2$ at room temperature [Eq. (a)]. The mechanism of the reaction is not yet established, although it is likely that the as yet unknown *tert*-butylarsaalkyne (**7**) is generated as an intermediate by base-catalyzed elimination of hexamethyldisiloxane from the arsaalkene followed by Co-assisted oligomerization of **7**, since no product is obtained in the absence of $CoCl_2$. Efforts to trap **7** as its $[Pt(PPh_3)_2]$ complex have thus far proved unsuccessful.[12]



The cubane structure of **4** is proposed on the basis of data from mass spectrometry and NMR spectroscopy. The parent ion (*m/z* 576) is observed in the mass spectrum of **4** together with the expected fragmentation pattern.[13] A singlet at $\delta = 1.01$ is observed in the ^1H NMR spectrum of **4**, and the $^{13}C\{^1H\}$ NMR spectrum shows the expected three singlets at $\delta = -46.5$ (CAs), 21.4 (CCH_3) and 31.4 (CCH_3).

$$Me_3SiAs{=}C(OSiMe_3)\mathit{t}Bu \xrightarrow{LiP(SiMe_3)_2} \mathbf{6} \qquad \text{(a)}$$

$$[\mathit{t}BuC{\equiv}As] \;(\mathbf{7}) \xrightarrow{CoCl_2} \mathbf{4}$$

The high-field shift of the cage C atom is particularly significant and comparable to that observed for the cage C atoms in **5**,[8] implying that there is a shift of electron density from As to C atoms in the cage.

The cubane structure of **4** was confirmed by a single-crystal X-Ray diffraction study (Fig. 1).[14] The cage framework consists of alternate C and As atoms with an average C–As bond length of 2.01 Å. The internal bond angles of the cage (average angles: C-As-C 83.9, As-C-As 95.8°) show the cube to be slightly distorted, and a similar distortion is observed in the analogous phosphorus cage **5**.[8] The exocyclic As-C-C bond angles are on average 120.9°.

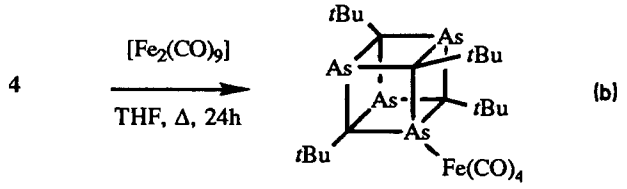
The arsaalkyne tetramer **4** reacts with $[Fe_2(CO)_9]$ in refluxing THF to give the tetracarbonyl iron(0) complex **8** [Eq. (b)], which has been fully characterized by IR and NMR spectroscopy.[15] The $^{13}C\{^1H\}$ NMR chemical shifts of the cage C atoms adjacent to the coordinated As atom are shifted downfield relative that of the other cage C atom as expected, thus showing a clear reduction in the shift of electron density from the As to the C atom on coordination of **4** to the metal center. Three ν(C=O) bands (2040, 1963, 1942 cm^{-1}) are observed in the IR spectrum of **8**, which are characteristic



(b)

8

for complexes of the type $[Fe(CO)_4L]$. Interestingly, these values are similar to those in complexes with L = PMe_3 and L = $AsMe_3$,[16] but are considerably less than those for L = $P(OMe)_3$[17] and L = PF_3,[18] suggesting that **4** is not a particularly strong electron-withdrawing ligand.

The molecular structure of **8** (Fig. 2)[19] shows the ligand **4** coordinated, as expected, in an axial position of the trigonal bipyramid; the Fe–As bond length is 2.370(3) Å. This bond

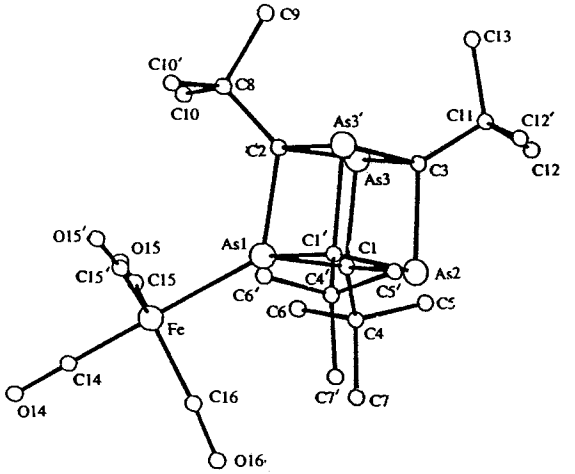


Fig. 2. The molecular structure of **8** [19]. Important bond lengths [Å] and angles [°]: Fe-As1 2.370(1), Fe-C14 1.772(9), Fe-C15 1.802(6), Fe-C16 1.778(9), As1-C1 2.011(6), As1-C2 2.039(7), As2-C1 2.025(6), As2-C3 2.029(8), As3-C1 2.038(5), As3-C2 2.023(5), As3-C3 2.018(6); Fe-As1-C1 128.3(1), Fe-As1-C2 127.0(2), C1-As1-C2 86.3(2), C1-As2-C3 84.7(2), C1-As3-C2 86.0(3), C1-As3-C3 84.6(3), C2-As3-C3 84.3(2), C1-As1-C1' 86.0(2), C1-As2-C1' 85.3(2), As1-C1-As2 94.2(2), As1-C1-As3 93.8(2), As2-C1-As3 94.9(2), As1-C2-As3 93.5(3), As2-C3-As3 95.4(2), As3-C2-As3' 95.3(3), As3-C3-As3' 95.7(3), As1-C1-C4 128.4(3), As1-C2-C8128.6(5), As2-C1-C4 117.8(4), As3-C1-C4 120.0(4), As3-C2-C8119.1(3), As2-C3-C11 121.7(6), As3-C3-C11 121.1(3).

is slightly longer than that observed in $[Fe(CO)_4AsMe_3]$ (2.30(3) Å).[20] The internal bond angles (average angles: C-As-C 85.3, As-C-As 94.7° of the coordinated cage in **8** are comparable to the free ligand; the exocyclic As1-C-C bond angles are increased, presumably to allow the $[Fe(CO)_4]$ metal complex fragment access to the As1 atom. A similar distortion is seen in the tetraphosphacubane **5**, when it is coordinated to an $[Fe(CO)_4]$ fragment.[21] In view of its considerable bulk, the coordination of **4** to other metal centers is currently under investigation.

Experimental Procedure

4: To a solution of $P(SiMe_3)_3$ (0.5 cm^3, 1.75 mmol) in dimethoxyethane (DME) (10 cm^3) was added 2.0 cm^3 of a 1.6 M hexane solution of *n*BuLi (3.2 mmol) at −40 °C. The solution was warmed to room temperature and stirred for 24 h. Arsaalkene **6** (2.0 g, 6.5 mmol) in DME (5 cm^3) was then added, and the resulting red solution was stirred for 72 h. Addition of a 5 cm^3 DME slurry of $CoCl_2$ (0.35 g, 2.7 mmol) gave a dark yellow mixture, which was stirred for a further 48 h. All volatile components were removed in vacuo at room temperature, and the residues were extracted with petroleum ether (PE). Column chromatography of the extracts (Kieselgel/PE) gave a yellow solution from which **4** could be crystallized at −20 °C. Yield: 300 mg (35%), yellow crystalline solid, m.p. 237 °C; satisfactory elemental analysis.

8: A solution of **4** (0.15 g, 0.26 mmol) and $[Fe_2(CO)_9]$ (0.20 g, 0.55 mol) in THF (10 cm^3) was refluxed for 24 h. Removal of solvent afforded a brown residue, which was washed with PE. The residue was redissolved in THF (ca. 3 cm^3) and cooled to −30 °C, which gave **8** as yellow crystals. Yield: 71 mg (46%), m.p. 196–198 °C (decomp); satisfactory elemental analysis.

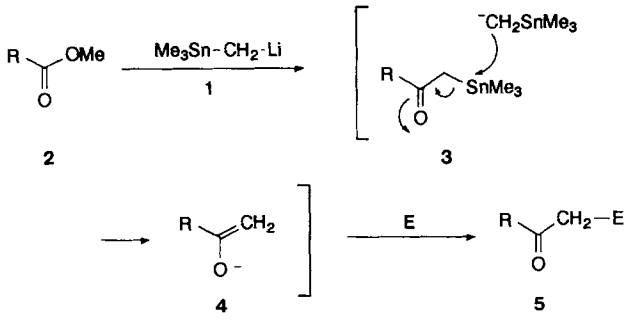
(Trimethylstannyl)methyllithium as a Source of a Methylene Bridge Connecting Two Acyl Groups: A Potential Route to D-Mycaroside**

By *Tadashi Sato** and *Shigeki Ariura*

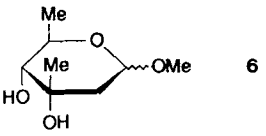
A few years ago we reported that compounds with both carbon–lithium and carbon–tin bonds, for example Me_3SnCH_2Li (**1**), could react with electrophiles in two consecutive steps; first as an explicit carbanion because of the carbon–lithium bond, and second as a latent carbanion because of the carbon–tin bond.[1] Consequently **1** is equivalent to a methylene dianion CH_2^{2-}, and we have reported several reactions of **1** with electrophiles.[2]

The reaction of **1** with esters **2** is typical for this reagent.[3] Conventional organometallic compounds react with esters usually producing tertiary alcohols, because the primarily produced ketones are more reactive toward the reagent than the starting esters. The primary product formed with **1**, the α-stannyl ketone **3**, however, is special: the attack of a second molecule **1** occurs preferentially at the electropositive tin atom rather than the carbonyl carbon atom. This attack, supported by the electron-withdrawing effect of the carbonyl group, induces a heterolytic cleavage of the tin–carbon bond to produce enolates **4**. If the resulting enolate is trapped with a suitable electrophile, the net result is a coupling of an acyl group and an E moiety through a methylene unit to give **5** (Scheme 1).

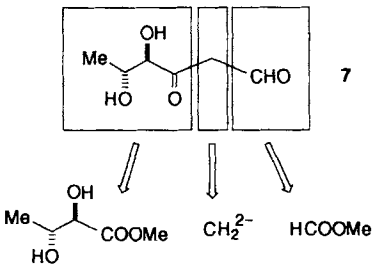


Scheme 1. Coupling of esters and electrophiles E with **1**.

We envisioned a one-step synthesis of β-ketoaldehydes (**5**, E = CHO) using formate as an electrophile, since the β-ketoaldehydes are desirable building blocks for 2-deoxysaccharides. The 2,6-dideoxysaccharides are important constituents of several antibiotics, and many homologues with various stereochemistries and branched carbon skeletons are known.[4] Since the biological activity of the parent antibiotics is influenced by the carbohydrate structure,[5] the development of methods for the synthesis of the deoxysaccharides is important. Frequently the deoxygenation of natural sugars is used; however, sometimes the selectivity of the regiochemical deoxygenation is not good or the starting material from the requisite chiral pool is not available. For instance, the synthesis of D-mycaroside **6** from methyl-α-D-mannopyranoside requires an eight-step reaction sequence (involving some purification processes) with an overall yield of 22%.[6] In contrast, the L-isomer has been synthesized in fewer steps because a suitable starting material, L-rhamnose, is readily

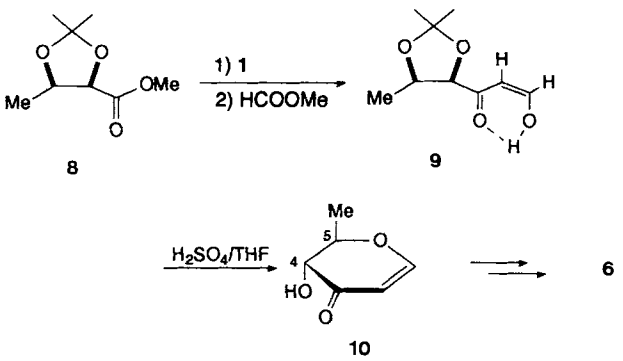


available.[7] Therefore a chiral synthesis from non-carbohydrate starting materials might be required. We have now constructed the major carbon skeleton **7** for the D-mycarose synthesis through the methylene connection reaction (Scheme 2).



Scheme 2. Retrosynthetic scheme for **7**, the carbon skeleton of D-mycaroside **6**.

When (2*R*,3*R*)-dihydroxybutanoate **8** was treated with two equivalents of **1** at −78 °C, and then with methyl formate at −78 °C to 0 °C, the one-pot reaction proceeded smoothly to afford **9** in 66% yield (Scheme 3). No epimeriza-



Scheme 3. Synthesis of **10** as a precursor for methyl D-mycaroside **6**.

tion occurred under these conditions, although some degree of epimerization was observed when the reaction temperature was raised to room temperature. The treatment of **9** with H_2SO_4 in THF afforded D-**10** (m.p. 87–88 °C) in 75% yield. In the same way, *rac*-**8** reacts to give *rac*-**10** (m.p. 66 °C). The *trans* arrangement of the substituents at C4 and C5 was confirmed by $J(H^4,H^5) = 13.8$ Hz in the ^1H NMR spectrum (400 MHz). Since the stereoselective synthesis of L-mycarose from L-**10** has been accomplished in two steps,[8] this reaction could provide a convenient route to D-mycaroside.

In addition, we applied the reaction described here to methyl hexanoate and methyl 2-butenoate, which afforded the corresponding β-ketoaldehydes as hydroxymethylene ketone tautomers in 53 and 79% yields, respectively. Although the yields are only moderate, pure products can be isolated when the quenched alkaline reaction mixture is washed with diethyl ether, and the aqueous layer is extracted with $CHCl_3$ after acidification with dilute HCl. Small amounts of the corresponding methyl ketones (**5**, E = H) and tin-containing

by-products of unknown structure were obtained from the ether layer.

Experimental Procedure

9: To a solution of bis(trimethylstannyl)methane (5.46 g, 16 mmol) in THF (32 mL) was added *n*BuLi (1.62 *M* hexane solution, 9.9 mL, 16 mmol) at −78 °C. After the mixture had been stirred for 15 min, a solution of **8** [9] (1.43 g, 8 mmol) in THF (8 mL) was added, and the mixture stirred for a further 20 min at this temperature. Methyl formate (3 mL, 49 mmol) was added, and then the reaction mixture was warmed up gradually and stirred for 4 h at 0 °C. The reaction mixture was quenched with aqueous $NaHCO_3$ solution and washed with diethyl ether. The aqueous solution was acidified with 4 *M* HCl and extracted with $CHCl_3$. After evaporation of the solvent pure **9** (981 mg, 66%) was obtained. ^{1}H NMR (60 MHz, CCl_4): δ = 1.15 (d, J = 7 Hz, 3H), 1.32 (s, 3H), 1.50 (s, 3H), 4.23–4.58 (m, 2H), 5.88 (d, J = 5 Hz, 1H), 7.91 (d, J = 5 Hz, 1H), 12.5 (br, 1H).

D-**10**: Compound **9** (365 mg, 2 mmol) was hydrolyzed by adding H_2SO_4 (3 drops) and refluxing in THF (20 mL) for 5 h. The reaction mixture was neutralized with $NaHCO_3$, concentrated in vacuo, and extracted with $CHCl_3$. Purification by sublimation afforded a pure sample of D-**10** (188 mg, 75%). M.p. 87–88 °C (sublimation); $[\alpha]_D^{23}$ = + 218 (c = 1.27, MeOH). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.57 (d, J = 7.6 Hz, 3H), 3.58 (s, 1H), 3.97 (d, J = 13.8 Hz, 1H), 4.20 (dq, J = 13.8, 7.6 Hz, 1H), 5.46 (d, J = 7.1 Hz, 1H), 7.38 (d, J = 7.1 Hz, 1H). ^{13}C NMR ($CDCl_3$): δ = 17.91, 72.69, 79.93, 103.4, 164.7, 194.2.

rac-**10**: m.p. 66 °C. Published value for L-**10** [8]: m.p. 86 °C (sublimation); $[\alpha]_D^{28}$ = − 227 (c = 1.3, MeOH).

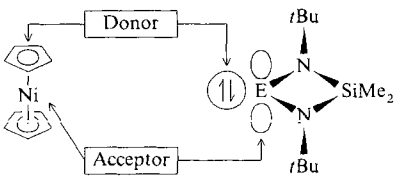
Novel Insertions of Carbene Homologues into Metal-η^5–Cp Bonds: Sandwich Complexes with Ge_2Ni and Sn_2Ni Cores**

By *Michael Veith** and *Lothar Stahl*

The carbene homologues $E(NtBu)_2SiMe_2$, E = Ge (**1**), Sn (**2**), are useful ligands for transition metal complexes because of their amphoteric Lewis acidic and Lewis basic properties.[1] It seemed promising to us to investigate their reaction behavior with the paramagnetic 20-electron complex nickelocene $[Cp_2Ni]$. When electrophiles react with $[Cp_2Ni]$ they should attack the Cp rings, in contrast nucleophiles should attack the Ni atom (Scheme 1).[2]



Scheme 1. E = element of Group 14.

If a green solution of $[Cp_2Ni]$ and **1** or **2** in toluene is heated to approximately 80 °C [Eq. (a)], this solution turns black-brown with the formation of the products **3** or **4**.

$$[Cp_2Ni] + 2\,E(NtBu)_2SiMe_2 \xrightarrow{80\ ^\circ C} [CpNi\{E(NtBu)_2SiMe_2\}_2(\mu\text{-}Cp)] \quad (a)$$
1: E = Ge, **2**: E = Sn → **3**: E = Ge, **4**: E = Sn

The NMR spectra (^{1}H, ^{13}C, ^{119}Sn) of **3** and **4**[3] have sharp signals, which indicate that these complexes are diamagnetic. Particularly striking is the occurence of two resonance signals for the Cp ligands with markedly different chemical shifts. The ^{1}H NMR spectrum of **4** shows a singlet at δ = 5.07 typical for η^5-bound Cp ligands, and a signal strongly shifted to low field at δ = 6.54 with tin satellites (J = 8.8 Hz, 27%). Coupling constants and intensities of the satellites indicate that the Cp ligand to which the signal at δ = 6.54 is assigned, is symmetrically π bound to two Sn atoms. As a result of the diastereotopic geminal $SiMe_2$ groups, the hydrogen atoms of the substituents of the SnN_2Si rings appear as three singlets. The NMR spectra hardly change on cooling the NMR samples to −80 °C; also the (cross-polarization magic angle spinning) CP-MAS ^{13}C NMR spectrum of solid **4** is almost identical with the spectrum recorded in solution. The presence of only one sharp signal at $\delta \approx$ 117 in the ^{13}C NMR spectrum shows that the bridging Cp ligand rapidly rearranges haptotropically in solution and in the solid state. The IR spectra, which are almost identical for **3** and **4**, also indicate π-bound Cp units because of the small number of bands for the Cp ligands.

Compounds **3** and **4** crystallize in monoclinic space groups with two molecules in the unit cell; their structures are not isotypic. The molecules lie on inversion centers of the space group $P2_1/c$ (different choice of cell for **3**: $P2_1/n$) which, however, is not in agreement with the NMR spectroscopic data. It became clear during the structure determination that a statistical disorder of a part of the molecules (Cp ligands and the nickel atom) was present as regards the inversion center of the space group; despite this shortcoming, resulting from the packing of the molecules (cf., e.g., ref. [4]), the structures could be refined accurately, and all hydrogen atom positions could be determined from difference Fourier analyses.[5]

The molecular structure of **4**, in which two Cp ligands are bound in different ways, is depicted in Figure 1. The Cp ligands are coordinated sandwichlike to the three metal atoms; Cp^1 (C31–C35) is bound η^5 to the Ni atom. The average Ni–C distance (2.097(9) Å) is shorter than that in $[Cp_2Ni]$ (2.18 Å),[6] indicating a strong Ni–Cp bond (the Ni centers in **3** and **4** each achieve 18-electron configurations). The two Ni–Sn bonds are likewise very short and both almost identical in length (Ni–Sn 2.326(2), Ni–Sn^A 2.369(2) Å); in the compound $[(C_2H_4)_2NiSn\{CH(SiMe_3)_2\}_2]$, in which double bond contributions for the Ni–Sn bond are

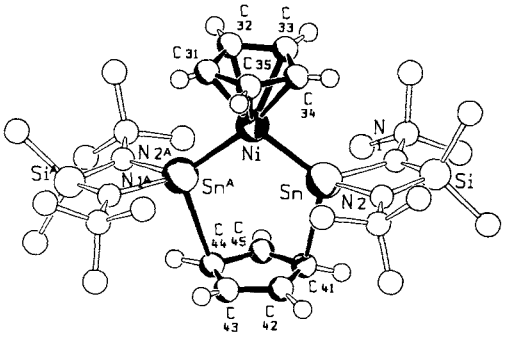

Fig. 1. Molecular structure of **4** (SCHAKAL [11b]). (The atoms labeled with the superscript A are symmetry equivalent [5].) Selected distances [Å] and angles [°] (See also the text): Sn-Ni1,2 2.083(8), Si-N1,2 1.749(5), Sn $\cdots$ Sn^A 3.648(4); Sn-Ni-Sn^A 102.0(1), Ni-Sn-C41 116.7(2), Ni-Sn^A-C44 112.5(2), N1-Sn-N2 75.5(1).

discussed, the Ni–Sn distance is 2.387(1) Å.[7] The center of the Cp^1 ligand, the two tin atoms, and the Ni atom lie almost in one plane. The most unusual structural element in **4** is without doubt the coordination of the second Cp ligand, which symmetrically bridges the two stannylene units via the tin atoms in a π bound manner. One C atom of the Cp^2 ligand (C41–C45) is coordinated to one of the Sn atoms and another C atom of the Cp^2 ligand (C41–C45) is coordinated to the other Sn atom. The distances vary slightly (2.702(12) Å (Sn–C41) and 2.608(11) Å (Sn^A–C44)). The bond lengths correspond to the average Sn–C distance in stannocene (2.71 Å);[8] σ-bound Cp ligands have significantly shorter Sn–C distances (2.15–2.20 Å).[9] To our knowledge this is the first structure in which a Cp ligand bridges μ-η^1:η^1 two main group elements. Both Cp rings are planar and arranged almost parallel (deviation 3.1°); they form dihedral angles of 9.4° (Cp^1) and 6.3° (Cp^2) with the SiN_2Sn metallacycles. The C atoms of Cp^2 bound to the Sn atoms lie, as expected, approximately 0.01 Å above the best plane, the corresponding H atoms (H41, H44) lie relatively far below (approximately 0.38 Å) this plane. The C–C bond lengths of the Cp ligands vary from 1.389(15) to 1.486(17) Å and are typical for Cp ligands with a delocalized π system.

The structure of **3** (Fig. 2) is similar to that of **4**. However, the Ni–Ge and Ge–Cp^2 distances differ considerably more than the corresponding Sn distances in **4**. The Ni–Ge bond

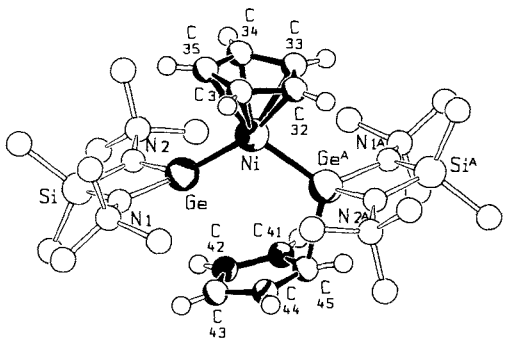

Fig. 2. Molecular structure of **3** (see also legend in Fig. 1). Other selected distances [Å] and angles [°] not discussed in text: Ni-C31-35 2.057(20), Ge-C41 3.007(7), Ge-C44 3.016(8), Ge-N1,2 1.864(3), Si-N1,2 1.729(2), Ge $\cdots$ Ge^A 3.549(7); Ge-Ni-Ge^A 109.6(1), Ni-Ge^A-C45 113.9(2), N1-Ge-N2 81.2(2).

lengths 2.085(3) and 2.258(3) Å differ significantly; the former distance is extremely short. The coordination of the "bridging" Cp^2 ligand (C41–C45) must be described as η^1-π in **3**, since all the Ge–C distances of this ligand are greater than 3.0 Å with the exception of the Ge^A–C45 bond (2.329(8) Å). The Ge–Ni distance is short, but the Ge–Cp^2 distance is long; exactly the opposite is true for the distances to the Ge^A atom. The asymmetry of **3** compared to **4** in the solid state reflects the formation process of the compounds by insertion of the carbene homologue into the Ni–Cp bond far better than the structure of **4**. As for the Sn–Cp^2 bond in **4**, the Ge–Cp^2 interaction in **3**, however, is clearly to be considered as a π bond, which is revealed both by the long Ge–C45 distance compared to usual σ bonds and also the C–H coupling constants.[3]

The structures of **3** and **4** are also interesting in view of the elucidation of the reaction mechanism of a Lewis base attack on $[Cp_2Ni]$.[2] Compounds **3** and **4** can be considered as intermediates of such reactions, which cannot be isolated for usual Lewis bases (CO, PR_3).

Experimental Procedure

$E(NtBu)_2Me_2Si$ (E = Ge (**1**), Sn (**2**) [10]) (6.3 mmol) was added to $[Cp_2Ni]$ (500 mg, 2.65 mmol) in toluene (30 mL), and the mixture was heated to 80 °C. After 36 h, the solution was filtered and concentrated to approximately 25 mL. After 48 h at −20 °C, yellow-brown crystals of **3** (1.91 g, 91.0%, m.p. 155–157 °C) or brown-black, rhombohedral crystals of **4** (1.90 g, 86.8%, m.p. 145–147 °C) were formed. Elemental analyses and mass spectra are in agreement with the empirical formulas.

Bonding in Endohedral Metal–Fullerene Complexes: f-Orbital Covalency in Ce@C_{28}**

By *Notker Rösch,** *Oliver D. Häberlen,* and *Brett I. Dunlap*

The technology for preparing macroscopic amounts of empty fullerenes[1] has been developed to furnish comparable quantities of host–guest complexes with one to three metal atoms inside the fullerene.[2] The host fullerenes for these complexes are the size of C_{82} and larger, providing a single guest atom with a large volume in which to move around.[3] The smallest experimentally relevant fullerene, C_{28},[4] forms endohedral compounds with uranium, hafnium, zirconium, and titanium, which were detected by mass spectrometry.[5] These experiments indicate that the stabilization of this fullerene by tetravalent atoms, as measured by the relative abundance of the endohedral complexes, increases in the order $Ti@C_{28} < Zr@C_{28} < Hf@C_{28} < U@C_{28}$, where the @ notation indicates endohedral complexes.[7,2a] The proposed tetrahedral structure of C_{28}[5] is drawn in Figure 1. Inside C_{28}, titanium, the smallest of these

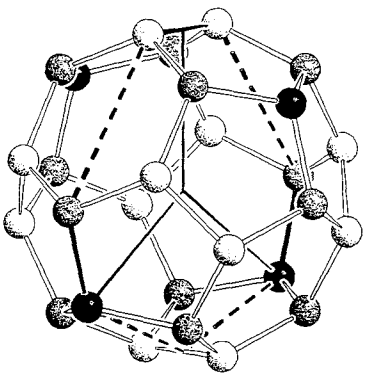

Fig. 1. Structure of the tetrahedral fullerene C_{28}. One of six symmetry-equivalent planes that contain two atoms of each of the three sets of symmetry-equivalent atoms is indicated by solid and dashed lines. In this plane there are two threefold axes from the center to a black atom and one twofold axis from the center to the center of a bond connecting nearest-neighbor white atoms. Gray and white atoms alternate around the circumference of the four hexagons diametrically opposite the four black atoms.

endohedral atoms, is strongly attracted (off-center by about 0.5 Å) to one of the four "black" atoms, which form the corners of a tetrahedron, together with its three nearest-neighboring "gray" atoms.[6] If a larger endohedral atom forms stronger simultaneous bonds to all four corners of the tetrahedron of black atoms, then the experimental trend in the stability of the $M@C_{28}$ complexes could be rationalized.

Such bonding is facilitated by sp^3 or sd^3 (or even sf^3) hybridization on the central atom. Alternatively, C_{28} may be stabilized by bonding between the endohedral atom and the six nearest-neighbor pairs of "white" atoms (see Fig. 1) that form an octahedron around the center of C_{28}. The radial distance from the center of C_{28} to the latter atoms is actually about 0.1 Å shorter than to the black atoms. If the sixfold coordination prevails, then metal–fullerene bonding would be facilitated by sp^3d^2 or sd^2f^3 hybridization on the central atom. The question of f orbital covalency in endohedral fullerene complexes, that is, whether the f orbitals of an endohedral atom contribute to the metal–cage bonding, however, cannot be decided by simply considering localized bonds to atoms (or combinations of atoms). If all possible valence orbitals (s, p, d, and f) of an endohedral f element atom, such as uranium, are employed in the bonding to the cage, then a maximum of 16 localized bonds can be formed. Group theory reveals that all these metal orbitals will be employed when localized bonds are formed to the sets of four black ($a_1 + t_2$) and twelve white (or, alternatively, twelve gray) atoms ($a_1 + e + t_1 + 2\,t_2$).

If a compound exhibits a sufficiently high symmetry then the bonding contributions can be isolated according to the irreducible representations of the molecular orbitals. Historically the di-π-[8]annulene complexes, $[M(C_8H_8)_2]$ where M = Ce, Th, Pa, U, Np, and Pu, have provided fertile ground for such analyses.[7,8] Due to the D_{8h} symmetry, of all the metal atom valence orbitals only the f orbitals can contribute to an e_{3u} HOMO. Indeed, calculations[7,8] and analysis of photoelectron spectra[8c] showed an f orbital contribution to the metal–ring bonding in these sandwich complexes.

Fullerenes are spheroidal shells of atoms often also having high symmetry. Endohedral fullerene complexes may thus be used to assess f orbital covalency with the help of symmetry arguments. At the center of buckminsterfullerene, icosahedral C_{60}, f orbitals can only contribute to g_u and t_{2u} molecular orbitals; at the center of tetrahedral C_{28}, only the f orbitals of the s, p, d, and f valence atomic orbitals can contribute to a t_1 molecular orbital. The f electrons of $Eu@C_{60}$ und $U@C_{60}$ remain localized on the metal atom, however,[9] because the interior volume of C_{60} is too large to allow sufficient overlap between the central f orbitals and the π orbitals of the carbon frame. When the surface of a fullerene is approximated as a sphere with a fixed surface area per carbon atom, the usable interior volume of the fullerene is proportional to the number of carbon atoms to the power 2/3.[10] In this approximation the interior of C_{28} is 40% smaller than the interior of C_{60} (51% smaller than the interior of C_{82}), and even the f electrons of a lanthanide or an actinide atom might participate in the bonding.

This spherical approximation provides yet another, unique way to analyze the electronic structure of fullerenes and endohedral fullerene complexes. The fullerenes can be viewed as spherical shells on which a single π orbital per carbon atom can delocalize forming molecular orbitals to be filled in the order s, p, d, f, etc., according to their nodal character.[11] Real spherical harmonics of rank l have l distinct nodal circles. On a fullerene shell these nodal lines must deform slightly to avoid atomic cores, thus lifting the m_l degeneracy, but the fact that the HOMO and LUMO of C_{60} belong to an incompletely filled h shell ($l = 5$) is obvious from contour plots of those orbitals.[12] This same spherical approximation applied to any isomer of C_{28} suggests that it can be viewed as having four electrons too few to complete its f shell. In particular, the HOMO group of tetrahedral C_{28}, $8a_1$, $14t_2$, and $7t_1$ (see Fig. 2), is ideally set up to overlap with f orbitals on the central atom.

The bonding of a lanthanide atom inside C_{28} is best studied using a scalar-relativistic extension[13] of the first-principles linear combination of Gaussian-type orbitals local density functional (LCGTO-LDF) method.[14] This two-component approximation to the four-component Dirac

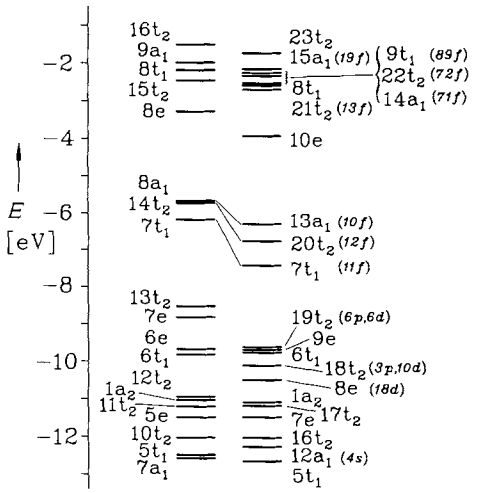

Fig. 2. One-electron energy level diagrams (LDF Kohn–Sham eigenvalues) for C_{28} and Ce@C_{28}. The LUMOs are 8e and 10e, respectively. The empty fullerene has an open-shell quintet ground state; the levels $14t_2$ and $8a_1$ are half filled. The spin-restricted levels are plotted for clarity of presentation; the splittings due to spin-polarization are very small as every orbital is spread out evenly over at least four different symmetry-equivalent atoms. The electronic structure of Ce@C_{28} is closed-shell. The Mulliken contribution of the cerium atom to each level is given in parentheses (in % together with the appropriate angular momentum) where it is significant.

form of the Kohn–Sham equations essentially takes into account the Darwin and mass–velocity terms.[13] We chose cerium as the endohedral atom because it can be tetravalent, because some aspects of its organometallic chemistry are strikingly similar to that of uranium,[7] and because we have a good Gaussian basis set for all-electron quasi-relativistic LCGTO calculations with this atom.[13a] We used an optimized empirical-potential geometry for C_{28}[15] that compares well with the cage geometries of Ti@C_{28} and Zr@C_{28} optimized in tetrahedral symmetry at the Hartree–Fock level of theory.[5b]

We employed a LDF exchange-correlation potential that interpolates between the essentially exact free-electron gas calculations in the completely ferromagnetic and completely paramagnetic limits.[16] The starting orbital basis set for C (9s/5p),[17a] was augmented with a d exponent of 0.6[17b] (all exponents are given in atomic units) and contracted to an atomic 5s/4p/1d basis according to a spin-restricted atomic calculation. The orbital basis set for Ce, 21s/16p/11d/9f,[13a] was contracted similarly to an atomic 11s/10p/8d/5f basis. The 9 C s and the 21 Ce s orbital exponents were scaled by 2 and 2/3 to generate atom-centered s-type functions for the charge density and exchange-correlation fitting bases, respectively.[18] The 5 C p and the 16 Ce p orbital exponents were scaled in the same way to generate the atom-centered r^2-type fitting basis functions. To fit nonspherical contributions around both types of atoms we employed additional fitting functions with higher angular momentum quantum numbers. A geometric series of 5 p-type fitting exponents, 0.1, 0.25, 0.625, 1.5625, and 3.90625, was used in both fitting bases of carbon.[18b] These exponents were scaled by a factor of three to get f-type (the lowest nonzero angular momentum allowed by tetrahedral symmetry at the origin) fitting exponents for Ce that have radial maxima at the same distances.

The symmetry of C_{28} is high enough that a rather complete picture of it may be formed by considering a special single slice through it. Such a plane is indicated by the bold solid and dashed lines in Figure 1. We studied the motion of a Ce atom along the symmetry axes shown in Figure 1 when the structure of the cage was kept fixed at the geometry determined by the empirical potential. The equilibrium position of Ce is at the center to an accuracy of 0.05 Å. The vibrational frequency along the threefold axis is 360 cm^{-1} and that along the twofold axis 350 cm^{-1}. The binding energy of Ce@C_{28} with respect to Ce $f^1d^1s^2$ (the experimental Ce ground state) and C_{28} $^5A_2$ is quite large, 13.7 eV, even if one takes into account that the LDF approximation tends to overestimate binding energies[19] and that the LDF ground state for Ce differs slightly from experiment.

The electronic structures of the empty and filled fullerene show that the spherical approximation is quite good in the case of C_{28}. The energies of the one-electron orbitals of C_{28} and Ce@C_{28} show that two large gaps isolate the f-like orbitals (see Fig. 2). Of these, the $8a_1$ and the three degenerate $14t_2$ orbitals are singly occupied in the ground state of C_{28}. The entire set of corresponding f-like orbitals, $13a_1$, $20t_2$, and $7t_1$, is completely filled in Ce@C_{28}. These f-like orbitals undergo strong downward shifts in energy due to the covalent metal–cage bonding. Similarly, the lower lying d-like orbitals, $13t_2$ and $7e$ of C_{28}, are shifted even lower in energy ($18t_2$ and $8e$ of Ce@C_{28}). These bonding interactions should be reflected in the photoelectron spectrum of the two fullerene compounds. We calculated (as a difference between two all-electron total-energy calculations) the first ionization potentials of C_{28} and Ce@C_{28} to be 7.40 and 8.27 eV, respectively. In their photoelectron spectra both systems are expected to have a gap of similar size (about 2.4 eV) after the first three bands which correspond to the emission of an electron from the HOMO and from the second and third highest levels (C_{28}: $8a_1$, $14t_2$, $7t_1$; Ce@C_{28}: $13a_1$, $20t_2$, $7t_1$). These three orbitals each have significant Mulliken f electron population (approximately 0.1) on the Ce atom and lie within 1.2 eV of each other (see Fig. 2 and Fig. 3 a–c). These bonding f contributions are comparable to those found in uranocene $[U(C_8H_8)_2]$.[7]

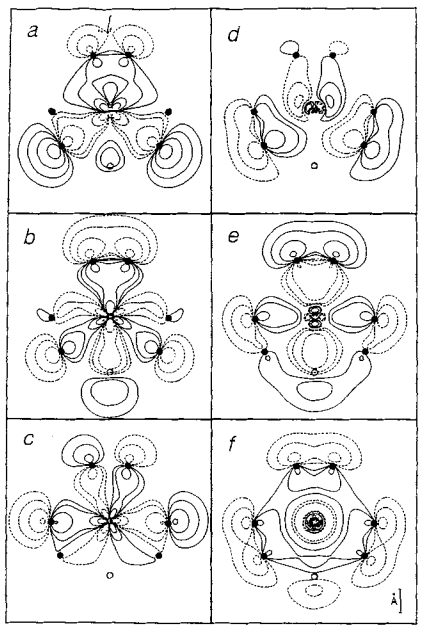

Fig. 3. Contour plots of the LDF one-electron orbitals with significant cerium character (in the plane defined in Fig. 1). The three highest occupied levels, a) the $13a_1$ orbital, b) the $20t_2$ orbital, and c) the $7t_1$ orbital, exhibit Ce f character as can be seen from the nodal patterns at the center of the plots. Orbitals with significant Ce d character are d) the $18t_2$ orbital and e) the $8e$ orbital. The LDF valence orbital with some Ce s character is f) the $12a_1$ orbital. The values of the contour lines are $\pm$ 0.015, $\pm$ 0.03, $\pm$ 0.06, and $\pm$ 0.12 a.u., solid and dashed lines indicate values of opposite sign. The positions of carbon atoms in the plane and the midpoint between out-of-plane white atoms are indicated by black dots and an empty circle, respectively.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1993 0570-0833/93/0101-0109 $ 10.00+.25/0

Covalent orbitals with a similar amount of Ce d Mulliken population, the $18t_2$ and $8e$ orbitals, lie roughly 3 eV lower in one-electron energy and within 0.4 eV of each other (see Fig. 2 and Fig. 3 d, e). The near degeneracy of these d shell orbitals indicates that the tetrahedral (four corners) and the octahedral (six pairs of bonds between white atoms) contributions to the ligand field are of comparable strength. Lower still in energy by 2 eV is the only valence orbital with significant Ce s character (0.04) (see Fig. 2 and Fig. 3 f). The LUMOs of C_{28} and $Ce@C_{28}$ are rather similar in nature: they are cage π orbitals. The metal–cage antibonding Ce f orbitals lie higher in energy ($14a_1$, $22t_2$, and $9t_1$) and exhibit a ligand-field splitting of 0.26 eV. All other Ce valence orbitals are pushed to even higher energies than displayed in Figure 2.

A picture of all the bonding contributions in $Ce@C_{28}$ is provided by the charge density difference map (Fig. 4) which is taken with respect to the charge density of the noninteracting fragments Ce and C_{28}. It is clear that cerium forms

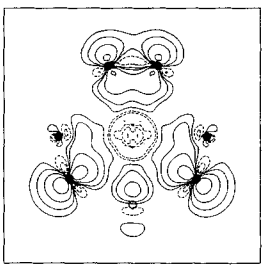

Fig. 4. Contour plot of the charge density difference for $Ce@C_{28}$ with respect to the noninteracting fragments Ce and C_{28}. The values of the contour lines are $\pm 0.003 \times 2.5^n$ a.u. ($n = 0$–3). Solid and dashed lines indicate positive and negative values, respectively. The positions of the cage atoms are marked as in Figure 3.

strong bonds to the tetrahedral (black) atoms as well as to the pairs of octahedral (white) atoms (see Fig. 1). The bonds to the gray atoms are significantly weaker. The net Mulliken charge on the Ce atom is +1.1e.

Our scalar-relativistic, all-electron, total-energy LDF calculations show that in contrast to titanium,[6] cerium is large enough to lie at the center of C_{28}. Because to a good approximation the fullerene is a spherical cage with frontier orbitals of F character, there is significant F covalency as indicated by Ce F population in the three highest occupied orbitals. These metal orbital contributions should be identifiable in variable-energy photoelectron spectra.[8c]

Due to its high symmetry $Ce@C_{28}$ obviously provides an ideal case for a detailed analysis of the metal–cage bonding in endohedral fullerene complexes. The general possibility of overlap characterized by rapid angular modulation will certainly also be found in less symmetric molecules. Strong bonds will arise when the valence orbitals of the enclosed system favorably complements the frontier orbital shell of the fullerene cage and have the proper radial extent, resulting in a closed-shell electronic structure. The isolobality principle[20] with its emphasis on orbital topology comes to mind. For example, in $Sc_3@C_{82}$[2e] an i orbital of C_{82} with its six lobes in one plane might favorably match a molecular orbital of a Sc_3 cluster formed by an antibonding combination of three in-plane d orbitals.

Organic Clathrate-Forming Compounds as Highly Selective Sensor Coatings for the Gravimetric Detection of Solvent Vapors**

By *Albert Ehlen, Claus Wimmer, Edwin Weber,** and *Joachim Bargon**

The need for chemical sensors[1] to measure concentrations for medical purposes and industrial process control applications, for warning and safety systems, in environmental analysis, etc. is great.[2] However, the properties of the

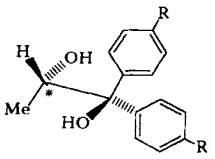
Wegelerstrasse 12, D-W-5300 Bonn-1 (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie.

chemical sensors already on the market or still in the development stages leave much to be desired. The bottleneck in the construction of chemosensors is the availability of chemically sensitive materials with sufficient stability and high sensitivity.[3] This is particularly pertinent for the gravimetric sensor, which functions either on the principle of the quartz microbalance (QMB) or on the principle of the surface-acoustic oscillator;[4] here a broad selection of selective coatings should rapidly lead to a breakthrough for the method.[2, 3] Among the organic inclusion compounds,[5] only cyclodextrins[6] and a few other macrocyclic compounds containing cavities have found application.[7, 8]

We have discovered that acyclic organic clathrate-forming compounds,[9] which are much more readily accessible and can be structurally modified, can similarly be used to construct active coatings for sensors and now report our initial results on the detection of solvent vapors with the quartz oscillation apparatus (QMB cell). The clathrate-forming compounds **1** and **2** are bulky derivaties of natural lactic acid, which display enantioselective sorption and are suitable for the preparative resolution of organic building blocks.[10] As this investigation shows, the crystalline substances **1** and **2** also proved to be highly selective sorbents for organic solvent vapors. The change in the mass on the formation and dissociation of the clathrates can be determined from the shift of the basic frequency of a quartz oscillator coated with these compounds.



1, R = H
2, R = CMe_3

On applying the simple model of the Langmuir adsorption isotherms to the absorption and adsorption processes,[3, 11] a linear relation between the change in frequency Δf and the concentration c for the system sensor coating/solvent vapor in the region of low partial pressures is obtained [Eq. (a)].[7]

$$\Delta f = -Kc \qquad \text{(a)}$$

The constant K is a measure of the sensitivity of the procedure. For host/guest components that show only unspecific interactions, this configuration is less sensitive than for a clathrate-forming sensor layer/vapor combination (Fig. 1).

The host:guest stoichiometries of the clathrates can also be determined from the measurement of the quartz oscillator frequency. An increase in the vapor concentration to above saturation enables the molar host:guest ratio γ for the saturated crystals to be determined from the quotient of the frequency shift caused by the host coating without guest (Δf_h) and the frequency shift for inclusion of the guest at saturation $\Delta f_{g,sat}$ according to Equation (b) (M_h = molar mass of host, M_g = molar mass of guest). As anticipated, the

$$\gamma \frac{M_h}{M_g} = \frac{\Delta f_h}{\Delta f_{g,Sat}} \qquad \text{(b)}$$

frequency differences $\Delta f_{g,sat}$ at saturation increase linearly with thickness of the coating. This is documented in Figure 2 for the system **1**/dioxane. From the slope of this plot

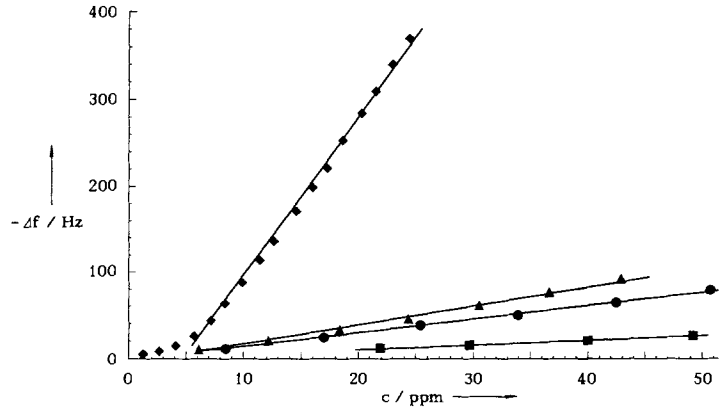


Fig. 1. Concentration dependence of the absorption for the sensor coating **2**. ◆ = 1-butanol, ■ = acetone, ● = methanol, ▲ = 2-propanol.

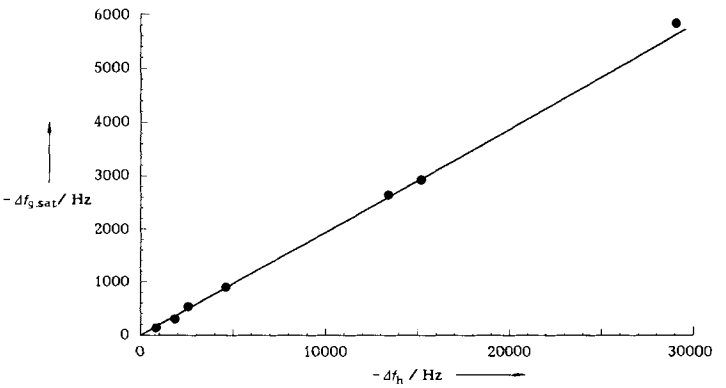

Fig. 2. The dependence of the frequency difference $\Delta f_{g,sat}$ for the inclusion at saturation on the thickness of the coating Δf_h for the system **1**/dioxane. The solid line corresponds to a host:guest inclusion ratio of 2:1.

[$\gamma^{-1} M_g M_h^{-1}$, according to Eq. (b)] a molar inclusion ratio γ of 2:1 (**1**:dioxane) is determined. This corresponds exactly to the stoichiometry of a cocrystallized sample (^{1}H NMR intergration).

Up to this point, a lot of attention was paid when using the quartz microbalance that the electrode coating on the quartz was as smooth and uniform as possible. Agreement with the spectroscopic analysis implies that quantitative measurements are possible also for irregularly crystalline materials. Presumably this is true only for comparative measurements,

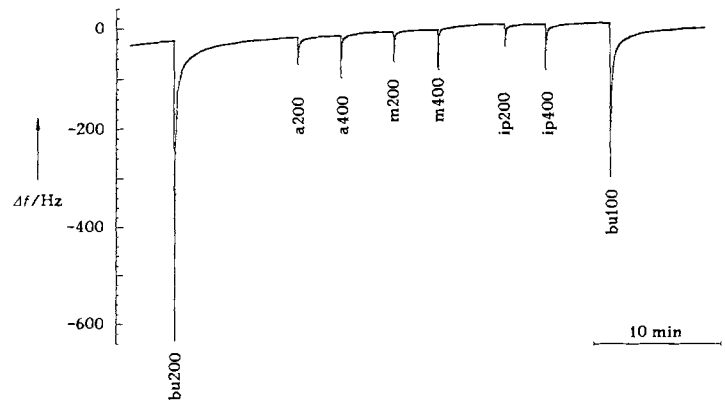

Fig. 3. Flow-through diagram with **2** as sensor coating. The numbers after the letters give the amount of solvent used in μL (bu = 1-butanol, a = acetone, m = methanol, ip = 2-propanol).

since the change in mass (here the inclusion of the guest) adjusts with the unevenness of the quartz coating.

The selective sensor properties of **1** and **2** are particularly obvious when potential guest compounds are compared with other solvent vapors in a series of flow-through experiments. Thus crystalline **2** as sensor coating shows a pronounced affinity for 1-butanol (Fig. 3). In spite of higher polarities and smaller spatial demands, acetone, methanol, and 2-propanol yield much smaller signals even when larger quantities are injected. The high selectivity of **1** for dioxane is demonstrated in Figure 4. Particularly remarkable is the behavior of cyclohexane, which although it has a similar structure to dioxane, gives only small signals.

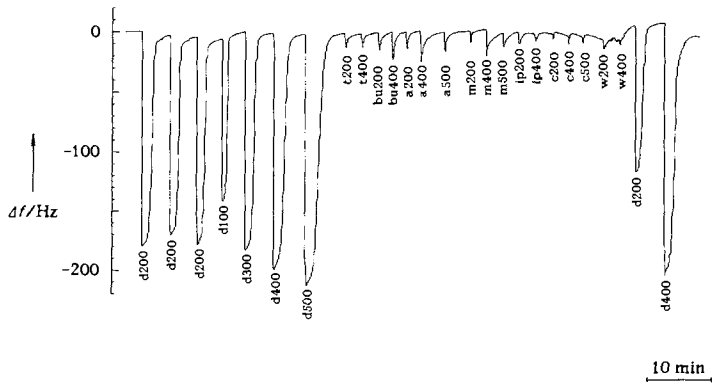

Fig. 4. Flow-through diagram with **1** as sensor coating. The numbers after the letters give the amount of solvent used in μL (bu = 1-butanol, a = acetone, m = methanol, ip = 2-propanol, d = dioxane, c = cyclohexane, t = toluene, w = water).

Thus, the selectivity of the sensor coating depends on the structure of the host molecule, which can be widely varied. The results also encourage the study of clathrate host compounds with other structural characteristics[5, 9] for suitability as sensor coatings.

Experimental Procedure

Apparatus: The quartz oscillator hangs in a cylindrical detector chamber, which is provided with several systems for the introduction of samples and can be evacuated through a suction port. The fundamental frequency of the oscillator used is 5 MHz.

Coating of the quartz oscillator: A solution of the appropriate host substance (100 mg) in THF (2 mL) was transferred in portions to the surface of the electrode. To be certain that the crystallization was complete, the coated electrode was only used on the following day.

Determination of the concentration dependence: For each solvent, a series of volumes of the air/solvent mixture was removed from the saturated vapor phase above the liquid surface in a 20 mL syringe and injected into the evacuated apparatus. The concentrations injected were determined from the equilibrium partial pressures.

Recording the flow-through diagrams: A stream of air enriched with the required solvent vapor was passed through the apparatus. This enrichment of the carrier stream is performed by successively injecting the different solvents from a syringe through a septum into a small flow-through vessel. The diagrams in Figures 3 and 4 were recorded at a flow of several liters per minute. The intensity of each signal reflects the momentary concentration, and the integration of the signals corresponds to the total injected dose (specific for each type of guest molecule) in each case.

Metathesis of Sulfur-Containing Olefins with a Metallacyclic Aryloxo(chloro)neopentylidenetungsten Complex**

By *Jean-Luc Couturier, Katsumi Tanaka, Michel Leconte, Jean-Marie Basset,** and *Jean Ollivier*

The application of olefin metathesis[1] to acyclic or cyclic olefins bearing functional groups probably constitutes one of the most promising uses of this reaction, since it allows access to valuable organic products and polymers which are often difficult to obtain by other methods.[2, 3] To date, the metathesis reaction has been applied to olefins containing oxygen, nitrogen, halogen, and silicon heteroatoms, but to our knowledge there are no reports of successful reactions of sulfur-containing acyclic or unstrained cyclic olefins.[4, 5] This lack of data was attributed to the fact that functional groups containing sulfur atom(s) may poison the catalyst; such an effect was reported for some classical heterogeneous and homogeneous catalytic systems.[6] However, this specific application of olefin metathesis could be of particular interest, since it would expand the field of thiochemistry and offer the possibility of synthesizing known or new olefinic compounds containing sulfur by a novel and simple route. We report here on the successful metathesis of olefinic sulfides with a homogeneous catalyst, aryloxo(chloro)neopentylidenetungsten complex **1**, which we recently synthesized and which proved to be highly active in the metathesis of olefins and olefinic esters.[7]

since the change in mass (here the inclusion of the guest) adjusts with the unevenness of the quartz coating.

The selective sensor properties of **1** and **2** are particularly obvious when potential guest compounds are compared with other solvent vapors in a series of flow-through experiments. Thus crystalline **2** as sensor coating shows a pronounced affinity for 1-butanol (Fig. 3). In spite of higher polarities and smaller spatial demands, acetone, methanol, and 2-propanol yield much smaller signals even when larger quantities are injected. The high selectivity of **1** for dioxane is demonstrated in Figure 4. Particularly remarkable is the behavior of cyclohexane, which although it has a similar structure to dioxane, gives only small signals.

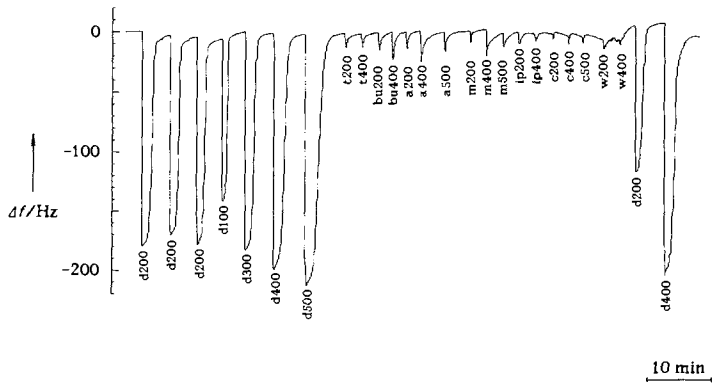

Fig. 4. Flow-through diagram with **1** as sensor coating. The numbers after the letters give the amount of solvent used in μL (bu = 1-butanol, a = acetone, m = methanol, ip = 2-propanol, d = dioxane, c = cyclohexane, t = toluene, w = water).

Thus, the selectivity of the sensor coating depends on the structure of the host molecule, which can be widely varied. The results also encourage the study of clathrate host compounds with other structural characteristics[5, 9] for suitability as sensor coatings.

Experimental Procedure

Apparatus: The quartz oscillator hangs in a cylindrical detector chamber, which is provided with several systems for the introduction of samples and can be evacuated through a suction port. The fundamental frequency of the oscillator used is 5 MHz.

Coating of the quartz oscillator: A solution of the appropriate host substance (100 mg) in THF (2 mL) was transferred in portions to the surface of the electrode. To be certain that the crystallization was complete, the coated electrode was only used on the following day.

Determination of the concentration dependence: For each solvent, a series of volumes of the air/solvent mixture was removed from the saturated vapor phase above the liquid surface in a 20 mL syringe and injected into the evacuated apparatus. The concentrations injected were determined from the equilibrium partial pressures.

Recording the flow-through diagrams: A stream of air enriched with the required solvent vapor was passed through the apparatus. This enrichment of the carrier stream is performed by successively injecting the different solvents from a syringe through a septum into a small flow-through vessel. The diagrams in Figures 3 and 4 were recorded at a flow of several liters per minute. The intensity of each signal reflects the momentary concentration, and the integration of the signals corresponds to the total injected dose (specific for each type of guest molecule) in each case.

Metathesis of Sulfur-Containing Olefins with a Metallacyclic Aryloxo(chloro)neopentylidenetungsten Complex**

By *Jean-Luc Couturier, Katsumi Tanaka, Michel Leconte, Jean-Marie Basset,** and *Jean Ollivier*

The application of olefin metathesis[1] to acyclic or cyclic olefins bearing functional groups probably constitutes one of the most promising uses of this reaction, since it allows access to valuable organic products and polymers which are often difficult to obtain by other methods.[2, 3] To date, the metathesis reaction has been applied to olefins containing oxygen, nitrogen, halogen, and silicon heteroatoms, but to our knowledge there are no reports of successful reactions of sulfur-containing acyclic or unstrained cyclic olefins.[4, 5] This lack of data was attributed to the fact that functional groups containing sulfur atom(s) may poison the catalyst; such an effect was reported for some classical heterogeneous and homogeneous catalytic systems.[6] However, this specific application of olefin metathesis could be of particular interest, since it would expand the field of thiochemistry and offer the possibility of synthesizing known or new olefinic compounds containing sulfur by a novel and simple route. We report here on the successful metathesis of olefinic sulfides with a homogeneous catalyst, aryloxo(chloro)neopentylidenetungsten complex **1**, which we recently synthesized and which proved to be highly active in the metathesis of olefins and olefinic esters.[7]

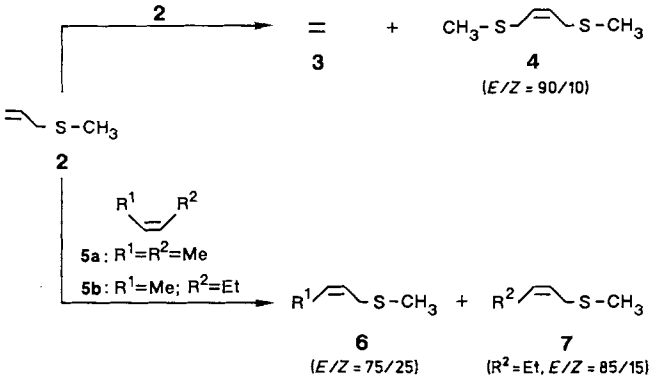
25/1	100/1	–	20	15	95	–	–	95	–
20/1	–	20/1	80	15	60	5	5	30	20

[a] The metathesis reactions were carried out with 0.025 mmol of **1** and 5 mL of C_6H_5Cl as solvent. [b] Initial molar ratios. [c] Reaction temperature. [d] Reaction time. [e] Yields based on initial **2**.

Complex **1** can be prepared by two independent routes starting either from $[WCl_3(CCMe_3)(dme)]$[8] (dme = dimethoxyethane) or from $[WCl_4(2,6\text{-}Ph_2C_6H_3O)_2]$.[9] Complex **1** achieves coordinative saturation by complexing an Et_2O molecule, which also increases the steric shielding of the tungsten center; the coordination sphere is also expected to be extremely rigid due to the metallacyclic structure.

In the presence of **1**, allyl methyl sulfide (**2**) undergoes self-metathesis, leading to **3** and **4**, and cometathesis with *cis*-2-butene (**5a**) and *cis*-2-pentene (**5b**), leading to **6** and **7**[10] (Scheme 1 and Table 1).[11] The turnover rates are lower

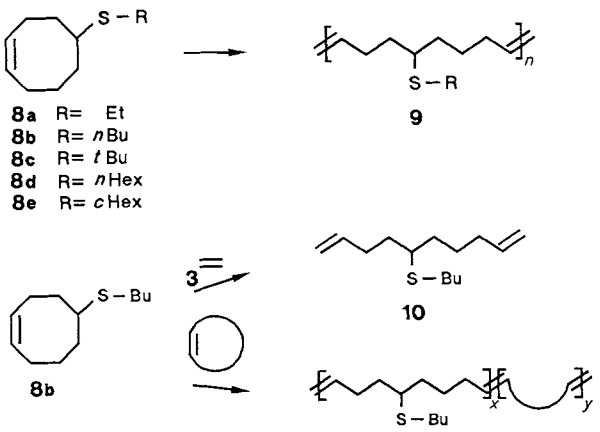


Scheme 1. Metathesis of **2** with acyclic olefins.

than those obtained with **1** in the metathesis of 2-pentene or ethyl oleate,[7] which suggests a reversible coordination of the sulfur compound to **1** and a partial deactivation of the catalyst. Nevertheless, the reaction is highly selective (only the expected metathesis products are detected), and the conversion of **2** can reach a high value when an excess of the coreactant olefin is used.

Cometathesis of **2** with cyclopentene or norbornene in the presence of **1** leads to the dienes depicted in Scheme 2.[10-12] The cross-metathesis reaction is favored with respect to ring-opening metathesis polymerization of cyclopentene or norbornene when an excess of allyl methyl sulfide is used.

Ring-opening metathesis polymerization of various 5-alkylthiocyclooctenes (**8a–e**)[13] leads to the olefinic sulfur polymers **9** (Scheme 3 and Table 2);[14] turnover rates were higher than those observed in the metathesis of allyl methyl sulfide (**2**). The results in Table 2 show that the alkylthio



Scheme 3. Metathesis of alkylthio-substituted cyclic olefins.

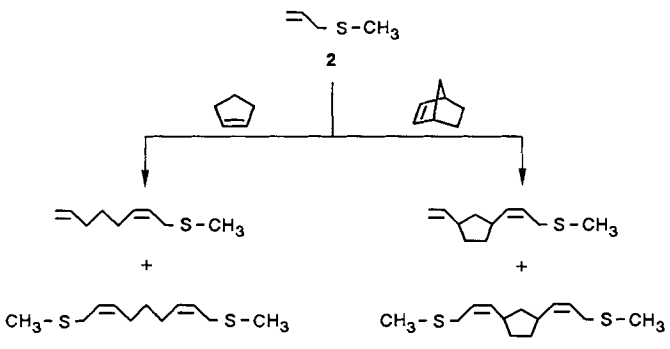
[a]–[d] See Table 1. [e] Polymerization performed without solvent. [f] Yield of isolated polymer (M_w = 140100, M_N = 39700, M_w/M_N = 3.5, T_g = – 26 °C).



Scheme 2. Metathesis of **2** with cyclic olefins.

substituent strongly affects the rate of polymerization: the greater the steric demands of the alkyl substituent, the faster the polymerization. This confirms the hypothesis that bulky substituents around the sulfur atom could decrease the inhibiting effect induced by a possible coordination of the sulfur to the tungsten atom. The turnover rates can be increased by increasing reaction temperature and/or by performing the polymerization without a solvent. The rather high polydispersity of the polymer obtained from **8c** (M_w/M_N = 3.5) is probably due to the extremely high activity of the catalyst during propagation: this catalyst can open acyclic *and* cyclic double bonds, the consequence being chain-transfer reac-

tions. The catalysts that give living polymers are usually active in metathesis of cyclic olefins and not in that of acyclic olefinic double bonds.[5a, 15, 16]

Reaction of *n*-butylthiocyclooctene **8b** with ethylene (**3**) in the presence of **1** leads to alkylthiodiene **10** (Scheme 3).[10] A decrease of the initial **8b**/**1** molar ratio leads to a slight increase of the final conversion of **8b**, while an increase of the initial **3**/**8b** molar ratio gives, as expected, a higher yield of **10** (Table 3). High reaction temperatures drastically enhance the turnover rates.

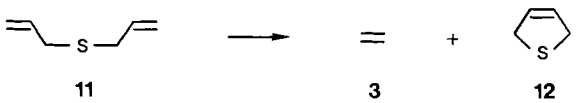
Table 3. Cometathesis of **8b** with ethylene (**3**) catalyzed by **1** [a].

8b/**1** [b]	**3**/**1** [b]	*T* [°C] [c]	*t* [h] [d]	Conversion of **8b** [%]	Yield of **10** [%] [e]
200/1	200/1	20	8	82	39
100/1	200/1	20	6	96	59
50/1	200/1	20	6	99	72
50/1	200/1	80	0.25	93	61
25/1	200/1	20	6	99	75

[a]–[d] See Table 1. [e] Yields based on initial **8b**.

Copolymerization of **8b** with various cyclic olefins (cyclopentene, cyclooctene, cyclododecene, 1,5-cyclooctadiene, 1,5,9-cyclododecatriene, norbornene, and dicyclopentadiene) can also be achieved (Scheme 3).[17] The composition of the copolymers (*x*/*y* ratio) depends not only on the initial ratios of the two comonomers, but also on their relative reactivities in metathesis. In reactions with highly reactive comonomers such as norbornene or dicyclopentadiene, the thiocycloolefin is not easily incorporated in the polymer ($x/y \approx 20/80$ starting from an equimolar ratio of the two reactants). Conversely, less active cyclic comonomers (cyclopentene, cyclooctene, etc.) are favorable for incorporating thioolefin ($x/y \approx 50/50$).

Finally, in the presence of **1**, diallyl sulfide (**11**) undergoes an intramolecular metathesis reaction resulting in a cyclization and in the formation of ethylene (**3**) and 2,5-dihydrothiophene (**12**)[18] (Scheme 4).[19] The turnover rates are



11 **3** **12**

Scheme 4. Intramolecular metathesis of **11**.

rather high and the yield of **12** can reach approximately 90% (Table 4) (the main by-products are most likely oligomers resulting from an intermolecular metathesis reaction of **11**). Interestingly, metathesis of **11** can be easily achieved in the absence of a solvent, which proves to be particularly useful

Table 4. Metathesis of **11** catalyzed by **1** [a].

11/**1** [b]	*T* [°C] [c]	*t* [h] [d]	Conversion of **11** [%]	Yield of **12** [%]

for synthetic purposes. This reaction opens a new route to the synthesis of thiophene.

In summary, we have shown a new property of the neutral metallacyclic neopentylidene–tungsten complex **1** in the catalysis of the metathesis of sulfur-containing olefins. The reactivity of **1** is not completely understood, although it might be due to the high rigidity of the metallacyclic structure and the steric crowding at the tungsten center which prevents strong coordination of the thioether moiety to the metal atom. This hypothesis is corroborated by the observation of a steric effect at the sulfur atom which seems to play a similar role. To our knowledge, it is the first report related to the metathesis of *acyclic* and *unstrained cyclic* olefins containing sulfur. Our results could have a great impact on thiochemistry as well as on polymer science.

The fact that a tungsten-based catalyst could be so active in the metathesis of functionalized olefins deserves some comment. So far, it was implicitly assumed that tungsten-based catalysts with a d^0 configuration, even if they were good metathesis catalysts for simple olefins, could not tolerate functionalized olefins since the heteroatoms would coordinate to the metal center. Therefore, much effort was invested in the recently reported metathesis of functionalized olefins with ruthenium-based catalysts that are obviously less inclined to strongly coordinate heteroatom-containing olefins.[20] The fact that a tungsten-based catalyst with a d^0 configuration is able to catalyze the metathesis of sulfur-containing olefins opens up new possibilities in the choice of the metal best suited for the metathesis of functionalized acyclic and cyclic olefins as well as the ligands for the steric and electronic control of the reactivity of the metal with a d^0 configuration. Obviously, aryloxide ligands are very versatile in this respect.

Organometallic Oxides: Lacunary Lindqvist-Type Polyanion-Supported Cyclopentadienylrhodium Complex Fragments**

By *Anna Proust, Pierre Gouzerh,** and *Francis Robert*

In recent years there has been a growing interest in the chemistry of organometallic oxides,[1–3] not least the organometallic clusters derived from polyoxometalates. These can serve as models for metal oxide surfaces and thus help to provide a basic understanding of catalyst-to-support interactions in heterogeneous catalytic processes.[1, 3, 4] Some compounds have been found to display bifunctional catalytic activity.[5] As ligands, polyoxometalates exhibit unique properties.[4] Lacunary anions can be viewed as inorganic-porphyrin analogues[4] and their coordination chemistry has been extensively studied.[6] On the other hand, closed anions are potential polydentate bridging ligands if they use both their terminal and bridging oxygen atoms. For example, the $[V_6O_{19}]^{8-}$,[7] *cis*-$[Nb_2W_4O_{19}]^{4-}$,[8] $[CpTiMo_5O_{18}]^{3-}$,[9] β-$[SiW_9V_3O_{40}]^{7-}$,[10] and $[P_2W_{15}Nb_3O_{62}]^{9-}$[11] anions form stable adducts with cations such as $[M(Cp^*)]^{2+}$ (M = Rh, Ir), $[M(CO)_3]^+$ (M = Mn, Re), $[M(CO)_2]^+$ (M = Rh, Ir), $[Ru(C_6H_6)]^+$, $[Rh(C_7H_8)]^+$, and $[Ir(C_8H_{12})]^+$. Organometallic complexes containing metavanadates[12] and integrated cubane-type clusters[13] have also been characterized.

$(NBu_4)_2[Mo_5O_{13}(OCH_3)_4(NO)\{Na(CH_3OH)\}] \cdot 3CH_3OH$ **1a**

$(NMe_4)_2[Mo_5O_{13}(OCH_3)_4(NO)\{Na(H_2O)\}]$ **1b**

We recently reported the synthesis of **1a**, the anion of which can be viewed as a lacunary Lindqvist-type species.[14] The negative charge density on the terminal oxygen atoms is reduced by the electron-withdrawing effect of the $(MoNO)^{3+}$ unit. Nevertheless, the anion is sufficiently basic to react with various electrophiles; indeed the lacunary species needs some stabilization, otherwise it transforms into the closed $[Mo_6O_{18}(NO)]^{3-}$ anion. The $[Mo_5O_{13}(OCH_3)_4(NO)]^{3-}$ anion has been found to exhibit a rich coordination chemistry. We describe here the synthesis and characterization of two (pentamethylcyclopentadienyl)rhodium(III) complexes of this ligand.

Complexation of $[Rh(Cp^*)]^{2+}$ with $[Mo_5O_{13}(OCH_3)_4(NO)]^{3-}$ was achieved by refluxing a mixture of **1a** and $[\{Cp^*RhCl_2\}_2]$ for several hours in methanol. (Depending on the experiment, chloride was partially or totally removed by prior addition of $AgNO_3$.) The red precipitate of **2a** obtained from this reaction gave red octahedral crystals of **4a** · CH_2Cl_2 upon recrystallization from CH_2Cl_2. Compound **4a** was obtained directly as a red precipitate when 3/4 of the chloride had been removed. Complete removal of the chloride resulted in the precipitation of **3a** as an orange-brown solid; orange-red plates of **3a** subsequently grew from the filtrate. Starting from a sample of **1b**, which turned out to be slightly contaminated with NMe_4Br, red needles of **3c**, and red thin plates of **3b** crystallized successively after the refluxed solution had been cooled. When an excess of NMe_4Br was added to the reactant mixture, a red precipitate of **2b** was obtained, which gave red crystals of **4b** · CH_2Cl_2 upon recrystallization from CH_2Cl_2.

Compounds **2a** and **2b** have not yet been fully characterized. Compounds **3b**, **3c**, and **4b** · CH_2Cl_2 have been identified by X-ray crystallography.[15] Compounds **4a** · CH_2Cl_2 and **4b** · CH_2Cl_2 were found to be isostructural; the composition of **4a** has been confirmed by chemical analysis.

$(NBu_4)[Mo_5O_{13}(OCH_3)_4(NO)\{RhCp^*(solv.)\}]$ **3a**
(solv. = H_2O or MeOH)

$(NMe_4)[Mo_5O_{13}(OCH_3)_4(NO)\{RhCp^*(H_2O)\}] \cdot 2H_2O$ **3b**

$[\{RhCp^*\}_2(\mu\text{-}Br)_3][Mo_5O_{13}(OCH_3)_4(NO)\{RhCp^*(H_2O)\}]$ **3c**

$[Mo_5O_{13}(OCH_3)_4(NO)\{\{RhCp^*\}_2(\mu\text{-}Cl)\}]$ **4a**

$[Mo_5O_{13}(OCH_3)_4(NO)\{\{RhCp^*\}_2(\mu\text{-}Br)\}]$ **4b**

The crystals of **3b** consist of Me_4N^+ cations, water molecules of crystallization, and discrete $[Mo_5O_{13}(OCH_3)_4(NO)\{RhCp^*(H_2O)\}]^-$ anions in which the nitrosyl polyoxomolybdate acts as a bidentate ligand. The anion has $C_s(m)$ crystallographic symmetry (Fig. 1). The $[Mo_5O_{13}(OCH_3)_4(NO)]$ subunit is less symmetrical than that found in **1a**. Indeed, while the Mo–O(Rh) distances are not significantly different from the unperturbed Mo–O_t distances, the two Mo–OMe bonds *trans* to the rhodium-ligated oxygen atoms are significantly shorter than the other ones. Compound **3a** is assumed to contain the same complex anion as **3b** on the basis of analytical and IR spectral data. This anion is also found in **3c** according to a preliminary X-ray study.

The crystals of **4b** · CH_2Cl_2 consist of discrete molecules that have $C_s(m)$ crystallographic symmetry (Fig. 2). Here the $[Mo_5O_{13}(OCH_3)_4(NO)]$ subunit behaves as a symmetrically bridging tetradentate ligand.

In both **3b** and **4b**, the rhodium atoms are approximately octahedrally coordinated and they achieve an 18-electron configuration with two terminal axial oxygen atoms, the Cp* ring, and either a water molecule or a bromide ligand. Compounds **3b** and **4b** represent a new class of complexes sup-

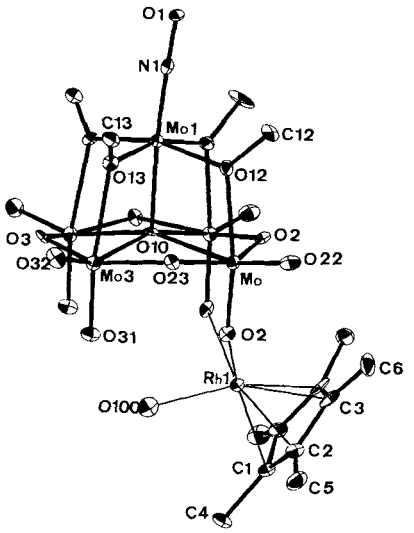

Fig. 1. Structure of the anion of **3b**. The anion lies at a special position with crystallographic *m* symmetry; the mirror plane passes through the Mo1, N1, O1, O10, O2, O3, Rh1, and O100 atoms. Selected bond lengths [Å] and bond angles [°]: Mo1-N1 1.77(3), N1-O1 1.21(4), Mo1-O10 2.14(2), Mo1-O12 2.01(2), Mo2-O12 2.20(1), Mo1-O13 1.94(2) Mo3-O13 2.33(1), Mo2-O22 1.66(2), Mo3-O32 1.69(2), Mo2-O21 1.75(2), Mo3-O31 1.70(1), Rh1-O21 2.11(2), Rh1-O100 2.13(2), Mo1-N1-O1 177.9(27), O10-Mo1-N1 174.8(11), Mo1-O12-Mo2 108.2(7), Mo1-O13-Mo3 106.1(6), O21-Rh1-O100 86.2(7), O21-Rh1-O21′ 82.6(8).

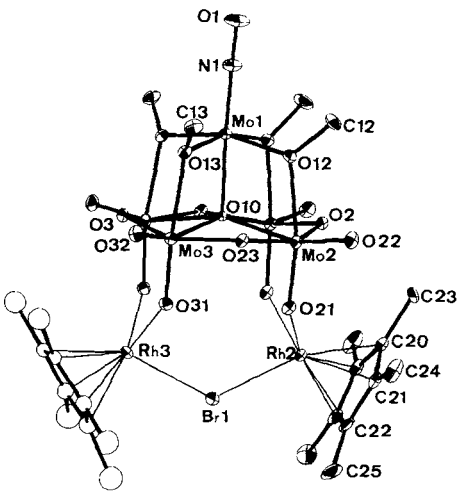

Fig. 2. Structure of the anion of **4b**. The anion lies at a special position with crystallographic *m* symmetry, the mirror plane passes through the Mo1, N1, O1, O10, O2, O3, Rh2, Rh3, and Br1 atoms. The Cp* ligand attached to Rh3 is disordered. Selected bond lengths [Å] and bond angles [°]: Mo1-N1 1.78(1), N1-O1 1.16(2), Mo1-O10 2.123(9), Mo2-O21 1.753(8), Mo3-O31 1.740(8), Mo2-O22 1.688(8), Mo3-O32 1.683(8), Rh2-O21 2.100(8), Rh3-O31 2.118(8), Rh2-Br1 2.539(2), Rh3-Br1 2.550(3), Mo1-N1-O1 178.7(19), O10-Mo1-N1 177.5(7), O21-Rh2-Br1 91.4(2), O31-Rh3-Br1 92.4(2) O21-Rh1-O21′ 82.6(4), O31-Rh3-O31′ 81.4(2), Rh2-Br1-Rh3 125.70(8).

ported on polyoxomolybdates where the organometallic fragment is bound to the terminal oxygen atoms of the open face of a lacunary polyoxoanion. They demonstrate the unique properties of $[Mo_5O_{13}(OCH_3)_4(NO)]^{3-}$ as a ligand.

Experimental Procedure

3a: $AgNO_3$ (0.084 g, 0.5 mmol) was added to a solution of $[\{RhCp^*Cl_2\}_2]$ (0.078 g, 0.125 mmol) dissolved in CH_3OH (10 mL). After the solution had been stirred for approximately 30 min, AgCl was filtered off and washed with methanol (5 mL); the filtrate was added to a solution of **1a** (0.34 g, 0.25 mmol) in methanol (5 mL). The mixture was refluxed for 7 h, during which time **3a** was deposited as an orange-brown solid. It was collected by filtration (yield: 35%). IR(KBr): $\tilde{\nu}[cm^{-1}]$ = 1625 (NO); 935, 895, 855 (MoO_t).

4a: Compound **4a** was similarly prepared from $AgNO_3$ (0.375 mmol), $[\{RhCp^*Cl_2\}_2]$ (0.125 mmol), and **1a** (0.25 mmol) (yield: 50%). IR (KBr): $\tilde{\nu}[cm^{-1}]$ = 1635 (NO); 940, 855 (MoO_t).

Axial Ligation of Diazacyclooctanenickel and -Zinc Complexes**

By *Dawn C. Goodman, Thawatchai Tuntulani, Patrick J. Farmer, Marcetta Y. Darensbourg,** and *Joseph H. Reibenspies*

The 1,5-diazacyclooctane (daco) molecule has proven to be a useful precursor for building ligands with various donor atoms, including those of import to the biological chemistry

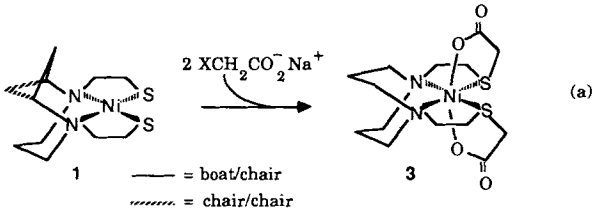
[**] This work was supported by the National Institutes of Health (RO1 GM44865-01) and the National Science Foundation (CHE-8513273 for purchase of the X-ray diffractometer and crystallographic computing system; CHE-8912763 for the EPR spectrometer). We thank Prof. Paul Lindahl for helpful discussions.

of nickel—N, S, and O.[1-5] The coordination of a metal center M results in the formation of two diazametallacyclohexane rings which share an N-M-N unit. A plethora of X-ray crystal structures has established that the common form of the two six-membered rings in metal-bound daco is the boat/chair form (see **1**, Equation (a)). Due to the steric hindrance of the β-methylene CH_2 group in the boat/chair form, axial ligation at the metal is blocked on one side, thus accounting for examples of tetra- and pentacoordinate Ni^{II},[1-3] and pentacoordinate Co^{II} and Co^{III} complexes.[4] This conformational preference is rationalized as avoiding cross-ring methylene C–H interactions that might result from the chair/chair form of the metalladiazacyclohexane rings. Nevertheless, MM2 calculations that we[6] and others conducted suggest that, in the absence of C–H/metal agostic interactions, the differences between the two conformers represented in structure **1** are minor. In fact, the conformation lower in energy, the chair/chair conformation, is the one typically *not* seen in the X-ray crystal structures thusfar reported.[2-6, 8-10] Although disorder in the structure of 1,5-diazacyclooctane-1,5-diylbis(ethylthiolato)nickel(II) (**1**)[5] may be indicative of a mixture of chair/chair and boat/chair conformers, bona fide examples of exclusive chair/chair conformers are rare.[6]

The methylation of **1** yields *N,N'*-bis(3-thiabutyl)-1,5-diazacyclooctanenickel(II) iodide (**2**),[5] suggesting that the nucleophilic character of the nickel-bound thiolate sulfur atoms may be engaged to extend the denticity of the N_2S_2 ligand by the introduction of additional donor atoms that can bind to the Ni atom in axial positions. We report here on the X-ray crystal structure of a Ni complex with a hexadentate $N_2S_2O_2$ ligand and that of a Zn complex with a pentadentate N_2S_2O ligand. These structures aptly illustrate that the steric shielding of the metal center by the daco ligand may be overcome when the metal atoms can attain a preferable coordination number and when ligands with strong binding abilities are employed.

Blue, paramagnetic Δ-1,5-diazacyclooctane-1,5-diylbis (3-thiapentanoato)nickel(II) (**3**), analytically pure as the trihydrate, was obtained as illustrated in Equation (a) and crystallized in the tetragonal space group $P4_32_12$ (no. 96) or $P4_12_12$ (no. 92).[11] Analysis of structural refinement indicated that



(a)

$P4_32_12$ was the correct space group.[11] Each chiral nickel complex molecule in the asymmetric unit cell possesses a C_2 axis and is hydrogen-bonded through the distal oxygen of the carboxyl group into a three-dimensional network of water molecules. This serpentine of hydrogen bonds through the lattice has no influence on the hydrocarbon portion of the hexadentate ligand and its directionality results from the chirality of the space group of **3**. As illustrated in Figure 1, the Ni^{II} resides in a slightly distorted octahedron whose equatorial positions are taken up by N_2S_2 units and the apexes by O_2 donor atoms. The Ni–S distance of 2.435(2) Å is within the usual range reported for six-coordinate Ni^{II}–SR_2 complexes (d = 2.416 Å),[12] but more than 0.22 Å

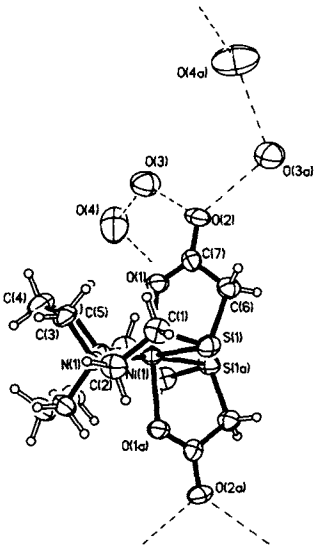


Fig. 1. Crystal structure of **3** · $3H_2O$ (thermal ellipsoids at 50% probability). The atoms labeled **a** are related to the corresponding unlabeled atoms by a C_2 axis; hydrogen atoms on waters removed for clarity. Selected bond lengths [Å] and angles [°]: Ni(1)-S(1) 2.435(2), Ni-O(1) 2.067(3); Ni-N(1) 2.094(4), O(1)-C(7) 1.261(6); C(7)-O(2) 1.254(6); S(1)-Ni-S(1a) 98.5(1). N(1)-Ni-N(1a) 85.7(2); S(1)-Ni-N(1) 88.6(1), O(1)-Ni-O(1a) 170.6(2); O(1)-Ni-S(1) 80.9(1), O(1)-Ni-N(1) 96.7(1); C(3)-C(4)-C(5) 118.2(5); C(3)-N(1)-C(5a) 112.5(4); Ni-S(1)-C(6) 95.0(2).

longer in **3** as compared to the tetradentate square-planar complex **2** (d = 2.211(3), 2.204(3) Å).[5] The C–O bonds have essentially the same length, regardless of whether the O atom is bound directly to nickel or distal to the metal center and hydrogen-bonded to water molecules. The $-CH_2-CO$ unit eclipses the Ni–S bond, creating fairly planar five-membered $NiSC_2O$ rings whose planes form a dihedral angle of 100°; in other words, there is an opening of the S-Ni-S angle by about 10° as compared to complexes **1** or **2**, which show regular 90° angles in the N_2S_2Ni plane.

The most striking feature of the structure of **3** is the uncommon chair/chair conformation of the diazametallacyclohexane rings. Some steric repulsion of the β-CH_2 groups in the folded-back daco ring is evident by the distortion of the bond angles at C5 and C4 from tetrahedral; bond angles of 118.0(4)° and 118.2(5)° are obtained for N1a-C5-C4 and C3-C4-C5, respectively.

Attempts to generate a pentacoordinate Ni^{II} complex by addition of only one equivalent of ICH_2CO_2Na to **1** led to a green product, which on subsequent addition of a second equivalent of ICH_2CO_2Na yielded blue **3**. Elemental analysis of the green material showed it to be the sodium salt of the complex anion iodo(5-sulfidoethyl-1,5-diazacyclooctyl)-3-thiapentanoatonickelate(II). This indicates that the axial oxygen donor atom promotes hexacoordination to the Ni center.[6] In contrast, ICH_2CO_2Na did not react with the dimeric zinc complex **4**.[10] However, from the reaction of **4** with a fourfold excess of $ClCH_2CO_2H$, low yields of **5** · H_2O were obtained [Eq. (b)].

The X-ray structure[11] of **5** (Fig. 2) provides interesting structural contrasts to that of compound **3**. Notably, the

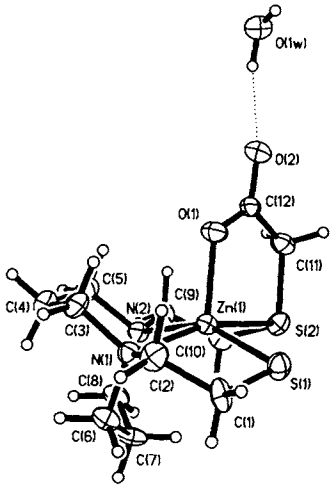

Fig. 2. Crystal structure of $5 \cdot H_2O$ (thermal ellipsoids at 50% probability). Selected bond lengths [Å] and angles [°]: Zn-S(1) 2.295(3); Zn-S(2) 2.584(2); Zn-N(1) 2.184(6); Zn-N(2) 2.189(7), Zn-O(1) 2.005(5) O(1)-C(12) 1.279(9); C(12)-O(2) 1.232(8), O(2)-O(1w) 2.85(1); S(1)-Zn-S(2) 95.6(1); N(1)-Zn-N(2) 83.8(2); S(1)-Zn-N(1) 88.5(2); S(2)-Zn-N(2) 84.3(2); S(1)-Zn-N(2) 153.6(2); S(2)-Zn-N(1) 161.0(2); O(1)-Zn-S(2) 82.6(1); S(1)-Zn-O(1) 112.1(2); C(3)-N(1)-C(6) 111.2(6); C(3)-C(4)-C(5) 115.8(7), Zn-S(2)-C(11) 93.5(2).

diazametallacyclohexane rings are in their usual chair/boat configuration with tetrahedral bond angles at the C atoms. The zinc ion is 0.431 Å above the N_2S_2 best plane, and shows a distinct difference in distances to sulfur: d ($Zn-S_{thioether}$) = 2.584(2) Å, whereas d ($Zn-S_{thiolate}$) = 2.295(3) Å. In contrast to **3**, there is a difference in the lengths of the two C–O bonds; that directed toward the zinc atom is some 0.05 Å shorter than that whose oxygen atom forms a hydrogen bond to the one water of crystallization. The NCH_2CH_2S arms are eclipsed across the MN_2S_2 plane in **4**; in **3**, they are staggered.

In contrast to **1** and **2** (as well as to other sulfidoalkyl- or thioether/daco derivatives), which have electrochemically accessible $Ni^{II/I}$ couples,[5] complex **3** shows no reduction to −2.0 V (cyclic voltammogram in acetonitrile referenced to $Ag^{\circ}/AgCl$). However, the oxidation at +0.99 V is reversible (Fig. 3a) and, as shown by the following EPR results, takes place at the metal center.

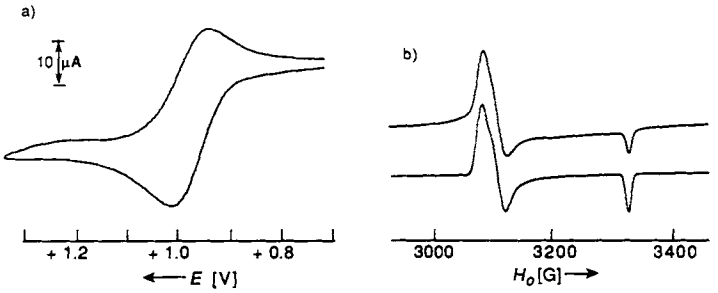

Fig. 3. a) Cyclic voltammogram of **3** (2 mM) in CH_3CN, 0.1 M Bu_4NPF_6. $E_{1/2}$ = 989 mV (Ag/AgCl reference), with $\Delta E_{a/c}$ = 65 mV, i_{pa}/i_{pc} = 0.91. b) Observed and calculated X-band EPR spectra for **3** (4 mM) in CH_3OH bei 10 K (ν = 9.419 GHz). Calculated g-values: 2.190, 2.170, 2.024.

Chemical oxidation of **3** with cerium ammonium nitrate produced an air-sensitive, brick-red, paramagnetic compound which is long-lived even at 22 °C. The simple features of its EPR spectrum, measured on a frozen solution sample, are consistent with a single EPR-active species with nearly axial symmetry (Fig. 3b). Spectral simulation (Fig. 3b) reveals a small anisotropy in the $g_{\perp}$ feature; the best-fit values are $g_{xx} = 2.190$, $g_{yy} = 2.170$, and $g_{zz} = 2.026$.[13, 14] These EPR features indicate that the unpaired electron resides in the d_{z^2} metal orbital of an elongated octahedral d^7 metal complex.[15, 16] However, in the absence of any hyperfine interactions from donor atoms, assignment of the z axis and structural inferences based on EPR spectra are equivocal.

Experimental Procedure

Preparation of **3**: Addition of two equivalents of ICH_2CO_2Na dissolved in methanol to a purple solution of **1**, in CH_3CN at 60 °C with stirring results in a color change, first to brown, then gradually to a forest-green, and finally to aquamarine-blue over the course of 4 h. Filtration and slow evaporation of solvent in an open vessel gave blue, paramagnetic crystals of $3 \cdot (H_2O)_3$ (H_2O from the hygroscopic Na acetate and from the air) in over 90% yield. Correct C,H,N analysis. UV/VIS: λ_{max}[nm] (ε) = 600(49), 364(31); IR(KBr): $\tilde{\nu}$ [cm^{-1}] = 1593, 1385.

Preparation of **5**: A solution of $ClCH_2CO_2H$ (70 mg, 0.67 mmol) in 5 mL of anhydrous CH_3OH was added to **4** (100 mg, 0.17 mmol) in a 50:50 mixture of hot CH_3OH/CH_3CN and refluxed for 1 h. A small amount of white solid precipitated upon cooling and stirring overnight. Recrystallization from pyridine/ether yielded colorless crystals in 15% yield. Correct C, H, N, analysis. IR(KBr): $\tilde{\nu}$[cm^{-1}] = 1633, 1344.

Oxidation of **3** for EPR sample: A 42 mg (91 mmol) sample of **3** was dissolved in 20 mL of anhydrous, degassed MeOH and stirred under N_2. To this blue solution was added with stirring one equivalent of cerium ammonium nitrate dissolved in MeOH. A 500 µL brick-red sample for EPR study was withdrawn and immediately frozen at −70 °C. The red color of the frozen sample remains indefinitely; however, in the course of 30 min at 22 °C, the reaction mixture changed from red back to the original blue. EPR data on frozen solutions were obtained at 77 K on a Bruker ESP 300 spectrometer equipped with an Oxford Instruments ER910 A cryostat. An NMR gaussmeter (Bruker ERO35M) and Hewlett Packard frequency counter (HP5352B) were used to calibrate the field and microwave frequency, respectively.

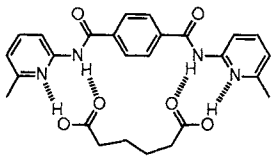
A Self-Assembling, Hydrogen-Bonded Helix**

By *Steven J. Geib, Cristina Vicent, Erkang Fan,* and *Andrew D. Hamilton**

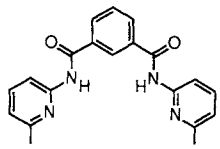
In memoriam Margaret Etter

The design of molecular subunits that self-assemble into defined structures in solution or in the solid state is an area of intense current interest.[1] A key to controlling the shape of the aggregate lies in manipulating the type and orientation of the noncovalent interactions between the subunits.[2] The strong and directional nature of hydrogen bonds has led to their widespread use in self-assembling systems. In the solid state, rules have been delineated to allow the reasonable prediction of hydrogen-bonding packing patterns in crystals.[3] This has led to a search for molecular components that because of their hydrogen-bonding characteristics will form persistent packing motifs in well-defined shapes or patterns. Recent results have demonstrated the formation of two- and three-dimensional networks of di- and tetrapyridones;[4] extended sheet structures of ureylenedicarboxylic acids;[5] molecular tapes or (3 + 3) cyclic aggregates made up of alternating melamine and barbiturate derivatives;[6, 7] and variable molecular ribbons composed of hydrogen-bonded acylaminopyridine and acid subunits.[8] In this paper we report the design and structural properties of a molecule that in the presence of an aliphatic dicarboxylic acid of the correct length will self-assemble into a helical arrangement of alternating components held together by a network of hydrogen bonds.[9–11]

We have previously shown[12] that a receptor molecule made up of two 2-amino-6-methylpyridine units separated by a terephthalate spacer and in a *syn* orientation will form strong complexes with dicarboxylic acids of appropriate length with four hydrogen bonds as in **1** with adipic acid. Increasing the length of the dicarboxylic acid beyond the optimum leads to the *anti* conformation of the receptor molecule and formation of ribbon structures with bidentate hydrogen bonding between the two alternating components.[8b] We were interested in investigating the recognition properties of the related isophthalate receptor molecule **2** (formed from isophthaloyl dichloride and 2-amino-6-methylpyridine) since this now has three primary conformations (due to rotation about the phenyl-CO bond); *syn-syn* (see **2**), *syn-anti*, and *anti-anti*. In the *syn-syn* conformation the hydrogen-bonding cavity of **2** is appropriate for binding to urea or barbiturate derivatives[13] but would be too small to form 1:1 complexes with dicarboxylic acids. The carboxylic acid groups on two different molecules could, however, bind to **2**

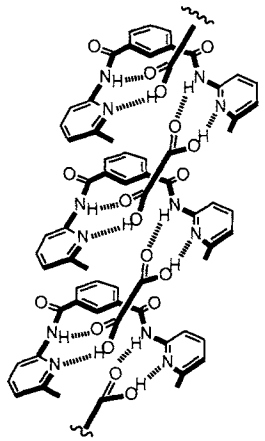


1



2

with one aminopyridine unit directed above and the other below the plane of the binding cavity. Propagation of this arrangement with a dicarboxylic acid would lead to an extended helical structure, as shown in **3**.



3

Crystallization of a 1:1 mixture of **2** and pimelic acid (heptanedioic acid) by slow diffusion of hexane into $CHCl_3$ gave colorless triclinic needles. X-ray diffraction analysis[14, 15] showed a polymeric cocrystal composed of alternating units of **2** and pimelic acid linked by a network of hydrogen bonds (Fig. 1). Compound **2** is not planar in the

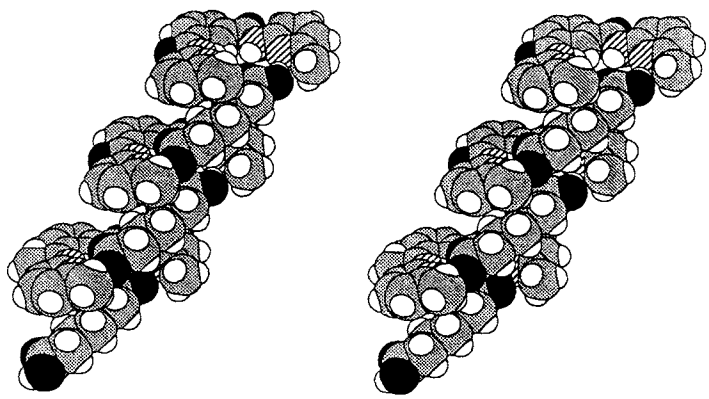


Fig. 1. Section of the X-ray structure of the polymeric 1:1 complex of **2** and pimelic acid (stereoview).

complex; one acylaminopyridine is 20.5° above and the other 9.4° below the plane of the isophthalate ring. Each pimelic acid molecule retains its preferred all-*trans* conformation and forms two pairs of hydrogen-bonding interactions (NH···O 2.18, N···HO 1.86 Å) to different receptor units.[8b] However, the U-turn shape of the *syn-syn* conformer of **2** enforces an overall helical arrangement onto the strand. A top view of the structure (Fig. 2) shows the perfect alignment of the individual subunits with a spacing of 7.04 Å between each isophthalate ring on neighboring receptor molecules. There are substantial helix–helix contacts in the crystal lattice. Most importantly, each hydrogen-bonded helix is interlocked with a second helix of opposite handedness, as seen in Figure 3. This interaction involves the isophthalate groups of one helix in a face-to-face stacking arrangement (ring–ring distance 3.44 Å)[16] with the corresponding groups of the second helix. Such an intercalation is only possible between right-handed and left-handed helices.

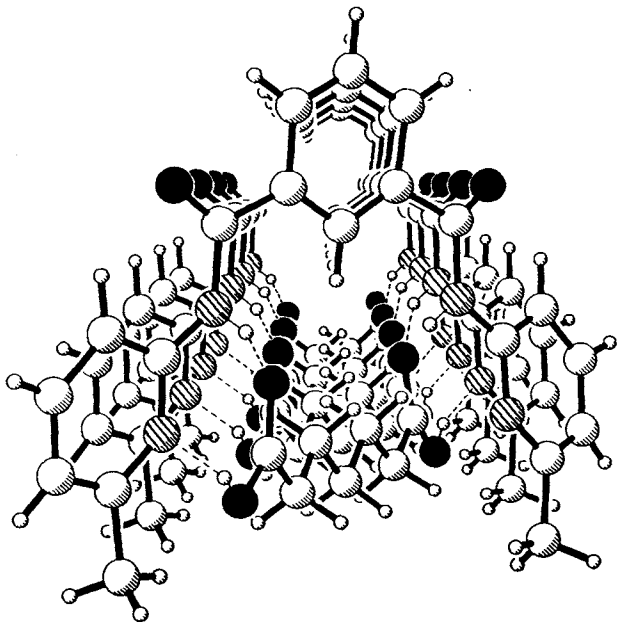

Fig. 2. A top view of the X-ray structure of the polymeric 1:1 complex of **2** and pimelic acid.

One important question is whether a helix of type **3** can exist in solution as well as the solid state. The NMR spectrum of a 0.01 M solution of **2** and pimelic acid (1:1) in D_8[THF]/CD_2Cl_2 (5%) shows large downfield shifts for the pyridine-NH protons indicative of hydrogen-bond formation in solution. Cooling the solution from 298 to 223 K led to upfield shifts of the pimelate-β and -γ CH_2 resonances ($\Delta\delta$ = 0.14 and 0.20) and the observation of NOEs between them and the pyridine-3,-4, and -5 proton resonances. While not conclusive, both of these observations are consistent with a helix-like conformation in solution in which the pimelate alkyl chain is positioned below the plane of one of the pyridine rings.[17]

The stability of the helix structure in the solid state appears to be dependent on the length of the dicarboxylic acid used. Shortening the dicarboxylic acid will reduce the distance between neighboring isophthaloyl rings and inhibit the intercalation interaction seen in Figure 3. Crystals of the 1:1 complex between **2** and glutaric acid were grown from THF (vapor diffusion of hexane), and X-ray analysis was carried out.[15, 18] The structure (Fig. 4) shows the same extended, hydrogen-bonding motif as seen in **3**, reflecting its persistence despite changes in the components and their orientation.[12] In this case, however, **2** has taken up a *syn,anti* conformation, and the glutaric acid displays one *trans* and one *gauche* conformation about its CH_2–CH_2 bonds. The result is a planar ribbon structure stabilized by a hydrogen-bonding network in the plane and stacking interactions between the planes. Figure 4 represents a "squashed" form of the helix in **3** which can, in theory, be converted back to the helix by a rotation of each *anti* phenyl-CO bond by 180° in the same direction towards the center of the spiral.

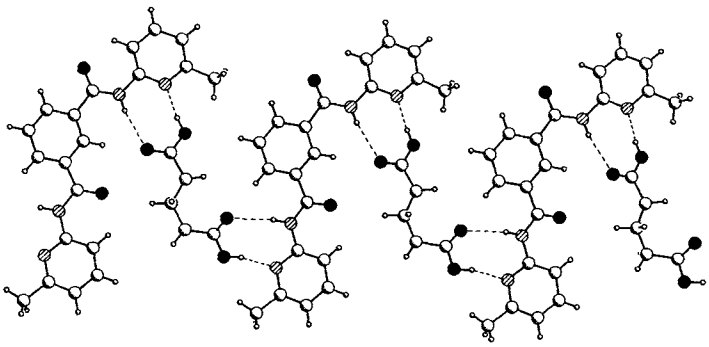

Fig. 4. X-ray structure of the polymeric 1:1 complex of **2** and glutaric acid.

In summary, we have shown that a simple monomeric subunit can be induced, by means of controlling the direction of hydrogen-bonding sites, to interact with aliphatic dicarboxylic acids and self-assemble into an extended helical structure.

Preparation and Structure of Two Highly Reactive Intermediates: $[Li(thf)_4][Cu_5Cl_4R_2]$ and $[Li(thf)_4][AlCl_3R]$, R = $Si(SiMe_3)_3$**

By *Andreas Heine* and *Dietmar Stalke**

The large steric requirement and the good solubility of the products in organic solvents make the tris(trimethylsilyl)silyl ligand developed by Gilman and Smith[1] a versatile ligand both in transition metal chemistry[2–4] and main group metal chemistry.[5–8] With this information and the electron-releasing properties of the $Si(SiMe_3)_3$ unit, we thought that this ligand would also be suitable for the stabilization of intermediates.

The importance of silyl groups in organic synthesis is undoubted, however, very little is known about the structures of the intermediates involved in lithium cuprate reactions.[9, 10] This and a report by Eaborn et al. in 1983 on the preparation and structure of the lithium cuprate $[Li(thf)_4][Cu\{C(SiMe_3)_3\}_2]$[11] encouraged us to react $[(Me_3Si)_3SiLi(thf)_3]$[12] with Cu^ICl at −78 °C. The reaction mixture was stored without workup at −30 °C. A brown powder precipitated (LiCl, $Cu^{II}Cl_2$, and elemental copper), in which deep purple crystals grew. After 14 days these crystals were suitable for an X-ray crystallographic study and were mounted directly on the goniometer head from the mother liquor at approximately −30 °C. At temperatures slightly above −30 °C they decompose instantaneously.

The structure analysis reveals the formula **1**[13] (Fig. 1).

$[Li(thf)_4][Cu_5Cl_4\{Si(SiMe_3)_3\}_2]$ **1**

This empirical formula can be rationalized a posteriori as $[Li(thf)_4][Cu\{Si(SiMe_3)_3\}_2]$ containing four additional Cu^ICl units. At the end of the reaction this lithium silylcuprate, similar to that described by Eaborn et al., might be the main product, although we have been unable to confirm that unequivocally. Figure 1 shows the cuprate anion. To

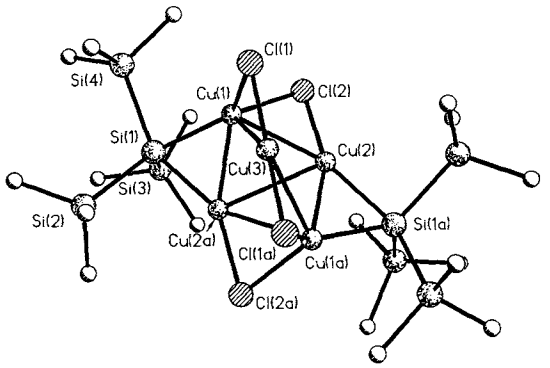

Fig. 1. The structure of the anion in **1** in the solid state. Selected bond lengths [Å] and angles [°]: Si(1)-Cu(1) 2.348(3), Si(1)-Cu(2a) 2.334(3), Cu(1)-Cu(2a) 2.403(2), Cu(1)-Cu(2) 2.654(2), Cu(1)-Cu(3) 2.736(2), Cu(2)-Cu(2a) 2.952(3), Cu(1)-Cl(1) 2.321(3), Cu(3)-Cl(1) 2.127(4), Cu(1)-Cl(2) 2.358(3), Cu(2)-Cl(2) 2.185(3), Si-Si 2.353(4)*; Cu(1)-Si(1)-Cu(2a) 61.75(7), Si(1)-Cu(1)-Cu(2a) 58.86(8), Si(1)-Cu(2a)-Cu(1) 59.40(8), Si-Si-Si 109.96(16)*. Those marked with an asterisk are average values.

our knowledge **1** is the first structurally characterized lithium silylcuprate,[14] a class of compound which is used more and more in situ in organic synthesis. As yet only one other Si–Cu bond length has been determined by X-ray analysis; that found in $[Ph_3SiCu(PMe_3)_3]$.[15] The central silicon atom Si(1) in **1** is in a very unusual bonding situation; it is bonded to three trimethylsilyl groups and two copper atoms, and is thus pentacoordinated. The μ_2-bridging mode for silyl groups is very rare,[16] analogously bound alkyl and aryl groups are, however, well known. The two Si–Cu bonds in **1** are approximately the same length (2.348(3) and 2.334(3) Å) and very similar to the Si–Cu bond length in $[Ph_3SiCu(PMe_3)_3]$ (2.340(2) Å).

The molecule has C_2 symmetry. The bridged Cu(1)–Cu(2a) bond (2.403(2) Å) is by far the shortest of the Cu–Cu bonds in **1** and 0.25 Å shorter than the next longest Cu–Cu bond (Cu(1)–Cu(2) 2.654(2); Cu(1)–Cu(3) 2.736(2); Cu(2)–Cu(2a) 2.952(3) Å). Although slightly shorter Cu–Cu distances are known in complexes where the Cu atoms are forced to come into close contact by chelating ligands

Tammannstrasse 4, D-W-3400 Göttingen (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

(2.348(1) and 2.361(1) Å)[17–19], to our knowledge this distance is the shortest in a Cu_5 complex.[20] Thus the bonding in the almost equilateral triangle $SiCu_2$ can be described in terms of a three-center two-electron bond. The Cu(1)-Cu(2) and Cu(1)-Cu(3) bonds are μ_2-bridged by chlorine atoms. The long Cu(2)···Cu(2a) vector remains unbridged.

In another reaction we treated $[(Me_3Si)_3SiLi(thf)_3]$ with $AlCl_3$ at −78 °C. The reaction mixture was allowed to warm up to room temperature and after the white precipitate that formed had been filtered off the solution was stored at −30 °C. After 2 days at this temperature colorless crystalline blocks began to grow. Single crystals suitable for an X-ray structure analysis were mounted directly on the goniometer head from the mother liquor at about −50 °C. At temperatures slightly above −15 °C these blocks transform into a white insoluble powder. Presumably coordinated THF leaves the lattice and the lithium cation is coordinated to the anion in the form of a contact ion pair.

The reaction product is the aluminate in **2**,[13] where $[Li(thf)_4]$[4] is again the cation (Fig. 2). This molecule may be

$[Li(thf)_4][AlCl_3Si(SiMe_3)_3]$ **2**

interpreted as an intermediate in the reaction to form $[(SiMe_3)_3SiAlCl_2]_2$, which would be of the same structural type as Al_2Cl_6. The structure of **2** proves that the Si–Li bond

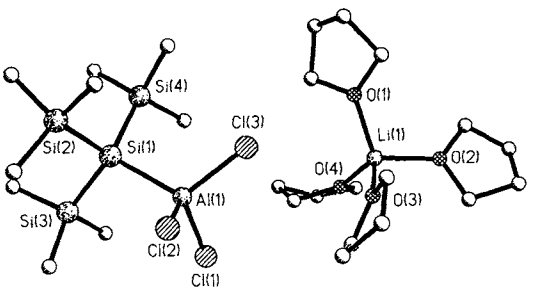

Fig. 2. The structure of **2** in the solid state. Selected bond lengths [Å] und angles [°]: Si(1)-Al(1) 2.446(1), Si-Si 2.341(1).* Al-Cl 2.165(1),* Si-Si-Si 109.96(4),* Cl-Al-Cl 106.34(6)*. Those marked with an asterisk are average values.

in the starting material $[(Me_3Si)_3SiLi(thf)_3]$ is cleaved, and a new Si–Al bond is formed leaving the $AlCl_3$ unit intact, and that LiCl does not precipitate out. Evidently, $AlCl_3$ is a better Lewis acid than the relatively hard lithium atom. The Si(1)-Al(1) bond length (2.446(1) Å) is in good agreement with known values,[21] however, approximately 0.2 Å shorter than the average Si–Li bond length in $[(Me_3Si)_3SiLi(thf)_3]$ (2.644 Å).[22] The average Si-Si-Si angle (109.96°) in **2** indicates than the Si–Al bond is much more covalent than the Si–Li bond. The Si-Si-Si angle in $[(Me_3Si)_3SiLi(thf)_3]$ (102.43(8)°) and in $(Me_3Si)_3SiLi \cdot 1.5$ DME (DME = dimethoxyethane) (104°)[23] indicate that the bond in each case has to be more ionic. The lone pair at the silicon atom $\geqslant Si:^{-}$ $^{+}Li(thf)_3$ fragment reduces the Si-Si-Si angle compared to that in $[(Me_3Si)_3SiAlCl_3]^-$ by more than 7°. The less sterically demanding $-Si-AlCl_3$ covalent bond leads to an Si-Si-Si angle of approximately 110° (**2**). We are currently trying to isolate further intermediates in both reactions.

Experimental Procedure

1: A solution of $[(Me_3Si)_3SiLi(thf)_3]$ (modified preparation ref. [12]) (1.88 g, 4.0 mmol) in pentane (5 mL) was added to $Cu^{I}Cl$ (1 g, 10.1 mmol) in THF at −78 °C over 2 h. A dark purple solution was formed and, after removal of the pentane/THF solvent, cold toluene added, and the solution was cooled to −30 °C. A brown powder of LiCl, $Cu^{II}Cl_2$, and Cu precipitated slowly. After 14 d at −30 °C, cubic, air-sensitive, and extremely thermolabile blocks, identified as **1**, were isolated. Yield ≤ 20%, decomp $T > -30$ °C, color: deep purple. Because of the extreme sensitivity of the compound it was not possible to obtain any spectroscopic data.

2: A solution of $[(Me_3Si)_3SiLi(thf)_3]$ (modified preparation ref. [12]) (2.0 g, 4.3 mmol) in toluene (25 mL) was added to a suspension of $AlCl_3$ (0.5 g, 3.8 mmol) in toluene (20 mL) at −78 °C over 2 h. The solution was stirred for 7 h at −78 °C, then for 10 h at 0 °C, and finally for 7 h at room temperature. The white precipitate, which formed during stirring, was filtered off. A white precipitate was formed from the clear solution at −30 °C, which was redissolved by adding cold THF (3 mL). After 2 days clear, colorless crystals of **2** were obtained at −30 °C. ^1H NMR ([D$_8$]toluene, 25 °C): $\delta = 0.217$ (s, 27H, $Si(SiMe_3)_3$); 1.776, 3.618 (32H, THF); ^{29}Si NMR (THF/[D$_8$]toluene, 25 °C): δ −155.66 ($Si(SiMe_3)_3$), −11.468 ($SiMe_3$).

Intensities of a rapidly cooled crystal (dimensions 0.5 × 0.4 × 0.2 mm) in an oil drop were collected by the $2\theta/\omega$ method in the range $8 \leq 2\theta \leq 45°$. Of the 2095 collected reflections, 2083 were independent and corrected for absorption with a semiemperical method, largest difference maximum and minimum: 0.85 and −0.45 eÅ^{-3}. $R_1 = 0.044$ and $wR_2 = 0.113$ (all data). The absolute structure has been determined by refining the Flack parameter to 0.02(3) (H. D. Flack, *Acta Crystallogr. Sect. A* **1983**, *A39*, 876). **2**: $C_{25}H_{59}AlCl_3LiO_4Si_4$, $M_r = 676.35$, triclinic, space group $P\bar{1}$, $a = 10.606(2)$, $b = 13.699(2)$, $c = 13.754(2)$ Å, $\alpha = 87.40(2)$, $\beta = 86.59(2)$, $\gamma = 89.33(2)°$, $V = 1992.7(3)$ Å^3, $Z = 2$, $\varrho_{calcd} = 1.127$ Mg m^{-3}, $F(000) = 728$, $\lambda = 0.71073$ Å, $T = 153$ K, $\mu(Mo_{K\alpha}) = 0.397$ mm^{-1}, data were collected on a Stoe-Siemens-AED. Intensities of a rapidly cooled crystal (dimensions 0.6 × 0.6 × 0.4 mm) in an oil drop were collected by the $2\theta/\omega$ method in the range of $8 \leq 2\theta \leq 50°$. Of a total of 7543 reflections, 7012 were independent and corrected for absorption, largest difference maximum and minimum: 0.34 and −0.20 eÅ^{-3}, respectively. $R_1 = 0.045$ and $wR_2 = 0.109$ (all data). Both structures were solved with direct methods (SHELXS-90) [24] and refined by full-matrix least-squares of F^2 (SHELXL-92) [25]. The hydrogen atom positions were refined with a riding model where the CH_3 groups were free to rotate around their local threefold axis. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

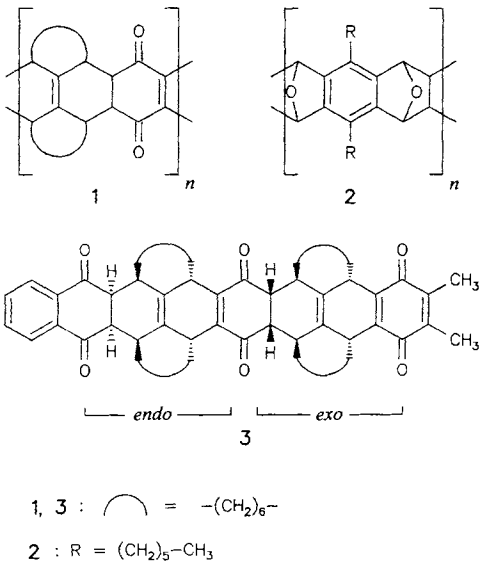
On the Shape of a Diels–Alder Ladder Polymer**

By *Britta L. Schürmann,* Volker Enkelmann,* Matthias Löffler*, and *Arnulf-Dieter Schlüter**

We have developed a new generation of double-stranded (ladder) polymers, which have poly-Diels–Alder addition reactions as a basis for their synthesis.[1] Polymers **1** and **2** were studied extensively as representatives of this group of polymers and found to be extremely soluble in common organic solvents. Not only was their double-strandedness unambiguously proven.[2] but for the first time in the history of ladder polymers, comprehensive information on the molecular weights,[3] the nature of end groups,[3] and configurational and conformational aspects[4] was also obtained. In addition, a model for the shape of polymer **1** was proposed, according to which, the polymer attains the structure of a three-dimensional coil.[4] In this paper, we mostly provide



1, 3 : ⌒ = $-(CH_2)_6-$

2 : R = $(CH_2)_5-CH_3$

theoretical evidence that certain ladder polymers in solution may attain the unprecedented shape of a two-dimensional coil, as is illustrated by the computer-generated structure of polymer **2** (Fig. 1).

The formulas of **1** and **2** suggest that both double-stranded polymers have a symmetry plane (σ_{xy}) perpendicular to the plane sketched here, which cuts the bonds that connect the two strands. However, for **1**, model studies clearly show that this is not the case. In constrast to the *endo*-configurated unit (see **3**), the cyclohexene ring of the *exo*-configurated repeat units exists in one of the two possible staggered conformations,[5] which are both nonsymmetrical about σ_{xy}. Figure 2a shows the (published[4]) molecular structure of model compound **3** in the crystal to visualize the consequences for the shape of **1**. Whereas the *endo*-unit has plane symmetry, the *exo*-unit does not. It is this unit that forces the backbone of **1** into the third dimension.

[**] This work was supported by the Bundesministerium für Forschung und Technologie and the Fonds der Chemischen Industrie. We are grateful to Prof. G. Wegner, Mainz, for his interest in and support of this work.

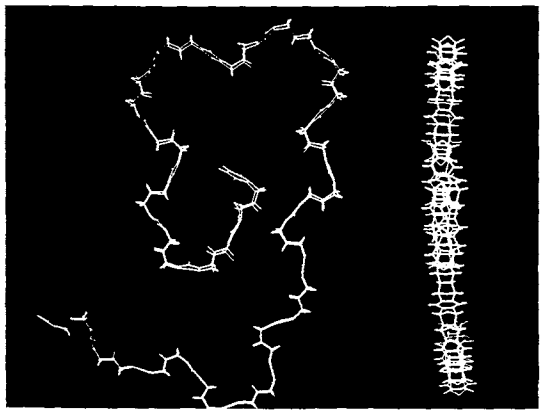

Fig. 1. Top and side view of a computer-generated structure of **2** (alkyl substituents omitted) with a statistical sequence of *syn*- and *anti*-oriented oxygen bridges.

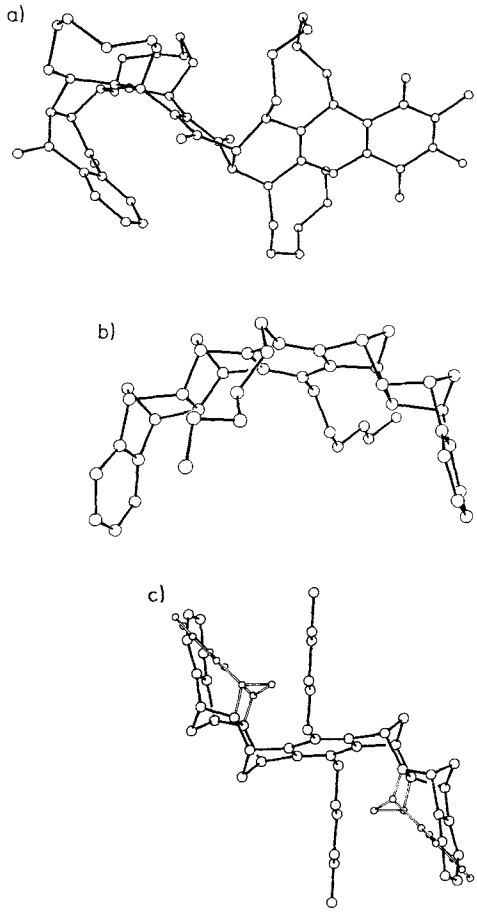

Fig. 2. ORTEP representations of the structures in the crystal of **3** (a), all-*syn*-**6** (b), and all-*anti*-**6** and *syn*/*anti*/*syn*-**6** (mixed crystal) (c).

The structural characteristics of polymer **2** differ distinctly from those of **1**, even though its backbone also consists of linearly annulated, all-carbon, six-membered rings. However, all these rings are now conformationally rigid and have the proper symmetry elements for the polymer to show plane symmetry. Compound **6**, a model for **2**, was selected to demonstrate this point. The three diastereoisomers, all-*anti*-**6**, all-*syn*-**6**, and *syn*/*anti*/*syn*-**6** were synthesized by reacting the bisdienophile **4**[6] with two equivalents of a precursor for isobenzofuran (**5**),[7] single crystals were grown, and the structures in the crystal determined. All-*anti*-**6** and *syn*/*anti*/

7

syn-**6** are unique cases because they form mixed crystals with statistical disorder.[8] As can be expected, all isomers have a symmetry plane in which the oxygen atoms lie (Fig. 2b, c).[9–11] These structures, however, and the vague description of the fragments of **2** as being rigid are not sufficient to lead to the conclusion that **2** attains the shape of a (snake-like) two-dimensional coil. This would depend upon the degree of anisotropy of the flexibility of **2** in the plane and out of the plane.[12] All-atom molecular dynamics (MD) is an appropriate method to gain information on the fluctuations of the atoms' positions in molecules. It takes into account the chemical structure as well as all the interactions between each two particles of a given ensemble. Hence, we applied this method (AMBER program[13]) to help solve the problem of the shape of polymer **2** in solution. An assessment of the reliability of this method has been published, in which structural predictions based on MD are compared with results obtained from, for example, 2D NMR or X-ray investigations.[14]

Polymer **7**, which consists of seven repeat units carrying no alkyl chains[15] and terminated by benzene rings, was selected as a model for **2**.[16, 17] The MD studies were carried out a) with two different starting conformations of **7** (A and B) to avoid a dependence of the result upon the initial structure and b) in the presence of solvent molecules (benzene), since polymer/solvent effects have considerable influence on the conformation of a polymer chain.[18] The starting structure A of model **7** was constructed by using bond lengths and angles from the X-ray structures of **6** and the AMBER data bank which gives it plane symmetry.[13, 19] Conformation B is an equilibrated structure (after 30 ps) which was created from A by performing a MD calculation in vacuo. During the calculation (without solvent) the initially two-dimensional coil starts to deviate significantly from planarity, which is initiated by higher fluctuations of the termini. This can be seen from the values of the moments of inertia (I_x, I_y, I_z) about the x, y, and z axes which remain similar and constant (over 65 ps) after equilibrium is reached (Fig. 3a).

Both initial structures were placed in a box of constant volume filled with benzene molecules of realistic density at 300 K, and the molecular dynamics were simulated under periodic boundary conditions.[20] The results are as follows: Conformation A keeps its two-dimensional shape over the entire period of simulation (130 ps). This was derived from the dependence of I_x, I_y, and I_z on time. As is required for a nonspherical structure, the values of I_x and I_y are significantly larger than those of I_z (Fig. 3b). Visualization of the molecular dynamics in a movie showed that the structure, on a time average, retains the symmetry plane σ_{xy}. To avoid the local minimum problem, the calculations were repeated at

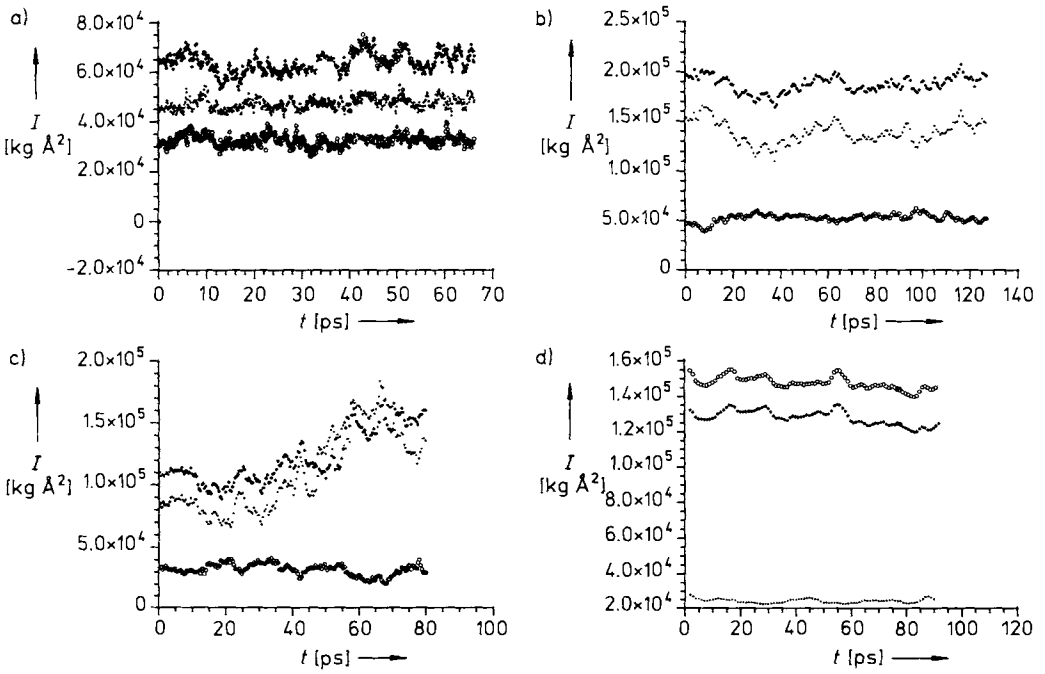

Fig. 3. Dependence of the moments of inertia I_x ◆, I_y (○), and I_z (●) about the x, y and z axes on time (t) of the two different starting conformations A and B (see text) of compound **7**. a) B obtained from A in vacuo, and b) A in benzene (both runs at 300 K after equilibrium is reached). c) B at 700 K during equilibration, and d) B at 300 K after heating to 700 K (d).

400, 500, 600, and 700 K[21] followed by cooling to 300 K, which yielded results in full agreement with those obtained at 300 K.

For starting structure B, the simulation in benzene at 300 K did not lead to any significant change of the gross conformation even at extended simulation time (200 ps). Therefore, the system was heated to 700 K in steps of 100 K. After each run had equilibrated, the system was cooled to 300 K. Finally, in the 700 K case for this conformation, a change in a plane-symmetrical geometry takes place. Figure 3c shows that the moments of inertia about the three axes split into two sets of values (I_x, I_y, and I_z), which are retained upon cooling (Fig. 3d).[22] As in the case of conformation A, the visualization of the molecular motion revealed that conformation B was not spherical anymore but, in fact, two-dimensional and disc-like (on a time average). However, the end-to-end distance was now smaller by a factor of approximately 2 and did not converge within 100 ps to that of the equilibrated conformation A. Undoubtedly, this is due to the large time scale within which the backbone is stretched out.

Regardless of the starting conformation, **7** in benzene solution equilibrates to a two-dimensional conformation, which indicates a unique structural feature of **2** and other ladder polymers of comparable rigidity and symmetry. It is important, however, to realize that this calculation does not account for other effects which might play a role during synthesis of the polymer. It may well be the case that, as the polymer chain grows, larger fragments of the same polymer chain overlap each other irreversibly or that intermolecular effects (for example: formation of entanglements) prevent the polymer from relaxing into a two-dimensional geometry. Small-angle X-ray scattering is an appropriate method with which one can approach this problem experimentally.[23]

Experimental Procedure

A suspension of a mixture of *anti*-**4** and *syn*-**4** [6] (3.0 g, 7.9 mmol) and **5** (8.38 g, 15.8 mmol) in toluene (80 mL) is heated at reflux for 24 h under nitrogen, whereupon the solvent is removed. The crude material obtained is chromatographed through silica gel with petroleum ether (60/40)/ethyl acetate (9/1) as eluent to remove 1,2,3,4-tetraphenylbenzene. A mixture of at least four of the six possible diastereomeric adducts (NMR) is then recovered from the column by using THF as eluent. Yield: 4.37 g (90%). Correct elemental analysis. Fractionating crystallization from chloroform affords pure all-*anti*-**6**, whose solubility is the lowest of all diastereomers obtained, pure all-*syn*-**6**, as well as mixed crystals of all-*anti*-**6** and *syn*/*anti*/*syn*-**6**. ^{1}H NMR (300 MHz, $CDCl_3$): all-*anti*-**6**: δ = 2.38, 2.49 (2m; 4H; α-CH_2), 2.64 (dd, J_1 = 3.2, J_2 = 1.7 Hz; 4H, H-5a, 8a, 14a, 17a), 4.61 (s; 4H, H-6, 8, 15, 17), 5.25 (dd, J_1 = 3.2, J_2 = 1.7 Hz; 4H, H-5, -9, -14, -18); all-*syn*-**6**: δ = 1.87 (s; 4H, H-5a, 8a, 14a, 17a), 2.57 (t, J = 7.6 Hz; 4H, α-CH_2), 5.39 (s; 4H, H-5, 9, 14, 18), 5.40 (s; 4H; H-6, 8, 15, 17); *syn anti syn*-**6**: δ = 1.95 (s; 4H, H-5a, 8a, 14a, 17a), 2.45–2.67 (m; 4H, α-CH_2), 5.44, 5.46 (2s; 8H; H-5, 6, 8, 9, 14, 15, 17, 18).

Berendsen, *Angew. Chem.* **1990**, *102*, 1020; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 992; H. Frühbeiß, R. Klein, H. Wallmeier, *ibid.* **1987**, *99*, 413 and **1987**, *26*, 403.

[15] The alkyl chains containing six C atoms are expected to have only minor influence on the conformation of the backbone.

[16] The sequence of the relative configurations of neighboring oxygen bridges in **7** is *anti*/*anti*/*syn*/*syn*/*syn*/*syn*/*anti*/*syn*/*anti*/*anti*/*anti*/*syn*/*syn*/*anti*/*anti*.

[17] The structure shown in Figure 1, though having all features required for the formation of a two-dimensional coil, could not be used for simulations *in solution* because of the large number of atoms.

[18] For example see M. Depner, B. L. Schürmann, *J. Comput. Chem.* **1992**, *13*, 1210.

[19] The partial charges used to describe Coulombic interactions were obtained from MNDO calculations and scaled by the empirical factor of 1.3, a factor generally used to obtain consistency with the AMBER force field. [13]

[20] An appropriate distance (1.2 Å) between the solvent and solute molecules was chosen to ensure the correct physical density of the solvent. For a more detailed description, see ref. [18].

[21] The heating was performed to explore the conformational space in the sense that kinetic energy pumped into the ensemble is used to overcome the energy barriers separating the different local minima. Bond breaking cannot occur because of the particular mathematical expression used for the potential.

[22] The I_x, I_y, and I_z values of the two-dimensional coils obtained from starting conformations A and B, respectively (Fig. 3b and d), vary due to differences in the shape of these coils as reflected by the different end-to-end distances.

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Inorganic Chemical Nomenclature. By *B. P. Block, W. H. Powell,* and *W. C. Fernelius.* American Chemical Society, Washington, DC, 1990. 224 pp., hardcover $ 59.95.—ISBN 0-8412-1697-5; paperback $ 39.95.—ISBN 0-8412-1689-3

The task of chemical nomenclature is to provide a systematic method for naming chemical substances. It is in the nature of things that the rules developed for this purpose cannot remain static, but must continually grow to accommodate new classes of substances and increasingly complex structures. How and to what extent this is done are matters that must be kept continually under review. These questions are the particular concern of the IUPAC nomenclature panels, whose members published in 1990 a considerably enlarged and thoroughly revised new edition of the 'Red Book' that has, since 1970, contained the IUPAC recommendations for inorganic chemical nomenclature (see the book review by G. B. Kauffman: *Angew. Chem.* **1991**, *103*, 738; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 721). Almost simultaneously with the latter publication the book reviewed here appeared. It is the result of an initiative by the nomenclature committees of the American Chemical Society (ACS), and is intended to be complementary to the book "Nomenclature of Organic Compounds, Principles and Practice", published by the ACS in 1974.

A question that must arise is whether a useful purpose is served by now having two books available on the same topic. There can be no doubt that as a compilation of rules this book must be measured against the 1990 version of the IUPAC recommendations. If in addition it succeeds, as the introduction claims, in equipping the reader with the knowledge required to undertake searches in the older literature, and in conveying a fundamental understanding of the principles of modern inorganic nomenclature, then it should certainly be regarded as a valuable addition to the Red Book.

The problem of dealing with the older literature and with compound names that are no longer in common use has been solved effectively, by including notes scattered throughout the book explaining the older naming conventions, and citing the earliest use of the names that have replaced them. Also the coverage of the individual subject areas could hardly be bettered as regards being complete and up-to-date. The weaknesses of this work lie rather in the method of treatment: the authors devote a disproportionate amount of space to their specialist fields at the expense of topics of more general interest. For example, one finds just four pages on organometallic compounds (Chapter 12), compared with 16 pages on boron hydrides (Chapter 11), 10 on quasi-single-strand polymers (Chapter 7), and 14 on isotopically labeled compounds (Chapter 15).

Unfortunately the care that has been devoted to the latter chapters is lacking in some other parts of the book. After an introductory first chapter, which discusses in a very general way the relationship between language and nomenclature, Chapter 2 launches into the main subject. Here it would undoubtedly have been more sensible to place the explanations of important terms used in inorganic chemistry (oxidation number, binary, ligand, etc.) before the section on "Nomenclature—Conventions" rather than after it. Unfortunately also the description of different systems of nomenclature has been limited to merely listing them, which fails to convey the advantages of particular methods, such as general applicability and simplicity. It should have been pointed out at this stage that the additive nomenclature for inorganic compounds is the most universally applicable. The discussion of the "Grammar of Nomenclature", in which the components of chemical names, such as multiplicative prefixes and locants, is very comprehensive, except for free radical points. The comparatively rare use of the symbol Δ in organic chemistry is explained in detail, whereas its much more important use in inorganic chemistry as a structural descriptor for polyhedral compounds (Ch. 11) is not mentioned. Here, as also in other parts of the book, there is a lack of coherent structure within the individual chapters. After reading Chapter 3 on "Homoatomic Species", one feels compelled to make a case for trivial names. Where these are simple and concise they are definitely preferable to overelaborate systematic names. Otherwise one might in future have to worry about a *catena*-trioxygen hole in the stratosphere! Two lines further on from this example one ought, for consistency, to refer to *tetrahedro*-tetraphosphorus as the systematic name for white phosphorus.

Here in passing is another curiosity. If at any time one needs to give names to 'elemental associates', one should refer to Section 3.2.7. Here one learns, for example, that a particle made up of a muon and an electron is nearly always called 'muonium'. In Chapter 4, which deals with the nomenclature of heteroatomic species, the term 'radical' is applied exclusively to species with unpaired electrons, which is certainly a sensible usage. However, systematizations such as that in Section 4.3.3 ("Binary Oxo Groups") are more likely to confuse; it would have been sufficient to list them. Names such as '... ferrocyanide' (Section 4.3.3) should now be a thing of the past, and radicals should be clearly identified as such (Section 4.5.4).

Chapter 5 has the title "Additive Nomenclature". Here it would certainly have been useful for quick reference to include the nomenclature of coordination compounds. In Section 5.3.5.2 where the κ convention is introduced, it would have been better in the reader's interest to completely avoid the abbreviated way of writing the formulas; in this and certain other cases (Section 5.3.5.3 and parts of Chapter 6, "Multinuclear Complexes") structural formulas are clearly preferable. This would also avoid the need to label the coordinating centers with an asterisk, a symbol that is best reserved for chiral centers and excited states. Also it would have been better to stick to examples in which the use of the κ convention is essential—it is unnecessary in $K_4[Fe(CN)_6]$ and in the symmetrically bridged carbonyl compound $[(CO)_3Co(\mu\text{-}CO)_2Co(CO)_3]$. In Section 5.3.6.3, where the structural prefixes *fac* and *mer* are introduced, it should have

been mentioned that these are no longer to be used as parts of names, but only as general descriptions of complexes of this type; for more complex systems one should use the procedures described in Chapter 16.

Oxo acids, which are treated in Chapter 8, "Acids and Bases", belong to the classical territory of inorganic chemistry, so it is not surprising that this area has a liberal scattering of trivial and non-systematic names. If one adopts from the start such rather unusual structure-based formulas as $ClO_3(OH)$ or $SO_2(OH)_2$ (despite the fact that clear IUPAC recommendations exist for these also), one should then use these forms consistently, and avoid later writing, for example, H_3PO_2 or H_2MnO_4. Here again a too rigorous systematization does not make for easy comprehension; for example, the prefixes ortho and meta were used to distinguish acids that differ in their water content, a terminology that has persisted to the present day in names such as metaboric acid and (less commonly) orthophosphoric acid. But when one finds 'orthosulfurous acid', $S(OH)_4$, alongside 'metasulfurous acid', with an explanation in a footnote that 'meta' can usually be omitted, this is too much of a good thing. Also it is noticeable that whereas the 1957 and 1970 IUPAC inorganic rules and the 1979 IUPAC organic rules are cited frequently, there are only a few references to the 1990 rules. This is especially irksome in cases where discrepancies arise, as in the heteropolyanion $[O_3SOCrO_3]^{2\ominus}$, where the latest IUPAC recommendations now specify that the constituents should no longer be given in alphabetical order, but with the ligand first followed by the transition metal; this results in different names.

In Chapter 9, which is concerned with the application of the substitution nomenclature system for inorganic compounds, especially molecular hydrides, it would have been better to use the names consistently for the parent compounds that are listed in Table AVIII. This applies especially to Section 9.4, dealing with the naming of ions, where the names derived from the parent compounds have important advantages. Of the four names given for the $NH_2^{\ominus}$ ion, the systematic name 'azanide' is the most unambiguous, while the trivial name 'amide' and the radiofunctional name 'azanyl anion' are also acceptable. On the other hand a name such as 'dihydronitride' should be avoided. 'Hydro' is only permissible for complex borates, and it would have been better to omit the rules that are given for constructing such names. Even if one were to describe the ion by a name of this kind, the correct form would be 'dihydrogen nitride' (in analogy to dihydrogen sulfide). The use of 'hydro' becomes very confusing when $H_2NNH^{\ominus}$ is called 'trihydrodinitride'.

Chapter 10 on "Chains and Rings" gives a brief account of methods such as the 'a' nomenclature and the Hantzsch–Widmann nomenclature that are already familiar from organic chemistry, and of names based on repeated identical subunits. Here it would have been useful to also refer briefly to alternative methods such as the recent (1989) IUPAC proposals for inorganic systems, in which W. H. Powell was himself involved. The short Chapter 13 on "Addition Compounds" is followed by one on "Nonstoichiometric Species"; this chapter could usefully have been extended to include polyoxoanions and zeolites. The latter are mentioned in Chapter 13, but only briefly. Topics such as the Niggli notation or the 'i/a' notation (Schäfer, von Schnering) might also have been covered briefly.

Lastly, the final Chapter 16 is in a style that would have been preferable for the entire book. A short historical introduction to the topic is followed by a selection of examples with plenty of illustrations and an informative commentary.

Thus, the overall impression left by the book is rather mixed. Specialists will probably pick up answers to specific problems here and there, but the book only meets the needs of beginners to a limited extent. It forms an acceptable complement to the Red Book, which is, however, due to be followed by a further volume dealing with specialist topics. One is left wondering whether, in the interests of more effective communication between chemists, it might not have been better to combine the efforts to produce a single authoritative book of rules on nomenclature.

The Historical Development of Chemical Concepts. By *R. Mierzecki*. Kluwer Academic Publishers, Dordrecht, 1991. XI, 281 pp., hardcover HFl 240.00.—ISBN 0-7923-0915-4.

This book is a translation from the Polish original published in 1985. It gives silent testimony to the difficulties of scholarship in Eastern Europe. For instance, the index fails to give J. Desmond Bernal's year of death (1971), presumably through lack of documentation. The book does not rise to its ambition, it is a textbook on the history of chemistry, not a scholarly monograph. The viewpoint is that of Whig historiography, truth arising gradually from misconceptions. It has the merit of stressing the contributions of Eastern scientists, sometimes neglected in standard treatments. An example is the Russian pioneer Mikhail Lomonossov. Conversely, the coverage of Western chemists is inadequate. One may ask how any serious historical study of the history of chemistry can fail to mention the likes of Max Born, Lazare Carnot, Georges Darzens, Victor Grignard, Fritz Haber, René-Just Haüy, Roald Hoffmann, Hans Meerwein, R. S. Mulliken, Joseph Needham, Robert B. Woodward...

Besides the absence of such great names, treatment of the concepts is skeletal. It has not been fleshed out with the excitement of the actual history. Take catalysis as an example. It is given a little over a page, focussing only on Wilhelm Ostwald, the Arrhenius activation energy, autocatalytic reactions, and the notion of chain reactions (Nernst–Hinshelwood–Semenov). What a pity, when the actual discovery makes such wonderful history. I cannot resist, as a positive contribution in this review, recapitulating it for the reader. Kirchhoff decomposed starch with sulfuric acid into dextrin and saccharose in 1811. Thénard decomposed hydrogen peroxide in the presence of manganese dioxide or platinum in 1818. Thénard had earlier (1813) reported decomposition of ammonia over heated metals. Then Humphrey Davy found (1817) that preheated platinum wire would continue to glow in mixtures of flammable gases. His cousin Edmund Davy, who had been his assistant at the Royal Institution, carried on this line of work. Then came a crucial set of observations. Johann Wolfgang Döbereiner, who had been interested for years in platinum chemistry, repeated the 1820 experiments of Edmund Davy, ascertained that Davy's powder was platinum suboxide, and showed that it was unchanged by the process it took part in. On July 27, 1823, Döbereiner prepared finely divided platinum metal on filter paper and exposed it to hydrogen gas. He witnessed such a strong reaction that it could extract in a few minutes all the oxygen from its mixture with 99% nitrogen. Two days later, Döbereiner wrote to his friend Goethe, then a Privy Councillor and Minister of State to Duke Carl-August in Weimar,

bursting with excitement about the new phenomenon. Goethe was not a total stranger to catalysis—as the phenomenon would be termed by Berzelius in 1835; in his chemical novel *Wahlverwandtschaften* (Elective Affinities) in 1809, the arrival on the scene of Mittler (the "go-between") triggers all sorts of catastrophes!

Basic Principles of Membrane Technology. By *M. Mulder*. Kluwer Academic Publishers, Dordrecht, 1991. XII, 363 pp., hardcover HFl 200.00.—ISBN 0-7923-0978-2

Membrane separation methods are rapidly gaining in importance in many areas of chemical and biochemical process technology. Regrettably, there has up to now been no textbook to make it easier for advanced students of chemistry, process technology, or related disciplines to become involved in this field. This book claims to fill that gap, according to the author's preface.

Unfortunately, however, large parts of the book fail to justify that claim. This failure is mainly due to the book's many didactic shortcomings, beginning with the visual presentation. The small line spacing does not make for easy readability, and the absence of spaces beneath the headings accentuates the impression of a tightly cramped text. Moreover, this is not always accompanied by a high density of information, as the author's style is long-winded and inclined towards repetition. The introductory chapter is frankly confusing; for example, terms such as "ultrafiltration", "dialysis", and "pervaporation" are first encountered in a table in which separation techniques are related to molecular properties. The newcomer to membrane technology who starts to read the book from the beginning will learn very little from this table. Often the explanations of symbols used in equations, in terms of the common descriptions of the quantities represented, come too late after their first appearance (e.g., p. 150: coupling coefficient). Basic chemical and physical concepts are sometimes repeated, while on the other hand one often comes across equations that appear from nowhere, or whose derivation is not properly explained. The list of inadequacies of presentation could be continued.

The many omissions are also a source of annoyance; the following are a few examples. Permeation by vapors is only mentioned in passing. In the discussion of the individual methods, no indication is given as to which of these are already established as the state of the art and which are still at the development stage. The amount of space devoted to discussions of individual membrane techniques in Mulders' book gives no clue as to their relative importance; for example, seven pages are devoted to membrane distillation, which has long been of little importance, whereas for the widely used method of dialysis one finds only two-and-a-half pages. In most cases the author does not discuss the capabilities and limitations of the various theories for describing material transport through membranes; for example, it would be useful to have comparisons between theory and experiment in the form of graphs or tables.

Lastly, this reviewer noticed a few inaccuracies. The first example occurs in the introduction, where density, vapor pressure, and freezing point are incorrectly referred to as "molecular properties". On page 224 one finds the sentence: "The dimensions for permeability coefficients indicate that they depend on the membrane thickness, the membrane area, and the driving force." In fact, exactly the opposite is true. On page 236, the unsuitability of polydimethylsiloxane membranes for removing water from trichloroethylene is due not to the organophilic character of these membranes, but to the fact that they undergo severe swelling in solutions containing trichloroethylene as the main component. On pages 334 ff., diafiltration is compared to a process in a continuous stirred reactor. This comparison is incorrect, as the depletion of one component through diafiltration is analogous to the conversion of a component in a discontinuous stirred reactor, as the equations (VIII-28) to (VIII-34) make clear. Regrettably, this list of inaccuracies too could be further extended.

Nevertheless, the positive aspects of the book must not be overlooked. The manufacture of membranes is treated in great detail, including the thermodynamics of the process. The treatment of ultrafiltration (UF) includes a critical discussion of the "cut-off" value. Some very useful X-ray microanalysis results on UF membranes are included. The discussions of facilitated-transport processes and concentration polarization are highly instructive. In the chapter on "Applications", the author meets the needs of the reader who wants quick information by providing brief summaries in note form at the ends of the sections. Other good features are the section on calculating the required membrane areas for gas permeation plants, and the numerical examples on plant layouts at the end of the book.

To summarize, it must be concluded that, despite a few bright points, the various errors, inaccuracies, omissions, and most of all the shortcomings in presentation, prevent the book from fulfilling the claim mentioned at the beginning. A good, comprehensive textbook on membranes is still awaited.

Atoms in Molecules. A Quantum Theory. (International Series Monographs on Chemistry, Vol. 22). By *R. F. W. Bader*. Clarendon Press, Oxford, 1990. XVIII, 438 pp., hardcover £ 50.00.—ISBN 0-19-855168-1

In a series of papers Richard Bader has developed a view on molecules, often referred to as "Bader analysis", which is based on a mathematical description of the electron density as a function of the spatial coordinates, and which allows one to get relevant information on bonding within a molecule. One can thus define a "molecular structure" that is quite distinct from the molecular geometry. One can further construct boundary surfaces that divide a molecule into its constituent atoms in such a way that the same atom looks similar in different but related molecules. Changes in the electron density due to changes in the geometry, e.g. in chemical reactions, can be described by means of catastrophe theory. More recently Bader's interest has shifted to the field generated by applying the Laplacean $\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$ to the electron density. This field, referred to as the "Laplacean of the density", contains information about, for example, the localization of electron pairs.

The fact that this very useful method of analysis has currently found only little acceptance in main-stream quantum chemistry, and is usually regarded as some kind of curiosity, is partly due, paradoxically, to Bader's claim that his approach is unique and universal. In this very spirit one reads

in the introduction that nowhere in this book must the reader accept arbitrary assumptions or the author's personal view; nevertheless, this book is very personal. But it does present a both valid and unconventional introduction to theoretical chemistry, based on the Bader analysis of electron density.

One may argue that it is unsatisfactory to insist on analyzing the electron density without first worrying about its physical origin, in other words, without first considering the solution of the Schrödinger equation. In fact, the presentation given here is essentially based on a classical picture (the electron density as a classical variable). The Schrödinger equation is mentioned for the first time on page 130. The subtitle "A Quantum Theory" is nevertheless not unjustified, if one considers some of the discussions in Chapters 5, 6, and 8.

For someone working in the field of theoretical chemistry, Bader's book is stimulating, though sometimes hard to read. It is, again paradoxically, the claim that it should be understandable even for the uninitiated reader which makes the access to this book difficult. In fact in addition to a presentation of the author's own work, one finds a great deal of well-known material, which is often so disguised that one does not recognize it immediately. Perhaps a naive reader who reads this book as it is intended--as an introduction to theoretical chemistry--will not mind this.

Manganese Redox Enzymes. Edited by *V. L. Pecoraro*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1992. X, 290 pp., hardcover $ 110.00/DM 186.00--ISBN 0-89573-729-9/3-527-27934-2

This volume presents a detailed overview of the current state of knowledge of manganese containing metalloenzymes that participate in oxidation/reduction processes, most of which evolve dioxygen in their reactions. Heavy emphasis is given to the oxygen evolving complex (OEC) from photosystem II which performs the light driven four-electron oxidation of water to dioxygen, the reverse of the more commonly studied reaction of dioxygen reduction. The problem is presented primarily from a bioinorganic perspective, with emphasis on biophysical measurements which depend on metal centered physical properties and on manganese coordination chemistry.

Based on the contents of this book, the field of manganese redox biochemistry has made significant progress and is poised to make solid advances in understanding this central and highly complex chemistry. The current level of understanding is significantly behind that of iron sulfur, iron porphyrin, copper metalloprotein, and photosynthetic reaction center chemistry in that there is relatively little structural information on the proteins and there are no clearly correct low molecular weight model compounds. However, the amount of physical information on the proteins and low molecular weight compounds and the general knowledge of the coordination chemistry of polynuclear Mn compounds with oxidation states above II is increasing rapidly. The readers of this book will get a good feeling for the level of knowledge and the excitement of the field, as well as the controversies and uncertainties.

Technically, the book is well produced in a consistent typeface. There are few typographical errors, and figures are generally clear except for several of the crystal structure (ORTEP) representations which are poorly labeled and reproduced.

There are 12 chapters in the book. The first is a general review (E. L. Larson and V. L. Pecoraro) of Mn coordination chemistry and magnetic properties of Mn-containing molecules, as well as a summary of the properties of Mn-containing biomolecules and the current candidates for low molecular weight model systems. Chapter 2 (J. E. Penner-Hahn) concerns Mn catalases and presents kinetic as well as structural and magnetic data. Chapter 3 (W. D. Frasch) presents kinetic data on OEC reactions with alternate substrates and inhibitors (H_2O_2, alcohols, NH_2OH, CN^-, Ca^{2+}) and is concerned with photosystem 2 preparations which contain more components than those discussed by other authors. Chapter 4 (C. F. Yocum) discusses the requirement for Ca^{2+} and Cl^- by the OEC. Chapter 5 (J. P. Dekker) concerns interpretation of an optical signal in the 250–350 nm range which varies with oxidation state change in the OEC. Chapter 6 (T. Vänngård, Ö. Hansson, and A. Håddy) is particularly focussed on the complex problem of the EPR signals generated by OEC preparations. Chapter 7 (G. W. Brudvig and W. F. Beck) reviews, particularly up to late 1989, the available information on the interactions of "ligands" (Cl^-, amines, ammonia, NH_2OH, hydrazine, H_2O_2) with the OEC. Chapter 8 (K. Sauer, V. K. Yachandra, R. D. Britt, and M. P. Klein) provides a discussion of the particularly important EXAFS results that many of the other authors quote in order to focus the speculation regarding the structure of the Mn center(s). Further EPR results are also extensively discussed. The use of solvent NMR relaxation as a probe is presented in Chapter 9 (R. R. Sharp). Chapter 10 (V. L. Pecoraro) presents a detailed overview of known low molecular weight Mn complexes and discusses the limitations on Mn–Mn distances provided by various bridging atom arrangements. Chapter 11 (M. K. Stern and J. T. Groves) discusses a separate issue in small molecule Mn chemistry, oxygen transfer by oxo-Mn porphyrins. The last chapter (W. H. Armstrong) presents more results and the motivation behind the construction of some polynuclear model compounds.

Reflections on Symmetry in Chemistry ... and Elsewhere. By *E. Heilbronner* and *J. D. Dunitz*. Verlag Helvetica Chimica Acta and VCH, Basel and Weinheim, 1993, 154 pp., hardcover DM 58.00—ISBN 1-56081-254-0

The book seems to have come out at the wrong time, just *after* Christmas! But there are Christmases to come and this marvelous, handsomely produced volume will find a place under many (slightly unsymmetrical) trees, a token of affection from the chemist's significant other (or vice versa). Like other gifts under those trees, it is almost certain to be wrapped in multicolored paper decorated with some repeating pattern. I remember well as a child looking for the repeat in the paper. The revealable mysteries of these patterns are the melody of this book. Each motif in the Christmas wrap is unique (though designers do tend to copy each other), but if it is to be repeated regularly ("translated") throughout the plane, the pattern, in its symmetries, is constrained by the geometry of our space. There is an infinite variety of designs for the basic unit, but only 17 ways to propagate them in the plane.

"Reflections on Symmetry" is the best popular exposition ever written on symmetry and its role in chemistry. What makes it so good? First, the mastery of the authors, two chemists who have thought more deeply about symmetry and structure (geometrical and electronic) than most of us. Their expertise is a gift to us. Then, the authors are both master tellers of stories, chemical raconteurs. They will not pass up a tale of folly, you can be sure. One wonderful and instructive story they relate is of some crystallographers who took too seriously (or were too lazy to build a model) a distorted journal drawing of a cyclohexane ring. Or the incensed reaction of Henry Edward Armstrong to W. L. Bragg's "failure" to find NaCl molecules in the structure of solid salt: "Chemistry is neither chess nor geometry, whatever X-ray physics may be ...". Third, Dunitz and Heilbronner are master teachers. They know how to rivet our attention with a cigar game (most appropriate to one of the authors, who once gave me a twisty Havana I couldn't find in Havana) that teaches us the importance of perceiving inversion symmetry. Or a striking way of solving a chessboard tiling problem as a lead-in to orbital symmetry control, that phenomenon illustrated with patented blue and yellow orbitals. Only rarely, once in a blue moon (or in a yellow, purple and brown tiling of scalene and equilateral triangles), do the authors misjudge the abilities of lesser mortals to juggle shapes.

The story, that of the role of symmetry in chemistry, is told by Dunitz and Heilbronner with immense wit, best characterized as Scottish/Bavarian. The great and utterly untranslatable German humorist, Karl Valentin, would have been proud of his disciples. So the way an enzyme deals differently with two seemingly symmetrical faces of a molecule is made crystal clear by a photo of a tea cup worn asymmetrically after many years of use by one of the authors. And a hand holding a handed molecule in an illustration sports a bloodied bandage, perhaps the result of a right-hander coping with a left-handed scissors.

The authors, in love with structure, following the pictorial nature of chemistry, of course use a multitude of drawings and photographs. Ruth Pfalzberger deserves great credit for these. The drawings are effortlessly integrated into the text. And it is striking the way they too partake of the wit and pedagogic sensitivity of Dunitz and Heilbronner. Thank God, there are not too many Escher reproductions.

What would I fault? Nothing in the book itself, only an attitude, one I can understand, that gives more value to simplicity and symmetry than it deserves. Symmetry is beautiful (in a simple way), symmetry elicits a sense of peace, repose, and stability. But it's really asymmetry that's interesting. In asymmetry is variety and tension. And richness. Especially in chemistry should we value diversity and difference—what's interesting about steroids is not the underlying molecular skeleton, but the variety of function and biological activity that comes from asymmetrical substitution. Perhaps I'm not entirely fair. Asymmetry without an inkling of order is chaos. Whatever beauty is, the tense edge of symmetry and asymmetry contributes to it. Heilbronner and Dunitz sing the praises of symmetry, but in a closing sentence to a chapter they say "... it could appear that the Gods, unlike humans, have a long-term preference for low symmetry".

It is rare that a book that teaches fundamentals of a science carries the clear stylistic mark of its authors. On every page this gem of exposition does: I read it, and I see the white-haired gentleman who asks hard questions about structures while walking up a Swiss mountain trail; I hear the jovial raconteur of orbital follies handing me a cigar and a glass of wine. I see and hear, and you can read, both of them telling, with deep affection, the wonderful story of symmetry in chemistry.

Sequential Transformations in Organic Chemistry: A Synthetic Strategy with a Future

New Synthetic Methods (88)

By Lutz F. Tietze* and Uwe Beifuss

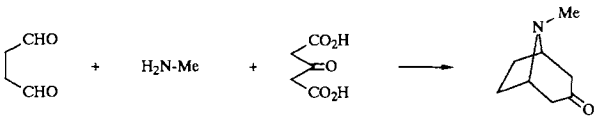
Dedicated to Professor Burchard Franck

Organic-chemical synthesis has always fascinated chemists and will not lose its importance in the future. It is a truism that all chemists—and others too—are dependent on the synthesis of those compounds with which they want to work. As a result, organic-chemical synthesis today is more than ever before the cutting edge of organic chemistry, biology, biochemistry, medicine, physics, and material science. Synthesis is also the basis of the chemical industry. For the passionate synthetic chemist, however, synthesis is much more than just a method for obtaining compounds; it is the expression of his creativity, intelligence, ability, and also his perseverance.

Introduction[**]

In the early days of organic synthesis only simple molecules were prepared. In the meantime, the complexity of target molecules has increased considerably. The current pinnacle has been reached with the synthesis of palytoxin with 64 stereogenic centers,[1] of which, in principle, over 10^{19} stereoisomeric forms can exist. For this reason it has been necessary to develop chemical transformations with increasingly higher selectivity. Thus, in the past few years a wealth of chemo-, regio-, diastereo-, and enantioselective reactions has been discovered and developed, the selectivity of which frequently approaches that of enzymatic processes. Nevertheless, if we compare our synthetic performance to date with that of Nature, then we must recognize that Nature is not just highly selective, but also very efficient, often employing sequential transformations. By this we understand a series of reaction steps in which several bonds are formed or broken, without the isolation of any intermediates.

Important examples include the biosynthesis[2] of alkaloids,[2a] terpenes,[2b] and steroids.[2c] The bicyclic tropane skeleton, an important constituent of numerous alkaloids such as cocaine and atropine, is obtained by a double Mannich reaction of a Δ^1-pyrrolinium salt (formed from ornithine) with an acetoacetate derivative.[3] The analysis of the biogenesis led to an elegant preparation of tropinone **4** by a sequential transformation of succinaldehyde **1**, methylamine **2**, and acetonedicarboxylic acid **3**.[4] Another



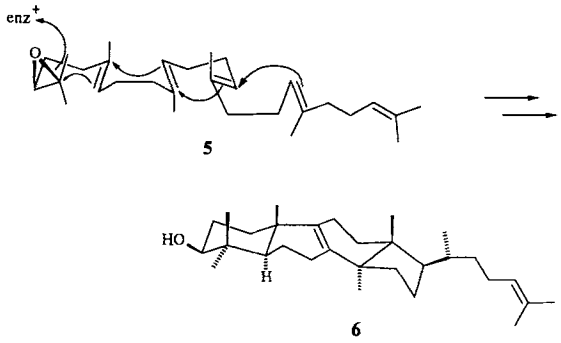
1 2 3 4

particularly fascinating example from Nature is the cyclization of squalene oxide **5** to give lanosterol **6**, a starting material for steroids.[5]

Sequential reactions are characterized by their great elegance, frequently high stereoselectivity, and by the simple manner in which they may be carried out. They permit complex molecules to be constructed in only a few steps. Moreover, the development of this type of synthetic method can lead to a reduction in the amount of undesired by-products, thereby contributing to the protection of the environment.

[*] Prof. Dr. L.F. Tietze, Dr. U. Beifuss
Institut für Organische Chemie der Universität
Tammannstrasse 2, D-W-3400 Göttingen (FRG)

[**] The sections of this review are not numbered systematically; the numbering which begins in the section after next is oriented according to the classification of sequential transformations given in Table 1



For example, the quantity of solvents and eluents required in comparison with stepwise processes is considerably reduced. Sequential reactions should, therefore, be more frequently included in future synthetic planning. In some cases biogenesis could serve as a prototype, but fundamentally new reaction sequences must be developed. In this review we attempt to classify sequential transformations and, with the help of examples from the literature and from our own work, to demonstrate their possibilities. It is not possible, of course, to discuss all known examples. We show, however, that the map of sequential transformations contains numerous gray areas, which should serve to stimulate new discoveries.

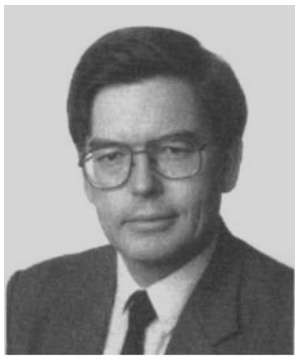
Definitions and Classification

Sequential transformations, which are known to every chemist under the all-embracing term "one-pot reactions", can be divided into two groups:

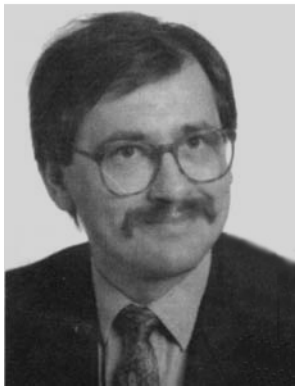
1. Domino Reactions
2. Consecutive Reactions

This division, as well as the following definitions of terms, are of course not compulsory, but appear to us to be sensible and useful. By a *domino reaction*,[6] frequently also described as *tandem or cascade reaction*, we understand a process involving two or more consecutive reactions in which subsequent reactions result as a consequence of the functionality formed by bond formation or fragmentation in the previous step. The preliminary formation of a reactive intermediate such as a carbocation or a carbanion is not counted here as a reaction step. On the other hand, the formation of a diene by a retro-Diels–Alder reaction with a subsequent cycloaddition would be considered as a domino reaction. In the ideal case the individual reaction steps should have comparable rates; for noncomparable rates it should be possible—with or without catalyst or mediator—to carry out reactions at a single temperature. Enrichment of an intermediate, therefore, does not occur. Rather, a "steady-state" concentration of the intermediate is formed, as we have been able to show by NMR spectroscopy for the tandem Knoevenagel hetero-Diels–Alder reaction.[6d]

In a *consecutive reaction* another reagent, mediator, or catalyst is added after the first transformation without isolation of the first formed product; the subsequent reaction steps then lead to the final product. Strictly speaking, sequences in which the individual steps are carried out at different temperatures should also be included in this group; we have not, however, applied too stringent criteria. Finally, the term *iterative process* is also found in the literature; by this term we understand the reiteration of a given transforma-



Lutz F. Tietze was born in Berlin in 1942, studied chemistry at the Universities of Kiel and Freiburg (1961–1966), and received his doctorate in 1968 with B. Franck in Kiel on the biomimetic synthesis of alkaloids. After a two-year post-doctoral period with G. Büchi at Massachusetts Institute of Technology in Cambridge, USA, and a brief research study with A. R. Battersby in Cambridge, England, he obtained his habilitation in 1975 in Organic Chemistry at the University of Münster. In 1977 he was appointed Professor in Dortmund, and in 1978 Full Professor and Director of the Institute of Organic Chemistry of the University at Göttingen, Germany, where he still works. He has been a Guest Professor at Madison, Wisconsin, USA, is a Member of the Scientific Academy in Göttingen, a Fellow of the Royal Society of Chemistry, holder of the Karl-Winnacker prize and the Literature Prize of the Fonds der Chemischen Industrie (together with T. Eicher). His research interests include the development of selective and efficient synthetic methods, reactions under high pressure, photochemical transformations, the stereoselective syntheses of natural products, and also the development of new concepts for a selective cancer therapy, based on phenotypic differences of normal and cancer cell population.



Uwe Beifuss was born in Tornesch/Holstein in 1957 and during the period 1975–1982 studied chemistry at the Universtity of Kiel, the Swiss Federal Institute of Technology (ETH) in Zürich, and at the University of Göttingen. He obtained his doctorate in 1987 with Prof. L.F. Tietze with a dissertation on highly diastereoselective ene reactions for the synthesis of sesquiterpenoids. He spent the period 1987–1988 as a post-doc with Prof. A. R. Battersby in Cambridge, England, where he worked on the biosynthesis of porphyrins. He has been at Göttingen since the end of 1988, working towards his habilitation. In addition to investigating selective reactions with thiocarbenium ions, he is working on the development of new types of dyes for photodynamic cancer therapy.

tion, which can also be carried out as domino, consecutive, or individual reaction.

In this review emphasis will be placed on the domino reaction, because it is often quite elegant and efficient. A typical example of this is the tandem Knoevenagel hetero-Diels–Alder reaction[6a, c] we have developed. In the first step of this process an aldehyde undergoes condensation with a 1,3-dicarbonyl compound to give an activated heterodiene, which then reacts with a dienophile in the second step. Vicinal difunctionalizations,[7] to which the Diels–Alder reaction, 1,3-dipolar cycloadditions, carbene additions to alkenes, and [2 + 2] photoadditions formally belong, are not regarded as domino reactions. In principle, however, all those reactions in which more than one bond is formed can also be classified as multistep processes. In this way, Diels–Alder reactions can frequently be formulated as tandem Michael reactions, which, according to our classification, are genuine domino reactions.

To classify domino reactions we have developed a frame that permits systematic arrangement, taking as a basis the reaction type of the first two synthetic steps (Table 1). Initially four groups are defined, each of which, according to the assignment of the second transformation, can then be classified into four subgroups. Because it is not possible to classify every reaction under this scheme, additional groups must be inserted. The main criteria of the schematic classification were the reactive species, such as cations, anions, or radicals, which can generally be formed in a preliminary reaction. The term cation here is a synonym for electrophile and that of anion for nucleophile. The addition of a nucleophile to a C=C or a C=X group—whether protonated or not—is formulated as an anionic transformation. The Mannich reaction, one of the oldest domino reactions, is thereby classified as an anionic–anionic process. For most domino reactions the first two transformations are of the same type, and anionic–anionic reactions are most common. In the overwhelming majority of domino reactions the second and subsequent steps are intramolecular. Every synthetic chemist knows that this can only be an advantage.

Table 1. Classification of domino reactions [a].

Section	1. Transformation	2. Transformation
1.1	cationic	cationic

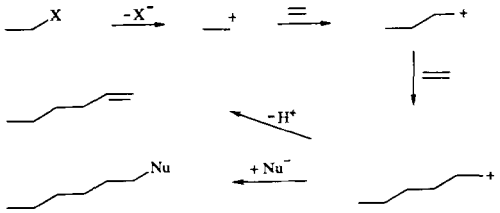
[a] The division is a schematic classification. For example, cationic polyene cyclization is treated under cationic–cationic, without considering the possibility that a concerted process is also feasible.

1. Cationic Primary Step

In this process a carbocation is formed, either formally or in reality. This cation can be formed, for example, by elimination of water from alcohols, of alcohols from acetals, or by addition of a positive particle such as a proton to an alkene or an epoxide. The carbocation then reacts with a nucleophile to form a new carbocation, that undergoes one or more comparable further transformations in a cationic–cationic process (Section 1.1), finally being trapped by a nucleophile or stabilized by elimination of a proton (Scheme 1). Rearrangement reactions, in which numerous cationic species appear, similarly belong to this type of reaction.

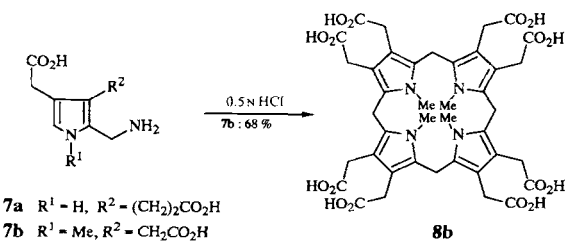


Scheme 1. Cationic–cationic domino reaction.

Formally, in the cationic–anionic (Section 1.2) and in the cationic–radical process (Section 1.3) a two-electron or a single electron transfer, respectively, must take place intermediately. No examples of this type of process have been reported. In the cationic–pericyclic process (Section 1.4) the cation formed by reaction with a nucleophile reacts either as an activated allyl cation or, after loss of a proton, as an alkene in a pericyclic reaction. No examples have been found of the first of these reaction types; the well-known acid-catalyzed reaction of allyl alcohols with orthoesters can be assigned to the second reaction type, although this reaction will not be treated in this review.

1.1. Cationic–Cationic Sequences

An iterative cationic–cationic domino process of considerable biological importance is the cyclotetramerization of porphobilinogen **7a**, the biosynthetic precursor of the "Pigments of Life" protoheme, chlorophyll, and vitamin B_{12}.[8] The acid-catalyzed cyclotetramerization of **7a** is so effi-

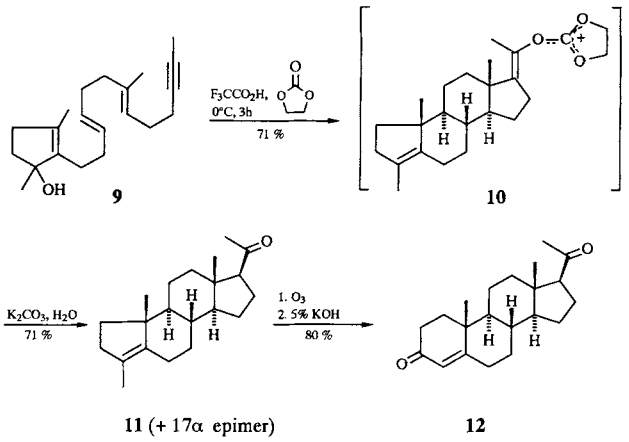


7a R^1 = H, R^2 = $(CH_2)_2CO_2H$
7b R^1 = Me, R^2 = CH_2CO_2H

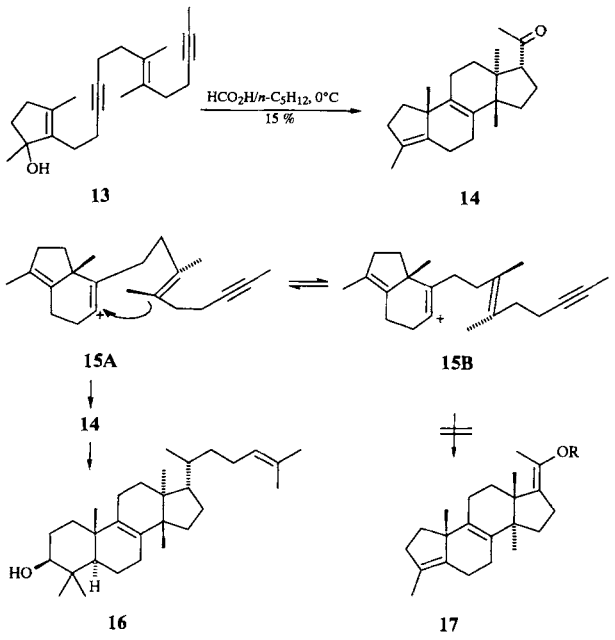
8b

cient[9] that even strongly sterically hindered cyclotetramers of pyrrole can be constructed. Thus, Franck and Wegner found[8a, 10] that the pyrrole derivative **7b** gave a 68% yield of crystalline **8b** within 30 minutes by heating in 0.5 N hydrochloric acid. Interestingly, all attempts to synthesize *N,N,N,N*-tetramethyl compounds of this type by methylation of the corresponding cyclotetramers with free NH groups failed. This result underlines once again the efficiency of biosynthetic transformations. We have recently been able to show, by calculations and experimentally, that this self-organizing process of cyclotetramerization can be traced back to the substitution pattern on the pyrrole moiety.[11]

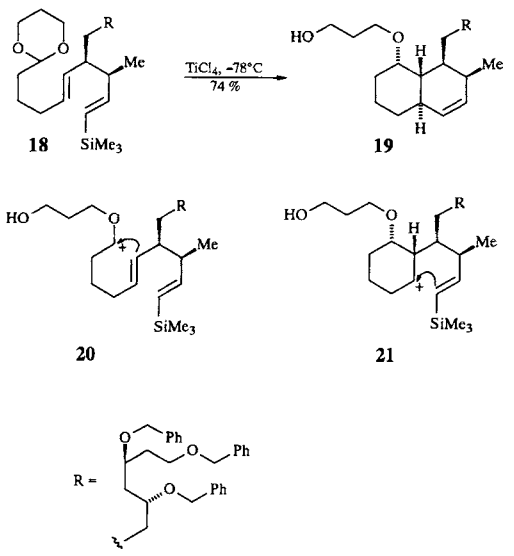
The biomimetic cyclization of polyenes, which often shows a high diastereoselectivity, is equally of great biological importance. Considering the stereochemical course of the abiotic cyclization of squalene oxide as a *trans-anti-parallel* electrophilic addition, a concept developed by Eschenmoser et al.[12] and Stork et al.,[13] van Tamelen and Corey conducted in vitro experiments[5, 14] that culminated in the elegant terpene and steroid syntheses of Johnson.[15] The principle of cationic cyclization of polyenes has been used intensively in many areas.[16] In an earlier synthesis of (±)-progesterone (**12**) by Johnson et al., hydroxypolyenyne (**9**) underwent acid-catalyzed cyclization to give **10** in the presence of ethylene carbonate. Subsequent hydrolysis gave ke-



tone **11** in 71% yield. Ozonolysis of **11** led to (±)-progesterone (**12**) in 80% yield.[17] A new piece of work involves the synthesis of tetracyclic euphane–triterpenes,[18] which uses dienediynol **13** as substrate. Methanolysis of **13**, followed by treatment with acid, gave a mixture of two isomeric tetracyclic compounds, from which the ketone **14** could be separated by crystallization as the major product. It is assumed that the vinyl cation **15** is formed first, reacting to form **14** via conformation **15A**. The tetracyclic triterpene euphol **16**, from the group of euphanes, was obtained by cleavage of the C–C double bond in **14** with ozone followed by an aldol reaction. Cyclization products with the configuration of lanostane **17**, which could be formed from the vinyl cation **15** via **15B**, were not found. It should not be forgotten that in polyene cyclizations—as elegant as they are—the synthesis of the precursors is frequently difficult and the yields of cyclization products are not always satisfactory.

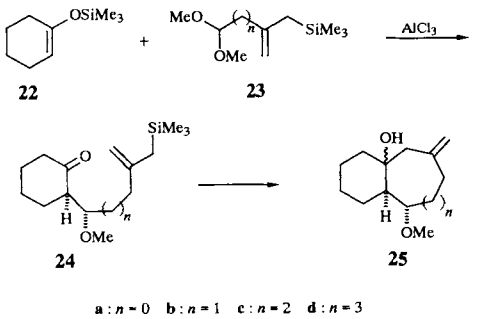


Allyl- and vinylsilanes are often used as terminators in cationic polyene cyclizations.[19] One of several interesting examples from the group of Burke[20] is the Lewis acid-induced formation of the enantiomerically pure acetal **18**,[21] which was formed by enantioselective reduction of a propargylketone with BINAL-H followed by an Ireland–Claisen rearrangement. Reaction of **18** with titanium tetrachloride at −78 °C gave the *trans*-coupled octahydronaphthaline **19** as major product in 74% yield, in addition to other diastereomers as by-products. Compound **19** was used as a precursor for dihydrocompactin. The carbocations **20** and **21** could be considered as intermediates.

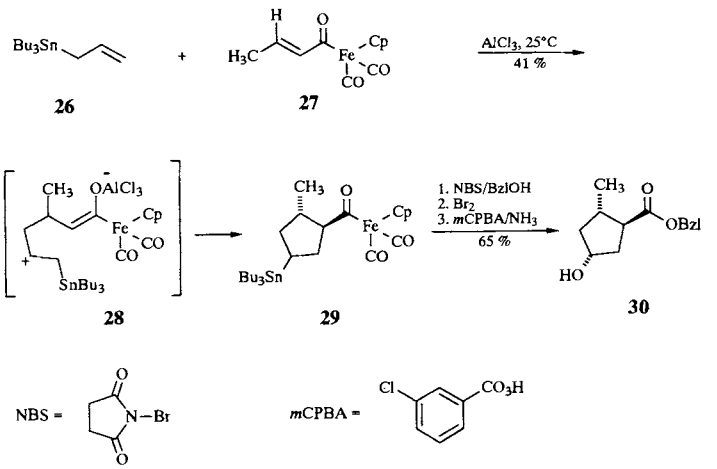


Another cyclization sequence, in which the first step is intermolecular, is the Lewis acid-induced reaction of a trimethylsilyl enol ether **22** with an acetal **23**, which contains an allylsilane unit.[22] In this way the ketone **24**, formed by cationic C–C coupling, underwent intramolecular reaction

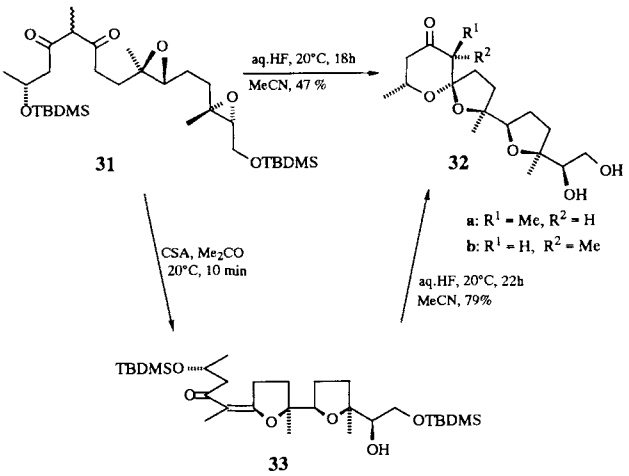
with the allylsilane group to give the bicycle **25**. In this fashion annelated ring systems of various sizes can be constructed. Interestingly, the intramolecular cyclization of the bifunctional substrate **23** with $n = 0$, 1, and 2 occurs more slowly than the intermolecular reaction with the enol ether **22**. On the other hand, acetal **23d** leads exclusively to the 3-methylenecyclohexyl methyl ether by an intramolecular process. As an explanation for the different reactivities of the acetals **23a–c** and **23d**, it is assumed that the intramolecular cyclization of **23a–c** is not kinetically favored as a result of stereoelectronic effects.[23]



A comparable reaction is the Lewis acid-induced reaction of allylstannane **26** with an α,β-unsaturated acyl iron complex **27**.[24] Depending on the configuration of the double bond in **27** *cis*- and *trans*-1,2-disubstituted cyclopentanes **29** can be formed highly stereoselectively. For example, the (*E*)-crotonyl iron complex **27** gave exclusively the *trans*-cyclopentane derivative **29** (41% yield), which could be converted into **30** in three steps.

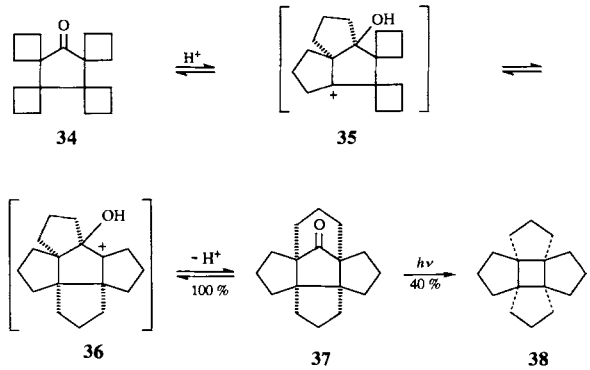


A nice example of a cationic domino reaction is the biomimetic cyclization of polyepoxides[25] for the construction of polyether–ionophores.[26] In the synthesis of polyethers like monensin and etheromycin Paterson and Craw[27] converted the bisepoxide **31** directly into the polyethers **32a** and **32b** (5:1), which contain two tetrahydrofuran groups and one spiroacetal group, in 47% yield by treatment with aqueous hydrofluoric acid in acetonitrile at room temperature. Compound **32b** could be transformed into **32a** by epimerization with potassium carbonate in methanol. When camphorsulfonic acid (CSA) was used as catalyst the reaction of **31** stopped at the stage of the bis(tetrahydrofuran) **33**, since the *tert*-butyldimethylsilyl protecting group was not cleaved under these conditions and, therefore, the spiroacetal unit could not be formed. Reaction of **33** with hydrofluoric acid then gave **32a** and **32b** (2.2:1).

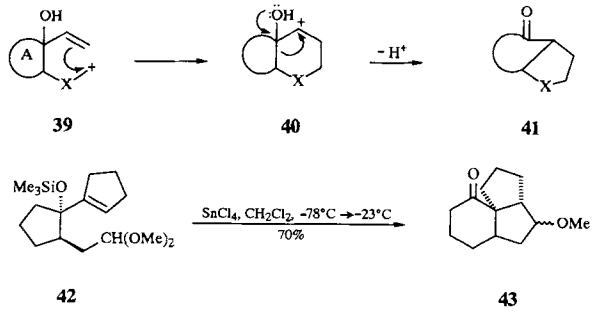


TBDMS = *t*BuSiMe$_2$

Cationic rearrangements such as 1,2-shifts in spiroketones or the Pinacol rearrangement can also be used very efficiently for domino reactions. Fitjer and Quabeck[28] observed multiple cationic 1,2-shifts by treatment of the tetraspiroketone **34** with *p*-toluenesulfonic acid in benzene. Compound **34** isomerized quantitatively within 30 minutes, possibly via the intermediates **35** and **36**, to give the bridged ketone **37**, photochemically induced decarbonylation of which concluded an elegant synthesis of [4.5]coronane **38**.



The cationic cyclizations with subsequent Pinacol rearrangement of compounds of type **39**, developed by Overman et al.,[29] are of great synthetic value. Compound **39** can be used for the construction of annelated carbocycles and heterocyclic five-membered rings **41**. The cation **40** is assumed to be an intermediate, undergoing a 1,2-shift with enlargement of ring A. Thus, reaction of acetal **42** with $SnCl_4$ gave the diastereomers of tricyclic ketone **43** (2:1, 70%).

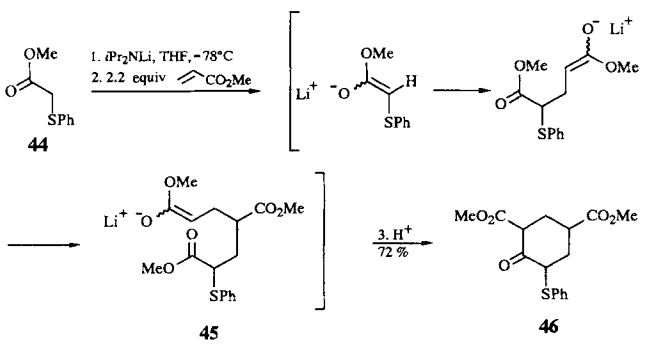


2. Anionic Primary Step

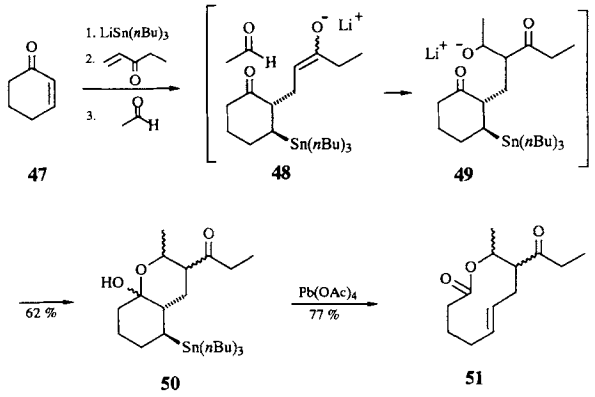
In reactions of this type the primary step is the formation of an anion or a nucleophile. The majority of cases involve the deprotonation of a CH group with the formation of a carbanion, which then reacts with an electrophile to form a new anionic functionality. This anion then attacks another electrophile in an anionic–anionic process. The sequence is completed by reaction with an electrophile, for example, a proton, or by elimination of an X^- group (Section 2.1). In the increasingly important anionic–pericyclic process, the anion formed in the anionic step is converted into a compound containing a multiple bond, which is then capable of undergoing a pericyclic reaction (Section 2.4). For the anionic–cationic and anionic–radical reaction sequences no examples are known.

2.1. Anionic–Anionic Sequences

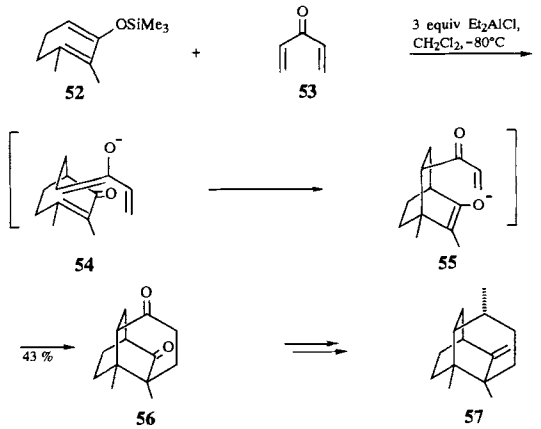
Polymerizations such as anionic polymerization of α-activated olefins[30] involve an iterative process, which is concluded by chain termination steps. To use such processes for the synthesis of homogeneous compounds of low molecular weight, the chain growth must be stopped after a defined number of steps. As Posner et al. have demonstrated, intramolecular cyclizations, in which the possibility of further polymerization is excluded, are suitable for this purpose,[6c] for example, in the synthesis of cyclohexanone **46** by an intramolecular Dieckmann reaction. After the iterative Michael addition of two molecules of acrylate to the lithium enolate of **44**, with formation of the probable intermediate **45**, potential polymerization was hindered.[31] Termination of the reaction after two additions can also be achieved by an intramolecular Wittig reaction.[32]



The versatility of this approach could be increased considerably by achieving consecutive reactions with two different electrophiles. For example, the enolate obtained by reaction of 2-cyclohexenone **47** with tributylstannyllithium underwent a Michael addition with ethyl vinyl ketone to give **48**. The subsequent aldol reaction with acetaldehyde gave **49** followed by the intramolecular formation of a hemiacetal led to the annelated tetrahydropyran **50**. Oxidative fragmentation to give **51** completed this novel access to unsaturated macrocyclic lactones. The stereoselectivity of the individual steps is, however, low. The macrocyclic lactone was obtained as a mixture of two diastereoisomers (*trans*:*cis* = 0.7 (**51**)–5.3:1).[33c]

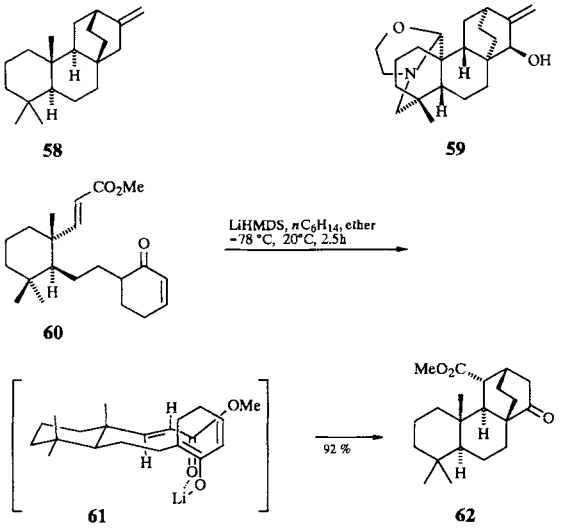


The synthesis of polycyclic systems has shown itself to be the domain of Michael–Michael reactions,[34] for example, in the preparation of the bicyclo[2.2.2]octane[35] and tricyclo[5.3.1.$0^{3,8}$]undecane skeletons,[36] and other framework types,[37] which are important intermediates in the construction of sesquiterpenoids. An attractive example is the synthesis of seychellene **57** from **52** and **53**, reaction of which with diethylaluminum chloride gave the tricyclic ketone **56** in 43% yield. Compounds **54** and **55** could be considered as intermediates. Compound **56** can be converted into **57** in a few steps.[36]

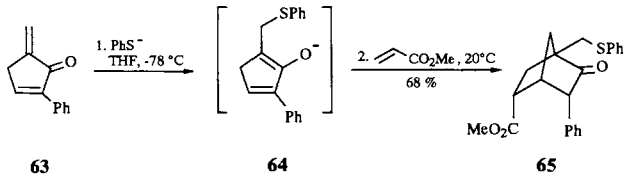


The key sequence in the synthesis of the diterpene (+)-atisirene **58** and the diterpene alkaloid atisine **59** by Fukumoto et al. is also a tandem Michael reaction.[38,39] Reac-

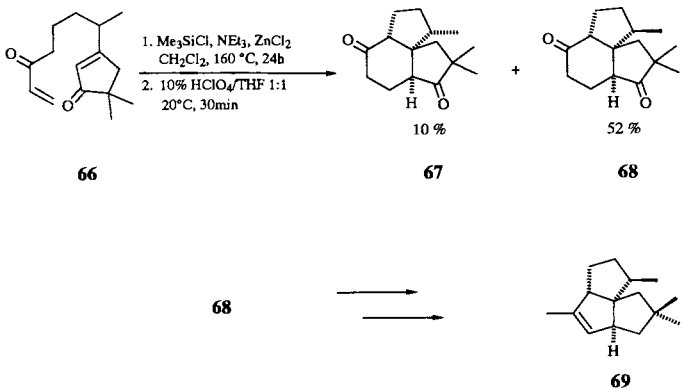
tion of **60** with lithium hexamethyldisilazide gave, via **61**, the tetracycle **62** with high diastereoselectivity. The latter could be converted into **58**.[38]



The synthesis of bicyclo[2.2.1]heptanes of type **65** possibly involves three consecutive Michael additions. Compound **64** was generated by an intermolecular 1,4-addition of the thiophenol anion to **63**, which then reacted with methyl acrylate in two further additions to give **65**.[40] The two intramolecular Michael reactions, however, can also be regarded as a Diels–Alder reaction of a cyclopentadiene with acrylate.

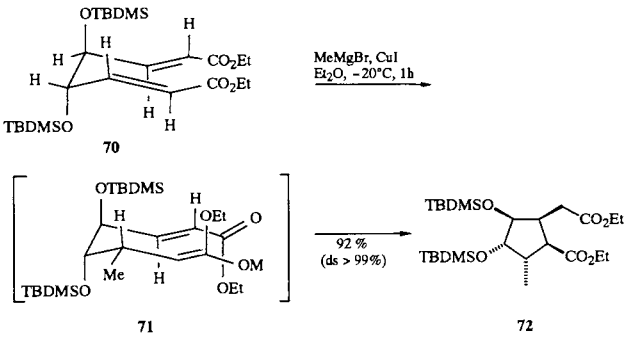


Tricyclo[7.3.0.$0^{1,5}$]dodecanes such as **68** are accessible by double Michael additions. With appropriate functionalization these compounds undergo rearrangement by ring contraction to give tricyclo[6.3.0.$0^{4,8}$]undecanes (e.g. **69**), the

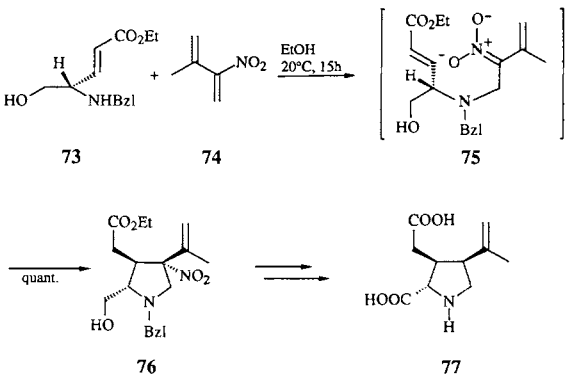


skeleton of some triquinane sesquiterpenes. Compound **66**, heated with chlorotrimethylsilane, trimethylamine, and zinc chloride in a sealed tube gave, in addition to **67** (10%), a 52% yield of **68**, a useful building block for the synthesis of some pentalenes, such as (±)-pentalenene **69**.[41]

Nevertheless, the potential of the tandem Michael reaction is not exhausted with the preparation of bicyclic and tricyclic systems. It can also be used for the efficient synthesis of highly functionalized carbo- and heterocyclic ring systems.[42–44] The synthesis of pentasubstituted cyclopentanes such as **72** from the L-tartaric acid derivative **70** is characterized by excellent diastereoselectivity (*ds* > 99%). The conformation of the transition state is presumably controlled by the *anti*-periplanar arrangement of the two bulky silyl ether groups. Thus, initial 1,4-nucleophilic attack of the cuprate reagent on **70** to give **71** can only take place on one of the two outward facing homofacial alkenoate groups. The subsequent intramolecular 1,4-addition of the ester enolate on the "inner side" of the remaining alkenoate group in **71** then led to the product **72**.[42]



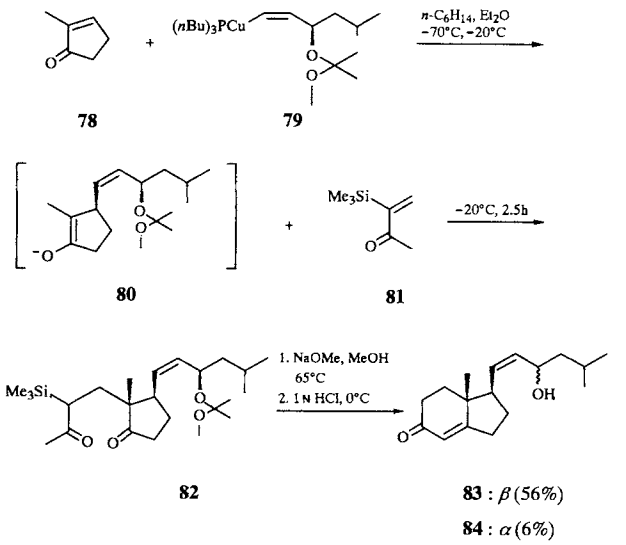
An example of a tandem Michael reaction for the formation of *N*-heterocycles[44] is the synthesis of (−)-α-kainic acid **77**.[44a] Reaction of γ-amino-α,β-unsaturated ester **73** (from D-serine methyl ester) with the nitrobutadiene **74** in ethanol at room temperature gave the pyrrolidine **76** as the only product in quantitative yield with the configuration required for synthesis of **77**.



The nitro group can ultimately be removed with retention of configuration by hydride transfer. The excellent diastereoselectivity in the cyclization of the intermediate **75**

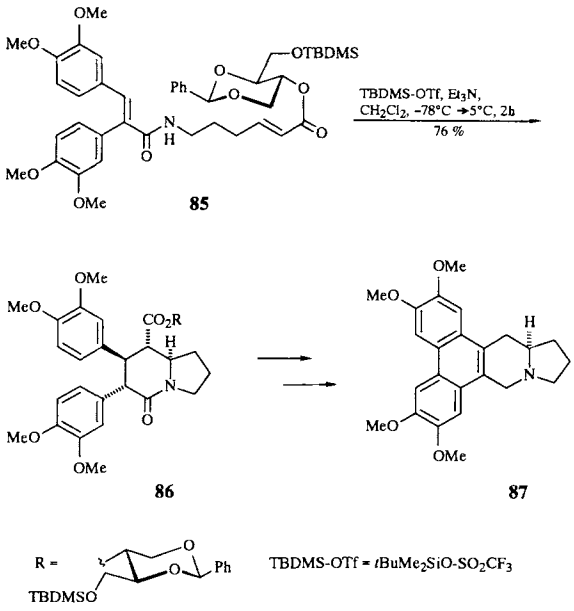
to **76** can probably be traced to the addition of nitronate to the acrylate being under the control of the existing stereogenic center in an *anti*-periplanar process.

Tandem Michael reactions have also found much importance in the synthesis of decalines,[45] steroids,[46] and steroid precursors.[47] A consecutive double Michael addition was employed by Takahashi, Tsuji et al. in a synthesis of an enantiomerically pure steroid CD-ring building block by transformation of 2-methyl-2-cyclopentenone **78** with an enantiomerically pure (*Z*)-vinylcuprate such as **79**. The intermediary enolate **80** was trapped by the subsequently added Michael acceptor **81** to give **82**, which was not isolated. The following aldol condensation and removal of the protecting group gave the notable yield of 56% **83** and only 6% **84** for this one-pot reaction.[47a, b]

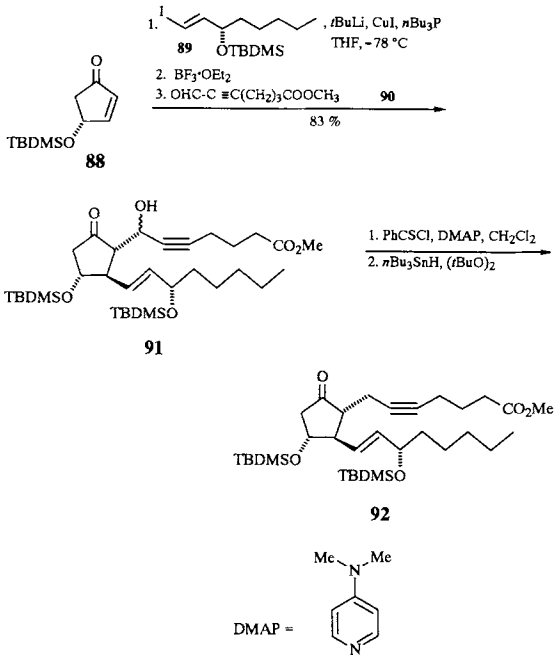


A simple synthesis of the phenanthroindolizidine alkaloid (−)-tylophorine **87** could be realized by an intramolecular tandem Michael sequence of the starting material **85**. Reaction with *tert*-butyldimethylsilyl trifluoromethanesulfonate under very mild conditions gave **86** in 76% yield, which could then be converted into **87**.[48] A glucose derivative was employed as chiral auxiliary in **85**. The diastereoselectivity of the transformation is > 99:1; only one product was found. The quinolizidine alkaloid (±)-epilupinine could be synthesized in the same manner.[49]

Michael and aldol reactions can also be coupled by allowing them to run one after the other. This principle has been used on numerous occasions, for example, for the synthesis of pyrones,[50] pseudoguanolides,[51] lignanes,[52] oxapropellanes,[53] and cyclopentane derivatives.[54] A particularly spectacular example is the synthesis of prostanoids.[55] Noyori et al. effected a "three-component coupling" as the target of a convergent prostaglandin synthesis. The strategy involved the introduction of a β-side chain by 1,4-addition to a cyclopentenone and trapping of the enolate by reaction with a functionalized α-side chain building block, which can be used as an iodide, a nitroolefin, or as an aldehyde. For the synthesis of the prostaglandin derivative **92** the enantiomerically pure cyclopentenone **88** was treated with the enantiomerically pure building block **89** (in the form of the

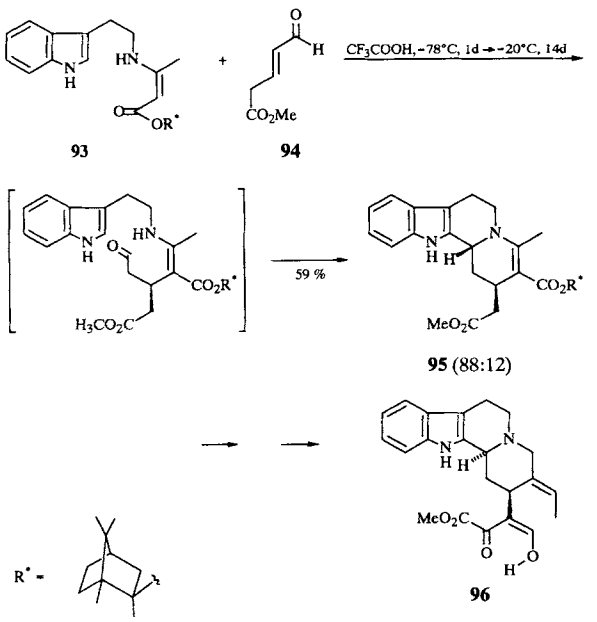


cuprate) in tetrahydrofuran at −78 °C, and the intermediate enolate trapped with **90** to give **91** as a 1:1 mixture in 83% yield.[55]

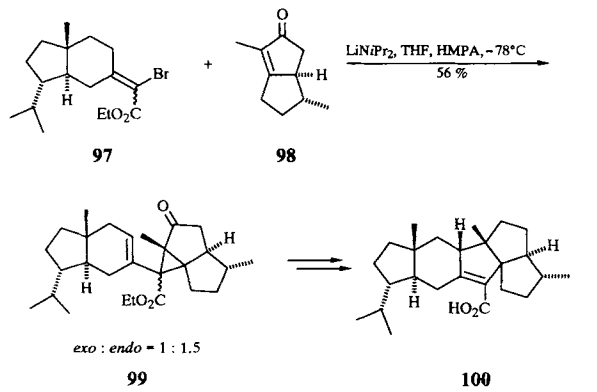


An elegant construction of the skeleton of the corynanthe alkaloids was achieved by Winterfeldt et al. by the reaction of the enantiomerically pure vinylic urethane **93** with the Michael acceptor **94**. Compound **95** was formed in the sequence composed of a diastereoselective Michael reaction (88:12), carbinol–amine formation, and a diastereoselective Pictet–Spengler reaction. Subsequent reduction, methylene–lactam rearrangement and isomerization permitted synthesis of (+)-geissoschizine **96** and (−)-geissoschizol.[56]

Another genuine domino reaction is the cycloalkylation sequence employed by Hudlicky et al. for the synthesis of

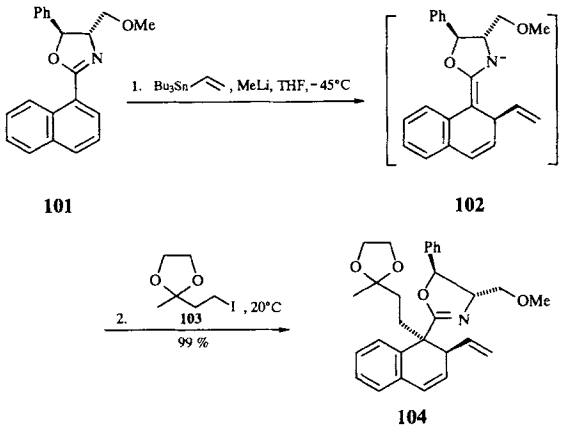


(−)-retigeranic acid (**100**). Michael addition of the dienolate **97** to the bicyclic enone **98** followed by intramolecular substitution with elimination of bromide gave the cyclopropane derivative **99** as a 1:1.5 mixture of the *exo/endo* isomers. Vinylcyclopropane rearrangement of **99** then led to the basic skeleton of **100** in one step.[57] Further related methods for the preparation of cyclopropanes[58] and higher cycloalkenes are known. The consecutive Michael alkylation sequence is established as one of the best methods for the synthesis of steroids and cyclopentanoid natural products.[59]

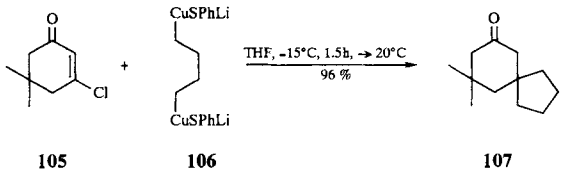


Meyers et al. have used naphthyloxazolines to serve in such sequences as a chiral template for the synthesis of enantiomerically pure substituted 1,2-dihydronaphthalines.[60] In model investigations for the synthesis of aphidicolin and scopadulcic acid, compound **101**, for example, was vinylated in a 1,4-addition to the suspected intermediate lithium azaenolate **102**, which could then be trapped in a diastereoselective reaction with the iodide **103** to give **104**.[60b]

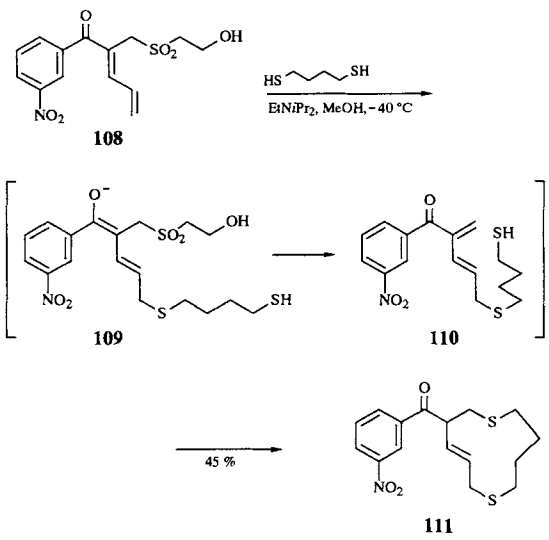
Organobisthiocuprates have emerged as extremely useful nucleophiles in the one-pot synthesis of spiro compounds, as Wender et al. have demonstrated in the reaction of **105** with **106** to give **107**. The reaction sequence is thought to consist



of a Michael addition, an elimination, and another Michael addition.[61]

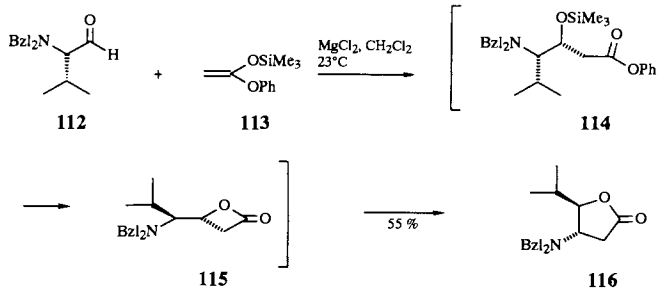


An unusual concept for the synthesis of heteromacrocycles such as **111** is based on the sequence of 1,6-Michael addition, an elimination, and finally a 1,4-Michael addition. Reaction of **108** with butanedithiol gave the enolate **109**, which underwent elimination to give the highly reactive cross-conjugated Michael acceptor **110**. Subsequent addition of the remaining SH group then led to the eleven-membered ring **111**.[62] A multitude of heteromacrocycles is available by variation of the starting materials.



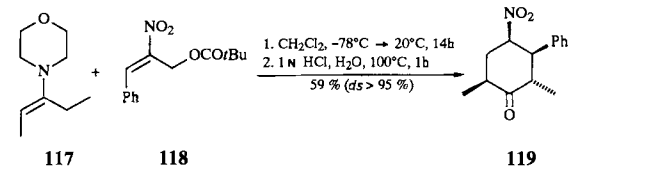
In a similar manner to the 1,4-additions, Reetz et al. have combined 1,2-additions with a series of other anionic processes to give domino sequences.[63] The transformation of *N,N*-dibenzyl-protected α-aminoaldehydes, such as **112**, with the *O*-silylketene acetal **113**, via **114** and **115**, gave

diastereo- and enantiomerically pure 4-substituted 3-amino-γ-lactones **116** in the sequence nonchelate controlled aldol addition, a lactonization and finally stereospecific dyotropic rearrangement.[63]



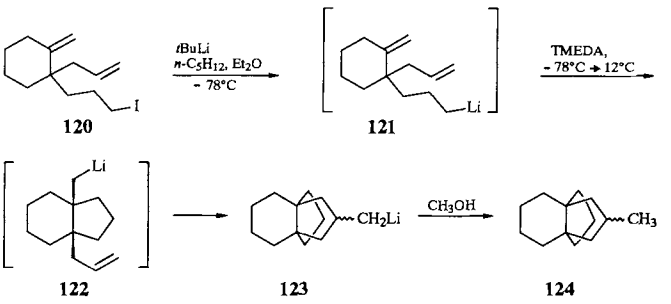
112 **113** **114** **115** **116**

Seebach et al. were able to show that the sequential reaction of enamines with pivaloates of 2-nitroallylic alcohols permits synthesis of six-membered rings.[64] Reaction of **117** with **118**, by way of numerous intermediates, gave **119** in 59% yield and high diastereoselectivity ($ds > 95\%$).[64]



117 **118** **119**

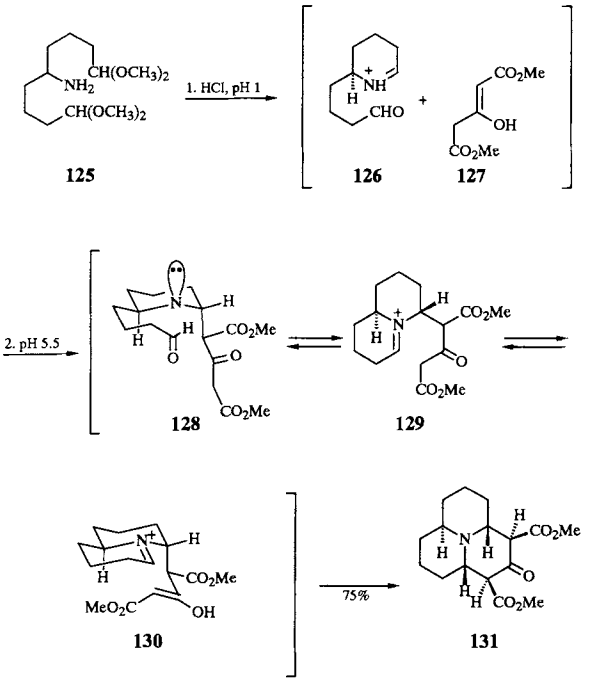
An attractive anionic domino olefin cyclization,[65,66] which, in contrast to the cationic and radical variants, was hitherto something of a sleeping beauty, was described by Bailey et al. with the reaction of **120** with *tert*-butyllithium. The intermediate **121** was formed first, cyclizing to **123** via **122**. Quenching with methanol gave **124** in 81% overall yield.[66]



120 **121** **122** **123** **124**

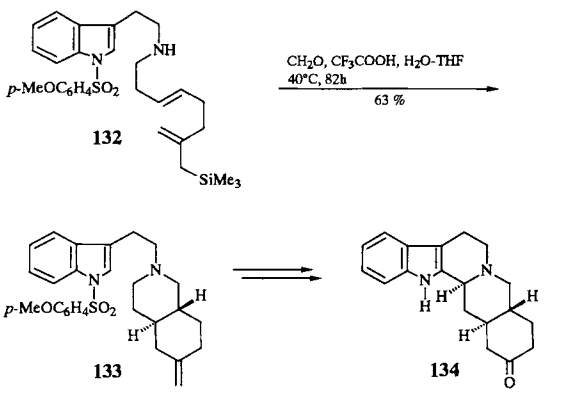
TMEDA = *N,N,N',N'*-tetramethylethylendiamine

One of the oldest domino transformations is the Mannich reaction, which, together with its modern variants, is one of the most important reactions for the formation of nitrogen-containing compounds. The abundance of material is almost limitless.[29c,67] We have selected only two examples, which involve further transformations after the Mannich reaction. The highly diastereoselective construction of the precoccinelline skeleton by Stevens et al. resulted from an intermolecular Mannich reaction of the aminodialdehyde liberated from **125** with methyl acetonedicarboxylate **127**. Compounds **126** and **128**–**130** are suspected intermediates.[68]



125 **126** **127** **128** **129** **130** **131**

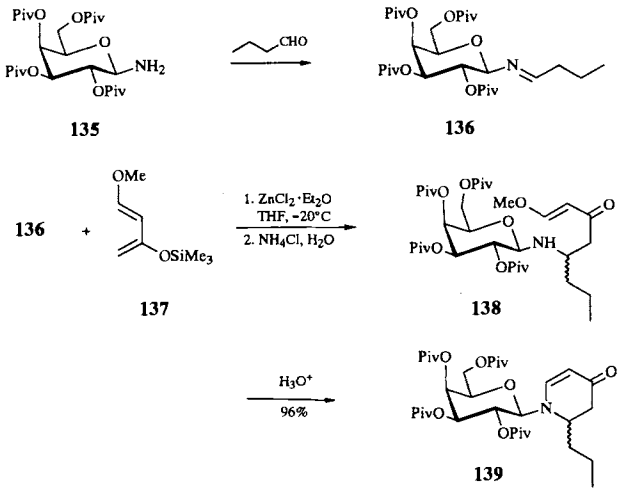
The combination of a Mannich reaction and a polyene cyclization with an allylsilane as terminator was used by Grieco et al. for a synthesis of (±)-yohimbone **134**. The *trans*-coupled D/E ring system **133** in the target molecule was generated diastereoselectively by treatment of **132** with formaldehyde and trifluoroacetic acid.[69]



132 **133** **134**

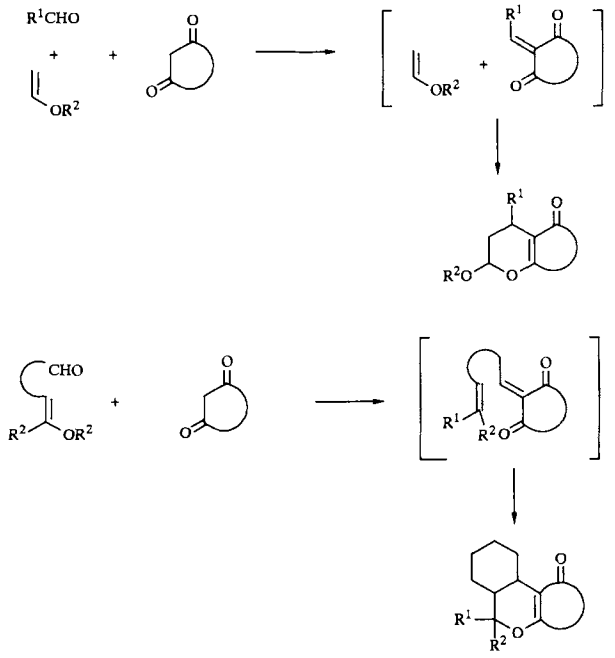
The range of application of the Mannich reaction could be extended considerably if the development of stereoselective variants were attained. Kunz at al. were recently able to demonstrate this with a synthesis of piperidine alkaloids. Reaction of the *O*-pivaloyl-protected galactopyranosylamine **135** with butanal gave the imine **136**. Treatment of this with the silylenol ether **137** led, with high diastereoselectivity, to the Mannich adduct **138** (demonstrated by TLC), which cyclized directly to the Michael product **139** on acidic

workup. Compound **139** can, after removal of the galactosyl auxiliary, be converted in a few steps to the piperidine alkaloid (*S*)-coniine.[70]



Piv = $(CH_3)_3CCO$-

($\alpha:\beta = 97.5:2.5$)



Scheme 2. Three- and two-component tandem Knoevenagel hetero-Diels–Alder reaction.

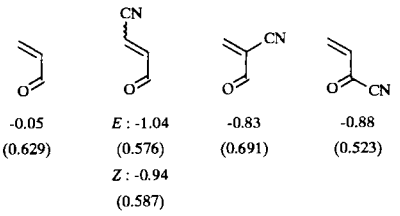
2.4. Anionic–Pericyclic Sequences

Three well investigated and versatile anionic–pericyclic domino reactions that we have developed are the tandem Knoevenagel hetero-Diels–Alder reactions,[6a, d] tandem Knoevenagel-ene reactions[71] and tandem Knoevenagel-allylsilane cyclizations.[72] With suitable choice of substrate an intramolecular-Prins reaction can be added to the sequence.[71a] All three sequences are characterized by being simple to carry out and—when the second reaction step is intramolecular—by very high stereoselectivity. In the tandem Knoevenagel hetero-Diels–Alder reaction a 1-oxa-1,3-butadiene is first formed[73] in situ by condensation of an aldehyde with a cyclic or highly reactive acyclic 1,3-dicarbonyl compound. The oxabutadiene then undergoes cycloaddition with a dienophile in the second step. Azabutadienes and diazabutadienes can also be formed in a comparable reaction involving condensation of amines with aldehydes. The sequence can be conducted as a three- or two-component reaction. In the first case, a mixture of aldehyde, 1,3-dicarbonyl compound, and dienophile, for example an enol ether, is used. In the second case, a 1,3-dicarbonyl compound is treated with an aldehyde that already contains a dienophile component; the Diels–Alder reaction then takes place intramolecularly.

In a similar fashion 1,3-dicarbonyl compounds such as malonate or malonodinitrile, which cannot undergo hetero-Diels–Alder reactions, are used in the tandem Knoevenagel-ene reaction; for the tandem Knoevenagel-allylsilane cyclization, aldehydes containing an allylsilane unit are used, which are easily available by photochemical Norrish type I cleavage of α-trimethylsilylmethylalkanones.[74] It is frequently advantageous to choose a consecutive reaction process for the tandem Knoevenagel-ene and the -allylsilane sequences, although this is not absolutely necessary (Section 5). The range of applications of these reactions is very large. Numerous aldehydes and 1,3-dicarbonyl compounds can be employed; limitations are not known. Enantiomerically pure products can be obtained by the use of enantiomerically pure aldehydes, enantiomerically pure 1,3-dicarbonyl compounds, or with chiral Lewis acids.

Three factors are essential for the high efficiency and the wide applicability of these sequences:

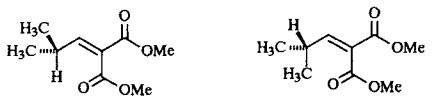
1. Simple preparation of reactive acceptor components by a Knoevenagel reaction[73] from easily available starting materials.
2. High reactivity of the acceptor components because of a low-lying LUMO and favorable coefficients. AM1 calculations[75] on CN-substituted acroleins show that the highest reactivity is expected for the C-3-substituted compound, as a result of the favorable coefficients, although the LUMO energies of the 4-substituted acroleins are slightly lower (Scheme 3).



Scheme 3. AM1(CI) calculations for CN-substituted acroleins (LUMO energies in eV, coefficients refer to the 4-position of the 1-oxa-1,3-butadiene).

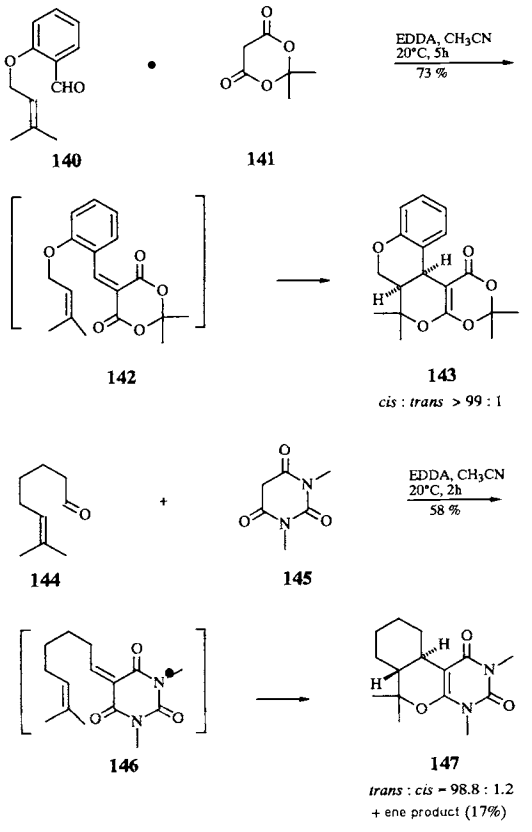
3. In the Knoevenagel condensation of aldehydes with 1,3-dicarbonyl compounds a trisubstituted double bond is formed. Molecules with this structural element thereby always contain both a *Z* orientation of the substituents at the double bond; as a result of this *Z* orientation a 1,3-

allylic strain generally appears.[76] We assume that in the following cyclization this allylic strain effects a conformative restriction on the transition state, thereby leading to the excellent stereoselectivity observed for the intramolecular reaction. According to the results of AM1 calculations, the ground state conformation A of the propylidene malonate is 10.2 kJ mol^{-1} more stable than conformation B (Scheme 4). This effect involves a common phenomenon that can generally be observed with intramolecular reactions of trisubstituted C=C and C=N bonds; for this reason we have named the spatial control that is obtained by geminal substitution at the terminus of a C=C or a C=N double bond the *sp²-geminal effect*.[71b]

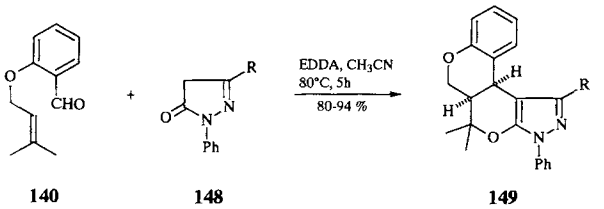


Scheme 4. AM1 calculations of the relative ground state energies for conformations of propylidene methyl malonate.

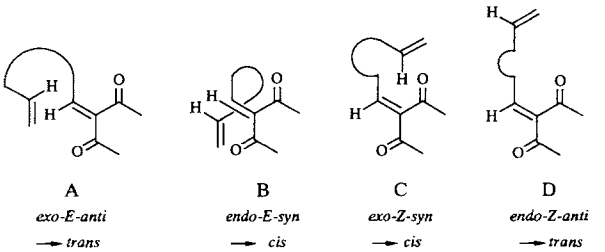
In the sequential reactions with an intramolecular second step two new rings are formed, connected either *cis* or *trans*. For example, the tandem Knoevenagel hetero-Diels–Alder reaction of aromatic aldehydes **140** with Meldrum's acid **141** gave (via the intermediate benzylidene-1,3-dicarbonyl compound **142**) the *cis*-coupled cycloadduct **143** exclusively (> 99:1),[77a] whereas aliphatic aldehydes such as **144**, for example with dimethylbarbituric acid **145** (or also with **141**), led predominantly to the *trans*-coupled product such as **147** (*trans*/*cis* = 98.2:1.8) via **146**.[77b-d]



Heterocyclic analogues such as pyrazolones **148** or isoxazolones can also be used as the 1,3-dicarbonyl compound in this reaction. The stereoselectivity is controlled here by the substituent R; in the reaction of aldehyde **140** to give the cycloadduct **149**, the *cis*-selectivity decreases with the decrease in the size of R (R = *tert*-butyl: *cis*/*trans* = 50.2:1; R = Me: *cis*/*trans* = 17.0 : 1; R = H: *cis*/*trans* = 4.6:1).[78]



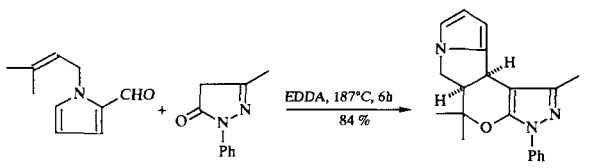
A 1-oxa-1,3-butadiene component with both *Z* and *E* configurations exists simultaneously in the intermediates **142** and **146**. Four different transition state structures can therefore be postulated (Scheme 5); for the classification, it has been decided here that the reacting CO group has the higher priority. The *trans* cycloadduct is formed via the *exo-E-anti* structure **A**, as the *endo-Z-anti* arrangement **D** exhibits too high an energy in the intramolecular reaction on steric grounds. The *cis* annelated compound can be formed from *endo-E-syn* or *exo-Z-syn* geometry, **B** and **C**, respectively. We assume, on the basis of calculations[79] and experiments,[77b,78,80] that *cis* cycloadducts, such as **143** or **149**, obtained from α,β-unsaturated aliphatic and aromatic aldehydes like **140**, are formed via *endo-E-syn* geometry. In contrast, an *exo-Z-syn* transition state must be considered for the reaction of the α,β-saturated aldehyde **144** to give the *cis*-annelated by-products.



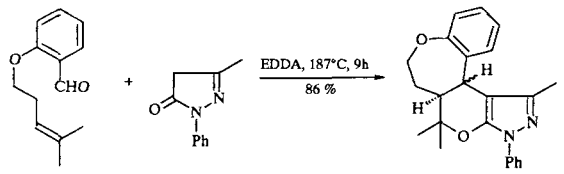
Scheme 5. Transition state structures for the hetero-Diels–Alder reaction of alkylidene- and benzylidene-1,3-dicarbonyl compounds.

These examples make quite clear that it is necessary to consider *E* and *Z* dienes in the discussion when analyzing the selectivity of Diels–Alder reactions. Thus, *trans*-substituted cycloadducts can generally be formed via a transition state with *exo-E-anti* or *endo-Z-anti* geometry, and *cis*-substituted compounds via *endo-E-syn* or *exo-Z-syn* geometry. Clearly also the possibility of isomerization of the diene or the heterodiene must be taken into consideration when discussing the stereochemical outcome of a Diels–Alder reaction.[81]

Annelated cyclopentanes and cycloheptanes can also be prepared by shortening or lengthening the chain attached to the reacting π-electron systems. As a consequence of the unfavorable geometry in the transition states, however, a higher reaction temperature is required. A mixture of **150** and **151**, in the presence of ethylenediammonium diacetate (EDDA) at 187°C gave exclusively the adduct **152** (*cis* > 99%) in 84% yield; reaction of **153** and **151** gave **154** and **155** in the ratio 99:1.[82]

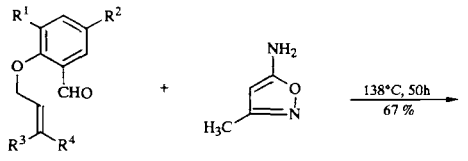


150 **151** **152**

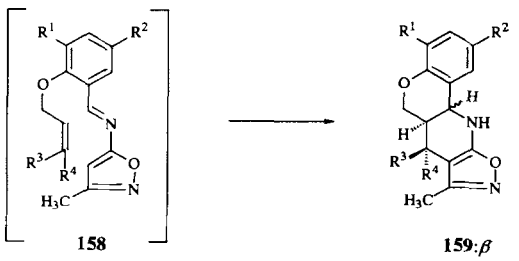


153 **151** **154** : α-H
155 : β-H

If an aldehyde is condensed with a compound formally containing an enamine structure such as **157**, 2-azabutadienes can be obtained as intermediates that can undergo an intramolecular cycloaddition. In this reaction one finds a surprising dependence of the selectivity on the substituents R^1–R^4. Reaction of **156a** with **157** in refluxing xylene gave exclusively *trans*-annelated **159a** in 67% yield, obtained from the first formed cycloadduct by a 1,3-hydrogen shift. If the reaction is conducted at 80°C, the 2-azabutadiene **158a** (postulated as an intermediate) can be isolated. Reaction of **156b** with **157** led to the *cis*-adduct **160b**. The varying selectivity can be traced back largely to changes in the dominant



156 **157**



158 **159**:β

orbital interactions (normal → inverse Diels–Alder reaction) arising from the substituents on the dienophile.[83]

Alkylidenemalonates such as **161** and **164**, which can be obtained from the corresponding aldehydes and malonates in good yield in the presence of piperidinium acetate, can be converted (without isolation) into cyclohexane and cyclopentane derivatives thermally at 180°C, with $ZnBr_2$ at 20°C, or with other Lewis acids such as $FeCl_3$ or Et_2AlCl at −78°C.[71, 84] The selectivity is again very high, thus the *trans*-1,2-disubstituted cyclohexane **162** is obtained exclusively (**162**/**163** > 99:1) from **161** under all conditions.[71e, 84] Surprisingly, by the reaction of **164**, also the *trans*-1,2-disubstituted cyclopentane derivative **165** is preferentially formed ($ZnBr_2$/20°C: **165**/**166** = 96.5:3.5).[71b] Our method was recently applied by Corey et al. for the synthesis of pseudopterosin-type sesquiterpenes.[85] Similar results were found with the allylsilanes **167** and **170**, although formation of the cyclohexane was less and that of the cyclopentane more selective (Table 2).[72]

Table 2. Lewis acid-induced reaction of **167** and **170**.

Starting materials	Products	Reaction conditions: $ZnBr_2$ (20°C)	$TiCl_4$ (−78°C)	Me_2AlCl (−78°C)	TMS-OTf (−78°C)
		Product ratio [yield in %]			
167	**168**/**169**	95.2:4.8 [56]	95.9:4.1 [70]	94.4:5.6 [90]	–
170	**171**/**172**	95.8:4.2 [54]	96.6:3.4 [81]	99.7:0.3 [86]	99.6:0.4 [97]

The particular importance of the sp^2 geminal effect (*geminal* substitution at the terminus of a C=C or a C=N bond) is shown by a comparison of the cyclization of **164** and **170**

with the reaction of the monoacceptor-substituted compounds **173** and **175a–d**. Thermal reaction of **173** gave **174** as an almost 2:1 mixture of the *cis* and *trans* isomers.[86] Reaction of **175a–d** with fluoride led to a 63.3–81.2:36.7–18.8 mixture of the corresponding *trans*- and *cis*-1,2-disubstituted cyclopentanes **176**. Reaction of **175** with Lewis acids resulted in desilylation.[87]

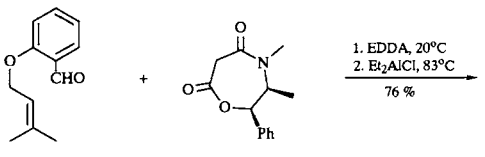
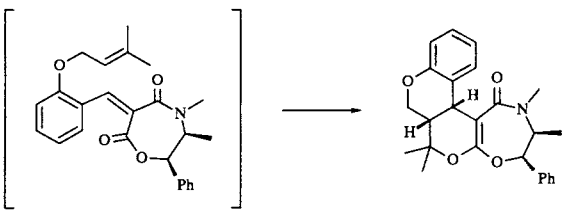
Oxazepandiones **177**, accessible from malonates and ephedrine, can be used as chiral 1,3-dicarbonyl compounds.[88] Reaction of **140** and **177** with ethylenediammonium diacetate and diethylaluminum chloride, in a consecutive sequence via the (*Z*)-benzylidene compound **178**, gave almost exclusively the *cis*-cycloadduct **179** (asymmetric induction > 99:1). The high diastereoselectivity of the hetero-Diels–Alder reaction can be traced back to a pseudo-boat conformation of the oxazepane ring in **178**, which hinders attack on the *Si* face.[89] It should be pointed out that reaction thereby occurs syn to the sterically more demanding groups at both stereogenic centers in **178**.[90] Our interpretation of the stereochemical control has since been confirmed by Trost et al. in their work with **177** as a chiral auxiliary.[91]

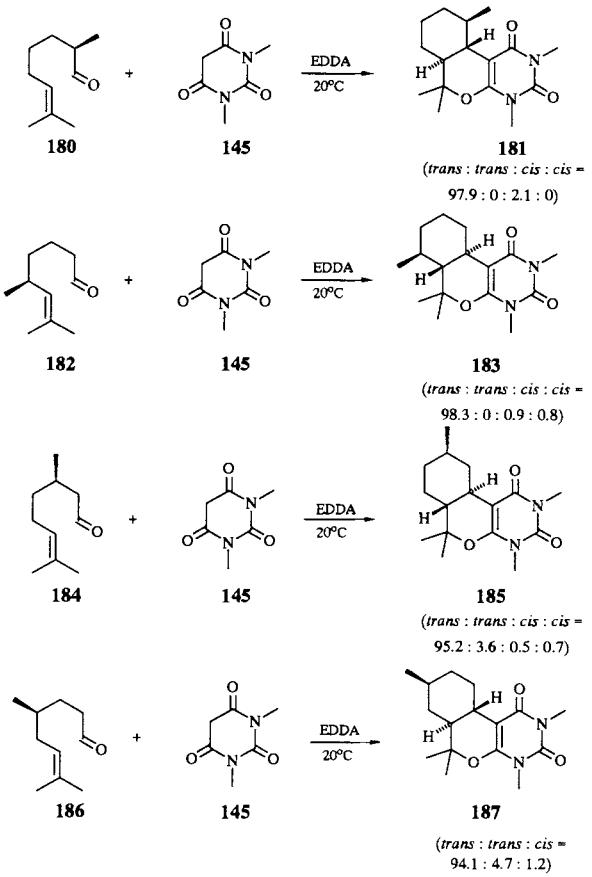


140 **177**



178 **179**

A high induced diastereoselectivity is also found in the tandem Knoevenagel hetero-Diels–Alder reaction with the aldehydes **180**, **182**, **184**, and **186**, which contain a substituent in the α, δ, β, or γ position, respectively. It is necessary here to differentiate between "steric interactions" of the substituents with the diene or the dienophile component and "conformation effects" of the chain. The steric interaction dominates in the case of the α- and δ-substituted aldehydes, the conformation effect for the β- and γ-substituted compounds. For the intermediate alkylidene compounds from **180** and **145** or **182** and **145**, a rigid conformative restriction in the transition state to the cycloadduct as a result of the 1,3-allylic strain (sp^2 geminal effect[71b]) must be assumed with preference of, for example, **188-K2** compared to **188-K1**. Thus, the induced diastereoselectivity in formation of



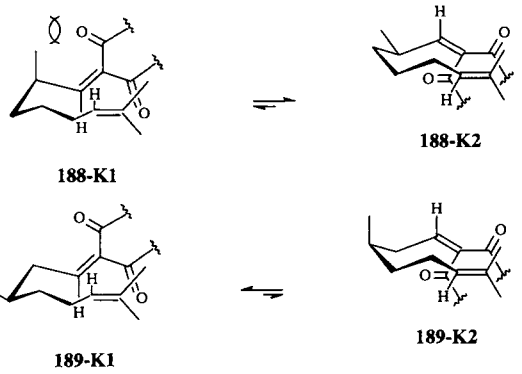
180 **145** **181**
(*trans* : *trans* : *cis* : *cis* = 97.9 : 0 : 2.1 : 0)

182 **145** **183**
(*trans* : *trans* : *cis* : *cis* = 98.3 : 0 : 0.9 : 0.8)

184 **145** **185**
(*trans* : *trans* : *cis* : *cis* = 95.2 : 3.6 : 0.5 : 0.7)

186 **145** **187**
(*trans* : *trans* : *cis* = 94.1 : 4.7 : 1.2)

the products **181** or **183** is > 99%. For the alkylidene compounds formed from **184** and **145** and from **186** and **145**, for example **189-K1**/**189-K2**, the driving force for the selectivity

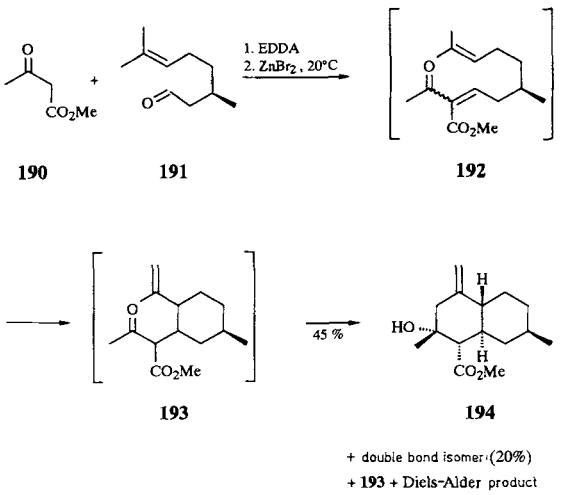


188-K1 **188-K2**

189-K1 **189-K2**

is the formation of a chair-like transition state with an equatorial arrangement of the substituents, as in **189-K1**. Thus, **185** and **187** are formed preferentially.[77b]

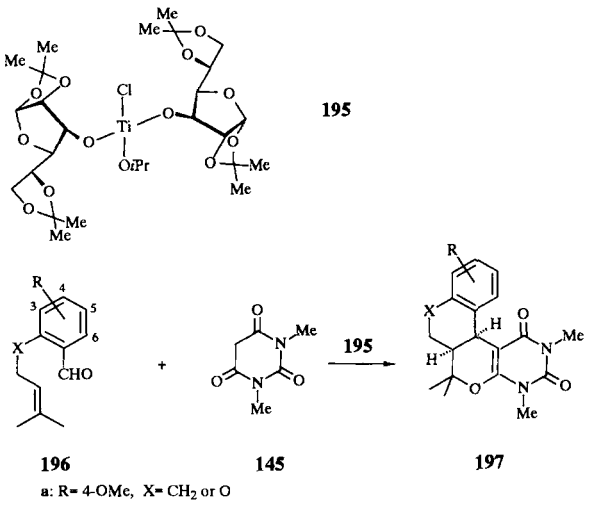
Yet higher selectivity is observed with the Lewis acid-initiated ene reaction of the Knoevenagel products of the aldehydes **180**, **182**, **184**, and **186** with malonates. Thus, reaction of the alkylidine malonates from **180** and **182**, initiated either by a Lewis acid or thermally at 180 °C, led in each case to only a single *trans*-1,2-disubstituted cyclohexane derivative;[92] use of the alkylidenemalonate from **184**, with catalytic amounts of $FeCl_3$ on Al_2O_3 (0.1 equiv), led to both possible *trans* products in the ratio 98.8:1.2.[93] An efficient and diastereoselective decalin synthesis based on this reaction was achieved with a Knoevenagel-ene-Prins sequence.[71a] The initially formed Knoevenagel product **192**, from citronellal **191** and methylacetoacetate **190**, reacted under the influence of $ZnBr_2$ to give **194** in 45% yield via the ene-product **193**. In addition, one obtained 20% of the double bond isomers of **194**, small amounts of a diastereomer (< 3%), together with the Diels–Alder product and the ene product **193**.



190 **191** **192** **193** **194**

Recently we achieved the development of an enantioselective variant of the tandem Knoevenagel hetero-Diels–Alder reaction by using a chiral Lewis acid. To date, enantioselective intramolecular reactions involving chiral catalysts or mediators have met with little success. As a result, it was hardly surprising that the first experiments with known chiral Lewis acids gave only very small enantiomeric excess (*ee* < 20%). In contrast, with the new chiral Lewis acid **195** (stoichiometric formula), easily available from 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (diacetone glucose), titanium tetraisopropoxide, and titanium tetrachloride (8:3:1), good enantiomeric excesses could be observed in the reaction of the aromatic aldehyde **196** with dimethylbarbituric acid **145** as a model process. The best results were observed with the domino reaction of 4-methoxybenzaldehyde **196a** with **145**, in which **197a** was formed with an *ee* of 88%.[94] The Lewis acid **195** catalyzed both transformations in the Knoevenagel Diels–Alder sequence; without the addition of **195** no Knoevenagel product was formed.

The tandem Knoevenagel hetero-Diels–Alder sequence and tandem Knoevenagel-ene sequence have already been



196 **145** **197**

a: R = 4-OMe, X = CH_2 or O

widely used in the synthesis of natural products. It has thus been possible to construct the basic framework of secologanin **202b** from a sequence involving a three-component reaction. (Secologanin possesses great importance as a key compound in the biosynthesis of monoterpene indole alkaloids as well as the ipecacuanha, cinchona, and pyrroloquinoline alkaloids.[95]) Thus, the mono-protected malondialdehyde **198**, the reactive 1,3-dicarbonyl compound **199** (equivalent to formyl acetate), and the enol ether **200** were mixed together in the presence of potassium fluoride as base. The domino reaction led directly to the dihydropyran **201**, which, after conversion of the trichloromethylcarbonyl into a methyoxycarbonyl group, elimination, hydrolysis of the thioacetal, and chromatographic purification, gave 1-ethoxysecologanin-aglucon **202a** in an overall yield of 12%.[96]

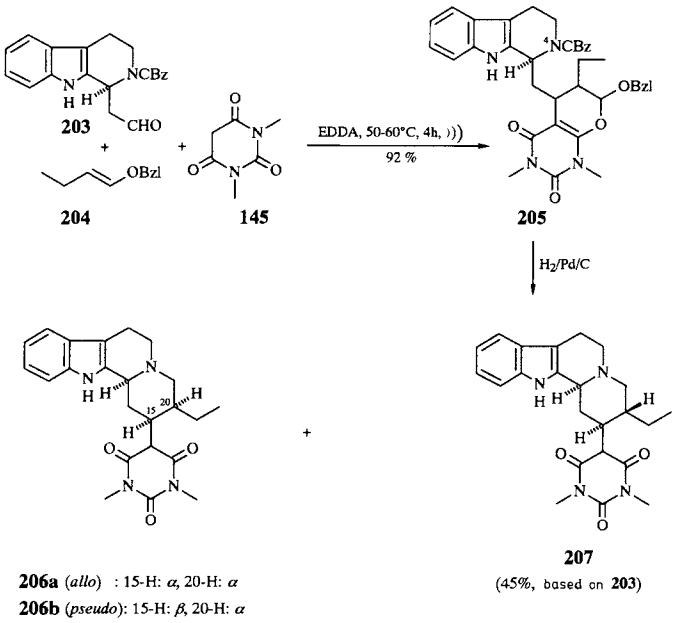
202a : R = Et (12%)
202b : R = β-D-Glc

DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene

A comparable synthetic sequence was used in the construction of the strictosidine analogue **207**. Strictosidine, total synthesis of which has not yet been achieved, is the first nitrogen-containing precursor of the monoterpenoid indole alkaloids and is formed in vivo by enzymatic condensation of tryptamine and secologanin.[97] Reaction of the enantiomerically pure aldehyde **203** with dimethylbarbituric acid **145** and the enol ether **204** in the presence of ethylenedi-

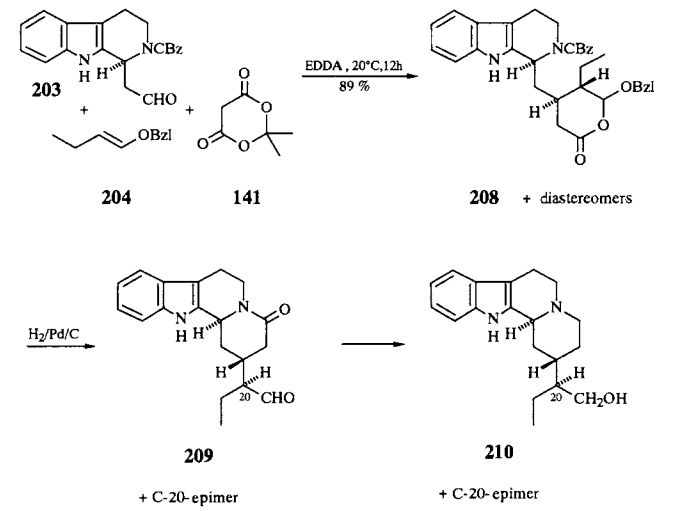
ammonium diacetate and by using ultrasound led to a 92% yield of **205** within 4 h at 20 °C. Hydrogenation of the crude diastereomeric mixture obtained with H_2/Pd/C, in a type of biomimetic transformation, with cleavage of both protecting groups, opening of the hemiacetal formed, condensation of N-4 with the aldehyde formed, and hydrogenation of the resulting iminium salt or the enamine, gave the dihydrocorynanthine derivative **207** (45%, based on **203**), with the correct relative and absolute configurations at all stereogenic centers.[98] In addition, 7% of the *allo*-compound **206a** and



203 + **204** + **145** → **205** → **206a** + **206b** + **207**

206a (*allo*) : 15-H: α, 20-H: α
206b (*pseudo*): 15-H: β, 20-H: α
207 (45%, based on **203**)

12% of the pseudo-compound **206b** were also obtained. In a similar manner, we synthesized the natural product dihydroantirhine **210** from **203**, **204**, and Meldrum's acid **141**, via the intermediates **208** and **209**.[99]

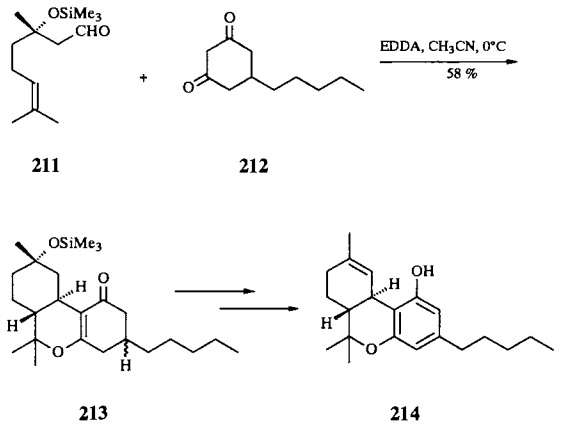


203 + **204** + **141** → **208** + diastereomers → **209** → **210**

209 + C-20-epimer
210 + C-20-epimer

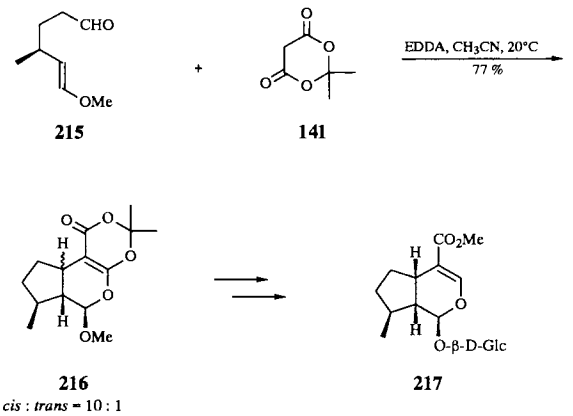
The tandem Knoevenagel hetero-Diels–Alder reaction with an intramolecular second step has, amongst other examples, been used for the synthesis of enantiomerically pure hexahydro-[100] and tetrahydrocannabinol **214**,[101] deoxyloganin **217**,[102] ajmalicine **220**,[103] tetrahydroalstonine **221**,[103] furofuran lignans,[104] heterosteroids **223**,[105] and D-homosteroids **225**.[106]

Reaction of **211**, from linalool, with 5-*n*-pentyl-1,3-cyclohexanedione **212** gave the adduct **213**, from which **214** was obtained in two steps.



211 + **212** → **213** → **214**

The condensation of aldehyde **215**, accessible from (*S*)-citronellal, proceeded similarly with Meldrum's acid **141** to give the tricycle **216** (*cis*/*trans* = 10:1) in 77% yield, which could be transformed to deoxyloganin **217** in four steps.

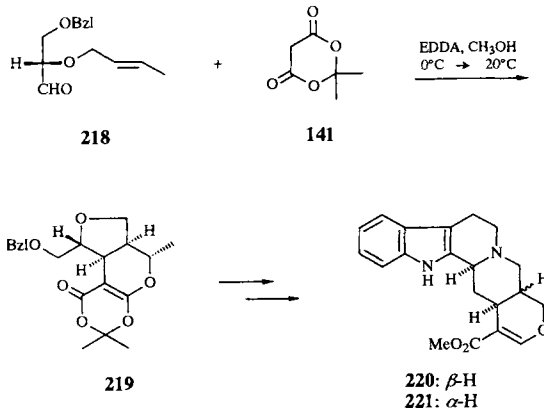


215 + **141** → **216** → **217**

216 *cis* : *trans* = 10 : 1

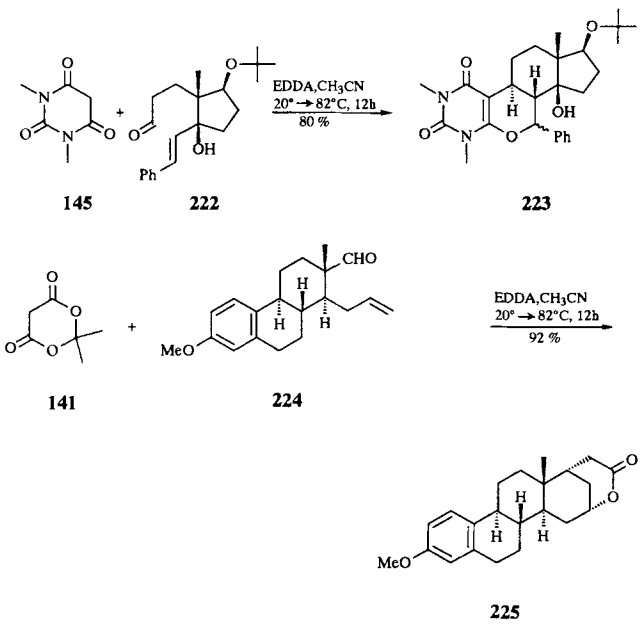
Other groups have also employed our tandem Knoevenagel hetero-Diels–Alder sequence for the synthesis of natural products, as demonstrated by the work of Takano, Ogasawara et al. in the preparation of furofuran–lignanes[104] and indole alkaloids.[103] Reaction of the enantiomerically pure aldehyde **218** with Meldrum's acid **141** gave the cycloadduct **219**, from which **220** and **221** were obtained.

We have synthesized numerous heterosteroids, such as **223**, by using domino reactions of enantiomerically pure **222** with 1,3-dicarbonyl compounds like, for example, *N*,*N*-dimethylbarbituric acid (**145**).[105] A further interesting example is the preparation of D-homosteroids **225** from Meldrum's acid **141** and aldehyde **224**, which can be obtained from estrone methyl ether.[106] In this case, the bridged cy-



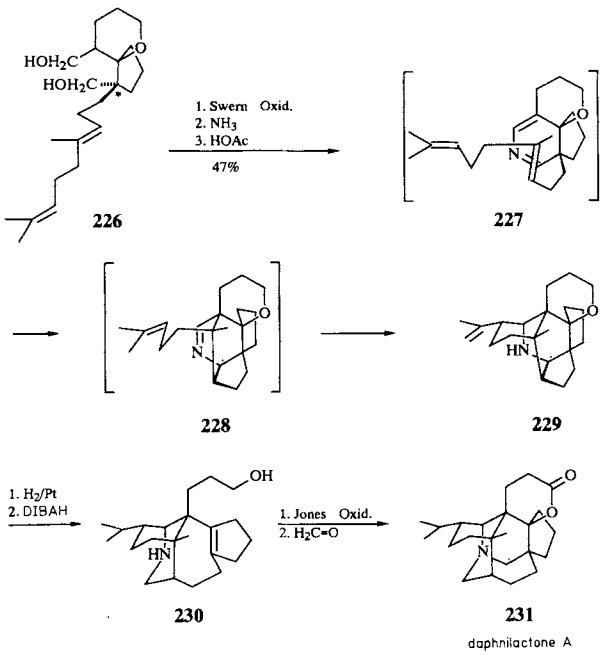
218 **141** **219** **220: β-H** **221: α-H**

cloadduct **225**, rather than the annelated compound, is formed exclusively as a result of the electron density distribution in the dienophile. In general, by suitable choice of the substituents on the dienophile, one can obtain at will either the bridged or the annelated products with the tandem Knoevenagel hetero-Diels–Alder sequence.[77a]



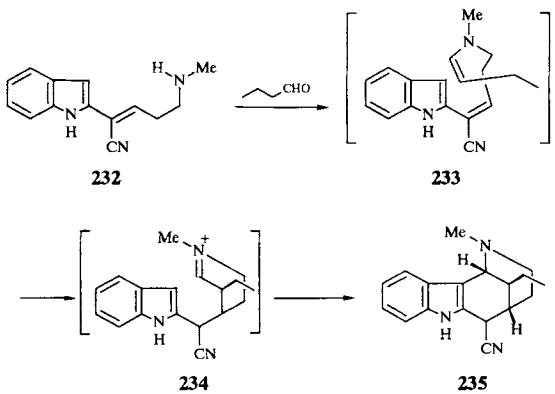
145 **222** **223** **141** **224** **225**

There are also, however, other possibilities to use anionic–pericyclic sequences. This principle was employed by Heathcock et al. in one of the best examples of the use of a domino reaction for the synthesis of a natural product. From simple starting materials they were able to construct, amongst others, the complex hexacyclic alkaloid daphnilactone A **231** in few steps and with high selectivity.[107] Thus, in one sequence, four rings and six new stereogenic centers were formed. Swern oxidation (oxalyl chloride/dimethylsulfoxide (DMSO)/Et_3N) of the easily accessible diol **226** led to the nonisolable dialdehyde, which cyclized to 3,4-dihydropyridine **227** on addition of NH_3. Compound **227** reacted as an 2-aza-1,3-butadiene in a type of Diels–Alder reaction with the central configuratively homogeneous olefinic double bond in the side chain to form the tetracycle **228**. The last step in the sequence to **229** is an intramolecular aza-Prins reaction of the imine formed in situ by the Diels–Alder reaction. A characteristic of the quality of this sequence is the high stereoselectivity of the indivual steps; thus only one diastereoisomer is formed, the absolute configuration of which is based on the stereochemistry of the quaternary C*atom in the substrate **226**. The structure of the carefully chosen starting material forces the subsequent steps to follow the desired route. The synthesis of daphnilactone A **231** was concluded by catalytic hydrogenation of the isopropenyl group, reductive fragmentation with diisobutylaluminum hydride (DIBAH) with formation of an unsaturated seven-membered ring, oxidation of the resulting alcohol to the acid, and finally reaction with formaldehyde to the iminium salt, which gave **231** by a double intramolecular cyclization.



226 **227** **228** **229** **230** **231**
daphnilactone A

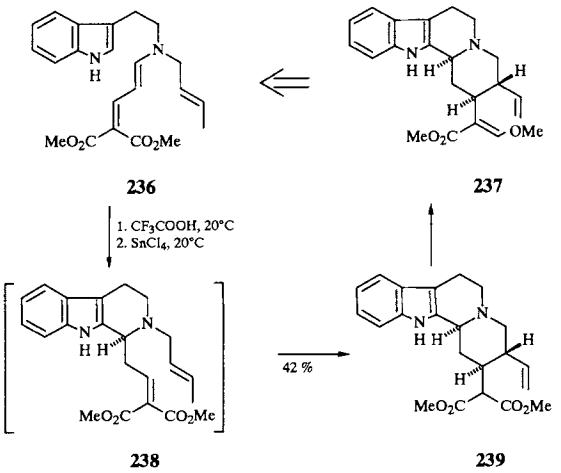
Similarly, sequential transformations that start with formation of an imine or an enamine have been developed by Blechert et al. for the synthesis of alkaloids.[108] Reaction of alkenylindole **232** with butanal was used to form the desired tetrahydrocarbazole structure **235**, to build the basic skeleton of the indole alkaloid *epi*-dasycarpidone. We have interpreted this sequence as an anionic–pericyclic process, where-



232 **233** **234** **235**

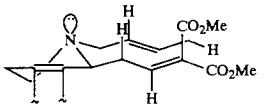
by the enamine **233** reacts to form **235** in a type of Diels–Alder reaction. It is, of course, also possible that **233** reacts first in a Michael reaction to **234**, which then undergoes a Mannich reaction. The alkenylindoles have also been prepared from aromatic hydroxylamines, an aldehyde, and an allene in a sequential process involving 1,3-dipolar cycloaddition and a 2,3-sigmatropic rearrangement.[108]

We have developed a sequence consisting of a Pictet–Spengler and an ene reaction for the synthesis of indole alkaloids of the corynanthe group, such as corynantheine **237**, from simple precursors corresponding to the retrosynthesis **237** ⇒ **236**. Thus, we have prepared, with high diastereoselectivity, the *trans*-indol[2,3-*a*]quinolizidine **239**, which can be further converted in a few steps into the racemic indole alkaloids corynantheine **237**, dihydrocorynantheine, corynantheol, and dihydrocorynantheol. Sequential treatment of **236** with trifluoroacetic acid and tin tetrachloride gave the tricycle **239** as solitary product in 42% yield.[109] The transi-



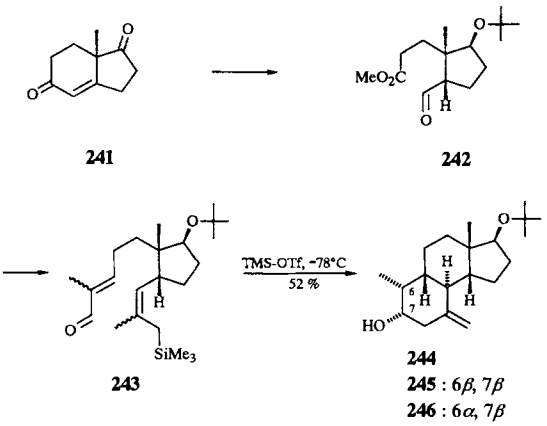
236 **237** **238** **239**

tion structure for the ene reaction **238** to **239** is assumed to have the conformation **240**, which is largely fixed because of the 1,3-allylic strain from the two terminal ester groups on the enophile (sp^2 geminal effect[71b]), thereby leading to the high selectivity observed.



240

Another new sequence in organic synthesis is the combination of a Sakurai with a carbonyl-ene reaction, which we have developed for the synthesis of 7-methylsubstituted steroids.[110] Compounds of this type frequently display, in contrast to the unsubstituted steroids, a higher biological activity. For example, 7α-methylprednisolone showed a five-fold greater antiphlogistic effect than cortisone.[111] For the synthesis of these compounds we started from the enantiomerically pure Hajos–Wiechert ketone **241**,[112] which can be converted via **242** into the aldehyde **243** required for



241 **242** **243** **244** **245** : 6β, 7β **246** : 6α, 7β

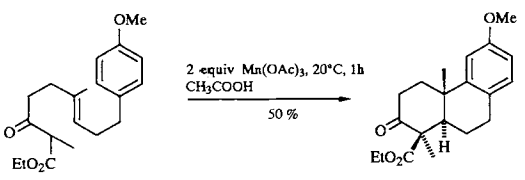
the domino reaction. Treatment of the isomeric mixture with trimethylsilyl trifluoromethanesulfonate (TMS-OTf) gave exclusively enantiomerically pure **244** with formation of four stereogenic centers. Interestingly, the stereoselectivity of the tandem Sakurai–Prins reaction can be controlled by the choice of the Lewis acid. Thus, treatment of **243** with Et_2AlCl leads to diastereomer **245**; nevertheless, the transformation is not as selective as that with TMS-OTf, as **246** is also obtained (**245**:**246** = 3:1). A new type of tandem Michael Diels–Alder sequence has been used by Naruta et al. for the synthesis of daunomycinone derivatives.[113]

3. Radical Primary Step

For those sequences that start with a radical primary step, we have found exclusively examples of radical–radical transformations (homosequence, Section 3.1). Thus an abundance of possibilities for further investigations exists in this area; the radical–pericyclic sequence in particular appears to us to be of great interest.

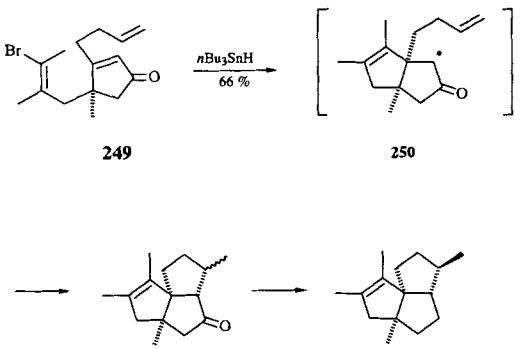
3.1. Radical–Radical Sequences

In the last decade radical reactions have gained importance, also for the synthesis of natural products. As with the cationic, anionic, and transition metal-catalyzed sequential cyclization of polyenes or polyenynes, a radical sequence is also possible for suitable substrates. The formation of the primary radical can result by reaction of halogens, phenylthio- and phenylselenium compounds with stannanes such as nBu_3SnH, silanes, and germanes.[114] Redox processes may also be employed; thus, the Mn^{III} oxidation[115,116] of C–H bonds, activated by one or two electron acceptor groups, is well established. Snider et al. used the reaction of **247** with $Mn(OAc)_3$ to form the tricycle **248** in 50% yield.[115c]



247 **248**

The syntheses of hirsutene,[117] $\Delta^{9,12}$-capnellene,[118] and silphiperfolene[119] are attractive examples of domino radical cyclizations involving halogen compounds. Curran et al. prepared a mixture of triquinanes **251** in 66% yield by reaction of the bromide **249** (obtained from 3-ethoxy-2-cyclopentenone in three steps) with nBu$_3$SnH via the radical **250**. Silphiperfolene **252** was then obtained by Wolff–Kishner reduction and separation of the resulting epimers by gas chromatography.[119]

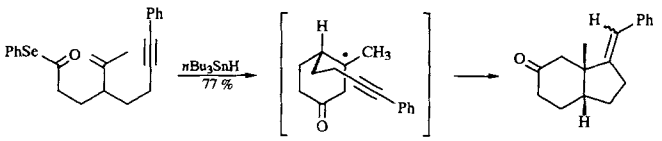


249 **250**

251 **252**

$\alpha:\beta = 3:1$

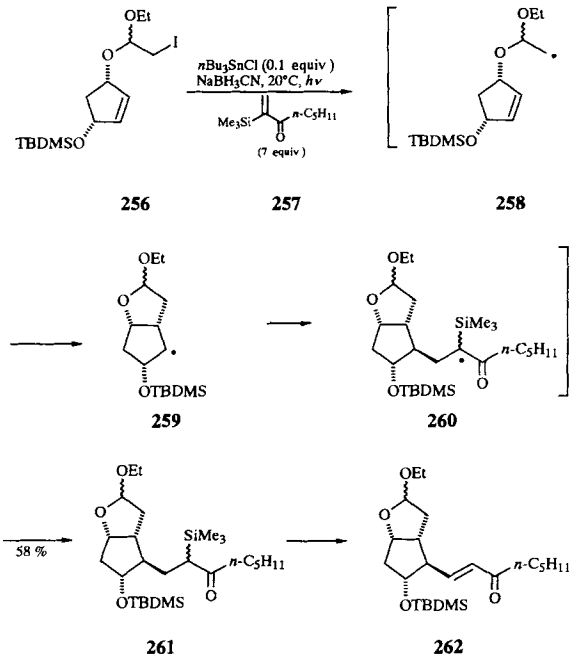
Acyl radicals can also be used for the domino polycyclization; these can be generated from phenylselenoesters with nBu$_3$SnH, among other methods. The efficiency of this method is demonstrated by diastereoselective formation of **255** from **253** via **254**.[120]



253 **254** **255**

> 98% *cis*

Tandem radical reactions, in which rapid intramolecular cyclization is followed by a slow intermolecular addition, are of particular synthetic interest. This method was successfully used by Stork et al. in the synthesis of prostaglandins.[121] In this case, in contrast to the three-component cuprate addition to enones, bond formation takes place first at C2 and then at C3. Reaction of the α-iodoacetal **256**, synthesized from cyclopentadiene, with seven equivalents of the α-trimethylsilylenone **257** and 0.1 equivalents nBu$_3$SnCl in the presence of NaBH$_3$CN led to a 58% yield of **261**, which could be converted into the prostaglandin precursor **262** by a Saegusa oxidation.[122] The radicals **258**, **259**, and **260** can be formulated as intermediates; the reaction sequence was concluded by transfer of a hydrogen atom from nBu$_3$SnH to **260**. The rapid intramolecular cyclization of **258** to **259**, in comparison with the addition of **257** to **258**, is of decisive importance for the success of this domino reaction. Among other factors, this result can be attributed to the oxygen atom in the chain.

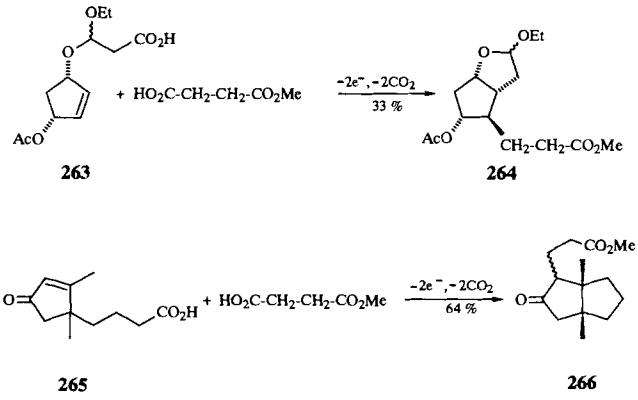


256 **257** **258**

259 **260**

261 **262**

Electrochemical processes may also be applied for the generation of radicals; such methods have the advantage, in contrast to the chemical methods, that toxic reagents such as nBu$_3$SnH are not required and that less waste is produced. Radicals can be formed very simply from carboxylic acids by Kolbe electrolysis (anodic decarboxylation). If coelectrolysis with a second acid is carried out, one obtains—as Schäfer et al. have shown—coupled products in a sequential transformation. Compound **263**, from 2-cyclopentene-1,3-diol, underwent electrochemical double decarboxylation with, for example, four equivalents of methyl succinate to give a 33% yield of **264**, which was used for prostaglandin synthesis.[123a] In similar fashion, perhydropentalene **266** was formed in 64% yield as a 1.25:1 mixture by coelectrolysis of **265** with methyl succinate.[123b]

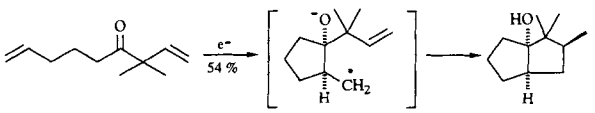


263 **264**

265 **266**

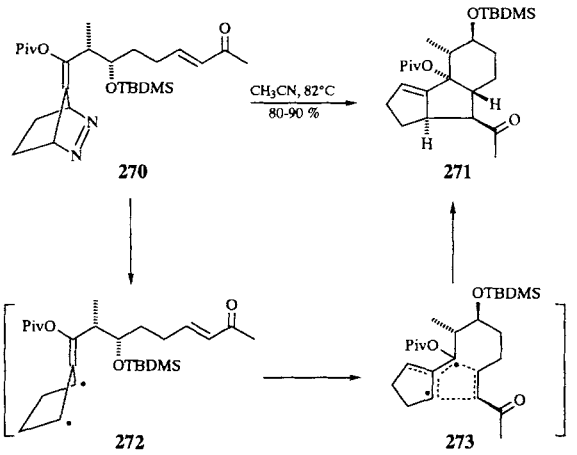
Radicals can also be formed by cathodic reduction of ketones. At a potential of −2.80 V electrolysis of **267** via **268** gave a 54% yield of the perhydropentalene **269**.[124]

The thermal elimination of nitrogen from diazenes, according to Little et al., is a simple method for the production of diradicals, which can undergo sequential reactions with



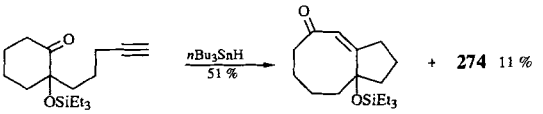
267 268 269

compounds containing multiple bonds. The diazenes required can be prepared by a Diels–Alder reaction of fulvenes with azodicarboxylates. Thermolysis of **270** at 82 °C gave the tricycle **271** in 80–90% yield. The diradical **272**, which reacts to form **271** by way of **273**, can be formulated as the reactive starting molecule in this highly diastereoselective cyclization, in which four stereogenic centers are constructed.[125]



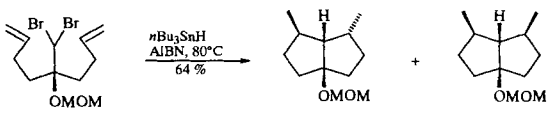
270 271 272 273

A certain amount of detective work is necessary to clarify the details of the conversion of **274** to **275**, which was observed under the classical conditions with nBu$_3$SnH and AIBN.[126]



274 275

The reaction of **276** to **277** and **278** in 64% yield in the presence of nBu$_3$SnH and AIBN, described by Wilcox et al., although not a genuine domino reaction according to our definition, is nevertheless an attractive one-pot multiple cyclization.[127]



276 277 278

MOM = CH_2OCH_3 AIBN = α,α'-azobisisobutyronitrile

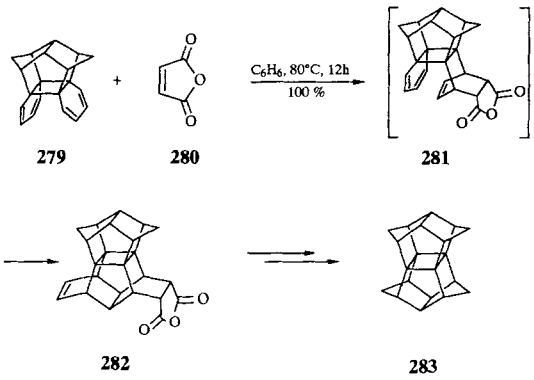
Other interesting radical sequences, also employing carbohydrates as chiral substrates, have been described.[128]

4. Pericyclic Primary Step

Pericyclic reactions can be combined easily with other pericyclic reactions to give sequences. This is particularly the case for the Diels–Alder reaction. Whether inter- or intramolecular, the all-carbon atom or the heteroatom variant, normal, neutral, or with inverse electron demand, this reaction is one of the most efficient methods in the repertoire of the organic chemist.[6a, 6d, 129] There are, however, also methods in which a pericyclic process is coupled with an anionic process (Table 1, Section 4.3). On the other hand, no examples are known for the pericyclic–cationic (Table 1, Section 4.2) or the pericyclic–radical sequence (Table 1, Section 4.4).

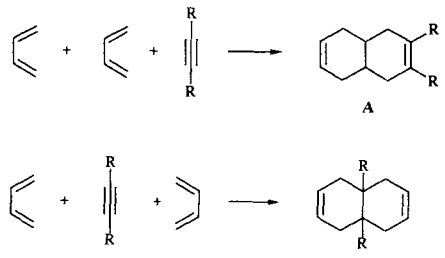
4.1. Pericyclic–Pericyclic Sequences

A domino Diels–Alder process is the key step in the synthesis of pagodane **283** by Prinzbach et al., in which the bisdiene **279** reacts with malonic anhydride **280** to give the cycloadduct **282** with excellent yield. Initially, attack of the



279 280 281 282 283

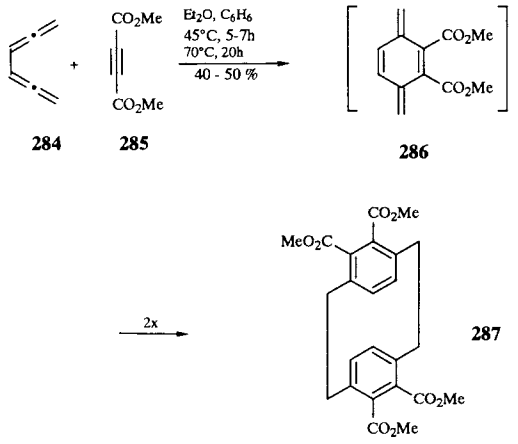
activated dienophile onto the outer face of **279** takes place by an intermolecular Diels–Alder reaction to give **281**, which could not be isolated, but which reacts further in an intramolecular cycloaddition to give **282**. Compound **282** can be converted to **283**.[130] If **279** is allowed to react with acetylenic dienophiles, in certain cases compounds of type **B** can be isolated in addition to those of type **A** (Scheme 6).[130]



Scheme 6. Types of Diels-Alder sequences A B

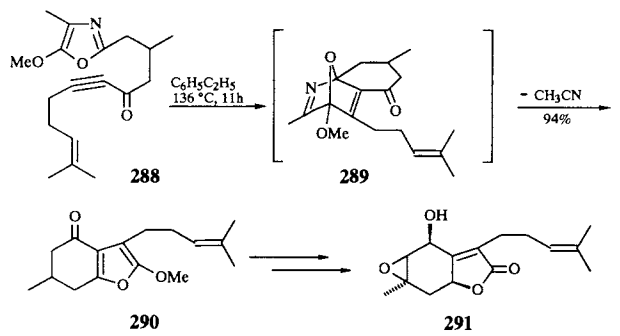
A comparable sequential transformation, which is composed of a Diels–Alder reaction and a subsequent dimerization, was used by Hopf et al for the elegant synthesis of

[2.2]paracyclophanes **287**. In this case, a 1,2,4,5-hexatetraene **284** reacts as a 4π-electron component with an electron-deficient acetylene **285**. The highly reactive *p*-xylylene **286** is formed initially, dimerizing with itself to give **287**.[131]



284 **285** **286** **287**

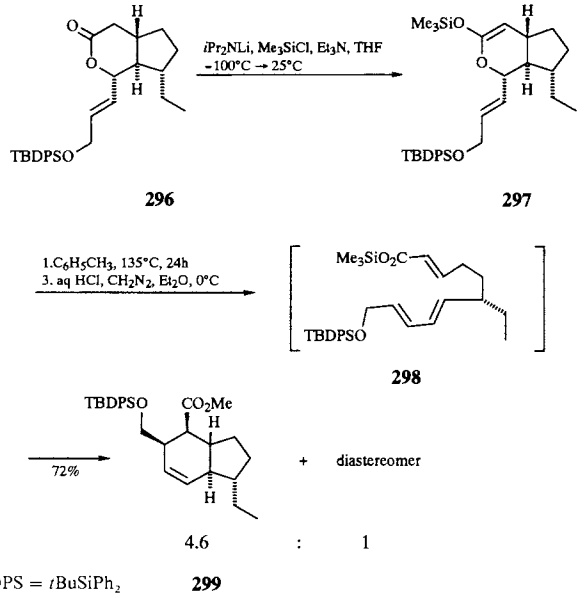
Diels–Alder reactions can also be coupled with retro-Diels–Alder reactions[132] to form interesting sequences. An illustrative example is the reaction of **288** to give **290** via the nonisolable Diels–Alder adduct **289** used by Jacobi et al. in a synthesis of paniculide A **291**. The elimination of acetonitrile from the primary cycloadduct **289** in this sequence is worthy of note.[133]



288 **289** **290** **291**

The synthesis of ansa compounds from steroids by Winterfeldt et al., in which the steroid framework is almost completely dismantled, is an attractive example of a Diels–Alder retro-Diels–Alder process. Thus, reaction of ergosterolacetate **292** with propargylaldehyde **293** in refluxing toluene led directly to the ansa compound **295**. On the other hand, the primary cycloadduct **294** can be isolated if Lewis acids are used at room temperature. Heating leads again to **295**.[134]

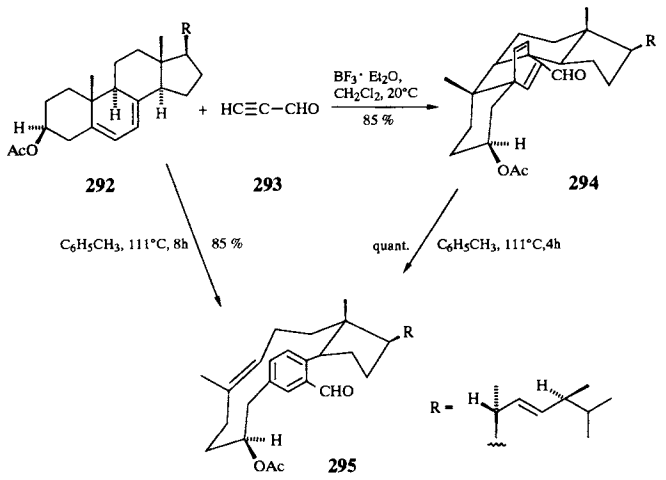
The reverse order, the retro-Diels–Alder Diels–Alder sequence, is also known.[135] In experiments aimed at the synthesis of the antibiotic indanomycin, Burke et al. unexpectedly isolated the indene derivative **299** in the reaction of **296** with lithium diisopropylamide and chlorotrimethylsilane. The silylketeneacetal **297** and the retro-Diels–Alder adduct **298** are assumed as intermediates.[135a]



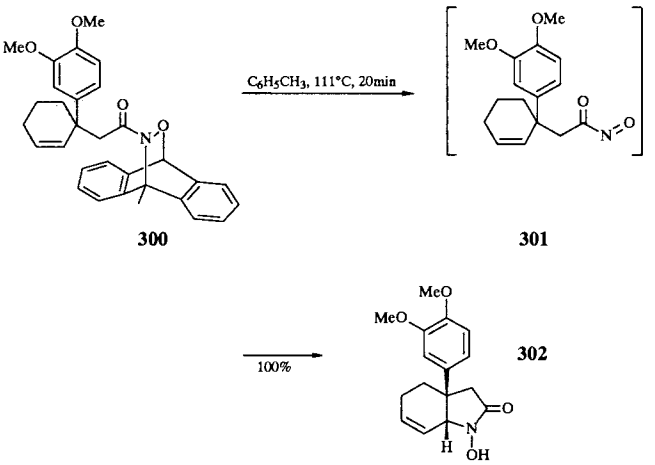
296 **297** **298** **299**

TBDPS = *t*BuSiPh$_2$

To the best of our knowledge, Diels–Alder-ene[136] and retro-Diels–Alder-ene[137] sequences have not been investigated systematically, although isolated examples are known, for example, the reaction of **300** to **302** for the synthesis of alkaloids containing the perhydroindole skeleton, reported by Keck et al. Presumably a retro-Diels–Alder reaction leads to intermediate formation of the acylnitroso-olefin **301**, which then reacts to form **302** in a hetero-ene reaction.[137a]

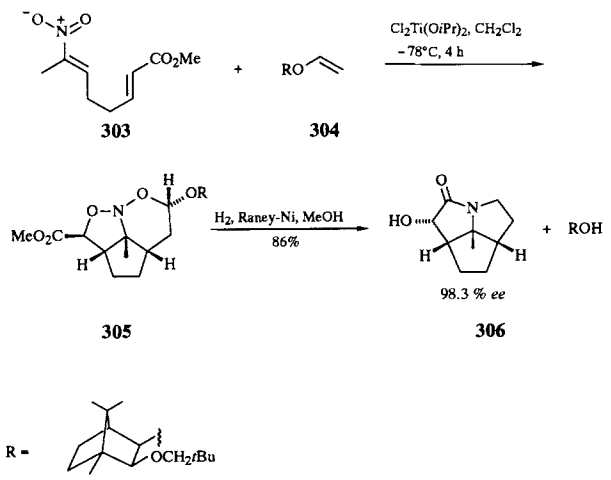


292 **293** **294** **295**

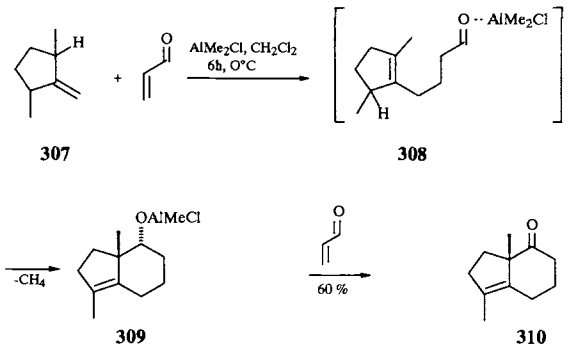


300 **301** **302**

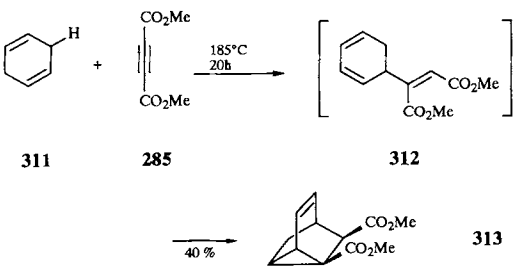
Heterocycles can be constructed by the sequence of Diels–Alder reaction and 1,3-dipolar cycloaddition of functionalized nitroalkenes or nitrodienes.[138] For example, Denmark et al. have obtained the nitrosoacetal **305** with high-induced (98.3%) and noninduced (99%) diastereoselectivity from the enantiomerically pure vinyl ethers **304** and **303**. Compound **305** could be converted into the α-hydroxylactam **306** by reduction with elimination of the chiral auxiliary.[139]



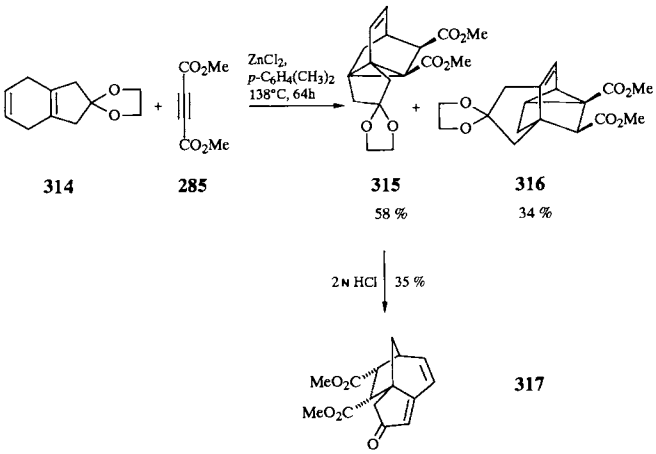
The ene-reaction[140] can, as with the Diels–Alder reaction, be combined with itself or with other pericyclic and related processes. Snider et al. have introduced a new type of annelation method with the reaction of **307** with acrolein to give **309** by way of **308**. Use of an excess of acrolein led to a subsequent Oppenauer oxidation.[141]



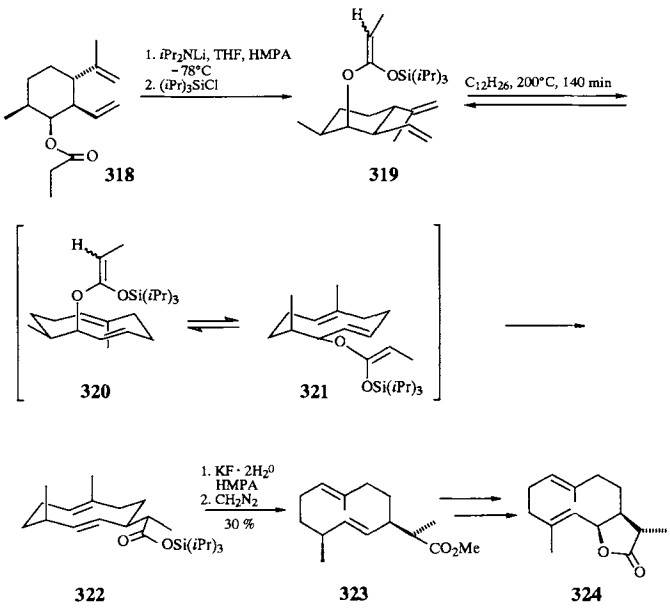
The ene-Diels–Alder sequence was first described 40 years ago with the reaction of 1,4-cyclohexadiene **311** with acetylene dicarboxylate **285** to give **313** via **312**.[142a] In the intervening period the process has been improved.[142b,c]



This sequence was adopted by Giguere et al. for the synthesis of the basic framework of khusimone and zizaene. Heating **314** with **285** in xylene under reflux in the presence of $ZnCl_2$ gave **315** (58%) and **316** (34%). The major product can be transformed into the desired tricyclo[6.2.1.$0^{1,5}$]undecane derivative **317** by a subsequent acid-catalyzed reaction.[143]

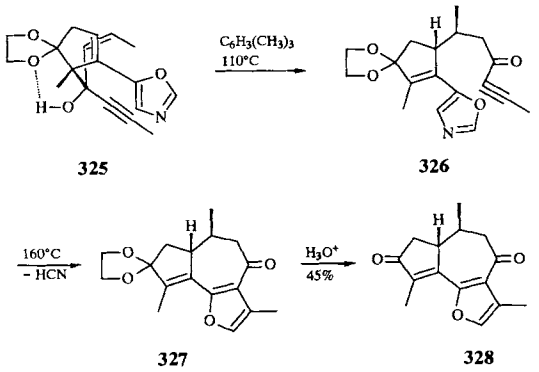


The coupling of Claisen and Cope reactions has already been used on numerous occasions for the synthesis of natural products. Thomas et al. successfully used the Claisen–Cope sequence[144] for the synthesis of sesquiterpenes such as β-sinensal.[145] The efficiency of the Cope–Claisen sequence[144a,146,147] has been demonstrated by Raucher et al. with a synthesis of the germanocrolide (+)-dihydrocostunolide **324**. Thermolysis of the keteneacetal **319**, ob-



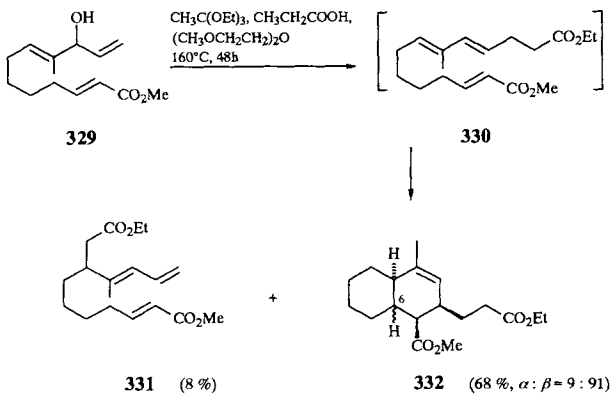
tained by deprotonation of the corresponding propionate **318** in tetrahydrofuran/hexamethylphosphoric acid amide (HMPA) followed by trapping of the enolate with chlorotriisopropylsilane, gave the decadiene **322** via **320** and **321**. Subsequent hydrolysis and esterification led to **323** as a single stereoisomer in 30% yield.[147a]

Examples of the Oxy-Cope–Claisen and Oxy-Cope–Cope sequences are also known.[148] In the synthesis of the tumor inhibitor gnididione **328** by Jacobi et al., the intramolecular Oxy-Cope rearrangement forms the prelude for the conversion of **325** to **327**. The isolable Oxy-Cope product **326**, obtained by heating **325** at 110 °C, underwent a Diels–Alder retro-Diels–Alder reaction at 160 °C to form **327**. Finally, hydrolysis delivered the target molecule **328** in 45% yield.[149]



325 **326** **327** **328**

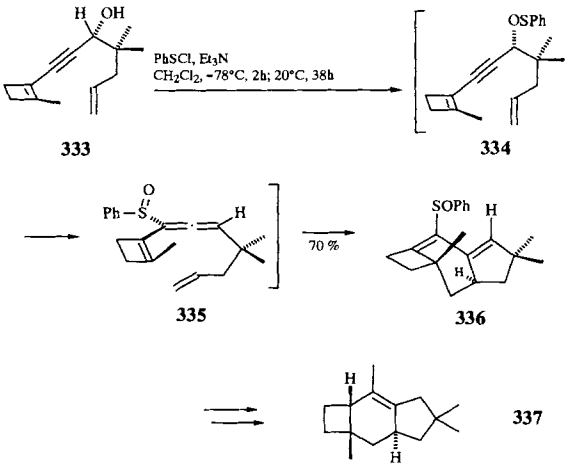
Claisen–Diels–Alder sequences have been applied by Kraus et al. for the synthesis of anthracyclines, for example, 11-deoxydaunomycinon.[150] Another example of this sequence is the diastereoselective synthesis of *trans*-decalines by Mulzer et al. Heating the secondary alcohol **329** with ethyl orthoacetate in the presence of propionic acid at 160 °C first gave the Claisen products **330** and **331**. Whereas **331** can be isolated, **330** reacts further under the reaction conditions to give **332** by an intramolecular Diels–Alder reaction.[151]



329 **330** **331** (8 %) **332** (68 %, $\alpha:\beta = 9:91$)

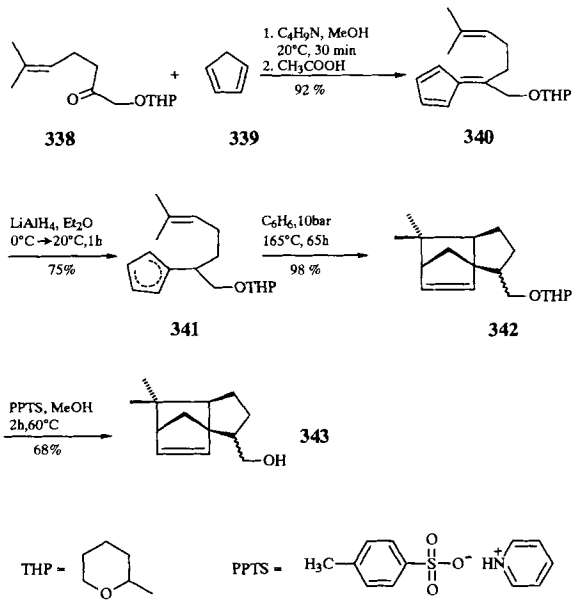
Okamura et al. found that allenylsulfoxides and allenylphosphaneoxides could be prepared from sulfenates or phosphinates, respectively, by a [2,3]-sigmatropic rearrangement, and used to react with dienophiles as part of a diene in a Diels–Alder reaction.[152] This strategy formed the key feature in the synthesis of the sesquiterpene (+)-sterpurene **337**. Thus, **333** was allowed to react with phenylsulfenylchloride to give **334**, which then led to the tricyclic **336** in 70% via the suspected intermediate **335**.[153]

A 1,5-hydrogen shift followed by a Diels–Alder reaction formed the starting point for the synthesis of the naturally



333 **334** **335** **336** **337**

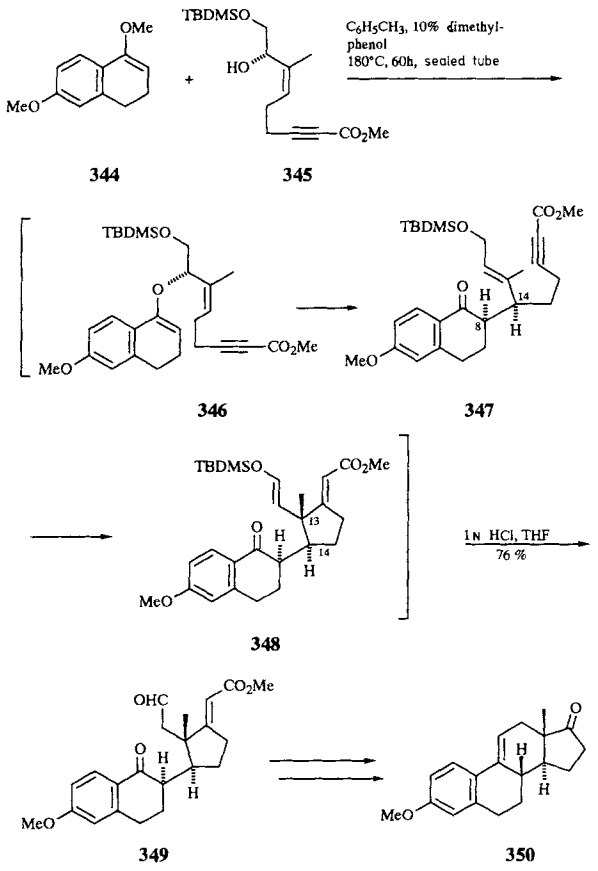
existing isocedrene derivatives in racemic form by Bohlmann et al. Condensation of the tetrahydropyranyl ether of 1-hydroxy-6-methyl-5-hepten-2-one **338** with cyclopentadiene **339** afforded the pentafulvene **340**, which gave the substituted cyclopentadiene **341** as a tautomeric mixture on treatment with $LiAlH_4$. The isomers exist in a dynamic equilibrium through a 1,5-hydrogen shift. In the subsequent intramolecular Diels–Alder reaction only one of the isomers reacts, with constant adjustment of the equilibrium, to form the tricyclic product **342**, which gave **343** on hydrolysis.[154]



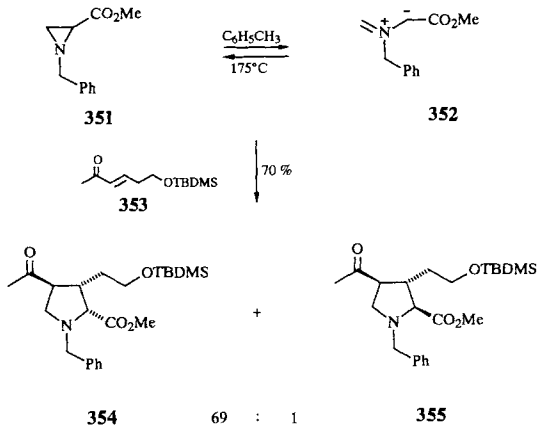
338 **339** **340** **341** **342** **343**

The Claisen-ene strategy can also be used for the synthesis of complex molecules.[140, 155] Thus, the acid-catalyzed reaction of the cyclic enol ether **344** with the enantiomerically pure (*S*)-(*Z*)-allylic alcohol **345** at 180 °C, according to Mikami et al., gave, after acidic workup, the cyclopentane derivative **349** with high diastereoselectivity (C13/C14:100% *trans*; C8/C14:90% *cis*). Compound **349** was subsequently converted to the (+)-dehydroestrone derivative **350**. The Claisen reaction of **346** to give **347**, in which the configuration of the two stereogenic centers C8 and C14 are formed with a *syn* selectivity of 9:1, presumably takes place

via a chair-like transition structure, the following intramolecular ene reaction leads to only one diastereomer, such as **349**, as major product.[156]

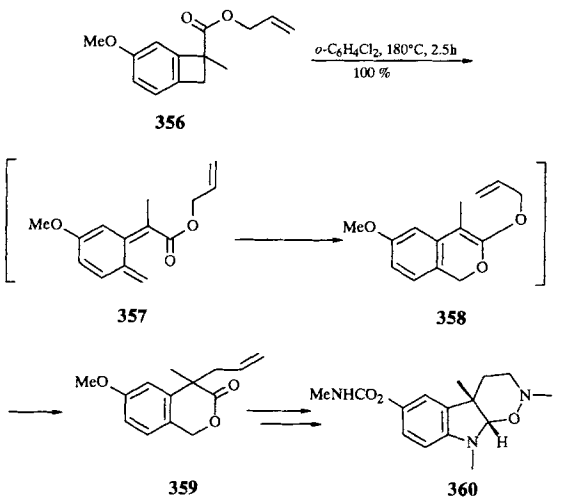


Most of the 1,3-dipoles employed in 1,3-dipolar cycloadditions are generated in situ from suitable precursors.[157] Thus, the classical entry to azomethine-ylides is the electrocyclic ring opening of aziridines.[157b] Thermolysis of the

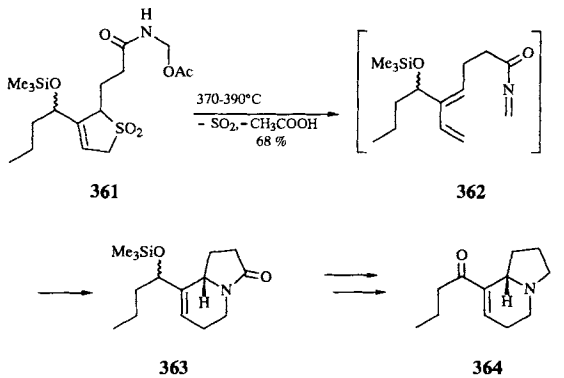


aziridine **351** to give **352**, followed by 1,3-dipolar cycloaddition to the (*E*)-enone **353** in toluene at 175 °C gave the pyrrolidines **354** and **355** regio- and diastereoselectively in 70% yield. Compound **354** was converted by DeShong et al. into the amino acid (±)-*allo*-kainic acid.[158]

As it is well known, orthoquinonedimethanes play a prominent role as 1,3-dienes in domino processes.[159] They can be generated in a great variety of ways, including thermally allowed, conrotatory, electrocyclic ring opening of benzocyclobutenes.[159] With a subsequent intramolecular Diels–Alder reaction it was possible to achieve the formation of numerous complex molecular frameworks.[129, 159] Classic examples include the numerous syntheses of steroids carried out by this route.[59c, 160] Fukomoto et al. showed with the synthesis of some alkaloids from calabar beans that orthoquinodimethanes do not just find application as 1,3-dienes in Diels–Alder reactions.[161] The key step in the synthesis of (±)-geneserine **360** is the thermal reaction of **356**. Thus, electrocyclic ring opening with formation of **357** took place first, followed by electrocyclic ring closure to give **358**, and finally a [3,3] sigmatropic rearrangement afforded **359**.[161]



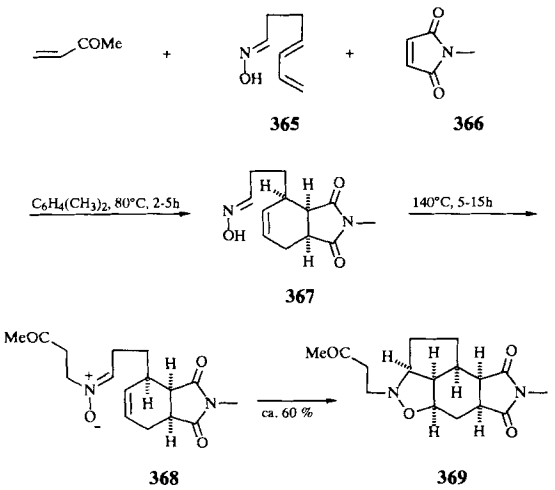
Orthoquinodimethanes and other 1,3-dienes can also be formed by cheletropic reactions. The reaction most used synthetically is the extrusion of SO_2 from sulfones.[162] In the synthesis of elaeokanine A **364** by Weinreb et al. thermolysis of **361** at 370–390 °C gave the bicyclic lactam **363**, formation of which presumably takes place via nonisolable **362**.[163]



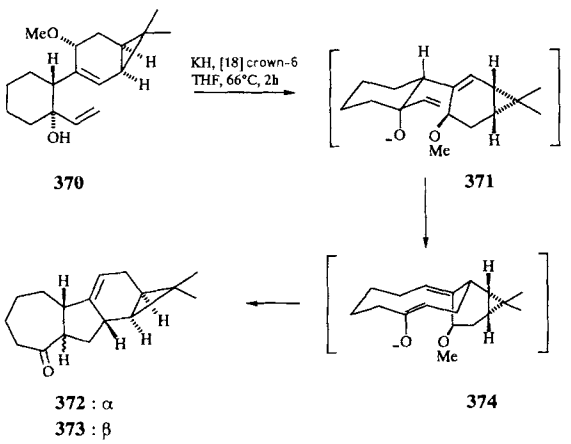
4.3. Pericyclic–Anionic Sequences

Combinations of a pericyclic with a non-pericyclic process have hitherto not been investigated very frequently. That

such a sequence is possible was shown by Grigg et al. with the reaction of a mixture of methyl vinyl ketone, **365**, and **366** in xylene at 80 °C. Initially, the cycloadduct **367** was formed from **365** and **366** in an intermolecular Diels–Alder reaction. At 140 °C **367** and methyl vinyl ketone underwent an intermolecular Michael addition to form the 1,3-dipole **368**, which ultimately reacted by an intramolecular process to give **369**.[164]



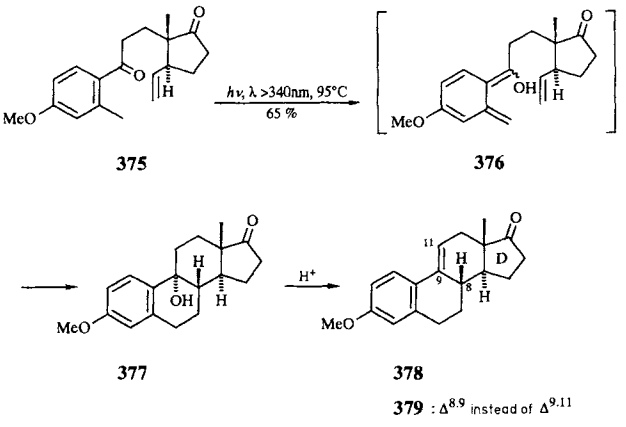
A domino process, consisting of an anionic Oxy-Cope reaction followed by an S_N' reaction for the synthesis of hydroazulenones, was realized by Paquette et al. for the reaction of **370**. Reaction of **370** with potassium hydride in tetrahydrofuran in the presence of [18]crown-6 led, after formation of the alcoholate **371** via a chair-like transition structure with an axial oxyanion group, to *trans,trans*-cyclodecadiene **374**. In this orientation a transannular S_N' substitution resulted in formation of the hydroazulenone **373**. Nevertheless, under the reaction conditions an enolate was formed that, on quenching with aqueous ammonium chloride solution at −78 °C, gave a 2:1 mixture of **372** and **373**.[165]



5. Photochemical Sequences

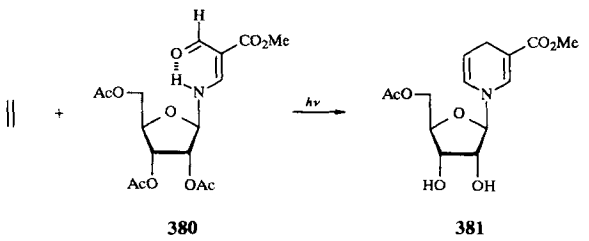
The combination of photochemical and thermal reactions has not been investigated much so far, although there is considerable potential. The reagent "*hν*" can tolerate many functional groups and reagents and can be very effective. Isomerizations, additions, eliminations, and also rearrangements can be initiated by light.

An elegant sequential synthesis of enantiomerically pure estrone was achieved by Quinkert et al. by the application of a photochemical isomerization. They showed that reactive *o*-quinonedimethanes are not just available by electrocyclic ring opening of benzocyclobutenes, but can also be prepared by light-induced tautomerization from *o*-alkyl-substituted derivatives of acetophenones. Irradiation of **375** with light of wavelength > 340 nm led initially to **376**, which then underwent a stereoselective intramolecular Diels–Alder reaction to give **377** as main product. Compound **377** was not isolated because of its instability, but was dehydrated with oxalic acid directly to the constitutionally isomeric steroids **378** and **379** (**378**:**379** = 95:5).[166]

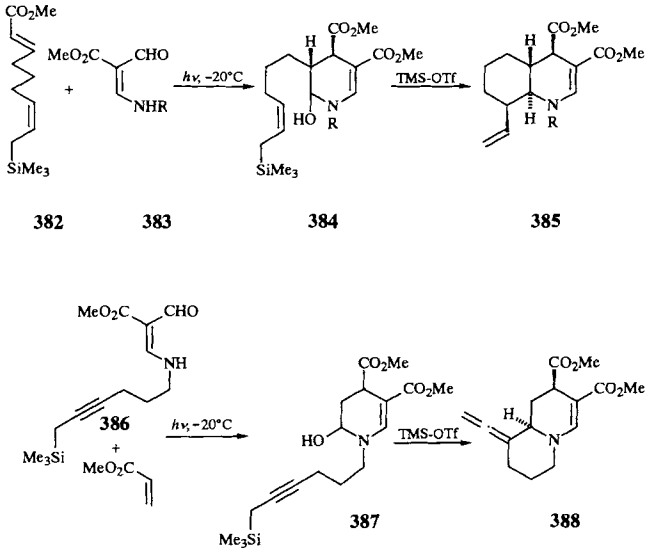


The [2+2] cycloaddition of olefins and cyclic enones or 1,3-dicarbonyl compounds count as one of the most productive photoreactions. In the photoaddition of 1,3-dicarbonyl compounds, known as the de Mayo reaction, a retroaldol reaction and recyclization to dihydropyrans generally follows.[167] This strategy has been used in a variety of ways for the synthesis of iridoids and secoiridoids.[168]

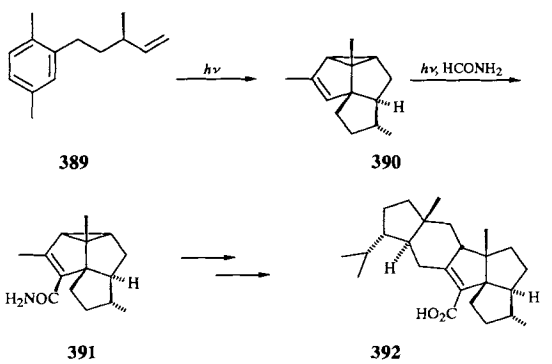
We have recently shown that substituted 1,4-dihydropyridines can also be synthesized with very good yields by the photochemical cycloaddition of enaminecarbaldehydes and alkenes.[169] An example of this is the preparation of the NADH analogue **381** from **380** and ethene.[169b] In these reactions a 2-hydroxytetrahydropyridine is formed as the first isolable compound that gives (via an iminium ion) a 1,4-dihydropyridine in the presence of acid. The iminium salt can also be trapped intramolecularly by allylsilane or propargylsilane moieties in the substrate.[170] Strictly speak-



ing this does not, however, represent a domino reaction as the cycloaddition partner (added in excess) must first be removed before the Lewis acid required for the second cyclization step can be added. The allyl- or propargylsilane unit can be present either in the alkene or in the enaminecarbaldehyde. Quinolizidines, cyclohexanopyridines, pyridinoazepines and cyclopentanopyridines can also be constructed by altering the chain length. All reactions proceed with high stereoselectivity: for example, in the reaction of **382** and **383** via the intermediate **384**, only one of the eight possible diastereoisomers was formed, namely **385**.[170a] Irradiation of a mixture of methyl acrylate and **386** gave **387**, which, after distillation of the excess acrylate, led to allene **388** on treatment with trimethylsilyl trifluoromethanesulfonate.[170b]

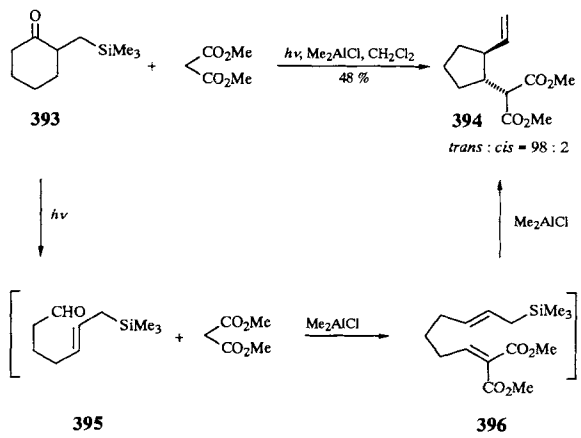


The photochemical *meta* cycloaddition of arenes and alkenes, in which three C–C bonds are formed, is a powerful sequence for the construction of complex molecules.[171] The photoaddition, starting from simple substrates, proceeds with almost quantitative yield. The process has already been employed by Wender et al. in various ways for the synthesis of natural products such as silphenes, subergorgic acids, grayanotoxin and retigeranic acid **392**.[172] The *meta*



photoaddition of enantiomerically pure **389** led to the angular annelated tricylcopentane system **390**, which, after addition of formamide, gave triquinane **391** in a second photochemical step with opening of the vinylcyclopropane. The complex pentacyclic retigeranic acid **392** can then be formed from **391** in a few steps;[172b] the process includes an intramolecular Diels–Alder reaction for the formation of the 5,6-ring system.

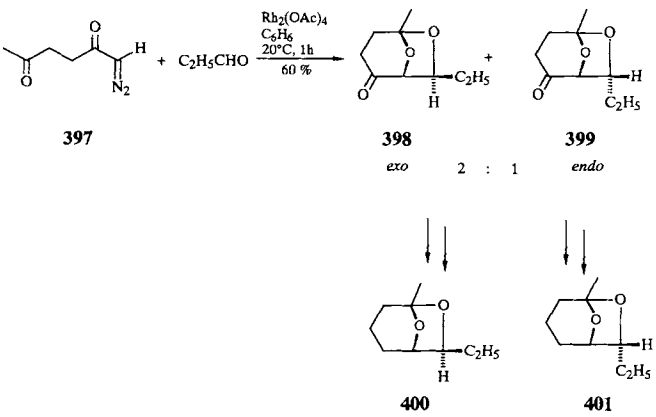
The combination of photochemical cleavage with thermal reactions can also be employed. We have shown that allylsilanes containing an aldehyde group are photochemically accessible by Norrish type I cleavage of trimethylsilylmethylcycloalkanones.[174a] The combination of this reaction with the tandem Knoevenagel-allylsilane cyclization permits an efficient and stereoselective entry to *trans*-substituted cyclopentanes and cyclohexanes from simple precursors.[173] Irradiation of a mixture of **393**, dimethyl malonate and dimethylammonium chloride with a high-pressure mercury lamp ($\lambda > 280$ nm) led directly to **394**. The aldehyde **395** and



the Knoevenagel product **396** appeared as intermediates in this sequence.

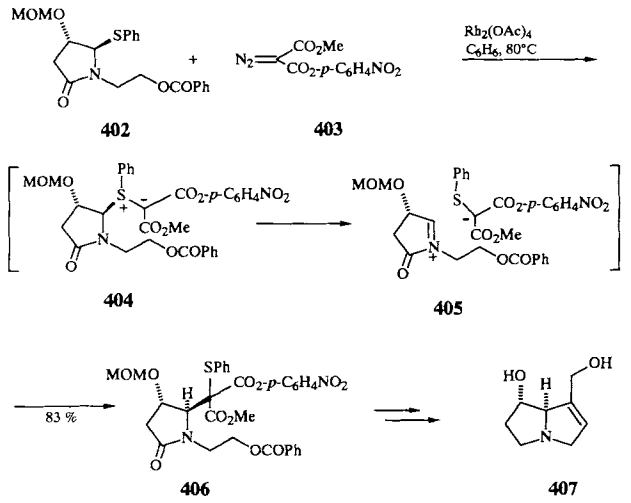
6. Sequences Involving Carbenes

As is well known, carbenes and carbenoids can react with a series of functional groups, whereby a more reactive intermediate is frequently formed that can undergo further subsequent reactions. Cyclic carbonyl ylides, for example, can be prepared by intramolecular reaction of metal carbenoids with carbonyl groups, and subsequently used with dipolarophiles in inter- or intramolecular 1,3-dipolar cycloadditions. This sequence permits the synthesis of a multitude of



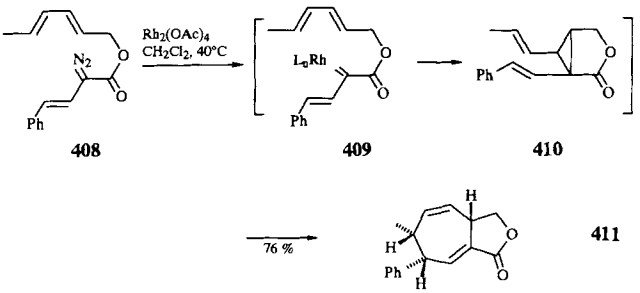
substituted furans.[174] Padwa et al. obtained a 2:1 mixture of the *exo* and *endo* products **398** and **399**, which could be converted into *exo*- or *endo*-brevicomin **400** and **401**, respectively, by the reaction of **397** and propionaldehyde with rhodium(II) acetate.[175]

The in situ formation of sulfonium ylides by an inter- or intramolecular reaction of a sulfide with a carbene forms the basis of a strategy by Kametani et al., which has so far permitted synthesis of penems, carbapenems, and pyrrolizidine alkaloids.[176] Compound **406** was synthesized, from **402** and **403**, presumably via **404** and **405**, and ultimately transformed into (+)-heliotridine **407**.[176a]



402 **403** **404** **405** **406** **407**

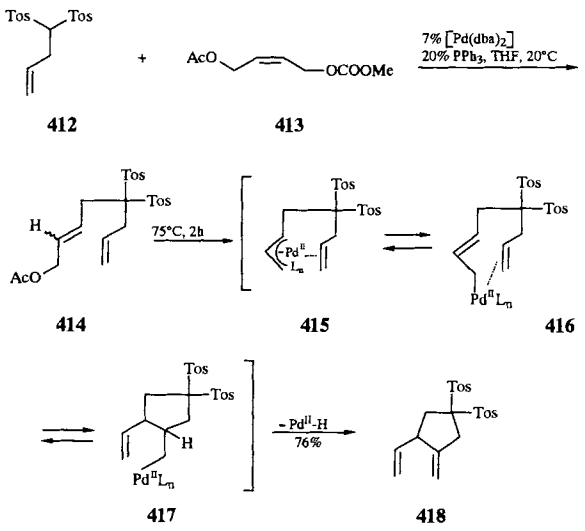
Davies et al. have shown that various ring systems, such as [3.2.1]bicycloocta-2,6-dienes, cyclopentenes, and cycloheptadienes are accessible by a stereoselective rhodium(II)-catalyzed intramolecular cyclopropanation followed by a Cope rearrangement.[177] In the synthesis of cycloheptadiene **411**, a stereospecific intramolecular cyclopropanation took place after formation of the styrylcarbenoid **409** from the diazocompound **408**. Under the prevailing reaction conditions the *cis*-divinylcyclopropane **410** then underwent an intramolecular Cope rearrangement to give **411**.[177a]



408 **409** **410** **411**

7. Sequences Involving Catalysis by Transition Metals

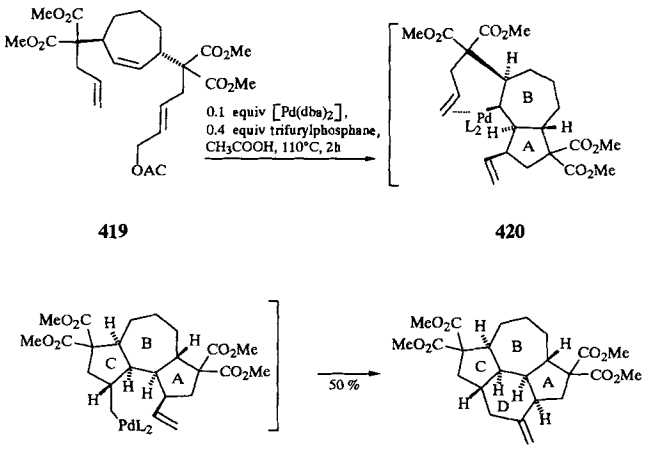
For a long time transition metal-catalyzed reactions have played a subordinate role in the synthesis of complex organic molecules; in the meantime this picture has been altered completely.[178] The magnesium-ene reaction and related stoichiometric processes possess considerable importance in organic synthesis, in particular for the construction of carbocycles.[179] On the other hand, the catalytic variants, such as the palladium-ene reaction followed by irreversible β elimination or insertion and subsequent reductive elimination, are even more attractive.[180] In some cases it is even possible to generate the system capable of cyclization in situ. Thus, **414** was formed in the reaction of **412** with **413** by Pd^0-catalyzed alkylation; **414** cyclized to the ene-product **417**, presumably via **415** and **416**. The subsequent β elimination to give **418** completed the reaction series.[181]



412 **413** **414** **415** **416** **417** **418**

[Pd(dba)$_2$] = bis(dibenzylidenacetone)palladium

It has since been discovered that the intramolecular Heck reaction can compete successfully with the β elimination. Thus, the palladium-catalyzed reaction of the 1,4-*trans*-substituted cycloheptene **419** gave the tetracycle **422** in 50% yield. As a result, ring A is closed first with the formation of **420**, presumably in a palladium-ene reaction. Rings C and D are then constructed in two intramolecular Heck reactions (**420** → **421** → **422**). Surprisingly, in the metal-ene reaction

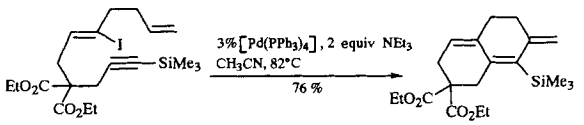


419 **420** **421** **422**

attack of the allyl-palladium component takes place on the *Re* side of the cycloheptene, leading to formation of a *trans*-annelated perhydroazulene. With the corresponding cyclohexene derivative attack takes place "from below".[182]

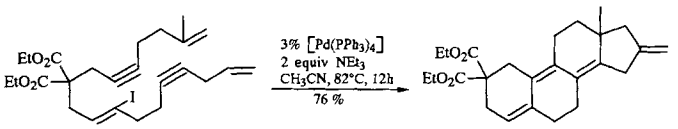
The alkyl-, alkenyl-, or allyl-palladium species appearing in the inter- and intramolecular Heck reaction can be trapped by a variety of nucleophiles, for example, C, N, and O nucleophiles.[183]

Two rings can be formed in a single synthetic operation when the first Heck reaction is followed by a second Heck reaction, that is, when the palladium species obtained in the first C–C bond forming step reacts with another double or a triple bond in the molecule (e.g. **423** → **424**).[184] The reactive intermediate formed by the second Heck coupling can also be trapped with nucleophiles.[185]



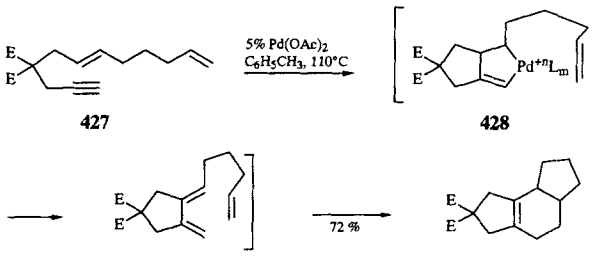
423 **424**

Recently it could be shown that three and even four rings can also be formed in a synthetic sequence with the help of such intramolecular domino Heck cyclizations (e.g. **425** → **426**).[186]



425 **426**

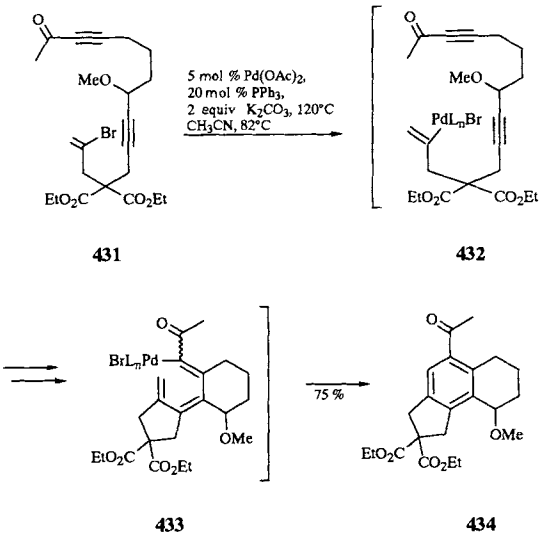
More recently the palladium-catalyzed reactions have been enriched by one more facet, in particular by Trost et al., namely the cycloisomerization of enynes and related systems.[187] Thus, the 1,3-diene **429**, which cyclized under the reaction conditions in the following intramolecular Diels–Alder reaction to give **430**, was formed by treatment of the dienyne **427** with $Pd(OAc)_2$. Compound **428** is a suspected intermediate in this cycloisomerization.[187a] The palladium-



427 **428** **429** **430**

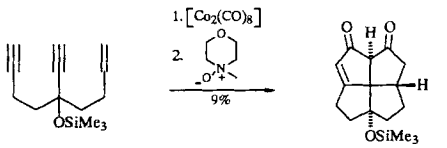
catalyzed alkylation cyclization of enynes[188] and the palladium-catalyzed trimethylenemethane cycloadditions,[189] also developed by Trost et al., are of considerable use.

The synthesis of *o*-bis-annelated arenes by domino cyclization of enediynes, achieved by de Meijere et al., also takes place under Heck conditions.[190] Thus, the reaction of **431** with $Pd(OAc)_2/PPh_3$ under basic conditions (K_2CO_3) led probably to the initial formation of the corresponding alkenyl-palladium derivative **432**, which presumably reacted to give **433** in two consecutive *exo-dig* cyclizations. Compound **433** led to **434** either by Heck coupling or by an electrocyclic reaction with subsequent elimination.[190c]



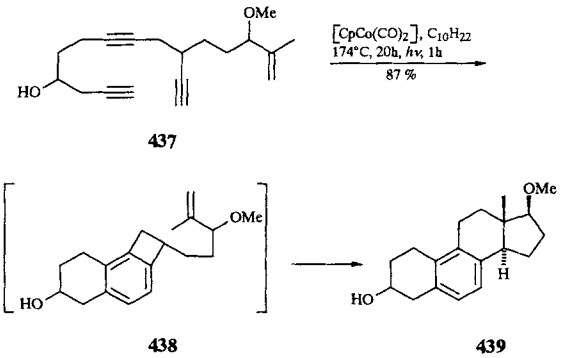
431 **432** **433** **434**

Efficient sequential reactions catalyzed by transition metals are not restricted to organopalladium reactions.[191] Keese et al. used two consecutive intramolecular Pauson–Khand reactions to convert the open-chain enediyne **435** into the tetracyclic fenestrendione **436**.[192]



435 **436**

The construction of steroids with an aromatic B ring in only one step from the acyclic precursor **437** by using $CpCo(CO)_2$ as catalyst is an attractive example of the efficiency of organometallic reagents. Thus, an intramolecular



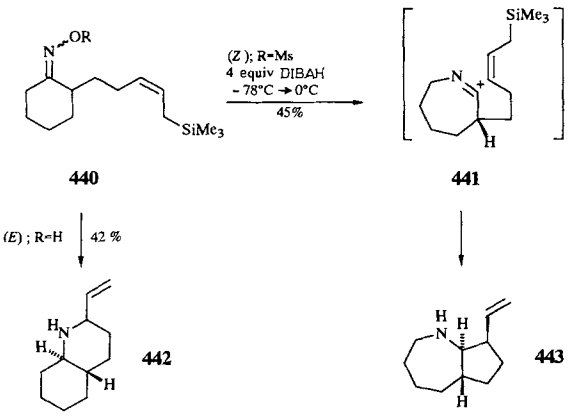
437 **438** **439**

alkyne cyclization with formation of the isolable cyclobutahydronaphthalene **438** takes place first. Electrocyclic ring opening and intramolecular Diels–Alder reaction then gives the steroid derivative **439** in high yield.[193] However, compound **438** can also be isolated by slightly altering the reaction conditions. Cobalt-catalyzed reactions have been used by Vollhardt et al. in a variety of ways, also for the synthesis of other interesting compounds.[194]

8. What Else is There?

In the preceding chapters we have shown that sequential reactions can be started by cationic, anionic, radical, pericyclic, photochemical, or with metal-catalyzed processes. Nevertheless, there is also an abundance of other possibilities, namely rearrangements, fragmentations, oxidations, reductions, and enzymatic processes. The only requirement here is again the formation of a highly reactive group in the presence of one or several other functional groups.

A domino-Beckmann rearrangement-allylsilane cyclization has been described by Schinzer et al. A reactive iminium ion **441** was formed from the (*Z*)-oximesulfonate **440** (R = Ms) and four equivalents of DIBAH; the iminium ion underwent a stereoselective intramolecular reaction with the allylsilane component in **441** to give **443**. In contrast, the (*E*)-oxime **440** (R = H) led surprisingly to **442**, as the allylsilane cyclization takes place more rapidly than the Beckmann rearrangement.[195]

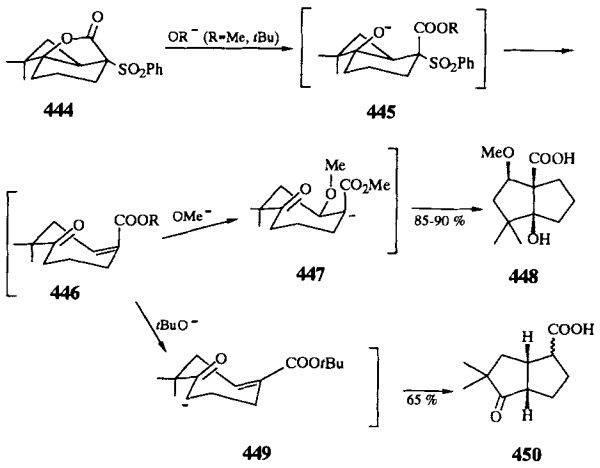


440 **441** **442** **443**

Interesting routes are also opened up when, after a preliminary fragmentation of a bicycle to give a ring extended intermediate, a recyclization takes place. Thus, Kende et al. described the formation of **446** by Grob fragmentation of **444** via **445**; **446**, depending on the choice of base, underwent either an aldol-like reaction to give **448** via **447** or a 1,4-addition to form **450** by way of **449**.[196]

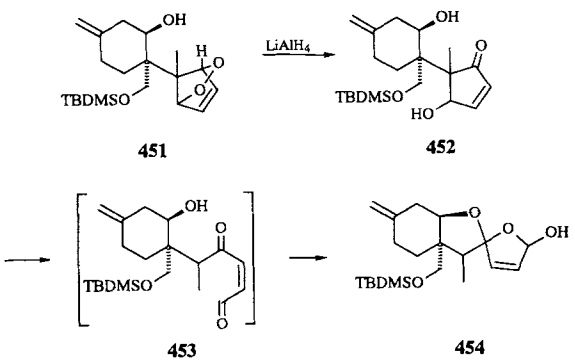
Ziegler and Sobolov found a domino fragmentation retroaldol reaction in the synthesis of the tricycle **454** in attempts to prepare the trichothecene anguidine. The $^1O_2$ cycloadduct **451** fragmented on treatment with $LiAlH_4$ to give **452**, which underwent a retroaldol reaction to give **453** and double C=O addition with formation of **454**.[197]

Oxidative and reductive processes are frequently preliminaries to complex sequence reactions in biosynthesis. One



444 **445** **446** **447** **448** **449** **450**

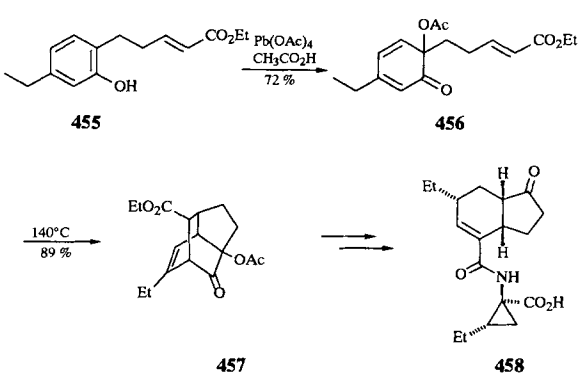
needs only think of the oxidation of phenols,[198] the arachidonic acid cascade,[199] and photosynthesis.[200] Of particular interest in this connection is the toxicity of natural products containing an enediyne group, such as neocarzinostatin, which alludes to the intermediate formation of an aryldiradical.[201] Reductions[202, 203] and oxidations[204, 205] can also initiate processes in organic synthesis.



451 **452** **453** **454**

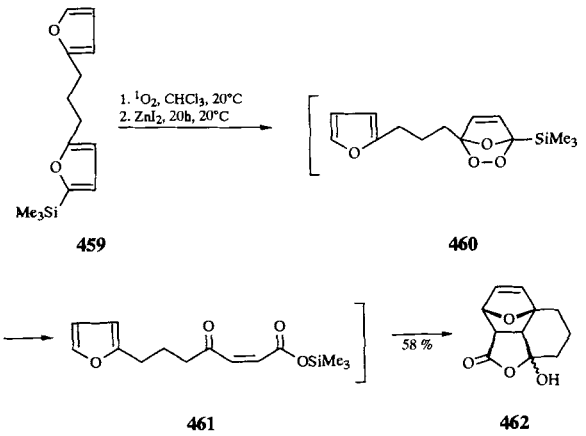
Yates et al. synthesized twistane by a sequence consisting of Wessely oxidation and an intramolecular Diels–Alder reaction. The phenol **455** was oxidized with lead tetraacetate to the intermediate **456**, which reacted to form **457** at 140 °C. Compound **457** was converted into (±)-coronafacic acid **458** in the course of further synthesis.[204b]

Furans can be easily oxidized to γ-keto-α,β-unsaturated esters, which can undergo Diels–Alder reactions as electron-



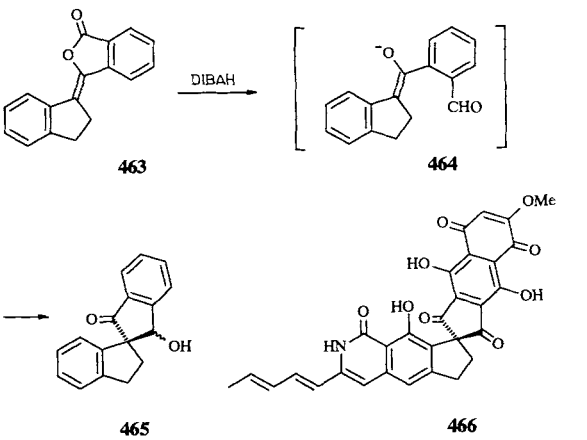
455 **456** **457** **458**

poor dienophiles.[205] In a notable one-pot reaction Feringa et al. achieved formation of the endoperoxide **460** by selective photooxidation of the bisfuran **459** with $^1O_2$; **460** opened to give **461**, which cyclized to **462** after addition of ZnI_2.[205a]



459 **460** **461** **462**

In a model study for the synthesis of (±)-fredericamycin A **466**, the dihydrolactone **463** was reduced with DIBAH to give the enolate **464**, which then cyclized in situ to the spiroketol **465** in an intramolecular 5-(enol-*endo*)-*exo*-*trig* reaction of the aldol type. A corresponding series of reduction and aldol reaction could also be employed for construction of the skeleton of this natural product.[203]



463 **464** **465** **466**

Summary and Outlook

Sequential transformations permit a simple, elegant, efficient and often highly selective entry to a multitude of complex compounds; several reactions are combined here to form a sequence, which then takes place in a sort of domino or consecutive process. Cationic, anionic, radical, pericyclic, organometallic, photochemical, oxidative, and reductive processes can be employed as the first step. The following steps may be of the same or a different type; sequences with identical processes are frequently found, but other reaction series, in particular the anionic–pericyclic sequence, can also be used with much success.

Nevertheless, sequential transformations are not simply efficient and aesthetic; they also make a contribution to the protection of the environment. We are concerned here with a new synthetic strategy, one that can help reduce the production of waste. Thus, numerous workup steps, such as chromatographic purification, extraction, recrystallization, etc. can be avoided with sequential transformations. Of course, the same demands must be met as those of a conventional synthesis: the reactions must be highly selective, give high yields, and it must be possible to carry them out without using highly toxic reagents or solvents. It is also understood that it makes no sense to develop sequences—even elegant sequences—when the synthesis of the starting materials required for the sequence demands a longer route than that for the synthesis of the target molecule by single step processes. The requirements set out here are met in, for example, the tandem Knoevenagel hetero-Diels–Alder reaction, developed by us, in exemplary fashion. They proceed with good yields and under mild conditions, generally at 25 °C and pH 7.0 with the application of a catalytic amount of an ammonium salt, with almost complete regio- and stereoselectivity. The range of application is immense and the starting materials—simple aldehydes and 1,3-dicarbonyl compounds—are readily available.

In this review the legitimacy of sequential transformations is demonstrated, which provides the basis for the discovery of hitherto unknown reactions of this type. There are numerous gray areas on the map of sequential transformations—particularly those involving combinations of nonidentical reactions. These gray areas should stimulate new activity. Sequential transformations must be included in future to a much greater extent in synthetic planning. The development and application of new, efficient, and selective reaction sequences will certainly form an interesting and topical research area over the coming years.

It is a particular pleasure for one of us (L.F.T.) to warmly thank my co-workers for their commitment and their excellent performance, as reflected in the numerous scientific publications. We would like to thank Mrs Sharon Williams and Mrs Vivian Reither for their help in the preparation of the manuscript and the drawings and Mr Jens Fennen for numerous literature searches. We would also like to express our gratitude to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, Bayer AG, BASF AG, Degussa AG, Hoechst AG, and Merck AG for support of the work described here.

Received: April 14, 1992 [A 891 IE]

Chemistry of and with Highly Reactive Metals

By Alois Fürstner*

New Synthetic Methods (89)

Today, the synthetic chemist has a large repertoire of metal activation methods at his disposal. After a first breakthrough was made at the beginning of the seventies with the introduction of the Rieke metals, a series of further, in part more efficient methods were described, based on which not only classical metal-induced reactions could be substantially improved but also completely new reactions could be discovered. In this article the individual activation methods are discussed and compared as far as is possible using the currently available data. Especially noteworthy are the metal–graphite combinations because of their unsurpassed reactivity and concomitant easy preparation and manipulation. As shown by numerous applications of these reagents on polyfunctional substrates, particularly natural products, high reactivity of the metal and excellent selectivity are by no means precluded. Besides the purely preparative aspects also insights gained so far into the general principles and limits of metal activation are outlined, and attempts at determining the morphology of highly dispersed systems are reported.

1. Introduction

"Sometimes I have the distinct feeling that organometallic chemists think of both solid state chemistry and surface science as the other side of the moon.
Roald Hoffmann et al. [1]

The simplest way to activate a solid is to dissolve it in a suitable solvent. Reactions in the homogeneous phase are generally easy to reproduce and control, and permit (comparatively) straightforward determination of the reaction mechanism at the molecular level with the repertoire of spectroscopic and kinetic methods developed for this purpose. In general these advantages do not apply to heterogeneous processes. Therefore it is hardly surprising that the marked qualitative and quantitative impetus in organic chemistry in the last decades has changed little in the preference for homogeneous reactions.

Many reasons call for reconsidering this general paradigm. Not only in technical application and industrial production but also in the chemistry of the cell, heterogeneous reactions such as reactions with carrier-bound (e.g. membrane-bound) reagents are notably frequent. Here and there the reasons are similar: enrichment of a reaction partner on a carrier can lead to higher reaction rates and to improved selectivities by synergic effects, the stability of the reagents is increased, manipulation made more reliable, and simple filtration generally suffices for workup of the reaction mixtures.[2] However, phase interfaces have many parameters and it is difficult to determine their properties precisely, especially since they may change when the reaction proceeds.[1] Thus, chemists often depend on purely empirical work as the only means to improve the preparative results. This also holds true for the large range of metal-induced heterogeneous processes to which the following progress report is devoted. Since more or less "activated" forms of almost every metal of the periodic table of the elements have been described, this paper gives preference to a methodological classification rather than a mere descriptive account of various activation techniques.[3]

1.1. General Principles of Metal Activation

Studies on the solid-state chemistry of metal-induced reactions have long been neglected; this is clearly illustrated, for example, in the case of the Grignard reaction. More than seven decades (!) after its discovery and after numerous empirical improvements Whitesides et al., in a series of notable studies, made the first clear statements on the influence of the nature of the magnesium on the course of the reaction; thus, they have also thrown light on the, in part, rather alchemistic practice of metal activation.[4] According to these studies, the initiation of a Grignard reaction takes place *exclusively* at physical defects on the metal surface, that is, at dislocations, edges, and corners. The "chemical" activators[5] (iodine, bromine, 1,2-dibromoethane etc.) commonly used by preparative chemists can only accelerate corrosion; however, they are not capable of creating initial sites for the reaction, whose density is dependent only on the surface structure of the magnesium sample used. Since Grignard reactions of alkyl iodides and bromides are diffusion-controlled after their "initiation", the reaction rate is directly proportional to the available metal surface area.[4]

The fact that those atoms of the surface with the smallest number of direct neighbors (Fig. 1) are the most reactive is reminiscent of the basic concepts of complexation chemistry, according to which the presence of free coordination sites at the central atom is a prerequisite for the chemical reactivity of a complex.[6] In addition, the easier steric accessibility of the atoms on the corners and edges has to be taken into account.

Metal activation thus consists in the creation of a high density of reactive dislocations on a surface that is as large as possible and not passivated. Extrapolation of this definition could lead to the assumption that a metal reaches its maximum reactivity when monatomically distributed. This sup-

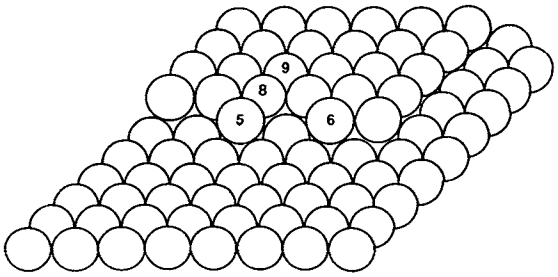

Fig. 1. Schematic representation of a metal surface. The number of nearest neighbors of the atoms at corners, edges, and on terraces is given.

position, however, has been disproved at least for oxidative insertions with magnesium and calcium (Table 1). Both experimental as well as theoretical studies indicate that clusters are more reactive than single atoms, and that larger clusters are more reactive than smaller ones;[7] the decisive factor is possibly the lower ionization potential. Furthermore, more favorable geometries of the transition state are possible for the insertion of a cluster into a C–X bond.[7]

Table 1. Overview of the reactivity of magnesium and calcium atoms and clusters towards methyl halides CH_3X under matrix isolation conditions (according to Klabunde et al. [7b]). (+): oxidative insertion; (–): inert; (?): data obtained are not conclusive.

CH_3X	Ca	Ca_2	Ca_x	Mg	Mg_2	Mg_3	Mg_4	Mg_x
CH_3I	+	+	+	–	+	+	+	+
CH_3Br	–	+	+	–	+	+	?	+
CH_3Cl	–	+	+	–	–	?	–	–
CH_3F	+	+	+	–	–	–	+	+

This set target in physical chemistry, to search for the maximum reactivity of a metal in the area of larger clusters, underscores the insufficiency of the classical repertoire of metal activation. Preparative chemists' current "tricks" for enforcing the initiation of metal-induced reactions are confined to the modification or post-treatment of commercial metal samples by chemical or physical means (e.g., additives such as iodine, 1,2-dibromoethane, CCl_4 etc.; amalgamation, metal/metal coupling, removal of oxide layers by washing with mineral acids; filing, grinding, milling).[5] The production of the finest particles or, in the ideal case, even of large clusters is far from being achieved in this way. High activation results only upon severe attack on the texture of the solid. However, the preparative effort inevitably associated with achieving this goal must in each case be weighed against the increase in efficiency of the metal-induced reaction. Some of the activation methods outlined in the following sections differ considerably with respect to such a preparative "balance" whereby high efficiency does not necessarily exclude user convenience.

2. Methods for the Preparation of Highly Reactive Metals

2.1. Rieke Methods

Rieke et al. made a first breakthrough in the area of high activation of metals in the early seventies with the in situ preparation of highly reactive metal powders by reduction of metal salts by using alkali metals in an inert solvent (Scheme 1).[8, 9] The boiling point of the solvent must exceed

$$MX_n + nK \xrightarrow{\Delta} M^* + nKX$$

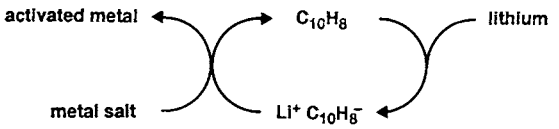
Scheme 1. Preparation of Rieke metals M*.

the melting point of the alkali metal (e.g. potassium/THF, sodium/dimethoxyethane (DME) or xylene). Ethereal solvents are generally preferred because of the better solubility of the metal salts. However, in the preparation of aluminum, chromium, indium, or uranium, cleavage of ether was observed under these conditions,[9] so that these metals can only be obtained from the corresponding halides in hydrocarbons (xylene is mostly used because of its higher boiling point).[9] Apart from these few exceptions the Rieke process is nevertheless a universally applicable method that has proven very useful in a series of mechanistically different metal-induced reactions and has often been reviewed.[9] Consequently, only recent developments and improvements of the original procedure will be outlined in this article.

A considerable disadvantage of this method is that the metal salts and the reducing agent must be heated together until the alkali metal melts, but the ensuing exothermic reduction might well be difficult to control. Particular attention must be paid to this when the reaction is performed on a large scale.[9c, d] Moreover, with fine metal powders there is the danger that their reactivity is strongly impaired by agglomeration, sintering, and recrystallization of the particles, particularly at higher temperatures and with long reduction times. Hence, no effort has been spared to make the original Rieke method better controllable, and to avoid subsequent loss of activity by use of more suitable reducing agents.

Alois Fürstner, born 1962 in Bruck/Mur, Austria, studied chemistry at the Technische Universität Graz, where he gained his doctorate under the supervision of Prof. Hans Weidmann. After postdoctoral studies with Prof. W. Oppolzer's research group at the Université de Genève, Switzerland (1990–1991), he returned to Graz to complete his habilitation in Organic Chemistry (1992). He was awarded the Angewandte Chemie *prize in 1992 for the best presentation at the Chemiedozententagung in Heidelberg. His research interests include carbanion chemistry, homogeneous catalysis, and natural product synthesis.*

Both these goals can be achieved by the use of alkali metal/naphthalene ($M^+C_{10}H_8^-$) or alkali metal/biphenyl as a substitute for metallic potassium. Two kinds of applications must be distinguished: the addition of merely catalytic amounts of naphthalene (5–10 mol%) to a mixture of lithium and the metal salt in THF already suffices to effect its reduction.[9, 10] As shown in Scheme 2 the arene functions as



Scheme 2. Modified Rieke method. Naphthalene ($C_{10}H_8$) as single-electron transfer agent.

an electron-transfer agent. Since one is working at room temperature this modified Rieke method is safe in its application and mostly affords more active metal samples than the original method. Disadvantageous are the usual, very long reduction times. However, stoichiometric amounts of $M^+C_{10}H_8^-$ can also be used as reducing agent,[9, 11] and almost any salt can be rapidly reduced thereby to highly reactive metal suspensions even at low temperatures. But the complete removal of large amounts of naphthalene before or after the desired metal-induced reaction can be tedious.

The use of complex metal hydrides as reducing agents for metal salts also represents a variant of the Rieke method. Besides $LiAlH_4$, which has been recommended for the preparation of activated tin[12] and titanium,[13] tetraalkylammonium (or alkali) hydrotriorganoborates in particular offer preparative advantages.[14] With their help transition metal colloids with a narrow particle size range could be obtained which are stabilized by interactions of surface charges on the metal particles with the large tetraalkylammonium ions or the boron complexes occurring in the reduction. Such colloids can also be fixed on inert carriers, thus offering the prospect of promising applications in heterogeneous catalysis (see Section 4.7).[14] A series of other reducing agents such as sodium/potassium alloy[15] or potassium–crown ether mixtures[16] have also been used.

Furthermore, the activity of the Rieke metals obtained can be influenced by the type of metal salt to be reduced as well as by additives. This effect is particularly evident in the preparation of Rieke copper, which serves for the direct preparation of functionalized organocopper compounds (see Section 4.3). Rieke-Cu, obtained by reaction of CuI and potassium in the presence of naphthalene (10 mol%), is especially susceptible to sintering.[15] Only the reduction of copper salts such as $CuCN \cdot 2LiX$ (X = Cl, Br),[17] $CuI \cdot PR_3$ (R = Et, Bu, Cy, Ph)[18] and lithium 2-thienylcyanocuprate,[19] which are readily soluble in THF, with stoichiometric amounts of $Li^+C_{10}H_8^-$ affords adequately active metal samples for achieving direct oxidative insertion into carbon–halogen bonds in good yields. The lower the temperature in the reduction of $CuCN \cdot 2LiX$, the more active the metal suspension obtained.[17]

Also the use of additives (Table 2)[20] or of ultrasound during the reduction process[21] can increase the activity of Rieke metals significantly. To simplify workup of the reaction mixture the use of polymer-bound Rieke metals has also been reported.[22] The need for tailor-made polymers, however, limits the practical use of this approach.

Table 2. Effect of diverse additives on the reactivity of Rieke magnesium in the reaction with *p*-chlorotoluene at 0 °C [20].

Additive	Mg/Additive	% of Grignard reagent after 10 min	120 min
–	–	0	0
KI	10	17	85
KI	4	29	88
KI	2	46	91

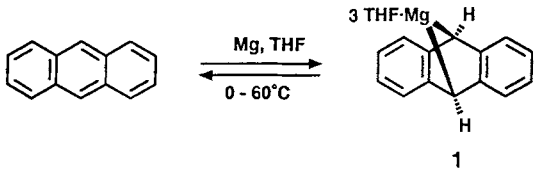
KI	0.5	45	93
LiI	2	0	11
NaI	2	6	70
CsI	2	12	89
I_2	20	10	64

2.2. Magnesium–Anthracene Methods

Upon reaction with anthracene derivatives in THF, metallic magnesium readily forms complexes of type **1** (Scheme 3), the spectroscopic and chemical properties of which have been investigated in detail.[23] The X-ray structure analysis



1

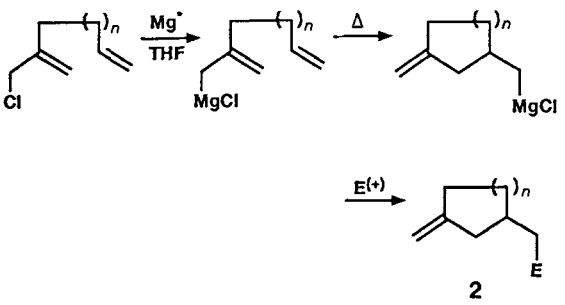
Scheme 3. Preparation of the magnesium-anthracene complex **1**.

of a representative of this series shows pentacoordinated magnesium with unusually long bonds to the carbon atoms (2.32 Å) and a significantly bent dihydroanthracene ligand.[24] In view of these structural features the low thermal stability of the metallacycle is evident, which is further reduced by substituents, especially in the 9- and/or 10-position of the anthracene.[25] The unusual structure of this complex is paralleled by its widely diverse chemical behavior. Complex **1** reacts with many electrophiles (e.g. CO_2, alkyl halides, ketones, oxetanes, dichlorosilanes and dichlorostannanes, and Cp_2TiCl_2) as a (di)nucleophile, but acts as an electron donor for aryl halides and as a source of "soluble" magnesium for allyl and benzyl halides, thus enabling these substrates to be converted efficiently into the corresponding Grignard reagents.[26] Even toluene is suitable as solvent. Further, in contrast to Rieke magnesium, **1** permits the metalation of a polystyrene bearing *p*-(chloromethyl) groups.[27] Propargyl chloride is smoothly converted into allenylmagnesium chloride by **1**, which is quite remarkable given the considerable difficulties with which the preparation of this reagent was formerly associated.[26] This "magnesium source" can also be polymerically bound to a polystyrene functionalized with anthracene residues.[28]

As already mentioned, complex **1** is thermally unstable and affords highly reactive pyrophoric magnesium powders with extraordinarily high specific surface areas (up to 110 $m^2 g^{-1}$) and correspondingly high reactivity upon heat-

ing in inert solvents or upon heating neat under vacuum.[23, 29] These powders likewise give Grignard reagents in very good yields upon reaction with a series of different halohydrocarbons in THF, toluene, and in some cases even in heptane. Magnesium powder obtained in the thermal decomposition of activated MgH_2 has proven to be only slightly less reactive.[29]

In any case the activity of such magnesium samples is far superior to that of commercially available metal turnings and compares favorably with that of Rieke magnesium or of magnesium that has been activated by metal vapor techniques (cf. Section 2.3). This has been clearly demonstrated for example by a comparative study of a magnesium–ene reaction (Scheme 4, Table 3).[30] Since the preparative outlay



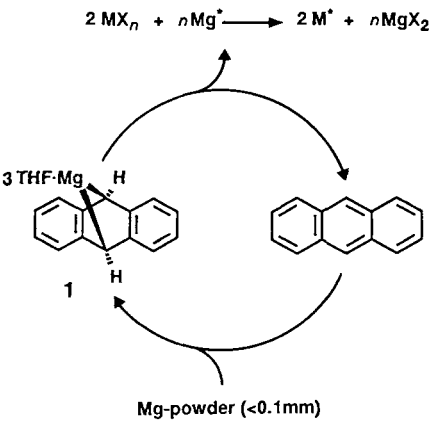
Scheme 4. Magnesium–ene reaction (see Table 3).

Table 3. Comparison of the activity of various magnesium samples in the formation of compound **2** according to Scheme 4 [30].

n	E	Vapor-activated Mg[%]	Anthracene–Mg[%]	Rieke Mg[%]
1	OH	55	56	55
1	CONHPh	71	67	64
2	OH	57	51	48
2	CONHPh	72	69	64

for each of the individual activation methods differs considerably yet the results achieved are comparable, their respective "economy" can be estimated.

In the Rieke process for the reduction of salts, magnesium is suitable only in exceptional cases as a substitute for potassium. However, the ready formation of the anthracene com-



Scheme 5. Preparation of activated metals with the help of magnesium–anthracene complex **1**.

plex **1** can also be exploited for this purpose. As shown in Scheme 5 not only activated metals can be generated by a catalytic cycle, but, in the presence of suitable ligands, also complexes with a zero- or low-valent central atom such as $[M(cod)_2]$ (M = Ni, Pt), $[Cp_2M]$ (M = V, Co, Fe), and $[Pd(PPh_3)_4]$, [Mo(butadiene)$_3$].[31]

2.3. Metal Vapor–Solvent Cocondensation Techniques

Metals are largely monoatomic after vaporization.[32] Although partial dimerizations and oligomerizations of the atoms to clusters have already been observed upon precipitation of such vapors in noble-gas matrices,[32] unprecedentedly high degrees of metal distribution as are required for studying the physics of highly disperse systems can be obtained reproducibly in this way. As has already been mentioned in Section 1.1 spectroscopic studies on matrices doped with alkyl halides have provided insights into the limits of metal activity.[7, 33]

Vaporization can also be used for preparative purposes as a method for the activation of metals.[34–37] It is generally achieved by resistance heating of an appropriate metal block in a high vacuum; in special cases, however, (Table 4) evaporation by electron bombardment or lasers must be resorted to, which increases the cost of equipment tremendously.[36]

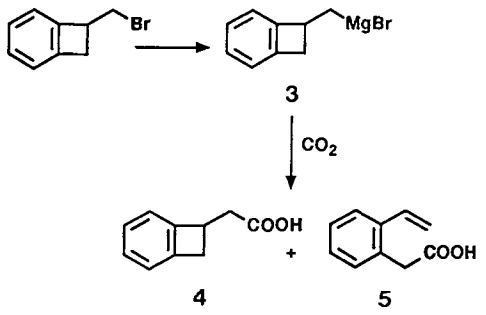
Table 4. Vaporization temperature ranges *T* of metals in high vacuum (according to P. L. Timms [36]).

T[°C]	Metal
<1000	Li, Na, K, Rb, Mg, Ca, Zn, Sr, Cd, Sm, Eu
1000–1400	Be, Mn, Cu, Ag, Au, Sn, Pr, Nd, Gd, Tb, Dy, Ho, Er, Tm
1400–1700	Cr, Fe, Co, Ni, Pd, La, Ce, Lu
1700–2000	Ti, V, U
2000–2500	Zr, Ru, Rh, Pt
>2500	Nb, Mo, Hf, Ta, W, Re, Os, Ir

The vapor generated is condensed at low temperatures into a suitable solvent and then the desired reaction is carried out with the resulting suspension. A relatively simple apparatus for this purpose related to a rotary evaporator has been described in detail.[36, 37a]

One of the advantages of this method is that, in contrast to most other methods, metal suspensions completely free of halogens and arenes are obtained. With the proper apparatus even larger amounts of metal can easily be activated.

One of the main areas of employment of the metal-vapor activation technique was in the preparation of metal complexes form "naked" transition metal atoms.[32, 34–36] Also in the field of Grignard reagents progress could be made, inter alia, in the synthesis of allylmagnesium halides and labile reagents, for example cyclopropylmethyl- and benzocyclobutenylmethylmagnesium bromides **3** which undergo ring-opening under conventional conditions (Scheme 6, Table 5). As the previously mentioned comparative study has shown, the magnesium activated by such vaporization is however neither superior to Rieke magnesium nor to magnesium–anthracene (Table 3).[30] Linked with the undoubtedly greater cost of the equipment, this could be responsible for the few recent applications of this technique in organic synthesis.[35d, f]



Scheme 6. Labile Grignard compounds. Preparation and reaction of benzocyclobutenylmagnesium bromide **3** (see Table 5).

Table 5. Comparison of the efficiency of magnesium activated by vaporization with that of commerically available metal for the synthesis of benzocyclobutenylacetic acid **4** (Mg* = magnesium activated by vaporization) [37a].

Mg sample	Solvent	T[°C]	Yield [%]	**4**:**5**
Mg turnings	THF	+30	61	0:100
Mg*	THF	−75	82	45:55
Mg*	Et_2O	−50	80	100:0

2.4. Metal–Graphite Reagents

Many factors speak in favor of immobilization of reagents on inert carriers:[2] the simple workup of the reaction mixture by filtration is manifested in high yields; the greater stability and safer manipulation of carrier-bound materials make the preparative work easier. In addition, there is the concentration effect by local enrichment of the reagent, the lowering of the activation energy observed in some cases, and the sometimes remarkable concentration of the dissolved reaction partner at the phase boundary by interactions with polar or charged units on the surface.[2] These advantages are already exploited in many instances in industrial production, where the trend to heterogenization of homogenous reactions continues without diminishing.

The choice of carrier material is of considerable importance. It should be inexpensive, readily available, and essentially inert, although synergic effects with the bound agent are possible. Of the materials in question graphite assumes a special position, since it not only can serve as simple carrier but is also capable of intercalating atoms or molecules between its layers, which are held together only by weak van der Waals forces.[38] The intercalation compounds thus obtained are characterized as "laminar", "covalent", or "residual" compounds according to the kind of interaction between host and guest. All applications of graphite are determined by an interplay of interlaminar events and reactions at the surface (see Section 3).[38]

Although metal–graphite reagents have been known for some decades, they have nevertheless long been underestimated as regards their preparative potential. For example, potassium–graphite (C_8K)[39] first described as long ago as 1926, was still classed in the late seventies as being too aggressive because of its extraordinarily high reactivity;[40] extensive application in organic synthesis was thus excluded. Nevertheless, this bronze-colored substance (Fig. 2) has a number of interesting features: 1) C_8K is easily prepared in a few minutes by stirring a dry mixture of potassium and graphite at 150 °C under argon (Scheme 7). 2) C_8K has an extremely high (compared to potassium even increased) reducing power. 3) Since the 4s electrons of the potassium are delocalized in the conduction band of the graphite, C_8K can be regarded as a polymeric analogue of alkali metal/naphthalene ($M^+C_{10}H_8^-$).[38,40] 4) Through its characteristic coloration both the formation as well as the conversion of C_8K are self-indicative. 5) The undoubtedly most serious yet readily controllable disadvantage of C_8K is its pyrophoric character.

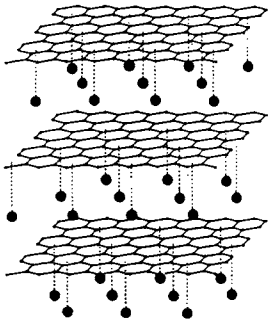


Fig. 2. Structure of C_8K.

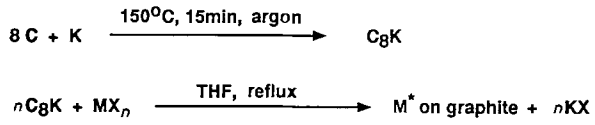


Scheme 7. Preparation of C_8K and metal–graphite reagents.

Apart from its use as a reagent in organic (organometallic) reactions[38] its properties suggest the use of C_8K as a reducing agent for various metal salts.[38,41] It thus provides an activation method which in expense and performance is similar to the Rieke process, which it may clearly surpass, however, with respect to reactivity. Since the reducing agent concomitantly affords the carrier material the metals obtained are protected against subsequent sintering from the moment of their formation. Instead of the limited surface of the molten potassium in the Rieke method the reduction reaction with C_8K can take place at any site on the extended graphite surface, resulting in smaller particle sizes of the metal powder formed (cf. Section 3). C_8K thus combines the favorable reducing properties of alkali metal/naphthalene with the advantage of a conceivably simple workup by filtration.

Metal–graphite combinations prepared as in Scheme 7 first received attention as potential reagents in organic and organometallic synthesis in the seventies, but were mostly tested on simple achiral substrates.[38] Their extraordinary potential for the chemo-, regio-, and stereoselective derivatization of highly functionalized and enantiomerically pure products was fully exploited only recently. An overview of this development with emphasis on our own work in this field is given in Sections 4.2 and 4.4–4.6 of this article.

In some cases a noteworthy chemical enhancement of activation in addition to the activation as a result of the extremely fine distribution of the particles formed on graphite is achieved by the *coreduction* of a mixture of two salts with C_8K. Such synergistic effects have been observed for the metal couples Zn/Ag on graphite ($ZnCl_2$:AgOAc = 10:1)[42]

and Ni/Cu on graphite ($NiBr_2$:$CuCl_2$ = 8:1).[43] However, the reasons for these effects are entirely different for each of the two metal couples, as shown by electron microscopic investigations: In the case of the Ni/Cu couple the reduction of $NiBr_2$ and $CuCl_2$ by C_8K is incomplete (with formation of Ni(0) and CuBr) and the better activity observed in the dimerization of benzyl halides upon using Ni/Cu–graphite instead of Ni–graphite is therefore associated with the catalytic influence of monovalent copper on such Wurtz-type couplings.[44] In the case of Zn/Ag–graphite, on the other hand, which forms an intimate conglomerate of very fine zinc and silver particles on graphite, the increase in activity achieved is not due to alloy- but rather to half-element formation. The interface between the two metals proved to be the preferred site for attack by halogen compounds.[45]

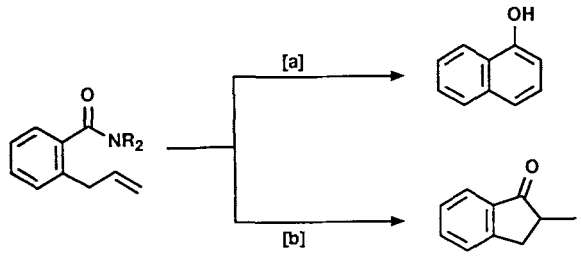
Finally, it should be noted that graphite powder accelerates decomposition of the magnesium–anthracene complex **1**, whereby the liberated metal precipitates on the graphite surface. Again no signs of intercalation have been found in this preparation of a magnesium–graphite combination.[46]

2.5. Metal Activation by Ultrasound

In solutions ultrasound causes "cavitation", that is, the formation, growth, and final collapse of very fine bubbles of gas.[47] In multiphase systems this produces shockwaves which increase mass transfer and can lead to erosion at the surface of a solid. In addition, the strong turbulence gives rise to collisions of the particles distributed in the solvent, which can lead to considerable morphological changes, either by disintegration of the particles or even by their fusing together due to local overheating upon collision.[48] Such collisions are also said to be responsible for the degradation or even the complete destruction of surface oxide layers. In such cases sonication of the metal prior to its use has comparable activation effect as sonication of the whole reaction mixture. This was demonstrated experimentally in Reformatsky reactions, copper-induced Ullmann couplings, and in the preparation of activated nickel powder.[47, 48]

Besides these examples, in which ultrasound essentially exercises a mechanical effect on the solid,[48] reactions whose mechanism is fundamentally changed upon sonication are also known in the literature. Thus, for example, in lithium-induced Barbier reactions the profound influence of ultrasound on the metal surface, which consists in the perpetual creation of new initiation sites for the reaction, has been clearly demonstrated by electron microscopy. Yet this effect does not suffice for an exclusive explanation of all experimental data.[49] Rather, it must be assumed that ultrasound strongly accelerates single-electron transfer (SET) from the metal to the substrate.[50] It was therefore important to seek cases in which a SET mechanism can be increased in such a way by sonication that it overcomes a dominating ionic pathway under thermal reaction conditions. The lithium-induced cyclization of *ortho*-allylbenzamides is one of several examples of such a "sonochemical switching"[50] between competing mechanisms (Scheme 8).

A practical advantage of metal activation by ultrasound lies in the fact that in many cases the conventional ultrasonic purification baths used in the laboratory already suffice to



Scheme 8. "Sonochemical switching" in the lithium-induced cyclization of *o*-allylbenzamides: [a] Li, reflux, ionic reaction; [b] Li, ultrasound, radical reaction.

achieve a satisfactory effect. This, however, in no way approaches the performance of the most efficient high-activation methods presented above, but can be further increased by applying higher energetic ultrasound (immersion horns). Also the simple and harmless application of ultrasound on a large-scale is sure to guarantee further use and development of this technique in the future.

2.6. Special Methods

Many metals (e.g. magnesium) are mechanically less stable. Thus, a commonly used magnetic stirring rod suffices to grind down such metals to a finely divided and, in the case of magnesium, blackish-gray powder within about 15 hours under inert gas. This powder is excellently suited for the preparation of Grignard compounds from benzyl, allyl, and propargyl halides.[51]

Attempts were made to exploit the advantages of carrier-bound systems with finely dispersed potassium on aluminum oxide[52] and sodium on active charcoal[53] in the reductive decyanation of alkyl nitriles and the alkylation of ketones. Also the generation of colloidal potassium in toluene using ultrasound has been described.[54]

3. The Morphology of Highly Reactive Metals

Although a detailed knowledge of the morphology of activated metals is undoubtedly a prerequisite for an understanding of their reactivity, the information available so far is in many respects inadequate. Thus, the structural investigations on Rieke metals were almost exclusively carried out with samples that had been filtered and dried before the analyses, without the effect of such treatment on the results obtained being considered more closely.[9] As the electron microscopic and X-ray diffraction data measured on these powders show, in the case of Rieke metals the samples were microcrystalline or X-ray amorphous solids having particle sizes in the micrometer or submicrometer range which may aggregate in a spongelike manner.[9] Also BET analyses indicate a favorable mass/surface area ratio. In the case of Rieke cobalt considerable sintering upon thermal loading of the sample has been demonstrated.[55] Exact correlations between genesis and morphology of the metal powders, however, have yet to be carried out.

A knowledge of the particle size distribution of an activated metal is in itself insufficient for an understanding of the properties of the metal. Since one knows from elemental

analyses about the complex composition of highly reactive metal powders, it follows that investigation of the surface properties is equally essential.[55, 56] Thus, in the case of Rieke nickel (NiI_2, lithium, THF, ultrasound, 30 °C, 10–30 min) carbonyl ligands were found to be tightly bound to the Ni atoms of the metal surface. These ligands originate from cleavage of ether during the preparation of the metal, as control experiments with toluene as solvent have confirmed, and they are essential for the catalytic activity of the nickel sample.[57]

The interrelation between preparation of activated magnesium and its preparative properties is well documented for the anthracene method outlined in Section 2.2. Besides publishing detailed elemental analyses Bogdanović et al.[29] reported a beautiful correlation between increasing X-ray amorphous character and the increasing specific surface area of differently prepared magnesium powders with a wealth of preparative results in the field of Grignard compound formation and the hydrogenation of Mg to MgH_2. Precise analyses are also available for metal samples prepared by the reduction of salts with hydrotriorganoborates.[14] Investigations of the mechanical effect of ultrasound on diverse metals (Li, Zn, Cu, Ni) by scanning electron microscopy[47–49] were already referred to in Section 2.5.

The misconceptions prevailing in the older literature about the morphology of metal–graphite combinations[58] have recently been cleared up. The combined use of electron microscopic (TEM = transmission electron microscopy, HREM = high-resolution electron microscopy, EDX = energy dispersive X-ray spectrometry. EELS = electron energy loss spectroscopy, SAED = selected area electron diffraction) and X-ray diffraction techniques has shown beyond doubt that the reagents prepared according to Scheme 7 are extremely finely divided metals *on* graphite as inert carrier (average particle sizes: Zn 2–10 nm; Ni 2–7 nm; Pd 2–5 nm; Ti 1–2 nm; Pt 3–5 nm etc).[44, 45, 59–61] In none of the cases investigated was there any indication of the postulated intercalation of the metal atoms between the graphite layers.[58] Since these compounds do not have a well-defined structure in the sense of the laminar potassium–graphite C_8K, they are referred to as metal–graphite "combinations". In these structural investigations the expected but up to now neglected effect of the sample preparation was apparent for the first time, since such finely divided metals are extremely readily oxidized and aggregated on exposure to air.[59] In the case of nickel it emerged that this oxidation takes place only superficially on larger particles with formation of a 2–3 nm thick $Ni(OH)_2$ layer, whose composition was determined by photoelectron spectroscopy (XPS) and EELS.[44] This finding explains why the catalytic activity of nickel–graphite as hydrogenation catalyst clearly diminishes upon washing with H_2O but is not completely removed (see Section 4.7).

According to these structural investigations, the method for activating metals by reduction of their salts with potassium–graphite laminate C_8K affords particles a few nanometers in diameter with little outlay, which approaches the optimum regarding metal reactivity at reasonable preparative expense. Since the 4s electrons of the potassium atoms, the actual reducing agent, are delocalized in the conduction band of the graphite and are available on its whole surface, the metal

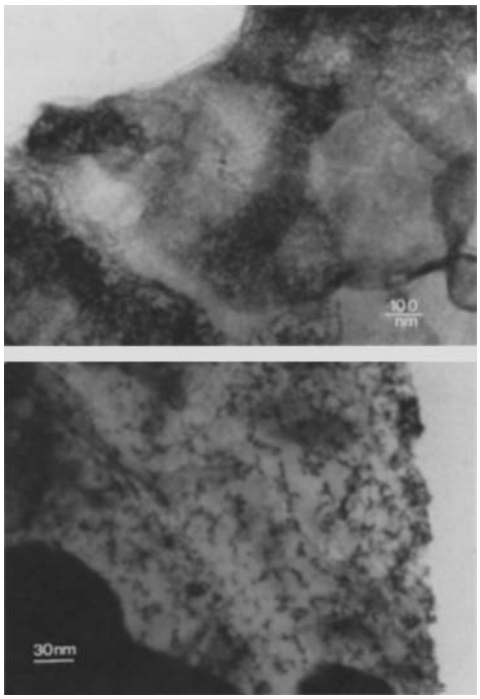


Fig. 3. Top: Transmission electron microscopic (TEM) images of zinc on graphite. Bottom: TEM image of palladium on graphite. Especially in the top picture the uniform coating of the graphite surface with fine particles of metal is evident.

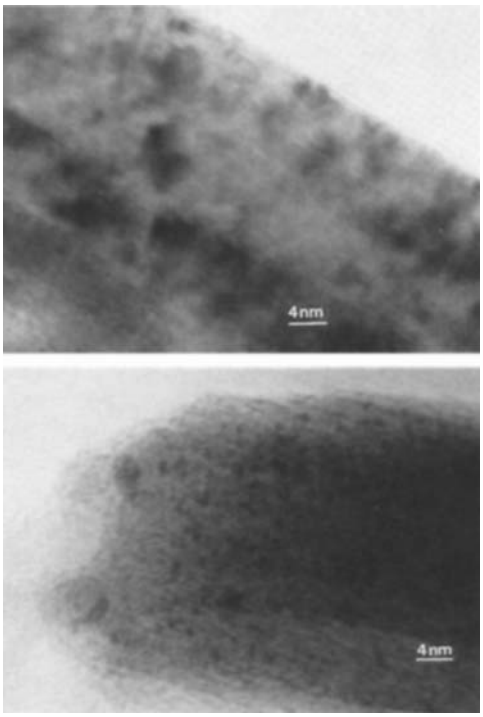

Fig. 4. Top: High-resolution electron microscopic (HREM) image of synthetic graphite (Lonza KS-5-44) shows a regular ordering of graphite layers with constant interlamellar distances. Bottom: HREM image of palladium–graphite. The severe dislocations of the graphite lattice and irregular interplanar distances are a result of the potassium intercalation/deintercalation during the preparation of this surface compound with promising catalytic properties (see Section 4.7).

coating of the graphite platelets should be uniform.[44, 59, 60] As shown in Figure 3 this is largely the case upon using natural graphite. With synthetic graphite, on the other hand,

the metal deposition, for example of palladium (Fig. 3, bottom), preferably takes place along the defects of a clearly imperfect surface.[45]

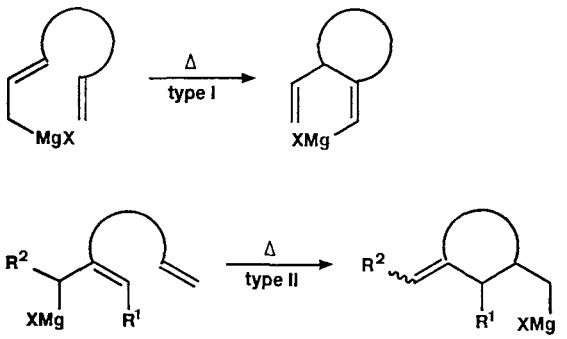
In the preparation of metal–graphite reagents outlined in Scheme 7 the graphite remains chemically unchanged, whereas its lattice structure suffers considerable damage, as is evident upon comparison of the HREM images of synthetic graphite before and after preparation of palladium–graphite (Fig. 4).[45]

4. Recent Applications of Highly Reactive Metals in Synthetic Chemistry

4.1. Recent Developments in the Use of Alkaline Earth Metals in Organic Synthesis

The skill and intuition of the preparative chemist have long been materially decisive for the success or failure of Grignard reactions. Not only the synthetic potential of this classical reaction but also its reliability has profited considerably from the use of highly reactive magnesium. As the examples presented in the previous sections of this article have shown, activated magnesium can be used to convert substrates such as benzyl, allyl, *tert*-alkyl, cycloalkyl, and long-chain alkyl halides as well as aryl chlorides, and in some cases even fluorohydrocarbons, all previously considered to be problematic, into Grignard reagents in high yields[5, 9, 10, 20, 26, 27, 29, 37, 62] The preparation of highly reactive metals has also contributed appreciably to the study of the elementary steps in the oxidative insertion of metal atoms into carbon–halogen bonds and in the synthesis of chiral organomagnesium halides from enantiomerically pure alkyl halides.[63, 4g]

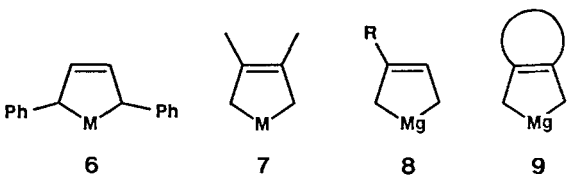
The possibilities of the applications to more complex reactions increase with this increased efficiency. The intramolecular magnesium-ene reactions which have been systematically investigated by Oppolzer (Scheme 9) represent an obvious example of such sophistication. Their high preparative value



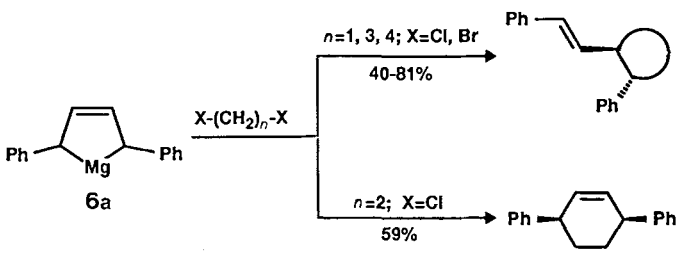
Scheme 9. The two possible types of magnesium–ene reactions.

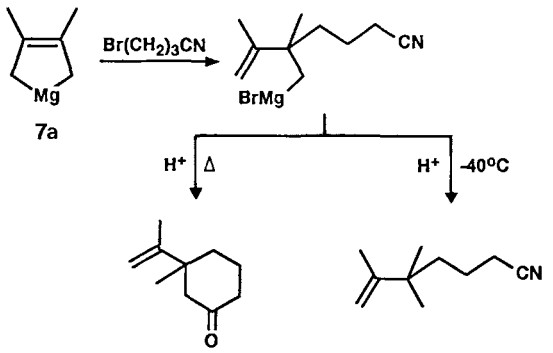
has already clearly been proven in numerous syntheses of natural products.[64] A prerequisite for their success is a reliable entry to allylmagnesium halides which react thermally with suitably positioned C=C bonds in the sense of an Alder–ene reaction with transfer of the metal. Since allyl halides tend to undergo Wurtz coupling on reaction with magnesium turnings under conventional conditions, the use of high-activation methods (Rieke process, Mg–anthracene method, metal vapor–solvent cocondensation techniques, see Table 3) forms a conditio sine qua non for the success of this process. Where the compatibility of the Grignard reagents with the functional groups in the substrate did not suffice, stoichiometric zinc-ene reactions and especially transition metal catalyzed ene processes further extended the synthetic possibilities.[64]

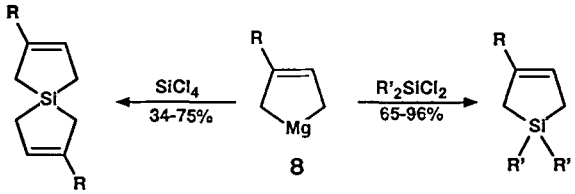
That metallic magnesium is able to react with conjugated alkadienes has been known for some time, and this branch of organomagnesium chemistry has recently also received great impetus through the use of activated metals. For example, reaction of Rieke magnesium with substituted butadienes in THF at room temperature leads to excellent yields of metallacycles of type **6**–**9** (Scheme 10, M = Mg), which function as dinucleophiles (Scheme 11).[65] They can be converted with



Scheme 10. Metallacyclopentenes from alkadienes and Rieke metals. **6a**, **7a**: M = Mg; **6b**, **7b**: M = Ca; **8**: R = Me, Ph, $CH_2CH_2HC{=}CMe$.







Scheme 11. Reactions of magnesiacyclopent-3-ene derivatives with electrophiles. Selected examples.

α,ω-dihaloalkanes into carbocycles, whereby the substituents on the metallacycle and the chain length of the electrophile determine the regiochemistry of the ring-closure.[65b,c] The conversion with ω-haloalkyl(aryl) nitriles, after aqueous workup of the reaction mixture, affords cyclanones as reaction products, whose formation is explained in terms of alkylation of the magnesiacyclopentene and subsequent intramolecular attack of the resulting Grignard compound at the cyano group (Scheme 11).[65b] When 1,2-dimethylenecycloalkanes are used as dienes, spiroannelated ring systems are formed in an analogous way via metallacycle **9**.[65d] With compound **7** the consecutive conversion with two different electrophiles is also possible, whereas all magnesiacycles react with dichlorosilane or $SiCl_4$ as electrophiles to give (spiro)silacyclopent-3-ene derivatives (Scheme 11).[65a,b]

Rieke calcium, which is prepared by reduction of CaX_2 (X = Br, I) with lithium/biphenyl, likewise reacts with butadiene derivatives with formation of the hitherto unknown calcium metallacycles **6b** and **7b** (M = Ca).[66] Their behavior towards electrophiles resembles qualitatively that of the magnesium analogues, but surpasses the latter in reactivity. Further, the fact that Rieke calcium reacts smoothly with all kinds of halohydrocarbons to give organocalcium reagents seems remarkable.[66] The oxidative insertion already takes place at low temperatures (alkyl halides at −78 °C, aryl halides at −30 to −20 °C) and even problematic substrates such as 1-bromoadamantane, halogenated polystyrene, and even aryl fluorides react without difficulty, the latter, however, first at room temperature. The organocalcium compounds thus formed combine good thermal stability with high reactivity towards carbonyl compounds and can be transmetalated in the usual way with copper(I) salts to organocalcium cuprates (Table 6).[66,67] These promising results are supplemented by H. Yamamoto's observation that the reaction of allyl chlorides with carbonyl compounds induced by highly reactive barium is distinguished by excellent regioselectivity and practically complete retention of the stereochemistry of the allyl double bond (Scheme 12).[68] In view of the hitherto insignificance of the higher alkaline earth metals in organic chemistry, the Grignard reaction may possibly arouse an unexpected competition from this corner of the periodic table.

Table 6. Reactivity of organocalcium compounds [66]

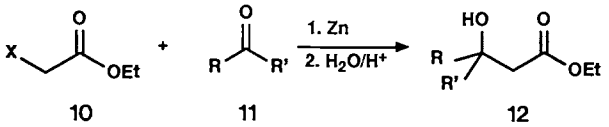
4.2. Actualization of Classical Synthetic Methods Exemplified by the Reformatsky Reaction

The Reformatsky reaction (Scheme 13) consists in the oxidative insertion of a metal into a carbon–halogen bond activated by neighboring carbonyl groups and the subsequent reaction of the resulting enolates with electrophiles. The reaction was traditionally confined to α-haloesters as donors, zinc as metal, and carbonyl compounds as acceptors, but has seen considerable extension in recent years.[69] The contribution that the high activation of metals has made to the improvement of this classical and, to many, conventional synthesis can be gleaned from the model experiments summarized in Table 7. Thus, on using highly reactive zinc instead of the usual procedure (Zn dust, etheral solvent or aromatic hydrocarbons, reflux), a lowering of the temperature by up to 160 °C (!) is possible with concomitant increase in the yields, increase in the reaction rate, and complete suppression of side reactions.



Scheme 13. Principle of the Reformatsky reaction.

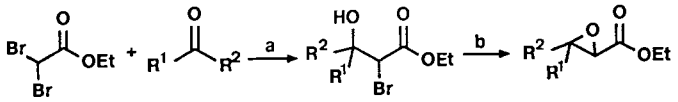
[a] Not determined. [b] 6–8 h.

Highly reactive zinc has also been used in more complex applications. Thus, with the drastic lowering of the reaction temperature there is a considerable gain in stereoselectivity upon reaction of the resulting zinc enolates prepared in situ with diastereotopic carbonyl compounds. This became apparent in the Zn/Ag–graphite-induced stereoselective branching of uloses[42,70] and chain-extension of aldonolactones[71] as well as in an elegant total synthesis of *N*-acetylneuraminic

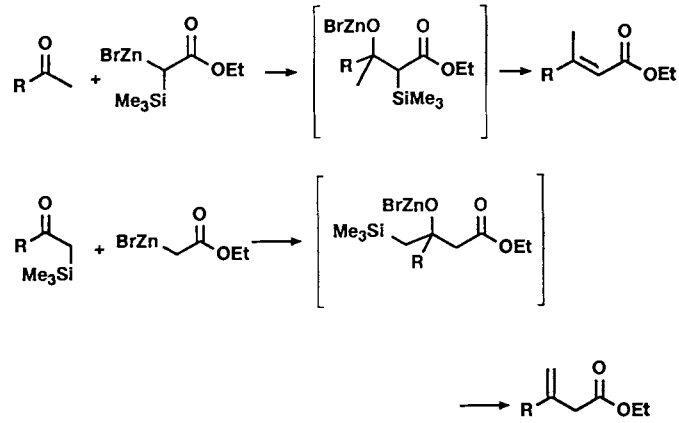
acid based on a Reformatsky-type reaction of bromomethyl acrylate with an acyclic sugar aldehyde.[72]

Also the use of other haloalkanoates has contributed to the progress made in this field. Thus, for example, reaction of α-dihaloesters with Zn/Ag–graphite and carbonyl compounds at low temperatures leads to glycidates (Scheme 14),[73]



Scheme 14. Reformatsky-type Darzen's glycidate synthesis: [a] Zn/Ag–graphite, THF, −78 °C; [b] base.

whereas α-bromo-α-trimethylsilyl acetate under the same conditions affords 2-alkenoates regioselectively via a Peterson elimination spontaneously following the Reformatsky step.[73] Complementary to this reaction, in the conversion of silylmethyl ketones with zinc ester enolates 3-alkenoates can be obtained by the same sequence from Reformatsky reaction and subsequent Peterson olefination (Scheme 15).[74] The use of acylsilanes as a novel class of electrophiles has also been described.[74]

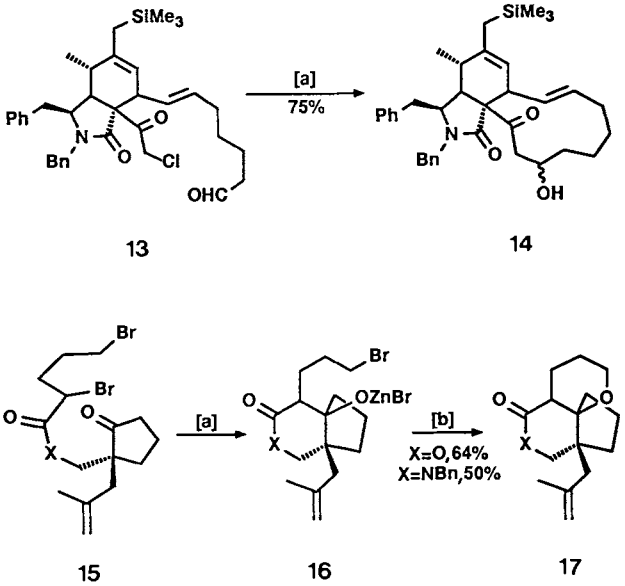


Scheme 15. Complementary syntheses of 2- and 3-alkenoates by Reformatsky–Peterson sequences.

Owing to the high efficiency of Reformatsky reactions with highly reactive zinc, they are also potentially useful as key steps in natural product syntheses. Illustrative examples in this context are the intramolecular reactions based on the use of Rieke zinc which have led to the formation of the 11-membered ring of cytochalasan (**13** → **14**) (Scheme 16)[75] and to the synthesis of the tricyclic skeletal framework of daphnilactone.[76] The latter synthesis is based on an etherification of the zinc aldolate (**16** → **17**) with the terminal bromide following the Reformatsky reaction with 2,5-dibromopentanoate or pentanamide **15**. Further developments in this field are summarized in ref. [69].

4.3. Functionalized Carbanions

The preparation of carbanions by oxidative insertion of metals into carbon–halogen bonds has so far been limited to

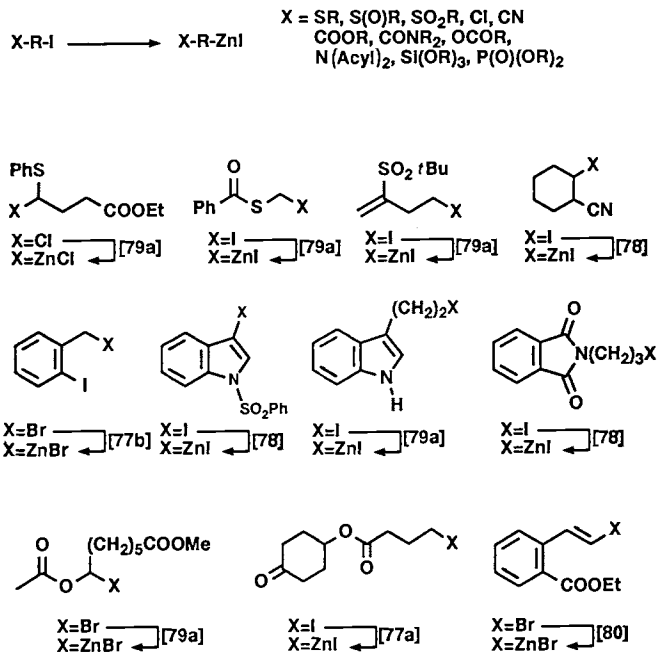


Scheme 16. Reformatsky reactions in natural product synthesis [a] Rieke Zn; [b] Addition of hexamethylphosphonic triamide.

a few elements, of which lithium and magnesium have played by far the most important role. Because of the relatively polar bond character the C-nucleophiles that are formed are, as a rule, very reactive and rarely tolerate electrophilic groups on themselves. However, the ability to undergo oxidative insertion into polarized bonds is a priori in no way confined to the electropositive metals, and in an appropriately activated form a wealth of main and sub-group elements are capable of such insertions.[3, 9, 34, 35, 38] This makes the generation and the chemoselective reaction of previously unknown highly functionalized organometallic compounds feasible.

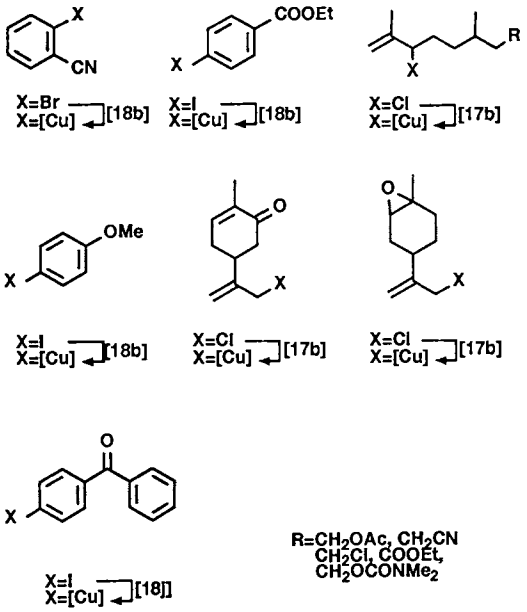
Zinc, which in its conventional form is relatively unreactive, can be sufficiently activated without great effort that it reacts with many halohydrocarbons under mild conditions to give the corresponding organozinc compounds. In many cases the pretreatment of zinc dust with 1,2-dibromoethane (4 mol%) and Me_3SiCl (3 mol%) suffices for this purpose. The following trends were evident:[77, 78] 1) The insertion of the metal into C–X bonds (X = halogen) is in many cases *facilitated* by neighboring functional groups; with suitable substitution even alkyl bromides or chlorides can be used. 2) Secondary alkyl iodides react with the pretreated zinc in THF at lower temperature (25–30 °C) than primary alkyl iodides (35–45 °C). 3) For the reaction of aryl and heteroaryl iodides, polar solvents (DMF, DMA) are necessary. 4) The amount of Wurtz coupling in the preparation of benzyl- and allylzinc compounds is in general small. The tendency of allyl bromides to dimerize increases with increasing electron density at the double bond.[79a] 5) The distance between metalated carbon atom and heteroatom is of decisive importance. Thus, e.g., all attempts to synthesize β-*S*-substituted alkylzinc compounds failed because of their high tendency to elimination. 6) Most important appears to be the fact that the preparation and reaction of the organozinc compounds are compatible with a large spectrum of functional groups.[78] Even compounds with moderately acidic protons (terminal alkynes, indoles, alkylamides etc.) can be employed.[79b]

Regarding the oxidative insertion, Rieke zinc, which was prepared from ZnX_2 (X = Cl, Br, I) and $Li^+C_{10}H_8^-$ in THF or DME, is still more efficient. This is evident, inter alia, from the fact that it is also capable of reacting smoothly with alkyl, vinyl, and aryl bromides which can likewise be substituted by a series of electrophilic groups.[80] The functionalized organozinc compounds prepared in this way (Scheme 17) react after transmetalation with Cu^I salts, in the presence of catalytic amounts of Pd^0 complexes, or under assistance of Lewis acids, with numerous electrophiles (inter alia, acid chlorides, vinyl, aryl, and alkynyl halides, 3-iodoenones, aldehydes, enones, alkynoates, nitroolefins, Bu_3SnCl) in good to very good yields.[78-80] Allylzinc compounds, which can be prepared with zinc–graphite in THF at 0 °C, react with nitriles to give the corresponding β,γ-unsaturated ketones after hydrolysis of the intermediary metalloaldimines.[81]



Scheme 17. Selected examples for the synthesis of functionalized organozinc compounds by oxidative insertion.

The situation is similar in the case of activated copper, which is capable of insertion into alkyl, aryl, and allyl halides as well as into allyl acetates.[17-19] In this way the usual transmetalation of reactive organolithium compounds can be avoided, and functionalized organocopper compounds can be prepared that are not accessible by the conventional route. In view of the importance of cuprates for the selective C–C bond formation[82] this new possibility is of particular interest. However, this example highlights the great deal of empirical optimization necessary before a synthetic method using highly reactive metals reaches preparative maturity. The strong tendency of conventional Rieke copper (CuI, potassium, 10 mol% naphthalene, DME, 8 h)[15] to agglomerate made the systematic search for more stable and thus more reactive forms of this metal necessary. The choice of the salt to be reduced thereby plays a decisive role. Particularly active copper samples are obtained in the reduction of $CuI \cdot PR_3$ (R = Et, Bu, Ph)[18] and of $CuCN \cdot 2LiX$[17] with $Li^+C_{10}H_8^-$ at low temperatures (< −100 °C) ($CuCN \cdot 2LiX$ is readily soluble in THF). Thus, reagents were prepared which contained, inter alia, ester, nitrile, carbamate, chloride, and in some cases even ketone, enone, and epoxy groups (Scheme 18), but otherwise showed the usual reaction profile of organocopper compounds.[17-19] They can be



Scheme 18. Synthesis of functionalized organocopper compounds by oxidative insertion of activated copper into carbon–halogen bonds. Selected examples.

converted with acid chlorides in good yields into substituted ketones, be cross-coupled with allyl halides, undergo 1,4-additions to enones, and afford epoxide openings in overall respectable yields. When, however, the distance between metalated carbon and oxirane group is appropriate, intramolecular epoxide openings with formation of carbocycles such as **18** and **19** take place (ring sizes from 3 to 7) (Scheme 19).[17b, 18b, c, f] The observed regiochemistry can in some cases be varied considerably by changing the solvent (Table 8).[18b, c] In the reduction of $CuI \cdot PR_3$, for example, the choice of phosphane not only determines the activity of the metal obtained but also influences the nucleophilicity of the carbanions formed.[18] Further applications of activated

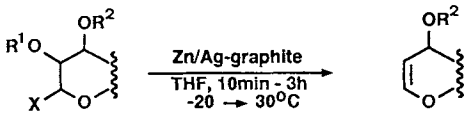
copper are the Wurtz coupling of halogen compounds (Section 4.5.1) and the formation of benzoin and benzil derivatives from aromatic acid chlorides.[83]

Rieke nickel is also capable of oxidative insertions into substituted halogen compounds. Applications to the synthesis of functionalized ketones and in the field of Ullmann biaryl synthesis are summarized in Section 4.5.1

4.4. Enantiomerically Pure Synthetic Building Blocks from Carbohydrates

Despite the proven versatility and reliability of highly reactive metals as tools in organic chemistry, the number of applications to complex substrates or in natural product synthesis has so far remained comparatively small. A few exceptions are found in the previous sections of this review. That high reactivity must not be equated with inadequate selectivity, however, is also demonstrated by the successful use of activated metals in the field of carbohydrate chemistry.

Glycals have long played a prominent role among the enantiomerically pure building blocks derived from sugars.[84] As cyclic enol ethers of the carbohydrate series, they combine an easily functionalizable anchor group with a skeletal framework of chiral centers. Their synthesis could be considerably improved in many respects by the use of graphite reagents. Thus, Zn/Ag–graphite is equally suitable for the reduction of pyranoid and furanoid glycosyl bromides (chlorides) (Scheme 20).[85] Since all operations are



Scheme 20. Principle of the first Fischer–Zach-type glycal synthesis in an aprotic solvent. X = Cl, Br; R^1 = acyl, alkylidene; R^2 = acyl, alkyl, alkylidene.

carried out in an aprotic solvent (THF) at low temperatures and under neutral conditions, not only are all important protecting groups compatible with this method but also the furanoid glycals (**26**–**28**) that rearrange allylically even in weakly acidic media are readily accessible. The latter could virtually not be obtained with the classical Fischer–Zach method (Zn dust in acetic acid). Zn/Ag–graphite has also proven useful in the synthesis of the labile L-fucal **25**[86] and of thioglucal **24**[87] (Scheme 21). In this context it should be pointed out that Rieke zinc, in contrast to Zn/Ag–graphite, is capable of reducing very unstable glycosyl iodides to glycals only.[88]

Besides this first Fischer–Zach-type method for glycal synthesis in aprotic solvent, C_8K is also well suited for this purpose. Its advantages are found in the first direct synthesis of per-*O*-alkylated glycals (Scheme 22) and in the one-pot synthesis of differently protected building blocks by selective protonation, alkylation, acetalization, silylation, or glycosidation of the intermediate potassium alkoxide formed in the fragmentation of 2,3-alkylidenated glycosyl halides (Scheme 23, Table 9).[89] The self-indicative character (by the color change from bronze (C_8K) to black (graphite)), the short

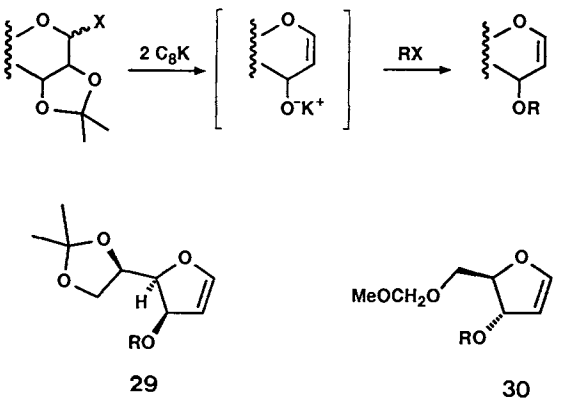

Scheme 23. One-pot synthesis of differently protected furanoid glycals using C_8K. Selected examples.

reaction times, and the simple workup procedure by filtration are further advantages of this novel glycal synthesis. Moreover, it disproves the opinion put forward in the litera-

Table 9. Synthesis of differentially protected furanoid glycals with C_8K (Scheme 23) [89].

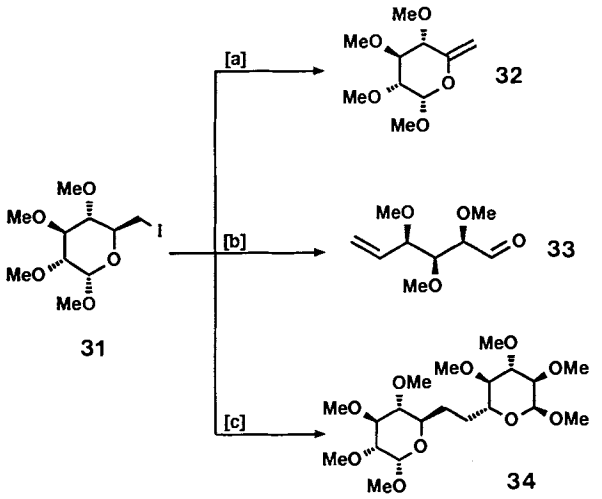
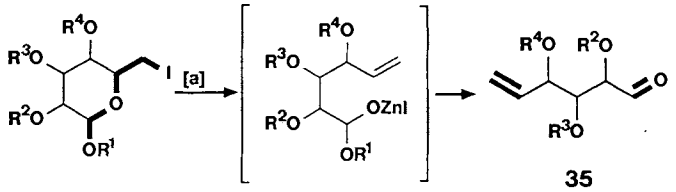
ture[40] that C_8K is far too reactive and therefore unsuitable for the transformation of sensitive starting materials.

The benefits of using highly reactive metals are also clear in the reactions of other carbohydrate derivatives. Scheme 24 illustrates, with the model substrate **31**, possibilities for chemoselective conversions by suitable choice of the respective metal–graphite compound.[90] In the case illustrated



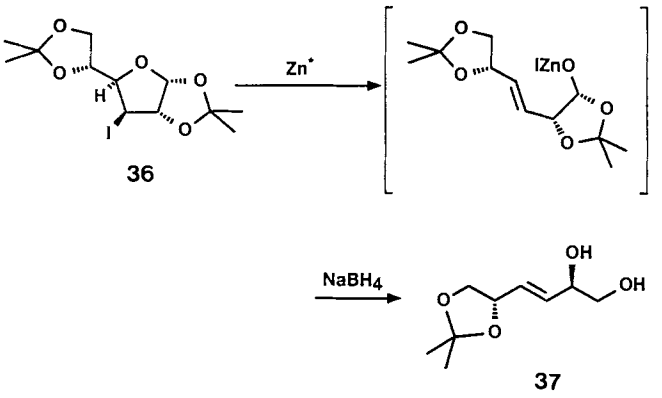
Scheme 24. Chemoselective reaction of 6-deoxy-6-iodopyranoside **31** with metal–graphite reagents: [a] C_8K, THF, 0 °C, 10 min, 94%; [b] Zn/Ag–graphite, room temperature, 10 min, THF, 93%; [c] Mg–graphite, THF, reflux, 3 h, 68%.

C_8K acts as a polymeric Lewis base, which leads to the dehydrohalogenation of the starting compound (**31** → **32**), whereas on using Mg–graphite Wurtz coupling of the substrate occurs (**31** → **34**). Zn/Ag–graphite deserves special attention because it represents by far the most appropriate agent for the reductive ring-opening of deoxyhalo sugars (**31** → **33**). Such dealkoxyhalogenations, in which both the ring oxygen as well as the halogen atom act as leaving groups (Scheme 25), can in principle be achieved even with less ac-



Scheme 25. Zn/Ag–graphite-induced dealkoxyhalogenation of deoxyhalo sugars; [a] Zn/Ag–graphite, THF or DME, ca. 25 °C, < 10 min.

tive zinc samples.[91] Zn/Ag–graphite in THF is, however, the only reagent operative in aprotic solvents; it consequently permits the synthesis of products sensitive to hydrolysis, it induces such reductions under comparatively mild conditions, and it surpasses all classical alternatives in terms of efficiency, suppression of side reactions, and reliability.[90, 92–94] This is clearly demonstrated, inter alia, by those cases in which conventional methods lead to decomposition of the substrate or to an unforseen reaction course, while Zn/Ag–graphite effects regular dealkoxyhalogenations (Scheme 26, Table 10).[92]



Scheme 26. Dealkoxyhalogenation of 3-deoxy-3-iodo-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose and subsequent reduction of the resulting enal (see Table 10).

Table 10. Zinc-induced dealkoxyhalogenation of 3-deoxy-3-iodo-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose **36** to enitol **37** (Scheme 26) [90, 92b].

Reagent	Solvent	T[°C]	t[min]	Yield [%]

[a] Affords 2,3-dideoxy-5,6-*O*-isopropylidene-D-*erythro*-hex-3-enose (63%) instead of **37**.

In numerous cases Zn/Ag–graphite-induced fragmentations of this kind have proven to be independent of the configuration and conformation of the carbohydrate precursor as well as of the leaving group at the anomeric center (e.g. glycoside, acetal, lactone); they take place in primary and secondary halides at comparable rates.[92, 93] Generally, they occur more readily in iodides than in bromides and more efficiently with pyranoses than furanoses, where simple dehalogenation can compete with ring-opening (Scheme 29).[92]

Their initiation is halogen-selective, which makes a series of other protecting and functional groups compatible with such reductive ring-openings (e.g. *O*-acyl, *O*-alkoxycarbonyl, *O*-alkyl, *O*-silyl, *O*-alkylidene, deoxy, deoxyfluoro, epoxy, nitrile, thioether, acylamido groups) (Schemes 25–29, Tables 11, 12).[90, 92, 93] The transformation **38** → **39** uses this principle for synthesizing substituted tetrahydrofuran derivatives from carbohydrates (Scheme 27).[92a]

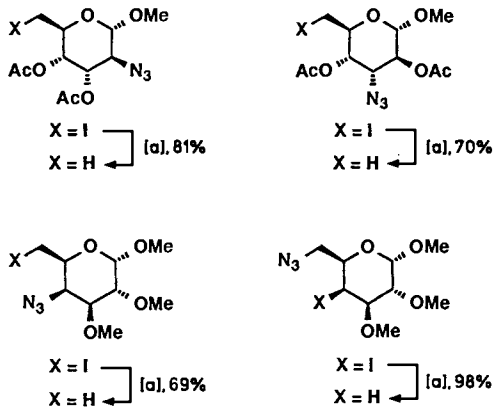
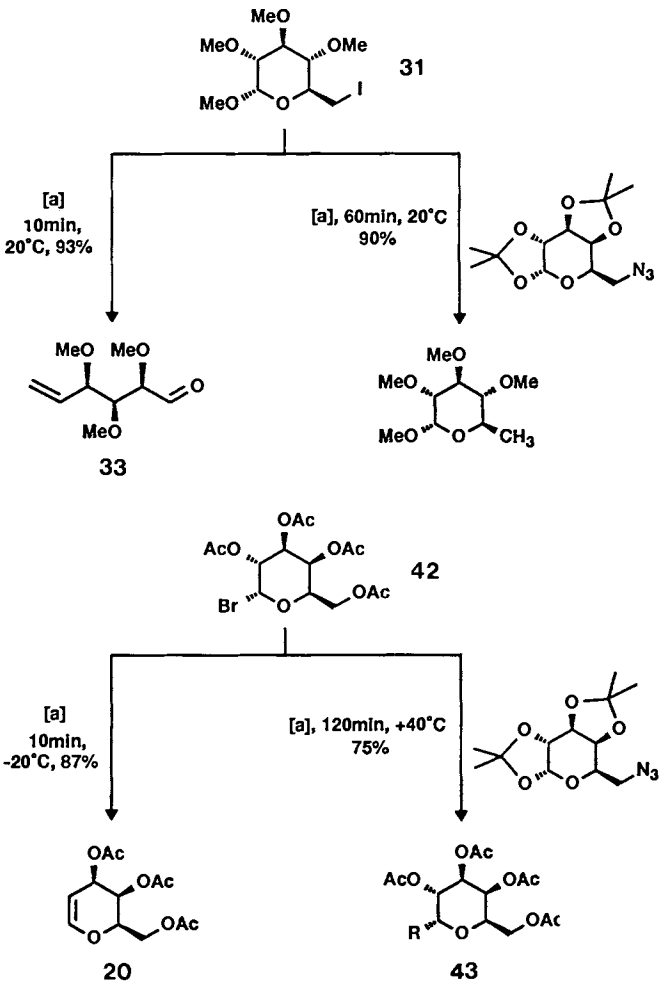
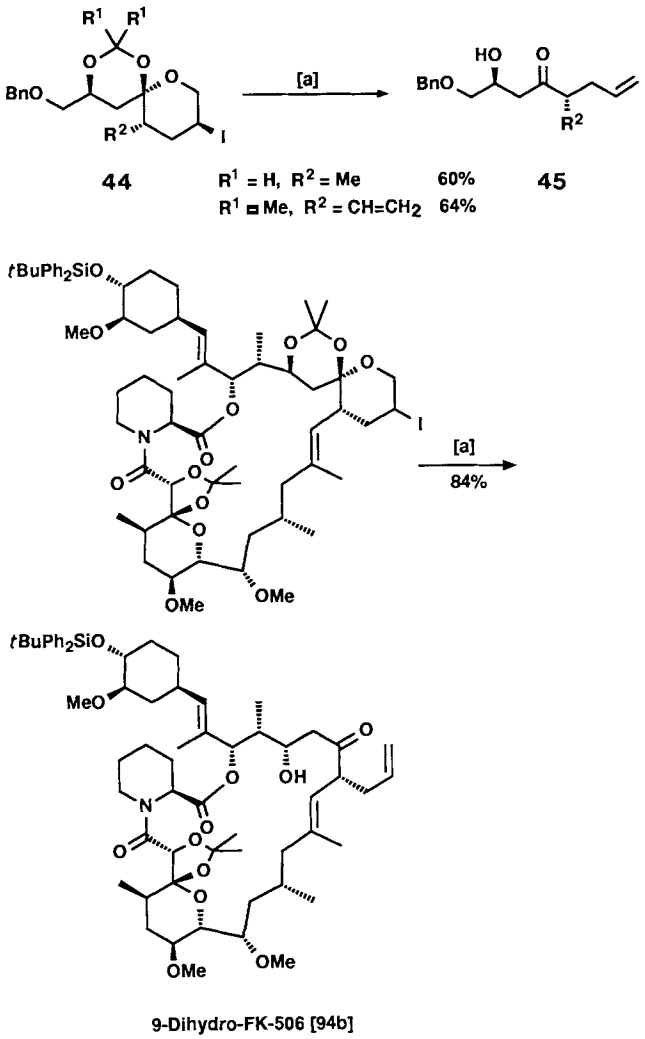
Regarding this high compatibility of the method with diverse functionalities, azidodeoxy groups form an interesting exception to the rule.[93] Although the azide itself generally emerges unchanged from the reaction with highly active zinc, it fundamentally changes its pathway, since instead of the ring-opening only dehalogenation of the substrate is observed (Scheme 30). This holds even when an azide is merely admixed with a starting material that normally undergoes



Scheme 30. The azide effect on zinc-induced reactions: [a] Zn/Ag–graphite, THF, room temperature.



Scheme 31. Effect of external azides on zinc-induced reductions of deoxyhalo sugars; the azide (1 equiv) is recovered unchanged after completion of the reaction: [a] Zn/Ag–graphite [93]. R = H, D.

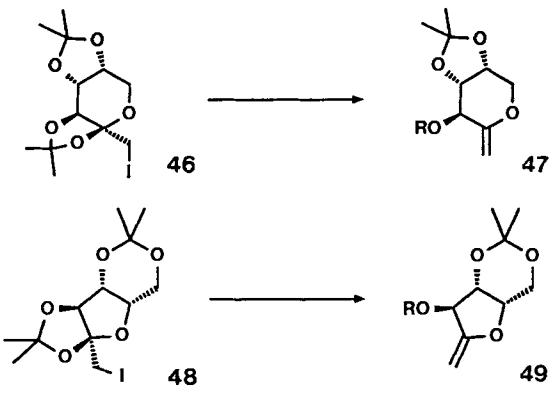


Scheme 32. Aldols by fragmentation of spiroketals [94]: [a] Zn/Ag–graphite, THF. R^1 = H, R = Me, yield 60%; R^1 = Me, R = $HC=CH_2$, yield 64%. Application to the synthesis of 9-dihydro-FK506.

facile ring-opening such as **31**. Likewise, the Zn/Ag–graphite-induced glycal synthesis (**42** → **20**) also fails in the presence of external organic azides (Scheme 31). Instead, dehalogenation with formation of the corresponding 1,5-anhydro sugar derivative (**42** → **43**) occurs. As could be confirmed by a labeling experiment, these simple reductive C–X bond cleavages proceed via radical intermediates for which the THF used as solvent serves as source of hydrogen.[93]

The high efficiency of the Zn/Ag–graphite-induced dealkoxyhalogenations is also the basis for a new, indirect entry to aldols by fragmentation of spiroketals such as **44** (Scheme 32).[94] The versatility and scope of this approach was impressively illustrated in a recent total synthesis of a derivative of the immunomodulator FK506.[94b]

The reactivity of graphite reagents in aprotic solvents is also the prerequisite for the synthesis of products such as the exocyclic enol ethers **47** and **49** (Scheme 33, Table 13),[92b] which are extremely sensitive to hydrolysis, and for the transformation of labile starting compounds. The recently described anomeric bromoimines (e.g. **51**)[95] prepared from glycosyl azides and NBS are in many respects most unstable substances but are nonetheless cleanly transformed by metal–graphite reagents in THF into aldononitriles (Scheme 34).[96] If, in this case, C_8K is employed instead of Zn/Ag–graphite



Scheme 33. Synthesis of exocyclic enol ethers from keto sugars (see Table 13).

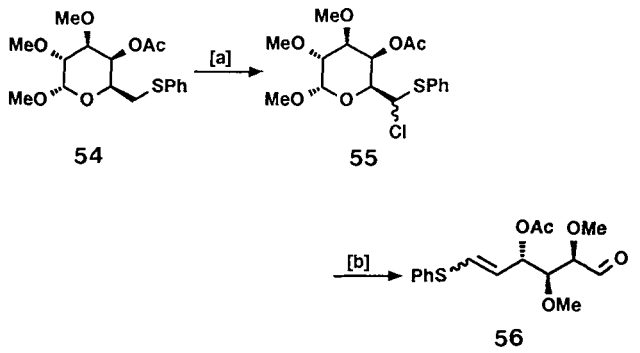
as reducing agent then the intermediary potassium alkoxide **52** ($M^+ = K^+$) can be trapped in situ by addition of a variety of electrophiles (Table 14). To our knowledge there is no precedence to the sequence glycosyl azide–bromimine–aldononitrile (**50** → **51** → **52** → **53**).

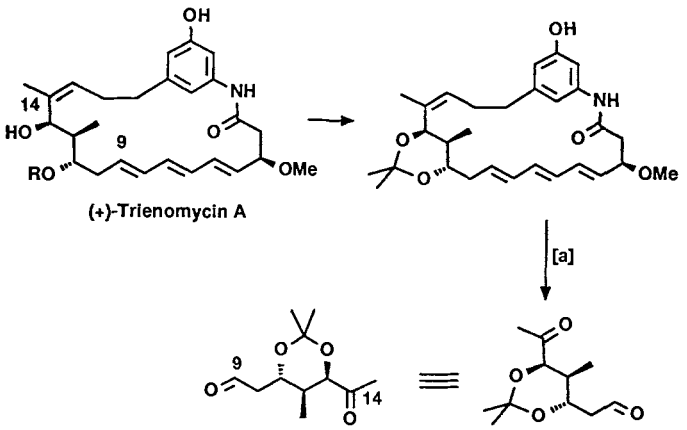
The substituted enals formed in the reductive ring-opening of ω-halo sugars find many applications as enantiomerically pure synthetic building blocks with adequate terminal differentiation. Their preparative use can be increased still further by direct functionalization of the terminal double bond. For

this purpose one exploits the well-known property of thioethers to be halogenated in a radical reaction at the α-position[97] in suitably protected 6-deoxy-6-*S*-phenylglycosides. Reaction of **54** with *N*-chlorosuccinimide (NCS) affords the hydrolysis-sensitive α-chlorothioether **55**, which, without further purification, is allowed to react with Zn/Ag–graphite in DME to give the acyclic thioenol ether **56** [(*Z*):(*E*) = 1:2] (Scheme 35).[98] This strategy forms the basis for the enan-



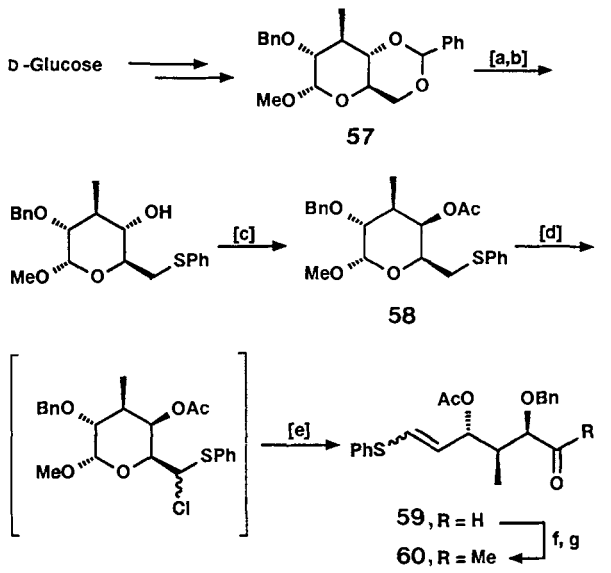
Scheme 35. [a] NCS, CCl_4, room temperature; [b] Zn/Ag graphite, DME, 60 °C, 64% (both steps).

tioselective synthesis of the C9–C14 fragment of trienomycin and mycotrienin antibiotics. This "chiral core" is identical in all members of this group of *ansa*-macrolides, and its relative and absolute stereochemistry has been determined by degradation of trienomycin A (Scheme 36).[99] A few standard steps permit conversion of the substrate **57**, accessible in gram amounts from D-glucose, into the thiophenyl ether **58** with the desired configuration at all the chiral centers. In situ halogenation with NCS followed by Zn/Ag–graphite-induced ring-opening affords compound **59**, which can be converted by chemoselective reaction of its aldehyde group with tris(isopropoxy)methyltitanium and subsequent oxidation of the alcohol formed with pyridinium chlorochromate (PCC) to give the final methyl ketone **60** (Scheme 37).[98] Both the two carbonyl groups as well as the alcohol functions are suitably differentiated, as is required for an intermediate of a total synthesis.



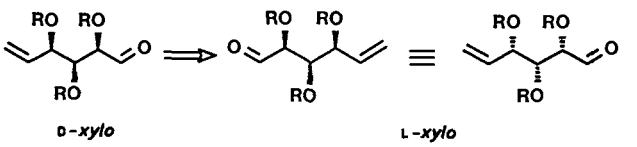
Scheme 36. Degradation of trienomycin A for the determination of the stereochemistry of the C9–C14 fragment [99]: [a] ozonolysis, 35%.

The advantage of the enantiomeric purity of carbohydrate-derived building blocks is limited by the relatively small number of sugars which are sufficient enough in nature to be likely starting compounds for multistep syntheses.[84] In particular, the lack of most sugars of the L series limits the accessible chiral building blocks drastically. This basically holds true also for the enal synthons dealt with herein. However, for these a practical way out of this dilemma is found



Scheme 37. Synthesis of the differentially protected C9–C14 fragment of the trienomycin and mycotrienin antibiotics: [a] *p*-TsOH · H_2O, THF, quant.; [b] PhSSPh, pyridine, Bu_3P, 83%; [c] (1) trifluoromethanesulfonic anhydride, pyridine, 0 °C; (2) $Bu_4N^+AcO^-$, acetonitrile, 78%; [d] *N*-chlorosuccinimide, CCl_4, 40 °C; [e] Zn/Ag–graphite, DME, 60 °C, 66% (via steps d and e); [f] $(iPrO)_3TiMe$, THF, 81%; [g] PCC, MS 3 Å, NaOAc, CH_2Cl_2, 72%.

with the sequence for transposition of their terminal groups as outlined in Schemes 38 and 39.[100] This method for the formal inversion of the configuration of the synthon, in which no *meso* form is passed through, consists in a well-tuned sequence of a nucleophilic attack at the aldehyde group by trimethylsilylmethylmagnesium chloride and dihydroxylation of the terminal double bond, followed by a Peterson elimination at the "head" of the molecule and subsequent periodate cleavage at its "tail". Since all intermediates do not have to be isolated, the overall yields of this reaction sequence



Scheme 38. Retrosynthetic analysis for the transposition of enals.

are satisfactory. In this way, for example, the complete set of all eight stereoisomeric 2,3,4-tri-*O*-methylhex-5-enoses was obtained from readily available parent sugars (D-glucose, D-mannose, D-galactose, D-allose) (Scheme 40).[100]

An application in natural product chemistry of this interplay of Zn/Ag–graphite-induced dealkoxyhalogenation and subsequent inversion of the stereochemistry of the building block obtained is the convergent synthesis of the C1–C13 fragment of amphoteronolide B (Fig. 5), the aglycone of the macrolide antibiotic amphotericin B used clinically as a fungicide.[101] Based on the hidden symmetry of this fragment,

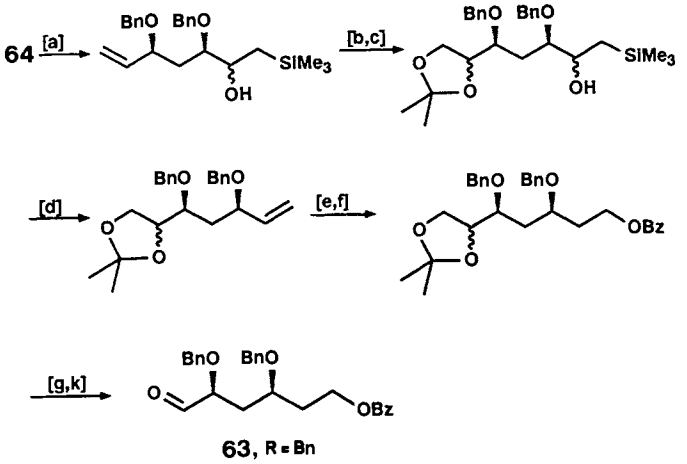
required for the coupling is obtained in a few steps from an enal; the latter are enantiomeric to each other and consequently are both accessible by ring-opening/transposition from the same central intermediate **66**, which in turn can be readily obtained in large amounts from D-glucose (Schemes 42 and 43).[102]



Scheme 43. Amphoteronolide B. Synthesis of the C1–C6 fragment **63'** from enal **64'** (see Scheme 42: **63'** = **63** with R = Bn, R'' = Bz). 4.5. Reductive Coupling Reactions

4.5.1. Coupling of Halogen Compounds

Copper powder is the reagent of the classical Ullmann biaryl synthesis.[103] In highly reactive form as Rieke copper it dimerizes allyl, benzyl, alkynyl, aryl, and primary alkyl halides in good yields and tolerates a remarkable spectrum of functional groups in the substrates.[15, 18a, g, i, 21] The coupling of secondary and tertiary alkyl halides and intramolecular reactions can be accomplished only in execptional cases (e.g. 1,3-dibromoalkanes) in good yields.[18i] Passage of oxygen through the solution of the intermediate organocopper compounds leads to their dimerization already at room temperature.[18g] The effect of additives and the importance of the choice of the copper salt to be reduced in such Wurtz couplings have been studied in detail.[21] The activation of commercially available copper powder with ultrasound, which is due to destruction of the oxide layer on the metal, likewise leads to substantial improvements of the Ullmann synthesis by the elimination of the induction period and an up to 64-fold increase in the reaction rate.[48c]

Similarly, activated nickel, either in the form of Rieke nickel[104] or nickel/copper–graphite,[43] dimerizes benzyl halides and aryl iodides in good yields, whereby the substrate can be likewise substituted by a series of functional groups. Bromobenzene derivatives are less suited for nickel-induced Ullmann reactions which are normally facilitated by electron-withdrawing substituents on the phenyl ring. On reaction of benzal halides or benzotrichloride with Rieke nickel the corresponding stilbene derivatives[104] are formed, whereas 1,1-dihalogenoethenes dimerize to allenes or cyclooligomerize to radialenes.[105]

If, on the other hand, a mixture of a benzyl, allyl, vinyl, or pentafluorophenyl halide and an acid chloride is allowed to react with Rieke nickel, cross-coupling preferably occurs with formation of ketones.[106] Mechanistically , this synthesis, which again is distinguished by wide applicability with numerous differently substituted starting compounds, proceeds via oxidative insertion of the nickel into both coupling partners.[106] Due to this ability to form acylnickel compounds and its suitability for the direct preparation of π-allylnickel complexes from allyl halides,[107] activated nickel is a likely substitute for soluble Ni^0 complexes (e.g. $[Ni(CO)_4]$, $[Ni(cod)_2]$), which in some cases are toxic and difficult to handle.

Wurtz-type couplings can also be carried out on a series of structurally different halogen compounds with lithium activated by the use of ultrasound.[108] Table 15 gives a comparison of the above-mentioned methods.

Table 15. Selected examples of the dimerization of halohydrocarbons with activated metals.

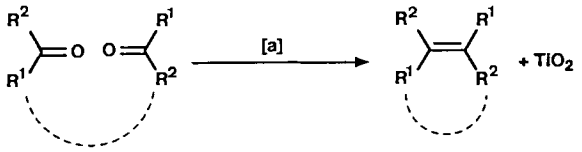
4.5.2. Coupling of Carbonyl Compounds

In the years 1973 and 1974 three research groups reported independently of one another on carbonyl coupling reactions with formation of alkenes using zero- or low-valent titanium

reagents (Scheme 44).[13, 109] This reductive dimerization, generally referred to as the McMurry reaction[110] demonstrates quite clearly the problems of metal activation. Com-



Scheme 44. Principle of the McMurry reaction: [a] low-valent titanium compound.

mercially available titanium powder is unsuitable for this reaction, and the highly reactive metal shows considerably different degrees of activity depending on its genesis. Despite intensive efforts the structure of the metal samples generated in situ is still unclear.[111] These morphological studies are hampered by the complex redox behavior of low-valent titanium compounds, the tendency to ether cleavage, the high oxophilicity, and the potential danger of artefacts during sample preparation. There are numerous indications that $TiCl_4$ is not reduced to metallic titanium by conventional reducing agents in solution.[112–114] In the case of the reaction of $TiCl_3$ with $LiAlH_4$ recent investigations confirm the formation of chlorohydridotitanium complexes as the actual active species.[115] Model investigations on single crystals of titanium dioxide, whose surfaces are partially reduced by ion bombardment likewise show that the presence of zero-valent titanium is not an essential prerequisite for reductive alkene syntheses from carbonyl compounds.[116] Summarizing, these results further strengthen the view that structurally different McMurry agents might be present and could be active, depending on their preparation.

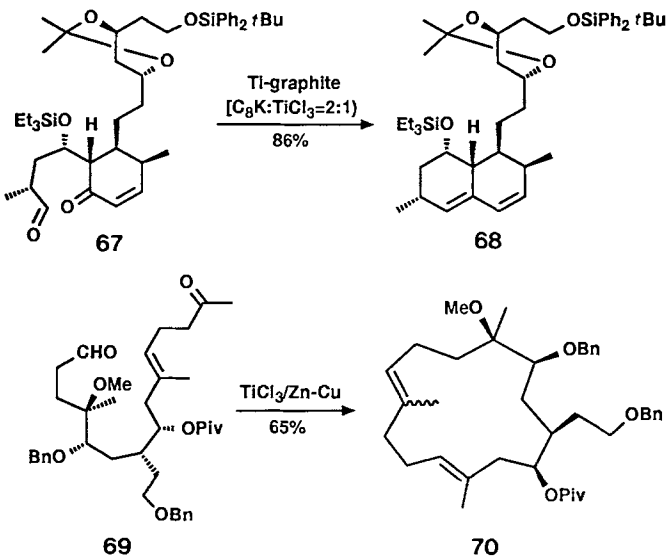
In view of the great preparative potential of the McMurry reaction much empirical work has been devoted to its improvement and standardization by variation of the titanium halide, the solvent, the reducing agent, and the reaction time, as well as by addition of additives (pyridine, triethylamine).[110] Of the numerous procedures, three recent developments deserve special mention. Firstly, McMurry et al. have worked out an optimized procedure for the intra- and intermolecular coupling of (di)carbonyl compounds based on the use of $TiCl_3 \cdot DME_{1.5}$ as source of titanium, Zn/Cu couple as reducing agent, and DME as solvent which affords reproducible results in all the cases investigated.[117] Also the coupling of diisopropyl ketone to tetraisopropylethylene could be considerably improved under these conditions (87% in contrast to 37% with $TiCl_3$/Zn–Cu and 12% with $TiCl_3/LiAlH_4$).

Secondly, studies on the influence of the solvent on the (*Z*)/(*E*) ratio of the alkene formed and the influence of ultrasound on the course of the reaction have been reported.[118] According to these studies, in the intermolecular coupling of acetophenone in DME the (*E*) alkene is preferably formed, whereas in THF, the (*Z*) alkene is the major product. When ultrasound is used the reaction that normally takes place under reflux already occurs at 30 °C, whereby the alkene is only formed in THF (again the (*Z*) isomer predominates), while in DME the reaction stops at the pinacol stage.[118] The general validity of these observations needs to be checked on further examples.

Finally, regarding methodological developments, the high activity of titanium–graphite prepared from $TiCl_3$ and C_8K in all types of McMurry reactions should be mentioned.[114, 119–121] This is an extremely efficient reagent for the inter- and intramolecular coupling of aromatic and aliphatic aldehydes, ketones, dialdehydes, and diketones to alkenes or cycloalkenes, respectively. Since C_8K reduces titanium trichloride much more rapidly (1.5 h) than other reducing agents (e.g. 12–16 h for potassium) the overall reaction time is shortened considerably.[114] Titanium–graphite also proved to be very efficient in the synthesis of *ansa*–titanocene derivatives by dimerization of acylcyclopentadienyl anions.[120] Furthermore, slightly modified titanium–graphite ($TiCl_3$:C_8K = 1:2) has been described as the most suitable reagent for the coupling of highly oxygenated substrates and for annelation reactions.[121]

When titanium tetrachloride is reduced with C_8K a chemoselective titanium reagent is obtained which without reservation dimerizes aromatic carbonyl compounds to alkenes, but reacts with aliphatic carbonyl compounds to give only pinacols.[114] This clearly indicates the presence of different low-valent titanium species depending on the chosen source of titanium. Moreover, in the course of these investigations there were indications that the tertiary amines widely used as additives owe their activity to disproportionations of the low-valent metal.[114]

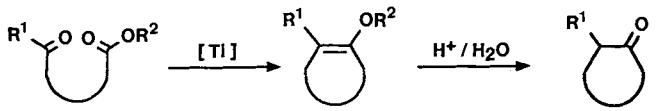
Since the previous applications of the McMurry reaction in organic synthesis have already been summarized in several excellent review articles,[110] only more recent developments in this field will be dealt with here. From the total syntheses using this reaction in a key step it is clear that the preparation of highly substituted natural products is increasingly approaching the realm of the possible. Thus, intramolecular couplings of highly oxygenated dicarbonyl compounds have been carried out, which in view of the exceptional affinity of low-valent titanium for oxygen are by no means trivial (Scheme 45). For example, of all the reagents tested for the



Scheme 45. Intramolecular McMurry reactions with polyoxygenated dicarbonyl compounds. Compound **70** reacts further to give the crassinacetate methyl ether. Piv = pivaloyl.

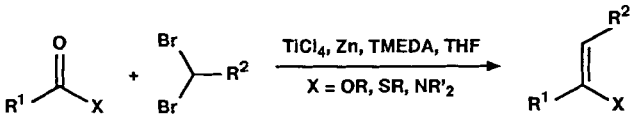
annelation of the A ring (**67** → **68**) in a late intermediate of a synthesis of (+)-compactin and (+)-mevindin, respectively, only titanium–graphite (C_8K:$TiCl_3$ = 2:1) promoted the desired coupling reaction.[122] Macrocyclization (**69** → **70**) with $TiCl_3$/Zn–Cu plays a central role in the synthesis of crassinacetate methyl ether, a representative of the cembran diterpenes.[123] However, in contrast to a SmI_2-induced pinacolization, all attempts to carry out a titanium-supported cyclization of a polyoxygenated ketoaldehyde in the synthesis of grayanotoxin failed.[124]

Although low-valent titanium compounds do not promote any acyloin condensations of diesters, they are capable of reductively coupling ketoesters to enol ethers, which upon acidic workup of the reaction mixture afford cyclanones as final products (Scheme 46). Such oxoalkanoate cyclizations have proven to be rather sensitive with regard to the titanium sample used. Successful applications have previously only been reported with a Rieke titanium modified by addition of triethylamine[125] and with titanium–graphite.[114] In contrast to other intramolecular McMurry couplings the success of this cyclanone synthesis is somewhat dependent on the ring size of the carbocycle synthesized;[125] also the chain length of the alcohol part of the ester (R^2 in Scheme 46) also appears to be of decisive importance for the outcome of the reaction.[126] This method of titanium-induced ketoester coupling has found uses in natural product chemistry in the syntheses of capnellene[127] and isocarophyllene.[128]



Scheme 46. Titanium-induced cyclization of oxoalkanoates.

Comparable *inter*molecular alkylidenations of acid derivatives with low-valent titanium compounds are the syntheses of enol ethers, enol thioethers, and enamines from carboxylic acid esters, thiol esters, and acid amides, respectively, upon reaction with geminal dibromides (Scheme 47).[129] However, these transformations presumably proceed via titanium carbenes and mechanistically resemble reactions with the Tebbe–Evans–Grubbs reagent.[130]



Scheme 47. Intermolecular alkylidenation of esters, thiol esters, and amides induced by low-valent titanium.

The efficiency of the titanium-induced ketoester cyclizations offers the possibility to extend this reaction to the related acyloxycarbonyl compounds (Scheme 48, X = O). This opens up a novel entry to heterocycles, as shown by the syntheses of furans (**73** → **74**) and benzofurans (**71** → **72**) summarized in Table 16 (Scheme 49).[126, 131] Although carboxylic acid amides were previously considered as largely inert under McMurry conditions, this completely new entry to aromatic heterocycles could also be extended to the formation

of indoles from acylamidocarbonyl compounds (**75** → **76**) (Scheme 50, Table 17).[126, 131a] This reaction has some remarkable characteristics. For example, the high-dilution technique commonly used in cyclizations is unnecessary, the indole formation can even be carried out at high concentrations in good yields and short reaction times without intermolecular coupling reactions competing. All kinds of amides, from formamide up to fatty acid amide, including aromatic and heteroaromatic ones, undergo comparatively rapid reac-

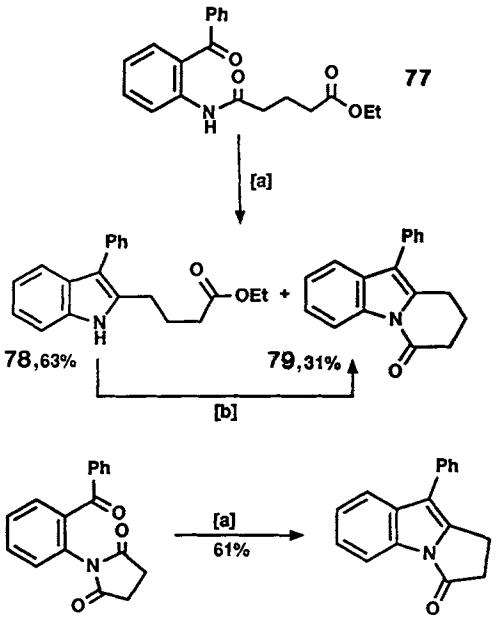
tions. More importantly, this indole synthesis based on a McMurry-type coupling can also be carried out with compounds bearing potentially reducible functional groups. The smooth synthesis of tricyclic skeletal frameworks is also possible, as shown by the reactions **77** → **79** and **80** → **81** (Scheme 51). Last not least, it should be mentioned that this reaction is insensitive with regard to steric hindrance (cf. Table 17, R^1 = Ph, R^2 = *t*Bu).[126]



Scheme 51. [a] Ti–graphite, DME; [b] NaH, THF, (**78** → **79**, quantitative).

As is evident in the synthesis of salvadoricine (**83**) (Scheme 52) such indole formations occur in good yields even if, as in compound **82**, an intramolecular diketone cyclization were possible, which would likewise lead to a highly stable heterocycle (quinolin-2-one).[132] This unpredented preference for keto–amide cyclization corresponds to a *complete reversal of the previously known chemoselectivities of titanium-induced reactions*. This also holds true for the preparation of compounds **85**, well-documented precursors (R = Me) for diazapam and (R = CH_2CN) for histamine and serotonin antagonists, by chemoselective keto–amide couplings, without the likewise conceivable keto–ester cyclization in substrate **84** competing (Scheme 53).[132] With this new approach to the indole nucleus by closure of the

4.5.3. Pinacol Coupling and Preparation of vic-Diamines

The McMurry reaction proceeds by the dimerization of ketyl radical anions to titanium pinacolates and their subsequent deoxygenation to the alkene and TiO_2.[110] In view of the striking shortcomings of the classical pinacol reduction there has been much effort to stop the McMurry reaction at the stage of the *vic*-diols. In general this can be accomplished by lowering the reaction temperature. The titanium-based pinacolization methods have contributed considerably to the development of this approach,[109, 113, 114, 134] though the complete suppression of alkene formation has proven difficult in some cases.[135]

In analogy to the classical agents for pinacol formation, aluminum and magnesium amalgam, the corresponding graphite combinations of these metals were examined with regard to their SET abilities. Aluminum–graphite was found to be unsuitable.[136] Magnesium–graphite, however, reduced all kinds of carbonyl compounds to pinacols in consistently high yields.[114b, 137] Its activity manifested itself quite clearly in a comparison with other one-electron transfer agents and in the intramolecular pinacolization of dicarbonyl compounds to cycloalkyl-1,2-diols of different ring size.[114b] The incompatability with chloro and nitro groups is its most serious disadvantage compared to SmI_2 as pinacol-forming agent. With magnesium on graphite, amalgamation is not necessary for promoting the latent single-electron transfer tendency of this metal. Thus, the fine distribution of the magnesium has in this case not only a quantitative but also a quality-changing effect.

Other approaches for a modern pinacolization methodology utilize the redox potential of the rare-earth metals or of transition metal complexes.[138] Of the numerous reagents which have been described in this context samarium diiodide[139] and vanadium(II) salts[140] deserve particular attention because of their versatility and efficiency.

The single-electron transfer reagents leading to the pinacolization of carbonyls, above all low-valent titanium, are also suitable for the reductive dimerization of aldimines or iminium salts to *vic*-diamines.[141]

4.6. Disilanes, Nucleophilic Silylations, Coordination Chemistry

Similarly to the Wurtz coupling of halohydrocarbons, activated metals permit also the efficient dimerization of chlorosilanes and chlorostannanes to disilanes and distannanes. Table 18 shows the exceptional effectivity of C_8K as reducing agent in such reactions.[142] Once again, when this reagent is used the reaction can be monitored easily by the change in color from bronze to black, and the workup consists merely of a filtration.

Also in the cleavage of phenyl-substituted disilanes to silylmetal compounds C_8K proves superior to the conventional methods (Scheme 55). The silylpotassium reagents **87** so obtained can be transmetalated in situ and their reactivity may thus be finely tuned to diverse electrophiles.[142a] Silylpotassium cuprates, manganates, and vanadates prepared in this way react with carboxylic acid chlorides directly to give acylsilanes **88** (Scheme 56, Table 19) and permit 1,4-additions to enones as well as to enoates.[142a]

New impetus has been given also to the use of C_8K as reducing agent for metal complexes. Hegedus et al. have recently pointed out the advantages of using this reagent as "polymeric" analogue of $M^+C_{10}H_8^-$ (M = Li, Na, K).[143] Reduction of $[Cr(CO)_6]$ with C_8K to $[K_2Cr(CO)_5]$ and its subsequent reaction with amides in the presence of Me_3SiCl provides simple access to aminochromium carbenes **89** (Scheme 57) and their multifarious chemistry. With 4-chloro-

butyryl chloride instead of the amide, pentacarbonyl[(tetrahydrofuran-2-yl)carbenechromium(0) can be prepared in this way. Since not only the yields are generally better than when using $Na^+C_{10}H_8^-$ (Table 20) but also the workup is much more straightforward, this approach based on C_8K

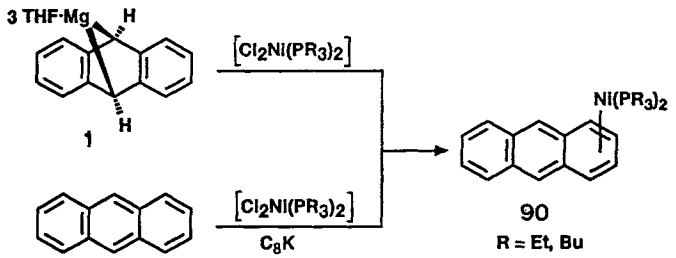
is the method of choice for the synthesis of such metal carbenes.[143]

Further, it should be pointed out that both the magnesium–anthracene complex **1** as well as C_8K have enabled entry to a new class of η^4-nickel–anthracene complexes **90** with pronounced dynamic behavior (Scheme 58).[144]

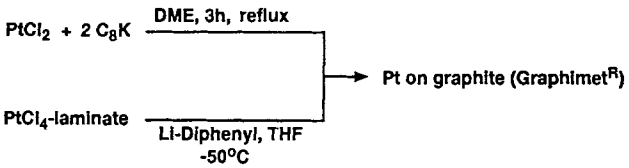


Scheme 58. Activated metals in complex chemistry [144].

4.7. Highly Reactive Metals as Catalysts

Sonication of commercially available nickel powder affords a catalyst which is a nonpyrophoric substitute for Raney nickel.[48a] The Rieke nickel formed in the reduction of NiI_2 with lithium in THF using ultrasound catalyzes both the hydrosilylation of alkenes at room temperature as well as the reductive coupling of phenylhydrosilanes to give di-, tri-, and tetrasilanes.[145] Essential for the activity of this nickel sample are the carbonyl ligands that are formed during the reduction of the salt by ether cleavage and are chemically bound to the metal surface.[57] Nickel–graphite, after addition of ethylenediamine, is a substitute for the classical Lindlar catalyst for the semihydrogenation of alkynes at room temperature and 1 atm H_2 with good to excellent (*Z*) selectivity ((*Z*):(*E*) = 93.6–98.9:6.4–1.1).[146] Upon exposure to air and washing of the catalyst (H_2O, THF) the finely divided nickel particles on the graphite surface are coated with a hydroxide layer a few nanometers thick (see Section 3);[44] though this reduces its catalytic activity, the selectivity with regard to the hydrogenation of different reducible groups or various substituted alkenes is increased.[146] Furthermore, the nickel–graphite treated in this way is storable for months without loss of activity.

High selectivity in the hydrogenation of aromatic halonitro compounds characterizes platinum–graphite as a catalyst.[60] Dehalogenation as well as hydrogenation of the arene remains low even with larger amounts of the catalyst and long reduction times. After the catalyst was used twenty times neither any noticeable decrease in the catalytic activity could be established nor could electron microscopic changes in the morphology of the catalyst be observed. Regarding both its structure as well as its catalytic properties platinum–graphite prepared from $PtCl_2$ and $2C_8K$ is largely identical[60] with the commericially available Platinum–Graphimet®, often erroneously referred to as an intercalation compound. The latter is obtained by low-temperature reduction of $PtCl_4$-laminate with lithiumdiphenyl in THF (Scheme 59).



Scheme 59. Two syntheses of Pt–graphite [60].

Highly dispersed metal colloids generated from transition metal salts and tetraalkylammoniumhydrotriorganoborates also exhibit interesting properties as hydrogenation catalysts.[114] After fixing to activated charcoal and doping with bis(η^6-toluene)titanium such catalysts (Rh,Pd,Pt) are far superior to the standard industrial systems with equal metal contents used for the hydrogenation of fatty acids and cinnamic or crotonic acid.[114]

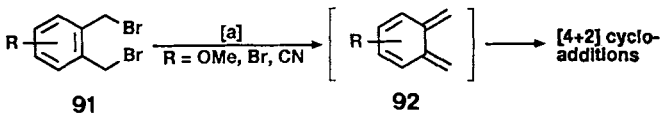
In the semihydrogenation of alkynes, palladium–graphite, like nickel–graphite, produces the corresponding (*Z*) alkenes with high selectivity.[147] Even more interesting is its ability to catalyze organometallic reactions for which hitherto soluble palladium(0) catalysts seemed to be reserved. For example, Heck reactions of aryl and vinyl iodides with activated alkenes using palladium–graphite have been reported to proceed in good yields and with high selectivity.[148] Rieke palladium is also suitable for oxidative insertions into activated carbon–halogen bonds.[56] In the presence of triphenylphosphane, palladium–graphite also permits nucleophilic substitutions of allyl esters with sodium benzenesulfinate, malonates, and enamines in complete analogy to π-allylpalladium chemistry employing soluble palladium complexes.[149] Even commercially available palladium/activated charcoal and palladium/Al_2O_3 can be used for such reactions, although their activity is lower. Since palladium–graphite can be reused after the reaction, these results show good promise for the heterogenation of homogeneous reactions with all perspectives for potential industrial applications.

The catalytic properties of C_8K and related intercalation compounds have been described in detail in relevant review articles.[38]

4.8. Miscellaneous

Finally, a few recent, potentially important applications of highly reactive metals in organic chemistry will be commented on. The first concerns the successful conversion of α,α'-dihalogeno-*o*-xylene derivatives into highly reactive xylylenes (**91** → **92**, Scheme 60) by activated nickel at room temperature; the xylylenes **92** can function as dienes for Diels–Alder reactions. Such metal-induced 1,4-dehalogenations are compatable with OMe, Br, and CN groups on the arene.[150]

Vedejs et al. report on reductive desulfenylation of a cyclic sulfide by treatment with $MeO^+BF_4^-$ and Rieke zinc in their total synthesis of zygosporin E.[151]



91 **92**

Scheme 60. Synthesis of xylylenes **92**: [a] Rieke Ni, THF, room temperature.

A more recent work describes the reduction of the triple bond of conjugated enynes and of propargyl alcohols to (*Z*) alkenes with Rieke zinc in THF/MeOH/H_2O at 65 °C. These reactions occur in high yields and with very good stereoselectivity, and proceed without overreduction to the alkane, which is difficult to avoid in catalytic hydrogenations on a Lindlar catalyst. Isolated alkyne groups are, however, inert under these conditions.[152]

6. Summary and Outlook

Today, a rich reservoir of methods of metal activation of various efficiency and demand are at the synthetic chemist's disposal. High reactivity of a metal in no way means unselective activity toward organic substrates. On the contrary, some of the results presented here prove that it is the availability of reactive metal samples that allows sensitive and/or highly substituted compounds to be selectively transformed. The exceptional performance of these synthetic tools not only resulted in substantial improvements of numerous classical processes, but also in the development of hitherto unknown reactions. Because of the amazingly high compatability with diverse functional groups these methods should find increasing attention in natural product chemistry and other multistep syntheses.

However, a certain backlog exists regarding the characterization of the metal powders generated in different ways. Without an in-depth consideration of the solid-state chemical aspects of metal-induced reactions and the increased use of modern analytical techniques to answer the associated physico-chemical questions, a better understanding and, consequently, a rational design of highly reactive metals are not to be expected. In view of the wealth of metals in the periodic system and of the reactions effected by them this topic may well continue to be of some importance in the future.

I sincerely thank all my co-workers and colleagues, whose enthusiasm has contributed considerably to the success of the "Graphite Project". Their names are to be found in the literature citations. Special thanks are due to Prof. Dr. H. Weidmann for his continuous advice. Our studies were financially supported by the Fonds zur Förderung der Wissenschaftlichen Forschung, Vienna, and by the Jubiläumsfonds der Österreichischen Nationalbank.

Aminoacyl-tRNA Synthetases: The Division into Two Classes Predicted by the Chemistry of Substrates and Enzymes

By Friedrich Cramer* and Wolfgang Freist*

In biological systems, almost all chemical reactions are catalyzed by enzymes. In order to understand the mode of action of these biocatalysts, we need to know precise details of their structures, their active sites, and their functional groups. Most important are those parts of the protein molecule that are responsible for precise recognition of the substrates, for the specific interaction between the enzymes and their reactants. Decades can pass between the isolation of an enzyme and the determination of its exact structure by X-ray analysis. For the chemist, however, means are known by which initial information may be gathered relatively quickly: the synthesis of modified substrates and affinity labeling. During the last twenty five years these two methods have been put to the test on aminoacyl-tRNA synthetases. Today, we know enough about the structures of these enzymes to evaluate the success of this "chemistry on macromolecules," or their substrates. Chemists have had some successes, which provided the structural analysts with valuable preliminary results.

1. Introduction

Aminoacyl-tRNA synthetases make up an important part of the translation apparatus, which transforms the information stored in the nucleotide sequences in every cell into the amino acid sequences of protein. They catalyze the esterification of a particular transfer-RNA (tRNA) with a particular amino acid. In the first reaction step, amino acid **1** and ATP **2** react to form an enzyme-bound aminoacyl-adenylate **3** [Eq. (a)]; the "activated" amino acid **3** is esterified in a second step with one of the two terminal OH groups of the tRNA[1-3] [Eq. (b)].

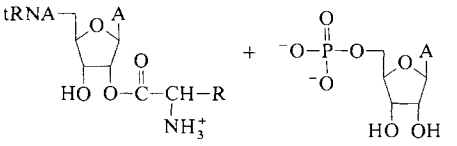
3 **5**

(b)



aa-tRNA AMP

6 **7**

Both steps make great demands on the specificity of the enzymes; they must recognize one particular amino acid from 20, some very similar with one another, and must select one particular tRNA from 40-60 (also very similar tRNA molecules), since otherwise faulty and possibly functionless proteins will be synthesized.

The high specificity of the aminoacyl-tRNA synthetases aroused great interest amongst chemists soon after the discovery of the enzymes, particularly with regard to their catalytic mechanism, the functional groups involved, and the position of the active site within the protein molecule. Thus, long before the structures of the enzymes were elucidated, modified substrates were synthesized, in order to identify the groups of atoms important for substrate recognition. At the same time, the essential groups in the active site were sought with affinity labeling.

2. Primary Structures of the Aminoacyl-tRNA Synthetases

Soon after the isolation of the first aminoacyl-tRNA synthetases, work began on determining their amino acid sequences by using the classical methods of protein sequencing. But even before a primary structure had been completely elucidated in this way, the route via sequencing of the synthetase genes proved to be quicker and more profitable. Thus, the partial structures obtained by Edman degradation of the isoleucyl-tRNA synthetase (containing 939 amino acids) from *Escherichia coli*[4, 5] were confirmed and completed with data obtained by DNA sequencing.[6] Despite the advances in the technique of gene sequencing, classical Edman degradation has not become redundant, since it has proved useful also to sequence a part of the protein by the

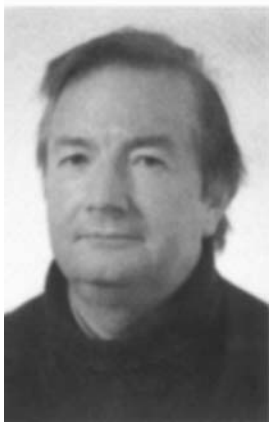
classical method. In this way a check is maintained that the individual amino acids of the protein sequence have indeed been assigned the correct nucleotides as triplets of the genetic code.[7]

In the meantime, all primary structures of the aminoacyl-tRNA synthetases, or their genes, are known from *E. coli*, and most of them are also known for the enzymes isolated from yeast. They are stored in accessible data banks such as the European Molecular Biology Organization (EMBO) library in Heidelberg, or the Genebank in Los Alamos. In solution, the enzymes are either monomeric (α) or exist as dimers with a quaternary structure of the type (α_2), or in one and two cases, respectively, as α_4 or $\alpha_2\beta_2$ (see Table 1).[8, 9] The molecular weights of the α units vary between 37000 and 126000, corresponding to about 300 and 1100 amino acid residues, respectively. Very few similarities were found between synthetases specific for different amino acids, but from the same organism, or from different organisms, but specific for the same amino acid. In most cases only about 20% of the amino acid residues were identical, after the total sequences had been suitably aligned with each other.[10]

2.1. Classification into Class I and Class II Enzymes

Despite the low sequence homologies of the synthetase primary structures, it was possible to classify the enzymes into two groups of ten enzymes each, on the basis of relatively short, common, partial sequences, so-called "consensus or signature sequences". These groups were named class I and class II.[11-13]

Adopting one-letter codes for amino acids, the two consensus sequences for class I were named "HIGH" (His-Ile-Gly-His) and "KMSKS" region (Lys-Met-Ser-Lys-Ser). From the three X-ray structure analyses that are available to date, these sequences point to a structural domain which is known as the "Rossman" or "nucleotide binding" fold.[11-19] This has previously been found in several dehydrogenases as the binding site for nicotinamideadeninedinucleotide (NAD^+),[20] and generally consists of two halves, each comprising three (or two) parallel β-strands, and two (or three) α-helices (Fig. 1). In all the class I aminoacyl-tRNA synthetases studied to date, the binding sites for ATP or the aminoacyladenylate and for the C-C-A end of the tRNA lie in this region.[11-19] An example of the structure of a class I synthetase is shown in Figure 2, the methionyl-tRNA synthetase of *E. coli*.[17] In this case, the complete, dimeric synthetase molecule could not be crystallized, but only a monomeric tryptic fragment which, although it was missing 125 *C*-terminal amino acid residues, nonetheless possessed complete enzymatic activity.[17, 26] The methioyl-tRNA synthetase consists of two domains and a *C*-terminal polypeptide. The first, *N*-terminal domain contains the "Rossman" fold, comprising six parallel β-strands and five α-helices (amino acid residues 1-360). The second domain (positions 361-525) consists predominantly of α-helices; the *C*-terminal polypeptide, which extends to position 551, is partially folded back in the direction of the *N*-terminus, and thus



Friedrich Cramer, emeritus Director at the Max-Planck-Institut (MPI) for Experimental Medicine in Göttingen, honorary Professor at the Universities of Göttingen and Braunschweig, was born in 1923. He studied chemistry in Heidelberg from 1944-1949, where he received his doctorate under the supervision of K. Freudenberg and habilitated in 1953. In 1953 and 1954 he was a guest docent at the University of Cambridge (UK), and in 1959 he was appointed Professor at the Technische Hochschule Darmstadt (FRG). From 1962 to 1991, he was Director at the MPI in Göttingen. He is a scientific member of the Max-Planck-Gesellschaft and a member of the Göttingen Academy of Science, the Heidelberg Academy of Science, the Polish Academy of Science and the European Molecular Biology Organization as well as an Honorary Fellow of the American Society of Biological Chemists. In 1990 he received the Bavarian state prize for Literature (Karl-Vossler-Prize) and in the same year the Kopernikus Medal of the Polish Academy of Science. He is the main author of approximately 400 publications and a series of books on a wide variety of topics including inclusion compounds, the synthesis of nucleic acids, the structure of transfer-ribonucleic acids, protein biosynthesis, molecular genetics and cell-cell specificity.

Wolfgang Freist, born in 1940, in Bremen, studied chemistry at the University of Kiel, where he received his doctorate in 1968 under the supervision of R. Greve for work concerning alkaloids. Since 1968 he has been a member of the Department of Chemistry at the Max-Planck-Institut for Experimental Medicine in Göttingen. His fields of interest include the syntheses of modified nucleotides as substrate analogues, the substrate specificity of enzymes of protein biosynthesis and enzyme kinetics.

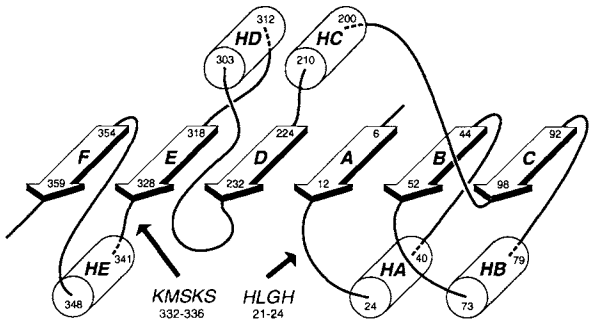


Fig. 1. Schematic diagram of the *N*-terminal domain of *E. coli* methionyl-tRNA synthetase. It displays the Rossman fold typical of class I synthetases, in which the binding sites for ATP and the C-C-A end of the tRNA are found. The numbers correspond to the number of the amino acids, beginning at the *N*-terminus. In this region of the enzyme one also finds the typical consensus sequences for class I, KMSKS and HIGH (HLGH in methionyl-tRNA synthetase). The β-strands (A,B,C,D,E,F) and helices (HA, HB, HC, HD, HE) are named as usual manner for methionyl-tRNA synthetase; for sheet F and for helix HE it is not clear whether they can generally be counted as part of the nucleotide binding fold [17]. (The diagram is a modified version of Figures 2, 3, 1 and 7 in references [16, 17, 103, 104].)

connects the *C*-terminal polypeptide with the *N*-terminal domains.

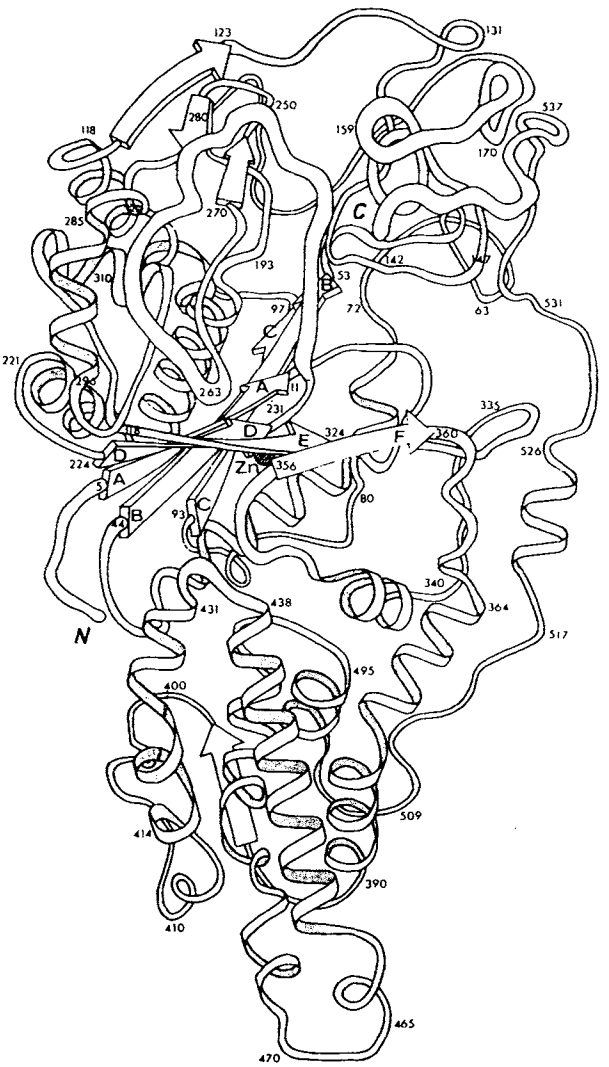

Fig. 2. Schematic diagram of the structure of a tryptic fragment of the methionyl-tRNA synthetase from *E. coli*, taken from ref. [17].

The synthetase structures known to date have recently been discussed in a review article by Moras.[21] Class I contains the synthetases that are specific for valine, leucine, isoleucine, glutamic acid, glutamine, arginine, tyrosine, tryptophan, methionine, and cysteine (Table 1). A more detailed comparison of the structure and sequence allows the class I enzymes to be further divided into three subclasses,[13] which here will be called Ia, Ib, and Ic. Subclass Ia consists of the tyrosyl- and arginyl-tRNA synthetases, subclass Ib contains the glutaminyl-, glutamyl-, and tryptophanyl-tRNA synthetases, while subclass Ic comprises those enzymes which react with leucine, isoleucine, valine, methionine, and cysteine.

The class II enzymes have three "sequence motifs" in common, called motifs 1, 2, and 3; however, two enzymes show motif 3 only (Table 1).[11, 12] Each motif has a prerequisite amino acid at its center. In motif 1 this is a prolyl P; "before" it are two, single, hydrophobic residues ϕ, each followed by two random aminoacyl groups x, and at the start of the motif is usually a glycyl g. "After" the proline residue one finds two hydrophobic groups ϕ:

gϕxxϕxxP$\phi\phi$ motif 1

Motif 2 consists of two parts. The first begins with a phenylalanyl F, tyrosyl Y, or histidyl H, followed by an unchangeable, central arginyl R, a variable residue x, and a glutamyl E, or aspartyl D:

(F/Y/H)Rx(E/D) motif 2, part 1

The second part of the motif begins between four and twelve aminoacyl groups "upstream", and consists of an arginyl R or histidyl H, followed by three variable residues x, and an unchangeable, central phenylalanine F. This is followed by three variable groups x, and an aspartyl D, or glutamyl residue E:

(R/H)xxxFxxx(D/E) motif 2, part 2

Motif 3 begins with the acyl residue of a short-chain amino acid λ, followed first by a variable x and a hydrophobic residue ϕ, and then by two pairs of the common glycyl residue g and a hydrophobic one ϕ. In front of the central arginyl R there is usually a glutamyl e (where the small letter means that this group can be varied), and the end of the motif consists of four hydrophobic residues ϕ:

λxϕgϕgϕeR$\phi\phi\phi\phi$ motif 3

The X-ray structure analyses of class II enzymes which are available, namely those of seryl-tRNA synthetase from *E. coli* and aspartyl-tRNA synthetase from yeast, show that the molecules are constructed of two domains, an *N*-terminal, "helical" domain, and a *C*-terminal, "catalytic" domain.[22-24] The three characteristic motifs are all found in the catalytic domain, which is built up around a heptastranded antiparallel β-pleated sheet[22-24] (Fig. 3). In Figure 4 the structure of the seryl-tRNA synthetase from *E. coli* is presented as an example.[23, 25] This enzyme belongs to the α_2 quaternary structure type, and each of the two subunits con-

Table 1. Classification of the aminoacyl-tRNA synthetases in classes and subclasses (the further subclassification of the enzymes is indicated by the broken line in row four and corresponds to a further subclassification after precise sequence comparisons [13,25]), as well as quaternary structures, aminoacylation positions, specificity in relation to the ATP analogues **A** (base modified) and **B** (sugar modified) and evolutionary tree of the aminoacyl-tRNA synthetases after sequence comparisons. s denotes that the substance for the corresponding enzyme is substrate. i denotes that the substance acts an inhibitor. A dash shows that the substance is neither a substrate nor an inhibitor.

sists of 430 amino acid residues. The structure reveals a *C*-terminal, catalytic subunit of 330 amino acid residues, which contains the heptastranded β-pleated sheet; the 100 *N*-terminal amino acid residues form a long arm, built up of two antiparallel helices. The active site is presumably formed from parts of the β-pleated sheet and of the connecting, single strands. An unstructured single strand which contains motif 2 appears to form a flexible "cap" over the active site.[25]

Motif 1 probably has only indirect importance for the active site through stabilization of its conformation.[23] From a

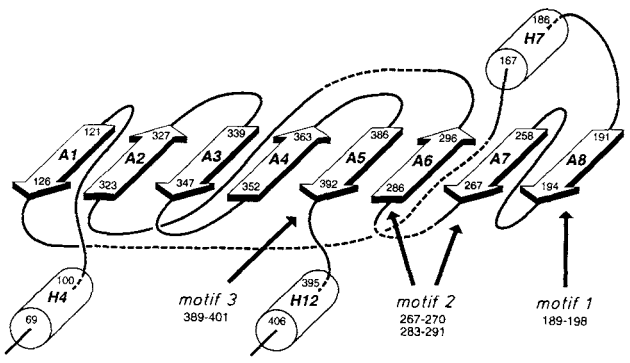

Fig. 3. Schematic diagram of the *C*-terminal, catalytic domain of the seryl-tRNA synthetase from *E. coli*. It is constructed of seven antiparallel β-strands, a structure considered typical of class II aminoacyl-tRNA synthetases. In the shaded regions, differences are found between this structure and that of the only other class II synthetase yet determined by X-ray crystallography, aspartyl-tRNA synthetase from yeast. The *C*-terminal domain of the enzyme contains the typical sequence motifs for class II. The numbers correspond to amino acids, numbered from the *N*-terminus; the nomenclature for strands and helices is the usual one for seryl-tRNA synthetase. (The diagram is based on Figures 7, 5, and 1 in refs [23, 24, 25]).

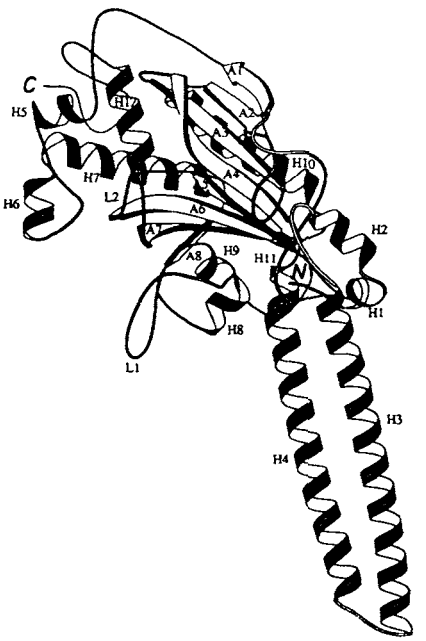

Fig. 4. Schematic diagram of the structure of *E. coli* seryl-tRNA synthetase; from ref. [25].

comparison of the seryl-tRNA synthetase amino acid sequence with those of other class II enzymes,[25] motif 1 is probably responsible for the association of the monomeric subunits of the enzyme to the α_2 quaternary structural type; the class II enzymes with four subunits generally lack this motif (see Table 1). Motifs 2 and 3, by contrast, are likely to be parts of the catalytic center presumed to be located in the *C*-terminal domain.[25] Comparison of the amino acid sequences of the class II enzymes also gave rise to a more detailed subdivision into subclass IIa, comprising the enzymes specific for serine, threonine, proline, and histidine, subclass IIb, comprising the tetrameric enzymes specific for aspartic acid, asparagine and lysine, and subclass IIc, comprising tetrameric enzymes specific for phenylalanine, glycine, and alanine (see Table 1).[25] Of the latter, the phenyl- and glycyl-tRNA synthetases show partial similarity with the enzymes of subclass IIb, while alanyl-tRNA synthetase has homologies to those of subclass IIa (see Table 1).

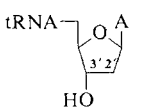
3. Synthetic Substrate Analogues

Influenced by Emil Fischer's "lock and key" model for enzyme–substrate interactions, chemists have long been synthesizing analogues of enzyme substrates, hormones, antibiotics, and plant substances. This has led not only to the development of new, highly potent pharmaceuticals, but has also yielded understanding of the mechanisms of enzyme-catalyzed reactions, and of the structures of substrate binding sites or receptors for hormones and pharmaceuticals.

Since aminoacyl-tRNA synthetases transform three substrates, they offer many possibilities to affect the course of catalysis by introducing chemical modifications in the substrates. Conclusions about the classification of the synthetases into different classes can only be expected from analogues of common substrates, such as ATP or the C-C-A end of the tRNA; amino acid derivatives can only yield information about their specific synthetase.

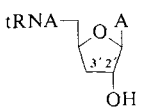
3.1. tRNA Analogues

Experiments with modified tRNAs proved to be unusually informative for detailed elucidation of the mechanism of the aminoacylation, and, as can now be seen, also for the classification of the synthetases. The terminal adenosine unit of these tRNAs **8**–**11** either lacks one of the free hydroxyl groups, or is replaced by an amino group.[26–32]



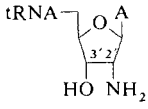
2'-deoxy-tRNA

8



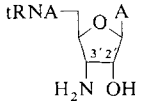
3'-deoxy-tRNA

9



2'-deoxy-2'-amino-tRNA

10



3'-deoxy-3'-amino-tRNA

11

These tRNA analogues were not, however, synthesized by direct chemical modification of the tRNA, but by enzymatic incorporation of the altered, terminal nucleotide N (as triphosphate NTP) after enzymatic removal of the terminal adenosine monophosphate of the tRNA[26–32] [Eq. (c)].

$$\underset{\textbf{12}}{\text{tRNA–C–C}} \xrightleftharpoons{\text{tRNA-Nucleotidyl-transferase, NTP}} \underset{\textbf{13}}{\text{tRNA–C–C–N}} + \text{PP}_i \qquad \text{(c)}$$

It was found that almost all the synthetases esterified only one of the two deoxy or amino-tRNAs with the amino acid (see Table 1).[26–32] From this it was concluded that the naturally occurring tRNA in the cell is also charged on only one of the OH groups of the terminal ribose, and that the primary product isomerizes spontaneously to give a mixture of the 2'- and 3'-*O*-aminoacyl esters.[32–34] When the synthetases were classified into 2'- and 3'- "chargers" (information obtained by modification of the tRNAs), an astonishing agreement was found with the classification into class I and class II enzymes: the class I synthetases esterify the tRNA on the 2'-OH group, while the class II synthetases use the 3'-OH group (see Table 1). This characteristic must therefore be defined by the principally different structure of the two aminoacyl-tRNA synthetase groups. The only exceptions are the phenylalanyl-tRNA synthetase which, as a class II enzyme, charges the 2'-OH group of the ribose, and the cysteinyl- and tyrosyl-tRNA synthetases, which appear to be able to esterify both groups.

Attempts to explain the observed 2',3'-specificity of the aminoacyl-tRNA synthetases, however, remained inconclusive. A speculative model published in 1983[35] considered the observation made on crystalline tyrosyl-tRNA synthetase; if it is alone in solution, AMP can also bind to the tyrosine binding site.[36] This finding led to the assumption that the adenosine monophosphate moiety of the aminoacyladenylate could also, possibly, bind both to the nucleotide and the amino acid binding sites. The change in position of the aminoacyladenylate thus made possible, could bring the carbonyl group of the aminoacyl residue into proximity of either the 2'- or the 3'-OH group.

The first X-ray structure analyses of complexes of tRNA, synthetase, and ATP, which are now available for the glutaminyl system (class I)[19] and the aspartyl system (class II)[24] show, however, that this cannot be the case.

The glutaminyl-tRNA synthetase, a monomeric enzyme built up of 553 amino acid residues, was crystallized as a complex with its cognate tRNA and ATP.[19] The X-ray structure analysis of this complex showed that the enzyme consists of four domains, of which three appear to be responsible for recognition of the tRNA, and one contains the active site (cf. Fig. 5). The latter is located at the *N*-terminus, and shows the Rossman fold typical of class I enzymes, consisting here of three β-strands and two α-helices in the first "half", and two β-strands and two α-helices in the second. Both the single strand connecting the two "halves", and the

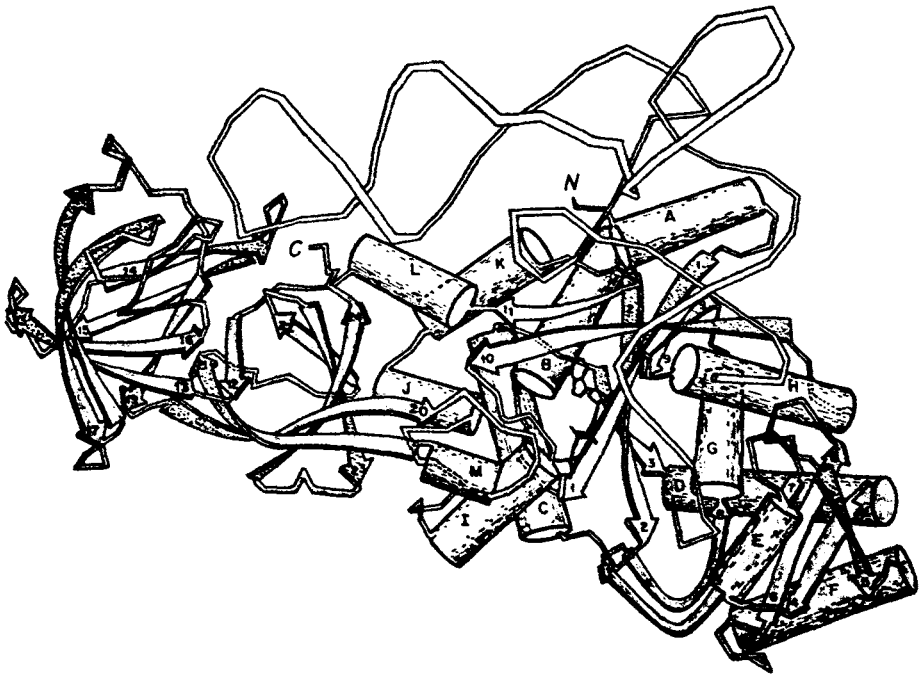


Fig. 5. Schematic diagram of the structure of *E. coli* glutaminyl-tRNA synthetase, complexed with $tRNA^{Gln}$ and ATP; from ref. [19].

second "half" of the Rossman fold are responsible for binding of the tRNA.

The α-phosphate group of the ATP molecule is situated at a distance from the 2′-hydroxy group of the terminal adenosine of the tRNA suitable for hydrogen bonding. The β- and γ-phosphate groups lie close to the two histidyl residues of the HIGH consensus sequence of the class I enzymes.

The first base pair of the aminoacyl acceptor stem of the $tRNA^{Glu}$-cloverleaf structure is opened, and the 3′ end of the tRNA forms a "hairpin" structure in which the unpaired bases form a loop bent back in the direction of the anticodon. The 2′-hydroxyl group of the terminal adenosine is thereby brought into the proximity of the carbonyl group of the glutaminyladenylate.

The aspartyl-tRNA synthetase from yeast, a dimeric enzyme of α_2 quaternary structure, with 557 amino acid residues per subunit, was crystallized as a complex with $tRNA^{Asp}$.[24] The dimeric enzyme binds two tRNA molecules. The X-ray analysis showed that the monomeric unit is composed of two domains, of which the *C*-terminal one contains the active site (cf. Fig. 6). Similarly to the seryl-tRNA synthetase, the catalytic subunit consists of an antiparallel β-pleated sheet surrounded by α-helices, and contains the motifs 1–3 characteristic for class II. Motif 1 causes the dimerization and motifs 2 and 3 the binding of the C-C-A end of the tRNA to ATP.

The C-C-A end of the $tRNA^{Asp}$ has a normal helical structure in the enzyme–tRNA complex. This ought to position the terminal adenosine so that aminoacylation of the tRNA on the 3′-hydroxyl group is made possible.[24] In a figurative sense, then, it is not the change in the position of the aminoacyladenylate which is responsible for the 2′,3′-specificity of the aminoacyl-tRNA synthetases, but that of the terminal hydroxy groups of the tRNA.

Fig. 6. Schematic diagram of the *C*-terminal domain of the aspartyl-tRNA synthetase, complexed with $tRNA^{Asp}$; from ref. [24].

3.2. ATP Analogues

The classification of the aminoacyl-tRNA synthetases, and indeed even a more detailed subclassification, was also carried out in extensive studies on numerous ATP analogues, before the elucidation of the first primary structures.[37–43] Since these results have already been described in detail elsewhere[3, 42, 43] only a few particularly characteristic findings that are important for the classification of the enzymes will be mentioned here (see Table 1). The clearest distinction between classes I and II is seen in the behavior of tubercidin triphosphate (TuTP) in the aminoacylation reaction (see Table 1). This modified ATP, in which the nitrogen atom in position 7 of the purine system is replaced by a carbon atom, can replace ATP as a substrate for the class I enzymes; for tryptophanyl-tRNA synthetase, however, it acts as an inhibitor (see Table 1). From six further ATP analogues, whose specificities are presented in Table 1, subclass Ib can be clearly distinguished from subclasses Ia and Ic. Even the possible

subdivision of subclass Ib, by which tryptophanyl-tRNA synthetase is separated from glutamyl- and glutaminyl-tRNA synthetase on the basis of the length of the the so-called "CP1" sequence,[13] is hinted at in the specificity table.

In class II, the subclasses IIb and IIa reveal the same specificities, with the exception of prolyl-tRNA synthetase. In the subclass of tetrameric enzymes, IIc, glycyl- and phenylalanyl-tRNA synthetases show the same ATP specificity as the enzymes of subclasses IIa and IIb. This agrees with the observation derived from sequence comparisons, that these proteins are related to subclass IIa.[25] Alanyl-tRNA synthetase, in contrast, displays the same specificity pattern as prolyl-tRNA synthetase, which is the single exception in subclass IIa. Here it should be mentioned that on the basis of sequence comparisons, alanyl-tRNA synthetase possesses a certain resemblance to the enzymes of subclass IIa.[25]

With the help of detailed sequence comparisons, the first trees have now been developed which show the evolutionary relationships between the two classes of aminoacyl-tRNA synthetases.[44] Since each of the two groups contains members of the entire spectrum of amino acid types (hydrophobic, basic, acidic), one can assume that today's system of twenty amino acid–synthetase pairs developed from two independent families of ten each. The evolutionary trees for classes I and II are shown in Table 1. They are also in good agreement with the classification that was developed earlier from the ATP specificities. The only exception in class I is the relationship between the tryptophanyl- and tyrosyl-tRNA synthetases, while in class II there are two exceptions, alanyl- and prolyl-tRNA synthetase, these are not related to each other but to the histidyl and threonyl enzymes, respectively. However, since the specificities towards ATP analogues probably depend on a small number of amino acid residues which are crucial for binding, divergences from relationships which are found by comparison of longer sequences are not unusual. All in all, the findings worked out from modified tRNA's and ATP analogues agree very well with the classification arrived at later by sequence comparison.

3.3. Amino acid analogues

Exact recognition of the amino acids by the aminoacyl-tRNA synthetases is a prerequisite for the biosynthesis of functional proteins. The first experiments on the in vivo specificity of protein biosynthesis showed that valine, isoleucine, leucine, tyrosine, and phenylalanine are replaced by each other in less than one in 3000 cases.[45] In more recent work, however, error rates of 1:100 to 1:1000 have been found for the exchange of arginine and tryptophan for cysteine.[46] The specificities of individual enzymes has been studied with respect to the twenty amino acids that occur naturally in proteins, and error rates both higher and lower than those mentioned above have been determined.[47-52] In contrast, amino acids that do not occur naturally seem to be distinguished less well in principle from the cognate substrates normally transformed by the enzymes.[45, 53] Clearly, the high specificity of the aminoacyl-tRNA synthetases has developed during the course of biological evolution primarily towards the twenty natural amino acids.

Systematic studies of the substrate characteristics of noncognate amino acids with individual enzymes can only ever yield information on the topography of the amino acid binding site of the protein concerned. Nonetheless, unifying principles of amino acid recognition can be determined, which may also divide classes I and II.[48-52]

According to the so-called "Stopper-model", four class I enzymes, whose amino acid specificity has been studied in detail, possess an amino acid binding pocket, which allows a particularly "tight" packing, and leads to strong hydrophobic interactions.[48-52, 54] The binding pocket is limited in length by an organic group or an amino acid side chain. In addition, other side chains extend into the binding pocket, and must be "pushed to the side" on binding of the substrate. Noncognate amino acids also displace the size-limiting group, and possibly others. The binding energy for the amino acid side chain is composed of positive energy contributions from hydrophobic interactions and, when possible, hydrogen bonding, and of negative contributions arising from the necessary displacement of the groups of atoms projecting into the binding site. In this model, the amino acid is so to speak assessed the by "fingers" of the protein. Noncognate amino acids either achieve fewer hydrophobic interactions, cannot form the corresponding hydrogen bonds, or have to displace additional amino acid side chains from their positions (Fig. 7). Their binding energy can be predicted to

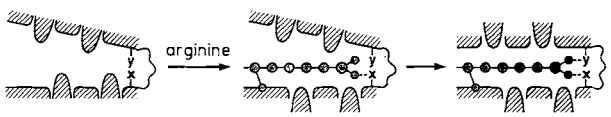

Fig. 7. Schematic diagram of the binding of arginine to arginyl-tRNA synthetase, as an example of one of the four class I enzymes studied. The binding takes place in two steps.

a good approximation by using the laws found for the natural amino acids.[48-50]

For all of the class I enzymes that have been studied in detail, kinetic and stoichiometric data lead to the conclusion that amino acid binding takes place in two steps (Fig. 7).[48-52] The first binding step is probably followed by a conformational change in the enzyme,[55] which leads to the structure described as "especially dense packing",[48-52, 54] which has strong hydrophobic interactions. These are approximately twice as strong as those otherwise found in the literature, 25 cal $Å^{-2}$ (10.5 kJ nm^{-2}).[56-58]

However, in addition to the "assessing" of the amino acid by the specific binding site, two hydrolytic test steps are also responsible for the amino acid specificity. In these, aminoacyladenylates of noncognate amino acids and the aminoacyl-tRNA's formed from them can be rehydrolyzed.[48-52] In most cases the first, pretransfer–correction step is predominant, while the second, posttransfer step plays virtually no role.

Of the class I enzymes, only the lysyl-tRNA synthetase has been studied in detail with respect to its amino acid specificity. It also performs the two hydrolytic correction steps, although rather less effectively.[59] The binding of the amino acid seems, however, to occur in a single step, and the binding site presumably already has a structure with dense pack-

ing (Fig. 8).The entire recognition process consists of only three steps, rather than four as in the class I enzymes. The specificity of the lysyl-tRNA synthetase towards noncognate amino acids is significantly less than that of the studied class I enzymes, but it is too early to tell whether similar results may be expected for all the class II enzymes, and whether this is a general difference between the class I and class II enzymes.

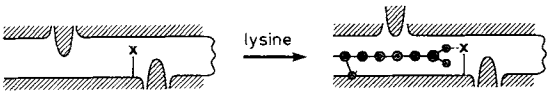

Fig. 8. Schematic diagram of the binding of lysine to lysyl-tRNA synthetase, the only class II enzyme yet studied in a similar manner to the four class I enzymes. Binding takes place in one step.

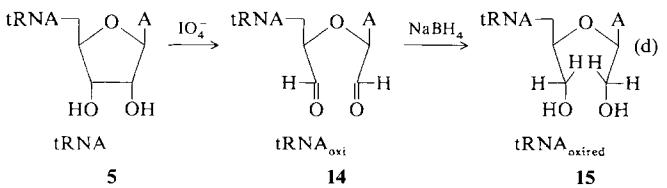
4. Affinity labeling

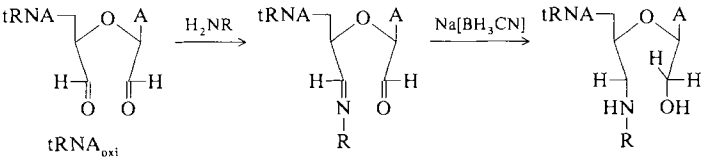
In order to determine which parts of the enzyme molecule are essential for specific substrate recognition, substrate molecules were provided with reactive groups capable of forming a covalent bond between substrate and enzyme. Partial degradation or sequencing of labeled enzymes can then be used to obtain information about which subunit or amino acid of the enzyme is responsible for binding the reactive group of the substrate. Here one assumes, not always quite correctly, as will be shown below, that the enzyme is labeled predominantly at the substrate binding site.

Successful experiments have been carried out with modified tRNAs and ATP analogues containing reactive halogen atoms such as bromine in bromoacetates,[60, 61] or chlorine in *N*-chloroethyl groups,[62] or with the azide group in *p*-azidoanilide residues.[62-65] Further reactive groups which have been used less frequently include 5,5′-dinitro-2,2′-dithiodibenzoate and *p*-nitrophenylchloroformate,[66] ^{3}H-labeled acetic anhydride,[67] pyridoxal phosphate,[68] 2,4,6-trimethylbenzoyl-AMP ("mesitoyl-AMP")[69] 3,3′-dithiobis(succinimidopropionate,[70] and adenosine(5′)triphospho(5′)pyridoxal **18** (see Section 4.3).[71] Covalent bonds in tRNA synthetase complexes have also been obtained by direct irradiation with UV light; these bonds probably arise between the bases of the nucleotides and the SH groups of the proteins.[72, 73]

The most informative experiments, however, were carried out with the dialdehydes **14** obtained by periodate oxidation of ATP **2** and tRNA **5**.[74-91] These aldehydes were originally reduced with sodium borohydride in order to obtain ATP and tRNA derivatives with a cleaved C2′–C3′ bond **15** [Eq. (d)].[92, 93]



5 **14** **15**



14 **16** **17**

On affinity labeling, the aldehyde groups react with the amino groups of lysine side chains to form Schiff bases **16**. These are then reduced to the amines **17** with sodium cyanoborotrihydridoborate,[80] to stabilize the label.

These stable, covalently bound labels survive degradation of the proteins and allow the identification of the single, reactive lysine side chain concerned.

The following sections will primarily discuss the results obtained with these dialdehyde-affinity labels.

4.1. Labeling with $tRNA_{oxi}$

The first results obtained from affinity-labeling experiments with the dialdehydes synthesized from tRNAs pertained to the composition of the enzyme–tRNA complexes. For methionyl- and tyrosyl-tRNA synthetases (quaternary structure α_2), the complexes found were composed of one covalently bound tRNA and the dimeric enzyme;[78, 84, 85] for leucyl-tRNA synthetase (quaternary structure α), one oxidized tRNA ($tRNA_{oxi}$ **14**) was found per monomeric enzyme.[90] In contrast, arginyl-tRNA synthetase (quaternary structure α) forms not only a 1:1 complex, but also approximately equal quantities of a compound consisting of two $tRNA_{oxi}$ units and the enzyme.[91] For the tetrameric phenalanyl-tRNA synthetase (quaternary structure $\alpha_2\beta_2$) two $tRNA_{oxi}$ were found to be bound; the bond was first postulated to be to the small β subunit,[79, 83] and later to the larger α subunit.[86]

A comparison of these stoichiometric ratios with values obtained by other methods is most interesting. The formation of an enzyme-tRNA complex in a ratio 1:1 was also found for the methionyl-tRNA synthetase by using fluorescence spectroscopy.[94] For tyrosyl-tRNA synthetase, anticooperative binding (i.e. binding hindered in the second step) of two tRNA molecules per enzyme molecule was found in one binding study between tRNA and enzyme,[95] while in another study, under catalytic conditions (i.e. in the presence of all three substrates), only one tRNA molecule was found to bind per enzyme molecule.[96] From a fluorescence titration, a stoichiometry of 1:1 was determined for the binding of tRNA to the arginyl-tRNA synthetase enzyme.[97] Here it is noteworthy that with $tRNA_{oxi}$, compounds are also formed from two $tRNA_{oxi}$ molecules and one enzyme molecule of quaternary structure α. This might confirm the possibility that even the monomeric enzymes operate in catalytic cycles, in the course of which two tRNA molecules can bind to the enzyme. Such cycles have until now only been postulated, on the basis of kinetic studies with, for example, isoleucyl-tRNA synthetase.[3, 98, 99] For methionyl-tRNA synthetase, the value of two bound tRNA molecules per enzyme molecule obtained by physical methods[99-101] agrees with the ratio obtained by affinity labeling.

For alanyl-,[87] phenylalanyl-,[86] tyrosyl-,[85] and methionyl-tRNA synthetases[88] even the individual amino acid to which the $tRNA_{oxi}$ covalently binds has been identified. In most cases it is a lysyl residue,[85-88] in some cases, though, an arginyl residue.[88] As expected in advance by critics of the method, the $tRNA_{oxi}$ is not bound to a single amino acid residue by the individual enzymes, but in several positions.[84-86,88] However, in the cases where an X-ray structure analysis of the enzyme is available (Tyr, Met),[85,88] the labeled amino acids are spatially not far apart.

After covalent binding of $tRNA_{oxi}$, the tyrosyl-tRNA synthetase from *E. coli* loses both its so-called ATP-pyrophosphate exchange ability (the reverse of the activation reaction [Eq. (a)]) and its ability to catalyze the aminoacylation of $tRNA^{Tyr}$.[85] Degradation of the labeled enzyme with chymotrypsin and degradation of the tRNA with ribonuclease A leads to isolation of two oligopeptides (positions 227-235 and 236-244) containing covalently bound adenosine. In the first peptide, which contains two lysyl residues (positions 229 and 234), it is primarily lysine 234 that reacts, and lysine 229 is less active. In the second peptide the sole lysine present (lysine 237) is completely labeled.

Comparison with the structure determined by X-ray diffraction of tyrosyl-tRNA synthetase from *Bacillus stearothermophilus*,[14,15] shows that the labeled lysyl residues belong to an unstructured part of the sequence which connects the *N*-terminal α/β-domains and an α-helical domain. The former contains the mononucleotide binding site, while the second is responsible for binding of the tRNA. The intervening portion containing lysine (and hence positively charged) is suitable for binding of the C-C-A end of the $tRNA^{Tyr}$, both because of possible interactions with the negative charges of the tRNA and because of its position. The lysyl residue 229 belongs to the KMSKS sequence which is characteristic of class I enzymes.

The fact that $tRNA^{Tyr}_{oxi}$ can react with three different lysyl residues suggests that several lysyl residues may be involved in binding of the C-C-A end, but also that it is not strongly fixed in the enzyme-tRNA complex and possesses a certain mobility, made possible by conformational changes in the tRNA, the enzyme, or both.

Similar results have also been obtained by affinity labeling of methionyl-tRNA synthetase with $tRNA^{fMet}$, which is specific for formyl methionine.[78,84,88] After reaction of the enzyme with $tRNA^{fMet}_{oxi}$, the resultant 1:1 complex loses its ability to catalyze ATP-pyrophosphate exchange and to charge the tRNA.[78] Digestion with chymotrypsin and Ribonuclease A yields three oligopeptides, which contain a covalently bound adenosine arising from the tRNA. Two of these contained one completely labeled lysyl residue (positions 61 and 335), while in the third oligopeptide fraction one of the lysyl residues 142, 147, or 149 was labeled. All of these lysyl residues belong to the *N*-terminal domain of the enzyme (position 1-360), which contains the nucleotide binding site fold; lysine 335 is part of the KMSKS signature sequence. According to the X-ray structure analysis of the crystallized enzyme, all the lysine residues lie within a radius of 5.5 Å ($\approx$ 1/10 of a domain radius), thus in this case it is possible to draw conclusions concerning the relative mobility of the C-C-A end of the tRNA in the enzyme-tRNA complex.

The amino acid residues that react with oxidized tRNA have been determined not only for the class I enzymes specific for tyrosine and methionine, but also for the phenylalanine and alanine-specific class II enzymes. In contrast to the class I enzymes, the class II retain their ability to catalyze ATP-pyrophosphate exchange, despite the presence of covalently bound tRNA.[86,87] For phenylalanyl-tRNA synthetase the $tRNA^{Phe}_{oxi}$ reacts with three lysyl residues (positions 2, 61, and 106), for alanyl-tRNA synthetase only with one (lysine 73). All of these lysine-positions lie within the *N*-terminal domains of the enzymes. However, since no X-ray structures of phenylalanyl- or alanyl-tRNA synthetase are available, no conclusions can be drawn about the spatial arrangement of the labeled lysyl-residues in the enzyme molecule.

Thus, one is tempted to assume that class I and class II enzymes may also be differentiated on the basis that the class II enzymes retain the ability to catalyze ATP-pyrophosphate exchange despite the covalent binding of a tRNA molecule. However, the number of enzymes studied is still too small for such a statement to be made. In addition, the results obtained with leucyl-tRNA synthetase are contrary to such a conclusion.[90] This class I enzyme appears also to catalyze amino acid activation after reaction with $tRNA^{Leu}_{oxi}$.

4.2. Labeling with ATP_{oxi}

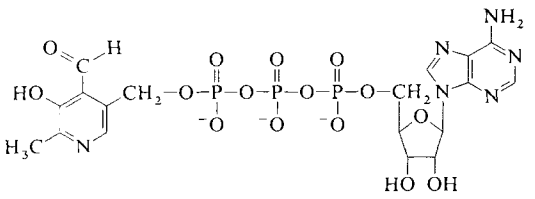
Aminoacyl-tRNA synthetases can also react with ATP oxidized to a dialdehyde,[74,75,77] just as they can with oxidized tRNA. Methionyl-, tyrosyl-, and tryptophanyl-tRNA synthetases (quaternary structure α_2) can no longer catalyze ATP-pyrophosphate exchange after binding of two molecules of ATP_{oxi}.[74] Phenylalanyl-tRNA synthetase (quaternary structure $\alpha_2\beta_2$) is only completely inactivated after binding of the second ATP_{oxi} molecule; isoleucyl-tRNA synthetase (quaternary structure α) is inactivated by binding of an ATP_{oxi} molecule, but if the Mg^{2+} ions required for catalysis were strictly excluded, a second ATP_{oxi} molecule was incorporated into the enzyme.[74]

This affinity-labeling method initially appeared promising, but proved later to be unsuitable. Detailed experiments with lysyl- and phenylalanyl-tRNA synthetases from *E. coli* showed that these enzymes can bind up to five and fifty ATP_{oxi} molecules per enzyme molecule, respectively.[75] Similar effects to those with ATP_{oxi} can also be achieved with oxidized GTP or uridine.[75] One tryptophanyl-tRNA synthetase (quaternary structure α_2) from bovine pancreas was able to form the tryptophanyl adenylate even after binding of two molecules of ATP_{oxi}.[77] From these findings one must conclude that ATP_{oxi} does not react specifically with lysyl residues in the ATP binding site, but additionally or predominantly with other, easily accessible lysyl residues on the enzyme surface.

4.3. Labeling with Adenosine(5′)triphospho(5′)pyridoxal (AP_3-PL)

The ATP derivative **18**, in which the γ-phosphate group of the ATP is esterified to the 5′-hydroxy group of a pyridoxal

unit, proved to be much better suited for affinity-labeling of the ATP binding site.[71] The aldehyde group of the pyridoxal unit can react with lysyl residues in the enzyme in a similar manner to the aldehyde groups of $tRNA_{oxi}$ or ATP_{oxi}.



adenosine(5')triphospho(5')pyridoxal (AP_3-PL)

18

Methionyl- and valyl-tRNA synthetases form a 1:1-complex with this reagent, and lose their ability to catalyze ATP-pyrophosphate exchange and the charging of tRNA.

In methionyl-tRNA synthetase a total of three lysyl residues are labeled, in positions 335, 402, and 528. The first lysyl residue (335) is still in the *N*-terminal domain of the enzyme, and belongs to the KMSKS consensus sequence. It also reacts with $tRNA_{oxi}^{fMet}$ during affinity labeling of the same enzyme. No conclusions can be drawn about the exact role of this lysyl residue during catalysis, but one can assume that it may be important either as a ligand for the C-C-A end of the tRNA, or for the phosphate groups of the ATP, or possibly both.[71]

The lysyl residue 528 is only 4 Å removed from Lys335, according to the X-ray structure analysis of the enzyme, thus its protonated NH_2 group can presumably interact (as can lysine 335) with both the phosphate groups of the tRNA end and those of the ATP. According to the X-ray structure analysis, lysyl residue 402 lies some 30 Å away from the active site of the molecule. It is presumed normally to be involved in binding of the tRNA, and that in this case nucleotides can also be bound instead of the tRNA.

In valyl-tRNA synthetase, three lysyl residues were also registered by the labeling reagent (positions 557, 593, and 909). Of these, lysine 557 once again belongs to the KMSKS consensus sequence. Since no X-ray structure is available for a valyl-tRNA synthetase, nothing can yet be said about the position of the other two lysyl residues in the tertiary structure of the enzyme. It can only be presumed that the *C*-terminal domain of the enzyme is similarly folded to that of the methionyl-tRNA synthetase. A similarity between the tertiary structures of the two class I enzymes is thus suggested, but there is almost no material to support a classification of the aminoacyl-tRNA synthetases on the basis of ATP-affinity labeling.

5. Summary and Outlook

The aminoacyl-tRNA synthetases represent a group of enzymes which are present in every cell and catalyze the same reactions. They are therefore particularly suited for testing the usefulness of experiments with modified substrates or reactive groups mounted on substrate analogues, once sufficient experimental data is available. In each case, systematic studies on a number of enzymes are necessary; however, due to the limits set by material and time, studies are often forced to focus on a few, selected enzymes, as seen here for affinity labeling.

By studying the substrate characteristics of tRNA and ATP analogues, it was possible to define a division of the synthetases into two classes of enzymes more than fifteen years before elucidation of the primary structures, obtained only recently, by gene sequencing. The value of this information was at first underestimated, and is only now discernible to its full extent, by comparisons with X-ray structure analyses. The evolutionary trees derived from the primary structures,[44] according to which the aminoacyl-tRNA synthetases are descended from two "primeval synthetases", provides a simple explanation of the division of the enzymes into two main groups, predicted by us.

Affinity labeling does not afford information in every case about the amino acid residues which are essential for substrate binding, but it almost always provides some indications about the neighborhood of the substrate binding site. Because of the small number of enzymes studied to date, the results from this work do not yet allow any detailed statement on a classification of the synthetases. However, the findings observed so far appear, in part, to confirm the division of the synthetases into class I and class II enzymes.

Despite decades of research, the exact catalytic mechanism of the aminoacyl-tRNA synthetases is still largely unknown. To date, we know neither all the amino acid residues involved in catalysis, nor the conformational changes which occur in the course of the catalytic cycle. Here, substrate analogues which react with specific amino acid residues, yet to be developed, could play an important part in final elucidation.

The knowledge of the structures and complex mechanisms of aminoacyl-tRNA synthetases which has been obtained through simple chemistry, gives one courage to develop these methods further, and also to apply them to other enzymes.

Computer-Assisted Solution of Chemical Problems—The Historical Development and the Present State of the Art of a New Discipline of Chemistry

By Ivar Ugi,* Johannes Bauer, Klemens Bley, Alf Dengler, Andreas Dietz, Eric Fontain, Bernhard Gruber, Rainer Herges, Michael Knauer, Klaus Reitsam, and Natalie Stein

Dedicated to Professor Karl-Heinz Büchel

The topic of this article is the development and the present state of the art of computer chemistry, the computer-assisted solution of chemical problems. Initially the problems in computer chemistry were confined to structure elucidation on the basis of spectroscopic data, then programs for synthesis design based on libraries of reaction data for relatively narrow classes of target compounds were developed, and now computer programs for the solution of a great variety of chemical problems are available or are under development. Previously it was an achievement when any solution of a chemical problem could be generated by computer assistance. Today, the main task is the efficient, transparent, and non-arbitrary selection of meaningful results from the immense set of potential solutions—that also may contain innovative proposals. Chemistry has two aspects, constitutional chemistry and stereochemistry, which are interrelated, but still require different approaches. As a result, about twenty years ago, an algebraic model of the logical structure of chemistry was presented that consisted of two parts: the constitution-oriented algebra of be- and r-matrices, and the theory of the stereochemistry of the chemical identity group. New chemical definitions, concepts, and perspectives are characteristic of this logic-oriented model, as well as the direct mathematical representation of chemical processes. This model enables the implementation of formal reaction generators that can produce conceivable solutions to chemical problems—including unprecedented solutions—without detailed empirical chemical information. New formal selection procedures for computer-generated chemical information are also possible through the above model. It is expedient to combine these with interactive methods of selection. In this review, the Munich project is presented and discussed in detail. It encompasses the further development and implementation of the mathematical model of the logical structure of chemistry as well as the experimental verification of the computer-generated results. The article concludes with a review of new reactions, reagents, and reaction mechanisms that have been found with the PC-programs IGOR and RAIN.

1. Introduction

Chemistry is concerned with the analysis and synthesis of chemical substances, the elucidation of molecular structures, and the reactivity and physical properties of chemical compounds. Apart from the fundamental gain in scientific knowledge, the manifold applications of chemistry justify the endeavors and expenditure of chemical research. The search for compounds with desirable effects, functions, and properties and the development of optimal methods for their synthesis, purification, and quality control are characteristic of research in applied chemistry.

Progress in chemistry is generally due to systematic research. It is evolutionary and takes place in small steps.[1] The rare revolutionary jumps of innovation are produced by new ways of thinking or expertly recognized and systematically exploited, fortunate, incidental observations. Examples are the insight into the significance of conformations[2] by Sachse[3] and Mohr,[4] Meerwein's concept of ionic reaction mechanisms,[5] the discovery of the first organometallic catalysts containing transition elements by Reppe et al.[6a] and Roelen,[7a] the solution of the absolute configuration problem by Bijvoet et al.,[8] and the development of the chemistry of superacids by Olah et al.[9]

For progress in applied chemistry, serendipity and initial misunderstandings can play an important role. Spectacular examples are the introduction of the sulfonamides by Domagk, Mietsch, and Klarer,[10] who thereby revolutionized chemotherapy of bacterial infections, and the discovery of the azole fungizides by Büchel and Plempel[11] that enabled efficient and broad chemotherapy of fungal infections.

The diversity of applications for computers in chemistry reflects the variety in chemical research. They have been used since they have been available and have become indispensable in all areas of chemistry. In 1959 Konrad Zuse,[12] the inventor of the computer, sold the first commercially available machine, the magnetic drum computer Z22, to Bayer AG, who used it partly for scientific purposes.

Initially computers were exploited exclusively for numerical computations, an application that is still on the increase. The term computational chemistry[13-15] is used for such applications, in which the calculation of molecular energy levels and geometries prevails. Their numerical capabilities make computers an indispensable tool of quantum chemistry and analytical chemistry, which include the elucidation of molecular structure by spectroscopic and X-ray methods. However, they are also useful in the determination of properties of substances, the design of experiments, the collection, evaluation, graphic display, and interpretation of experimental data, as well as in the visualization of molecular structures whose atomic coordinates are obtained from measurements, by quantum chemical computations, or by force-field methods.

To a larger extent these applications of computers in chemistry —mostly computations according to fixed "recipes"— can be automated. With the exception of molecular modeling where both the numerical and graphic capabilities of computers are exploited, an interactive participation of the user is not needed.

Many types of chemical problems can, however, not be solved by numerical computations. The solution of these chemical problems requires another kind of approach, incorporating the logical and combinatorial capabilities of computers. This discipline is called computer chemistry.[16-20] The latter term is not too well chosen, but is now widely used.

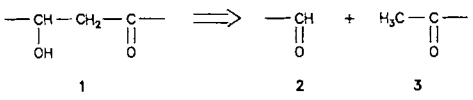
The oldest and best known computer programs for the direct solution of chemical problems serve to design syntheses and elucidate molecular structures from spectroscopic data. The search for synthetic routes or reaction mechanisms and the elucidation of molecular structures from spectroscopic data belong to the "classical" problems of chemistry. The solution of such problems involves finding molecules that have certain characteristic chemical features. Generally, the classical chemical problems have a significant combinatorial aspect, and have many solutions that cannot be obtained by numerical computations, although such computations may be of indirect use.[21] The best solutions are often found by intuition, creative thinking, or trial and error. The computer-assisted solution of chemical problems requires the interactive participation of the user, because there are always many potential solutions and no generally applicable rules. Therefore, a nonarbitrary selection of the practicable solutions is needed. The methods for solving such problems are, as a rule, nondeterministic in nature.

Joshua Lederberg and George Vleduts, who died in 1990, are the founding fathers of computer chemistry. Lederberg[22] initiated the DENDRAL project[23] to develop a computer program that determines the significant structural features of a molecule from spectroscopic data and then assembles its complete structure from its substructures.[24] Although, the DENDRAL project was terminated before all its goals were achieved, it nevertheless represents an important milestone in the development of computer chemistry.[13] It was the first computer program that exploited formal means for the solution of chemical problems. DENDRAL also promoted the notion artificial intelligence.[23]

In 1963, Vleduts[25] proposed the design of computer programs for planning multistep organic syntheses (CAOS: Computer-Assisted Organic Synthesis),[26] that is, for finding a way to synthesize a given target molecule from available starting materials in the best possible way according to the criteria that are applicable. As a pioneer of data banks of chemical reactions,[27] Vleduts was the first to discuss in detail how the reverse of stored chemical reactions, the so-called retroreactions, can be used to generate synthetic routes that lead from the target molecule via precursors to available starting materials. For instance, the structural feature **1** in a target molecule leads to the chapter of aldol condensations in the reaction library and thus to the precursors **2** and **3**.

From the precursors of the target molecule their precursors are obtained in turn, until the starting materials are reached. Thus, a tree of syntheses results that generally con-

Ivar Ugi was born in Arensburg in Estonia in 1930. The family moved to Dillingen an der Donau (Germany) in 1941, where Ivar Ugi completed his Abitur in 1949. In the fall of the same year he began his study of chemistry at the University of Tübingen, which he completed with a doctorate at the University of Munich in 1954 under Prof. Huisgen. He obtained his habilitation in 1959 for his work on pentazoles and isonitriles and continued as a research associate at the university for a further two years. In 1962 he joined the company Bayer in Leverkusen and rose to Director and Chairman of the Kommission für Grundlagenforschung. After six years his spirit of research led him to the USA: in 1968 Ugi became Full Professor of Chemistry at the University of Southern California in Los Angeles. In July 1971 he accepted a chair rich in tradition at the Technische Universität München, the Lehrstuhl I für Organische Chemie. Ivar Ungi is a member of committees for many foundations and has been a full member of the Swedish Royal Society for Science since 1987 and the Estonian Academy of Sciences since 1990. His scientific endeavors have been acknowledged with many awards: in 1964 he received the research prize of the Akademie der Wissenschaft in Göttingen and in 1988 the Philip Morris research prize for the Dugandji–Ugi model which he had developed with the topologist Dugandji. His life's work was honored in 1992 with the Emil-Fischer-Medaille der Gesellschaft Deutscher Chemiker not only for the development of mathematical models of the logical structure of chemistry, but also for the many new preparative methods arising from his isonitrile chemistry, four-component condensation, and stereochemical models, which open several new fields of research. These synthetic methods give strong impetus in particular to the chemistry of peptides, nucleotides, and β-lactam antibiotics.



1 2 3

tains many pathways from which one has to be selected. Corey[28] introduced the term retrosynthetic analysis for this procedure.

Bilateral synthesis design is an alternative to the retrosynthetic approach. When both the target molecule and a suitable set of starting materials are known, it suffices to find pathways that lead from the starting materials to the target molecule.

Computers can only be used for the solution of chemical problems when sufficient knowledge and experience are available for model concepts and reasoning by analogy. In the exploration of new domains in chemistry and in areas of incipient research, novel insights, visions, new ideas, and fortunate coincidences are still indispensable. Computers are here, at best, of indirect use, especially as a chemist would probably reject an "imaginative" computer-generated proposal as nonsensical artifact, even if it were completely realizable, instead of checking it in the laboratory.

Since computers do not have any creative intelligence, they are neither able to generate revolutionary ideas nor capable of pioneering scientific achievements. However, as an "amplifier of intelligence" a computer can, within the given body of knowledge, accelerate the progress of science, and also give impetus to research work that would not be feasible without computer-assistance. Even if a computer were able to generate all the conceivable solutions for a given chemical problem, the meaningful and creative solutions could not be selected without the participation of a qualified user.

2. Computer-Assisted Synthesis Design

2.1. Empirical Synthesis Design Assisted by Reaction Libraries

The programs for retrosynthetic design strategy based on data from reaction libraries LHASA,[29, 30] Wipke's SECS,[31] and Gelernter's SYNCHEM,[32] as well as the Leverkusener Peptide Synthesis Design Program, which operates along the bilateral principle,[33, 34] belong to the first computer programs for the solution of chemical problems. Since then, many groups have tried to develop computer programs with various success for the design of syntheses[18, 35].

Since the beginning of organic synthesis, chemists have planned syntheses by retrosynthetic reasoning,[36] mentally dissecting the target molecule while bearing in mind known synthetic reactions. Sir Robert Robinson[37] employed retrosynthetic reasoning particularly systematically. The disconnection method as recommended by Warren[38] also exercises retrosynthetic reasoning.

The early synthetic chemists did not attach a name to their procedure of synthesis design. Since the introduction of the terms synthon, transform, and retrosynthesis (also called antithesis), as well as the transform arrows (⇒) by Corey,[28] publications often contain a retrosynthetic analysis performed after completion of the synthesis. Multistep syntheses are certainly all based on some plan; however, the complex multistep synthetic pathways that are successfully executed in the laboratory cannot yet be planned to the last detail. They evolve from the set of proposed syntheses by trial and error and by successive adjustment of the design to what is feasible.

The empirical retrosynthetic programs are typical expert systems[39] with a knowledge basis and a set of rules. The empirical retrosynthetic programs generate synthetic pathways according to the perceived structural features of the target by application of the transforms, rules, and schemes. The precursors of a given target molecule are generated from it by breaking and making bonds according to stored information on chemical reactions and heuristic rules (see **1**–**3**). The process is iterated for each precursor until available starting materials are reached.

An empirical retrosynthetic program that is not confined to a narrow field of applications and a small repertoire of chemistry requires a large reaction library and a powerful computer. The creation and updating of large error-prone reaction libraries and the incorporation of synthesis-related experience into empirical synthesis design programs is time-consuming and costly. Reactions that are sequences of individual steps are particularly difficult to handle, because redundant information is stored. An advantage of empirical retrosynthetic programs is that they exploit existing chemical experience and therefore yield plans of syntheses that are combinations of known reactions and thus likely to succeed in the laboratory. The reaction library also determines the limits of the program, which is unable to break new territory. Moreover, since it is impossible to store all known reactions, reaction libraries provide to a more or less arbitrary choice of reactions.

Conceivable precursors can exist at any level of synthesis design. Thus, a rapidly expanding tree of synthetic pathways is generated. It is necessary—as in chess—to select particularly promising precursors with a view to finding the next precursors. Within the framework of programs for retrosynthetic analysis, this selection is based on heuristic strategies and selection rules.

The empirical retrosynthesis programs reached a very high level of perfection about 10 years ago. The most advanced example is CASP,[40] a modification and extension of SECS,[31] which was developed by large German and Swiss chemical companies at great expense. It is hardly conceivable that, apart from details, synthesis design programs based on reaction libraries will significantly surpass the present state of the art.

CASP was not sufficiently accepted by potential users, probably because its extremely large reaction library needs a powerful computer. It therefore cannot be directly accessed by bench chemists, but requires a computer specialist as a middleman. It also seems that chemists prefer to use stored information directly instead of having it manipulated by an empirical synthesis design program.

2.1.1. Which Are the Strategic Bonds in Ring Systems?

Many interesting target molecules contain complex polycyclic systems for which suitable strategies need to be planned

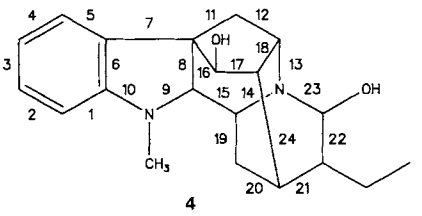
first.[41] Corey et al.[42,43] developed heuristic strategies for the synthesis of carbocyclic systems, which were particularly important computer-assisted retrosynthetic analysis. Their rules refer to "strategic" bonds that are preferentially broken and made, and can be summarized as follows (see Section 4.3.2):

1. A bond is strategic if it belongs to a four-, five-, six-, or seven-membered primary ring. A ring is primary if it does not contain two or more smaller rings.
2. A bond is strategic if it is directly connected to another ring (exo to another ring), unless this ring has only three members.
3. A strategic bond should belong to the ring that contains the highest number of bridged positions (bridgehead atoms).
4. If a ring of seven or more members is formed when a bond is broken, this bond is not strategic.
5. Bonds of an aromatic system are not strategic.
6. If a bridge contains a chiral center, none of its bonds are strategic, unless directly connected to the chiral center.

Bonds between carbon and heteroatoms are treated differently. Only rules 4, 5, and 6 apply, and rule 2 if a three-membered ring is involved.

2.1.2. *Difficulties in Identifying Strategic Bonds*

If the rules for strategic bonds are applied to bridged systems with four or more rings (according to Frèrejacques counting[44]) the results are sometimes less than satisfactory, especially when heteroatoms are present. This is because no hierarchy was defined for these rules, and they were conceived without sufficient attention to heteroatoms. As a consequence, in many cases several bonds are recognized as "strategic", with equal priority. An example is ajmaline (**4**),[45] for which six strategic bonds (bonds 9, 10, 15, 16, 23, and 24) are found according to the rules. Breaking bonds 9



4

and 10 does not simplify the molecular structure, while breaking only one bond does not lead to the formation of an accessible precursor, so other strategic bonds have to be determined. However, this does not necessarily lead to a simplification of the problem, because a burgeoning number of bonds qualify as strategic when the complexity of the ring system decreases. This leads to ever more precursors that have to be processed. Thus, breaking bond 16 of **4** produces seven new strategic bonds.

As mentioned above, the dissection of a bond does not necessarily lead to a "simplified" molecule. Corey's rules also lack a criterion for terminating ring fragmentations. Termination of the procedure after dissection of all bridges between rings would be advantageous; thus, nonbridging bonds such as 9 and 10 in **4** would not be considered.

Heuristic rules are not equally valid in all areas of chemistry, and usually their domains of validity cannot be clearly defined. The automated use of heuristic rules is therefore rather arbitrary and may lead to errors.[21]

Moderate amounts of data can be examined interactively by the user. This is widely applicable, and in computer-assisted synthesis design the interactive selection of synthetic routes by a knowledgeable chemist will yield better results than any automated, heuristic selection procedure. In automated retrosynthetic analysis, synthetic routes with favorable final steps will invariably be preferred over those with less favorable final steps.[46]

2.2. Semiformal Synthesis Design and Prediction of Reactions

The most severe limitations in "creativity" of the present semiformal synthesis design programs are their automated heuristic selection procedures; they are neither transparent nor well-founded.[21] Therefore, the full set of conceivable solutions can not be taken into account.

In principle, semiformal synthesis design programs can carry out all kinds of retrosynthetic analyses. However, they do not have selection procedures that can scan very large sets of solutions. Accordingly, the semiformal approach is limited to relatively small synthetic problems that fall within the domain of validity of the applicable rules and the underlying schematic procedures of the programs. Without a suitable formalism no interactive ordering and classification of the conceivable solutions is possible. For semiformal synthesis design programs, the selection procedures for precursors and retroreactions can still be substantially improved, but no major progress in generating the synthetic pathways seems possible.

In contrast to the empirical synthesis design programs, the semiformal and in particular the formal synthesis design programs have considerable innovative abilities. The semiformal programs cannot intentionally be used to "invent" new reactions (in contrast to the formal programs, e.g. IGOR; see Section 4.4.3), but can invent new types of molecules and chemical reactions when they are needed as a part of a synthetic route that is generated.

To our knowledge, no new compounds or reactions that have been predicted by a semiformal synthesis design program have been subsequently verified by experiment.

The program CAMEO of Jorgensen et al.[47] was developed for the prediction of reaction products, but it can also be used for the design of syntheses. CAMEO is based on the idea that most organic reactions can be represented by a combination of a few mechanistic elementary reactions (see also ref. [48]). The required chemical information is incorporated into individual program modules. Since CAMEO generates chemical reactions from their mechanistic steps, it is more capable of innovation than the retrosynthesis programs based on reaction libraries.[49]

Hendrickson[50] introduced the so-called half-reactions that can be combined to full chemical reactions according to valency considerations, without employing reaction mechanisms. Moreau[51] developed the semiformal synthesis design program MASSO on this principle. Shortly afterwards, Hen-

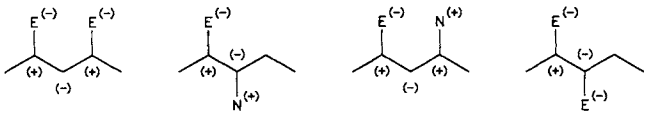
drickson et al.[52] completed SYNGEN, a similar program that is able to generate convergent syntheses from, at most, four subunits of the target molecule.

Modification and extension of the feasibility study CICLOPS[53] led to the first versions of the synthesis design program EROS,[54] which are of the formal type. Later versions of EROS[55] are essentially semiformal.

The selection processes of EROS for synthetic routes are heuristic in nature. They are based on assumptions on the lability of bonds and on physical data, which restricts the scope of reactions by defining, certain bonds as "breakable". In the course of multistep syntheses, often more than ten bonds are broken or made. Under the assumption that one to three bonds are broken or made per reaction, there are more than 7×10^6 synthetic routes that differ in the sequence of their operations, and that are by no means always equivalent (they would only be equivalent if all operations were independent of each other).

The semiformal synthesis design program TOSCA[56] is most remarkable because it is based on Evans' concept of consonant and dissonant molecules. In a lecture at the University of California at Los Angeles (UCLA) on 6th May 1971, D. A. Evans demonstrated the importance of consonant and dissonant structural features of molecules. Evans documented this concept in a paper with the title "Consonant and Dissonant Relationships—An Organizational Model for Organic Syntheses".[57] Although this paper was never published, its contents became well known in the chemical community, because in 1972 Evans distributed many copies among interested colleagues.

Evans' concept is based on Lapworth's polarity patterns of organic molecules that contain heteroatoms.[58] Evans termed these charge affinity patterns. Molecules like **5** and **6** are called consonant. They have alternating sites of positive and negative charge affinity, which can react as a nucleophile or an electrophile respectively. Molecules like **7** and **8** to



5 **6** **7** **8**

which no such patterns can be assigned are called dissonant. The syntheses of **16** from **9** and **10**, **11**, **12**, and **13**, and **14** and **15** are examples of consonant syntheses.

Evans showed that the conversion of consonant molecules into dissonant molecules and vice versa by ionic reactions requires "inversion operations", which correspond to Umpolung as defined by Seebach.[59] Recognition of consonant and dissonant structural features in the starting material and products of a synthesis is very important for the design of syntheses because the need for inversion operations must be taken into account. We use the Evans–Lapworth schemes in our bilateral synthesis design program RAIN (Reaction And Intermediate Networks).[60–63] With his consonance/dissonance concept Evans has made a far-reaching contribution to computer-assisted synthesis design.

2.3. Synthesis Design with Formal Foundations

2.3.1. What Does "Formal" Mean?

The disadvantages of programs for empirical, semiformal synthesis design can only be avoided by a comprehensive mathematical theory of chemistry that can be used to generate and to select by formal means all molecular systems and chemical reactions that must be accounted for in the selection of a given chemical problem.[21]

Different disciplines use the term formal differently. D. Hilbert and Bernays[64] called mathematics "the science of the formal systems". In informatics formal descriptions require a language (syntax), which may be mathematics, and a mathematically expressed meaning (semantics) together with definitions of rules for transformations and proofs. The validity and domain of a formal algorithm must be proven like a theorem. In chemistry, the term formal is not defined precisely, and is used quite randomly for all kinds of generalizations and classifications, as well as for more or less abstract representations and algorithms. As an empirical science, chemistry is not subject to any rigorously formal approaches in the sense understood in mathematics and informatics. However, our group attempts to put computer-assistance in chemistry onto a formal basis, as far as this is possible. Whenever this is not feasible, we avoid the use of heuristic rules with unpredictable consequences, leaving the required decisions to interactive user participation. The formal description of chemistry requires an adequate, detailed translation of chemistry, including its dynamic aspect, into the language of mathematics, and also a transparent translation of mathematical representations of chemical objects and facts back into the language of chemistry. This is accomplished through a mathematical model of the logical structure of chemistry that represents the molecular systems as well as the chemical changes that they may undergo (see Section 3).

Such a mathematical model can be implemented in computer programs whose applications are not restricted to a single type of problems and that can generate and select, through a formal algorithm, solutions of chemical problems without files of stored, detailed chemical information.[21] Such computer programs are well suited to explore new chemical terri-

tory, because they can propose molecules and chemical reactions that are without precedent, in particular when in dialogue with a creative, knowledgeable, and experienced chemist.

With suitable computer programs all of the combinatorially possible solutions of chemical problems, including those without precedent, can be taken into account. This is, however, of little use if the generated data cannot be ordered and the desired information cannot be extracted. To some extent, this is possible by formal means, but the interactive participation of the user is still required. His intuition and expertise are not only needed to formulate the problem, but also to select the best solutions.

The widespread opinion that a computer does not produce anything that has not been previously provided as data sounds plausible. It is, however, only strictly true for data banks and expert systems that rely solely on stored data.

2.3.2. *Mathematization of Chemistry*

Quantum chemistry has contributed a great deal to the mathematization of chemistry via physics. Quantum chemistry, a branch of molecular theoretical physics, is indispensable for understanding chemistry and for computing the numerical, measurable properties of well-defined molecular systems. The goal of mathematical chemistry is the mathematization of chemistry without the intermediacy of physics and the direct solution of chemical problems by qualitative mathematical methods. The traditional approaches for treating chemical problems by qualitative formulations of discrete mathematics are confined to a static perspective. Such mathematical chemistry does not reach beyond a group theoretical visualization and interpretation of the chemical constitution of molecules and of families of isomers[65-68] and the graph theoretical classification and enumeration of isomers and products of isomerizations.[69-77]

Neither quantum chemistry, which is often called theoretical chemistry, nor traditional mathematical chemistry are suitable as a theoretical basis for the solution of chemical problems with a strong combinatorial aspect, such as the search for molecules or chemical reactions that meet given chemical requirements. The computer-assisted solution of chemical problems by formal means requires global mathematical modeling of chemistry beyond the treatment of individual chemical objects. The model must represent the relations between the objects and the logical structure of chemistry as a whole. Constitutional chemistry and stereochemistry belong together, and yet they are so different that they require distinct mathematical perspectives and approaches. A global mathematical model of chemistry must therefore consist of two parts, one that represents constitutional chemistry and one that describes stereochemistry.

The theory of the be- and r-matrices[78] is an algebraic model of the logical structure of constitutional chemistry (see Section 3.2). It is also cited[79-81] as the "Dugundji–Ugi Model" or "Dungundji–Ugi Theory", abbreviated to the DU model. Besides the algebraic DU model, a graph theoretical model that was published later by Kvasnička et al.[80,81] can serve as a mathematical foundation of formal synthesis-design programs. The logical structure of stereochemistry can be represented by the theory of the Chemical Identity Group (CIG theory),[82] which is based on the notion of permutational isomerism.[76]

In contrast to traditional mathematical chemistry, the above models not only refer to, but even emphasize the dynamic aspect of chemistry. Within the framework of the DU model, chemical reactions are described by transformations of be-matrices. The be-matrices represent constitutional formulas which, in turn, correspond to graphs of the chemical constitution of molecules. In the CIG theory, the set-valued maps represent dynamic processes by which the stereochemical features of molecules are changed. These mathematical devices for the direct modeling of chemical processes are the theoretical foundation of the computer-assisted, deductive solution of a wide variety of chemical problems without reference to detailed empirical chemical information.

In the DU model and the CIG theory, the direct translation of chemistry into mathematics and vice versa is more important than the actual mathematical basis. Mathematics thus becomes part of the language of chemistry bringing its semantics and syntax, just as chemical formulas have been for decades.

2.4. Programs for Formal Synthesis Design

Through the DU model the objects of chemistry (molecules, ensembles of molecules (EM), chemical reactions) can be represented by objects of mathematics (matrices). Thus, chemical problems can be translated into mathematical problems, whose solutions are the solutions of the chemical problems.

This model started the development of formal algorithms, reaction generators, and computer programs for the deductive solution of chemical problems by mathematical means. The formal algorithms can not only generate solutions for many types of chemical problems but are also useful in the classification and selection of these solutions.[21]

The development of programs for formal synthesis design began with the feasibility study CICLOPS.[53] The purpose of CICLOPS was to ascertain whether chemical problems could, in principle, be solved with the DU model. In this respect the CICLOPS study was successful. However, it was also found that CICLOPS was bound to fail under the conditions of practical synthesis design of problems incorporating the combinatorial aspect. Gasteiger and Jochum[54] developed the first versions of EROS from CICLOPS, by reducing the reaction generator (see below) of CICLOPS from approximately 100 potential to the three most important r-classes (see Section 3.2.2) of chemical reactions and by adding a selection procedure for chemical reactions. In analogy to the selection procedure of Stevens and Brownscombe,[83] the choice is made on the basis of reaction enthalpy estimations.

Reaction matrices can be assembled from basic elements that correspond to the elementary reactions of mechanisms.[78] These can be used to create reaction generators that build chemical reactions from their elementary steps. The synthesis design program ASSOR[48] contains a reaction generator of this type and is therefore able to account for the mechanistic aspects of chemical reactions.

The DU model can be used in many ways as the theoretical foundation of monolateral synthesis design programs that

generate synthetic routes either from the target molecule in a retrosynthetic mode, or from the starting material in a synthetic mode. However, the possibilities that the DU model provides for the bilateral design of syntheses[84,85] seem to be more promising. The obvious combinatorial advantages of bilateral synthesis design have also been recognized by other authors. Johnson et al.[86] developed a bilateral synthesis-design program on the basis of LHASA, and recently Hendrickson and Parks[87] combined SYNGEN with the synthesis program FORWARD into a bilateral synthesis-design program.

In bilateral synthesis design, the synthetic routes are spread from both ends, the starting materials and target. At the moment, we are developing a system of computer programs for bilateral synthesis design that operates in three stages.[85,88,89] The partitioning of the problems by such a system provides substantial combinatorial advantages. First, a set of suitable starting materials is selected for the target molecule from a list of available compounds by the substructure correlation program CORREL-S (see Section 4.3.2). Then the co-products (ancillary products formed besides the target molecule) are determined (program STOECH, see Section 4.3.3). The result is a target EM that is isomeric (in terms of Section 3.1) to the EM of starting materials. In a third step, the computer program RAIN (see Section 4.4) generates a network of synthetic routes that connect both ends of the synthesis.

Other formal synthesis-design programs are FLAMINGOES,[90] PEGAS,[91] and MAPOS.[92] Hippe[93] tried to combine the advantages of the formal and empirical approaches in their programs SCANSYNTH, SCANMAT, and SCANPHARM. So did Johnson et al.[94] in their system SYNLMA.

3. The Logical Structure of Chemistry

3.1. The Hierarchy of Isomerisms

Chemistry is an empirical science. Nevertheless, its objects have a consistent logical structure, because all molecules are constructed according to uniform principles.[95] This logical structure is a system of equivalence relations. The most important relations are the various types of isomerism and the interconvertibility of isomeric molecules and ensembles of molecules. The logical structure is determined by the valence properties of the chemical elements and a few general principles. When chemistry is compared to a language, the chemical facts, objects, phenomena, and events correspond to the vocabulary, while the logical structure of chemistry corresponds to the grammar.

The backbone of the logical structure is the classification of molecules according to the various types of isomerism.[96] Isomers contain the same number and type of atoms and accordingly have the same empirical formula. The term "isomer" can be applied to molecules as well as to substances. From the existence of distinct isomers A. von Humboldt inferred that molecules must have an intrinsic structure. Otherwise substances with the same element composition would not be distinguishable.[97]

Those molecular systems that consist of the same collection of atoms—or more exactly, the same collection of atomic cores (i.e., nucleus plus electrons of the inner shells) and valence electrons—are isomeric EMs. The EMs may consist of one or more molecules. This extension of the notion of isomerism from molecules to EMs is one of the conceptual foundations of a mathematical representation of the logical structure of chemistry.[78]

The chemical constitution of molecules corresponds to the atomic neighborhood relations defined by covalent bonds. Isomers that differ by their chemical constitutions are called constitutional isomers.

By their classical definition stereoisomers are molecules with the same chemical constitution but different relative spatial arrangements of their constitutient atoms.[82,98] This definition is of limited usefulness, since many stereoisomers are nonrigid molecules that can not be adequately represented by rigid geometric models. A generally valid definition of stereoisomers that also accounts for flexible molecules is possible on the basis of the concept of chemical identity described in the next paragraph. This equivalence relation can also account for nonrigid chiral molecules.[73,98]

Molecules are chemically identical if they interconvert spontaneously under the given observation conditions and belong to the same uniform chemical compound. Two films showing the time-dependent changes of geometry of a molecule and of a chemically identical molecule will not be the same. However, the sets of molecular frames that are shown in the two films are identical. The same set will be obtained if a snapshot of a sufficiently large number of molecules of the corresponding compound is taken.

If molecules with the same chemical constitution are not chemically identical they are stereoisomers.[73,82,98] Stereoisomerism as defined thus is a principle of classification in its own right and is subordinate to constitutional isomerism.

3.2. An Algebraic Model of the Logical Structure of Constitutional Chemistry

The logical structure of constitutional chemistry follows from the following statements that were used by J. Dugundji and I. Ugi[78] as the axiomatic foundations of the theory of the be- (*b*ond and *e*lectron) and r-matrices (*r*eaction) published in 1973:

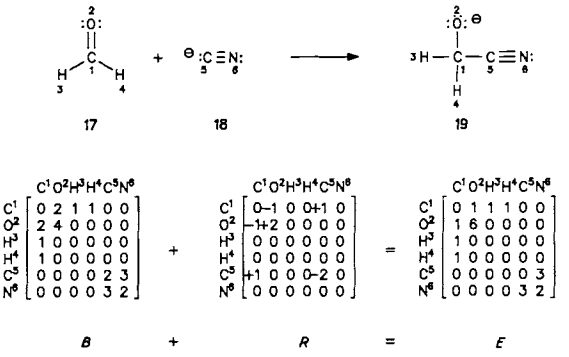
> Molecules consist of atomic cores and valence electrons, held together by covalent bonds. A covalent bond corresponds to a pair of valence electrons that simultaneously belongs to two adjacent atoms. A chemical reaction is the conversion of an EM into an isomeric EM by redistribution of valence electrons. During a chemical reaction the atomic cores and the total number of valence electrons remain the same.

The logical structure of constitutional chemistry can be illustrated by the chemistry of a fixed collection $A = \{A_1, \ldots A_n\}$ of atoms. Since any collection of atoms can serve as A, a model of the logical structure of the chemistry of A is valid for all chemistry.

The chemistry of A is given by the family of isomeric EM(A). EM(A) is an EM which contains every atom of A precisely once.[93]

Within the framework of the DU model, an EM of n atoms is described by its symmetric $n \times n$ be-matrix. The ith row

(and column) of a be-matrix is assigned to the atom A_i ($1 \leq i \leq n$). The entry b_{ij} ($= b_{ji}$, $i \neq j$) of the ith row and the jth column of a be-matrix $\boldsymbol{B}$ is the formal bond order of the covalent bond between the atoms A_i and A_j. The diagonal entry b_{ii} is the number of free valence electrons at the atom A_i. The entries $b_{12} = b_{21} = 2$ of the be-matrix of EM(**17**, **18**) signify that the C atom no. 1 and O atom no. 2 are connected by a covalent double bond, while $b_{22} = 4$ represents four free valence electrons at the O atom no. 2 (Scheme 1).



Scheme 1. A reaction and its matrix description.

The rows and columns of the be-matrices represent the number and position of the electrons (valence schemes) of the relevant atoms. It follows that all rows (columns) of be-matrices of stable EMs must correspond to allowable valence schemes of the represented chemical elements. They are the valence boundary conditions of the be-matrices.

The adjacency and connectivity matrices[99] that are used in chemical documentation differ from the be-matrices in their diagonal entries. These matrices are merely tables of bonds that represent chemical constitution. In contrast, the be-matrices do not only represent single molecules but also multimolecular EMs, and are genuine mathematical objects. The algebra of the be- and r-matrices forms a free additive abelian group.[78]

The redistribution of valence electrons by which the starting materials $EM_{\boldsymbol{B}}$ of chemical reactions are converted into their products $EM_{\boldsymbol{E}}$ is customarily indicated by "electron-pushing arrows", which are represented by r-matrices $\boldsymbol{R}$. The chemical reaction $EM_{\boldsymbol{B}} \rightarrow EM_{\boldsymbol{E}}$ corresponds to the additive transformation of the be-matrices $\boldsymbol{B}$ of the educts by the reaction matrix $\boldsymbol{R}$ into the be-matrix $\boldsymbol{E}$ of the products. $\boldsymbol{B} + \boldsymbol{R} = \boldsymbol{E}$ is the fundamental equation of the DU model.

The addition of matrices proceeds entry by entry, that is, $b_{ij} + r_{ij} = e_{ij}$. Since there are no formal negative bond orders or negative numbers of valence electrons, the negative entries of $\boldsymbol{R}$ must be matched by positive entries of $\boldsymbol{B}$ of at least equal values.

3.2.1. Chemical Distance

When the n^2 entries of the be-matrices are interpreted as coordinates of points in an n^2-dimensional euclidean space, the algebraic model of the logical structure of chemistry can be visualized as a geometric model.[78, 100] The EMs correspond to be-points and chemical reactions are described by connecting r-vectors. The L_1 length $d(\boldsymbol{B}, \boldsymbol{E})$ of an r-vector is the sum of the absolute values of the differences of the coordinates of the be-points $P(\boldsymbol{B})$ and $P(\boldsymbol{E})$. The L_1 distance ("taxi driver distance")[101] between the two be-points $P(\boldsymbol{B})$ and $P(\boldsymbol{E})$ is called the chemical distance (CD) between $EM_{\boldsymbol{B}}$ and $EM_{\boldsymbol{E}}$. It is twice the number of valence electrons that are redistributed when $EM_{\boldsymbol{B}}$ and $EM_{\boldsymbol{E}}$ are interconverted (see Table 1).[100]

$$d(\boldsymbol{B},\boldsymbol{E}) = \sum_{ij} |b_{ij} - e_{ij}| = \sum_{ij} |r_{ij}| \qquad (1)$$

When the lattice of points representing a family of all isomeric EM with paired valence electrons is viewed from any of its EMs, then the be-points are surfaces of concentric L_1 shells whose radii differ by four units. The radius of the largest sphere is the total number of valence electrons of the underlying collection of atoms. This aesthetic geometric picture of the logical structure of chemistry is a "map" of the

chemical reactions preferentially proceed by a minimal redistribution of valence electrons.	the atom-onto-atom correlations $EM_{\boldsymbol{B}}(A)$ and $EM_{\boldsymbol{E}}(A)$ with minimal $d(\boldsymbol{B}, \boldsymbol{E})$ are preferred.	preferred r-vectors for $EM_{\boldsymbol{B}}(A) \rightarrow EM_{\boldsymbol{E}}(A)$ lead from one point of the $\boldsymbol{B}$-cluster to the "nearest" point of the $\boldsymbol{E}$-cluster.

energy minima of the potential energy surface of the given collection of atoms.[102]

The solutions of the basic equation $\boldsymbol{B} + \boldsymbol{R} = \boldsymbol{E}$ of the DU model correspond to the solutions of a great variety of chemical problems. Accordingly, the DU model can serve as the universal theoretical foundation of computer programs for the deductive solution of constitution-related chemical problems. Furthermore, it is suitable as a basis of strictly formal, transparent procedures for the selection of chemically meaningful solutions from very large sets of conceivable solutions.[21] Here the Principle of Minimal Chemical Distance[78, 103-107] plays an important role. This principle is a quantitative version of the classical qualitative principle of minimum structure change:[108] The interconversion of isomeric EM by chemical reactions preferentially proceeds by redistribution of the minimum number of valence electrons.

The minimal CD corresponds to one or more atom-to-atom maps of the EM, because the CD between isomeric EMs depends on the correlation of their atoms. In a broad sense this is also true for sequences of reactions, that is, the CD of reaction sequences is rarely more than four units above the minimum of CD.

The principle of minimal CD can not only select the "shortest" pathways of chemical reactions but can also help to determine reactive centers, that is, those atoms whose covalent bonds and free valence electrons are immediately affected by the reaction. The complete set of reactive centers is called the core of the reaction. The bonds that are broken or made during a reaction are determined by the atom-to-atom maps of the interconnected EMs.

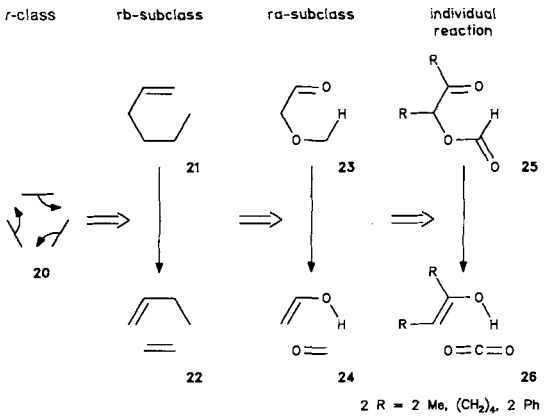
Various distance functions and measures of similarity have been published for molecular systems. In essence, they all rely on the fact that chemical reactions correspond to vectors (see Table 1) and have metric properties.[78] Other examples, besides CD,[100] are reaction distance that was defined differently by Kvasnička et al.[80, 81, 109] and by Hendrickson et al.,[87] synthetic proximity of Johnson et al.,[110] and adjacency distance, the sum of the absolute values of the t-matrices (differences of adjacency matrices) of Fontain.[111]

3.2.2. The Hierarchic Classification of Chemical Reactions

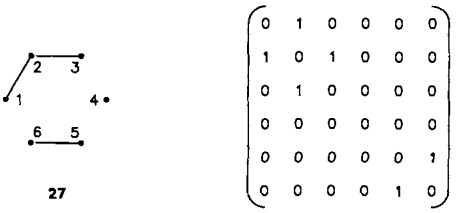
A hierarchic classification of chemical reactions by similarity classes[100] follows from the principle of minimal CD (see Scheme 2).

The position of a chemical reaction, for example **25** → **26**, in this hierarchic classification system is determined by stepwise neglect of its characteristic features. First, the reaction is reduced to its core of reactive centers by omitting all substructures that do not directly participate in the reaction. The result is the ra-subclass of the reaction, whose members have the same reaction core but different invariant molecular substructures.

The next step of abstraction is to neglect the differences between the chemical elements of the atoms of the core. This leads to the rb-subclasses (basic reactions). Their members are characterized by the same arrangement of covalent bonds between the atoms of the core (see **27**) and can be represented by the so-called intact be-matrix (Scheme 3).[79]



Scheme 2. The procedure for the hierarchic classification of chemical reactions. The individual reaction **25** → **26** is reduced to the electron redistribution scheme **20**.



Scheme 3. Intact be-matrix of the rb-subclass **21** → **22**.

Reactions with the same electron redistribution scheme and therefore the same irreducible r-matrix[100, 112, 113] belong to the same r-class. The r-matrix is converted into its irreducible r-matrix by removing all rows and columns that only contain zeros. The rows (and columns) of the irreducible r-matrix belong to the reactive centers of the reactants. The hierarchic classification of chemical reactions ends with the CD-classes.[79, 100, 112-114] Reactions belong to the same CD-class if the same number of valence electrons is redistributed during the course of the reaction and thus the same CD is covered.

Scheme 2[100, 114] illustrates the hierarchic classification of chemical reactions for the example of the extrusion reaction **21** → **22**. The rb-subclass is represented by the bonding scheme **27** and the corresponding 6 × 6 intact be-matrix of Scheme 3.

The classification described above does not only open new ways of documenting chemical reactions,[79, 100, 112, 113] but also plays an important role in the computer program IGOR (*I*ntermediate *G*eneration of *O*rganic *R*eactions).[114-116] It is used to select computer-generated chemical reactions and to assess their degree of novelty.[88, 117] The degree of novelty is determined by assigning classes and subclasses of the reaction in question and ascertaining the level of hierarchy above which no published reactions can be found. The higher this level is, the higher the degree of novelty of the reaction.[88, 113, 114, 117] The reaction **25** → **26** of Scheme 2 was discovered with computer-assistance. It belongs to the extrusion reactions **21** → **22**[114] (see Section 4.1.4.3) that are characterized by the bond system **27**, and that is contained in r-class **20** with 12 rb-subclasses.

No representatives of ra-class **23** → **24** are known. Accordingly the reaction **25** → **26**[114, 118] is novel up to the level of the ra-subclasses.

Almost twenty years ago, Brownscombe and Stevens[83] reported a computer program that was capable of generating any elements of the rb-subclass of extrusion reactions by permuting the chemical elements of the core of the reaction. Reaction **25** → **26** could have already been found with that computer program.

4. The Munich project

The applications of the DU model are not restricted to the design of syntheses. After the CICLOPS study[53] was terminated in 1974 (see Section 2.4) a comprehensive plan, the Munich project, was devised. Its aim was to extend and improve the DU model and to exploit it in as many ways as possible as a formal basis for the computer-assisted solution of chemical problems.[119] During its implementation, the Munich project was changed so much that only its basic ideas are left. However, it initiated the development of computer programs for the solution of chemical problems on a broad front. The Munich project, whose goals have nearly been reached, consists of the following subprojects:

a) Improvement and extension of the DU model, in particular for EMs with multicenter bond systems of delocalized electrons.

b) Development of a computer-oriented mathematical theory of stereochemistry that is able to account for the stereochemical aspect of chemical reactions.

c) Development of a software infrastructure for programs according to d).

d) Development of computer programs for the deductive solution of chemical problems. These programs should not only use the DU model for the generation of solutions of problems, but also for screening and selecting these solutions.

e) Testing and use of programs according to d) and improvement of these programs on the basis of gathered experience.

f) Experimental realization and verification of the results of e).

Progress on individual steps of the Munich project has been described together, as far as possible, with details of the computer programs, which often included the source codes, in order to ensure reproducibility. Here we give a survey of the subprojects of the Munich project, in the order a)–f), covering its historical development and current status.

4.1. Extension of the DU model

For a long time neither we nor others succeeded in extending the DU model as planned in a). Recently, however, a formalism was found through which EMs with multicenter bonds and delocalized valence electron systems (DE systems)[95] can be represented. The xbe-matrix (extended be-matrix) of an EM corresponds to its be-matrix which is extended by additional rows and columns. The be-matrix with n rows and columns refers to the localized covalent bonds whose formal bond orders and free valence electrons can be assigned to the individual atoms. The additional rows and columns with the indices $n + k$ belong to DE systems, for example, multicenter bond systems or delocalized π-electron systems. The off-diagonal entries $b_{i,\,n+k} = b_{n+k,\,i} = 1$ of the kth additional rows and columns indicate that the atom A_i participates in the $(k - n)$th DE system. The diagonal entries $b_{n+k,\,n+k}$ are the numbers of valence electrons that belong to the $(k - n)$th DE system. The xbe-matrix of π-allyl nickel bromide (**28**)[120] may serve as an example in Scheme 4; for the sake of simplicity, the CH bonds and the corresponding entries are omitted.

Scheme 4. Structural formula of **28** showing numbering and the xbe-matrix representing it. The row and column of the DE systems are indicated by dashed lines.

In analogy to the original DU model, chemical reactions are represented by addition of xr-matrices[95] to the xbe-matrices. The 18 theorems of the DU model are equally valid for the algebra of the xbe- and the xr-matrices, which is named the model of the chemistry of *d*elocalized *e*lectron (DE) systems.

In order to adapt this system to computers, a new data structure was introduced. At the moment, a reaction generator for reactions in which DE systems may also participate is being developed.[121] Here the particular properties of the DE systems must be accounted for by formulation of suitable boundary conditions.

4.2. Computer-Oriented Formalization of Stereochemistry—the Theory of the Chemical Identity Group and Accumulations

Stereochemistry is the science of the spatial structure of molecules and its observable consequences. The differences in the formation, reactions, and properties of stereoisomers are the central issues of stereochemistry. Stereoselective syntheses belong to the most attractive current topics of organic chemistry.[1] Therefore, the stereochemical aspect of computer-assisted chemistry is of particular interest. The large numbers of combinatorial possibilities create huge amounts of data in solving stereochemical problems, which can only be handled if the mathematical structures behind the problems are fully recognized and exploited. It is advantageous to introduce some suitable new concepts and approaches for this purpose.

4.2.1. *Traditional Approaches*

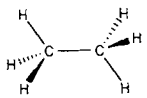
Corey et al.[122] supplemented the transforms of the individual reactions with detailed stereochemical information. This approach is very cumbersome; just the treatment of the stereochemistry of six-membered rings requires a large program of its own. Wipke and Dyott[123] proposed to solve stereochemical problems by assuming sufficiently rigid reactants that are determined by a procedure based on steric bulk. Hanessian et al.[124] assign chiral starting materials to chiral target molecules through their program CHIRON. In the early stages of the Munich project the stereochemical features of EMs with stereogenic subunits with coordination numbers ≤ 4 were represented by parity vectors.[125]

None of these approaches leads to a generally applicable method for the computer-assisted solution of stereochemical problems. The comprehensive computer-oriented formal treatment of stereochemistry requires a fundamentally different approach.

4.2.2. *A Nongeometric Alternative*

In traditional stereochemistry the facts and phenomena are interpreted and predicted on the basis of rigid geometric models. Thus, stereochemistry is reduced to elementary geometry. Molecular geometries and point group symmetries are drastically overemphasized. Widely applicable computer-assisted methods for the solution of stereochemical problems, however, require a theory that treats the static and dynamic aspects in a uniform way.

Many molecules are not rigid. Since their shapes vary with time, they are in general not adequately represented by geometric models. For instance, at 20 °C the methyl groups in ethane **29** rotate around the C–C bond with a frequency of $10^9\ s^{-1}$.[126, 127] This molecule can not be represented by a rigid geometric model.



29

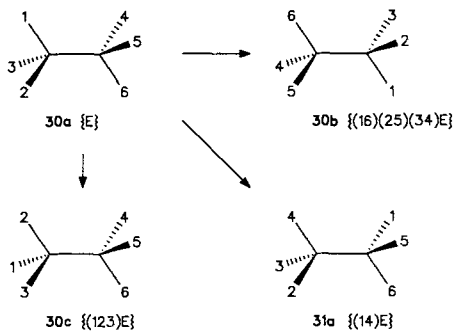
The first prerequisite for a comprehensive and uniform theoretical treatment of stereochemistry is that the traditional definition of stereoisomers should be replaced by a definition that is also able to account for flexible stereoisomers. This definition should be based on the notion of chemical identity (see Section 3.1) and should not refer explicitly to any geometry.

Permutation isomerism, as defined in 1970,[76] and the theory of the *c*hemical *i*dentity *g*roup (CIG theory), which was published in 1984,[82] have played an important role in the formalization of stereochemistry. The CIG theory is a group theoretical model of the logical structure of stereochemistry that not only accounts for the energy-related and geometric properties of the molecules, but also includes the valid observation conditions. It avoids explicit reference to rigid geometric models and their point group symmetries. In contrast to the traditional applications of group theory (see Section 2.3.2), the CIG theory does not only cover molecular objects, but also stereochemical relations and processes between molecular systems.

4.2.3. *The Basic Ideas of the CIG Theory*

A molecule can be dissected in the imagination into a molecular skeleton and a set of ligands. The distinct molecules that differ by positioning of the ligands at the skeletal sites, are the permutation isomers. The set of all permutation isomers that can be obtained from a reference isomer is called a family of permutation isomers.

Let m be a snapshot of a molecule. The conceptual separation of m into a molecular skeleton and a set L of ligands yields a reference model. The reference model belongs to an isomer X which serves as the reference isomer. In contrast to a molecule, a model in the present sense has a fixed spatial orientation. The chemical identity of a molecule is independent of its spatial orientation. There are permutations of ligands that convert one model into another that belongs to the same molecule (see Scheme 5). The chemical identity of X is preserved by all permutations of ligands through which models of X are converted into other models of X, for example, permutations that may be interpreted as rotations of the molecule as a whole.



Scheme 5. Ligand permutations of **30a**, the reference model of an arbitrarily substituted ethane molecule.

If all ligands in the set L are distinguishable, the identity-preserving permutations generally form a group $S(E)$. This is the CIG of the reference isomer X that is represented by the model E. $S(E)$ is a subgroup of the symmetric permutation group $Sym(L)$ of L. The distinct permutation isomers of X are represented by the left cosets $\lambda S(E)$ ($\lambda \in Sym(L)$) of $S(E)$ in $Sym(L)$.[*]

For a molecule with n ligands $Sym(L)$ consists of $n!$ permutations. This is the cardinality of the family of permuted models $P(E)$. The maximum number of chemically distinct permutation isomers is $n!/|S(E)|$, because all cosets have the same cardinality $|S(E)|$. The left cosets of the CIG in $Sym(L)$ or any of their elements can serve as nomenclature descriptors for the permutation isomers.[76] The left coset of a CIG corresponds to the permutation isomer of the reference isomer, whose models are obtained from the reference model by ligand permutations from the CIG, followed by a permutation from the considered left coset.

[*] For readers who are less familiar with mathematical concepts and symbols there is an appendix with brief explanations.

Permutations are customarily written as cycles,[128] for example, (123); the vector [123] of numbers is permuted into [231] by mapping $1 \rightarrow 2$; $2 \rightarrow 3$; $3 \rightarrow 1$. The combination (12)(123) of the permutations (12) and (123) corresponds to the action of (12) on the result of (123), that is (12)(123) transforms [123] into [132] and is thus equivalent to (23).

For example, the reference model **30a** of the ethane derivative **30** is converted into the model **30b** by the permutation (16)(25)(34) of the ligands; this corresponds to a rotation by 180° of **30a** around an axis that is perpendicular to the plane of the paper. Note that this rotation of the model **30a** does not superimpose the ethane skeleton onto itself, according to D_{3d} point group symmetry, since the different ligands destroy the symmetry of the skeleton (see Chapter 3 of ref. [82]).

Since the chemical identity of a molecule is independent of its spatial orientation, **30a** and **30b** are chemically identical. The model **30c** also belongs to **30** if the internal rotation around the C–C axis belongs to the spontaneous intramolecular motions, under the given observation conditions. This permutation can be represented by (123).

The CIG (2) contains all ligand permutations that preserve the chemical identity of **30**. The ligand permutations of

$$S(30a) = \{(), (123), (132), (456), (465), (123)(456), (123)(465), (132)(456), (132)(465), (14)(26)(35), (15)(24)(36), (16)(25)(34), (142635), (143526), (152436), (153624), (162534), (163425)\} \quad (2)$$

$S(30a)$ generate further models of $S(30a) \cdot$ **30a** from any model that belongs to $S(30a) \cdot$ **30a**. The ligand permutation (14) converts **30a** into **31a** which represents a permutation isomer of **30**. Likewise the ligand permutation (14) converts any model of **30** into a model of **31**. They can also be obtained by any other permutation of $S(30a)$, followed by any permutation of (14) $\cdot$ $S(30a)$. **30** and **31** are distinct permutation isomers if the ligands 1 and 4 are distinguishable.

In the following sections we will describe set-valued maps (SVM) and accumulations. These operations are very useful for representing permutation isomers with indistinguishable ligands and isomerizations which convert permutation isomers into each other.

4.2.4. Implementation and Applications of the CIG Theory

Within the framework of the CIG theory stereochemical equivalence relations are represented by surjective set-valued maps (SVM) of permutations onto sets of permutations that may be unions of cosets or Wigner subclasses[129] of subgroups of $Sym(L)$. The direct consideration of the dynamic aspect of stereochemistry is the most important contribution of the CIG theory to the mathematical treatment of stereochemistry.

The SVM were introduced into chemistry as a part of the CIG theory. They are a most versatile device for the solution of stereochemical problems that can be formulated as equivalence relations between permutation isomers. Such equivalence relations correspond to equivalence spaces that are generated by SVM.

Let M be a set which is partitioned into equivalence classes in two distinct ways (Fig. 1). The SVM of a class B from the partition $\mathscr{B}$ yields the union of those equivalence classes

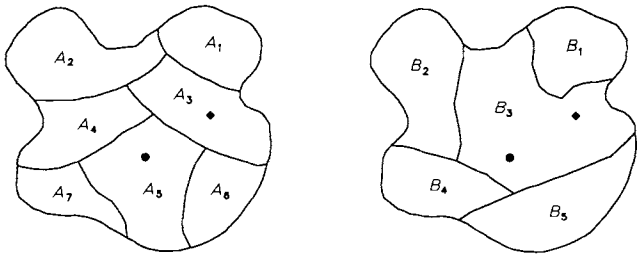


Fig. 1. Two partitions $\mathscr{A}$ and $\mathscr{B}$ of set M.

from partition $\mathscr{A}$ whose intersection with B is non-empty [Eq. (3)].

$$\mathrm{SVM}(\mathscr{A}, B) = \bigcup_{A \cap B \neq \{\}, A \in \mathscr{A}} A \quad (3)$$

For example, ♦ is an element of class A_3 and ● is an element of A_5. These elements also belong to class $B_3 \in \mathscr{B}$. All elements of class A_3 are equivalent to ♦. The elements of class A_5 are equivalent to ●. The elements ♦ and ● are also equivalent since they both belong to class B_3.

Equivalence relations are reflexive, symmetric, and transitive (p. 14 of ref. [128]). The equivalence classes A_3 and A_5 (and any further equivalence classes of $\mathscr{A}$ that intersect B_3) form a single equivalence class. We have the SVM given by (4).

$$(\mathscr{A}, B_3) = A_1 \cup A_2 \cup A_3 \cup A_4 \cup A_5 \cup A_6 \quad (4)$$

In recent years the CIG theory has been modified and extended. It is now more suitable as a foundation for the computer-assisted solution of a great variety of stereochemical problems. In particular, (equivalence) accumulations[130, 131] represent significant progress in practical computer-assisted stereochemistry.

The CIG and its cosets form a space of equivalence classes in $Sym(L)$. Since, by definition, cosets are disjoint, each coset can be interpreted as an equivalence class that represents a permutation isomer. One permutation is sufficient to represent the whole family of permutation isomers. Thus, the amount of data to be processed for stereochemical problems is reduced to a small fraction.

We consider a equivalence space A of molecular models and some independent information I about further equivalences of models, for example, from equivalences of ligands or interconvertibilities of models. According to the additional information I, there exists an equivalence space U which differs from A in that some of the equivalence classes of A merge into a single equivalence class. The information I is an equivalence relation corresponding to group theoretical relations between the individual models. Within the framework of the CIG theory, I can be expressed by a few generating elements that follow directly from the chemical properties of the molecules. An example for such information is the coset space of the CIG $S(30a)$ in $Sym(L)$ mentioned in Section 4.2.3: For each coset $\lambda S(30a)$, $\lambda S(30a) \cdot$ **30a** is an equivalence class of chemically identical models. All pairs of models in the equivalence class are elements of the equivalence relation I, that is, for all models $m, n \in \lambda S(30a) \cdot$ **30a** we have $(m, n) \in I$.

For a given set of models M that is partitioned according to the equivalence space A, and the information I, the accu-

mulation Acc(A, I) is defined according to (5)–(7) (+ represents the transitive closure[132] of a relation):

$$\mathrm{Acc}(A,I) := \{[m]_R \mid m \in M\} \tag{5}$$

$$\text{where} \quad R = (I \cup a \times a \mid a \in A)^+ \tag{6}$$

$$\text{and} \quad [m]_R = \{n \in M \mid (m,n) \in R\} \tag{7}$$

Ligands are considered to be equivalent, if their chemical interpretations are the same and their permutation does not affect the chemical identity of molecules. The permutations of equivalent ligands form the ligand equivalence group Σ. The right cosets of Σ in $Sym(L)$ represent those models that are potentially distinct if all ligands were distinguishable, but are chemically identical because of the equivalence of some of the ligands.

A ligand permutation that converts a reference model into a model of a distinct permutation isomer, followed by a ligand permutation from Σ, corresponds to a ligand permutation that belongs to a right coset of Σ.

Thus, the right coset space of Σ in $Sym(L)$ also contains the following information: the models λE in each equivalence class $\Sigma\mu$ are mutually chemically identical.

If this equivalence class $\Sigma\mu$ intersects with the equivalence classes $\lambda S(E)$ and $\sigma S(E)$ of the coset space of the CIG of E, permutations ρ and τ exist such that $\rho \in \Sigma\mu \cap \lambda S(E)$ and $\tau \in \Sigma\mu \cap \sigma S(E)$. Since $\rho \in \lambda S(E)$, the model ρE is chemically identical to all models $\lambda S(E)E$, and τE is chemically identical to all models $\sigma S(E)E$, because $\tau \in \sigma S(E)$. On the other hand, ρE and τE are chemically identical, because ρ and τ belong to the same right coset $\Sigma\mu$, that is the molecules that are represented by ρE and τE are chemically identical, because models ρE and τE differ only by a permutation of equivalent ligands.

Because as an equivalence relation chemical identity is reflexive, symmetrical, and transitive, all models belonging to $\lambda S(E)E$ are also chemically identical to τE (because ρE is chemically identical to all of those models). The right coset $\Sigma\mu$ contains the information that all models $\Sigma\mu E$ are chemically identical. Thus, the representatives $\lambda S(E)E$ and $\sigma S(E)E$ (and all further equivalence classes $\xi S(E)E$, with $\xi S(E) \cap \Sigma\mu \neq \{\}$) of the permutation isomers that were initially considered to be distinguishable, merge into the class of permuted models described by (8). This class models represents a single permutation isomer. Since such SVM do not take into account the full right coset space of Σ, in some cases the results may be incomplete. A coset $\lambda S(E)$ can exist whose intersection with $\Sigma\mu$ as well as with a further right coset $\Sigma\omega$ is non-empty. Then the SVM of $\Sigma\mu E$ does not yield the complete set of chemically identical models: The expression (9) states that the $\lambda S(E)$ models are chemically identical with all models from (10) and also with all models from (11).

$$\bigcup_{\xi S(E) \cap \Sigma\mu \neq \{\}} \xi S(E) \cdot E = \mathrm{SVM}(\{\lambda S(E) \cdot E \mid \lambda \in Sym(L)\}, \Sigma\mu \cdot E) \tag{8}$$

$$\lambda S(E) \cap \Sigma\mu \neq \{\} \wedge \lambda S(E) \cap \Sigma\omega \neq \{\} \tag{9}$$

$$\bigcup_{\xi S(E) \cap \Sigma\mu \neq \{\}} \xi S(E) \cdot E \tag{10}$$

$$\bigcup_{\xi S(E) \cap \Sigma\omega \neq \{\}} \xi S(E) \cdot E \tag{11}$$

Accordingly, all models that belong to any one of the above molecules are chemically identical. Such problems are avoided by the accumulation (12) by forming the transitive envelope (13).

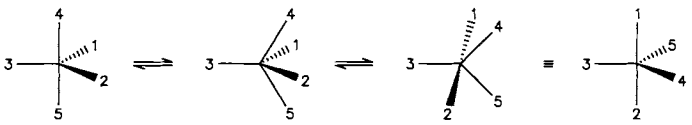
$$\mathrm{Acc}(\{\lambda S(E) \cdot E \mid \lambda \in Sym(L)\}, \{\Sigma\mu \cdot E \times \Sigma\mu \cdot E \mid \Sigma\mu \cdot E \in \{\Sigma\mu \cdot E \mid \mu \in Sym(L)\}\}) \tag{12}$$

$$R = (\{\Sigma\mu \cdot E \times \Sigma\mu \cdot E \mid \Sigma\mu \cdot E \in \{\Sigma\mu \cdot E \mid \mu \in Sym(L)\}\} \cup \{\lambda S(E) \cdot E \times \lambda S(E) \cdot E \mid \lambda S(E) \cdot E \in \{\lambda S(E) \cdot E \mid \lambda \in Sym(L)\}\})^+ \tag{13}$$

Thus, finally, a family of permutation isomers with a ligand set containing equivalent ligands is represented as a union of the double cosets $\Sigma\lambda S(E)$ ($\lambda \in Sym(L)$). In these cases the customary methods for the enumeration and classification of isomers[70, 72, 74] must be used with caution. In contrast to these methods, the CIG theory also indicates which isomers are involved, which isomers merge into a single isomer due to ligand equivalences, and which chiral isomers in turn yield chiral isomers.

The accumulation is a generalization of the SVM. It takes all of the available information I into account to determine the distinct permutation isomers. In this case this is the whole right coset space of Σ. Besides equivalence of ligands there are other reasons why permutation isomers that were initially regarded as distinguishable are to be classified as chemically identical.

Isomerizations of a permutation isomer X into a permutation isomer of the same family that proceed via a permutation isomer Y of a different family (see Scheme 6) are of particular interest. Let E and F be the reference models of X



Scheme 6. The reference reaction for the generation of graphs of the Berry pseudorotation and the turnstile rotation.

and Y. The reaction $E \rightleftharpoons F$ is used as the reference reaction, that is, it is assumed that any mutual interconversion between λE and λF (for all $\lambda \in Sym(L)$) is possible. When the permutation isomers of X are considered, the left coset spaces of the CIG $S(E)$ and $S(F)$ are generated. The left coset space of $S(E)$ corresponds to the distinct permutation isomers of X, as long as no isomerization takes place. The left coset space of $S(F)$ in $Sym(L)$ yields the information on the permutation isomers of X that are interconvertible by isomerization and that can thus be viewed as chemically identical. The procedure for determining the distinct permutation isomers of X under the given isomerization conditions corresponds to the procedure for the investigation of the equivalence classes of $S(E)$ when some of the ligands are equivalent.

The reaction schemes (or reaction graphs) that represent all interconversions of permutation isomers are obtained by the SVM of the left cosets $\lambda S(E)$ and $\lambda S(F)$ of the two CIGs $S(E)$ and $S(F)$.[82]

The generation of the graph of all Berry pseudorotations[133] and turnstile rotations[82, 134, 135] of the family **32** of permutation isomers from the reference reaction **32a** $\rightleftharpoons$ **32b** by SVM of the left cosets of $S(32a)$ and $S(32b)$ may

serve as an illustration (Scheme 6). For this, each of the individual members of the family **32** are represented by a left coset of *S(32a)* and also by a left coset of *S(32b)*. A SVM of the two left coset spaces is established.

The isomerization processes involving two or more families of permutation isomers like **32** and **33** can be represented by (equivalence) accumulations, if permutation isomers with the same set of ligands participate in the reference reaction. When **32a**$\rightleftharpoons$**33a** is the reference reaction, a graph of the Berry pseudorotation results, in which the reactants **32** are connected by transition states **33** (see p. 132 of ref. [82]).

Ligand permutations that belong to the same Wigner subclass[129] of the relevant CIG correspond to permutation isomerizations with analogous intramolecular motions, that is the same reorganization mechanism.[96, 134] The union of left cosets of a CIG that intersect with a Wigner subclass of this CIG represent a Musher mode.[82, 136, 137] The latter corresponds to those permutation isomers that are formed directly from a reference isomer by a given reorganization mechanism (or an equivalent mechanism). Berry pseudorotations and turnstile rotations yield equivalent results and thus belong to the same Musher mode. They are represented by the same isomerization graph (see p. 132 of ref. [82]).

Since the result of an (equivalence) accumulation is in turn a space of equivalence classes the procedure of accumulations can be restarted with further information (for example additional ligand equivalencies or isomerization processes). Finally an equivalence class space is obtained whose cardinality yields information about the number of distinct permutation isomers, and, through inclusion relations, also about chirality and hyperchirality.[138]

Since the accumulation algorithm is applied in steps, isomerization graphs can be obtained. Thus, accumulations are well suited for the analysis and description of stereoselective reactions. If the ligands 1 and 2 as well as 3 and 4 of **32** are chemically equivalent, then the equivalence space (14) is subjected to a further accumulation by the right coset space of the ligand equivalence group (15). The result is the new equivalence group (16).

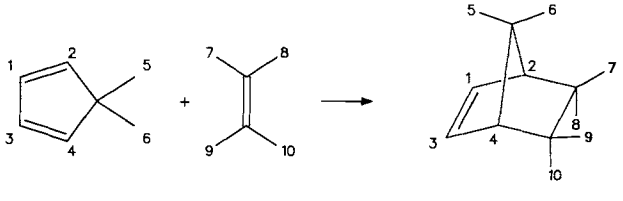
$$A = \mathrm{Acc}(\{\lambda S(32a) \cdot \mathbf{32a} \,|\, \lambda S(32b) \cdot \mathbf{32b} \in \{\lambda S(32b) \cdot \mathbf{32b} \,|\, \lambda \in Sym(L)\}\}) \tag{14}$$

$$\Sigma = \{(), (12), (34), (12)(34)\} \tag{15}$$

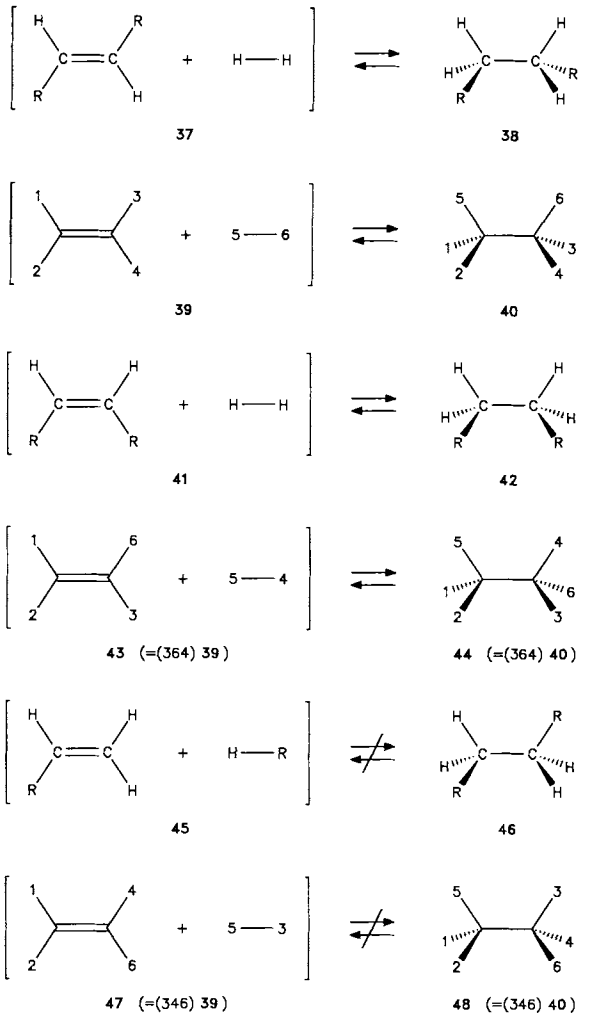
$$B = \mathrm{Acc}(A, \{\Sigma\mu \cdot E \times \Sigma\mu \cdot E \,|\, \Sigma\mu \cdot E \in \{\Sigma\mu \cdot E \,|\, \mu \in Sym(L)\}\}) \tag{16}$$

The graph of Berry pseudorotations/turnstile rotations changes accordingly (see p. 133 of ref. [82]).

Analogously it is also possible to determine which stereoisomers can be formed by a ligand-preserving reaction that affects the chemical constitution of the reactants. The formation of one of the stereoisomers can serve as the reference reaction, and the change in chemical constitution is treated as a transition from one family of permutation isomers to another. The representation of all Diels–Alder reactions that **34** and **35** may undergo in analogy to the reference reaction of Scheme 7 is an example.[98]



34 **35** **36**



37 **38** **39** **40** **41** **42** **43** (=(364) **39**) **44** (=(364) **40**) **45** **46** **47** (=(346) **39**) **48** (=(346) **40**)

Scheme 7. The *cis–trans* isomerization of alkenes.

The applications of accumulations described above emphasize the wide variety of problems that can be treated by SVM and reaction schemes.[94, 95, 97, 124]

In addition, even the isomerizations which interconvert the members of two families of permutation isomers X and Y (with reference models E and F) that have different sets of ligands can be treated by accumulations. In such cases a reference isomerization $E \rightleftharpoons F$ does not necessarily imply that all processes $\lambda E \rightleftharpoons \lambda F$ must take place. The *cis–trans* isomerizations of an alkene that proceed via an alkane may serve as a simple example (Scheme 8).

It is assumed that internal rotations around the C–C axis of the alkane take place freely under the given observation conditions. It follows that the models (346)**40** (= **48**), (364)**40** (= **44**) and **40**, are interconvertible, that is, "equivalent" in the present sense.

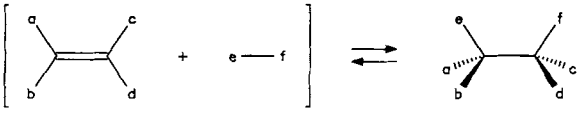
The CIG $S(40)$ contains the permutations (346) and (364). They belong to different left cosets of $S(39)$. Accordingly, the intersections $S(39) \cap (346)S(39)$, $S(39) \cap (364)S(39)$, and $(346)S(39) \cap (364)S(39)$ are empty. However, $S(40)$ intersects with each of these left cosets of $S(39)$: $( ) \in S(40) \cap S(39)$, $(346) \in S(40) \cap (346)S(39)$ and $(364) \in S(40) \cap (364)S(39)$.

It follows that **39**, (346)**39** (= **47**) and (364)**39** (= **43**) are chemically identical. This is certainly true for **39** and (364)**39**, because **37** can be converted into **40** by the hydration route **39** → **40** → (364)**40** → (364)**39**, followed by an internal rotation and subsequent formation of **41** by dehydrogenation.

The *cis–trans* isomers that were initially rated as distinguishable now become interconvertible and thus equivalent (according to the left coset space of $S(39)$ the internal rotation about the C–C bond is not allowable in this case).

In contrast to **39** ⇌ **40** and (364)**39** ⇌ (364)**40** the reaction (346)**39** ⇌ (346)**40** does not represent a hydrogenation/dehydrogenation. Therefore, even though **46** is equivalent to **38** and **42** it cannot be converted into **45**, and (346)**39** ⇌ (346)**40** does not correspond to a model reaction of a hydrogenation/dehydrogenation. In this case a straightforward determination of the intersections is not suitable for establishing the mutual interconvertibilities.

In the description of intermolecular relations chemical reality can be accounted for by so-called filters, which "filter" the feasible interconversions from the set of conceivable or theoretically possible interconversions $\lambda E \rightleftharpoons \lambda F (\lambda \in Sym(L))$. These "allowable" individual isomerizations $\lambda E \rightleftharpoons \lambda F$ are distinguished by characteristic placements of the ligands at the skeletal sites, which are specified as follows: In a reference model M ligand 1 is located at the skeletal site a(M), ligand 2 at the skeletal site b(M), etc. In the hydrogenation/dehydrogenation of Scheme 7, the assignment of the skeletal sites is shown in Scheme 8, in which **39a** = E and **40a** = F are the reference models.



39a (E) **40a** (F)

Scheme 8. Labeling of skeletal sites for the isomerization of Scheme 7.

The *syn* mechanism of hydrogenation/dehydrogenation requires that the skeletal sites e(F) and f(F), and also e(E) and f(E) are occupied by H atoms. The remaining skeletal sites may, in principle, bear any ligands. The only condition is that the corresponding skeletal sites, for example, a(E)/a(F), b(E)/b(F), must bear the same ligands. The filter for this isomerization is formulated in (17).

$$\Phi := \{a(E) = a(F) \wedge b(E) = b(F) \wedge c(E) = c(F) \wedge d(E) = d(F) \wedge e(E) = e(F) = H \wedge f(E) = f(F) = H\} \quad (17)$$

The statement ⟨skeletal site⟩ = ⟨skeletal site⟩ expresses that the two specified skeletal sites must carry the same ligands (e.g., a(E) = a(F)). The condition ⟨skeletal site⟩ = ⟨skeletal site⟩ = ⟨ligand⟩ states that a specific ligand must be present (e.g., e(E) = e(F) = H). Thus, the individual isomerizations $E \rightleftharpoons F$ and $(364)E \rightleftharpoons (364)F$ meet the criterion of the above filter, whereas $(346)E \rightleftharpoons (346)F$ does not.

There are also isomerizations that interconnect members of families which do not have the same set of ligands. Let E and F be the reference models of the participating compounds X and Y. The ligand set $L(E) = \{1, 2, 3, 4\}$ belongs to model E while $L(F) = \{1, 2, 3, 4, 5\}$ belongs to F. Evidently, the permutation (15) only acts on F, because E does not have a fifth ligand. Furthermore, ligand 4 may represent different chemical residues in E and F (e.g., 4(E) = Me; 4(F) = Et). Therefore, the chemical meaning of the permutation may differ depending on the model to which it is applied. In such cases interconvertible isomers of X and Y cannot be determined by intersecting the coset spaces of $S(E)$ and $S(F)$. Filters must be employed to pick the allowable isomerizations. This is an advantage of accumulations[130, 131] over SVM and reaction schemes.[82, 100] The automated elucidation of relations (e.g. interconvertibility) between permutation isomers (which may belong to different families) merely according to the non-empty intersections of equivalence classes restricts the range of applications of reaction schemes and SVM significantly. This restriction is overcome by accumulations which exploit any relation between models in families of permutation isomers.

For four years, we have been developing computer programs to solve stereochemical problems on the basis of the present mathematical concepts.[130, 131]

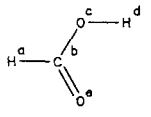
4.3. The Software Infrastructure

A suitable software infrastructure needed to be created for the computer programs for the deductive solution of chemical problems on the basis of the DU model and the CIG theory.

4.3.1. Canonical Indexing of Atoms

The algorithm and computer program CANON[139, 140] were developed for internal documentation. The algorithm CANON refers to the atomic numbers and coordination numbers of atoms as well as their covalently bound neighbors.

The principle of CANON is illustrated by a simple example (Scheme 9).



49

1. Atomic indices:	a: 3	b: 2	c: 1	d: 3	e: 1
1. Atomic descriptors:	a: 3.2	b: 2.113	c: 1.23	d: 3.1	e: 1.2
2. Atomic indices:	a: 5	b: 3	c: 2	d: 4	e: 1
2. Atomic descriptors:	a: 5.3	b: 3.125	c: 2.34	d: 4.2	e: 1.3

Scheme 9. An example to illustrate the principle of CANON.

CANON begins by arbitrarily labeling the atoms. In the example of **49**, the letters a–e serve as these arbitrary labels. The first atomic indices are assigned by starting with 1 for the atom with the highest atomic number and proceding in order with decreasing atomic numbers (O:1; C:2; H:3). The first atomic descriptors are formed from the first atomic in-

dices of the considered atom and in numerical order the indices of its covalently bound immediate neighbors (e.g., b: 2.113; c: 1.23; e: 1.2). Subsequently, the order of the first atomic descriptors taken as decimal numbers (lexicographic order) is used to determine the second atomic indices (e.g., b: 3; c:2; e: 1). The second atomic descriptors are formed analogously to the first atomic descriptors from the second atomic indices. Since the lexicographic order of the second atomic descriptors already corresponds to the second atomic indices, the latter are the final atomic indices according to CANON for this example. If this were not so, a further cycle would begin with the computation of the next atomic descriptors. If constitutionally equivalent atoms are present, any representative of their equivalence class can be selected arbitrarily without introducing ambiguity to the indexing procedure.

With CANON atomic indices are unequivocally assigned to atoms in molecules as well as to the corresponding rows (and columns) of the be-matrices with due consideration of chemical constitution and constitutional symmetries. Redundancies are thereby avoided.[21] For our purposes CANON is superior to the Morgan algorithm that is used by the Chemical Abstracts Service.[141] Since CANON recognizes constitutionally equivalent atoms, it is also suitable for ligand indexing in stereochemistry[140,142] and for predicting the chemical shift patterns of NMR spectra. When stereochemical problems are solved with computer-assistance, CANON-based ligand indexing has some significant advantages over the system of CIP rules.[143] In contrast to CANON, the system of CIP rules takes into account the formal bond orders instead of the coordination numbers of the atoms. CANON is simpler and unambiguous in all cases. In addition, CIP is based on a comparison of the individual ligands instead of an analysis of the whole chemical constitution of the considered molecules. The computer program CANON will soon be available for interested users.[144]

4.3.2. Recognition and Correlation of Substructures

For the computer-assisted solution of chemical problems the presence or absence of certain specified substructures in the generated molecules is often required. Therefore, the substructure search algorithm CABASS[145] based on central atoms and a computer program were developed. CABASS serves as a functional subunit in IGOR2.[115]

Substructure search systems, such as the DARC system of Dubois et al.,[146] often operate through a screening procedure and a subsequent atom-onto-atom mapping. The first procedures for atom-onto-atom mappings were published by the Chemical Abstracts Service[147] and by Sussenguth.[148] In its screening procedure, the DARC system uses spherical fragments that are coded as byte strings and embedded in tree structures for storage in a data bank. The search for substructures exploits this tree structure. The method of spherical fragmentation is also used by Lynch et al.[149] for the generation of screening systems for substructure search in structural data files. When Friedrich[150] analyzed the customary substructure search methods[146,151] he found that they are not suitable for the correlation of molecules according to common substructures. This is particularly the case when large files of data must be analyzed, because computing time and memory space increase more steeply than a polynominal curve with the size of the problem.[152]

Recently Ihlenfeldt[153] developed a computer program for structure-oriented correlation of molecules. Although this program is hampered by the disadvantages of the common procedures, it is capable of processing moderate amounts of data quite efficiently.

Fortunately, the complexity of molecular graphs is generally only moderate. Thus, it is possible to devise algorithms to correlate molecules through their substructures so that the need for memory space and computing time increases at worst polynomially (degree ≤ 5) with size and number of molecules that are to be considered. These algorithms are based on stepwise fragmentation of molecules and imbed the resulting fragments in a network of father–son relations which includes all the listed molecules. Based on this concept J. Friedrich[150] tested CORREL, a substructure correlation program for bilateral synthesis design. Improvements of CORREL led to CORREL 2,[154] which is more suitable for routine use. Recently, CORREL-S was employed for bilateral synthesis design;[155] it is based on a selection of substructures.

A special version of CORREL has been used for documentation and sequence matching of peptides[156] and is now being extended to include nucleotide sequences, as well as their correlation with peptide sequences.

The basic design of CORREL, published[150] with its source code, stimulated the implementation of several substructure search and correlation programs of similar design like RESY,[157] KOWIST,[158] HTSS,[159] S4,[151,160] and a program by Klopman.[161,162] The latter program as well as RESY and KOWIST are particularly suitable for structure–activity studies.[158]

Strategic Bonds and Substructures Relevant for Syntheses

For bilateral synthesis design it is necessary to find suitable starting materials for the synthesis of given target molecules. Here the largest common substructures are used as a guideline. CORREL-S was developed for this purpose.[89,155]

When a data bank of substructures relevant for synthesis is assembled, a set of rules about "breakable" bonds is required to reduce the size of the file in a meaningful way.[163] To establish this set, Corey's rules about strategic bonds were modified, hierarchically ordered, and provided with a termination criterion: the procedure is terminated when all nonaromatic rings have been dissected. A strategic bond must fulfill the following criteria:

1. The bond does not belong to a carbocyclic aromatic system. This does not apply to heteroarenes, which are often assembled in the course of a synthesis.
2. A bond is ranked by the number of rings its rupture will open. The higher this number, the higher the bond's preference; the number of rings is determined by CANON[139] and enumerated according to the Frèrejacques formula.[44]
3. If there are more than two bonds that qualify by rule 2, those that generate the fewest new rings are given priority.
4. Bonds at heteroatoms are strategic.
5. A bond is preferred if it is *exo* to other rings.
6. The bond must involve at least one carbon atom with more than two neighboring non-hydrogen atoms. This essentially corresponds to rule 5 when polycyclic structures are

present. However, rule 6 becomes relevant when only isolated single rings are left over.

7. A multiple bond is strategic.

8. The bond is a direct or next neighbor to a bond according to rule 4 or 7.

With these rules it is possible to process simple and complex ring systems. The preference rules help to restrict the number of strategic bonds and to establish the priorities for bond rupture in order to reach substructures relevant for the synthesis in available starting materials as soon as possible.

4.3.3. Stoichiometric Completion of Truncated Reaction Equations

The co-products of the target molecule of a synthesis, its stoichiometric complements in the target EM, are found with the computer program STOECH.[164] STOECH is based on a matrix formalism that was used in the elucidation of the reaction mechanism[165] of the four component condensation (4CC; α-addition of iminium ions and anions to isocyanides, followed by secondary reactions;[166] Ugi reaction[167]). Stoichiometric completion of truncated reaction equations[168] is now also of interest for the systematic documentation of chemical reactions based on their hierarchic classification (see Section 4.3.5).

4.3.4. Determination of Minimal Chemical Distance and the Corresponding Atom-onto-Atom Mappings

The repeated determination of the chemical distances (CDs) between isomeric EMs is a prerequisite for the optimization of reaction networks.[21, 100, 169] The associated atom-onto-atom mappings are needed in hierarchic reaction documentation.[79, 100, 112] Since the computer program PMCD[105] for the approximate determination of the minima of CD, which is based on a heuristic "branch-and-bound" algorithm,[170] does not always yield satisfactory results the computer program PEMCD[106] for the exact determination of the minima of CD was tested. A reaction core with 16 contiguous reaction centers is the upper limit for the present version of the PEMCD. We are therefore presently developing a more powerful computer program as a sucessor of PEMCD.

The CD between EMs with up to 100 reactive centers can be determined with a program that was recently implemented by Fontain.[107] This program is based on the "genetic algorithms".[171] Unfortunately this CD-minimization program does not yield all atom-onto-atom mappings that belong to the minima of CD.

4.3.5. Reaction Documentation

In the customary commercially available reaction documentation systems, chemical reactions are represented by their starting materials and products. This does not suffice to solve the reaction documentation problem satisfactorily.[172] Until recently ORAC[173] outstripped the available reaction documentation systems, but it is unfortunately no longer available. Since the deficiencies of traditional reaction documentation are known, and since reaction documentation belongs to the most important, yet unsolved problems of computer chemistry, many new approaches have been mooted in this field.[174, 175] Therefore within the Munich project, a hierarchically ordered system has been developed[79, 112] that refers directly to the processes of the chemical reactions as such; up to now this system has not found appreciable acceptance. The main reason is that the considered reactions must be stoichiometrically balanced, that is, they must be representable as isomerizations of EMs. In the chemical literature, reactions are often published in truncated form, where some of the participating reactants are omitted and would have to be stoichiometrically completed. This is now possible through the recently published program STOECH (see Section 4.3.3).

4.3.6. Graphic Output of Results

Since the results of the computer-assisted deductive solution of chemical problems are be-matrices, the graphic output program MDRAW[176] was developed. This converts the be-matrices into the graphic constitutional formulas that are more familiar to chemists. ARGOS, a similar program that was tested by J. Bauer and E. Fontain, is part of the user interface of IGOR and RAIN, and it has also been used routinely for several years by the Beilstein Institute for the conversion of connectivity lists into constitutional formulas.

4.4. The Multipurpose Programs IGOR and RAIN[*]

4.4.1. Formal Reaction Generators

The fundamental equation $\boldsymbol{B} + \boldsymbol{R} = \boldsymbol{E}$ of the DU model can be solved from a given be-matrix $\boldsymbol{B}$ by determining those pairs $(\boldsymbol{R}, \boldsymbol{E})$ which fulfill $\boldsymbol{B} + \boldsymbol{R} = \boldsymbol{E}$ under the given boundary conditions. We call these solutions the b-solutions. They are found by *r*eaction *g*enerators (RG) of the type RGB.[169, 177, 178] The equation $\boldsymbol{B} + \boldsymbol{R} = \boldsymbol{E}$ can also be solved from a given r-matrix $\boldsymbol{R}$. These r-solutions correspond to the pairs $(\boldsymbol{B}, \boldsymbol{E})$ for which $\boldsymbol{B} + \boldsymbol{R} = \boldsymbol{E}$ is fulfilled and are obtained by reaction generators of the type RGR.[114–116]

The two complementary types of solutions of the equation $\boldsymbol{B} + \boldsymbol{R} = \boldsymbol{E}$ and the respective RGs correspond to the two basic types of computer programs for the solution of chemical problems on the basis of the DU model. The centerpiece of the present version IGOR2[115] of the computer program IGOR[114–116] is an RGR. Recently RAIN[60–62, 169, 177, 178] also became generally available; the "engine" of RAIN is an RGB.

The RG of IGOR and RAIN are guided by *t*ransition *t*ables (TTs).[62, 63, 177, 178] A standard TT or a TT that is defined by the user is assigned to each chemical element that is taken into account. The allowable transitions are recorded in these TTs (see Fig. 2).

The computer programs IGOR and RAIN operate with strictly formal reaction generators, and are thus not restricted to the solution of a particular type of problem, such as retrosynthetic analysis. In combination with suitable auxil-

[*] IGOR and RAIN are available from the authors on request.

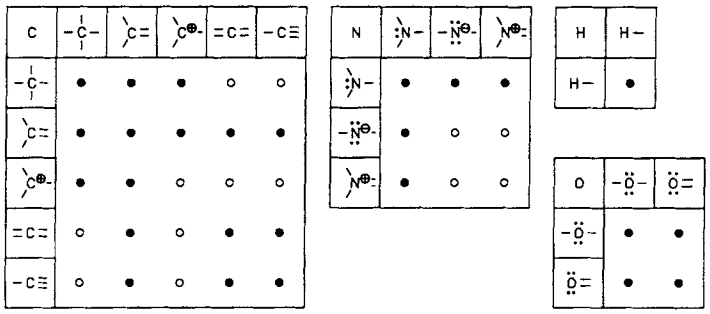


Fig. 2. Examples of transition tables. • = allowed transition, o = forbidden transition.

iary programs, both IGOR and RAIN can deal with a wide variety of chemical problems and deserve to be called multipurpose problem-solving programs. The solutions that they generate can belong to known chemistry, or they can be entirely without precedent, because these programs are independent of detailed empirical chemical information.

The first TT-guided RG (TRG) was the TRGR of IGOR, which solves the equation $\boldsymbol{B} + \boldsymbol{R} = \boldsymbol{E}$ from an r-matrix $\boldsymbol{R}$ and a list of the TTs of all relevant chemical elements. The user selects a suitable collection of TTs for each row/column pair of the potential solutions ($\boldsymbol{B}$, $\boldsymbol{E}$). The TRGR checks whether the entries of the TTs are compatible with $\boldsymbol{R}$ to provide a reduced collection of TTs, which are used to generate the be-matrix $\boldsymbol{B}$, row by row, column by column. From the rows and columns of $\boldsymbol{B}$, $\boldsymbol{R}$ generates rows and columns of $\boldsymbol{E}$. Now all row/column combinations of ($\boldsymbol{B}$, $\boldsymbol{E}$) are verified through use of the TTs. The novelty of each generated pair ($\boldsymbol{B}$, $\boldsymbol{E}$) is checked by CANON[139] in order to avoid redundancies. Subsequently the pairs of matrices are analyzed by CABASS[145] for forbidden or required substructures. The acceptable solutions are finally represented graphically on the screen or printed.

IGOR's TRGR generates pairs of starting materials and products according to a given irreducible r-matrix $\boldsymbol{R}$, which represents the redistribution of electrons (see Section 3.2.2). Thus, IGOR uses given "electron-pushing" patterns to "invent" chemical reactions. The r-matrices of such electron-pushing patterns can be produced by an independent computer program.[179] The reactions that are generated by IGOR are subjected to an interactive selection procedure that follows the hierarchic classification system for chemical reactions.[114]

In the structure-generating mode, a zero matrix $\boldsymbol{R} = \{\}$ is used as an r-matrix. IGOR then produces be-matrices $\boldsymbol{B}$ of molecules or EMs with $\boldsymbol{B} = \boldsymbol{E}$. Sets of molecules with the specified structural features can be obtained by restricting IGOR's output.[114, 177, 180, 181]

An RGB generates all EMs into which a given EM is directly convertible. Since an RGB may also use $-\boldsymbol{R}$ instead of $\boldsymbol{R}$, it can also generate the EMs from which the input EM can be obtained. When incorporated into a retrosynthetic program, an RGB can play the same role as a reaction library in combination with a structure-perceiving module, that is, the RGB finds the precursors of a given target molecule and their precursors, etc.

A TRGB operates in two steps: the first step is to determine the allowable valence schemes of those chemical elements that are assigned to the rows and columns of $\boldsymbol{E}$. They are obtained from the rows and columns of $\boldsymbol{B}$ through the TT. Subsequently, all $\boldsymbol{E}$s are generated that fulfill $\boldsymbol{B} + \boldsymbol{R} = \boldsymbol{E}$ under the given boundary conditions.

RAIN's TRGB[60, 63, 178] generates isomeric EMs from an $EM_{\boldsymbol{B}}$ that is represented by its be-matrix $\boldsymbol{B}$. The isomeric EMs correspond to the products that can be directly formed from $EM_{\boldsymbol{B}}$, or to starting materials for the $EM_{\boldsymbol{B}}$. RAIN is capable of simultaneously generating two trees of successive chemical reactions that consist of sequences of isomeric EMs. The "geometric" properties of the family of all isomeric EMs are exploited to direct the trees so that they grow from $EM_{\boldsymbol{B}}$ and $EM_{\boldsymbol{E}}$ and meet as soon as possible to form a contiguous network of reaction pathways; this bilateral generating process guides each reaction pathway to meet by checking the CD of the intermediate EMs[21, 100, 107, 182, 183] and is terminated as soon as an EM is reached from both sides. Thus, RAIN produces reaction networks that connect isomeric EMs.[60, 63, 177, 184, 185] By interactively specifying the lower and upper bounds and other characteristics of the reaction pathways (number and structural features of the intermediates, number of redistributed electrons per reaction step, etc.), the user can determine the nature of the network.[21] Depending on whether only the valence schemes of stable compounds are admitted, or also those of unstable intermediates, the networks that are generated contain only stable molecules or also short-lived intermediates.

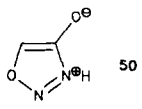
Accordingly, RAIN may be used for mono- and bilateral synthesis design,[84, 88, 89] for planning and predicting reactions, and also for the elucidation of biosyntheses and complex reaction mechanisms (see Section 4.4.4).

Recently, Valdés-Pérez[186] presented the system MECHEM that is capable of generating networks of reaction pathways by symbolic computation. However, the latter program can only take empirical formulas into account, and not constitutional formulas.

4.4.2. Structure Generation by IGOR and RAIN

In their structure-generating modes, IGOR and RAIN produce all constitutional formulas that meet the specified conditions. Thus, for instance, all 23 EMs with the formula $(CH)_8$ and all 18 1,3-dipoles[187] of the elements C, N, and O are generated.[114] In order to demonstrate how the number of isomers increases when the C and H atoms of hydrocarbons are partially replaced by heteroatoms, the number of constitutional formulas of compounds with the empirical formula $C_2H_2N_2O_2$ (nonionic; no triple bonds or cumulated double bonds in rings; ammonium or iminium N^+ or amide N^- and O^- allowable as electronically charged atoms) were enumerated by IGOR and RAIN. Both programs found 1806 EMs, whereas there are only six hydrocarbons C_4H_4. When these molecules are generated by RAIN, the network of all constitutional isomers was generated from two atoms of each of the elements C, H, N, and O. For comparison nonionic $C_2H_2N_2O_2$ isomers were also generated that have a five-membered ring and formally one positive and one negative electrical charge. Sydnone **50** and 51 of its analogues result.

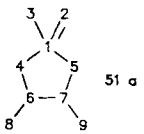
At present the customary reagents for the synthesis of oligonucleotides are derivatives of phosphorous acid[188] because, in general, the alternative phosphoric acid derivatives



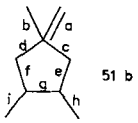
50

do not react sufficiently quickly with nucleoside derivatives. However, five-membered cyclic phosphoric acid derivatives react 10^5–10^7 times faster with nucleophiles or apicophiles than their acyclic analogues.[189, 190] Since 1973, the research groups of F. Ramirez and I. Ugi endeavoured to exploit this fact for syntheses by attempting to develop highly reactive five-membered phosphorylating reagents based on P^V for oligonucleotide syntheses.[191] These reagents would have some advantages over customary P^{III} reagents.[192]

After some initial success[193] the development stagnated, mainly because new ideas were lacking. Only after Ugi et al.[180] decided to review all of the candidate P^V compounds as defined by **51a** and **51b** with the aid of IGOR was progress again rapid.



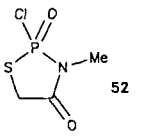
51 a



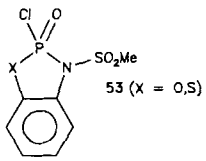
51 b

The following atoms were admitted for **51a**: 1 = P; 2 = O; 3 = X; 4, 5 = O, N, S; 6 = C, N, O, S; 7 = sp^2-C; 8, 9 = C, Cl, N, O, S. H atoms are placed according to valence rules. The covalent bonds are distributed as indicated by **51b**: a double bond; b, c, d: single bond; e, f, g: single or double bond; h, i: single or no bond. IGOR found 278 formulas **51** that complied with the restricting definitions.[180]

Five of these candidates were chosen to be investigated experimentally.[194] Already, two promising phosphorylating reagents, **52**[192] and **53**,[195] have resulted from these studies.

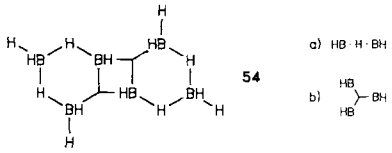


52



53 (X = O,S)

Lipscomb used the rules that he had established for the structure of boron hydrides to postulate structure **54** for B_6H_{14}, containing open (a) and closed three-center bonds (b).[196] Recent NMR data indicate that two kinds of B atoms (based on first-sphere neighbors) are present.[197] The formulas of Figure 3 generated by RAIN for B_6H_{14} agree with the observations.



54

Computer-assisted structure elucidation à la DENDRAL employing analytical data is a particularly promising application of IGOR and RAIN. The experimental evidence can be used as restricting conditions when molecular structures are generated. All constitutional formulas that are compatible with the measured data are obtained.

The graph theoretical representation of chemical constitution has already been successful within the DENDRAL pro-

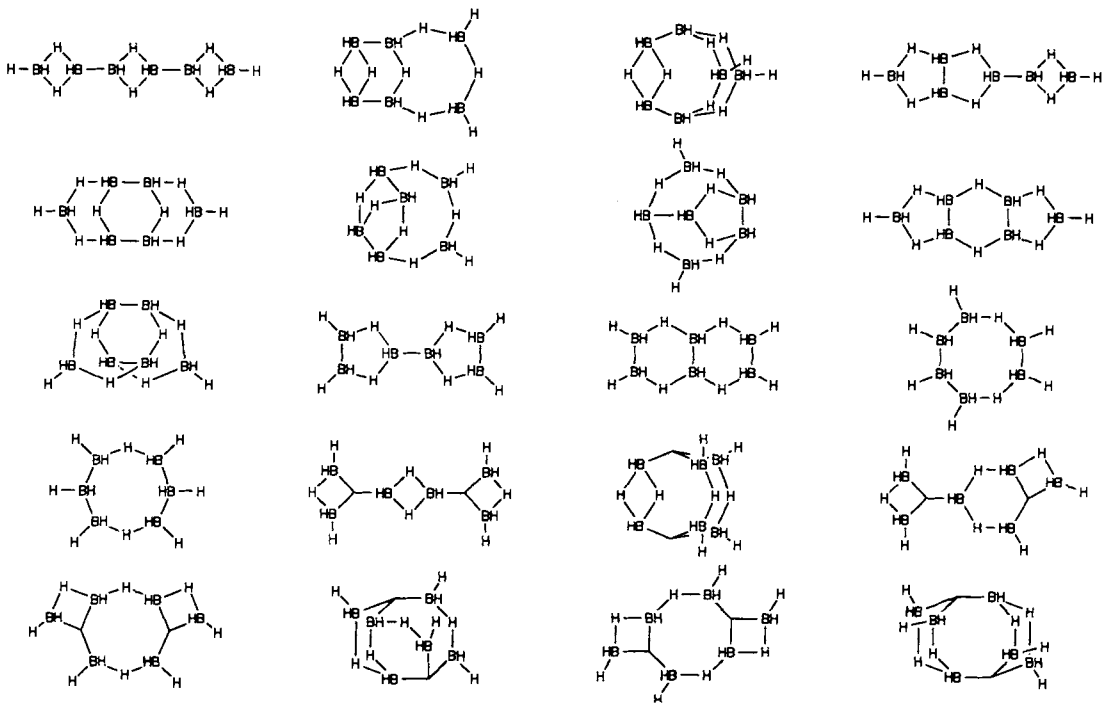


Fig. 3. Proposed structures of B_6H_{14} generated with RAIN.

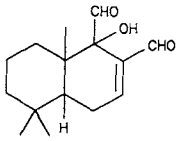
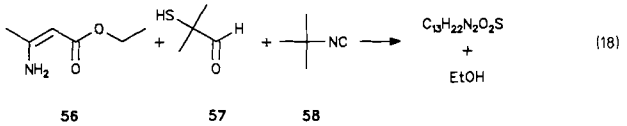
ject as a mathematical foundation of the computer programs CONGEN[198] and GENOA,[199] and also later in the comparable programs RASTR,[200] MOLGRAPH,[201] ESSESA,[202] and GEN,[203] which generate families of constitutional formulas. GENOA was the first functioning program within this category. The computer-assisted elucidation of chemical constitution of walburganal **55** with the aid of GENOA is one of the most impressive applications of DENDRAL.[24]



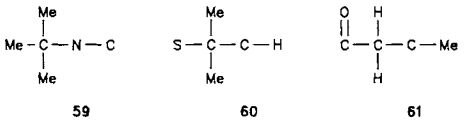
55

RAIN and GENOA generate the same set of 42 constitutional formulas, when the empirical formula $C_{15}H_{22}O_3$ of walburganal **55** and the substructures that are required or forbidden by the spectroscopic data are input. A substance with the empirical formula $C_{13}H_{22}N_2O_2S$ results from the reaction of ethyl β-aminocrotonate **56** and α-mercaptoisobutyraldehyde **57** with *tert*-butyl isocyanide **58**.[204]



(18)

56 **57** **58**



59 **60** **61**

Assuming that the substructures **59**–**61** in the starting materials are also present in the product, RAIN proposes the constitutional formulas of Figure 4.

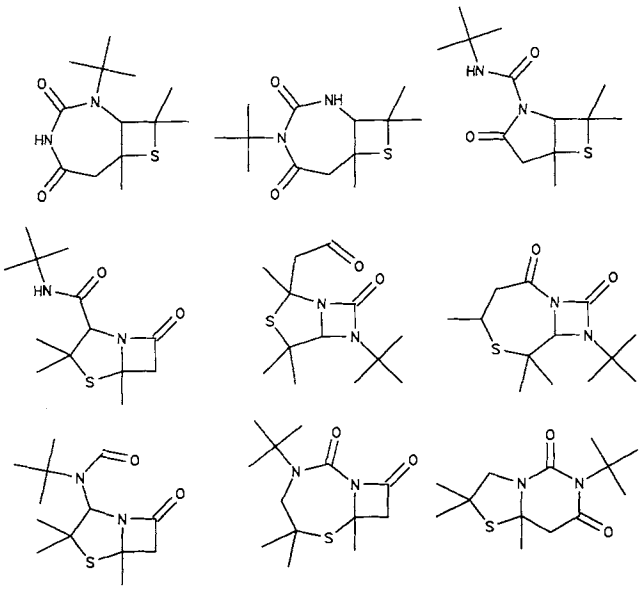


Fig. 4. Structures generated by RAIN as proposed products of reaction (18).

During routine runs, RAIN automatically recognizes the chemical equivalence of prototropic tautomers and resonance structures. For example, the tautomers and resonance structures of Figure 5 are obtained for the nucleobase cytosine.

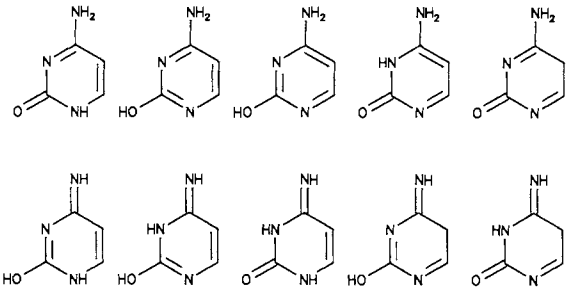

Fig. 5. The tautomers and resonance structures generated by RAIN for cytosine.

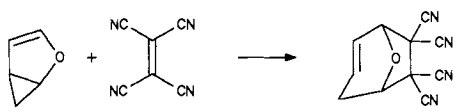
4.4.3. Generating Reactions with IGOR

Recently, Barton[205] published a very remarkable article on the systematic search for new reactions without computer-assistance. In this section the computer-assisted discovery of new reactions is described.

About ten years ago, R. Herges was given the task—as a part of his doctoral thesis—to find unprecedented reactions with the aid of the computer program IGOR,[116] which was then still under development, and to verify these reactions in the laboratory. The experience and suggestions gathered in the course of the investigations substantially improved the efficiency and user-friendliness of IGOR.

One of the results was that the chemist's participation varies strongly.[206] Computers only gave the inspiration for the development of cycloadditions of homodienes.[207] The systematic investigation of the r-class of the pericyclic 6-center 6-electron reactions demonstrated that in this 6,6 r-class of 13 basis reactions, only **25** → **26** with C atoms in the core of the reaction had not been studied much, although it was plausible. The reaction **62** + **63** → **64** was selected as an example according to heuristic criteria (ring strain, polarization, molecular geometry, etc.); this reaction succeeded in the laboratory.[114, 118]



62 **63** **64**

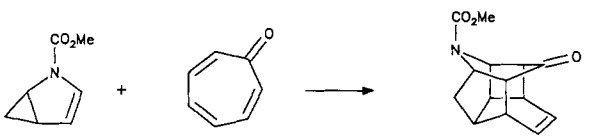
In this context, our experience was that it is very difficult to ensure the unprecedentedness of a reaction in terms of the chemical literature. The data banks of molecular structures (CAS online, Beilstein online, etc.), which contain data on almost all compounds that have ever been synthesized, are easy to research. The commercially available data banks of chemical reactions, however, are not sufficiently structured and far from complete, and precedence must be determined by searching for all potential starting materials and products of the considered reaction.

H. Prinzbach informed us that Fowler[208] carried out the cycloaddition of *N*-methylcarbonylhomopyrrole **65** to dimethyl acetylenedicarboxylate in 1971. This reaction is related to **62** + **63** → **64** because the reactants **62** and **65** are similar. We had overlooked this reaction.

The extrusion reaction **25** → **26** (Scheme 2) is a further example of an experimentally verified reaction that was found by IGOR through the hierarchic classification system of chemical reactions. Hydrogen was chosen as the group to be transferred, since hydrogen transfer reactions generally proceed with particular ease; a carbonyl oxygen atom appeared to be favorable as an sp^2 center. All other reactive centres of **25** → **26** were allowed to be C or O. Furthermore, the chemically meaningful condition was introduced that the extruded molecule must be CO_2. This led to four types of reactions, of which three were already known. One, however, was not, namely the pyrolysis of α-formyloxy ketones **25** to **26**. Three examples of this reaction were successfully carried out in the laboratory[114, 118] (see Scheme 2).

This reaction is of moderate novelty, because the rb-subclass of the extrusion reactions was put in. Accordingly, at best, a further extrusion reaction could be discovered as a "new" reaction. Nevertheless, reaction **25** → **26** is still interesting, novel, and even of preparative value. In the synthesis of cyclic ketones by acyloin condensation[209] it is superior to the customary reduction of acyloins by Zn/HCl.[210] Obviously, the above reaction could also have been found without computer-assistance, but it is interesting and surprising that an probable reaction in the intensively studied field of extrusion reactions had been overlooked. This demonstrates that the systematic search for new reactions is more successful with computer-assistance than without.

There are many conceivable reactions from the CD-class 8 (see Section 3.2.2) that are novel up to the level of the ra-subclasses.[114] Some years ago, a systematic search for pericyclic reactions whose basic reactions are without precedence was conducted with IGOR. The CD-class 20 (reactions with five redistributed electrons) was the first in which a new experimentally realizable pericyclic reaction was found[88, 117] (**65** + **66** → **67**).

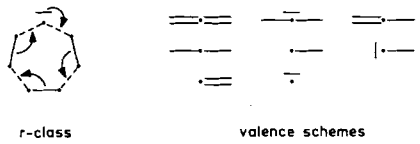


65 **66** **67**

Further reactions found through IGOR are a carbene rearrangement,[211] and a method for the synthesis of isocyanides containing electron-withdrawing groups.[206]

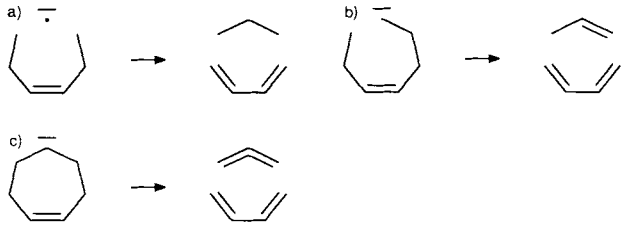
Besides systematic screening of classes of reactions for new reactions, a systematic search can be conducted for reactions that may be used for the synthesis of a given class of compounds. Herges and Hoock[212, 213] scanned the 7-center, 8-electron pericyclic reactions for syntheses of 1,3-dienes. The restrictions were given in the irreducible r-matrix and the valence schemes of the participating atoms (Scheme 10).

Of a total of 72 basic reactions generated (when triple bonds are admitted 470 basic reactions are generated), only three



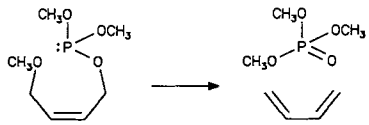
Scheme 10. Pericyclic 7-center, 8-electron reactions.

(Scheme 11) are suitable for the synthesis of 1,3-dienes (a butadiene fragment is produced in these cases).



Scheme 11. Potential reactions for the synthesis of 1,3-dienes according to Scheme 10. The arrow in a) indicates an atom possessing a lone pair of electrons (symbolized by a short line).

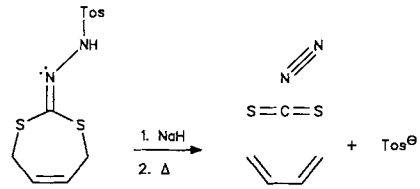
Only reaction a) is known through some variants involving heteroatoms. One example is the reduction of 1,4-dichloro-2-butene with Zn. To our knowledge, the basis reactions b) and c) have not been published. The variant **68** → **69** of basis



68 **69**

reaction b) was carried out recently, and yields 40% of butadiene in the gaseous phase at 0.40 Torr and 350 °C. It is not useful for syntheses, but is a novel type of 1,4-elimination.

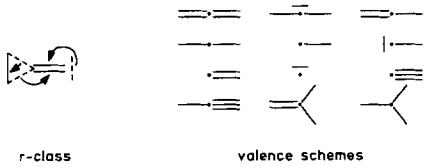
The example **70** → **71**[212] was verified as a representative of c).



70 **71**

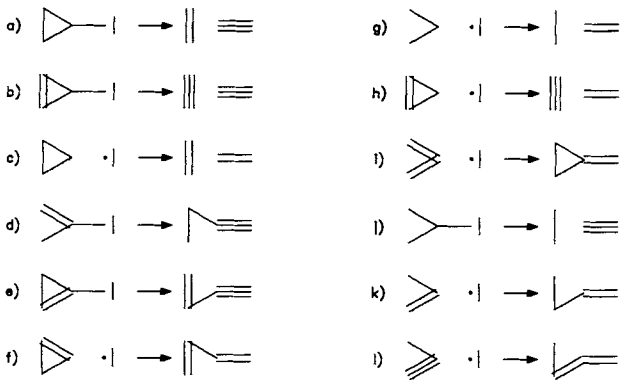
Not only pericyclic reactions can be generated in this way, but also reactions from other areas of organic chemistry. This can be seen in the example in Scheme 12 of a search for a novel carbene reaction.[214]

The first four basis reactions of Scheme 13 are illustrated in published examples. The fragmentations of cyclopropyl and 2-cyclopropyl carbene (a and b) have been thoroughly investigated.[215, 216] Also, reactions of carbenes with strained



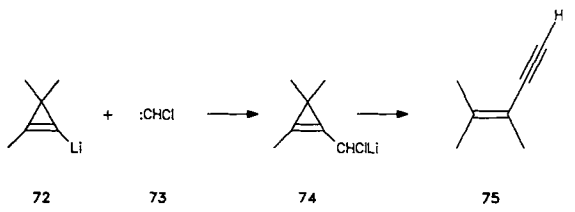
Scheme 12. Carbene reactions.

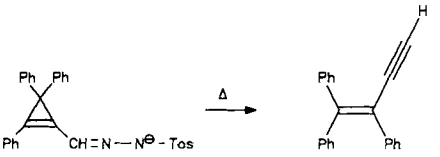
three-membered rings (c)[217] and the carbene rearrangement (d)[218] are already known. Herges[214] experimentally realized the unprecedented basis reaction (c) for two different carbene precursors (**72** + **73** → **74** → **75**; **76**–**77**).



Scheme 13. Potential carbene reactions. Lone pairs of electrons are symbolized by short lines.

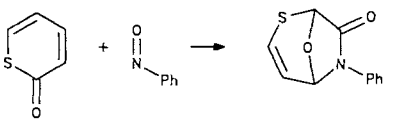
Recently, using IGOR2, Fisher, Juarez-Brambila, Goralski, Wipke, and Singaram[219] found and experimentally verified a novel rearrangement of α-aminoalkylboranes to the corresponding β-dialkylaminomonoalkylboranes.





4.4.4. *Generation of Reaction Networks with RAIN*

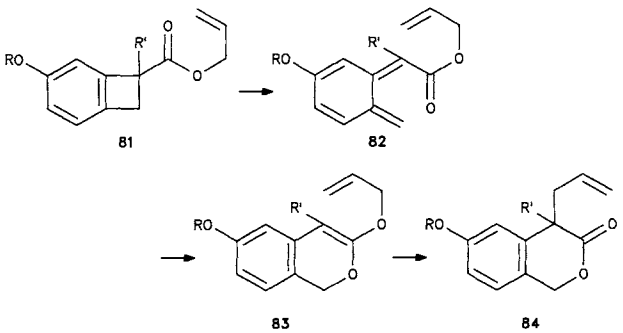
In the summer of 1982, a reaction mechanisms contest took place at the University of California at Los Angeles. The topic of this contest was the proposal of a plausible reaction mechanism for the newly published Streith–Defoin reaction **78** + **79** → **80**.



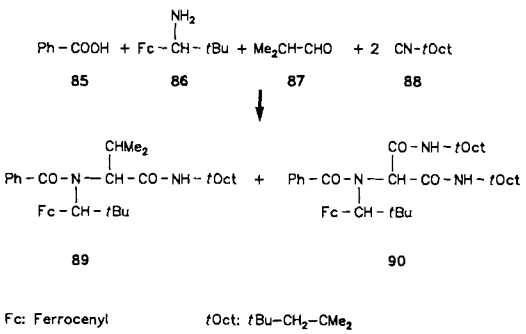
M. Jung, who organized the contest, asked I. Ugi to make some computer-generated proposals for the mechanism of for the Streith–Defoin reaction. We succeeded only after RAIN was available.[21, 60, 63] The Streith–Defoin reaction[220, 221] played an important role as a "fitness bicycle" in the development of RAIN. The network that RAIN generates under suitably chosen boundary conditions[63] contains the four best proposals of that contest; one of these corresponds to the reaction mechanism that has since been elucidated.[221]

Ried and Dietrich's indazole synthesis,[222] the thiazole synthesis by Hantsch,[223] and the Favorskii rearrangement[224] belong to the first applications of RAIN. Initially, a surprisingly large network of conceivable reaction mechanisms was found for the Favorskii rearrangement—116 intermediates at six levels and 43 intermediates at its "widest" level. Besides the published reaction mechanism,[224] this network contained many other mechanisms that are compatible with the known experimental results. When a suitable set of restrictions is input to the present version of RAIN, it generates a single reaction mechanism for the Favorskii rearrangement—the published one.

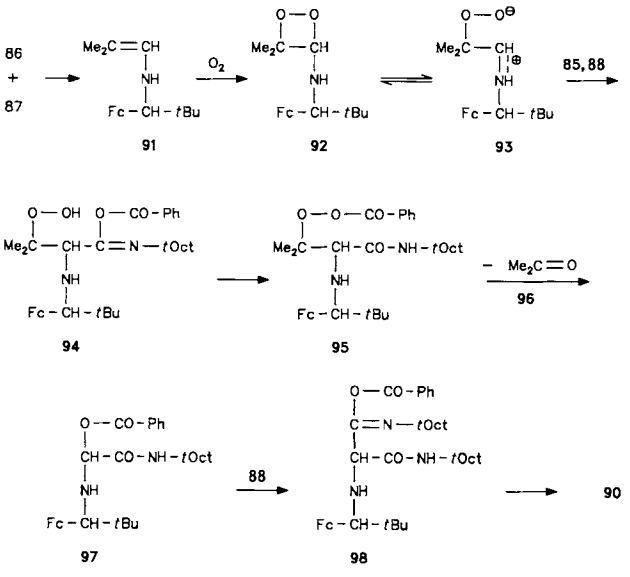
RAIN finds only one reaction mechanism for the rearrangement of benzocyclobutene **81** into isochroman **84**[62] that was studied by Kametani et al.[225] The intermediates were **82** and **83**.



Recently the mechanism of an undesirable side reaction of the four component condensation was elucidated with RAIN.[184, 185] The formation of **89** and the malonamide



derivative **90** from **85**–**88** served as a model reaction. Experimental evidence in combination with suggestions from RAIN leads to the assumption that **90** is formed by the reaction mechanism depicted in Scheme 14 via the intermediates **91**–**98**.



Scheme 14. Mechanism for the formation of **90**.

The elucidation of the mechanism of the hypothetical prebiotic synthesis of adenine from five molecules of hydrogen cyanide[226] is still open-ended, since the experimental evidence is not enough to decide which of the conceivable mechanistic alternatives proposed by RAIN is valid.

5. Perspectives

Nowadays computers belong to the standard instrumentation of chemical research, and it is safe to predict that computers will increasingly contribute to progress in chemistry in ever more diverse ways. The importance of numerical applications in chemistry, in particular in quantum chemistry and chemometrics but also in the planning, executing, and evaluating of measurements and in molecular modeling, will continue to soar. The use of computers in the documentation of chemistry-related data and information will develop vigorously in volume and efficiency.

It is foreseeable that computer programs for the direct solution of chemical problems will become routine in chemical research. In this context, formal algorithms will play an increasingly important role, even in expert systems that rely on stored detailed information. Empirical data will primarily be used for comparison with the results of computer programs that operate on a formal basis.

As a consequence of inquisitiveness of the potential users, computer programs with innovative capabilities will be preferred if the offered software has a convenient user interface and is suitable for widely available hardware. It is also important that such programs operate in an interactive mode, because an intelligent and experienced user wants to participate in the problem-solving process. With the aid of a suitable computer program it is, in principle, possible to generate all the conceivable solutions of a given chemical problem, including the most imaginative ones, but these solutions are worthless if they are hidden under enormous amounts of insignificant data; the meaningful and nonarbitrary selection of the solutions cannot be accomplished without the participation of a qualified user. The computer is able to provide assistance in arriving at new chemical ideas, but chemists must recognize their value and select them from a large number of conceivable alternatives. Thus, innovation may switch from the generation of proposals to their evaluation and selection, but new chemistry cannot be produced without the participation of human creativity. Progress in computer chemistry is based on new insights, ways of reasoning, formalisms, algorithms, software techniques, and also advances in computer hardware. Since the development of computers is still vigorous, it is too early to evaluate the future importance of single projects and tendencies. Much of what now looks impressive will be forgotten tomorrow, and what now seems to be excentric or irrelevant may turn out to be the beginning of a useful and important development.

We would like to thank the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, the Alexander-von-Humboldt-Stiftung, the Commission of the European Community, the Bundesministerium für Forschung und Technologie, and the Fonds der Chemischen Industrie for the generous financial support of our work.

Mathematical Concepts and Notations

Boolean Algebra (let a and b be Boolean values)

$\mathbb{B}$	set of Boolean values {O, L}
$\wedge$	conjunction (logical and): connective $\wedge: \mathbb{B} \times \mathbb{B} \rightarrow \mathbb{B}$ according to the table

$\wedge$	O	L
O	O	O
L	O	L

$\vee$	inclusive disjunction (logical or): connective $\vee: \mathbb{B} \times \mathbb{B} \rightarrow \mathbb{B}$ according to the table

$\vee$	O	L
O	O	L
L	L	L

$\Rightarrow$	implication ($a \Rightarrow b$: "if a then b"): connective $\Rightarrow$: $\mathbb{B} \times \mathbb{B} \rightarrow \mathbb{B}$ according to the Table

$\Rightarrow$	O	L
O	L	L
L	O	L

$\Leftrightarrow$	equivalence ($a \Leftrightarrow b$: "a is equivalent to b", "a has the same value as b"): connective $\Leftrightarrow: \mathbb{B} \times \mathbb{B} \rightarrow \mathbb{B}$ according to the Table

$\Leftrightarrow$	O	L
O	L	O
L	O	L

$\neg$	negation (logical not): $\neg: \mathbb{B} \rightarrow \mathbb{B}$ with $\neg(0) = L$ and $\neg(L) = O$.

Quantifiers

$\exists$	existential quantifier ("there exists at least one ...")
$\forall$	universal quantifier ("for all ...")

Sets (let A, B, M and N be sets)

$\in$	$m \in M$ signifies that m is an element of M.
$\cap$	The intersection $A \cap B$ of two sets contains the elements that belong to both sets A and B.
$\cup$	The union $A \cup B$ of two sets A and B contains those elements that belong either to A or to B.
$\setminus$	The difference $A \setminus B$ of two sets A and B contains those elements of A that do not belong to B.
$\{m: P(m)\}$	The set of all objects, for which the predicate P holds. For example, the expression $\{n: n = 2m;\ m \in \mathbb{N}\}$ describes the set of all even natural numbers.
$\lvert M \rvert$	Cardinality: the number of elements in a set M
$M \times N$	The set of all ordered pairs (m, n) that can be formed from the elements $m \in M$ and $n \in N$ of two sets M and N.
$\mathrm{SVM}(\mathscr{A}, B) = \bigcup_{A \cap B \neq \{\}, A \in \mathscr{A}} A$	The union of all sets A that belong to the family of sets $\mathscr{A}$ and have a nonempty intersection with the set B.

Relations, Mappings

binary relation A binary relation R associates pairwise the elements of two sets X and Y. Accordingly, R is the set of ordered pairs $X \times Y$, expressed by $(x, y) \in R$, or in infix terminology: xRy. A binary relation R may be defined by a predicate P that is valid for all pairs $R = \{(x, y) \in X \times Y: P(x, y)\}$; otherwise all pairs are stated explicitly.

transitive closure The transitive closure R^+ of a (binary) relation R is defined as follows:
(1) $(a, b) \in R \Rightarrow (a, b) \in R^+$
(2) $(a, b) \in R^+ \wedge (b, c) \in R \Rightarrow (a, c) \in R^+$
(3) R^+ contains only what follows from (1) and (2).
R^+ is the smallest transitive relation that comprises R.

equivalence relation Special case of a binary relation $R \subseteq X \times Y$ for which the sets X and Y are identical and which is also endowed with the following three properties:
(1) reflexivity: $\forall x \in X: xRx$ (i.e. each element is in relation with itself).
(2) symmetry: $\forall x, y \in X: xRy \Rightarrow yRx$ (i.e. a relation between elements x and y implies a relation between y and x).
(3) transitivity: $\forall x, y, z \in X: xRy \wedge yRz \Rightarrow xRz$ (i.e. if there is a relation between x and y, and between y and z, then there is also a relation between x and z).

Due to the symmetry of an equivalence relation R on X, for some pair $(x, y) \in R$, the phrase "x has a relation R to y" is generally replaced by "x and y have a relation R"; for any x the set $[x] = \{y: xRy\}$ is the equivalence class of x with regard to R. For z the equivalence class $[z]$ is either identical with $[x]$ if $z \in [x]$, or the equivalence classes are disjoint (i.e. without common elements). The partition $\{[x]: x \in X\}$ of X that is induced by the set of all equivalence classes is called a space of equivalence classes or a quotient set.

$[m]_R$ The equivalence class of m with regard to the equivalence relation R, that is, all elements that are equivalent to m according to the property that is represented by R. Whenever it is necessary to declare the equivalence of some permuted models within a family with regard to a given property, the equivalence relations are of interest in the theory of the CIG.

permutations In the present article permutations are denoted by lowercase Greek letters. A permutation of n elements is a bijective map $\lambda: L \to L$ of a set L onto itself. A permutation $\lambda(l_a) = l_b$, $\lambda(l_b) = l_c, \ldots, \lambda(l_s) = l_a$ can be written in cycle notation as $(l_a l_b \ldots l_s)$. All further elements $l \in L \setminus \{l_a, l_b, \ldots, l_s\}$ are mapped to themselves by λ.

Groups

group A group $G = (M, \bullet)$ consists of a set M and an operation $\bullet$ in M with the following properties:
(1) closure: The combination of any two elements $a, b \in M$ yields again an element of M.
(2) associativity: For all elements $a, b, c \in M$ we have $a \bullet (b \bullet c) = (a \bullet b) \bullet c$.
(3) existence of an identity element: There exists an identity element $e \in M$ such that we have for all elements $a \in M$: $a \bullet e = e \bullet a = a$.
(4) existence of an inverse element: For any element $a \in M$ there exists an element a^{-1} such that: $a \bullet a^{-1} = a^{-1} \bullet a = e$.

In the context of a group the operation symbol $\bullet$ is omitted and one writes "ab" instead of "$a \bullet b$". The cardinality of a group is also called its order. A subgroup of the group $G = (M, \bullet)$ is a group $U = (N, \bullet)$ with $N \subseteq M$.

coset The set aU that belongs to an element $a \in G$ is called a left coset of U; it comprises all elements au with $u \in U$. If the multiplication by a takes place from the right hand side, the right coset Ua result. If the direction of the multiplication follows from the context or is irrelevant, the term coset is used. The set of the (left/right) cosets of the subgroup U in the group G form a (left/right) coset space. A coset space of U in G is a partitioning of G. Any coset space is a space of equivalence classes.

transversals A minimal set T with the property $TU = G$ is called a complete left transversal of U in G, and analogously as a complete right transversal, if $UT = G$. If it follows from the context whether a left or right transversal is meant, the term transversal or system of representatives is used. If U is nontrivial—that is, U does not only contain the identity element—the transversal is ambiguous. The complete transversal of U in G contains precisely one representative from each coset of U in G. Any element of a coset may serve as its representative. The term leading elements of cosets is often used for representatives.

generators In order to define a group G, it suffices to specify the nature of the group operation $\bullet$ and a few elements that, together with their inverses, can be combined to yield G. The latter elements are called the generators of the group G. If the elements of a group are permutations, the term permutation group is used. The set P of all permutations on a set L of n symbols, together with the consecutive execution of permutations as the group operation $\bullet$, form a group $Sym(L) = (P, \bullet)$ with $n!$ permutations; it is called the symmetric group of degree n. Often it is not relevant which elements of L are permuted, but how many. Thus one writes $S_{|L|}$ instead of $Sym(L)$. In the theory of the CIG, permutation group have direct applications. Any family of permuted models $P(E)$ with a set of ligands L is isomorphic to the symmetric group $Sym(L)$, since the action of distinct permutations from $Sym(L)$ on the reference model E leads to distinct models in $P(E)$; any model from P(E) can be obtained by the action of a permutation of $Sym(L)$ on the reference model.

conjugates For $\lambda \in G$ the product $\lambda U \lambda^{-1}$ is called the $(\lambda -)$ conjugate of U in G. The conjugate of a group is itself a group. For $\mu \in G$, the set $\{\lambda\mu\lambda^{-1}: \lambda \in U\}$ is called a Wigner subclass of U in G. The set $\{\{\lambda\mu\lambda^{-1}: \lambda \in U\}: \mu \in G\}$ of the Wigner subclasses forms a space of equivalence classes of G.

Extending the Metal Cluster–Metal Surface Analogy

By *Bruce C. Gates**

By the early 1970s, the chemistry of metal clusters—compounds with metal–metal bonds stabilized by ligands such as carbonyls—was emerging from its infancy, as described in the seminal work of Chini.[1] In 1975 Muetterties[2] proposed analogies between metal clusters and metal surfaces and speculated that molecular metal clusters would be found to be catalysts with novel properties. A central argument was that clusters have reactivities different from those of complexes with a single metal atom because they have neighboring metal centers, and the unique metal–ligand bonding patterns in clusters could be expected to facilitate reactions like those occurring on metal surfaces.

In 1975, the western world had just undergone one of its periodic oil supply crises, and a result of this was a surge in interest in catalysis related to production of synthetic fuels; research on the chemistry of catalytic hydrogenation of CO to give hydrocarbons (Fischer–Tropsch chemistry) went through one of its periodic spikes of activity. Simultaneously, metal cluster chemistry became a "hot" topic, with much of the research motivated by the prospect of finding novel catalysts for CO hydrogenation, among other reactions.

A few years later, Muetterties et al.[3] published a detailed, quantitative assessment of the analogies in structure and bonding between metal clusters and metal surfaces, but reactivity and catalysis were largely missing from the assessment. A consensus emerged, articulated by Ertl,[4] that the cluster–surface analogy, although imperfect,[5] includes structure and bonding but does not extend to reactivity and catalysis. Surface scientists, building from this analogy, have now come to rely primarily on comparisons of vibrational spectra of adsorbed species with those of molecular metal clusters characterized by crystallography as the basis for determining structures of adsorbates on metal surfaces.[6] Thus the merging of organometallic chemistry and surface chemistry is well underway.[7]

The anticipated evidence of catalysis by metal clusters, however, has not emerged,[8] and the few examples of cluster catalysis are neither very well understood nor of practical importance; the prospects are limited by the lack of stability of most metal clusters. One consequence of the lack of practical successes has been a marked decrease in the attention paid to research on metal clusters, although progress had continued to be rapid.[9]

Now a pair of recent papers[10, 11] illustrates that the analogy between metal carbonyl clusters and metal surfaces with adsorbed CO ligands extends beyond structure and bonding: The reactivity of a CO molecule bridging metal atoms in a metal cluster reported by Chisholm et al.[10] is analogous to that of a CO molecule bridging metal atoms on a metal surface, reported by Yates et al.[10] The bridging CO dissociates into carbido and oxido ligands (Scheme 1). This step is important in the Fischer–Tropsch reaction catalyzed by metal surfaces.

Scheme 1. Dissociation of a bridging CO molecule.

Both the CO bound to alkoxidotetratungsten $[W_4(OR)_{12}]$ clusters[10] and the CO adsorbed on a sparsely covered Mo(110) surface react with dissociation to give carbido and oxo ligands bonded to neighboring metal centers. The evidence for this reactivity in molecular metal clusters is based on NMR spectra and crystallographic data for a family of clusters, including $[W_4(\mu_4\text{-C})(O)(O\mathit{i}Pr)_{12}]$, the skeleton of which is shown in Figure 1.[10] The carbido ligand is bonded to four tungsten atoms in a butterfly arrangement; the oxo ligand (O6) is bonded to two tungsten atoms. The species on the Mo(110) surface were characterized by vibrational (electron energy loss) spectroscopy, and indications of reactivities of variously bonded CO species were obtained by temperature-programmed desorption (thermal desorption) with analysis of the desorbed products by mass spectrometry.[11]

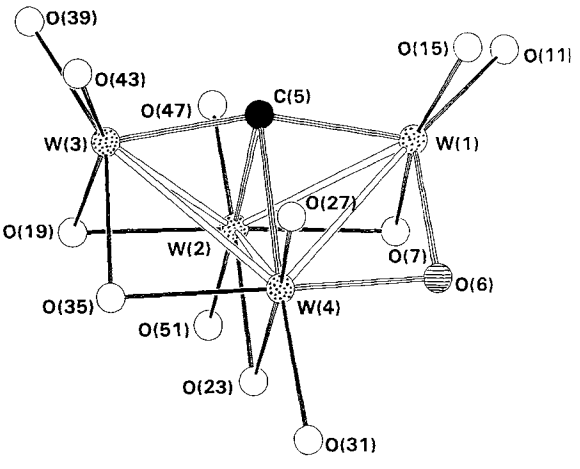

Fig. 1. The $W_4(C)(O)_{13}$ core of the $[W_4(\mu_4\text{-C})(O)(O\mathit{i}Pr)_{12}]$ cluster. O(6) is the oxo ligand (from ref. [10]).

The analogy between the reactivity of CO in the cluster and that of CO on the surface is thus clearly evident, confirming what had been supposed by Muetterties.[12] However, there are differences between the reactivity in the cluster and on the surface. Chisholm et al.[10] identified a cluster with a bridging $(\eta^2,\mu_4\text{-CO})$ group. This structural feature is most pertinent to the cleavage of a CO ligand; however, they found no direct evidence of the reaction of CO with the coordinatively unsaturated tungsten clusters to give $[W_4(OR)_{12}(CO)]$ intermediates, and they could only speculate that the CO may initially bind to one of the W atoms of the cluster framework. The results imply that the bonding of CO to the cluster must be the rate-determining step in the CO

dissociation. As the temperature was raised, indications of carbido ligands in the cluster appeared at 243 K.

In contrast, Yates et al.[11] observed variously bonded CO ligands on Mo metal at fractional surface coverages of less than 1. Some ligands were conventionally bound, and one of the CO ligands, characterized by a ν_{CO} band at 1130 cm^{-1}, was inferred (on the basis of a comparison with the IR spectra of carbonylmetal clusters) to bridge two Mo atoms: Mo–C–O–Mo. This is a stable intermediate in the dissociation reaction on the surface. At a surface coverage by CO of about 0.23, the only observed CO species was inferred to be inclined (ν_{CO} = 1345 cm^{-1}), with the C atom bonded to a Mo atom and the O atom interacting with a neighboring Mo atom but not bonded to it. This CO was converted to the bridging species (ν_{CO} = 1130 cm^{-1}), and at least some of the dissociation of adsorbed CO proceeded through this bridged intermediate. When the surface coverage was 0.17, the adsorbed CO was converted into C and O at about 200 to 250 K; the surface reaction was rate determining.

In summary, the data reveal differences in reactivity of the cluster and surface, characterized by different rate-determining steps and different rates of reaction—although these are not determined quantitatively. It is known[4, 10] that the rate of a reaction induced by a molecular cluster is usually less than that induced by a sparsely covered surface of the same metal. The initial step of bonding of a ligand to a cluster requires coordinative unsaturation of the cluster. Since most stable metal clusters are coordinatively saturated, reaction steps such as dissociation of a ligand or reaction of a pair of bound ligands with each other to free a coordination site are prerequisites. In contrast, relatively clean surfaces present arrays of rigid, stable coordinatively unsaturated sites where ligands can be readily bonded and activated.

Thus, although the reaction path of a ligand bonded to a molecular metal cluster and that of a ligand on a metal surface may sometimes be similar, the catalytic activity of a molecular metal cluster is usually expected to be less than that of a sparsely covered surface with a comparable arrangement of metal atoms. However, metal surfaces are usually largely covered with adsorbates during catalysis, and one might still be justifiably tempted to seek similarities between the catalytic properties of such surfaces and those of metal clusters. If metal cluster–metal surface analogies in catalysis are to be found, they are expected to be closest when the metals are dispersed in the form of small particles ("clusters") on solid supports, as was recognized early by Basset and Ugo.[13] This is precisely the form of many industrial metal catalysts. Relatively robust carbonylmetal clusters such as $[H_3Os_4(CO)_{12}]^-$ have been observed on surface suring catalysis of CO hydrogenation,[14] but their role in catalysis remains to be assessed. Furthermore, some industrial supported metal catalysts have such small clusters (typically, five or six Pt atoms in clusters supported in L zeolite[15] used to convert *n*-hexane into benzene) that they may be regarded as virtually molecular in character.

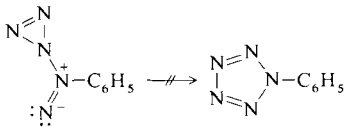
Pentazole and Other Nitrogen Rings

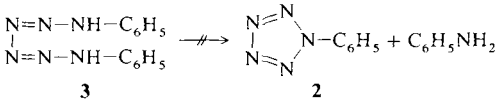
By *Rudolf Janoschek**

Although the road of the pentazoles through chemistry has not only just begun, its end is not yet in sight; they have proved that they can stay the distance. Their history began in 1903 when Hantzsch[1] tried in vain to form phenylpentazole (**2**) by rearrangement of benzenediazonium azide (**1**).[**]



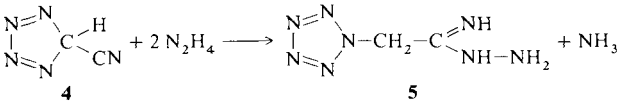
1 **2**

Dimroth and de Montmollin[2] also had no luck when they planned to prepare phenylpentazole from a chain of six nitrogen atoms (**3**). Then in 1915 success seemed to be at



3 **2**

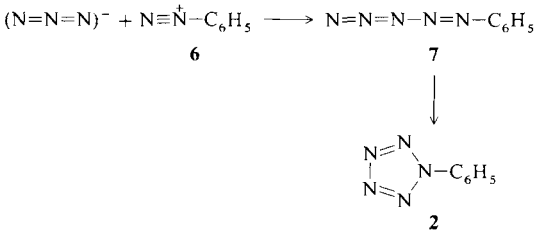
hand when Lifschitz[3] believed he had synthesized pentazolyl acetic acid amidrazone (**5**) from tetrazolecarbonitrile (**4**). But in the same year came a rebuttal from Curtius



4 **5**

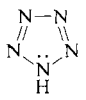
et al.[4] with the title "Die sogenannten Pentazol-Verbindungen von Lifschitz" ("The so-called pentazole compounds of Lifschitz"). They did not mince their words: "Ein derartiger Reaktionsverlauf wäre im höchsten Grade überraschend ... Lifschitz glaubt die Richtigkeit seiner Auffassung 'mit vollkommener Sicherheit' folgern zu müssen ... ohne weitere Prüfung in das Reich des Unmöglichen zu verweisen ... daß alle seine Beobachtungen und Folgerungen auf Irrtum beruhen ... von Pentazol keine Rede sein kann."[***]

Dispute, misunderstanding, and failure dogged the pentazoles from the beginning. Curtius's verdict hit hard. Almost half a century passed before anyone again ventured a search for pentazole. Huisgen and Ugi[5] thus solved a classic problem in 1956 when they proved that they could link the benzenediazonium ion (**6**) with the azide ion to form benzenediazoazide (**7**), which on ring-closure yielded phenylpentazole (**2**).



6 **7** **2**

The first structure determination by X-ray diffraction on a pentazole was performed in 1983 by Dunitz and Wallis.[6] The N–N bond lengths in the five-membered ring were all similar (1.31–1.35 Å) and lie between the standard values for N–N (1.449 Å) and N=N (1.252 Å), which can be interpreted as a clear sign of an aromatic ring with six π electrons. This information does not, however, close the chapter on the pentazoles. In fact quite to the contrary, it is now all the more puzzling why the parent compound of the pentazoles, HN_5 (**8**), is still unknown. After all, it would be the final



8

member of a well-known series that begins with pyrrole and breaks off prematurely at tetrazole. Perhaps theory can help solve the enigma.

The interest of the quantum chemists in pentazoles was only recently aroused by Ferris and Bartlett.[7] They employed ab initio calculations such as the *n*th order *m*any-*b*ody *p*erturbation *t*heory, abbreviated to MBPT(n), whose better known variant is the *n*th order Møller–Plesset perturbation theory, MPn. The MBPT(n) procedure takes account of *all* the terms to a predetermined final order *n* for the electron correlation. In the *c*oupled *c*luster (CC) theory, on the other hand, certain contributions from the MBPT formalism are summated for *all* orders *n*. Use of the DZP basis set with these procedures yielded the anticipated structural parameters for cyclic HN_5 (**8**) with C_{2v} symmetry and proof that it represents a minimum on the energy hypersurface. The energy barrier for potential decomposition into HN_3 and N_2 was given on the MBPT(2) level as 19.8 kcal mol^{-1}.

The question in the title of reference [7], "Does it exist?", can, of course, not yet be answered on these grounds alone. Experience shows that the MBPT procedure yields energy barriers that are too high. This will be demonstrated later in this highlight for the N_4 molecule. To estimate the kinetic stability of **8** more accurately, other calculation methods such as MP2, MP4, CC, or MCSCF-CI should also be employed. I therefore applied myself to the problem of the uncertainty in this decomposition barrier of 19.8 kcal mol^{-1}. Table 1 collates some of the results.

If electron correlation is considered, the height of the barrier varies between 13.7 and 20.9 kcal mol^{-1}, which might cast doubt on the kinetic stability. Furthermore, the energy hypersurface for the triplet state may not be ignored, because it might cross energy barriers leading to spin-forbidden processes (intersystem crossing) and thus to other decomposi-

Mozartgasse 14, A-8010 Graz (Austria)

[**] Formerly the azide structure was assumed to be a three-membered ring. This is documented on the Curtius monument in Heidelberg (FRG).

[***] "Such a course for the reaction would be extremely surprising ... Lifschitz believes he must conclude that his interpretation is correct 'in perfect confidence' ... without further proof it must be relegated to the realm of the impossible ... all his observations and conclusions are based on error ... there can be no question of pentazoles in this case."

Table 1. The activation barrier ΔE [kcal mol^{-1}] incorporating the zero-point vibrational correction for the decomposition $HN_5 \rightarrow HN_3 + N_2$, calculated with several methods.

Method [a]	ΔE
HF/6-31G*	36.9
MP2/6-31G*	13.7
MP4/6-31G*	18.9

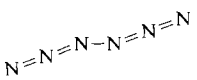
CCSD/6-31G*	20.9

[a] The calculations with the 6-31G* basis set were performed with the program GAUSSIAN 92.

tion pathways. Only one issue is definite: theory has pointed the way; the next step must be left to experiment. Matrix isolation has provided many a surprise in the past.

As dramatic as the tale of the pentazoles is the story of the vain attempt to detect a six-membered nitrogen ring. The first calculations were performed in the early seventies. In 1980 Vogler et al.[8] found indications that N_6 is cleaved on UV irradiation from *cis*-$[Pt(N_3)_2(PPh_3)_2]$ embedded in a matrix, but it is only stable at low temperature. At that time hexaazabenzene (**9**) was considered the only feasible structure for N_6. This report loosed an avalanche of quantum chemical calculations, in particular because **9** is isoelectronic with benzene and thus should likewise display aromatic stabilization. The calculations over the decade produced every conceivable answer: hexaazabenzene has D_{6h} symmetry ... has D_{3h} symmetry ... does not exist, because **9** is the transition structure for nitrogen exchange for $3N_2$. The latest MBPT calculations of Bartlett et al.[9] nullified all previous

9

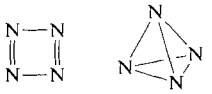


10

labors. According to them, hexaazabenzene cannot exist because this arrangement of atoms (D_{6h}) gives two imaginary frequencies for the out-of-plane vibrations. The naive view and the conclusions from it that *all* cyclic compounds with six π electrons must be aromatic had already been convincingly disproved by Shaik et al.[10] The idea that Vogler's N_6 could be diazide (**10**), which was shown by recent calculations[11] to be 35 kcal mol^{-1} more stable than **9**, was supported repeatedly during the past ten years.

Now that the birth of the five-membered nitrogen rings has been announced only after a long labor, and a six-membered nitrogen ring has even been disputed by theory, it is the turn of three- and four-membered nitrogen rings. In 1977 triaziridine N_3H_3 was discovered in small amounts bound as a complex to a zeolite crystal. X-ray diffraction confirmed the ring structure.[12] More recent ab initio calculations suggest that this compound can also exist in uncomplexed form, since the three-membered nitrogen ring represents a minimum on the energy hypersurface.[13] The authors of this paper, however, are even self-critical and issue a warning that applies to all the theoretical investigations considered here: "... but we must do more work to understand the kinetic lability of these compounds".

In the form of **11**, a structure isoelectronic with cyclobutadiene, N_4 is shown in the SCF approximation to be distinctly more stable than tetraazatetrahedrane (**12**). If the electron



11 **12**

correlation is taken into account, the order is reversed.[9] For this reason, and also because of the homology to the known tetrahedral P_4, more attention has been paid to structure **12** than to **11**. After the most thorough theoretical study yet undertaken,[14] Lee and Rice calculate a considerable energy barrier of 61 kcal mol^{-1} for the decomposition $N_4 \rightarrow 2N_2$. The authors exploited all possibilities both with the basis set (DZP, [4s, 3p, 2d, 1f]) and with the methods of calculation (CASSCF, MP2, CC) to separate the less appropriate methods from the better ones by comparing the different results. In the process, the energy barrier for the decomposition was lowered from 80 to 61 kcal mol^{-1}. Bartlett et al.[9] report a quite high value of 79 kcal mol^{-1} from only one MBPT calculation, which leads to the conclusion that energy barriers calculated with MBPT are too high as a result of a systematic error, and the kinetic stability of all the compounds covered here is therefore overemphasized. The lower, but nevertheless still substantial barrier for N_4 decomposition must not lead to a premature euphoria,[9] because the triplet energy hypersurface intersects this barrier low down,[14] as can be seen in Figure 1. A fast spin-forbidden process (double intersystem crossing) can therefore annihilate N_4. Incidentally, it should be said that a decomposition barrier of only 1 kcal mol^{-1} has been calculated with the semiempirical AM1 method.

This trail through the territory of the nitrogen rings should not end without mention of the latest candidates for experimental proof. Minima have been located on the energy hypersurface for bipentazole N_5–N_5[7] and octaazacubane N_8,[9] and structural data have been reported.

Have nitrogen rings or cages any interesting property that makes the effort to synthesize them worthwhile? A glance at the reaction energies on decomposition to N_2 gives an answer. The energy released per N_2 unit on decomposition of N_4 is 93 kcal mol^{-1} and of N_8, 112 kcal mol^{-1}. Such high energy density makes these compounds promising rocket

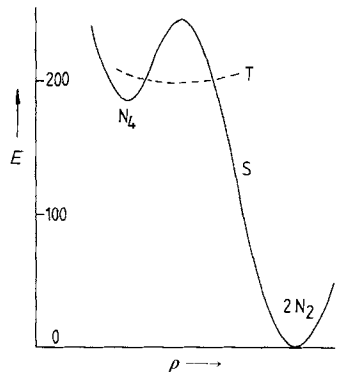


Fig. 1. The energy profile E [kcal mol^{-1}] for the decomposition of N_4 (T_d) to $2N_2$ along the reaction coordinate ρ. Solid line: singlet state (S); broken line: triplet state (T) (from [14]).

fuels. In fact, theory predicts a better efficiency for N_8 than for the conventional fuel, which is based on H_2 and O_2.

The intention of this short report was to show the advance of theory through ab initio calculations in the field of nitrogen rings. Although the calculated molecular properties can still be extended and refined, already a quite clear picture emerges. Nitrogen rings, and in particular nitrogen cages, are extremely energy-rich and kinetically labile systems. In comparison with the results of theoretical studies, the yield of the experimental investigations is as yet small. N_3H_3 and N_6 were unintentional successes. Well-targeted photochemical studies under matrix conditions will probably still expose several surprises.

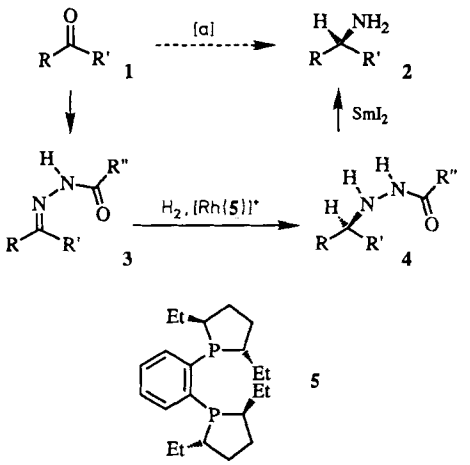
Enantioselective Transition Metal-Catalyzed Hydrogenation for the Asymmetric Synthesis of Amines

By *Carsten Bolm**

Catalyzed asymmetric reductions of functionalized olefins and ketones occur very selectively, in contrast reductions of C=N bonds have so far only led to low enantioselectivities.[1] In two recent publications Burk and Feaster[2] and also Willoughby and Buchwald[3] reported new transition metal catalysts for homogeneous asymmetric hydrogenation, with which optically active amines can be obtained with high enantiomeric excesses.

Following the investigations of the enantioselective hydrogenation of functionalized olefins with chiral bis(phospholane)rhodium(I) complexes,[4] Burk and Feaster have now used the new transition metal catalysts for the asymmetric synthesis of primary amines.[2] With 0.1 mol% of the catalyst system (Et-duphos)Rh^I $[Rh(\mathbf{5})]^+$, *N*-aroylhydrazones **3** of arylalkyl ketones and α-keto esters are reduced under mild reaction conditions (20 °C, 1–4 atm H_2, 1–36 h, in 2-propanol) to give the corresponding optically active *N*-aroylhydrazines **4** (Scheme 1).

In comparison with other chiral diphosphanes such as binap,[5] chiraphos,[5] or bdpp,[5] **5** proved to be the most effective ligand for the transition metal catalysts; enantioselectivities of up to 97% *ee* were achieved with **5**. If compound **4** is allowed to react with samarium iodide (≥2 equiv), the N–N bond can be cleaved and the corresponding amine **2** is obtained with no loss of optical purity. Thus, synthetically valuable primary amines are obtained as reaction products. The chiral α-hydrazino acid derivatives are of particular interest. These derivatives are obtained from α-keto esters and their hydrogenolysis leads to the optically active α-amino acids.



Scheme 1. [a] Reductive amination. R = aryl, CO_2Me, CO_2Et; R′ = alkyl, aryl; R″ = aryl; Et-duphos = **5**.

In their new work[2] Burk and Feaster refer to a series of experiments on the asymmetric reduction of C=N bonds with rhodium(I) catalysts for which molecular hydrogen[6] and silanes[7] were used as reducing agents.[8] In contrast to these known methods, which usually lead to the formation of secondary amines, the asymmetric reductive amination with the $[Rh^I(duphos)]$ complexes now introduced is also distinguished by an extended substrate range, higher enantio- and chemoselectivity as well as milder reaction conditions. Nitriles, imines, halides as well as carbonyl and nitro compounds are not reduced, nonfunctionalized olefins and alkynes are only hydrogenated in small amounts (<2%). Two factors are proposed to be responsible for this high chemoselectivity. A substrate chelation at the cationic transition metal center increases the rate of hydrogenation of the *N*-

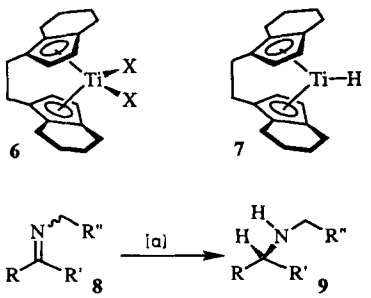
aroylhydrazones selectively, and the reduction of other functional groups is inhibited by the *N*-aroylhydrazines formed. The *N*-phenylimine and *N*-phenylhydrazone of acetophenone are correspondingly not hydrogenated under these mild reaction conditions. Osborn et al. previously reported[9a, b] similar high chemoselectivities in metal-catalyzed hydrogenations of *N*-arylketimines. The diphosphaneiridium complexes used here are very active, as Spindler et al. have also shown,[9c] but result in products with lower enantiomeric excesses.[9b, c] The optically active secondary and cyclic amines prepared with the iridium catalyst system are important intermediates in the synthesis of herbicides.

Willoughby and Buchwald have investigated[3] a fundamentally different catalyst system for the asymmetric reduction of C=N bonds. If 2–10 mol% of the chiral *ansa*-titanocene **6** is used as the catalyst for the hydrogenation of cyclic imines with molecular hydrogen excellent enantioselectivites (up to 98% *ee*; Scheme 2) are achieved. In contrast, the



Scheme 2. X_2 = 1,1'-binaphthyl-2,2'-diolate. [a] H_2 pressure, 2–10 mol% **6**; R,R',R" = alkyl, aryl.

reactions of acyclic compounds with C=N bonds occur less selectively; starting from *N*-benzylimines the products are only obtained with *ee* values of between 58 and 87%. Steric factors in the formation of diastereomeric transition states and competitive hydrogenations of stereochemically different substrate/catalyst complexes are thought to be responsible for this.

The authors assume that the hydridotitanium(III) complex **7** is the active form of the catalyst; **7** is prepared by the reaction of the stable complex **6** with *n*-butyllithium in situ and is stabilized by phenylsilane. The hydrogenation of the ketimines occurs in THF at 65 °C under increased hydrogen pressure (ca. 135 atm).

Willoughby and Buchwald have thus shown for the first time that the *ansa*-metallocenes[10] developed by Brintzinger et al. can also be used for the asymmetric hydrogenation of ketimines and thus for the enantioselective synthesis of amines. In the corresponding asymmetric reduction of olefins, structurally related *ansa*-zirconocene binaphtholates were previously tested by Waymouth and Pino as precursors for homogeneous Ziegler–Natta systems (65% ee_{max} for the deuteration of styrene).[11a] This reaction is also catalyzed by a cationic *ansa*-zirconocene hydride structurally analogous to **7**.[11b] The idea of using *ansa*-metallocenes as asymmetric catalysts[12a–d] or chiral reagents[12e, f] is based on their unusually high stereochemical control for the polymerizations and oligomerization reactions of olefins,[13] which can be used both for the formation of stereoregular products[14] of high molecular weight and also for the synthesis of optically active oligo- and polymers.[15]

The enantioselective syntheses of amines of Burk and Feaster,[2] and Willoughby and Buchwald[3] introduced here again illustrate the extraordinary potential of modified chiral transition metal complexes for asymmetric catalysis. Thus, they are not only interesting contributions to modern synthetic chemistry but also important steps on the often difficult path to a more selective and more efficient chemistry.

An Evaluation of the Peer Review Process at *Angewandte Chemie***

By *Hans-Dieter Daniel**

It is common practice in the sciences for peers (technical experts working in, or close to, the field or specialization in question) to be requested to assess the qualifications of applicants for academic positions, the merit of research proposals, and the quality of manuscripts submitted for publication in professional journals. For a number of years these "gatekeepers of science", as such reviewers or referees are often called,[1] have themselves been the subject of sharp criticism. Indeed, the publishing world has been asked to dispense with manuscript review altogether, substituting in its place a system of "uncensored" publication.[2] Critics of the peer review system contend that:

- the judgments of reviewers show very little agreement (a charge against poor "reliability" in the reviewing process),
- reviewers are often incorrect in their assessment of the significance of a piece of work (an accusation of low "predictive validity" for reviewer judgments), and
- reviewers' recommendations are frequently influenced by external considerations unrelated to the quality of the work and inconsistent with a fair review of the manuscript (the assertion that reviewers' judgments may be subject to "bias").[3]

In view of the significance that has been attached to the peer review process as a mechanism for self-regulation within science, it must come as some surprise that the process itself has rarely been the subject of empirical investigation. Empirical research has concentrated primarily on questions of reliability and fairness in the peer review process. By contrast, there has been little research into the validity of reviewer judgments and editorial decisions.

This communication describes an empirical study into the extent to which criticism of the peer review process is justified, and uses as an example manuscript reviews carried out for *Angewandte Chemie*. At the heart of the study are the three criteria for professional judgment: inter-referee agreement (reliability), fairness, and predictive validity (as measured by mean citation frequencies for accepted manuscripts and rejected manuscripts later published elsewhere).

[**] This work was supported by the Deutsche Forschungsgemeinschaft within the priority program "Science of Science".

The present evaluation is based on all 449 communications received from throughout the world for possible publication in *Angewandte Chemie* during the year 1984. Each communication was evaluated by two external referees working with fully structured reviewing forms and operating under the principle of one-sided anonymity (i.e., the referees knew the names of the authors, but the authors did not know those of the referees).

The year 1984 was chosen for our study of peer review at *Angewandte Chemie* since it represented the first year after the system was introduced in which all communications were judged by two independent experts according to a uniform questionnaire. Moreover, the selection of communications from 1984 resulted in a sufficiently long period of time thereafter to permit an analysis of the frequency of citation for both accepted communications and those that were rejected by *Angewandte Chemie* but subsequently published elsewhere.

All communications submitted to *Angewandte Chemie* first undergo an internal evaluation. Thus, the editor-in-chief indicates on an appropriate form whether in his judgment the manuscript should be accepted or rejected, or if he is uncertain as to the proper course of action. This initial assessment is generally accompanied by a brief comment: "good work"; "very nice"; "interesting reaction...quite poorly written"; "straightforward and brief, perhaps useful"; "provided the structure is correct, then everything is fine"; "much speculation, but little that is verifiably new"; "nothing new"; "too specialized"; "there's not enough here".

With respect to the manuscripts submitted for publication as communications in the year 1984, the editor-in-chief initially regarded 35% as suitable for acceptance and 8% worthy of rejection. He was in doubt about the appropriate fate for 57% of the submissions. After taking into account the recommendations of the referees, this same editor-in-chief ultimately accepted 72% of the submitted communications, while 26% were rejected and 2% were withdrawn by the authors themselves.

Table 1 shows the extent to which communications submitted for publication in *Angewandte Chemie* received consistent appraisals from the given pairs of referees ("first" and "second" is not meant to imply a hierarchical relationship, since the two worked independently and were accorded equal status). Inter-referee agreement in responses to the

Table 1. Concurrence and discrepancy in referees' response to the question: "Do you recommend acceptance of the communication?" [a].

Referee 1 (no. = 392) \ Referee 2 (no. = 392)	Yes, without alterations (no. = 77)	Yes, after minor alterations (no. = 154)	Yes, but only after major alterations (no. = 70)	No (no. = 91)
Yes, without alterations (no. = 79)	**20**	**38**	9	12
Yes, after minor alterations (no. = 167)	**33**	**75**	**31**	28
Yes, but only after major alterations (no. = 58)	10	**22**	**15**	**11**
No (no. = 88)	14	19	**15**	**40**

[a] Total agreement (main diagonal) and minor deviations (upper and lower off-diagonals) in referees' recommendations are in boldface.

question "Do you recommend acceptance of the communication?" is (after correction for chance agreement) actually quite low: the kappa coefficient,[4] which may assume values between -1.0 and $+1.0$, is 0.14 for the reviewer recommendations (the weighted kappa coefficient is 0.20, the intraclass correlation coefficient 0.25). A kappa coefficient of 0.14 indicates that referees agreed in their evaluations on 14% more of the manuscripts than would have been expected on the basis of pure chance.

The highest level of agreement was associated with the recommendation "Reject": On the question "Do you recommend acceptance of the communication?" the category-specific agreement coefficient for the response "No" is 0.28. The corresponding agreement coefficients for the three response categories "Yes, without alterations", "Yes, after minor alterations", and "Yes, but only after major alterations" are only 0.07, 0.10, and 0.09, respectively.

The coefficients established for reviewer agreement in the case of *Angewandte Chemie* are comparable in magnitude to chance-corrected agreement coefficients reported for professional journals in the fields of medicine, psychology, and sociology, which generally range from 0.20 to 0.40.[5] Walling[6] unfortunately does not provide any concordance coefficients for a study based on the *Journal of the American Chemical Society* (*JACS*). A former editor of *JACS*, he analyzed reviewer agreement from a random sample of 121 communications and a second random sample of 85 full papers submitted to that journal for publication in the year 1977. In the case of the communications, 43 (36%) were recommended for acceptance by both referees, 31 (26%) received two negative votes, and 47 (39%) obtained mixed reviews. In the case of the full papers, 45 (53%) were recommended for acceptance by both referees, 12 (14%) were opposed by both reviewers, and 28 (33%) received mixed reviews. Walling summarized his experience with referee judgments in the following observation:[6] "The correlation within pairs (of referees) isn't very good."

From a statistical point of view, the observed extent of referee agreement must be regarded as rather unsatisfying. According to Landis and Koch,[7] kappa coefficients between zero and 0.40 point to a relatively low level of agreement. Kappa coefficients between 0.41 and 0.80 are described as reflecting substantial agreement, and values >0.81 indicate excellent agreement. Nevertheless, no basis exists for dramatizing these low concordance coefficients, for the following reasons:

- Major discrepancies between referee votes are relatively rare: in only about seven percent of all cases did one referee recommend acceptance without alterations while the other recommended rejection.
- The true level of existing agreement is systematically underestimated, because diverging recommendations generally reflect not only the discordance component, the factor of interest, but also dislocational components.[8] Differences in the frames of reference on which reviewers' ratings are based (e.g., referee A may be fundamentally inclined to rate all manuscripts one level lower than referee B) must not be interpreted as truly discordant judgments. Data available for the present study unfortunately do not permit a clear separation of these two components by a one-way analysis of variance with repeated measures, because in most cases a given pair of reviewers had only a single manuscript to evaluate. For this reason, the observed reliability coefficients suggest a greater degree of discordant judgment than exists in reality.
- If one follows the recommendation of Crandall[9] and treats slightly differing votes as fully concordant (i.e., cases in which the reviewers' recommendations differ by only a single category), then the resulting concordance coefficients are much higher. In our study such a "kappa with scores computed as agreement if within one point"[10] is 0.67. A concordance coefficient of this magnitude is generally interpreted as reflecting a substantial degree of reviewer agreement.
- Editors of professional journals usually appoint as their reviewers one specialist and one generalist. A content analysis of reviewer comments indicates that the arguments provided by two reviewers examining the same manuscript rarely touch on the same points—a result entirely consistent with the intentions of the editors.[11] A high level of agreement in the recommendations cannot be expected if editors select their reviewers according to the principle of complementarity as a way of avoiding redundant comments.[12]
- A high level of agreement between two reviewers actually proves relatively little, because the reviewers might be equally mistaken in their judgments. In other words, high reliability provides no assurance whatsoever of valid conclusions.[13]

Editors of professional journals are often confronted with the assertion that external factors (so-called biases) influence the fairness of manuscript reviews. From among the many publication biases that have been discussed in the literature, I have chosen the subject-matter bias for a quantitative analysis. Thus, H. Werner,[14] for example, has suggested in a letter to *Angewandte Chemie* that the journal has an editorial bias in favor of communications dealing with organic chemistry.

In order to analyze whether or not the journal is subject to a publication bias a comparison of accepted manuscripts with those that were rejected was undertaken. Manuscripts rejected by *Angewandte Chemie* were divided for the following analyses into two groups: ones that were later published by another journal and those that were not. The bibliographic databases *Chemical Abstracts* and *Science Citation Index* were examined to ascertain whether a particular manuscript rejected by *Angewandte Chemie* was subsequently published elsewhere and, if so, where. Of the 115 communications rejected for publication by *Angewandte Chemie*, together with the 9 manuscripts withdrawn voluntarily by their authors, a total of 88 (71%) later appeared in other periodicals.

The subject area to which a particular communication should be assigned was established with the help of the abstracting service *Chemical Abstracts*. Results from this analysis reveal a very distinctive publication profile for *Angewandte Chemie*: 60% of all communications published in this journal in the year 1984 fall into only three of the *Chemical Abstracts* subject sections: Section 29 (Organometallic and Organometalloidal Compounds, including not only classical organometallic topics, often regarded as essentially inorganic, but also many papers related to organic synthesis, in which organolithium and organotin reagents, for example, play an important role), which comprised 40% of all the published communications; Section 22 (Physical Organic Chemistry), incorporating 10% of all the communications, and Section 78 (Inorganic Chemicals and Reactions), also 10% of all communications. If one also adds typical papers from the field of organic chemistry (Sections 23–28), constituting a 20% share, then these four areas alone account for 80% of all the published communications. In 1984 three of the five major fields of chemical research were either not represented at all in *Angewandte Chemie* (macromolecular chemistry) or represented only to a very limited extent (biochemistry and applied chemistry or chemical technology).

However a thematic analysis of communications rejected by *Angewandte Chemie* in 1984 also reveals a complete absence of submissions for 44 of the subject sections. Communications accepted for publication in *Angewandte Chemie* display a distribution across *Chemical Abstracts* sections similar to that of manuscripts which were rejected but later published by another journal. Thus, the "goodness of fit" chi square test shows that the two distributions of papers across the sections of *Chemical Abstracts* are very similar (chi square value of 48.995, with 35 degrees of freedom). The highly distinctive publication profile of *Angewandte Chemie* can therefore not be attributed to discriminatory decisions on the part of the editors. Instead, the observed distribution of research papers published in *Angewandte Chemie* more nearly reflect the types of manuscripts submitted.

Due to the high degree of thematic concentration in manuscripts submitted for publication, the analysis that follows regarding relationships among subject area, reviewers' recommendations, and editorial decisions must be limited to Sections 22, 23–28, 29, and 78 of *Chemical Abstracts*. The less frequently represented sections have been grouped together into an "Other" category.

Table 2 shows that organometallic communications (Section 29) achieve the highest marks from the referees—a phenomenon that applies to both first and second referees, and to an equal extent. Nevertheless, the observed differences in mean ratings are statistically not significant; the most one can say is that second referees tend to rate organometallic communications more highly (mean rating = 2.27 on a scale of 1–4) relative to physical organic communications (2.71; t-value = 2.48, $p \leq .10$).

Table 2. First and second referees' mean recommendations by sections of *Chemical Abstracts*.

Section of *Chemical Abstracts*	"Do you recommend acceptance of the communication?" [a]			
	First referee mean vote	No.	Second referee mean vote	No.
Organometallic and Organometalloidal Compounds	2.20	136	2.27 [b]	137
Inorganic Chemicals and Reactions	2.31	42	2.39	41
Physical Organic Chemistry	2.47	45	2.71 [b]	42
Organic Chemistry (Sections 23–28)	2.51	88	2.50	82
Other sections	2.33	79	2.36	76

[a] Four-category rating scale: 1) "Yes, without alterations", 2) "Yes, after minor alterations", 3) "Yes, but only after major alterations", 4) "No". [b] Two sample tests for equal means and variances have been carried out for all pairs of CA sections (the Bartlett test statistics and the single tests for equal variances are statistically not significant). Communications on Organometallic and Organometalloidal Compounds receive on average slightly better recommendations by second referees relative to communications on Physical Organic Chemistry (second referees: t-value of 2.48; first referees: 1.60). All differences in mean ratings are statistically not significant (n. s.).

Communications in the field of organometallic chemistry not only tend to receive the highest rating, they also have the (statistically significant) highest publication rate: 88% of all organometallic communications submitted to *Angewandte Chemie* in 1984 were accepted for publication (cf. Tables 3 and 3a). By way of comparison, communications covering organic chemistry (Sections 23–28), physical organic chemistry (Section 22), and inorganic chemicals and reactions (Section 78) enjoyed acceptance rates of only 70%, 72%, and 73%, respectively (average for all sections: 74%)

However, this remarkably strong emphasis on organometallic chemistry is not limited to communications in *Angewandte Chemie*. Indeed, organometallic chemistry is a subject pursued very successfully and intensively throughout the Federal Republic of Germany. Thus, *Chemical Abstracts* records a total of 18426 organometallic publications in the time period 1988–1990, 2975 of which originated in the Federal Republic of Germany—corresponding to a 16.1% share of world output.[16] Based on the total number of entries in the *Chemical Abstracts* database, the overall (West) German share of world research in chemistry as a whole amounted to only 6.1%. The 16.1% statistic for papers in organometallic chemistry therefore far exceeds the proportional contribution of the Federal Republic of Germany to worldwide research in chemistry generally. If one arranges the 80 sections of *Chemical Abstracts* in descending order according to number of contributions, organometallic chemistry is found to occupy 5th place in Germany, whereas worldwide it ranks 35th in number of publications.

Table 3. Publication outcome of communications submitted to *Angewandte Chemie* in 1984 by sections of *Chemical Abstracts* (in %) [a].

Section of *Chemical Abstracts*	Communication published in *Angewandte Chemie*	Other journals
[1] Organometallic and Organometalloidal Compounds (no. = 147)	88	12
[2] Inorganic Chemicals and Reactions (no. = 44)	73	27

Germany's leading role in the scientifically and technically very significant field of organometallic chemistry has doubtless played a role in the fact that *Angewandte Chemie* received in the past—and continues to receive—a large number of excellent manuscripts submitted for publication, especially since the most important specialized journals in this field (*Organometallics* and the *Journal of Organometallic Chemistry*) have markedly lower "ISI Journal Impact Factors" than *Angewandte Chemie*. Given this background, the publication bias of *Angewandte Chemie* in favor of this particular specialty cannot be regarded as grounds for broad-based criticism.

Finally, I turn to an aspect of the peer review process that has heretofore been only rarely investigated: validity. The validity of peer review was ascertained in the present study by the methods of Wilson[17] and Lock.[18] I began by identifying those journals in which manuscripts rejected by *Angewandte Chemie* were published, and noting their circulations and the corresponding ISI Journal Impact Factors.[19] I then conducted citation analyses for the individual papers, and citation frequencies for accepted manuscripts were compared with those for communications that were rejected by *Angewandte Chemie* but later published elsewhere.

Citation frequencies are obviously not the sole criterion for quality in a scientific paper. However, studies published

to date—and in keeping with the criticisms leveled against peer review—have without exception relied on citation frequency as their criterion for validity. Despite this fact, citation frequency remains a controversial measure of both quality and scientific progress.[20] The Chemistry Division of the American National Science Foundation (NSF) conducted a citation analysis in 1973 with the goal "to explore the use of this relatively new tool for what it might tell about the discipline, and its practitioners". The results of the NSF study "generally support the idea that citations are meaningful".[21]

Table 4 provides a list of all those journals in which more than one of the manuscripts rejected by *Angewandte Chemie* were subsequently published.

Communications rejected by *Angewandte Chemie* were ultimately published in a total of 39 journals, two-thirds of them in the 10 journals listed in Table 4. Only two of the papers appeared in journals with circulations exceeding that of *Angewandte Chemie* (Ulrich's[19a] reports the circulation for the German edition of the latter to be 5705 and 3000 additional copies were ascribed to the English edition): one publication each in the *Journal of the American Chemical Society* (with a circulation of 13019) and the *Journal of Organic Chemistry* (circulation 9907).

Table 4. List of journals that published more than one communication rejected by *Angewandte Chemie* in 1984, in descending order of number of publications [a].

Journal	Circulation [b]	Impact factor 1986	No. of publications
Tetrahedron Letters	3380	2.158	10
Inorganica Chimica Acta	–	2.439 [c]	8
Journal of Organometallic Chemistry	–	1.792	8
Journal of the Chemical Society, Chemical Communications	4000	2.385	8
Zeitschrift für Naturforschung, Section B (Chemistry)	3200	1.405	7
Chemische Berichte	2140	1.680	5
Chemistry Letters	4650	1.612	4
Synthesis [d]	3300	1.290	4
Journal of Fluorine Chemistry	–	0.905	3
Zeitschrift für Anorganische und Allgemeine Chemie	2450	1.326	2

[a] 29 other journals that published one communication rejected by *Angewandte Chemie* are not included in this table. [b] Source: Ref. [19a]. The circulations of journals published by Elsevier are not provided by this directory. [c] Impact factor 1987. [d] In the section Communications.

Impact Factors for the journals in which papers rejected by *Angewandte Chemie* later appeared range from 0.029 (*National Academy of Sciences, India. Science Letters*) to 4.435 (*Journal of the American Chemical Society*), with a weighted mean of 1.747.

It is worth noting that 83% of the communications that were rejected but subsequently published elsewhere appeared in their original form (i.e., as short papers: communications, letters, notes, etc.). Only 15 of the manuscripts (=17%) were published as full papers.

Based on ISI Journal Impact Factors the decisions of the *Angewandte Chemie* editors can be described as highly valid: none of the rejected manuscripts appeared in a journal with an Impact Factor higher than that of *Angewandte Chemie* itself – in one of the multidisciplinary "high-impact journals", for example. The mean Impact Factor for journals accepting the rejected manuscripts was 1.747, a value significantly lower than that assigned to *Angewandte Chemie* (1986: 5.335).[22]

Journal Impact Factors represent only a very crude measure of validity, since all contributions published in a given journal are characterized by a single mean value. This in turn means that frequently cited contributions are undervalued, whereas contributions that are rarely or never cited are overvalued. For this reason I went beyond the Journal Impact Factors to ascertain how frequently individual papers themselves were cited subsequent to their publication. The results of this citation analysis are presented in Figure 1. Based on the data, communications submitted in 1984 and published in *Angewandte Chemie* were cited twice as frequently on average as those that were rejected by *Angewandte Chemie* but published elsewhere.

Whereas by the end of 1989 only two percent of the communications published in *Angewandte Chemie* had never received a single citation, ten percent of the rejected publications appearing in other periodicals remained uncited. Communications published in *Angewandte Chemie* accumulated as many as 60 citations, as compared with a maximum of 35 for those published in other journals. The observed difference in mean citation frequency is statistically very significant ($F_{1/408} = 11.17$, $p \leq .001$). The analysis of covariance took into account an average delay period from the time of rejection by *Angewandte Chemie* to publication in another journal of almost exactly six months, resulting in a somewhat narrower time window for citation. The statistical significance of the findings becomes even more striking when

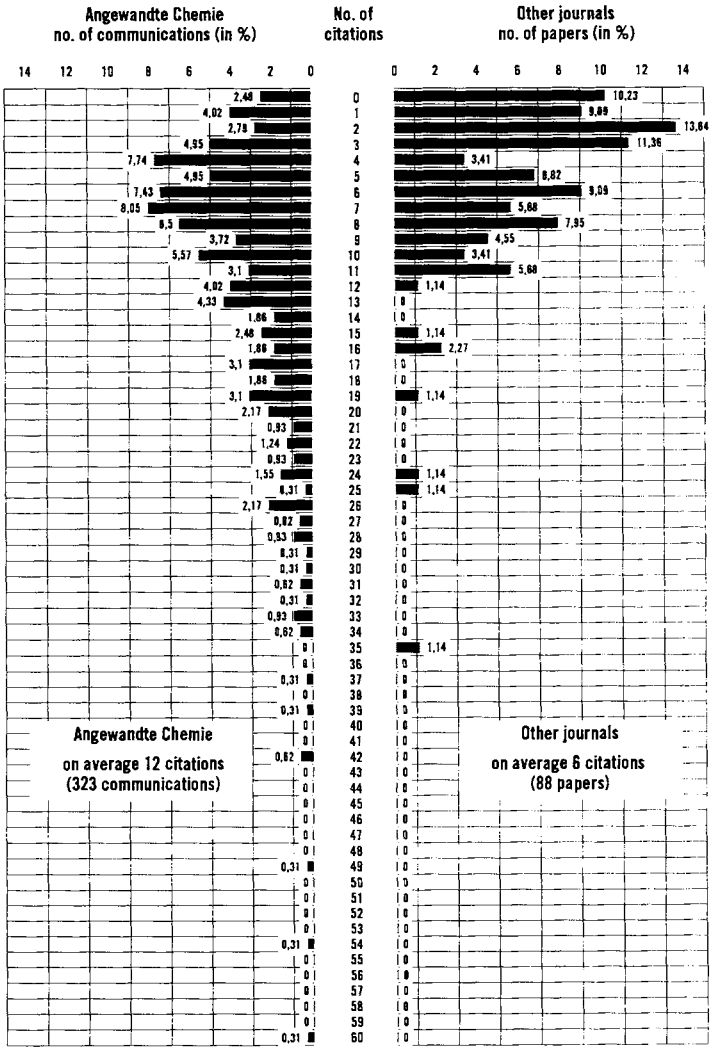

Fig. 1. Comparison of mean citation rates for communications accepted by *Angewandte Chemie* and those rejected by *Angewandte Chemie* but published elsewhere.

the citation frequencies are transformed logarithmically in order to obtain scores with a roughly normal distribution and homogeneous variances ($F_{1/408} = 20.41$, $p \leq .001$).

The results of our citation analysis are in very good agreement with those reported by Wilson,[17] who compared average citation frequencies of manuscripts accepted for publication in the year 1970 by the *Journal of Clinical Investigation* with those that were rejected but published in other journals during 1971. Articles in the *Journal of Clinical Investigation* were cited during the first four years after their publication roughly twice as often as papers that were rejected but later published in other journals. Lock[18] established very similar results for the *British Medical Journal*.

Based on average citation frequencies for accepted manuscripts and manuscripts that were rejected but later published elsewhere, the decisions of the editors in all the cases subjected to scrutiny appear to reflect a consistently high degree of predictive validity. These findings with respect to editorial predictive validity therefore suggest considerable exaggeration in the statement made by Ross[3] that "the data about validity against the single criterion of citation of a work urge that current editing-refereeing processes cannot distinguish a 'good' paper from a 'bad' paper" (p. 46). Indeed, all existing studies rather suggest that highly rated manuscripts are in fact cited more frequently after publication than those rated negatively.

The literature on reliability, fairness, and predictive validity of the peer review process has so far completely neglected one important function of manuscript refereeing, namely the improvement of a piece of work on the basis of reviewer comments. In a contribution by Abelson[23] on the occasion of the 100th anniversary of the journal *Science*, the author observes that virtually every manuscript is subjected to changes in response to reviewer suggestions. The same applies to communications appearing in *Angewandte Chemie*. The editors routinely record whether a given communication has been published without change or only after it has been supplemented or revised by the original authors. Nearly two-thirds (63%) of all communications published in *Angewandte Chemie* are revised by their authors. Comparisons based on mean citation frequencies reveal that revised manuscripts are cited with precisely the same frequency as manuscripts that were not subject to revision (t-test for difference between means, unequal variances, t-value = 0.45, not significant). This may be taken as evidence that reviewers' suggestions for improvement have had a significant impact on a large fraction of the published manuscripts.

Our appraisal is supported by a linguistic analysis carried out by Kretzenbacher and Thurmair[24] on a subset of reviewers' comments prepared for *Angewandte Chemie* in 1984: "It is apparent that efforts have been made to improve the final publications, thereby serving the interests of the entire scientific community, through often very detailed suggestions for changes in both content and style."

New Cu–Te Clusters**

By *Dieter Fenske** and *Jörg-Christian Steck*

PR_3 complexes (R = Et, *i*Pr, *t*Bu) of CuCl react with $Se(SiMe_3)_2$ in organic solvents with the loss of Me_3SiCl to give metal-rich copper clusters; examples include the complexes **A**–**D**.[1] Investigations previously carried out by us have

$[Cu_{20}Se_{13}(PEt_3)_{12}]$ **A** $[Cu_{30-x}Se_{15}(PiPr_3)_{12}]$ **B**, $x = 0,1$
$[Cu_{36}Se_{18}(PtBu_3)_{12}]$ **C** $[Cu_{70}Se_{35}(PEt_3)_{22}]$ **D**

shown that the structure of the cluster is dependent on the phosphane ligands and the conditions employed for the synthesis.[2] The reaction temperature, and the solvent are particularly important; a tendency toward the formation of Cu_2Se is observed even at room temperature. Although the structures of Cu_2Se and the cluster complexes are unrelated, the latter may be considered as possible intermediates for the synthesis of metastable, binary copper selenides. We have now studied analogous reactions of $Te(SiMe_3)_2$ with PR_3 complexes (Scheme 1).

No reaction occurs in THF or ether at $-78\,^{\circ}C$. Only after slowly increasing the temperature of the reaction are dark solutions formed over the course of several days, from which fine crystalline solids precipitate. Crystals suitable for struc-

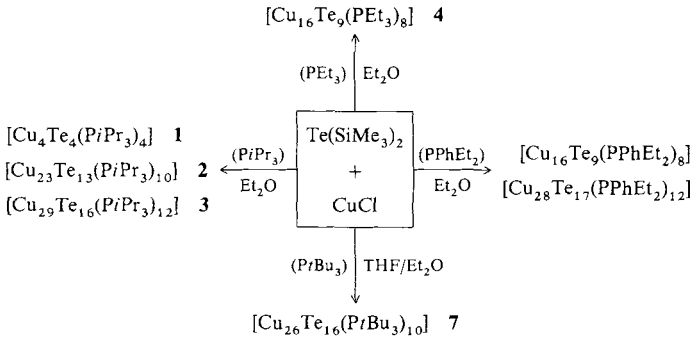

Scheme 1. Reactions of CuCl with phosphanes PR_3 and $Te(SiMe_3)_2$.

tural analysis are obtained if the volatile reaction products are distilled at $-40\,^{\circ}C$, and the residue is dissolved in a little THF or ether.[3]

Compound **1** forms red crystals and **2**–**7** from crystals displaying a metallic luster, which are sparingly soluble in organic solvents. The IR spectra are not very informative, since they only contain characteristic vibrations for the PR_3 ligands in the range 400–4000 cm^{-1}. Thus, X-ray crystal structure analyses were carried out to determine the molecular structures of **1**–**7**.[4]

If CuCl is allowed to react with $Te(SiMe_3)_2$ in the presence of $PiPr_3$, high yields of **1** are initially obtained. However, **1** is converted in ether into a crystalline mixture of **2** and **3** within a few days. In **1** (Fig. 1), the four Cu atoms form a butterfly structure, which is bridged by two μ_4-Te_2^{2-} ligands (Te–Te 280.0(3), 281.2(3) pm and Cu–Cu 279.4–309.5(4) pm). In addition, each Cu atom is bound to the P

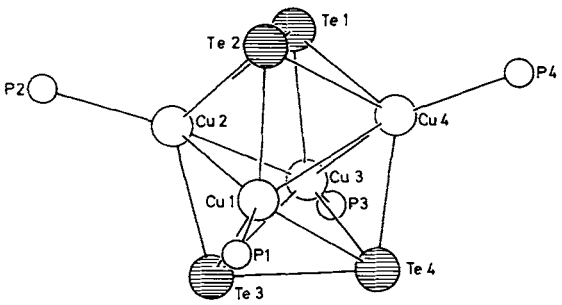

Fig. 1. Crystal stucture of **1** (without C atoms); Cu–Cu distances and Te–Cu distances up to 290 pm are drawn as bonds.

atom of a $PiPr_3$ ligand. Thus, each Cu is surrounded in a distorted tetrahedral manner by three Te atoms and one P atom. The Cu–Te distances are of different length and can be separated into a shorter one (257.4(2)–258.5(2) pm) and two longer ones (265.8(3)–285.6(4) pm). Other authors have already reported on tetranuclear metal clusters with butterfly structures; examples are summarized in Scheme 2.[5, 6]

$[Mo_4I_{11}]^{2-}$	$[Mo_4F_4(OtBu)_8]$
$[Mo_4X_8(PR_3)_4]$, X = Cl, Br; R = Ph, *i*Pr	
$[Os_4(CO)_{12}C_9H_4]$	$[Ru_4(CO)_{12}(\mu_2\text{-}C_2R_2)]$
$[Fe_4C(CO)_{12}]$	$[Ni_4Te_4(PPh_3)_4]$

Scheme 2. Tetranuclear metal clusters with butterfly structures.

Assuming that Te_2^{2-} ligands occur in **1**, the Cu centers must have the charge +1. Whereas several dichalcogenido-bridged complexes with S and Se are known, for example, $[Cp_2V_2Se_5]$ and $[(Co_3S(CO)_7)_2(S_2)I]$,[7] few compounds with Te–Te bridging ligands are known. In the complex $[\{(triphos)M\}_2Te_2]$ (M = Co, Ni; triphos = [2-{diphenylphosphino)methyl}-2-methyl-1,3-propanediyl]bis(diphenylphosphane)) the Te–Te distance is 280.2 pm,[8] in $[Cp_2Mo_2Fe_xTe_2(CO)_7]$ ($x = 1,2$) 313 pm,[9] in $[(Cp_2HfTe_2)_2]$ 280.2 pm,[10] and in the Ni_4Te_4 cluster (see Scheme 2) 286.1 pm. If the Te_2^{2-} ligands are considered eight-electron donors, **1** contains 64 valence electrons, which is in agreement with the 18-electron rule for butterfly structures.[11]

In **2** (Fig. 2 top), the Cu atoms form a nearly spherical cluster with approximately threefold symmetry. With the exception of Te4, which lies in the center of the molecule and is surrounded by nine Cu atoms, the other Te atoms occupy the cluster periphery and function as μ_5 (Te3, Te5–Te10,

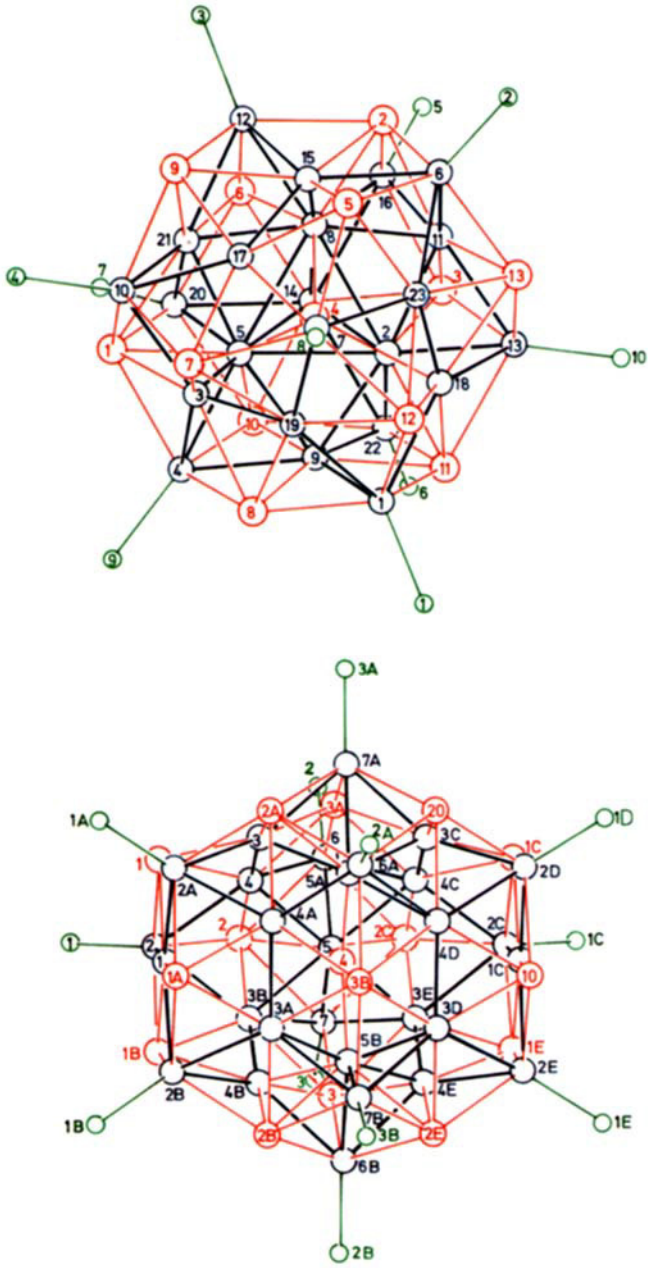

Fig. 2. Crystal structures of **2** (top) and **3** (bottom) (without C atoms); Cu: blue, Te: red, P: green. Cu–Cu bonds (blue) up to 300 pm and Cu–Te bonds (red) up to 290 pm are drawn. The Cu, Te, and P atoms are labeled only with blue, red, and green numbers, respectively. Important distances in **2** in pm (±1 pm): Te4–Cu 254–300, (μ_5-Te)-Cu 253–284, (μ_6-Te)-Cu 259–290; Cu–Cu distances about the Cu atoms (2, 5, 8): 254–263, about the Cu atoms (1, 4, 6, 7, 10, 12, 13, 16, 20, 22): 251–298; about the Cu atoms (17, 19, 23): 252–273; about the Cu atoms (3, 15, 18): 252–276, about the Cu atoms (9, 11, 21): 258–297, and about the Cu atom (14): 257–298.

Te 12, Te 13) or μ_6 bridging ligands (Te 1, Te 2, Te 11). The Cu atoms also occur in different bonding forms. The atoms Cu 2, Cu 5, and Cu 8 are within the cluster, and are each bound to three Te and eight Cu atoms. The Cu atoms (Cu 1, Cu 4, Cu 6, Cu 7, Cu 10, Cu 12, Cu 13, Cu 16, Cu 20, Cu 22) coordinated to P*i*Pr$_3$ are each surrounded by three Cu and three Te atoms. The remaining ten Cu atoms each contain three Te ligands in the coordination sphere and additionally, three Cu(Cu 17, Cu 19, Cu 23), four Cu(Cu 3, Cu 15, Cu 18), five Cu (Cu 9, Cu 11, Cu 21), or six Cu atoms (Cu 14) at a distance of 254–300 pm.

In an alternative description, the structure of **2** can also be derived from a distorted icosahedron, which is formed from the twelve peripheral Te atoms (Te–Te 393.7(7)–472.2(7) pm). Above the twenty Te$_3$ faces lie ten Cu atoms bound to P*i*Pr groups, and below the remaining faces ten further Cu atoms are arranged. The cavity formed in this way is occupied by three additional Cu atoms (Cu 2, Cu 5, Cu 8) and Te 4.

The cluster **2** is probably an intermediate in the formation of **3** (Fig. 2 bottom), which shows threefold symmetry and is constructed from five parallel, planar layers; **B**, $x = 1$ also has this structure.[1] The middle layer is a mirror plane and has the composition [Cu$_9$Te$_4$(P*i*Pr$_3$)$_6$] (Cu 5, Cu 6, Cu 7, Te 3, Te 4, P 2, P 3), the second layers bound to this comprise six Cu (Cu 3, Cu 4) and three Te atoms (Te 2), and the outer layers have the composition [Cu$_4$Te$_3$(P*i*Pr$_3$]. This latter structural fragment is also found in the structure of **2**. As in **2**, Te 4 is situated at the center of the cluster in **3**, and is bound to three Cu atoms (Cu–Te 255.1(3) pm) in a trigonal planar arrangement. The fifteen peripheral Te atoms form a Frank–Kasper polyhedron (Te–Te 392–480 pm) with 26 Te$_3$ faces.[12] Above twelve of the triangular faces of this polyhedron, Cu atoms (Cu 2, Cu 6, Cu 7; Cu–Te 266.7(3)–275.7(3) pm) are bound to P*i*Pr$_3$ groups. Below the remaining fourteen faces are found fourteen Cu atoms, which are generated by symmetry operations from Cu 1, Cu 3, and Cu 4 (Cu–Te 256.7(3)–259.9(3) pm). The Cu–Cu distances in **3** (256.3(3)–276.3(4) pm) are approximately 10–20 pm longer than in **B**, $x = 1$.[1]

Completely different products are obtained if triethyl- or diethylphenylphosphane is used as ligand, instead of the sterically demanding triisopropyl ligand.[13] Consequently, the clusters **4** and **5**, respectively, are obtained, which crystallize in the form of dark green needles (yield 40%).

Figure 3 shows the structure common to both clusters **4** and **5** (**4** is used as the example). Cluster **4** possess a mirror plane, which is formed from the atoms Te 4, Te 5, Te 6, Cu 8, and Cu 9. The structure of the Cu cluster can be derived from a distorted, trigonal Cu$_6$ prism (Cu 6–Cu 11, Cu–Cu 249.1(5)–306.0(5) and 329.2(4) pm), in which six edges are bridged by Cu atoms (Cu 2, Cu 4, Cu 12, Cu 14) or Cu$_2$ units (Cu 3/Cu 5, Cu 13/Cu 16). The framework of the cluster is completed by Cu 1 and Cu 16. Thus, butterfly structure fragments analogous to **1** are obtained, which are formed from the Cu atoms 1, 3, 5, and 6 as well as 11, 13, 15, and 16. The Te ligands function (with the exception of the μ_6-Te$_5$) as μ_5 bridging ligands.

In order to describe the structure of **6** (Fig. 4 top), it is appropriate to consider the sixteen phosphane-free Cu atoms (Cu 4, Cu 5, Cu 8, Cu 11, Cu 17–Cu 28) first. These

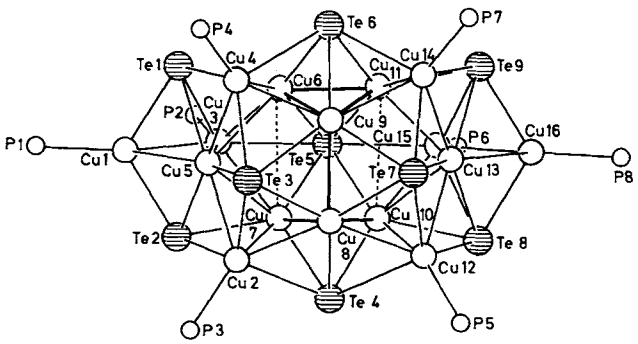

Fig. 3. Crystal structure of **4** (without C atoms). Important distances in pm (+ 0.4 pm): Cu 6–Cu 7 = Cu 11–Cu 12 329.2 (dashed), Cu 8–Cu 9 255.9, Te 5–Cu 258.0–275.4; Cu–Cu distances in the butterfly structure fragments Cu 1, Cu 3, Cu 5, Cu 6 257.3(4)–268.3(5), and Cu 11, Cu 13, Cu 15, Cu 16 258.9(5)–272.4(5).

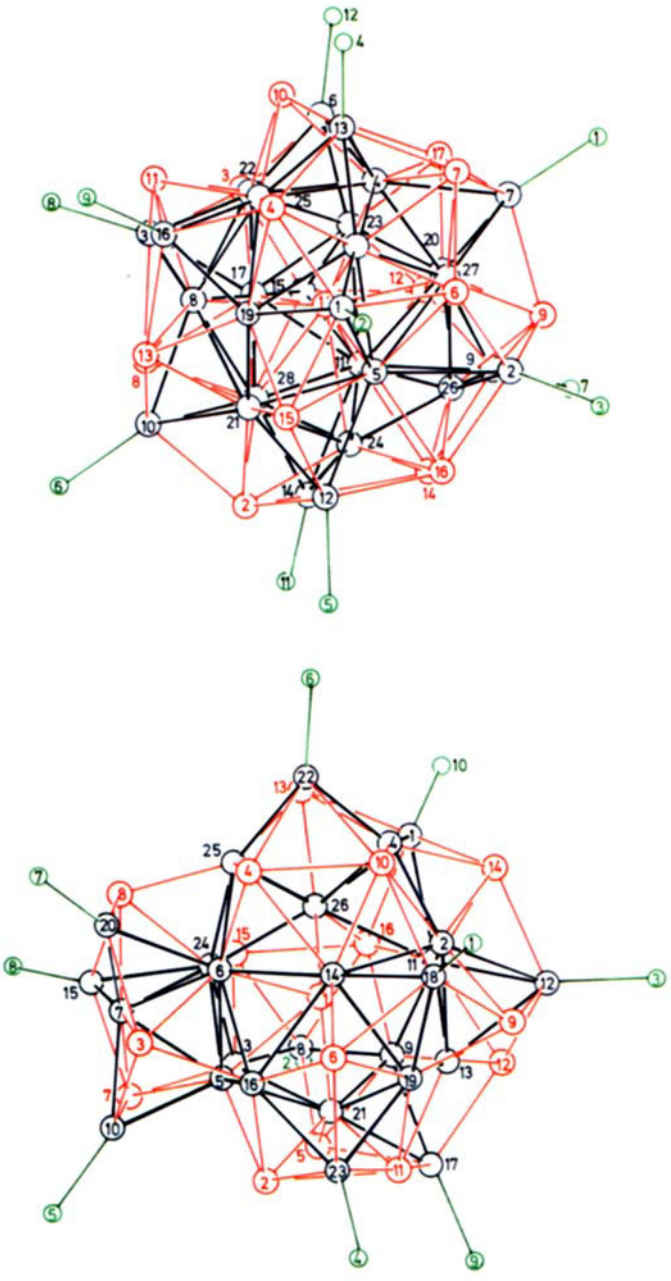

Fig. 4. Crystal structures of **6** (top) and **7** (bottom) (without C atoms); Cu: blue, Te: red, P: green. Cu–Cu bonds (blue) up to 300 pm and Cu–Te bonds (red) up to 290 pm are drawn. The Cu, Te, and P atoms are labeled only with blue, red, and green numbers, respectively. Important distances in pm (±0.5 pm): **6**: Cu–Cu 238.0–311.5, Te–Cu (1–3, 6, 7, 9, 10, 12–16) 260.0–273.1, Te–Cu (19–26) 242.0–260.7, Te–Cu (17, 18, 27, 28) 250.0-284.0, Te–Cu (4, 5, 8, 11) 269.2–283.4, Te 5–Te 8 287.9, Te 6–Te 7 289.3. **7**: Cu–Cu 258.1–290.7, Te–Cu (10, 15, 20) 261.0–269.6, Te–Cu (1, 8, 12, 17, 18, 22, 23) 264.7–297.7 Te–Cu (2–7, 9, 11, 13, 16, 19, 24, 25) 252.2–273.7, Te–Cu (14, 21, 26) 255.5–289.2.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1993 0570-0833/93/0202-0240 $ 10.00+.25/0

define a distorted, Frank–Kasper polyhedron with a central Te1 with 28 triangular faces, which are occupied by twelve Cu atoms (Cu1–Cu3, Cu6, Cu7, Cu9, Cu10, Cu12–Cu16) coordinated to $PPhEt_2$ and 16 peripheral Te ligands, which also describe a Frank–Kasper polyhedron, which is strongly distorted because of the Te–Te bonds (Te–Te 287.9(3)–469.8(7) pm).

The Cu–Cu distances vary greatly and are between 238(2) and 311.5 pm. Of the 28 Cu atoms, those twelve which are coordinated to phosphane are bound to three Cu and three Te atoms, the remaining have higher coordination numbers: Cu19–Cu26 form bonds to five Cu and three Te; Cu17, Cu18, Cu27, and Cu28 form bonds to five Cu and four Te, and Cu4, Cu5, Cu8, and Cu11 to six Cu and four Te atoms. The Te ligands function as μ_5 (Te2–Te4, Te9–Te16) or μ_8 ligands (Te1). Only Te5 and Te8 as well as Te6 and Te7 form Te_2^{2-} bridges, which are each bound to eight Cu atoms.

As in **3** and also in the complex **7** with the bulky ligand tris(*tert*-butyl)phosphane (Fig. 4 bottom), the fifteen peripheral Te atoms (Te2–Te16) form a Frank–Kasper polyhedron with a central Te1. However, this polyhedron is very strongly distorted because of the formation of Te–Te bonds (Te2–Te11, Te4–Te10, and Te15–Te16 287.7–289.5(5) pm). All the remaining Te–Te distances lie in the range of 418–488.3 pm. Above ten of these faces are found the Cu atoms (Cu1, Cu8, Cu10, Cu12, Cu15, Cu17, Cu18, Cu20, Cu22, Cu23) bound to $PtBu_3$, which are coordinated in different ways: Cu10, Cu15, and Cu20 form bonds to two Cu and two Te atoms, Cu8, Cu17, Cu18, Cu22, and Cu23 are surrounded by two Cu and three Te atoms, and Cu1 and Cu12 by three Cu and three Te atoms. Below the remaining 16 Te_3 faces, 16 Cu atoms are arranged (Cu2–Cu7, Cu9, Cu11, Cu13, Cu14, Cu16, Cu19, Cu21, Cu24–Cu26), which also have different coordination numbers: seven (three Te and four Cu atoms) is found for Cu3, Cu4, Cu9, Cu16, Cu19, and Cu25; Cu2 and Cu13 are bound to three Te and five Cu atoms, whereas Cu7 and Cu11 are surrounded by three Te and six Cu atoms, and Cu14, Cu21, and Cu26 by four Te and five Cu atoms. The highest coordination numbers are found for Cu5, Cu6, and Cu24, which are surrounded by three Te and seven Cu atoms. The Cu–Cu distances in **7** lie in the range 258.1–290.7(7) pm.

The Cu–Te fragments in **1**–**7** are not related to the structure of Cu_2Te.[14] In Cu_2Te a two-dimensional network of layers of hexagonal Cu_6 prisms is found, which are connected by Te_2 bridges. In contrast, **2**, **3**, **6**, and **7** have a much more shell-like construction, the Cu atoms, which form the inner shell, are surrounded by Te^{2-} in the first sphere and by Cu atoms coordinated to PR_3 in the second sphere; their structure principles, however, show striking similarities with those of intermetallic phases, for example, Laves phases.[15] In both cases, Frank–Kasper polyhedrons can be used to describe the structure. To illustrate this principle, the structure of the Te_{15} polyhedron in **3** and the Cu cluster, which penetrates this polyhedron, is given in Figure 5.

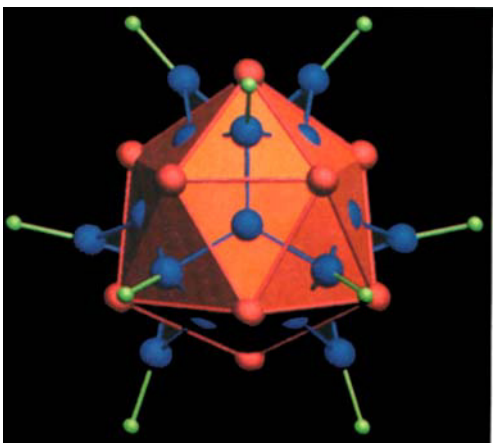

Fig. 5. Structure of the Te_{15} Frank–Kasper polyhedron (red) in **3** and of its penetrating Cu cluster (blue) [17].

The bonding in **2**–**7** can no longer be described with simple counting rules. On the understanding that Te^{2-} and Te_2^{2-} ligands occur, the Cu atoms in **1** would receive the formal charge +1 (d^{10} configuration), whereas mixed-valent conditions have to be assumed in **2**–**7**. Since the Cu–Cu distances in **1**–**7** (257–309 pm) are significantly longer than those discussed for Cu–Cu bonding, it can be assumed that binding Cu–Cu interactions are of little significance.[16] At present we are trying to calculate the electronic structures of the discussed clusters.

[3] General description for the synthesis of **1**–**7**: CuCl (1 mmol) was suspended in the solvent (50 mL)(THF, diethyl ether) and dissolved by the addition of the phosphane (CuCl:P = 1: 2.5–5.0). The clear, colorless solution was cooled to −78 °C and allowed to react with half an equivalent $Te(SiMe_3)_2$ (relative to CuCl) and subsequently allowed to warm up slowly. At approximately −40 °C, the reaction mixture darkens, and at this point volatile reaction products were distilled at constant temperature over approximately half an hour; a highly viscous oil remained. This oil was taken up in a little precooled solvent and the mixture was stirred shortly to allow complete homogenization. Thereafter, the solution was allowed to warm to room temperature under the exclusion of light over several days.

New Phosphido-Bridging Copper Clusters**

By *Andreas Eichhöfer, Dieter Fenske,** and *Werner Holstein*

Dedicated to Professor Hartmut Bärnighausen on the occasion of his 60th birthday

Silylated phosphanes react with transition metal halides with the formation of trimethylsilyl halides and multinuclear cluster complexes. In 1968 Abel reported that CuCl and $NiCl_2$ react with Ph_2PSiMe_3 to give insoluble, apparently oligomeric phosphides such as $[CuPPh_2]_n$ and $[Ni(PPh_2)_2]_n$, whose structures could not be elucidated.[1]

Recently, however, we showed that the reaction of $NiCl_2$ with $PhP(SiMe_3)_2$ afforded the nickel cluster $[Ni_{12}Cl_2(PPh)_2(P_2Ph_2)_4(PHPh)_8]$.[2] In contrast, if analogous reactions are carried out with $[MCl_2(PPh_3)_2]$ (M = Ni, Co) and $PhP(SiMe_3)_2$, $[Ni_8Cl_4(PPh)_6(PPh_3)_4]$ and $[Co_4(PPh)_4(PPh_3)_4]$ are isolated in very high yields.[3] Apparently, the structure of the cluster formed is influenced by the PR_3 ligands.

For this reason, we have now investigated systematically the reactions of CuCl with $RP(SiMe_3)_2$ (R = Ph), R_2PSiMe_3 (R = Ph, Me), and $KPPh_2$ in the presence of tertiary phosphanes. The multinuclear Cu cluster complexes **1**–**9** were isolated from these reactions (see Experimental Procedure).

Compounds **1**–**3** are formed as yellow crystals in yields of 80–90% (Schema 1). According to the X-ray crystal structure analysis,[4] **1** (Fig. 1a) contains a threefold axis and consists of a puckered Cu_3P_3 six-membered ring (Cu2 and P2), which is bridged by Cu1. The P atoms of the PPh_2 groups (P2) are thus μ_3-bridging atoms (Cu–P 233.5–243.0(3) pm). The coordination numbers of the Cu atoms vary; Cu2 is surrounded by P2 and the phosphorus atom of the $PnPrPh_2$ ligand (P1) in a trigonal-planar fashion, and Cu1 is surrounded by three PPh_2 ligands (P2) and one Cl ligand and exhibits a distorted tetrahedral coordination geometry. Recently Stelzer et al. reported a compound analogous to **1**, containing PMe_3 ligands.[5]

$$CuCl + Ph_2PSiMe_3 \xrightarrow{PnPrPh_2} [Cu_4Cl(PPh_2)_3(PnPrPh_2)_3] \quad \mathbf{1}$$
$$\xrightarrow{PHPh_2} [Cu_4(PPh_2)_4(PHPh_2)_4] \quad \mathbf{2}$$
$$\xrightarrow{PMe_3} [Cu_5(PPh_2)_5(PMe_3)_3] \quad \mathbf{3}$$

Scheme 1.

A topological relationship exists between the structures of **1** and **3**. Apparently **1** is a reactive intermediate on the way to the cluster **3**. Accordingly, the pentanuclear **3** (Fig. 1c) may be formed as a result of a reaction at the CuCl bond in **1**. With the exception of Cu4, which is coordinated in a distorted tetrahedral manner to four PPh_2 ligands (P1–P3, P5), Cu1–Cu3 and Cu5 exhibit a trigonal-planar coordination geometry.

The influence of the tertiary phosphanes on the formation of the structure of **2** is quite evident. As a result of the coordination of two sterically demanding $PHPh_2$ ligands (P5–P8) at Cu1 and Cu3, the formation of the structure type found in **1** is no longer possible. A nearly planar Cu_4P_4 ring exists in **2** (Fig. 1b), consisting of Cu1–Cu4 and the P atoms of the μ_2-PPh_2 groups (P1–P4). The deviations of these atoms from the best-fit plane are 3–20 pm. The Cu atoms in **2**, like those in **1** and **3**, have varying coordinations. Cu1 and Cu3 are tetrahedrally, and Cu2 and Cu4 are approximately linear (P1-Cu2-P2 166.2(3), P3-Cu4-P4 166.4(3)°) bound to the P ligands. The Cu–Cu distances indicate that no bonding interactions exist between these atoms (Cu1–Cu3 389–395, Cu2–Cu4 317.0(6) pm). In contrast, Cu–Cu distances of 244.5–255.8(2) pm are found in **1** and **3**.

The compounds $[Cu_4(PPh_2)_4(dppm)_2]$ (dppm = bis(diphenylphosphino)methane) and $[Cu_4(StBu)_4(PPh_3)_2]$[7] are structurally related to **2**.

A completely different structure is obtained if the sterically less demanding PMe_2 bridging ligands are used instead of PPh_2. Compound **4** crystallizes from the reaction solution of CuCl with PMe_3 and Me_2PSiMe_3 (in THF) [Eq. (a)], in the form of red needles (yield 90%).

$$CuCl \xrightarrow{PMe_3 + Me_2PSiMe_3} \underset{\mathbf{4}}{[Cu(PMe_3)_4]_2[Cu_{13}Cl_6(PMe_2)_9]} \qquad (a)$$

Compound **4** consists of two $[Cu(PMe_3)_4]^+$ cations and one $[Cu_{13}Cl_6(PMe_2)_9]^{2-}$ anion (Fig. 2 top). The basic cluster framework of the anion ($\bar{6}$ symmetry) is formed from a vertex-linked Cu_7 bitetrahedron (Cu1–Cu2), to whose basal faces six further Cu atoms (Cu3) are bound (Cu–Cu 247.4–257.4(3) pm). The polyhedron formed from thirteen Cu atoms is bridged by μ_3-PMe_2 ligands (P1, P2), and the six peripheral Cu3 atoms are additionally bound to Cl1. Thus Cu3 is linear coordinated (Cl1-Cu3-P1 176.6(2)°) to PMe_2 and Cl1, whereas Cu1 and Cu2 are each surrounded by three PMe_2 ligands (Cu–P 230.5–241.8(4) pm) in a distorted trigonal planar fashion.

Engesserstrasse, Geb.-Nr. 30.45, D-W-7500 Karlsruhe (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 195) and the Fonds der Chemischen Industrie.

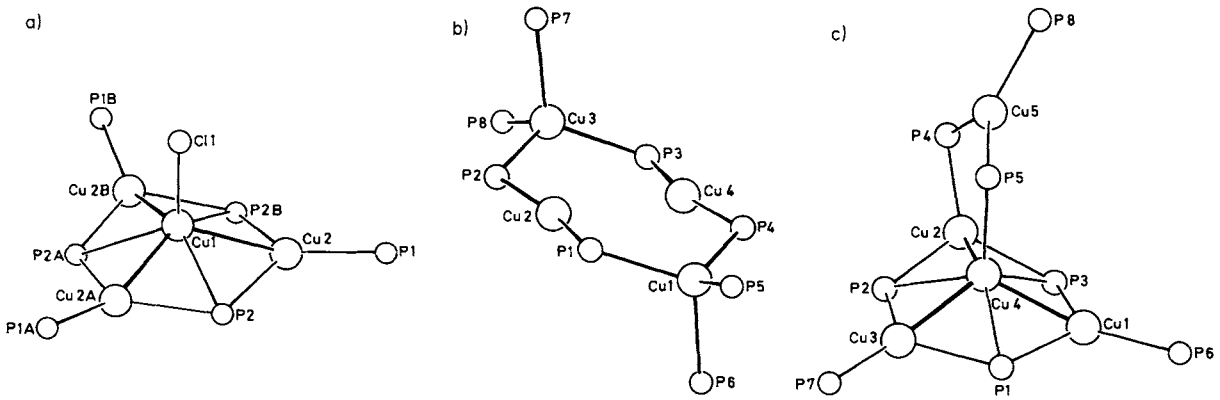

Fig. 1. Crystal stuctures of **1** (a), **2** (b), and **3** (c) (without C atoms). In **1**: P2 corresponds to the P atom of the PPh_2 and P1 to the P atom of the P*n*PrPh$_2$ ligand. In **2**: P1–P4 are the P atoms of the PPh_2 and P5–P8 the P atoms of the $PHPh_2$ ligands. In **3**: P1–P5 are the P atoms of the PPh_2 and P6–P8 the P atoms of the PMe_3 ligands.

Compound **4** is probably a sparingly soluble intermediate of the cluster condensation, whose end product would be $[CuPMe_2]_n$. In agreement with this is the observation that the initially formed red **4** rearranges when allowed to react longer into a completely insoluble, violet residue of the formula $[CuPMe_2]$.

The controlling influence of the bridging ligands on the structure of the cluster is also shown for the reaction of CuCl with $PHPh_2$ and a mixture of Ph_2PSiMe_3 and $PhP(SiMe_3)_2$ [Eq. (b)].

$$CuCl \xrightarrow{PHPh_2 + PhP(SiMe_3)_2 + Ph_2PSiMe_3} \underset{\mathbf{5}}{[Cu_{18}(PPh)_4(PPh_2)_{10}(PHPh_2)_3]} \quad (b)$$

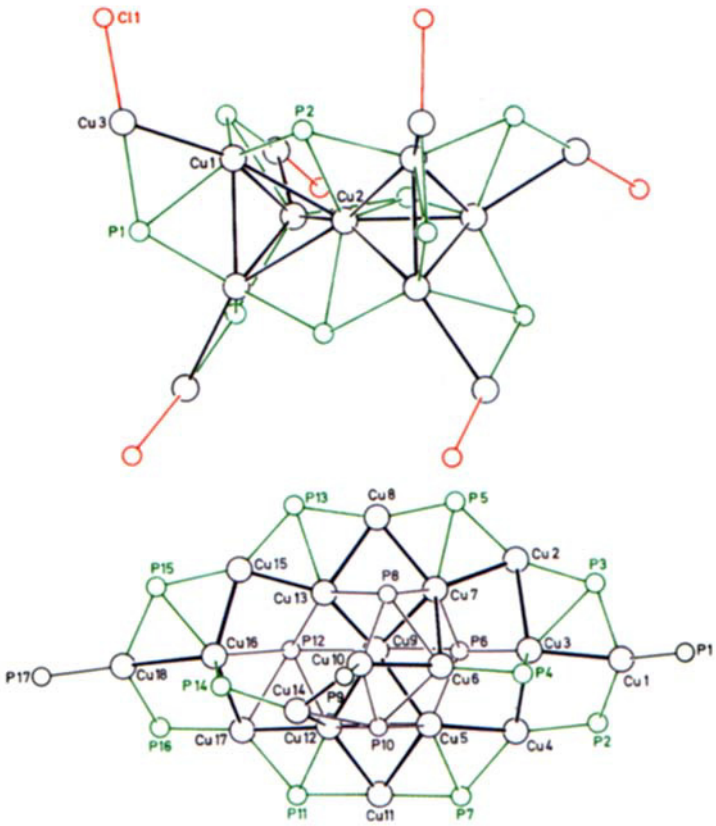

Fig. 2. Crystal structures of the anions in **4** (top) and **5** (bottom) (without C atoms). Cu: blue, Cl: red, P atoms of the PR_2 groups: green, P atoms of the PPh ligands: violet, P atoms of the $PHPh_2$ ligands: black.

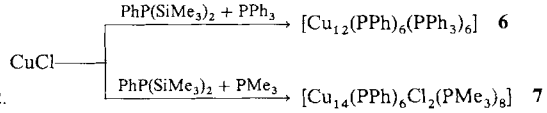
Compound **5** crystallizes from THF in the form of black rhombuses (yield 30%). Figure 2 (bottom) shows that **5** is not a spherical cluster. The 18 Cu atoms (Cu–Cu 244.9–271.8(1) pm) are bridged by PPh_2 groups differently: P2, P4, P14, and P16 are the bridging atoms of μ_2 ligands (Cu–P 221.0–229.1(2) pm); P3, P5, P7, P11, P13, and P15 are the bridging atoms of μ_3 ligands (Cu–P 224.0–265.9(2) pm).

The PPh groups are also bound in different ways: P6 and P8 are the bridging atoms of μ_4 ligands (Cu–P 227.2–244.9(2) pm) and P10 and P12 are the bridging atoms of μ_5 ligands (Cu–P 230.1(2)–254.9(2) pm). The Cu atoms of the cluster periphery (Cu1, Cu10, Cu18) are in addition coordinated to terminal $PHPh_2$ ligands (ν(PH) = 2310 cm^{-1}). As a result Cu2, Cu4, Cu8, Cu11, Cu14, and Cu15 are each coordinated to two P atoms of the PPh_2 groups, and all other Cu atoms are coordinated to three P atoms of the phosphane ligands.

The reaction of CuCl with PR_3 (R = Me, Ph) and PhP-$(SiMe_3)_2$ (Scheme 2) analogous to Equation (b) shows the



Scheme 2.

effect of the tertiary phosphanes and of the silylphosphane, on the structure of the cluster formed. A rapid coloring of the solution from colorless to black is observed when THF is used as the solvent, and **6** and **7** can be isolated as black crystals in yields of 30 and 80%, respectively.

Figure 3 (top) shows that **6** contains a Cu_{12} polyhedron ($\bar{1}$ symmetry), which is formed by linkage of three penetrating, planar Cu_6 rings (Cu2, Cu3, Cu4; Cu1, Cu2, Cu5; Cu1, Cu3, Cu6; Cu–Cu 256.3–278.3(2) pm). Alternatively **6** can be described as a compressed Cu_{12} cuboctahedron, which is surrounded by a distorted P_6 octahedron of the P atoms of the PPh ligands (P–P 387–453 pm). In the cuboctahedron, the distances between the Cu atoms (Cu4, Cu5, and Cu6) are extended to a nonbonding distance of 348–351 pm as a result of the bridging by the PPh ligands (P1–P3). These Cu atoms are each bound to a P atom of the PPh_3 ligands (P4–P6) and to two P atoms of the μ_4-PPh ligands (P1–P3) and exhibit a distorted trigonal planar coordination geometry. In contrast, the Cu atoms of the Cu_3 faces (Cu1, Cu2, Cu3) are coordinated to two μ_4-PPh ligands in an approximately linear (P-Cu-P 170.5(8)°) fashion. These coordination situations are a result of the steric shielding of these Cu atoms by the phenyl groups.

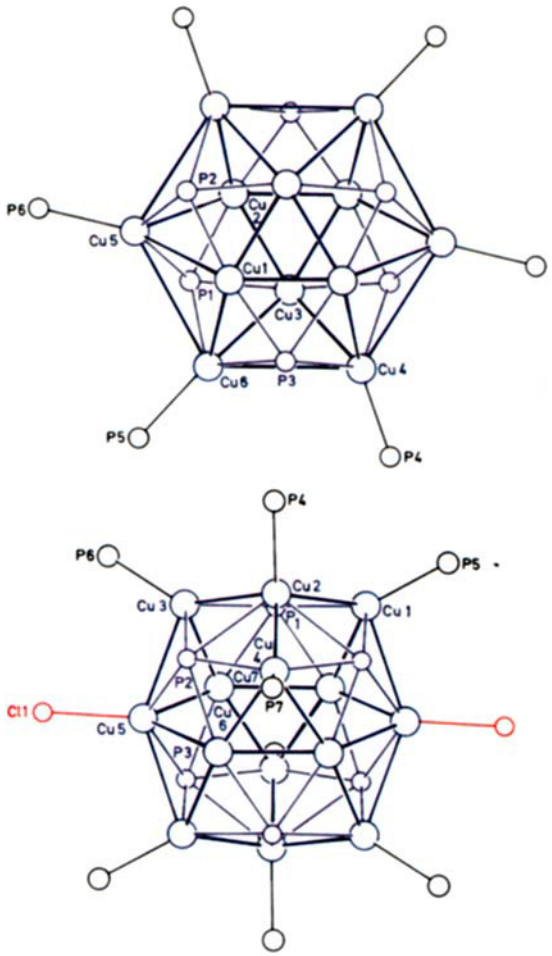


Fig. 3. Crystal structures of **6** (top) and **7** (bottom) (without C atoms). Cu: blue, P atoms of the PPh bridges: violet, P atoms of the PR_3 groups (**6**: R = Ph; **7**: R = Me): black.

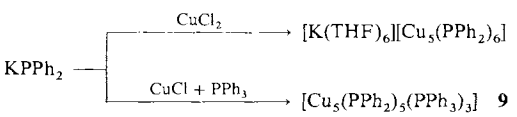
The structure of the Cu cluster ($\bar{1}$ symmetry) in **7** (Fig. 3 bottom) can be derived from **6** by insertion of two further Cu atoms (Cu 2) into the Cu_{12} cuboctahedron. The Cu_{14} polyhedron formed is bordered by planar Cu_5 and Cu_3 rings. The pentagonal faces of this polyhedron are bridged by μ_5-PPh ligands (P 1–P 3), and the Cu atoms show differing coordination geometries: Cu 6 and Cu 7 are bound to two PPh ligands in a nearly linear fashion (P 1-Cu 6-P 2 159.9(3), P 1-Cu 7-P 3 161.3(1)°); Cu 1, Cu 3, and Cu 4 are coordinated in a trigonal planar manner to two PPh ligands and PMe_3; Cu 5 is also surrounded by two PPh ligands and one Cl ligand in a trigonal planar fashion; Cu 2 is tetrahedrally coordinated by the P atoms of three PPh ligands and one PMe_3 ligand. The Cu–Cu distances in **6** and **7** are 256.3–278.3(2) and 248.4–253.8(3) pm, respectively.

$[Cu_{12}S_8]^{4-}$, a cluster which has a cuboctahedral arrangement of the Cu atoms, was reported by Krebs et al.[7] As previously shown by Issleib, metalated phosphanes are also suitable for the preparation of polymeric Cu phosphides.[8] Because the structures of these compounds were as yet unknown, we studied the reactions of CuCl with $KPPh_2$ (in the presence of PPh_3), and $CuCl_2$ with $KPPh_2$ (at −75 °C), which led to the compounds **8** and **9**, respectively (Scheme 3).



Scheme 3.

A trigonal Cu_5 bipyramid (Cu–Cu 332.9–412.2(2) pm) exists in **8** (Fig. 4) with a twofold axis. The edges to the axial positions are bridged by the P atoms of the PPh_2 groups. The Cu atoms are thereby coordinated either in a linear (Cu 1,Cu 3) (P-Cu-P 172.5(7)°) or trigonal planar fashion (Cu 2).

The geometry of the anion in **8** thus corresponds to that of $[Cu_5(StBu_6]^-$ previously described by Dance.[9] Thus it is clear that a similarity exists between the structures of clusters with PR_2 or SR ligands (R = organic group), which is derivable from the isolobal principle.[11]

Compound **9** forms yellow crystals; its $Cu_5(PPh_2)_5$ framework is analogous to that built in **3**.

A dark red colored amorphous powder is formed by the reaction of CuCl with Ph_2PX (X = K, $SiMe_3$) at room temperature, which corresponds to the formula $[CuPPh_2]$. The sparingly soluble $[CuPPh_2]$, however, can be dissolved in the presence of tertiary phosphanes. The previously discussed cluster complexes can be isolated from these solutions. Similar results were previously obtained by Stelzer et al., who reported multinuclear Cu complexes such as $[Cu_4(R_2PCH_2PR)Cl_3py]$ (R = *i*Pr, py = pyridine) and $[Cu_8(RPCH_2PR)_2Cl_2(py)_5]$.[5,12]

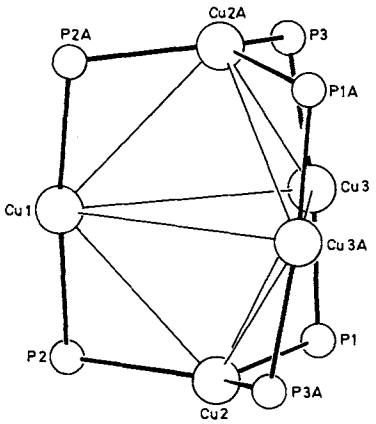


Fig. 4. Crystal structure of the anion in **8** (without C atoms).

If it is assumed that the ligands in **1**–**9** can be considered as Cl^-, PPh_2^-, PMe_2^-, and PPh^{2-}, the copper atoms in all compounds should have the formal oxidation state I (d^{10} configuration). Although the contribution of d^{10}–d^{10} interactions to the metal–metal bonding is controversial, examples are known which show that this can be significant.[12] The following range of Cu–Cu distances exist in **1**–**9**: **1**: 246.6(2), **2**: 317–395, **3**: 244.5–255.8(2), **4**: 247.4–257.4(3), **5**: 244.9–271.8(1), **6**: 256.3–278.3(2), **7**: 248.4–253.8(3), **8**: 332.9–412.2(2), **9**: 249.6–251.9(3) pm. These distances correspond to the values that have been found in other multinuclear Cu clusters and multinuclear Cu complexes with I^-, S^{2-}, Se^{2-}, SR^- ligands.[7,13]

The application of simple counting rules, for example the noble gas rule, is difficult for **1**–**9**. This is connected with the fact that it is not possible to make definite statements with regard to whether a Cu–Cu bond exists or not due to the varying metal–metal distances.

The bonding in **2** and **8** is relatively clear. The cluster complex **2** 64 valence elctrons (VE) at its disposal, which, as a result of the different coordinations, can be distributed to Cu 1–Cu 4, such that the nearly linear coordinated Cu atoms (Cu 2, Cu 4) have 14 VE, and the tetrahedrally coordinated Cu atoms Cu 1 and Cu 3 have 18 VE. Three linear coordinat-

ed (Cu1, Cu3, Cu3A) and two trigonal planar coordinated Cu atoms (Cu2, Cu2A) exist in **8**. Consequently, it could be assumed that Cu1, Cu3, and Cu3A with their ligands can each be described as 14 VE, as well as Cu2 and Cu2A correspondingly as 16 VE metal complex fragments. The fact that the 18-electron configuration is not attained, which is also observed in other coinage metal compounds, is apparently a characteristic of multinuclear complexes of these elements.

Initial studies into the reactivity of AgCl, $CdCl_2$, and $ZnCl_2$ with silylated phosphanes R_2PSiMe_3 (R = Ph) show that the previously described reaction type is a generally applicable method for the preparation of multinuclear, phosphido-bridged metal complexes. So far the following compounds could be isolated and structurally elucidated: $[Ag_4(PPh_2)_4(PMe_3)_4]$, $[Ag_6(PPh_2)_6(PtBu_3)_2]$, $[Zn_4Cl_4(PPh_2)_4(PnPr_3)_2]$, $[Cd_4Cl_4(PPh_2)_4(PnPr_3)_2]$.[14]

Experimental Procedure

1–**3**: CuCl (1.15 g, 0.012 mmol) was dissolved in THF (50 mL) with $PR'R_2$ (0.012 mmol, **1**: R' = *n*Pr, R = Ph; **2**: R' = H, R = Ph; **3**: R' = Me, R = Me). Subsequently Ph_2PSiMe_3 (2.8 mL, 0.012 mmol) was pipetted into the solution. On stirring, the solution turned yellow. Crystals suitable for X-ray structure analysis were obtained for **1** by layering the reaction solution with THF/heptane. Compound **2** crystallized from ether, and **3** from ether, after the addition of heptane (yields 80–90%).

4: CuCl (0.53 g, 5.35 mmol) was dissolved in THF (100 mL) with PMe_3 (0.55 mL, 5.35 mmol). Subsequently Me_2PSiMe_3 (0.8 mL, 5.35 mmol) was pipetted into the solution. After 3 h thin red needles crystallized from the red solution. At the end of the crystallization, the solution was clear and colorless (yield 90%).

5: CuCl (0.8 g, 8.1 mmol) was dissolved by the addition of $PHPh_2$ (1.5 mL, 8.1 mmol) in THF (75 mL). Subsequently Ph_2PSiMe_3 (0.46 mL, 2.03 mmol) and $PhP(SiMe_3)$ (0.46 mL, 2.03 mmol) were pipetted simultaneously into the solution and this was then stirred. The solution darkened after 15 min. After two days, the reaction solution was covered with a heptane layer, and black, rhombohedral, partly dendritic crystals were formed within a week at the solvent interface (yield 30%).

6: CuCl (0.4 g, 4 mmol) and PPh_3 (0.52 g, 2 mmol) were suspended in THF (50 mL). After the addition of $PhP(SiMe_3)_2$ (0.52 mL, 2 mmol), the solution turned black, and the reaction solution was stirred for 8 h. Crystals of **6** were obtained from the concentrated reaction solution or by layering the solution with heptane (yield 10%).

7: CuCl (0.65 g, 6.56 mmol) was dissolved in PMe_3 (1.4 mL, 6.56 mmol) in THF (50 mL). Subsequently $PhP(SiMe_3)_2$ (0.75 mL, 3.28 mmol) was pipetted into the solution with stirring. The solution quickly darkened in color through yellow to black, and **7** precipitated as a fine black crystalline solid. Crystals suitable for X-ray structure analysis were obtained when the reaction solution was layered with heptane (yield 80%).

8: CuCl (1.346 g, 0.0138 mol) was suspended with PPh_3 (7.24 g, 0.0276 mol) in THF (75 mL). It formed a white voluminous precipitate. Subsequently a solution of $KPPh_2 \cdot 2$dioxane (5.52 g, 0.0138 mol) in THF (25 mL) was added dropwise, and the mixture was stirred. After it had been stirred for two days, the yellow precipitate which formed was filtered off. The reaction solution was layered with THF/heptane, and yellow, rhombohedral crystals of **8** were formed at the solvent interface within two days (yield 80%).

9: A solution of $KPPh_2 \cdot 2$dioxane (22.62 g, 0.0565 mol) in THF (40 mL) was added dropwise to a suspension of $CuCl_2$ (3.8 g, 0.0283 mol) in THF (100 mL) at −75 °C, and stirred. Over 24 h the cold bath was warmed to room temperature, and the KCl formed was filtered off. The orange reaction solution was layered with THF/heptane, and yellow-orange crystals of **9** were formed at the solvent interface (yield 60%).

Synthesis and Characterization of a High Molecular Weight Stiff Dendrimer**

By *Zhifu Xu* and *Jeffrey S. Moore**

The synthesis and characterization of macromolecules with defined structure[1] such as dendrimers[2] are of widespread interest. The ability to manipulate molecular weight[3] and chemical constitution[4] precisely is typical with dendrimer syntheses; however, it is also important to begin to design approaches to macromolecules that have tailored conformations and well-defined three-dimensional architectures. This paper reports on the synthesis and characterization of a tridendron[5] based on phenylacetylene monomeric units. This macromolecule has a molecular weight in excess of 14 kDa and thus represents the largest pure hydrocarbon known.[6] Key to its synthesis is the proper choice of peripheral functionality (to aid solubility) and careful optimization of reaction conditions. Complete ^{1}H NMR assignment has made it possible to confirm the exact chemical structure. In spite of the high arene content and stiffness of this macromolecule, it is extremely soluble in pentane at room temperature.

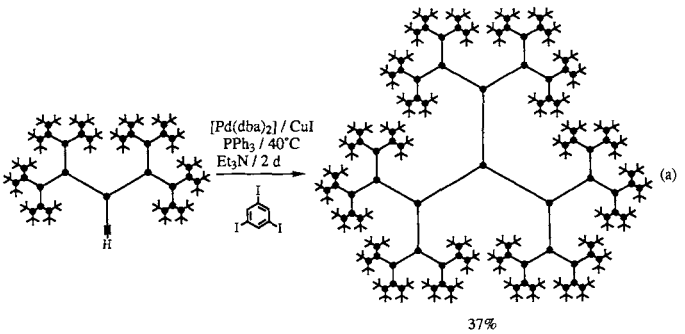
In a preliminary report, we described a synthetic scheme for the preparation of triconnected phenylacetylene monodendrons.[7] Difficulties arising from poor solubility and low chemical reactivity hampered our efforts in extending this scheme to high molecular weight generations of monodendrons and tridendrons. In our original communication, we noted that *para-tert*-butylphenyl peripheral groups promoted better solubility than the other groups that we examined. However, during further investigations with this system, we discovered that tridendrons and monodendrons possessing this peripheral group but containing more than 15 monomeric units were poorly soluble in common organic solvents. This behavior severely hampered our efforts to synthesize, purify, and characterize higher generation members of this series.

Here we report that a small change in the peripheral group functionality provides rather dramatic improvement in solubility. In particular, this involves the use of 3,5-di-*tert*-butylphenyl group instead of *para-tert*-butylphenyl as peripheral functionality, which has made it possible to continue the synthesis leading to the high molecular weight tridendron described below. In fact, all members of the phenylacetylene dendrimer series containing the di-*tert*-butylphenyl periphery and up to 94 monomer units are soluble in *pentane* at room temperature. Qualitatively, we note that the solubility is lowest for tridendrons and monodendrons having 10–15 monomer units and *improves* as the molecular size grows beyond this range. Powder X-ray diffraction shows that those dendrimers having only 10–15 monomers are partly crystalline while the higher members are totally amorphous.

One side reaction common to palladium-catalyzed cross-coupling chemistry is the formation of a self-coupling product. For cross-coupling chemistry involving 1-alkynes, the side reaction gives a diacetylene derivative. This side reaction is likely to be catalyzed by adventitious molecular oxygen. We observed that the amount of diacetylene product increases in higher generations, presumably due to the increasing steric congestion around the core. For the highest generations, diacetylene formation is significant even when molecular oxygen is rigorously excluded. Minimizing this side reaction is key to the successful syntheses of these dendrimers and their subsequent purifications. In our earlier publication, we demonstrated that enlarging the monomer for the higher generations is one way to overcome this problem.[7] Here we report reaction conditions that have proven to be successful at minimizing self-coupling without enlarging the monomer or core size.

Aryl iodides are greatly preferred to aryl bromides for the cross-coupling chemistry, since the coupling reaction must be performed at as low a temperature as possible. Long reaction times are required under these conditions, but the yield of the cross-coupling product is substantially higher. Moreover, as the molecular weight increases, substantially larger quantities of catalyst are necessary, which makes it extremely important to run the reaction at low temperature (35–40 °C) for longer periods of time (2 days). At higher temperatures (e.g. 80 °C) and with high catalyst concentrations, side reactions occur which predominately lead to the self-coupling side-product and to unidentified high molecular weight impurities.

Using the optimized reaction conditions described above and 3,5-di-*tert*-butylphenyl peripheral groups, we have successfully prepared the phenylacetylene tridendron containing 94 monomer units (Fig. 1) by coupling 4.0 equivalents of 31-mer monodendron with 1,3,5-triiodobenzene [Eq. (a),



dba = dibenzylideneacetone]. The yield of the final coupling step was 37% after purification by silica gel chromatography. This hydrocarbon dendrimer has the molecular formula $C_{1134}H_{1146}$ and a molecular weight of 14776, which represents the largest pure hydrocarbon reported. Molecular models indicate the diameter of this dendrimer to be about 55 Å. Space-filling molecular models (Fig. 1, right) show that the monomeric units in the outer tier of one arm can come into close contact with those of another arm. The overall structure is thus spherical or globular. Even so, the interior remains open with large voids and niches.

Confirmation of the chemical structure has been obtained through a variety of experiments. Analytical thin-layer chromatography (TLC) of the 94-mer reaction mixture reveals the presence of two new products in addition to the 30-mer diacetylene side-product carried over from the previous generation and a small amount of excess starting material. Separation of this mixture is possible by careful silica gel chromatography. Size exclusion chromatography (SEC) of the two new products shows that they are nearly identical in size. The SEC elution profile in each case is a single sharp peak ($M_w/M_n = 1.03$) and corresponds to a molecular weight of 9.0×10^3 relative to narrow molecular weight polystyrene standards. This value is significantly larger than the value of 6.1×10^3 observed for the starting monodendron which possesses 31 monomer units. The new product of higher R_f ac-

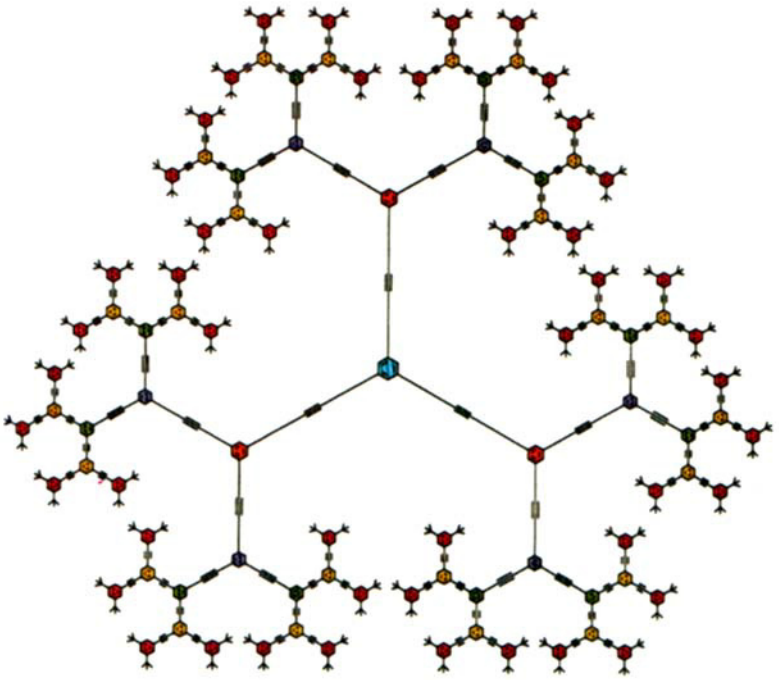

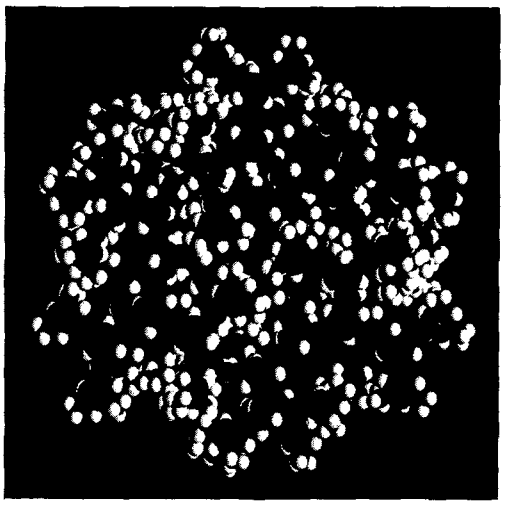

Fig. 1. Structural formula and molecular model of the 94-mer tridendron synthesized as shown in [Eq. (a)]. Equivalent aromatic rings are denoted by a common color, assuming rapid torsional rotation about the sp–sp^2 single bonds.

counts for about 20% of the mixture and is identical (^{1}H NMR, TLC) to the 62-mer diacetylene we synthesized independently. The major product (lower R_f) should thus correspond to the desired 94-mer, although we have also considered the possibility that this substance may be a 63-mer in which only two monodendrons coupled to triiodobenzene. However, the major product gave an elemental composition by combustion analysis of that expected for the 94-mer. This result disfavors the possibility that we isolated the 63-mer, since this monoiodide would have a carbon content 1% lower than the theoretical value of the desired tridendron (Calcd for 63-mer $C_{758}H_{765}$ I: C 91.02, H 7.71. Calcd. for 94-mer $C_{1134}H_{1146}$: C 92.18, H 7.82. Found: C 91.96, H 7.75).

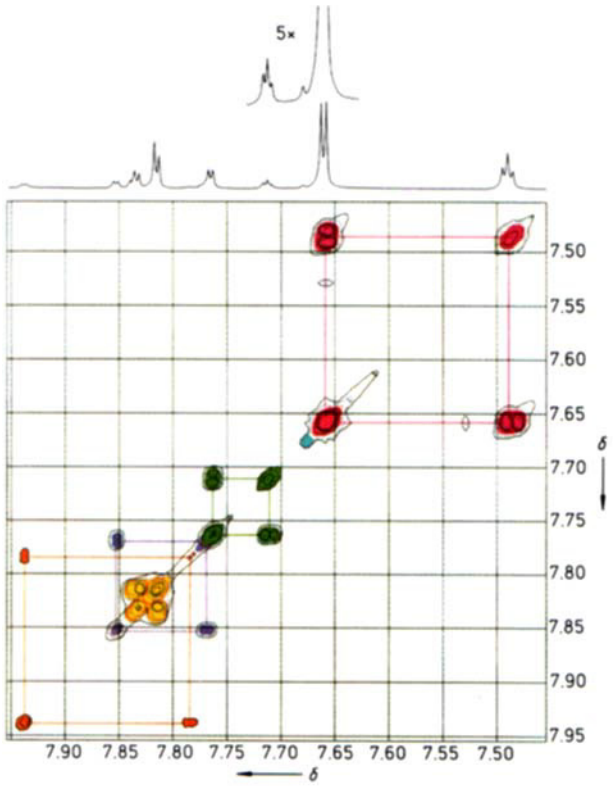

Fig. 2. ^{1}H NMR COSY-45 spectrum of the 94-mer tridendron recorded at 360 MHz in [D_6]benzene at 295 K. Resonances and cross peaks corresponding to the five different AB_2 spin systems and to the lone A_3 spin system are colored to match the structure shown in Figure 1.

Strong evidence in support of this conclusion has been obtained by extensive ^{1}H NMR experiments. In the aliphatic region, only a sharp singlet resonance corresponding to the *tert*-butyl protons is observed. In the aromatic region, adequate chemical shift dispersion for complete assignment has been realized by recording the NMR spectra in several solvents and at several temperatures. Good chemical shift dispersion is found for spectra recorded with [D_6]benzene or [D_8]THF. Spectra recorded in $CDCl_3$, on the other hand, are very congested and contain little information. The COSY-45 spectrum of the 94-mer in [D_6]benzene at 295 K is shown in Figure 2. Five cross peaks corresponding to the five different AB_2 (nearly AX_2) spin systems expected for this compound can clearly be identified. Two-dimensional *J*-resolved spectroscopy has established that each of these cross peaks correlates a triplet–doublet pair. The relative integral intensity of these spin systems follows the predicted ratio of 1:2:4:8:16. Most importantly, a small singlet is observed at $\delta = 7.68$, confirming the presence of a C_3 rotational axis in this molecule. This singlet displays a fairly strong, temperature-dependent chemical shift to lower field at higher temperatures. At 300–330 K, it is possible to separate the singlet from the intense doublet at $\delta = 7.66$ and obtain accurate integral intensities. Careful integration of the singlet against the doublet further downfield gives the expected 1:2 ratio. We believe that the complete assignment of the ^{1}H NMR signals together with the elemental composition data constitutes unambiguous proof of the chemical structure of the 94-mer.[8] We are continuing to explore other synthetic strategies for stiff dendrimers with novel architectures and will report these findings in due course.

Experimental Procedure

A single-neck Schlenk flask was charged with the deprotected 31-mer monodendron (140 mg, 0.0286 mmol), triiodobenzene (3.3 mg, 0.007 mmol),

$[Pd(dba)_2]$ (1.6 mg, 0.003 mmol), triphenylphosphane (6 mg, 0.023 mmol), copper(I) iodide (0.6 mg, 0.003 mmol), and dry triethylamine (3 mL). The flask was stoppered, degassed under vacuum, back-filled with nitrogen and stirred at 40 °C for 2 days. The consumption of the 1-alkyne was monitored by TLC. After completion, the reaction mixture was diluted with dichloromethane, washed with water (3 ×) and saturated aqueous sodium chloride, dried over anhydrous $MgSO_4$, and filtered. The crude mixture was separated by gravity column chromatography by eluting with hexane/CH_2Cl_2 (7:1 increasing to 6:1) to give the major product as a clear, colorless glass (40 mg).

^{1}H NMR (360 MHz, [D_6]benzene, 295 K): δ = 7.94 (d, 6H), 7.86 (d, 12H), 7.84 (t, 24H), 7.81 (d, 48H), 7.79 (t, 3H), 7.77 (t, 6H), 7.76 (d, 24H), 7.71 (t, 12H), 7.68 (s, 3H), 7.66 (d, 96H), 7.49 (t, 48H), 1.37 (s, 864H); ^{13}C NMR (90 MHz, $CDCl_3$): δ = 150.86, 134.69, 134.45, 134.31, 134.06, 133.88, 133.32, 125.95, 124.69, 124.36, 123.84, 123.73, 123.64, 123.34, 123.05, 121.77, 91.84, 89.41, 89.08, 88.87, 88.54, 86.61, 34.78, 31.29. Correct elemental analysis.

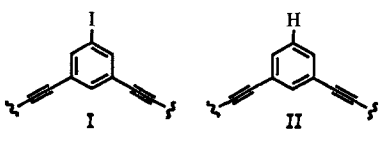
[8] We have considered other explanations consistent with our synthetic chemistry to account for the appearance of the signal at δ = 7.68; however, on the following basis, we rule out these possibilities. First, we note that the T_1 value for this signal is similar to the T_1 values of protons on neighboring aromatic rings (ca. 4 s). Second, by comparison to the ^{1}H NMR spectrum of authentic 62-mer diacetylene, we rule out the possibility of its presence. Third, if only two monodendrons coupled to triiodobenzene, then the innermost ring should have structure I or, if reductive deiodination occurred then structure II is possible. Resonances due to protons of I or II would only



show the appearance of a singlet if theses spin systems were strongly second order. Given the expected chemical shifts of I and II (based on model compounds), this is not likely. Moreover, integration of the signal at δ = 7.68 with respect to the furthermost downfield doublet would be 3:4 and 4:4 for I and II, respectively, instead of the observed 1:2 ratio.

Self-Assembly and Liquid Crystal Formation of Folic Acid Salts**

By *Stefania Bonazzi, Monica Miranda DeMorais, Giovanni Gottarelli,* Paolo Mariani,** and *Gian Piero Spada*

Molecular recognition and self-organization processes are of great interest; in some cases they may lead to the formation of liquid crystalline mesophases.[1] A few biologically relevant molecules are known to exhibit such behavior.[2] Ordered mesophases are also useful for obtaining information, by X-ray diffraction studies, on the supramolecular architecture afforded by self-assembly.[3] Here we report that in water dipotassium folate[4] forms a hexagonal lyotropic liquid crystalline phase by a self-organization process which generates supramolecular objects with a chiral columnar shape.

CD spectra of folate recorded at low and high concentration are shown in Figure 1; these spectra are significantly different. Also the absorption spectra at high concentration

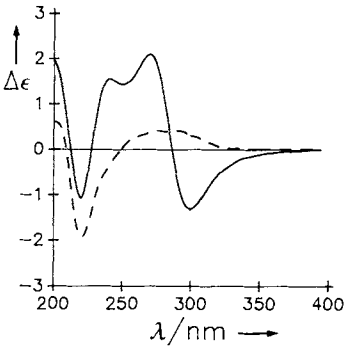


Fig. 1. CD spectra of dipotassium folate in water for concentration $c = 8.4 \times 10^{-5}$ mol L^{-1} (dashed line; recorded at 20 °C; the spectrum does not change on heating to 80 °C) and $c = 8.4 \times 10^{-2}$ mol L^{-1} (solid line; recorded at 5 °C). Measurements were performed with a Jasco J-710 dichrograph in cells fitted with a thermostat and with path length ranging from 0.001 to 1 cm.

show considerable hypochromicity. The CD spectrum of the concentrated solution displays exciton patterns characteristic of a helical arrangement of the chromophoric groups. At a concentration of about 35 wt%, the solution at 25 °C becomes birefringent and textures (Fig. 2) similar to those for the hexagonal mesophases formed by homoguanylic oligodeoxynucleotides,[3, 5] DNA,[6] and "chromonic" phases are observed with a microscope.[7]

In previous research we have shown that several deoxyguanosine derivatives form liquid crystalline phases.[3, 5, 9] The building block of these phases is a chiral columnar aggregate composed of a stacked array of Hoogsteen-bonded guanosine tetramers. Considering the similarity of guanine and pterin (Fig. 3), it seems natural to propose that also for the folate self-assembly leads to the formation of chiral columnar aggregates composed of a stacked array of folic acid tetramers. The stereogenic center in the side chain of the chromophoric groups generates the supramolecular chirality of the columns as revealed by CD spectroscopy. The CD

The bar corresponds to 80 μm.

spectra show that the planar chromophoric tetramers are not exactly superimposed, but are rotated with respect to the one another in a way similar to that found in poliguanylic acid tetramers.[10-12]

The X-ray diffraction profile observed at 25 °C in the concentration range between 35 and 70 wt% is characterized by several low-angle narrow peaks; from the ratios of their spacings in values of s ($s_{hk} = 2\sin\theta/\lambda$, where 2θ is the scattering angle and λ the x-ray wavelength) of $1:3^{1/2}:4^{1/2}:7^{1/2}:9^{1/2}\ldots$, a hexagonal two-dimensional lattice is clearly derived. In such a concentration range, the high-angle region of the diffraction pattern ($s > (10\ \text{Å})^{-1}$) shows a sharp peak centered at $s = (3.3\ \text{Å})^{-1}$. According to the structural model outlined above and proposed previously for the liquid crystalline mesophases of guanosine derivatives,[3, 5, 9] such an X-ray diffraction pattern indicates that this phase could consist of parallel columnar aggregates packed in a two-dimensional hexagonal lattice. Each rod is composed of a stacked array of tetramers,[13] equally spaced at a distance of 3.3 Å and formed by four hydrogen-bonded folate residues. By assuming cylindrical-like aggregates embedded in the water matrix, but not penetrated by water molecules,[3, 9, 14] the cylinder radius was calculated: it is almost independent of the water content and is about 14.5 Å.[15]

It is interesting to analyze the effects of the concentration on the x-ray diffraction profile characteristics. The length a of the hexagonal unit cell appears to be a function of the concentration, changing from 36.2 Å ($c = 70$ wt%) to about 48.6 Å ($c = 36$ wt%) (Fig. 4). Moreover, when the isotropic liquid phase transition is approached (in particular for concentrations lower than ca. 45%), only the first low-angle peak still remains and becomes broad and diffuse. This observation could indicate a transition to a nematic, columnar phase when the water content increases. Quite surprisingly, dilution also modifies the high-angle pattern: in particular the position of the peak appears to change as a function of the folate concentration (Fig. 4 right). In the vicinity of the isotropic liquid phase transition, the peak becomes very large and diffuse. However, studies by optical microscopy seem to support the presence of a direct isotropic liquid to

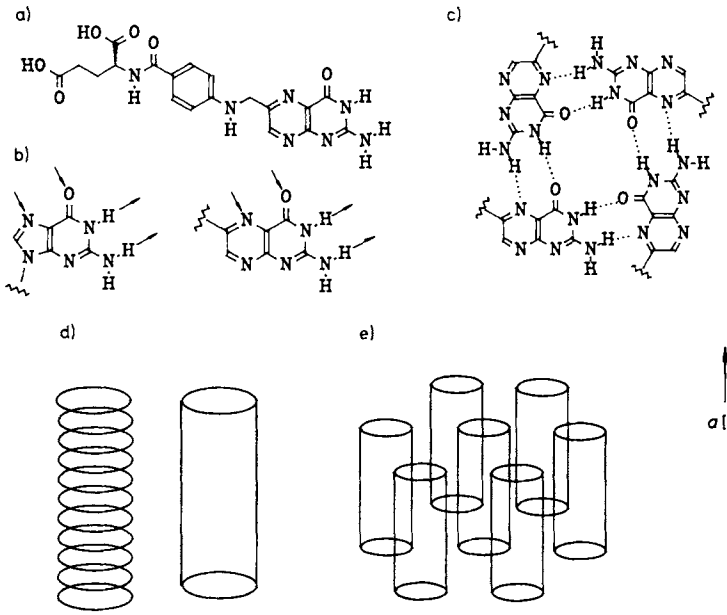

Fig. 3. a) Structure of folic acid and b) the similarity between the guanine and the pterin moieties; c) the proposed tetramers formed by four folic acid molecules. These tetramers may stack to form cylindrical aggregates (d) that in the liquid crystalline phase exhibit a hexagonal order (e).

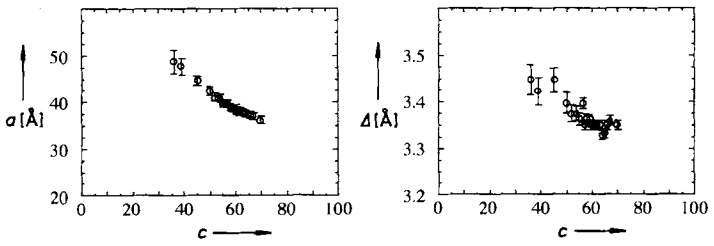

Fig. 4. Variations of two of the structural parameters of the columnar hexagonal phase at 25 °C as a function of folate concentration. Left: hexagonal unit cell parameter a, as calculated from the spacings of the x-ray diffraction low-angle peaks. Right: distance between the stacked tetrameric disks, as determined from the position of the high-angle peak. c = concentration of dipotassium folate in wt%. Range of angles for low-angle peaks $2.5 < 2\theta < 10°$ and for high-angle peaks $25 < 2\theta < 27°$.

hexagonal liquid crystal phase transition. Therefore, from a structural point of view, it appears that dilution establishes a large disordering of the hexagonal packing which completely disappears only when the isotropic phase is reached. Since the previously investigated guanosine derivatives[3, 5, 9] also form a cholesteric phase, this behavior is quite new and could correspond to a loose conformation of the columnar folate aggregates. In particular, the constant cylinder radius and the continuous change of position of the high-angle peak when the water content increases, suggest that the loss of aggregate rigidity could arise from a stacking interaction between the disks, weaker than that for the previously reported guanosine derivatives.[3, 5] The change in position of the high-angle peak might be due to an interaction of water with the polar groups in the side chain. Also a small temperature effect is observed on the hexagonal structural parameters: in particular, when the temperature increases, the dimesions of the unit cell do not change, but the tetramer repeat distance increases (from 3.32 to 3.42 Å in a sample with a folate concentration of 52 wt% when the temperature is raised from 2 to 60 °C).

The electron density map of the sample with a folate concentration of 59.5 wt% calculated from the diffracted intensities by performing a swelling experiment[3, 5, 9, 16] is reported in Figure 5. The map clearly shows the electron-dense rod cross-sections, surrounded by a smooth region of lower electron density, which is associated with the water.[17] There is an excellent agreement between the diameter of the rod determined directly from the map and the one calculated from our model (see above). The central region of the rod cross-section is characterized by a minimum in electron density, corresponding to the "hole" in the tetramer folate arrangement, which is in agreement with the assumption that the central region of the tetramer could contain the K^+ ion.[3, 9]

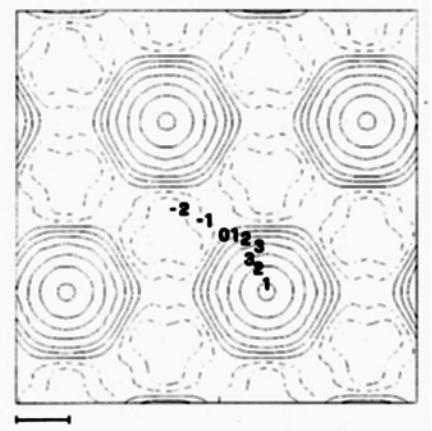

Fig. 5. Electron density distribution of the hexagonal phase in a sample with 59.5 wt% folate concentration. The electron density scale is arbitrary: the intensity data have been normalized so that the sum of the scattered intensity is equal to 1 [17]. Therefore, the corresponding electron density map is a normalized, dimensionless expression of the electron density fluctuation. The density lines are equally spaced: the dotted lines correspond to the region of lower electron density (i.e. to negative values in our data normalization), while the solid lines correspond to the higher electron density region (i.e. to positive values) (see ref. [17]). The structure factors $F(h,k)$, where h and k are the Miller indices, are $F(1,0) = +0.348$, $F(2,1) = -0.165$, $F(2,0) = -0.055$, $F(3,1) = -0.077$, $F(3,0) = 0$, $F(4,2) = +0.029$, $F(4,1) = +0.036$. The bar corresponds to 10 Å.

Since the critical concentration at which the liquid crystalline phase appears is not markedly affected by exchanging potassium for sodium, the ion dependence is not as specific as for guanosine derivatives, and also water molecules may fit into the central cavity.

The presence of small folate aggregates in the isotropic phase is also confirmed by a preliminary analysis of the small-angle neutron scattering: The scattering observed in sample with a folate concentration of 1 wt% is in accord with the existence of rod-like scattering particles with an average length of about 80 Å and a sectional gyration radius of about 14.5 Å. According to the results of similar experiments,[18] a model with cylindrical-like aggregates formed by stacking about 20 folate tetramers seems to fit these data.

The Application of Au_{55} Clusters as Quantum Dots**

By *Ulrich Simon, Günter Schön,* and *Günter Schmid**

The availability of smallest solids like larger transition metal clusters[1] opens a field of research raising basic questions: How small must the number of atoms be in order for the typical properties of the original bulk metal to be lost? What can be anticipated in the application of metal clusters in nanotechnology, that is, in microelectronic quantum devices? The nonpareils of miniaturization in microelectronics are the so-called quantum dots, zero-dimensional (0D) quantum devices with diameters on the nanometer scale, whose response is based on single-electron processes. Current investigations worldwide concentrate on tailoring the mesoscopic semiconductor regions in a surrounding bulk material with a broader band gap. However, until now,

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. U. Kreibig and Dr. M. Herrmann for the STM images (Fig. 1), R. Blümel for providing the fitting program, and the Deutsche Gesellschaft für das Chemische Apparatewesen und Biotechnologie (DECHEMA) for valuable discussions on particle size effects.

quantum devices as small as clusters have not been obtained. We believe that they could be better prepared from metal clusters with semiconducting behavior: With respect to electrical conductivity, Nimtz et al.[2] defined the SIMIT, the Size-Induced Metal–Insulator Transition observed when the volume of metallic particles is reduced down to a diameter of about 20 nm. This size-dependent quantization effect may be considered the beginning of a possible metal–semiconductor transition at the very end of metallic behavior or—with respect to the molecular state—at the beginning of metallic behavior.

Recently numerous physical investigations such as Mössbauer[3] and solid-state NMR spectroscopy,[4] conductivity[5] and susceptibility[6] measurements, and EXAFS[7,8] and optical investigations[9] were performed on transition metal clusters. The results, which depend somewhat on the method, suggest that for ligand-stabilized transition metal clusters about 50–100 metal atoms and a cluster diameter between 1 and 2 nm are necessary for metallic behavior. At this transition from molecular to bulk material, metal particles in the microcluster domain are expected to have novel electronic properties when the boundary conditions given by their dimensions (e.g. the diameter x) reach the order of magnitude of the de Broglie wavelength λ of the valence electrons.[2] Indeed, metal clusters with such diameters can be regarded as custom-made 0D quantum dots, in which a few free electrons are localized geometrically as well as from the point of view of quantum mechanics. By means of Impedance Spectroscopy (IS) it has been shown that as a result of this Quantum Size Effect (QSE), the first (or the last) two metallic valence electrons of cluster **1** are trapped in a quantum box consisting of its own Au_{55} metal core.[10]

$[Au_{55}(PPh_3)_{12}Cl_6]$ **1**

The main difficulty in the application of metal clusters in microelectronic 0D quantum devices seemed to be how to insulate them and simultaneously keep them in contact with their neighbors: This procedure is necessary to build up a so-called cellular automaton[11] or to make a 1D quantum channel (quantum wire) from a chain of single clusters or aggregates of clusters without coalescence to materials with solid-state properties. Figure 1 shows a quantum wire which happened to be observed by means of Scanning Tunneling Microscopy (STM).[12] The single quantum dots most probably consist of molecules of **1** which are aggregated to superclusters $[(\mathbf{1})_{13}]$.

We report here on some of the experimental findings and describe a practical construction of quantum devices with ligand-stabilized metal clusters. The way to a new generation of single-electron devices[13] consisting of the smallest building blocks possible may be opened. In such devices "switchable" quantum dots and quantum channels with correlated electrons could reduce the dimensions of classic electronic switches and memories by many orders of magnitude, possibly resulting in a new generation of computers with tremendous, multidimensional capacity or very simple miniature lasers.[11]

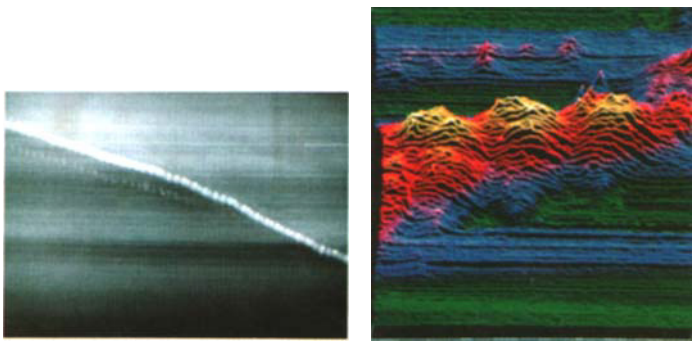

Fig. 1. Left: A quantum wire formed from a solution of **1** which happened to be detected by Scanning Tunneling Microscopy (STM). The diameter of the single particles is about 6 nm. This corresponds to an aggregate of 13 molecules of **1** forming a $[(\mathbf{1})_{13}]$ supercluster. Right: A magnified section of this quantum wire showing three superclusters.

Impedance Spectroscopy (IS) has become a powerful method for tracing macroscopic properties of different, even heterogeneous, materials back to their origins, even if these properties result from a variety of microscopic processes.[14] In analogy to hopping ion processes, electronic relaxation processes can also occur in the low-frequency range. Here, too, coupling with the environment plays a decisive role. One speaks of hopping electrons, or of localized electrons in traps, in which (excited) electronic states such as long-lived exitons can have lifetimes up to seconds. Such localized states are well known from disordered structures like glassy materials.[15–17] We recently demonstrated[10] that this type of phenomenon is also expressed in or on stabilized clusters by electron resonances which reveal fine structures in the low-frequency immittance spectra.[10]

The powdery samples of **1**, whose particles can be regarded as monodisperse within the limits of the following interpretation, were pressed up to an average, gravimetrically defined density of 3.37 $g\,cm^{-3}$. This value approaches that of a theoretical closest sphere packing (3.704 $g\,cm^{-3}$) by a factor of 0.91. Measurements were performed between 253 and 333 K by means of a fully automatic impedance spectrometer, which has been described in detail elsewhere.[18] For the measurements the sample, which looks like a disk of silicon, was placed under N_2 between various noble metal electrodes. As shown in Figure 2, the measurements on compact samples of **1** reveal a depressed arc in the Argand diagram with relaxation frequencies in the range of 10^4 to 10^5 Hz.

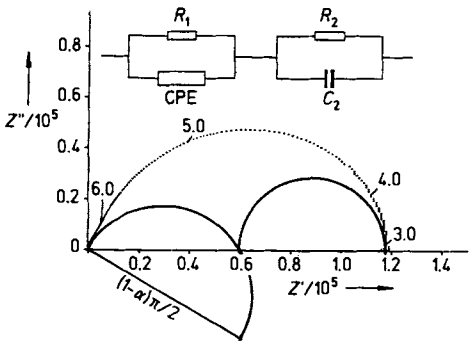

Fig. 2. Result (dotted line) of an impedance measurement on **1** at 293 K. In this unscaled Argand diagram the real part of the impedance Z' is plotted versus the imaginary part of the impedance Z'' in the complex plane. The numbers along the plot indicate the logarithm of the measuring frequency ν. In the upper section a circuit equivalent for the electric behavior of the sample is given. Below the measured plot are the Argand circles belonging to each separate link (solid lines).

By means of a novel mathematical fitting program for immittance data,[19] a circuit equivalent for the sample behavior of **1** was calculated. This yielded an error less than 1.8%. As shown in Figure 2, it consists of a parallel (ideal) Debye R,C link with the resistance R_2 and the capacitance C_2 (low-frequency resonance process 2), and a Cole–Cole R,

CPE link (higher frequency process 1) with the resistance R_1 and a parallel capacity element (Constant Phase Element, CPE).[13]. A Cole–Cole parameter $\alpha \approx 2/3$ is obtained from the fitting data. This value is typical for a percolation mechanism usually described by power laws for the frequency-dependant conductivity (with α as an exponent).[14] The Argand diagram provides the total resistance $R_t = R_1 + R_2$, and because $R_1 \approx R_2$, $R_t = 2R_1$. For the two different conductivity processes the specific conductivities are $\sigma_1 = 1.61 \times 10^{-4}\ \mathrm{Ohm^{-1}\,m^{-1}}$ and $\sigma_1 = \sigma_2 = 3.23 \times 10^{-4}\ \mathrm{Ohm^{-1}\,m^{-1}}$ at 298 K. From the temperature dependance of the conductivities were calculated activation enthalpies EA for the thermally activated processes; for the Debye relaxation process $EA_2 = 0.16 \pm 0.03$ eV and for the Cole–Cole process $EA_1 = 0.15 \pm 0.03$ eV. This means that within the limits of experimental accuracy $EA_2 \approx EA_1$. The relaxation times $\tau_{1/2}$ and the relaxation frequencies $\nu_{1/2}$, however, differ by a factor of two. For both processes $\tau_{1/2}$ shows the same temperature dependance as the resistance $R_{1/2}$, and it follows from the relation $\tau = R \cdot C$ that the capacitances C_2 and CPE must be independent of temperature. This resembles the electronic response of semiconductor–insulator interfaces, in which capacitances are built up and show relaxation in the low-frequency range.[13, 20]

In refs. [5, 9] the frequency dependance of the conductivity of **1** was measured and interpreted by means of a stochastic multiple-site hopping mechanism (a percolation process in which electrons tunnel between clusters), which was predicted to change into a two-site process at higher frequencies. Accordingly, we want to interpret the (higher frequency) Cole–Cole process 1, which we measured as a relaxation of an *inter*cluster process. This is supported by the occurrence of a distributed capacitance element (CPE instead of a single capacitance) caused by a distribution in hopping lengths (or jump times) between clusters, since in the transition of single electrons from one core of a cluster to the core of a neighboring cluster a fluctuating ligand shell must be passed through by tunneling.

We wish to interpret the Debye process 2, proven for the first time in our work, as an *intra*cluster step, which in concentrated samples is necessarily coupled to the intercluster process previously mentioned. In the immittance spectra the Debye process 2 is evident from a sharp resonance beside the broadened intercluster relaxation.

According to the SIMIT experiments, electronic resonance processes in particles with diameters on the nanometer scale should proceed in the range of microwaves, whereas we observe them by impedance spectroscopy already in the kHz range. That means that resonances in this low-frequency range can only be detected on densely packed samples of **1** because of the coupling of the electron processes to the environment. The low-frequency Debye process 2 is determined by the intracluster conductivity $\sigma_2 \approx 1/R_2$, which for **1** is dependent on dimension[10] like the SIMIT. Consequently, the cause of the low-frequency appearance is the capacitance $C_2 = 48$ pF, built up at the ligand shells. Its value is determined by the structure and the polarizability of the shell, for which an exact geometrical picture is not necessary. According to the formula $\tau_2 = R_2 \cdot C_2$ the relaxation time τ_2 is 2.6×10^{-6} s.

The value of the average Cole–Cole relaxation time is smaller by a factor of two and can be explained correspondingly. Both processes show equal conductivities, so that the distributed capacitance CPE equals a mean effective capacitance $C_{1\mathrm{eff}} \approx 1/2\,C_2 \approx 24$ pF. This would be in accordance with the idea that in a tunneling step both ligand shells of a cluster pair must be passed through. Such a single-electron transition corresponds chemically to a disproportionation step, for which a Coulomb energy contribution of ≈ 0.2 eV has already been estimated in comparison to its measured enthalpy of 0.3 ± 0.1 eV.[9] In our experiment the energy of disproportionation must equal the sum of the activation enthalpies $EA_1 + EA_2 = 0.31$ eV. In Figure 3 the total sequence of processes is shown in a simplified manner.

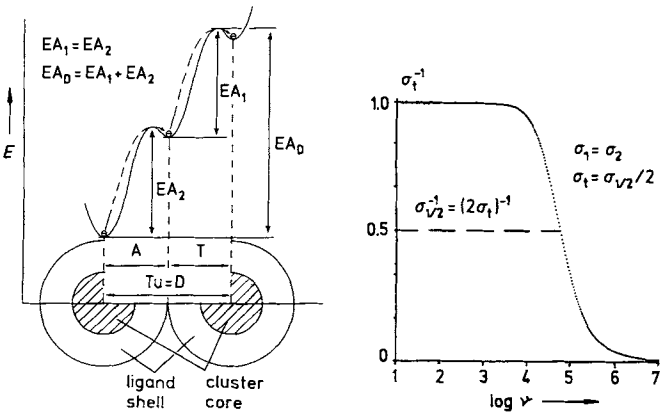

Fig. 3. Left: Scheme of the potential profile for a cluster pair. Activation step (A) and transport Step (T) cause the tunneling step (Tu) which is equal to a disproportionation step (D) with an activation enthalpy EA_D. Distance is plotted on the x axis. Right: A sequence of both steps leads to a total conductivity σ_t which is doubled under resonance conditions to $\sigma_1 = \sigma_2$.

Supposing that in the concentrated samples of **1** partial capacitances are produced in the area of the ligand shell(s) of one cluster or two neighboring clusters, we may determine an experimental density of the electronic states participating at the Debye process 2 $D_{ex} = \mathrm{d}N/\mathrm{d}\varepsilon$ from the capacitance C_2 (see ref. [13]). Assuming an approximately closest sphere packing of the clusters of **1** within the sample and scaling the capacitance $C_2 = 48$ pF to the capacitance of an unit volume, we obtain $D_{ex} \approx 10.75\ \mathrm{eV^{-1}}$. Therefore $\mathrm{d}N$ has the meaning of a number in a partial volume per cluster with its energy contribution $\mathrm{d}\varepsilon$. No other assumptions were made with regard to the effective cluster diameter x or to the distances of the charges.

According to the investigations cited in the introduction it seems possible that the quantum box of **1** has a minimum size, in which the last free electrons of the metal in the form of a free-electron gas are fenced in the cluster interior at the very end of the SIMIT. Due to the Pauli principle, the number of electronic states $N_{(ex)}$ participating in the resonance process would then be one *or* two with energies $E_{ex1/2}$ from D_{ex}. According to the formula for the 3D electron gas in a quantum box consisting of one cluster, an expression for the lateral extension x can be derived [Eq. (a)], where m is the

$$x = \hbar \cdot \pi (2m\,E_F)^{-1/2} \qquad \text{(a)}$$

electron mass and E_F is the Fermi energy. For $E_{ex1} = 0.093\ \mathrm{eV} = E_{F1}$ the lateral extension x_1 is 2.01 nm, and for $E_{ex2} = 0.186\ \mathrm{eV} = E_{F2}$ x_2 is 1.42 nm.

These two values are very close to the diameter of the cluster **1** with ligands (2.1 nm) and the metal core (1.4 nm), respectively. In the first case the quantum box should contain one electron, in the second two electrons (Fig. 4). It seems that the metal core is completely occupied with $N_{(ex)} = 2$ free electrons with a Fermi energy of $E_F \approx 0.19$ eV in the ground state. Free electrons with higher energies can no longer be bound in the cluster. Thus for **1** the density of

states (DOS) on the Fermi plane of a 3D electron gas can be estimated according to Equation (b). The experimental value

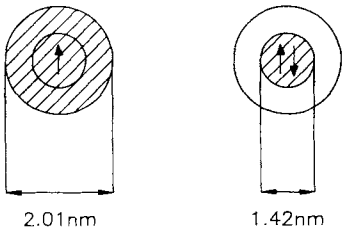

Fig. 4. Illustration of the two possibilities for the occupation of the quantum dot **1** with free electrons according to experiment.

$$D(E_F) = (m/6\,\hbar^2)x^2 \qquad \text{(b)}$$

of 1.42 nm for the diameter of the metal core leads to a density of states of 4.40 eV^{-1} per cluster.

Our experimental results disclose that **1**, a collective of 55 metal atoms within a ligand shell, still displays metallic properties. The effect of the QSE seems to be that in the frontier of the transition from metallic to molecular behavior in the range from 1 to 2 nm the last metallic valence electrons are localized in a quantum box with the lateral dimension of the cluster and that they move freely in this box independent of the particular nature of the respective cluster. The realization of such a quantum dot, in other words its chemical stability, depends on whether the binding energy of these electrons exceeds the de Broglie energy. In **1**, the quantum box is occupied by two electrons from the metal core according to the Pauli principle and may then serve as an electron source. If another electron is added, the nucleus may operate as an electron sink. The particle size implies that two electrons may be charge carriers for the intracluster conductivity, whereas the intercluster conductivity is determined by the tunneling of single electrons.

Compact samples of **1** are handy devices with astonishing electronic quantum properties even at room temperature. In principle, the following microelectronic quantum devices can now be realized by size reduction or/and precise addressing:

1) A Tunnel Resonance Resistance (TRR, see Fig. 5 left), a complete device, the total resistance of which is halved by applying a suitable resonance frequency at ambient temperature. The minimum working unit is as small as a pair of cluster molecules (see Figs. 3 and 6a) with a diameter of 4 nm. (In contrast, the smallest devices currently available have a lateral dimension of about 250 nm.) The resistance of one cluster is coupled to that of a chain of consecutive of single clusters, resulting in 1D quantum channels for correlated electrons (Fig. 6b). According to theory, the total resistance should only change with multiples of the fundamental quantum resistance $\pi\hbar/2e^2$. We will return to this problem later when we attempt to derive a phase relation between the Single-Electron Tunneling (SET) oscillations[13] and our resonance frequencies.

2) A cellular automaton (TRCA) with contacts only at the marginal points (see Fig. 5 right). Due to the tunnel conductivity, however, each quantum dot corresponds with twelve neighbors in strong parallelism.

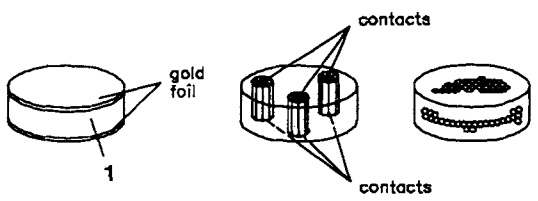

Fig. 5. Compressed disc of ligand-stabilized metal clusters which may be contacted facially by gold foils to build up a Tunnel Resonance Resistance (TRR) (left) or contacted by microscopic scanning patterns to include quantum channels (middle). The contacts may be placed facially and laterally (right).

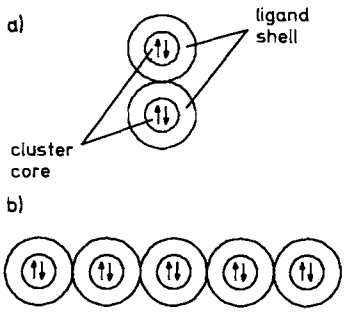

Fig. 6. a) Quantum device consisting of two clusters of **1**. This is also the smallest functional unit of a Tunnel Resonance Resistance (TRR). b) 1D quantum channel made up of clusters of **1** (section of the closest sphere packing in a compressed disc).

Finally, some advantages of the above devices should be mentioned: Firstly, these components can be operated with a defined (tunnel) current which can be doubled when switched by resonance. For this purpose, an additional rest current can be neglected. Furthermore, defects in single clusters and in the package of the pellets as well as single disorders (vacancies of clusters) do not substantially affect the function of the whole device. If single quantum dots or channels fail, they are omitted or possibly repaired by the formation of neighboring bypasses. Secondly, although with the present technology only larger areas of about 50 nm as shown in Figure 5 middle can be addressed and not single quantum dots, only the material between or within the contact areas is wasted.

Besides possible applications of these or similar quantum devices one should keep in mind that our investigations prove that for suitably tailored metals a clear transition to molecular behavior exists in range of 1 to 2 nm. Thus, the present concentration on semiconducting materials with these dimensions, which then should be beyond this transition, is probably not the best approach to ultimate miniaturization.

Superconductivity and Phase Separation in Na_xNbO_2 ($x < 1$)**

By *Maria A. Rzeznik, Margret J. Geselbracht, Mark S. Thompson,* and *Angelica M. Stacy**

The superconductors with the highest known transition temperatures, T_c, are copper oxides with strong covalent bonding between the copper and oxygen atoms within layers, and no copper–oxygen bonds between these layers. The prevalence of layered structures among the copper oxide superconductors has led us to search for new oxide superconductors with anisotropic structures. We recently reported that the layered phase Li_xNbO_2 ($x \approx 0.5$) exhibits superconductivity below 5.5 K.[1] This phase has a hexagonal structure, consisting of $(NbO_2)_n^{n-}$ layers of edge-shared NbO_6 trigonal prisms, analogous to MoS_2; the lithium atoms occupy a portion of the octahedral holes between the layers.[2] $NaNbO_2$[3] is isostructural with $LiNbO_2$ (see Fig. 1). We have now found that Na_xNbO_2 is a superconductor, and that the sodium content of this niobate cannot be varied continuously.

Sodium-deficient samples of Na_xNbO_2 were prepared by partial deintercalation of $NaNbO_2$. Pure $NaNbO_2$ was obtained by reacting sodium metal and NbO_2 in a 1:1 ratio in a sealed tantalum tube. Subsequently, products with nominal compositions of $Na_{0.90}NbO_2$, $Na_{0.80}NbO_2$, $Na_{0.70}NbO_2$, and $Na_{0.65}NbO_2$, were prepared by reaction of $NaNbO_2$ with I_2 in acetonitrile at 298 K. Analyses of the Na:Nb ratio in the products by atomic emission spectroscopy with inductively coupled plasma excitation (AES-ICP) gave values for x within approximately 10% of the nominal values as shown in Table 1.

The powder X-ray diffraction patterns[4] indicate that a phase which is isostructural with $NaNbO_2$ is present in all of the sodium-deficient products; we refer to this as Phase I. As shown in Table 1, the lattice parameter a obtained for Phase I is identical to that of $NaNbO_2$, but c is about 0.1 Å larger. Since a second phase appears in samples with $x < 0.9$, we conclude that $Na_{0.9}NbO_2$ is located at a phase boundary.

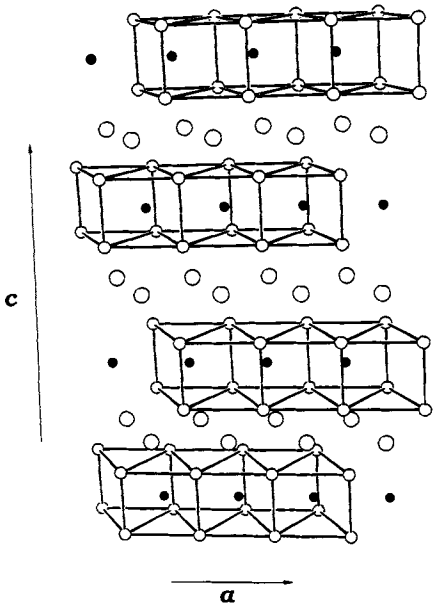

Fig. 1. Schematic representation of the structure of $NaNbO_2$. The layered structure consists of a hexagonal array of niobium atoms (solid circles) sandwiched between hexagonal arrays of oxygen atoms (small open circles). The coordination geometry of oxygen atoms around the niobium atoms is trigonal prismatic. The sodium atoms (large open circles) are located in octahedral sites between the oxygen–niobium–oxygen layers.

A second phase with a related structure is observed for samples with $x < 0.9$, as shown in Figure 2; we refer to it as Phase II. The new reflections can be indexed to a hexagonal unit cell with the same indices as the corresponding reflections in the diffraction pattern for Phase I. Based on this assignment of Miller indices, the lattice parameter a of Phase II is 0.01 Å smaller than that obtained for $NaNbO_2$, and c is approximately 0.4 Å larger, as shown in Table 1.

Table 1. Composition and lattice parameters [Å] for Na_xNbO_2.

Sample	Composition [a]	Phase I		Phase II	
		a	c	a	c
$NaNbO_2$	$Na_{1.1}NbO_2$	2.949(2)	11.556(2)	–	–
$Na_{0.90}NbO_2$	$Na_{0.92}NbO_2$	2.949(2)	11.657(4)	–	–
$Na_{0.80}NbO_2$	$Na_{0.82}NbO_2$	2.949(3)	11.666(3)	2.939(3)	12.005(5)
$Na_{0.70}NbO_2$	$Na_{0.68}NbO_2$	2.947(3)	11.696(2)	2.935(3)	11.964(2)
$Na_{0.65}NbO_2$	$Na_{0.60}NbO_2$	2.946(3)	11.685(5)	2.932(2)	11.984(1)

[a] Determined by AES-ICP.

The intensities of the reflections associated with Phase II increase relative to those of Phase I as x decreases. Therefore, we conclude that the amount of Phase II increases as the sodium content decreases, and that Phase II is sodium-poor compared with Phase I. Since samples with an average value of $x = 0.65$ contain both phases, the sodium-poor phase must have a composition with $x < 0.6$.

The large increase in the lattice parameter c also supports the claim that Phase II is comparatively sodium-poor. Simi-

lar increases in c by approximately 0.4 Å have been observed for Na_xTiS_2 as x is decreased.[5] The structure may remain identical to that of $NaNbO_2$, or a related polytype may form instead. For example, in Na_xTiS_2, a change in the coordination sphere about the sodium atoms from octahedral to trigonal prismatic is observed as x decreases.

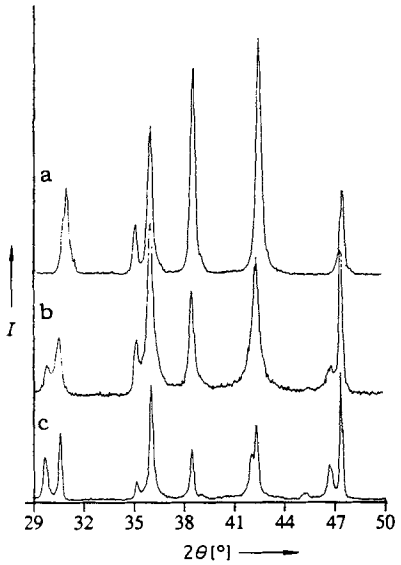

Fig. 2. Powder X-ray diffraction patterns of a) $NaNbO_2$, b) $Na_{0.80}NbO_2$, and c) $Na_{0.65}NbO_2$. The latter two samples contain both a phase that is isostructural with $NaNbO_2$ plus a second phase with a related hexagonal structure. The intensities of the peaks associated with the second phase increase with decreasing sodium content. I = intensity in arbitrary units.

Attempts to isolate a pure sample of Phase II by reactions similar to those described above have not been successful thus far. When greater than 0.2 equivalents of I_2 were used to prepare samples with an average value of $x < 0.6$, the powder diffraction pattern showed many broad reflections of low intensity indicating that the product was poorly crystalline; the peaks associated with Phase I and Phase II were not observed. Clearly, the sodium-deficient phase is not very stable in the presence of oxidizing agents.

The magnetic properties of $NaNbO_2$, $Na_{0.90}NbO_2$, $Na_{0.80}NbO_2$, $Na_{0.70}NbO_2$, and $Na_{0.65}NbO_2$ were measured by cooling samples in magnetic fields of less than 20 G.[6] Although we do not observe superconductivity down to 2 K for $NaNbO_2$, the susceptibility of $Na_{0.65}NbO_2$ drops steeply to diamagnetic values below 4.2 K as shown in Figure 3; this transition indicates the onset of superconductivity. The gram susceptibility at 2 K is -2.8×10^{-3} emu g^{-1}, corresponding to a 25% Meissner fraction.[7] This value of the susceptibility is sufficiently negative to conclude that a substantial fraction of the material is a bulk superconductor.

Superconductivity was also observed for $Na_{0.90}NbO_2$, $Na_{0.80}NbO_2$, and $Na_{0.70}NbO_2$ with a T_c (onset) = 4.2 K, identical to that observed for $Na_{0.65}NbO_2$. However, the magnitude of the diamagnetic signal decreased dramatically as the sodium content increased. Since the magnitude of the diamagnetic signal correlates with the amount of Phase II observed in the powder diffraction patterns, we propose that it is the sodium-poor phase that exhibits superconductivity. Furthermore, the observation that T_c is invarant points to the existence of a single superconducting material with a fixed sodium content in the samples we have prepared.

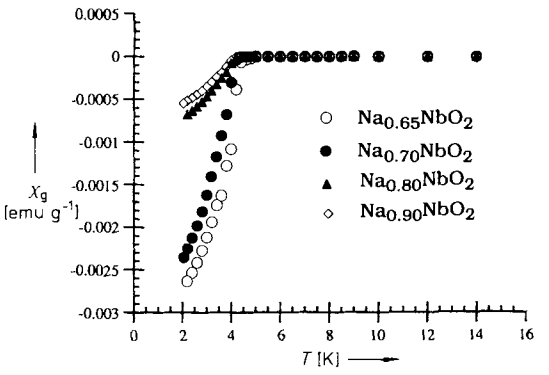

Fig. 3. Meissner effect of $Na_{0.90}NbO_2$, $Na_{0.80}NbO_2$, $Na_{0.70}NbO_2$, and $NaNb_{0.65}NbO_2$ prepared by deintercalation of $NaNbO_2$ with I_2. The onset of superconductivity occurs at 4.2 K. The magnitude of the diamagnetic signal increases as the sodium content decreases.

We conclude that the sodium composition in $NaNbO_2$ cannot be changed continuously by deintercalation reactions with varying amounts of I_2 at 298 K; rather, the products obtained are a two-phase mixture consisting of a nonsuperconducting sodium-rich material and a superconducting sodium-poor material. It is notable that phase separation is often associated with the transition to the superconducting state as the composition is varied in transition metal oxides.[8] Therefore, Na_xNbO_2 is a valuable system for further study of the stability of oxide superconductors.

Experimental Procedure

$NaNbO_2$ was prepared by reacting sodium metal (0.312 g, 13.6 mmol) and NbO_2 (1.70 g, 13.6 mmol). The reactants were loaded under inert conditions into a tantalum tube that was welded shut under an argon atmosphere in an arc furnace. The sealed tantalum tube was placed inside a fused silica ampoule that was evacuated to 4×10^{-5} Torr and sealed. After the ampoule had been heated at 850 °C for three days, a free flowing dark violet powder was obtained. Since this product turned black rapidly upon exposure to air, all sample manipulations were performed under an inert atmosphere. The product obtained was single phase as determined by powder X-ray diffraction, and lattice parameters similar to those reported previously (see ref. [3]) were obtained.

For the deintercalation reactions, the $NaNbO_2$ powder was placed in contact with a stoichiometric amount of a 0.068 M solution of I_2 dissolved in acetonitrile (distilled over calcium hydride) for five to seven days. The product was filtered, washed with acetonitrile and ethanol, and dried under vacuum.

A New Layered Ternary Sulfide: Formation of Cu_2WS_4 by Reaction of WS_4^{2-} and Cu^+ Ions**

By *Eugene A. Pruss, Barry S. Snyder,* and *Angelica M. Stacy**

The tetrathiometalates MS_4^{2-}, where M = V, Mo, W, and Re, have been used extensively for the synthesis of a wide variety of transition metal sulfides. Products that have been obtained range from small metal sulfide ions to heterometal clusters.[1] Here we show that solid-state sulfides with extended structures also can be prepared by using thiometallates as reactants. Cu_2WS_4, a new layered ternary sulfide, is obtained by reaction of $[Cu(CH_3CN)_4]BF_4$ and $(NH_4)_2WS_4$ in a mixture of *N,N*-dimethylformamide and butyronitrile; in this phase, the WS_4^{2-} units remain intact and are linked into layers of Cu^I ions.

Layered transition metal chalcogenides have attracted much attention because they have many useful properties that are a direct consequence of their low-dimensional structures.[2] Specifically, these materials consist of covalently bound layers of metal atoms bridged by sulfur atoms, and have only weak van der Waals interactions between these layers. Although there are a wide variety of applications for these "two-dimensional" materials, including uses in batteries[3] and as catalysts,[4] only a limited number of phases and structure types are known; these are almost exclusively binary phases.

Typically, the binary layered phases are prepared by direct reaction of the elements at temperatures above 400 °C. Since few ternary sulfides have been prepared under similar conditions, precipitation from organic solvents at lower temperatures is an attractive route to their preparation. Cu_2WS_4 is obtained by reaction of $[Cu(CH_3CN)_4]BF_4$ and $(NH_4)_2WS_4$ in a 2:1 ratio in a mixture of *N,N*-dimethylformamide and butyronitrile at 135 °C. The CH_3CN ligands which are relatively labile, are readily displaced by the WS_4^{2-} ions. After 24 h a bright orange precipitate formed, and was subsequently isolated. The product was found to be diamagnetic, as expected for Cu^I and W^{VI}.

Since we were unable to grow single crystals, the structure solution was obtained by analysis of powder X-ray diffraction data. The calculated and difference profiles of the Rietveld refinement are shown in Figure 1. Atomic coordinates and temperature factors are listed in Table 1, and bond lengths and angles are given in Table 2. Müller and Menge have reported the preparation of an amorphous form of Cu_2WS_4;[5] the properties of the amorphous form are not the same as those observed for the crystalline form reported here.[6]

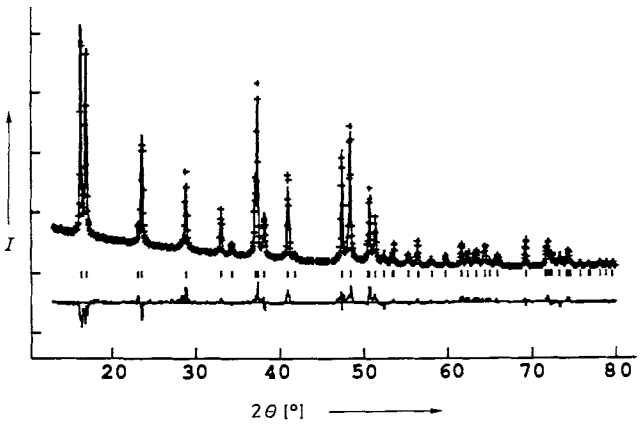

Fig. 1. Powder X-ray diffraction pattern for Cu_2WS_4, including observed (+) and calculated (−) profiles, as well as the difference profile (observed − calculated).

Table 1. Positional parameters and isotropic temperature factors of Cu_2WS_4; space group: $P\bar{4}2m$, lattice parameters: a = 5.4244(2) and c = 5.2336(3) Å

Cu	2e	0	0.5	0	1.075(8)
S	4n	0.2482(7)	0.2482(7)	0.2617(5)	0.552(7)

Table 2. Selected bond lengths [Å] and angles [°] of Cu_2WS_4.

Bond lengths		Bond angles	
W-Cu	2.712(1)	S-W-S	109.9(1)
W-S	2.345(1)	S-W-S	108.6(1)
Cu-S	2.356(1)	S-Cu-S	110.3(1)
S-S	3.808(1) [a]	S-Cu-S	108.9(1)
	3.855(1) [b]	S-Cu-S	109.16(1)
	3.841(1) [c]	W-S-Cu	70.45(1)
	3.699(1) [d]		

[a] S–S bond lengths for adjacent S atoms both coordinated to W and in the planes parallel to the a direction. [b] S–S bond lengths for adjacent S atoms both coordinated to Cu and in the planes parallel to the a direction. [c] S–S bond length for the intralayer distance for adjacent S atoms that lie above and below the metal atom planes. [d] S–S bond length for the interlayer distance between adjacent S atoms in different layers.

The structure of Cu_2WS_4 can be viewed as layers of Cu_2WS_4 as shown in Figure 2; the layers are perpendicular to the c direction. The atoms within the layers are covalently bound, while there are only van der Waals interactions between the layers. Each layer consists of W atoms in a square array; the Cu atoms lie along the edges of the square between the W atoms. Each S atom is μ_3-bridging, and spans a W atom and two adjacent Cu atoms; the S atoms alternate above and below the metal atom planes. In comparison, while Cu atoms link WS_4^{2-} units into layers in Cu_2WS_4, WS_4^{2-} units are linked into $CuWS_4^-$ chains in NH_4CuWS_4.[5]

The distances in the WS_4^{2-} units in Cu_2WS_4 deviate slightly from those of the isolated anion. The distortion at the metal center from tetrahedral is manifest in the S-W-S angles which range from 108.6(1) to 110.3(1)°; the S-Cu-S angles are similar (see Table 2). The W–S bond length of 2.345(1) Å is longer than has been observed previously. In comparison, the W–S bond length is 2.177 Å in isolated WS_4^{2-} ions with terminal S atoms.[1a] For S atoms bridging Cu and W in the polynuclear clusters $(PPh_3)_3[Cu_2WS_4] \cdot 0.8\ CH_2Cl_2$[7] and $(PPh_4)_2[Cu_2Cl_2WS_4]$,[8] the bond lengths are 2.217(8) and 2.228(7) Å, respectively. Additionally, the S atoms in $(PPh_3)_3S[Cu_3WS_3Cl]$,[7] $(PPh_4)_2[Cu_{2.5}Cl_{2.5}WS_4]$,[8] and $(PPh_3)_4O_2[Cu_4W_2S_6]$[9] are in a similar environment to that observed in Cu_2WS_4; however, the W–S bond lengths in

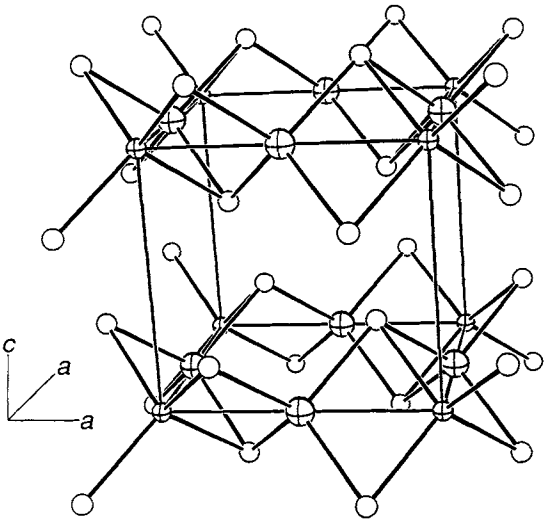

Fig. 2. View of the unit cell of Cu_2WS_4. The small circles with crosses are the W atoms, the large circles with crosses are the Cu atoms, and the open circles are the S atoms.

these polynuclear clusters of 2.261(4), 2.256(3), and 2.206(1) Å, respectively, are also significantly shorter. In contrast, the Cu–S bond length of 2.356(1) Å in Cu_2WS_4 is comparable to the Cu^I–S lengths observed in the five polynuclear clusters mentioned previously (e.g., 2.328(8)[7] 2.240(9),[8] 2.343(4),[7] 2.234(6),[8] and 2.358(4) Å,[9] respectively).

Another description of the structure follows from the recognition that the sulfide lattice can be viewed as a distorted cubic close-packed array of S atoms. The two-dimensional structure results from metal atom occupation of 3/4 of the tetrahedral holes in alternating layers along the *c* direction; only 3/8 of the total number of tetrahedral holes are filled. The interlayer distances between the planes of S atoms that lie parallel to the *a* direction are approximately 2.5(1) Å, while the intralayer distances are 2.7(1) Å. Therefore, the layers containing the metal atoms are expanded along the *c* direction compared with the distance between layers. For actual S–S distances see Table 2.

Although occupation of only 3/8 of the tetrahedral holes has been reported for Al_2CdS_4, β-Ag_2HgI_4, β-Cu_2HgI_4, and In_2CdSe_4, which contain cubic close-packed anions, these structures consist of tetrahedra linked by their vertices in three dimensions.[10] The most analogous structure type to Cu_2WS_4 is that of $K_2Mn_3S_4$, which consists of $[Mn_3S_4]$ tetrahedral layers separated by alkali metal ions.[11] However, since the precise ordering of the tetrahedral vacancies in the $[Mn_3S_4]$ layers is not known, a direct comparison cannot be made. The structure of Cu_2WS_4 can also be described as a defect anti-PbO type with 3/4 of the oxygen positions occupied by the metal atoms.[10]

It is notable that Cu_2WS_4 cannot be prepared by reaction of the elements at elevated temperatures; only binary sulfides are obtained. Furthermore, Cu_2WS_4 decomposes in argon above approximately 175 °C. We conclude that thiometalates are useful reactants in the synthesis of solid-state sulfides, and in particular, new layered ternary phases. Three other new materials, $CuReS_4$, $CsCuWS_4$, $[(CH_3CH_2)_4N]AgWS_4$, prepared by similar methods will be reported in the near future.

Experimental Procedure

All manipulations prior to product formation were performed under a pure dinitrogen atmosphere by using standard Schlenk techniques.

Cu_2WS_4: Butyronitrile (15 mL) was added with a syringe to a flask containing $[Cu(MeCN)_4]BF_4$ (0.14 g, 0.6 mmol) [12] and *N,N*-dimethylformamide (15 mL) was added with a syringe to a flask containing $(NH_4)_2WS_4$ (0.10 g, 0.30 mmol) [13]. After dissolution of the reactants, the Cu complex was transferred via cannula into the flask containing WS_4^{2-}. The resulting solution was stirred for 15 min, and then heated in an oil bath at 135 °C for 24 h. Subsequently, a bright orange, polycrystalline precipitate was isolated from an orange solution. The yield was 0.088 g (67%). The solution became clear, and the yield could be increased to 100% by addition of acetonitrile; however, the product obtained was poorly crystalline as determined by powder X-ray diffraction. Elemental analysis (atomic absorption spectroscopy) gave Cu:W = 2:1.04. One absorption band was observed in the IR spectrum at 443 cm^{-1} [14], and three absorption bands were observed in the diffuse reflectance UV/VIS spectrum, at 22000, 29000, and 34000 cm^{-1}.

Structure Determination: The structure solution was obtained by analysis of powder X-ray diffraction data (SIEMENS D500 diffractometer, θ-2θ geometry, flat-plate sample, curved Ge single-crystal monochromator (λ = 1.542 Å), position-sensitive detector operating in constant scan mode at 1° min^{-1} over the range $10° < 2\theta < 120°$). The diffractometer zero-point was determined from an external Si standard. The autoindexing program TREOR [15] was used to determine the unit cell parameters; a good fit was obtained with a tetragonal unit cell with a = 5.4244(2) and c = 5.2336(3) Å. There are no systematic absences to narrow the choice of space groups; however, if we assume that the WS_4^{2-} tetrahedral ion remains intact, the most reasonable choices are the noncentrosymmetric space groups: $P\bar{4}$, $P422$, $P\bar{4}2m$, and $P\bar{4}m2$. The structure determination proceeded by trial and error methods. Rietveld refinement was carried out by using the software package GSAS [17]. The usual profile parameters were refined (scale factor, lattice parameters, peak profile coefficients, atomic coordinates, and isotropic thermal parameters). Linear interpolation between data points was used to fit the background. The peak profiles were modeled with a pseudo-Voigtian function which included a small linear Gaussian contribution, nonlinear Lorentzian components, and an asymmetry correction. Refinement of the powder diffraction data was attempted for all of the non-centrosymmetric space groups. However, only two ($P\bar{4}2m$ and $P\bar{4}$) of the four possible space groups gave a satisfactory fit to the diffraction pattern. Since the R values for both of these space groups were identical, the higher symmetry space group, $P\bar{4}2m$ was chosen. The final agreement factors were $R_P = 0.097$, $R_{WP} = 0.0643$, and $\chi^2 = 5.3$ for 11 variables and 7 parameters.

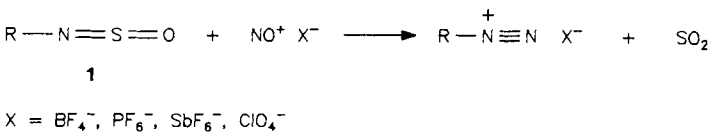
Cyanosulfines: An Unexpected Reaction of *N,N*-bis(trimethylsilyl)ynamines**

By *Thomas Schmid, Michael Hanack,* Cäcilia Maichle,* and *Joachim Strähle*

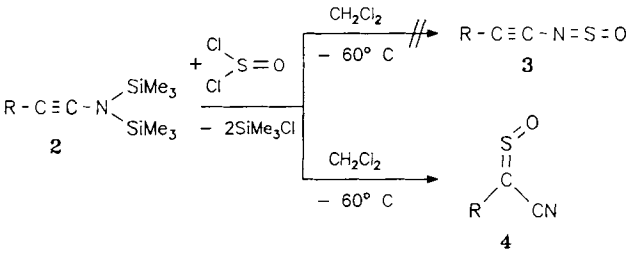
In 1988 we detected an alkynyl cation on tritium decay of a 1-tritiumalkyne.[1] Alkynediazonium salts might also generate alkynyl cations, although it is not certain from calculations whether they decompose to nitrogen and alkynyl cations.[2] We have described alkynediazonium salts, which are, however, not stable in either protic or nucleophilic media.[3] The most common syntheses for alkane- or arenediazonium compounds can therefore not be applied.

Alkane- and arenediazonium salts can also be obtained from sulfinylamines **1** on reaction with NO^+X^- (Scheme 1).[4, 5]



Scheme 1. Formation of diazonium ions from sulfinylamines.

Sulfinylamines **1** are easily prepared from amines (also bissilylated amines) and thionyl chloride.[6] We intended to synthesize alkynylsulfinylamines **3** from bissilylated alkynylamines **2a–d** by reaction with thionyl chloride and to transform these into alkynediazonium salts. To our surprise we obtained not the alkynylsulfinylamines **3**, but the cyanosulfines **4** (Scheme 2).

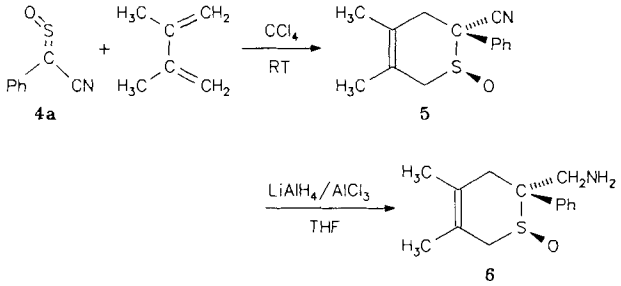


a: R = Ph, **b**: R = *t*Bu, **c**: R = *n*Pr, **d**: R = cyclohexyl

Scheme 2. Reaction of *N,N*-bis(trimethylsilyl)ynamines **2** with $SOCl_2$.

Phenyl cyanosulfine (α-sulfinylbenzylcyanide) **4a** is known; it was synthesized from phenylacetonitrile by reaction with thionyl chloride under HCl catalysis, as well as by an alkylation of SO_2 with α-silylated carbanions.[7] Compound **4a** proved to be identical with an independently synthesized sample of phenyl cyanosulfine.[7b] The cyanosulfines **4a–d** smell unpleasant to repulsive. For **4c** and **4d**, *cis/trans* isomers were detected by gas chromatography and NMR spectroscopy, but **4a** and **4b** are sterically uniform.

Sulfinylamines **3** and the cyanosulfines **4** are distinguishable by spectroscopy only with difficulty. To confirm the structure, **4a** was therefore treated with 2,3-dimethyl-1,3-butadiene. The product was 2-cyano-2-phenyl-4,5-dimethyl-3,6-dihydro-2*H*-thiopyran-1-oxide (**5**), which can only form from cyanosulfine **4a**, but not from sulfinylamine **3a**. Compound **5** was reduced with $LiAlH_4$ to the amine **6**, which was characterized by spectroscopy (Scheme 3).



Scheme 3. Diels–Alder reaction of phenyl cyanosulfine **4a** with 2,3-dimethyl-1-3-butadiene and reduction of the resulting dihydrothiopyran-*S*-oxide **5** with $LiAlH_4$. RT = room temperature.

According to X-ray structural analysis, **5** is clearly a dihydrothiopyran-*S*-oxide (Fig. 1). The structure of **5** also shows that the phenyl cyanosulfine **4a** is present in the *E* form.[8]

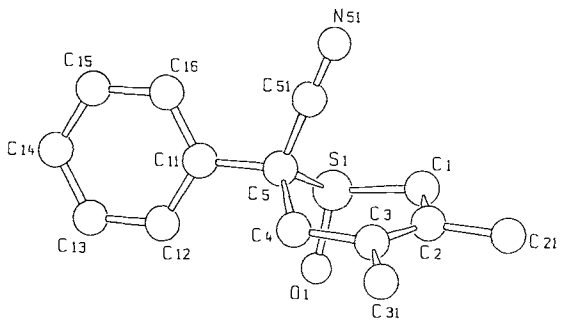


Fig. 1. Crystal structure of the dihydrothiopyran-*S*-oxide **5** (H atoms omitted for clarity).

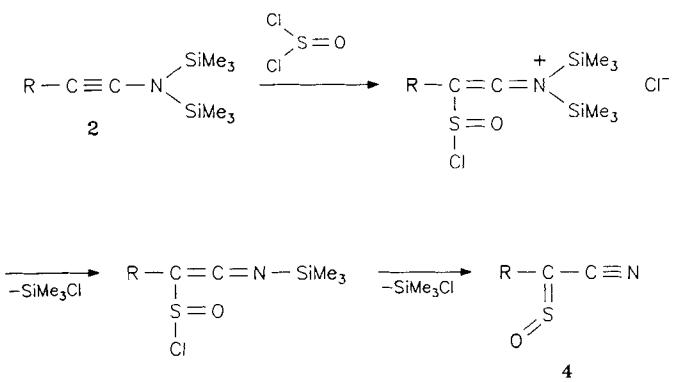
The unexpected formation of cyansulfines is attributed to the strongly nucleophilic character of the β-C-atom of the *N,N*-bis(trimethylsilyl)ynamine **2**. The $SOCl_2$ thus attacks at this C atom.[9] Scheme 4 shows a proposed mechanism for the formation of cyanosulfines.



Scheme 4. Mechanism of the cyanosulfine formation.

Experimental Procedure

2: The ynamines **2c,d** were synthesized by adapting the procedure described in [10].

4: To a solution of $SOCl_2$ (6.4 mmol) dissolved in CH_2Cl_2 (10 mL) and cooled to −80 °C was added dropwise a solution of **2a** (6 mmol) in CH_2Cl_2 (4 mL).

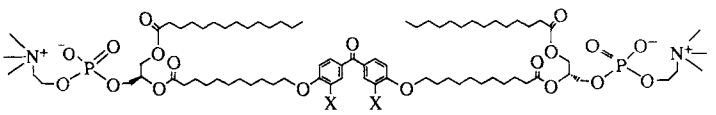
Selective Photolabeling near the Middle of Bilayers with a Photosensitive Transmembrane Probe

By *Masakuni Yamamoto, William A. Warnock, Alain Milon, Yoichi Nakatani*, and *Guy Ourisson**

In the 1970s Khorana et al.[1] and Breslow et al.[2] attempted to explore the internal structure of membranes by using photoreactive molecular probes designed so as to be incorporated and oriented properly in the phospholipid bilayer. These amphiphilic molecules contained the photosensitive group positioned at a certain distance from the head group such that it should, when activated, label carbon atoms of the membrane constituents situated near the middle of the bilayer. However, the results were disappointing, as the distribution of cross-linking sites after irradiation was broad both when the probe was used to label phospholipids, and when it was used to label proteins (for the proteins, the attack depended more on the nature of the amino acids than on their localization). These results indicated extensive dynamic disorder of the phospholipid matrix, or disorder induced by the incorporation of the probe or of the protein, or a combination of all these factors.

We have tried to improve the regioselectivity of such probes by selecting as the photosensitive group a 4,4'-dialkoxybenzophenone unit, well known for the high quantum yield of its photoreaction with C–H bonds,[3] and by placing it in the middle of a carbon chain terminated at either end by a lecithin head group, and long enough (about 30 Å) to span the usual biomembranes. We have described previously the synthesis of a transmembrane probe of this type, **1**,[4] and



1, X = H; **2**, X = D

have shown that it has some very favorable properties: mixtures of **1** and 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) form vesicles by sonication in water; over the concentration range of 2–20 mol%, **1** is almost completely incorporated into DMPC vesicles and its benzophenone chromophore appears from its absorption spectrum to be localized in a lipidic environment, that is inside the bilayer. We now show that its incorporation into DMPC vesicles is accompanied by complete miscibility in the fluid phase, that it is oriented mostly perpendicularly to the bilayer, and that it photolabels neighboring molecules (phospholipids, sterols, and also proteins as will be reported later) very efficiently and regioselectively near the middle of the membrane. This regioselectivity is extremely high (ca. 90% labeling within 3 Å of the middle of the membrane), when, and only when, the DMPC vesicles also contain cholesterol in normal bioconcentrations.

The phase diagram of mixtures of DMPC (T_m = 25 °C, ΔH = 24 kJ mol^{-1}) and **1** (T_m = 51 °C, ΔH = 70 kJ mol^{-1}) was studied by differential scanning calorimetry (DSC) with increasing concentrations of **1** (Fig. 1). The phase transition of DMPC at about 25 °C remains sharp, its intensity decreasing progressively with increasing content of the probe. Thus, the solidus line is indicative of monotectic phase behavior, that is immiscibility in the gel state. Another transition (liquidus line) appears at temperatures increasing from 25 to 51 °C as the relative content of **1** in the mixture increases from 0 to 100%. This implies complete miscibility of the two

lipids in the liquid crystal phase, which corroborates well with the results of the study by UV spectroscopy on these liposomes.[4] Therefore, we have used the liquid crystal state for the photoaffinity labeling experiments.

In order to define the orientation of the probe in the membrane, the deuterated probe **2** was synthesized from its 3,3'-diiodo derivative. The solid-state ^{2}H NMR spectrum was measured (Bruker MSL-300 spectrometer) on an oriented multibilayer sample obtained from a solution of DMPC (90 mol%) and the probe **2** (10 mol%) in 2-propanol, according to a procedure described previously.[5] The ^{2}H NMR spectrum of the multibilayer system (oriented at 90° to the magnetic field, $T = 318$ K; Fig. 2) shows two quadrupolar splittings: $\Delta\nu_{Q_A} = 2.75$ kHz (ca. 90% intensity) and $\Delta\nu_{Q_B} = 10.75$ kHz (ca. 10% intensity). After taking into account the internal flexibility and geometry of the benzophenone structure,[6] the first splitting (A) was interpreted as corresponding to the transmembrane orientation of the probe **2**, and the second one (B) to a U-shaped conformation, in which both head groups are on the same face of the membrane. ^{2}H NMR experiments were also performed with the unlabeled probe **1** inserted into deuterated DMPC. The quadrupolar splittings (angle 90°, 313 K) of oriented bilayers of pure 1-myristoyl-2-[D_{27}]myristoyl-*sn*-glycero-3-phosphocholine ([D_{27}]DMPC) and of [D_{27}]DMPC + 10 mol% probe **1** were compared, and found to differ by less than 8% at each position of the 2-myristoyl chain in [D_{27}]DMPC, thus showing that, at this concentration, the probe causes practically no perturbation of the internal mobility of chains of DMPC in the vesicles.

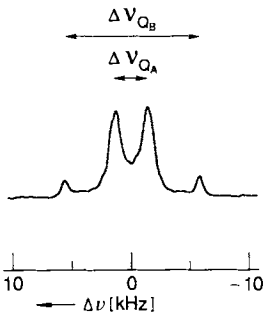

Fig. 2. ^{2}H NMR spectrum of 90° oriented multibilayers of DMPC + 10 mol% **2** at 318 K.

Irradiation (125 W HPK mercury lamp, Philips) of a suspension of vesicles from 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC, 95 mol%) and **1** (5 mol%) at 50 °C for 3.5 hours resulted in the complete disappearance of the benzophenone absorption band in its UV spectrum.

After lyophilization, sodium methoxide in methanol was added to cleave the polar heads by transmethylation. The photolabeled compounds were separated from the crude product on a Sephadex LH-20 column ($CHCl_3$/MeOH = 1/1), and the photolabeled mixture was analyzed by FAB mass spectrometry (ZAB-HF double-focussing mass spectrometer). Examination of the intensity of the fragments derived from the photolabeled palmitate (from DPPC) and myristate (from **1**) (4:1) indicated that the intermolecular and intramolecular reactions are almost equally efficient. This is easily explained in a compact system, where intra- and intermolecular reactions do not differ entropically, and where the probe is largely diluted in the phospholipid matrix: assuming that each transmenbrane chain is surrounded by six fatty acid chains, one of which is that of the probe molecule, the expected ratio of intensities would then be 5:1. This slight difference between the intra and intermolecular reactions is crucial, since it is the intermolecular reaction which will be used for topographical analysis.

The distribution of the positions of attack in the myristoyl chains in DMPC/**1** vesicles was next investigated (Fig. 3). The crude product from the photoreaction was separated by chromatography into fractions of various molecular sizes, and the fraction containing tertiary alcohols was dehydrated with iodine, and then cleaved with sodium periodate and catalytic amounts of ruthenium chloride, using Breslow's procedure.[2] For attack at any atom other than C-14, a

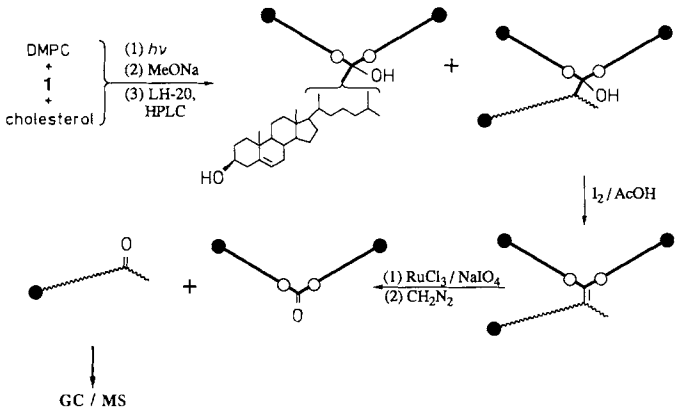

Fig. 3. Reaction sequence for the determination by the photoreaction of the functionalized positions in the myristoyl chains. Irradiation of the DMPC vesicles containing probe **1** and cholesterol gives photolabeled cholesterol and photolabeled methyl myristates, which are separated by chromatography. According to the results from mass spectrometry the label is exclusively on the side chain of cholesterol. The photolabeled methyl myristates are dehydrated with I_2 and oxidatively cleaved with $NaIO_4$ to give the dimethyl ester of the diacid formed from **1**, and a series of methyl *n*-oxomyristates ($n = 4-13$) (analyzed by GC-MS). The black circles symbolize methyl ester groups; the open circles, phenoxy groups (see **1**).

mixture of oxo-esters is produced, with the keto group located at the site of attack; after attack of the terminal C-14 position, the monoester of an α,ω-diacid is obtained, the treatment of which with diazomethane converts it to an α,ω-diester. The reaction mixture was analyzed by GC–MS. With vesicles comprising only DMPC and the probe, attack was mostly observed at C-13 ($\omega-1$: 33%) and C-12 ($\omega-2$: 13%) but was measurable as far from the middle of the bilayer as C-4 (Fig. 4). The small amount observed at C-14 (ω: 0.6%) is consistent with the methyl group being much less reactive than the methylene groups.

The low regioselectivity is not really satisfactory, even though it is higher than those obtained previously.[1, 2] That

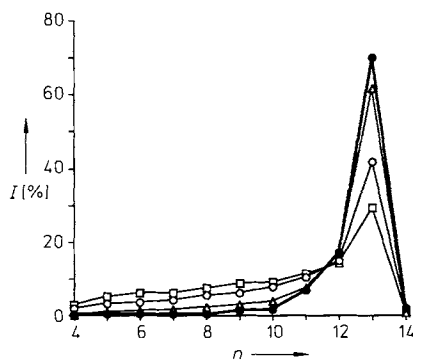

Fig. 4. Distribution of functionalized positions, □: in the absence of cholesterol, ○: with 10 mol% cholesterol, △: with 20 mol% cholesterol, ●: with 33 mol% cholesterol. Percentage of attack at each position of the myristoyl chain: $n = 1$, carboxyl; $n = 14$: C-14 (position ω).

positions as far from the middle layer of the membrane as C-4 are attacked may be due to the presence of the U-shaped conformation of the probe molecule mentioned above, which would make it possible for the excited carbonyl group to "explore" all the carbon atoms of the neighbouring chains. We felt, therefore, that we should attempt to eliminate such a U-shaped conformation; this could be done by selecting more rigid variants of **1**, which are now being synthesized, or by favoring the extended conformation of **1**, which we felt could be achieved by increasing the anisotropy of the bilayer by the addition of a rigidifying partner. Indeed, a spectacular improvement in regioselectivity was observed when cholesterol, a normal constituent of eucaryotic biomembranes, was added to the mixture of phospholipids at progressively higher concentrations until, with 33 mol% of cholesterol,[7] the sum of attack at $(\omega-1)$ and $(\omega-2)$ reached 90% (attack at $\omega-1$: 72%). This remarkable increase in selectivity is of course explainable by the ordering effect of cholesterol on the lipid bilayers, which has been demonstrated previously by different biophysical methods.[8] We have still to check whether the major effect is felt by the probe, or by the phospholipid matrix.

As expected, the inserted cholesterol was also attacked by the photoexcited probe on the side chain, but not at all on the ring system, as shown by FAB-MS analysis of the photolabeled cholesterol fraction. The precise localization of the site(s) of attack of the side chain is presently being studied.

These results show that our transmembrane probe, when used with cholesterol in phospholipid assemblies, can overcome the "inherent" character of lipid bilayers, that is, their disorder above T_m. This should make it possible to investigate more precisely the topography of the polypeptide chains of a membrane-bound protein; in this case, the exceptional topographic specificity of our system should be of crucial importance. Indeed, in collaboration with Dr. F. Pattus (EMBL, Heidelberg) and Dr. A. Van Dorsselaer (Strasbourg), the characterization of the C-terminal, membrane-bound, domain of the bacterial protein colicin A[9] incorporated in a model membrane system has been undertaken and cross-linking between the probe and the polypeptide has been observed. Precise characterization of the site and specificity of labeling is underway.

The principles described here could be extended to a wide variety of probes, differing from **1** by their head groups, the length of the chains, the nature and the position of the photoactive group, etc.

Polyoxovanadium–Organophosphonates—Properties and Structure of an Unusual Pentavanadate Species with a V=O Group Directed Toward the Interior of the Molecular Cavity**

By *Qin Chen* and *Jon Zubieta**

Metal phosphonates have received significant attention in recent years because of their potential uses as sorbents, catalysts and catalyst supports.[1–5] Numerous new materials have been synthesized including monomolecular coordination compounds,[6, 7] one-dimensional complexes,[8] and layered compounds.[9, 10] Specifically for solid oxovanadium organophosphonates which are members of the structurally rich, general class of V-P-O solids,[11–13] layered structures with alternating organic and inorganic layers have been prepared. These compounds can recognize and selectively discriminate between alcohols.[10, 14] Furthermore, hydrothermal synthesis has been exploited to prepare a number of large polyoxovanadium–organophosphonate anions which form inclusion compounds with cationic and neutral molecules, such as $[(Me_4)N^+ \subset H_6(VO_2)_{16}(CH_3PO_3)_8]^{7-}$[15] and $[(H_2O)_x \subset H_{12}(VO_2)_{12}(PhPO_3)_8]^{4-}$.[16] In contrast to these developments in the solid-state chemistry and the hydrothermal synthesis of large oxovanadium organophosphonate clusters, the chemistry of these compounds in organic solvents under conventional synthetic conditions remains unexplored. We report here the synthesis and structure of a novel pentanuclear oxovanadium organophosphonate $\mathbf{1}\cdot CH_3OH$.

$(C_4H_9)_4N[V_5O_7(OCH_3)_2(PhPO_3)_5]\cdot CH_3OH$ $\quad$ $\mathbf{1}\cdot CH_3OH$

Red, parallelepiped crystals of $\mathbf{1}\cdot CH_3OH$ were prepared in 32.4 yield by the reaction of $[(C_4H_9)_4N]_3[V_5O_{14}]$[17] and $PhPO_3H_2$ in methanol.[18] X-ray structure analysis[19] of $\mathbf{1}\cdot CH_3OH$ revealed the presence of discrete Bu_4N^+ ions and methanol of crystallization in the lattice, as well as a $[V_5O_7(OCH_3)_2(PhPO_3)_5]^-$ ion (Fig. 1). In contrast to the

highly symmetrical toroidal structures of the dodecanuclear and hexadecanuclear V^{IV} species synthesized hydrothermally,[15, 16] the structure of the anion of **1** is distinctly irregular. The core of the structure consists of a trinuclear $[(VO)_3(\mu_2\text{-}O)_2]$ unit connected through four of the five phenylphosphonate ligands to the *endo*-$[(VO)(OCH_3)]$ moiety (V5) and through three phenylphosphonate ligands to the *exo*-$[(VO)(OCH_3)]$ moiety (V1). While vanadium centers V1 to V4 exhibit distorted square pyramidal geometries, V5 displays distorted octahedral geometry with four oxygen donors of the phosphonato ligands occupying the equatorial positions and a terminal oxo group (O23) and a methoxy group in the axial positions.

Several structural motifs common to the solid-state structures of layered vanadium phosphonates[10] and of vanadium phosphates are present in the structure of the anion of **1**.[20, 21] The fusing of dimeric units bridged through two bidentate phosphato ligands $[(VO)_2(\mu_2\text{-}O_2PO(X))_2]$ (X = R, O, or OH) is a common feature of the solid-state structures. This is also observed in the structure of the anion of **1**, where the octahedrally coordinated V5 center displays this type of bridging to the other four vanadium centers. Likewise, the fundamental structural principle of mixed oxophosphonato-bridged binuclear moieties $[(VO)_2(\mu_2\text{-}O)(\mu_2\text{-}O_2PO(X))]$ is observed in the structure of the anion of **1**.[22, 23]

The anion of **1** has a pseudo-mirror plane through V3/V5/O23/P1/V1, resulting in four structurally distinct vanadium centers. The square-pyramidal sites V2 and V4 form the termini of the $[(VO)_3(\mu\text{-}O)_2]$ fragment and are each coordinated to a terminal and a bridging oxo group and to three $(\mu\text{-}O_3PPh)$ ligands. The central vanadium atom V3 of this trinuclear unit is bound to a terminal and two bridging oxo groups and two $(\mu_3\text{-}O_3PPh)$ units. The unique octahedrally coordinated V5 atom caps the bowllike fragment formed by the fusing of the square pyramidal geometries of the vanadium atoms of the central $[(VO)_3(\mu\text{-}O)_2]$ moiety and four (O_3PPh) tetrahedra (P2–P5). The V1 center has "condensed" onto the surface of the cluster so as to satisfy the coordination requirements of the phosphonato ligands P1, P2, and P5.

The most unusual feature of the structure of the anion of **1** is the projection of the oxo group at the V5 atom into the cavity of the molecule, as illustrated by the polyhedral representation in Figure 2. Vanadate clusters form a variety of structures encapsulating different guest molecules or anions;[24] however, the structure of the anion of **1** is unique in providing a primitive prototype of a highly unsymmetrical bowllike structural element folded about a coordinated terminal oxo group. The presence of the fragment at V1 as a unit condensed onto the surface of the bowllike core is also unprecedented.

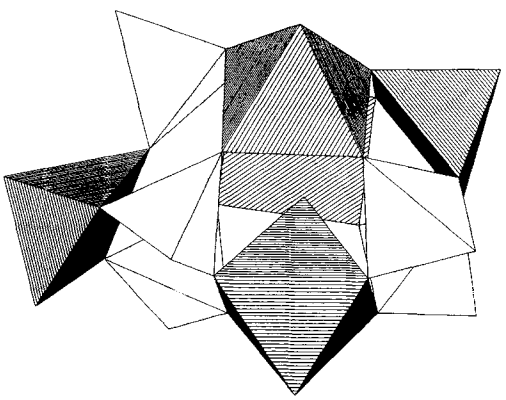

Fig. 2. A polyhedral representation of the structure of the anion of **1**, showing the projection of the terminal oxo group O23 into the central cavity of the cluster.

Protic degradation of **1** in MeOH/HCl yields the binuclear species $[\{VOCl(PhPO_3H)(H_2O)\}_2]$ (**2**),[25] which in turn serves as a simple precursor for condensation reactions of fragments by mild hydrolysis. Controlled hydrolysis of **2** in MeOH yields mixtures of **1** and larger oligomers, whose properties are under investigation. Under more forcing conditions of hydrolysis/condensation, **2** yields the solid phase **3** with a layered structure,[26] which intercalates alcohols to give compounds of the type **4**. Both **1** and **2** are readily reduced to give microcrystalline green products, one of which has been identified as **5**. Compound **5** is structurally analogous to the arsonate derivative recently reported by us, $(Bu_4N)_2[V_6O_{10}(PhAsO_3)_4(PhAsO_3H)_2]$.[27] Cluster **5** may also be employed in hydrolysis/condensation reactions to yield a variety of products.

$[VO(PhPO_3)] \cdot H_2O$ **3**
$[VO(PhPO_3)] \cdot H_2O \cdot ROH$ **4**
$(Bu_4N)_2[V_6O_{10}(PhPO_3)_4(PhPO_3H)_2]$ **5**

Vanadium organophosphonates clearly possess a varied synthetic and structural chemistry which has yet to be fully developed. They afford a variety of polynuclear species of which **1** and **5** have been structurally characterized. The elucidation of these structures may help determine the principles governing the hydrolysis/condensation reaction pathways for this class of compounds and for general reactions of this type, a process of considerable scientific and technological interest.[28]

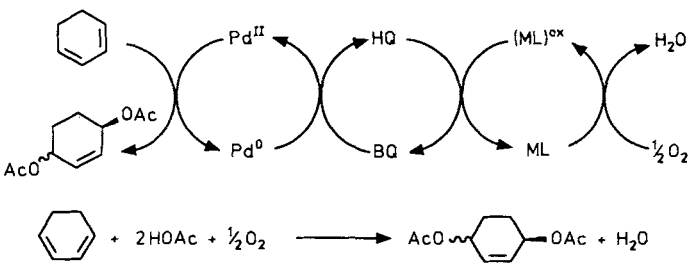
Cobalt Tetra(hydroquinone)porphyrin: An Efficient Electron Transfer Reagent in Aerobic Pd-Catalyzed 1,4-Diacetoxylation of 1,3-Cyclohexadiene**

By *Helena Grennberg, Sylvie Faizon,* and *Jan-E. Bäckvall**

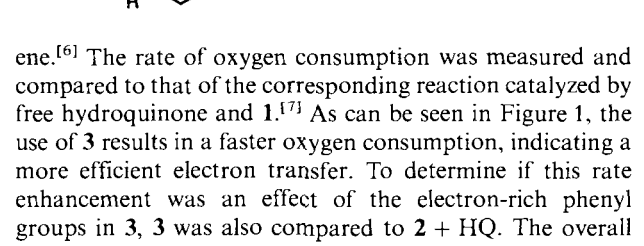
The palladium-catalyzed 1,4-diacetoxylation of 1,3-dienes[1] was recently developed into an aerobic process by the use of a one-pot triple catalytic system (Scheme 1).[2] The triple catalytic system involves selective interactions between each consecutive catalyst, and the reoxidation of hydroquinone (HQ) to benzoquinone (BQ) is a crucial step. If a quinone-containing macrocycle is used, an intramolecular electron transfer between the hydroquinone unit and the oxidized metal-containing macrocycle may be achieved.[3]



Scheme 1. The triple catalytic system and the overall reaction of the diacetoxylation of 1,3-cyclohexadiene. ML = metal-containing macrocycle.

This was expected to lead to a more efficient overall reaction than that observed for the system with the hydroquinone and metal-containing macrocycle as separate molecules. We report here on the significant increase in the rate of the aerobic 1,4-diacetoxylation of 1,3-cyclohexadiene obtained by the use of a porphyrin with hydroquinone units.

Cobalt tetra(hydroquinone)porphyrin [Co(TQP)] (**3**) was prepared by a Lindsey condensation of 2,5-dimethoxybenzaldehyde and pyrrole. This initially afforded the protected *meso*-tetra(2,5-dimethoxyphenyl)porphyrin (TDMPP), which was then demethylated with BBr_3 and metalated with $[Co(OAc)_2] \cdot 4H_2O$.[4, 5] The new bifunctional catalyst **3** was used for the aerobic 1,4-diacetoxylation of 1,3-cyclohexadiene.[6] The rate of oxygen consumption was measured and compared to that of the corresponding reaction catalyzed by free hydroquinone and **1**.[7] As can be seen in Figure 1, the use of **3** results in a faster oxygen consumption, indicating a more efficient electron transfer. To determine if this rate enhancement was an effect of the electron-rich phenyl groups in **3**, **3** was also compared to **2** + HQ. The overall performance of **2** + HQ was more similar to that of **1** + HQ than **3**, indicating that the increased reaction rate for the catalysis with **3** was not an electronic effect from the substituted phenyls.



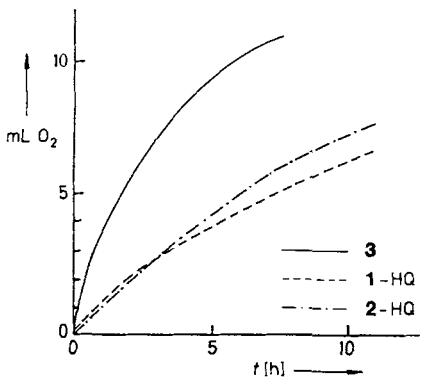


Fig. 1. Aerobic 1,4-oxidation of 1 mmol of 1,3-cyclohexadiene by addition of 2.5 mol% of $[Pd(OAc)_2]$.

Under standard conditions[1, 2] (5 mol% $[Pd(OAc)_2]$), the reaction catalyzed by **3** was complete in 10 h; all substrate was oxidized to give 1,4-diacetoxy-2-cyclohexene **4** and benzene.[2b] The reaction catalyzed by **1** + HQ ceased after 18 h.[8] The yields of **4** are about the same for both reactions (ca. 75%). However, when a smaller amount of $[Pd(OAc)_2]$ (2.5 mol%) was used, the reaction catalyzed by **3** was unaffected, whereas the rate of that catalyzed by **1** + HQ decreased, yielding 65% of **4** after 28 h (Table 1).[8] In addition the reaction catalyzed by **2** + HQ was slow under these conditions, and gave 60% **4** together with benzene after 24 h.[8, 9] The relative stereochemistry of **4**, previously shown to be dependent on both the type and amount of lithium salt

Table 1. Aerobic 1,4-oxidation of 1,3-cyclohexadiene [a].

Catalyst	LiOAc [mol]	Product [b]/Selectivity [%]	Yield [c]/Time [%] [h]
3	0	*trans*-**4**/70	70/10
	0.6	*trans*-**4**/63	70/10
1 + HQ	0	*trans*-**4**/60	65/28
	0.6	*trans*-**4**/ > 90	65/28
2 + HQ	0	*trans*-**4**/65	60/24
	0.6	*trans*-**4**/87	60/24

[a] Conditions: 2.5 mol% of $[Pd(OAc)_2]$, 2–2.5 mol% of [Co(porphyrin)], 10 mol% HQ (for **1** and **2**) in 2 mL HOAc at room temperature and 1 atm O_2. [b] The relative stereochemistry of **4** was determined by ^1H NMR spectroscopy. [c] Isolated yield.

present[1] and the structure of the quinone,[1, 10] was also found to be dependent on whether the reaction was catalyzed by **3** or **1** + HQ. With **1** + HQ,[2] *trans*-**4** was obtained with a stereoselectivity of > 90% whereas with the catalyst **3** only a moderate stereoselectivity (70% *trans*) was achieved.

At least two pathways for the electron transfer in the bifunctional Co(porphyrin-hydroquinone) molecule are possible. The observed efficiency of the quinone-containing porphyrin **3** is best explained by an intramolecular electron transfer from the hydroquinone unit to the oxidized cobalt atom via the π-electron system of the porphyrin. An alternative mechanism would involve intermolecular interactions via a "liquid polymer"[11] coordination of the hydroquinone unit of one porphyrin molecule to the metal center of a second molecule.

Thus the bifunctional catalyst **3** not only accelerates the electron transfer but also acts as an efficient oxygen activating agent in the aerobic palladium-catalyzed *trans*-1,4-diacetoxylation of 1,3-cyclohexadiene.

Experimental Procedure

$TDMPPH_2$ was prepared by a Lindsey condensation [4a]: a solution of trifluoroacetic acid (0.46 g, 4 mmol) in CH_2Cl_2 (50 mL) was added over 15 min to a degassed solution of 2,5-dimethoxybenzaldehyde (1.1 g, 6.6 mmol) and freshly distilled pyrrole (0.51 g, 7.5 mmol) in CH_2Cl_2 (250 mL, distilled from CaH_2). The mixture was stirred under an N_2 atmosphere for about 15 h. A toluene solution of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (1 g in 10 mL) was added and the mixture was heated at reflux for 1 h, then filtered through basic alumina and evaporated to dryness. The crude product was dissolved in $CHCl_3$ and precipitated with pentane to yield 0.21 g (15%) $TDMPPH_2$. UV (CH_2Cl_2): λ[nm] = 398 (sh), 418, 513, 545, 588, 643. ^1H NMR ([D_6]acetone): δ = 8.80 (br s, 8H, β-pyrrole), 7.64 (m, 4H, *o*-Ph), 7.38 (br s, 8H, m, *p*-Ph), 3.95 and 3.55 (m, 12H each, OCH_3), −2.66 (br s, NH). Correct elemental analysis (C,H,N) for $C_{52}H_{46}N_4O_8$.

$TQPH_2$: To a cooled (−75 °C) solution of $TDMPPH_2$ (0.20 g, 0.23 mmol) in dry CH_2Cl_2 (20 mL) under an N_2 atmosphere was added BBr_3 [4b,c] (20 mL of a 1 M CH_2Cl_2 solution) over 30 min. The green mixture was stirred at −75 °C for 75 min, at room temperature for 1.5 h, and then slowly poured into 300 mL of a crushed ice-H_2O mixture. The biphasic mixture was stirred until the ice had melted. Subsequently EtOH (200 mL) was added and then solid $NaHCO_3$ until the mixture turned red. The mixture was then extracted with CH_2Cl_2 and ether, washed with H_2O, dried over $MgSO_4$, and evaporated to yield 0.15 g (71%) $TQPH_2$. UV (acetone): λ[nm] = 417, 512, 544, 589, 645.

2 and **3** were prepared by treating the porphyrin free bases with an excess of $[Co(OAc)] \cdot 4H_2O$ in refluxing, freshly distilled DMF, in accordance with the literature [4d]. UV (acetone) of **3**: λ[nm] = 407, 530 (unresolved). UV (CH_2Cl_2) of **2**: λ[nm] = 414, 438, 529, 546 (unresolved).

[6] A Co(salen-HQ) was recently reported as a catalyst in a Pd-catalyzed allylic oxidation of cyclohexene [5b]. When this catalyst was tried and compared to **3** in a 1,4-diacetoxylation, we found that the salene-HQ complex led to a considerably lower reaction rate and was also less stable to the reaction conditions than the porphyrin: S. E. Byström, E. M. Larsson, B. Åkermark, *J. Org. Chem.* **1990**, *55*, 5674.

[7] The oxygen consumption gives a good estimate of the progress of the Pd-catalyzed oxidation; 12 mL of O_2 corresponds to conversion of 1 mmol of the substrate [2b].

[8] In the reaction catalyzed by **1** + HQ, the free quinone was consumed in a Diels–Alder reaction with 1,3-cyclohexadiene, and no benzene formation was observed (by GC or GC-MS).

[9] a) A control experiment employing **2** *without* hydroquinone yielded a very rapid and unexpected [9b] oxygen consumption. In only 4 h all diene was converted to **4** and benzene, of which **4** was isolated in 35% yield. Interestingly, the relative stereochemistry of the product was reversed from the 70% *trans* obtained by using **3** to 75% *cis* with **2**. This mechanistically interesting observation will be the subject of a separate study. b) Employing **1** without a quinone yielded only porphyrin degradation products.

Surprising Differences in the Cycloaddition Reactions of Cumulenes and Heterocumulenes to Vinylidenetitanocene: Formation of Four- or Five-Membered Titanacycles**

By *Rüdiger Beckhaus,* Isabelle Strauß, Trixie Wagner,* and *Paul Kiprof*

The stabilization of the vinylidene group $H_2C{=}C{:}$, tautomeric to acetylene, by complexation as metallaallene **1** led to an extensive chemistry, particularly for electron-rich transition metals.[1, 2] The methylidene titanacyclobutane **3**, accessible from the divinyltitanocene **2** in almost quantitative yield,[3a, b] is an efficient source for vinylidenetitanocene **4**,[4] which is formed from **3** by heating to cleave ethylene. Extended Hückel MO calculations show that the electronic structure of **4** makes it ideally suited for cycloaddition reactions with multiply bonded systems.[4]

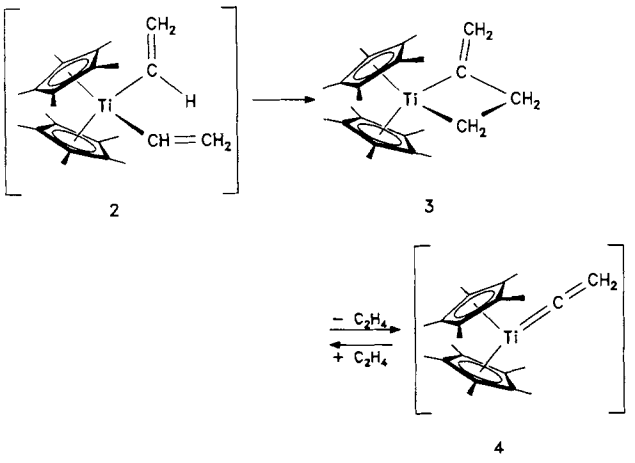
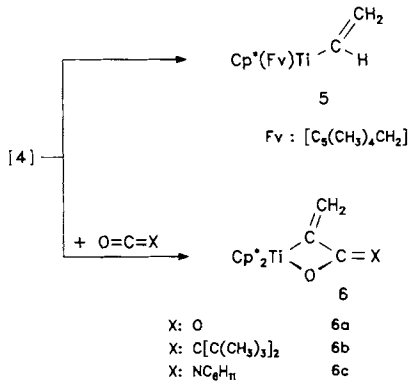
[+] Present address:
Department of Chemistry, University of Wisconsin
Madison (USA)

[**] The experimental studies were partly carried out during a visit to the Anorganisch-chemisches Institut der Technischen Universität München (extraordinary research grant of the Alexander von Humboldt Foundation for RB). RB thanks Prof. P. Hofmann for his continued interest. Financial support from the Fonds der Chemischen Industrie is gratefully acknowledged.



Attempts to stabilize thermally generated **4** with phosphanes were unsuccessful, in contrast to reactions with similar metallacyclobutanes[5, 6] and titanium–carbon double-bond systems.[7, 8] The product of this reaction, the fulvene complex **5**, can also be conveniently prepared as dark green solid by "dry" thermolysis of **3** under vacuum, or in solution from $[Cp^*_2Ti(CH_3)(CH{=}CH_2)]$ ($Cp^* = \eta^5$-$C_5(CH_3)_5$) by elimination of methane.



If **3** is heated in the presence of acceptor ligands containing cumulative double bonds, for example carbon dioxide, ketenes, or isocyanates, ethylene is liberated and the cycloreversion products **6a**, **b**, and **c**, respectively, are formed. The NMR spectra of **6** (Table 1) confirm the presence of a metallaoxetane unit. Particularly characteristic are the ^{1}H NMR signals of the exocyclic methylidene group [$\delta = 7.17$, 4.79 (**6a**); 6.49, 4.57 (**6b**), 7.21, 4.68 (**6c**)] and the chemical shift of the ring carbon atoms Ti–C [$\delta = 194.5$ (**6a**); 184.4 (**6b**); 193.7 (**6c**)] and O–C [$\delta = 159.9$ 9 (**6a**); 143.1 (**6b**); 146.7 (**6c**)]. A feature of the crystal structure analysis of **6c** (Fig. 1) is a twisted metallaoxetane in which C 1 lies 0 .090(4) Å above and C 3 0.116(3) Å below the plane defined by the Ti, O, and C 2 atoms. The titanium atom has pseudotetrahedral coordination, as anticipated, with typical Ti–Cp* distances (2.0939(6), 2.0979(6) Å) and a characteristic Cp*-Ti-Cp* angle of 140.78°. The Ti–O and Ti–C bond lengths of 1.983(2) and 2.121(3) Å, respectively, lie in the usual range. Double-bond lengths of 1.325(4) and 1.285(4) Å were found for the exocyclic C=CH_2 and C=N groups.

The use of hexacarbonylchromium, or -tungsten, cymantrene ([CpMn(CO)$_3$]), or methylcymantrene ([Cp′Mn(CO)$_3$], Cp′ = η^5-$C_5(CH_3)H_4$) in reaction with **3** (→ **4**) surprisingly affords the binuclear Fischer carbene complexes **7** containing a five-membered titanacycle. Accordingly, the ^{1}H NMR

Table 1. Spectroscopic data of **5**–**7** [a].

5: ^{1}H NMR (270 MHz): $\delta = 1.73$ (s, 15H, $C_5(CH_3)_5$), 1.22, 1.40, 1.61, 1.97 (s, each 3H, CH_3), 1.31, 1.80 (dd, ^2J(H,H) = 4.2 Hz, each 1H, $C_5(CH_3)_4CH_2$), 4.27 (dd, ^2J(H,H) = 3.4 Hz, ^3J(H,H) = 22.9 Hz, 1H, =CH_2), 5.29–5.11 (m, 1H, =CH), 5.67 (dd, ^2J(H,H) = 3.4 Hz, ^3J(H,H) = 18.5 Hz); ^{13}C{^{1}H} NMR (125 MHz): $\delta = 12.1$ ($C_5(CH_3)_5$), 118.8 ($C_5(CH_3)_5$), 10.6, 10.7, 10.9, 16.6 ($C_5(CH_3)_4CH_2$), 76.1 ($C_5(CH_3)_4CH_2$), 120.7, 124.0, 125.9, 126.6, 129.5 ($C_5(CH_3)_4CH_2$), 113.6 (TiC=CH_2), 208.0 (TiC=CH_2)

7d: ^{1}H NMR (500 MHz): $\delta = 1.60$ (s, 30H, $C_5(CH_3)_5$), 1.96 (s, 3H, $(C_5H_4)CH_3$), 4.42, 4.55 (t, J(H,H) = 1.9 Hz, each 2H, $(C_5H_4)CH_3$), 6.73 (d, ^2J(H,H) = 8.8 Hz, 1H, =CH), 7.17 (d, ^3J(H,H) = 8.8 Hz, 1H, =CH); ^{13}C{^{1}H} NMR (125 MHz): $\delta = 11.9$ ($C_5(CH_3)_5$), 124.0 ($C_5(CH_3)5$), 14.5 ($C_5H_4CH_3$), 85.8, 88.2, 101.2 ($C_5H_4CH_3$), 154.0 (TiCH=*C*H), 227.2 (TiCH=CH), 236.8 (CO), 322.6 (C=Mn); IR (*n*-heptane): $\tilde{\nu}$[cm^{-1}](CO) = 1911, 1847; MS (70 eV): *m/z* 563 ($M^{\oplus}$, 25%), 506 ($M^{\oplus}$ − 2CO, 100)

[a] NMR spectra were recorded at 25 °C; solvent C_6D_6, standard TMS.

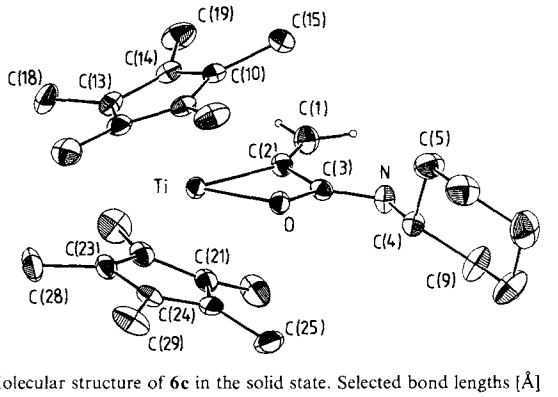

Fig. 1. Molecular structure of **6c** in the solid state. Selected bond lengths [Å] and angles [°] (Cp1 and Cp2 represent the centers of the Cp* ligands at the titanocene fragment: Ti-Cp(1) 2.09339(6), Ti-Cp(2) 2.0979(6), Ti-O 1.983(2), Ti-C(2) 2.121(3), C(2)-C(1) 1.325(4), C(1)-H1$_a$ 0.99(3), C(1)-H1$_b$ 0.95(4), C(2)-C(3) 1.477(4), C(3)-N 1.285(4), N-C(4) 1.459(4), C(4)-C(9) 1.516(4), C(3)-O 1.348(3); Cp(1)-Ti-Cp(2) 140.78, C(2)-Ti-O 67.6(1), Ti-O-C(3) 96.7(2), O-C(3)-C(2) 107.9(2), C(3)-C(2)-Ti 87.2(2), C(1)-C(2)-Ti 147.3(3), H1$_a$-C(1)-H1$_b$ 114.(3) [15].

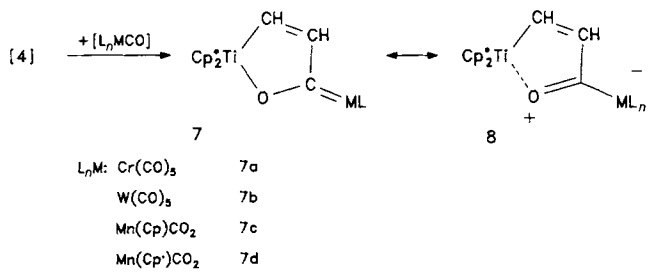
spectrum contains an AB pattern for the CH=CH–E unit that bridges the titanium and carbon atoms, and the ^{13}C NMR spectrum shows typical $^{1}J_{C,H}$ coupling constants for methine carbon atoms (**7c**: $J = 156$, 143 Hz). The chemical shifts of the carbene carbon atoms lie in the expected low-field region [δ = 325.4 (**7a**); 305.5 (**7b**); 322.5 (**7c**); 322.6 (**7d**)].



The X-ray structure analysis of **7d** confirms the presence of an almost planar metallacyclopentene unit whose C(4)–C(5) bond is 1.330(5) Å long, which corresponds to a double bond (Fig. 2).

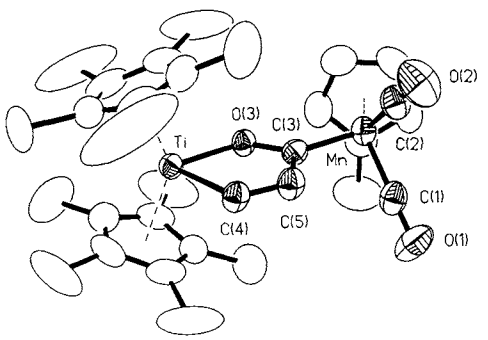


Fig. 2. Molecular structure of **7d** in the solid state. Selected bond lengths [Å] and angles [°] (Cp1 represents the center of the five-membered ring of the methylcyclopentadienyl ligand at the manganese center; Cp2 and Cp3 represent the centers of the Cp* ligands at the titanocene fragment): Mn-C(1) 1.776(3), Mn-C(2) 1.767(4), Mn-C(3), 1.915(4), Ti-O(3) 1.983(2), Ti-C(4) 2.109(3), O(1)-C(1) 1.154(5), O(2)-C(2) 1.156(5), O(3)-C(3) 1.314(4), C(3)-C(5) 1.472(5), C(4)-C(5) 1.330(5), Mn-Cp(1) 1.791, Ti-Cp(2) 2.092, Ti-Cp(3) 2.112, C(1)-MnC(2) 89.3(2), C(1)-Mn-C(3) 90.2(2), C(2)-Mn-C(3) 90.2(2), Cp(1)-Mn-C(2) 126.3, Cp(1)-Mn-C(3) 124.6, Mn-C(1)-O(1) 178.2(4), Mn-C(2)-O(2) 178.8(3), Mn-C(3)-O(3) 125.2(3), Cp(2)-Ti-Cp(3) 141.6, Ti-O(3)-C(3) 122.4(2), Ti-C(4)-C(5) 112.4(3), O(3)-Ti-C(4) 125.0(2), Cp(2)-Ti-O(3) 106.2, Cp(2)-Ti-C(4) 103.7, Cp(3)-Ti-O(3) 105.6, Cp(3)-Ti-C(4) 103.9, O(3)-C(3)-C(5) 125.0(2) [15].

The bond lengths are characteristic for Fischer carbene complexes.[10a] The relatively long Ti–O bond typical for oxatitanacycles (1.983(2) Å) lies opposite a shorter C3–O distance (1.314(4) Å). Similar bonding relationships occur in the cycloaddition product from [Cp$_2^*$Ti(C$_2$H$_4$)] and [Re$_2$(CO)$_{10}$] (Ti–O 2.02(2) Å).[10b] The Ti–O distance in **7d** is larger than in titanium alkoxide [Cp$_2$Ti(Cl)(OCH$_2$CH$_3$)] (Ti–O: 1.855(2) Å)[11] or the titanium enolate [Cp$_2$Ti-(OCH=CH$_2$)$_2$] (Ti–O 1.903(2) Å).[12] Thus the ionic resonance structure **8** may be invoked in the description of **7**.

The carbene complexes **7** are thermally remarkably stable and decompose in the solid state only above 200 °C. In the mass spectra the molecular ions are observed, and their fragmentation patterns are characterized primarily by a stepwise and complete loss of all CO ligands.

The formation of the five-membered metallacycles **7** instead of the four-membered rings **6** corresponds formally to a cycloaddition of an acetylene intermediate to a C–O bond of the metal carbonyl. The transformation of vinylzirconocenes take a similar course.[13] A vinylidene–acetylene rearrangement would correspond to the behavior of the free vinylidene, which very rapidly transforms into the tautomeric acetylene because of the low energy barrier.[14] At present we are investigating the mechanistic aspects of the formation of **7**, such as participation of primary cycloaddition products similar to **6** or to vinyl intermediates **5**.

Experimental Procedure

5: Compound **3** (500 mg, 1.3 mmol) was heated in a sublimation apparatus under vacuum (10^{-3} Torr) to 120–140 °C. The product **5** sublimed as dark green substance. Yield 320 mg (71%).

6a: Compound **3** (500 mg, 1.3 mmol) was dissolved in *n*-heptane (30 mL) and heated in a dry CO_2 atmosphere at 80 °C for 45 min. After concentration at −10–0 °C, red-violet, light-sensitive crystals of **6a** formed. Yield 450 mg (86%).

6b and **6c**: Heating **3** (500 mg, 1.3 mmol) and O=C=C[C(CH$_3$)$_3$]$_2$ (250 mg, 1.6 mmol) or **3** (370 mg, 1 mmol) and cyclohexylisocyanate (150 µL, 1.2 mmol) in *n*-heptane at 70–90 °C for 3 h, followed by filtration and concentration of the solution at 0–10 °C gave, respectively, golden yellow crystals of **6b** (450 mg, 65%, m.p. 143 °C) and red crystals of **6c** (352 mg, 75%, m.p. 128–131 °C).

7a–d: Heating **3** (500 mg, 1.3 mmol) and a stoichiometric amount of [M(CO)$_6$] (M = Cr, W) or [LMn(CO)$_3$] (L = Cp, Cp') in *n*-heptane (100 mL) at 90–100 °C for 4 h, followed by separation of the small amount of insoluble precipitate from the still warm solution by filtration, gave after crystallization at −35 °C red (for **7a**, **b**) or orange-yellow crystals (for **7c**, **d**). Yields (%): for **7a** 30, **7b** 45, **7c** 60, and **7d** 65. All compounds gave correct elemental analyses (C, H, N, Ti).

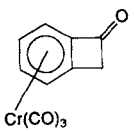
η^6-(1,2-Dioxocyclobutabenzene)tricarbonylchromium(0): Starting Material for Double Anionic Oxy-Cope Rearrangements under Very Mild Conditions**

By *Michael Brands, Richard Goddard, Hans G. Wey,* and *Holger Butenschön**

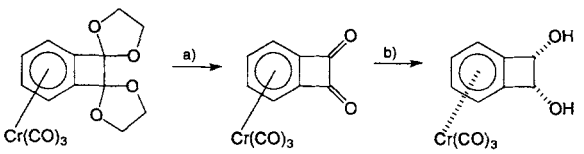
Reactions of arenetricarbonylchromium(0) complexes[1] are of great interest in organic synthetic chemistry. We recently found an efficient access to **1**, the tricarbonylchromium(0) complex of 1-oxocyclobutabenzene.[2] The alcohols which are readily accessible from this complex undergo distal[2] and proximal[3] four-membered ring openings under very mild conditions. Because of the increased reactivity of



1

the keto group as a result of the coplanarity with the coordinated, electron-deficient arene ring, we have also investigated the corresponding complex **3** of 1,2-dioxocyclobutabenzene. We report here on the synthesis and structure of this complex, and some of its reactions, including double anionic oxy-Cope rearrangements, which occur under remarkably mild conditions.

Attempts at the direct complexation of 1,2-dioxocyclobutabenzene with hexacarbonylchromium(0) were unsuccessful, thus **3** was prepared similar to **1** by hydrolytic cleavage of the easily accessible diacetal **2** (Scheme 1).[4] The



2 **3** **4**

Scheme 1. a: concentrated HCl, 2 h, 25 °C, 80%; b: $Li[AlH_4]$, Et_2O, −78 °C, 90%, *dr* 88%.

treatment of **2** with concentrated hydrochloric acid gave the diketone complex **3** as a burgundy red powder in 80% yield. (NMR data of all new compounds are given in Table 1.) Crystals of **3** suitable for an X-ray structure analysis[5] were obtained from a mixture of dichloromethane and diethyl ether (Fig. 1). In the asymmetric unit are two independent molecules with similar structures.

The annelated four-membered ring in **3** is bent away from the plane of the arene ring toward the chromium atom by about 8° (±1°).[6] The large value (8°)—usually 2 to 3°—can be understood as a result of a stronger coordination of C2a and C6a to the metal center, which leads to a reduction of the ring strain.

Table 1. ^1H NMR data of **3**–**7**, **9**, and **10**.

3: (200 MHz, [D$_8$]THF): δ = 5.76 + 6.26 (AA'BB' system, 2 × 2H, 3(6)-H, 4(5)-H)
4: (200 MHz, [D$_8$]THF): δ = 4.42 (br, 2H, OH), 4.96 [s, 2H, 1(2)-H], 5.25 + 5.48 (AA'BB' system, 2H, 3(6)-H, 4(5)-H)
5: (200 MHz, [D$_6$]acetone): δ = 1.95 (m, 4H, 7(8)-H), 2.73 (m, 4H, 6(9)-H), 5.87 (m, 4H, 1(4)-H, 2(3)-H)
6: (200 MHz, [D$_6$]acetone): δ = 5.33 (dd, 1H, *cis*-8-H, $^3J_{7,cis\ 8}$ = 10.6 Hz, $^2J_{trans\ 8,cis\ 8}$ = −0.8 Hz), 5.40 (dd, 1H, *trans*-8-H, $^3J_{7,trans\ 8}$ = 17.4 Hz), 5.63 (dd, 1H, 4-H or 5-H, J = 5.8, 6.1 Hz), 5.83 (dd, 1H, 4-H or 5-H), 5.87 (d, 1H, 3-H or 6-H), 6.07 (d, 1H, 3-H or 6-H), 6.22 (dd, 1H, 7-H).
7: (200 MHz, [D$_6$]acetone): δ = 1.21 (d, 3H, 11-H, $^3J_{6,11}$ = 6.6 Hz), 1.85 (m, 2H, 7-H or 8-H), 2.10 (m, 2H, 7-H or 8-H), 2.48-2.73 (m, 2H, 9-H), 3.02 (m, 1H, 6-H), 5.60 (d, 1H, 1-H or 4-H, J = 6.1 Hz), 5.74 (dd, 1H, 2-H or 3-H, J = 6.4 Hz), 6.01 (dd, 1H, 2-H or 3-H), 6.08 (d, 1H, 1-H or 4-H)
9: (400 MHz, CD_2Cl_2): δ = 1.15 (d, 3H, 14-H, $^3J_{10,14}$ = 6.8 Hz, 1.39 (s, 3H, 13-H), 1.61-1.70 (m, 2H, 12-H), 1.77 (m, 1H, 10-H or 11-H), 1.87-1.98 (m, 2H, 10-H or 11-H), 5.44 (m, 1H, aromat.), 5.68 (m, 3H, aromat.)
10: (200 MHz, CD_2Cl_2): δ = 0.10 (s, 18H, 11-(13)-H), 1.39 (s, 6H, 12(14)H, 14-H), 2.13 + 3.21 (AA'BB' system, 2 × 2H, *endo*-7(8)-H, *exo*-7(8)-H), 5.38 + 5.81 (AA'BB' system, 2 × 2H, 1(4)-H, 2(3)-H)

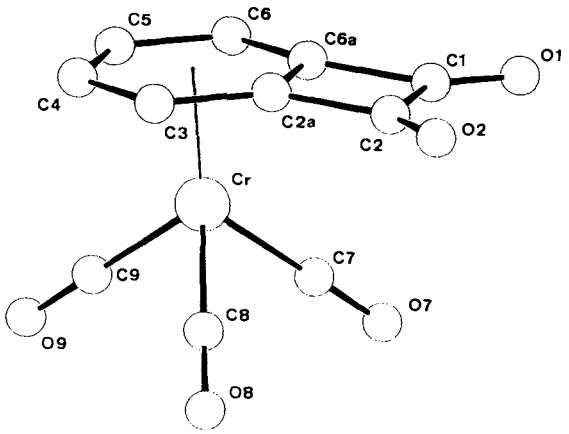


Fig. 1. Structure of **3** [5]. The asymmetric unit contains two independent molecules of similar structure, only one of the two is shown here. Selected average bond lengths [Å]: C1–C2 1.566(7), C1–C6a 1.507(6), C2–C2a 1.504(6), C2a–C6a 1.418(3), Cr–C2a 2.152(23), Cr–C3 2.221(4), Cr–C4 2.208(8), Cr–C5 2.205(14), Cr–C6 2.222(2), Cr–C6a 2.159(16).

Compound **3** reacts with $Li[AlH_4]$ in diethyl ether already at −78 °C to give the diol **4** in 90% yield.[7] The diastereomeric excess (88%) is somewhat less than for the reduction of **1**; in addition to **4**, a small amount of the *trans* reduction product is obtained. The mild conditions and the high yield indicate an increase in the reactivity of the keto group in **3** as a result of the coordination to $Cr(CO)_3$.[2, 8]

If the diketone complex **3** is treated with seven equivalents of vinylmagnesium bromide or better vinyllithium in THF at −78 °C, not the expected double Grignard adduct is obtained after hydrolysis at −78 °C, but the tricarbonylchromium(0) complex **5** of benzoannelated cyclooctan-1,4-dione (87%, m.p. 145–146 °C, Scheme 2) as a result of a double anionic oxy-Cope rearrangement.

Through the double nucleophilic attack from the side of the ligand which faces away from the chromium,[9] the synperiplanar orientation of the two vinyl groups favorable for the double anionic oxy-Cope rearrangement is achieved. This reaction is one of the few double anionic oxy-Cope rearrangements known so far;[10, 11] the reaction occurs at

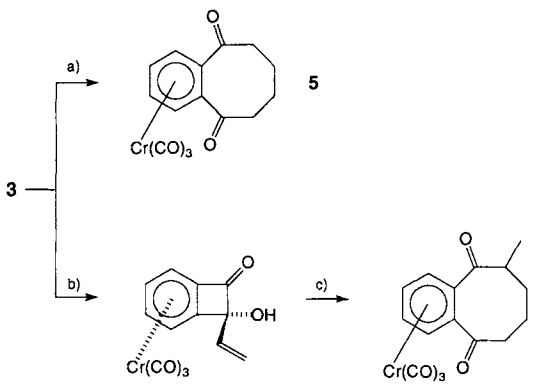
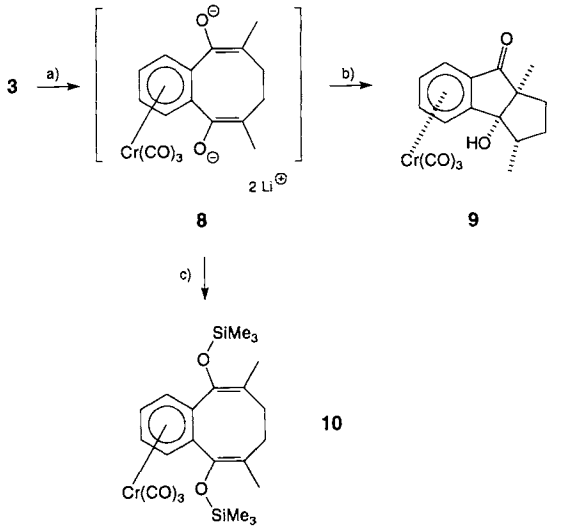
B. the Deutsche Forschungsgemeinschaft for a Heisenberg Fellowship. Our thanks also go to the Director of the Max-Planck-Institut für Kohlenforschung, Prof. Dr. G. Wilke, for his supporting interest. We thank C. Wirtz for recording the NMR spectra.



Scheme 2. a: 1) 7 equiv vinyllithium, −78 °C, 2) H_3O^+, −78 °C, 87%; b: 1) 2 equiv vinylmagnesium bromide, −78 °C, 2) H_3O^+, −78 °C, 90%; c: 1) 6 equiv 2-propenyllithium, −78 °C, 2) H_3O^+, −78 °C, 60%.



Scheme 3. a: 1) 7 equiv 2-propenyllithium, −78 °C; b: H_3O^+, −78 °C, 48%; c: trimethylsilyl trifluoromethanesulfonate, −40 °C, 70%.

−78°, to our knowledge the lowest temperature so far observed for such a rearrangement, room temperature is usual. In contrast to most known examples,[10, 11] it is not necessary to isolate the diallyl diol; the diolate is produced directly by the double addition of the alkenyl metal reagent to the 1,2-dione. This is the first example of the formation of a cyclooctadione derivative by a double anionic oxy-Cope rearrangement, in which the hydrolysis product itself can be isolated, without immediately undergoing a subsequent reaction (aldol reaction, see below). Remarkably, the reaction of the noncomplexed 1,2-dioxocyclobutabenzene, under the reaction conditions used for **3**, only leads to a complex mixture of products, which contains the ligand of **5** at best in trace amounts.

If **3** is treated with only two equivalents of vinylmagnesium bromide, the adduct **6**[7] is obtained diastereoselectively in 90% yield. This opens up the possibility of obtaining products from "mixed" double anionic oxy-Cope rearrangements by the reaction of **6** with another alkenyl Grignard or alkenyllithium reagent. The corresponding reaction of **6** with 2-propenyllithium gave the methyl-substituted product **7** as a single diastereomer in over 60% yield. In order to investigate this more closely, **3** was treated with a sevenfold excess of 2-propenyllithium with the intention of obtaining a symmetrical, double methyl-substituted derivative. After hydrolysis of the enolate **8** at −78 °C, however, the tricyclic complex **9**, which results from an intramolecular aldol addition, was obtained diastereomerically pure in 48% yield together with two by-products[12] (1:1). Following characterization by NMR spectroscopy, the relative configuration was determined by an X-ray crystal structure analysis.[13] Thereafter protonation of an enolate group occurs followed by the intramolecular nucleophilic attack on the carbonyl group formed, preferably from the side of the bicyclic ligand which faces away from the metal atom.

In order to show that **9** really forms via the dienolate **8** as the primary product of the double anionic oxy-Cope rearrangement, **8** was trapped with trimethylsilyl trifluoromethanesulfonate. The bis(trimethylsilyl enol ether) **10** (70%) thus obtained should be suitable for the introduction of further substituents in the α positions.[14]

We have showed that by the coordination of 1,2-dioxocyclobutabenzene to a tricarbonylchromium(0) unit, double anionic oxy-Cope rearrangements are made possible under very mild conditions, which lead to differently substituted benzocyclooctan-1,4-dione complexes. We are currently investigating the extent to which this reaction could provide an alternative access to eight-membered ring compounds by reactions with other alkenyllithium reagents.[15]

Experimental Procedure

All operations were carried out under an inert atmosphere.

3: Concentrated HCl (125 mL) was added to **2** (2.99 g, 8.4 mmol) [4] at 0 °C and then vigorously stirred for 2 h at 20 °C. The reaction was monitored by thin-layer chromatography (diethyl ether/pentane 2:1, SiO_2). During the reaction the mixture turned deep red and at the end of the reaction time it was red brown. Compound **3** precipitated partly as a burgundy-red solid. The mother liquor was removed with a capillary and retained. The residue was washed with water, dried under vacuum, washed twice with a little cold pentane, and dried once again under vacuum. 1.56 g of **3** remained. The mother liquor was extracted with diethyl ether, the extracts were dried over $MgSO_4$ for 2 h, and the solvent was removed under vacuum. The residue was washed with a little cold pentane and then dried under vacuum. 0.23 g of **3** was obtained. Thus, total yield of **3** was 1.79 g, (6.7 mmol, 80%) (m.p. 132.2 °C).

5: A solution of **3** (304 mg, 1.13 mmol) in diethyl ether/THF (100 mL) (1:1) was added dropwise over 4 h at −78 °C to a 0.5 M solution of vinyllithium in THF (15.8 mL, 7.9 mmol); the reaction mixture immediately turned black after the first few drops had been added. The mixture was stirred for 16 h at −78 °C and subsequently hydrolyzed at −78 °C with saturated aqueous ammonium chloride solution. The red solution obtained was extracted with water, and the organic phase was dried over $MgSO_4$. After the solvent had been removed under vacuum, **5** was obtained as a red oil. Following purification by column chromatography (SiO_2, diethyl ether/pentane 5:1) and crystallization from diethyl ether/pentane **5** was obtained (320 mg, 0.99 mmol, 87%; m.p. 145–146 °C).

S-Glycosylated Cyclic Peptides**

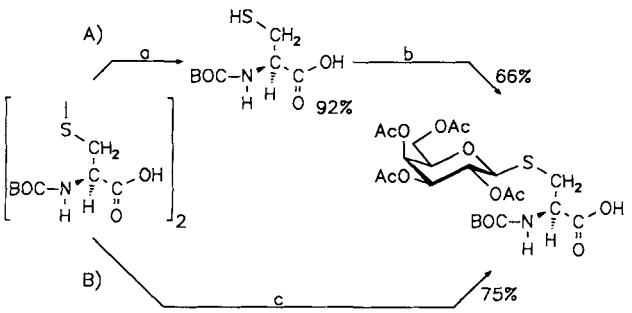
By *Manfred Gerz, Hans Matter,* and *Horst Kessler**

The biological importance of naturally occurring glycopeptides[1–3] stimulates the idea to use modified glycopeptide structures for pharmaceutical purposes. One goal of chemical modification is to increase metabolic stability. The peptide moiety might be protected against proteolysis caused by exopeptidases by cyclization, whereas the glycosidic bond between the saccharide and peptide can be stabilized by using thioglycosidic analogues. The higher chemical stability of *S*-glycosylated amino acids was proven by Baran and Drabarek.[4] Cyclic *S*-glycopeptides are preferably prepared by peptide synthesis with *S*-glycosylated amino acid building blocks, because glycosylation of cyclic peptides may be difficult for conformational reasons. A comparison of the spatial structure of a cyclic *S*-glycopeptide with analogous *O*- and *N*-glycopeptides permits investigations of peptide–sugar interactions.

Here we describe a new method of preparation of *S*-glycosylated cysteine derivatives (Table 1) and their use in the synthesis of the cyclic glycosylated hexapeptide *cyclo*-(-D-Pro^1-Phe^2-Ala^3-Cys^4(*β*-D-galactopyranosyl)-Phe^5-Phe^6-). The conformation of the peptide in [D_6]DMSO was determined by 2D NMR spectroscopy in combination with molecular dynamics (MD) calculations, and is compared to the structure of analoguous hexapeptides.

Previous syntheses of *S*-glycosyl cysteine derivatives[4–6] yielded products not bearing orthogonal protection of amino, carboxyl, and hydroxyl functions that consequently were not suitable for the synthesis of peptides. An exception is the *S*-glycosylation of *C*-terminally unprotected Fmoc amino acids under Lewis acid catalysis recently published by Eloffson et al.[7] These building blocks were employed in the solid-phase synthesis of linear *S*-glycopeptides.

For the preparation of a *tert*-butoxycarbonyl(BOC)-protected glycosylated cysteine with free carboxyl function *N,N'*-bis(*tert*-butoxycarbonyl)cystine was first reduced by triethylphosphane[8] (92%), and the resulting cysteine derivative treated with sodium hydride to form the S,O-dianion, which reacts with 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide (acetobromogalactose) to give the *S*-glycosylamino acid in 66% yield (method A). A better yield was obtained by reduction and deprotonation in one step (method B): reduction of *N,N'*-bis(*tert*-butoxycarbonyl)-cystine with sodium in liquid ammonia directly gives the S,O-dianion, which after removal of the ammonia was dissolved in dry THF and treated with acetobromogalactose. The *β*-thiogalactoside was formed in 75% yield (Scheme 1).



Scheme 1. a) Triethylphosphane, THF/water (9:1); b) 1. NaH, THF, 2. acetobromogalactose; c) 1. Na, liquid ammonia, 2. acetobromogalactose, THF.

Problems in the purification of products with free carboxyl functions prompted us to attempt the synthesis of *S*-glycosylated *C*- and *N*-terminally protected cysteine derivatives which could be purified easily by chromatography on silicagel. Ogawa et al. converted *β*-configurated peracetyl sugars to methyl-*β*-thioglycosides by treatment with Bu_3SnMe and $SnCl_4$.[9] Analogously Z-Cys(Bu_3Sn)-OBzl (Z = benzyloxycarbonyl), prepared by azeotropic stannylation of Z-Cys-OBzl with $(Bu_3Sn)_2O$ in toluene in a Dean–Stark trap,[10] affords the *β*-configurated product in 51% yield when reacted with pentaacetyl-*β*-D-galactose under $SnCl_4$ catalysis. Application of Koenigs–Knorr[11] conditions with $HgBr_2$ as promotor and acetobromogalactose as glycosyl donor raises the yield to 60%. The glycosylation yield depends significantly on the size of the *N*-terminal protecting group: The BOC group totally inhibits glycosylation even when the small allyl group is used to protect the carboxyl group (difficulties with glycosylation of BOC-protected amino acids have already been described by Paulsen et al.[12]). In contrast, the benzyloxycarbonyl group allows the glycosylation of the thiol function in good yields, especially when the carboxyl group is protected as an allyl ester. The preparation of the allyl ester was carried out by esterification of an *N,N'*-diprotected cystine derivative with allyl bromide by using the cesium carbonate procedure[13] and subsequent cleavage of the disulfide bond by triethylphosphane. Introduction of a disaccharide donor does not reduce the yield, as was demonstrated by the reaction of Z-Cys-OAll with acetobromocellobiose (85% yield). However, the tripeptide Boc-Phe-Cys-Ala-OBzl did not react under these conditions, probably because the reactivity of the thiol function was

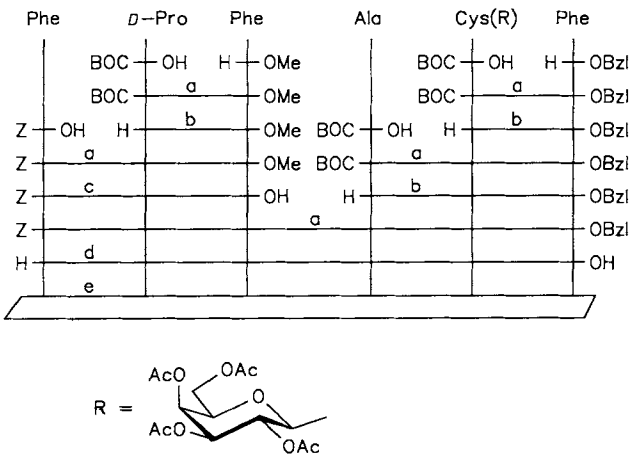
reduced by hydrogen bonding. Only β-thioglycosides were isolated, as expected for sugars bearing an acetate function in the 2-position. The results of the glycosylation experiments are summarized in Table 1.

Table 1. Glycosylation yields of different thiolamino acid derivatives under Koenigs–Knorr conditions with $HgBr_2$ promotor.

Acceptor	Donor	Yield [%]
Z-Cys(Bu_3Sn)-OBzl	pentaacetyl-β-D-galactose	51 [a]
Z-Cys(Bu_3Sn)-OBzl	acetobromogalactose	60
Z-Cys-OBzl	acetobromogalactose	71
BOC-Cys-OBzl	acetobromogalactose	-
BOC-Cys-OAll	acetobromogalactose	-
BOC-D-Pen-OAll [b]	acetobromogalactose	-
BOC-Phe-Cys-Ala-OBzl	acetobromogalactose	-
Z-Cys-OAll	acetobromogalactose	77
Z-Cys-OAll	acetobromocellobiose	85

[a] $SnCl_4$ as promotor; [b] D-Pen = D-penicillamine (β,β-dimethylcysteine). Z = benzyloxycarbonyl.

These *S*-glycosylcysteine derivatives were used for the synthesis of the cyclic hexapeptide *cyclo*-(-D-Pro^1-Phe^2-Ala^3-Cys^4(β-D-galactopyranosyl)-Phe^5-Phe^6-). As depicted in Scheme 2, the synthesis was performed by [3 + 3] fragment condensation, cyclization (azidodiphenylphosphate/$NaHCO_3$), and deacetylation (NaOMe/MeOH). The compound is an analogue of the previously described *N*- and *O*-glycopeptides[14, 15] *cyclo*-(-D-Pro^1-Phe^2-Ala^3-Xaa^4-Phe^5-Phe^6-) [with Xaa = Gln(*N*-2-acetamido-2-deoxy-β-D-glycopyranosyl) or Ser(*O*-β-lactopyranosyl)].



Scheme 2. Synthesis of the cyclic glycopeptide *cyclo*-(-D-Pro^1-Phe^2-Ala^3-Cys^4(β-tetra-*O*-acetylgalactopyranosyl)-Phe^5-Phe^6-). a) EtN=C=N-$(CH_2)_3NMe_2$·HCl (EDCl), 1-hydroxy-1*H*-benzotriazole (HOBt), THF/dimethylacetamide (2:1); b) trifluoroacetic acid (TFA), CH_2Cl_2; c) 1 N NaOH, isopropanol; d) H_2, Pd/C, methanol; e) azidodiphenylphosphate, $NaHCO_3$, dimethylformamide (DMF). Z = benzyloxycarbonyl.

For the structure determination of the deprotected glycopeptide all ^1H and ^{13}C resonances were assigned by modern NMR spectroscopic techniques (see refs. [14–16] for methods). Experimental parameters including homo- and heteronuclear coupling constants as well as 43 NOE values were extracted from 1D and 2D spectra. The distances obtained by quantitative evaluation of the NOEs were used as restraints in MD calculations. For the GROMOS force field additional parameters for the thioglycosidic bond were applied: C–S distance of 181 pm and C–S–C angle of 100.2° were taken from an X-ray analysis of a β-thioglycoside.[17] The force constants used were the same as those for *O*-glycosides.

The averaged structure (with additional energy minimization to eliminate physically unrealistic artifacts) of the 70 ps MD trajectory in DMSO as solvent[16] is shown in Figure 1.

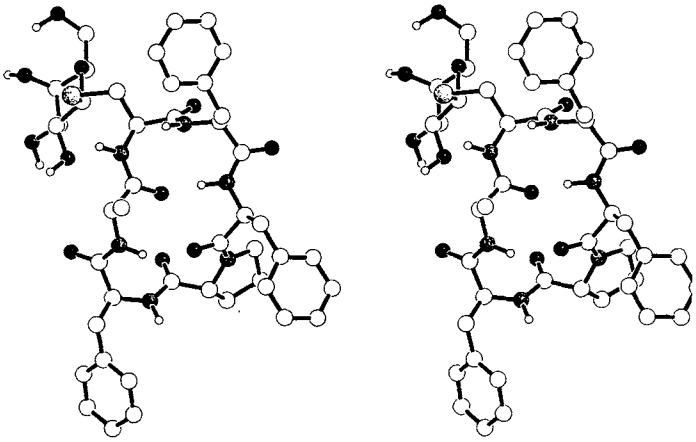


Fig. 1. Stereoplot of the major conformation of the cyclic glycopeptide *cyclo*-(-D-Pro^1-Phe^2-Ala^3-Cys^4(β-D-galactopyranosyl)-Phe^5-Phe^6-) in [D_6]DMSO. This structure is obtained by averaging over the last 70 ps of a 100 ps restrained MD simulation in DMSO using the GROMOS package [18]. Experimental restraints were derived from 600 MHz NOESY data. The calculation follows the protocol previously described [14]. The side chain conformations are shown as the dominating rotamers derived from NMR spectroscopy.

Two transannular hydrogen bonds (Ala^3-NH···OC-Phe^6 and Phe^6-NH···OC-Ala^3) were observed consistent with two standard β-turns: a stable βII′ turn with D-Pro^1 in the i + 1 position and a βI turn about Xaa-Phe^5. A detailed analysis of the NOEs in the latter, however, provides strong evidence for the existence of an equilibrium between two types of turns (βI, βII), as was previously found in several analogous peptides.[14, 15] The hydrogen bond pattern is not changed by glycosylation of the amino acid in the i + 1 position, which can be seen from the comparison with the non-glycosylated peptide *cyclo*-(-D-Pro^1-Phe^2-Ala^3-Ser^4-Phe^5-Phe^6-) in the crystal and in solution.[15]

In conclusion, we have found that *N*-, *O*-, or *S*-glycosylation in the i + 1 position of a β-turn does not influence the structure and dynamics of the peptide moiety. The comparison of a series of glycosylated hexapeptides leads to the conclusion that it should be possible to modify the pharmacokinetic and pharmacodynamic properties of a peptide by introduction of glycosylated amino acids in suitable positions, while maintaining the biological activity of the parent compound. Hence, one can use the "recognition function" of the saccharide substituents for drug targeting as a physiological address (interaction with sugar-binding receptors) to prepare drugs which develop specific activities at defined loci. The chemical and enzymatic stability of the thioglycopeptides presented here should be of importance for the realization of this concept.

Two New High-Pressure Modifications of NaOH**

By *Horst P. Beck** and *Gunda Lederer*

NaOH crystallizes in three forms, depending on the temperature; listed in order of increasing temperature they are the anti-Tl I type, then a variant that is a deformation thereof, and finally a NaCl-analogous structure ("NaCl I"), in which the OH particles appear isotropic as a result of dynamic disorder.[1–3] Studies under pressure with differential thermal analysis indicate that above 1–2 GPa at least one further form exists.[4] However, no structural information on the high pressure phases was available, because they could not be quenched and thus could only be characterized in situ.[5]

Use of a diamond anvil cell with a heating device in a special X-ray diffractometer[6, 7] enabled us to define the boundaries in the p,T field of two high-pressure modifications, to determine their structures, and to refine one with the Rietveld method. Furthermore, our new techniques yield such good diffraction data even under pressure that the usual structure solution and refinement procedures may be applied.

Figure 1 shows the extended phase diagram for NaOH in which the domains of the known normal pressure modifications are also plotted. At higher temperatures ($T > 70\,^{\circ}C$) and under pressure ($p > 1.3$ GPa), another phase with the NaCl structure ("NaCl II") forms. It appears that its p,T stability range remains distinctly separate from that of NaCl I even at higher temperatures. The bonding in the two phases is therefore different.[8] We propose that this high-pressure phase is a NaCl type with static disorder, which cannot transform continuously into the type with dynamic disorder because the required activation volume for free rotation under pressure can no longer be accommodated.

At higher pressures and lower temperatures the domain of the other new modification, "NaOH II", borders on that of the NaCl II phase. The NaOH II structure[9] is depicted in Figure 2. It is best described as a deformation variant of the NiAs type in which the Na atoms deviate most from the ideal positions in the aristotype. Because of the high density under these conditions, the OH groups have no chance of rotating freely. We find them in defined orientations, and this forces the cations to shift from their positions. Although the sites of the hydrogen atoms have not yet been detected experimentally, the analysis of the cation shifts shows that the positive ends of the OH dipoles probably point between two Na ions related by translation perpendicular to the plane viewed in Figure 2 rather than toward an adjacent OH group. The suspected orientation of the OH groups is included in the figure.

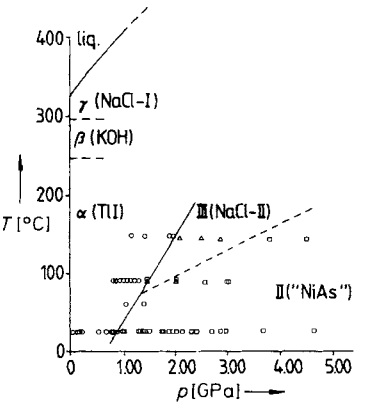

Fig. 1. p,T diagram for NaOH. Normal pressure phases are indicated by Greek letters, high pressure phases by Roman numerals; the assigned structural type appears in brackets.

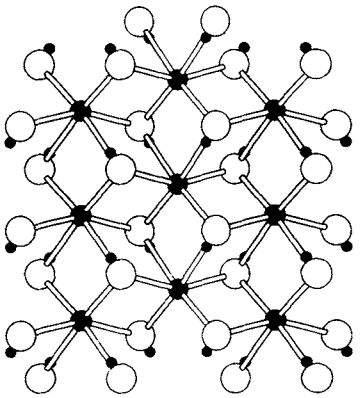

Fig. 2. Structure of the high-pressure phase NaOH II viewed along [001]. Solid circles represent Na, large open circles O, and small solid circles the presumed hydrogen positions.

The diversity of the structural chemistry of the alkali metal hydroxides is governed by the quotient of the radii and the variety of orientations for the OH groups, which leads to hydrogen bonds of different strength. Since their contribution to the energy is relatively small, slight temperature changes can lead to a reorganization of the OH dipoles. Under high-pressure conditions the possibility of hydrogen bond formation becomes less important than the drive to minimize the volume and the interatomic repulsion. To achieve a more dense packing, the phase is forced into an electrostatically less favorable constellation.

[8] The NaCl I phase at normal pressure and 320 °C has the same molar volume as the NaCl III phase at 2 GPa and 120 °C. A continuous transition from NaCl III to NaCl I on increasing the temperature and subsequently reducing the pressure would certainly lead to a distinct increase in volume. The volume changes can only be explained if along the described route a domain of another modification is traversed, which must form by contraction from the phase of type NaCl III on raising the temperature. Such a process implies that $\Delta U > 0$. In fact, differential thermal analysis [3] indicates that other phases exist in the region of the p,T field in question, but their structures are unknown.

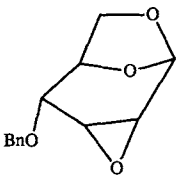
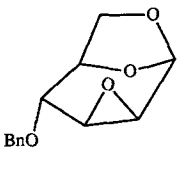
A Simple Route from Glucal to Cerny Epoxides

By *Gilbert Lauer* and *Franz Oberdorfer**

Ring opening of the conformationally fixed "Cerny epoxides" **1** and **2**[1, 2] takes place regio- and stereoselectively with formation of the corresponding Fürst–Plattner products in which the resulting substituents are aligned in *trans*-diaxial fashion. Numerous selectively substituted pyranoses, which are valuable chiral starting materials for enantiospecific syntheses, can be obtained by using this strategy.



1



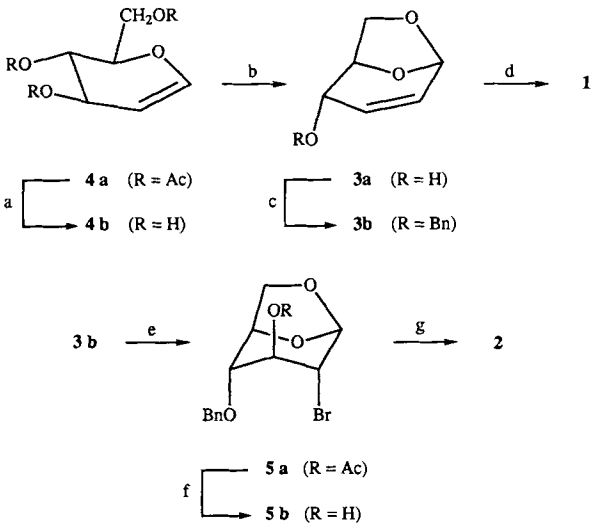
2

Our interest in these diastereomeric compounds came about for the following reason: they force the hexoses out of the stable $^1C_4$ conformation into the ^5H_O conformation, which is higher in energy and easily attacked by nucleophiles, thus enabling a variety of applications. Compounds **1** and **2** are, therefore, ideal starting materials for the selective formation of pyranose derivatives functionalized at C2, C3 or C4. The preparation of such compounds by other methods is usually tedious.

[*] Dr. F. Oberdorfer, Dipl.-Chem. G. Lauer
Deutsches Krebsforschungszentrum
Abteilung Radiochemie und Radiopharmazeutische Chemie
Im Neuenheimer Feld 280, D-W-6900 Heidelberg (FRG)

The known syntheses of **1** and **2** start either from levoglucosan,[2] which is either commercially available but expensive, or only accessible by pyrolysis or from dimers of acrolein.[3] These syntheses are laborious, multistep processes requiring costly separations and providing less than satisfactory yields. As a result, it is hardly surprising that the obvious synthetic potential of the Cerny epoxides has been little used.

We describe here an elegant, short, and new synthetic route to **1** and **2**, which provides both diastereomeric oxiranes without difficulty and in good yield from the readily available tri-*O*-acetyl-D-glucal (Scheme 1).



Scheme 1. Synthesis of **1** and **2** (room temperature, if not stated otherwise). a: **4a**, CH_3OH/LiOH, 10 min, according to Zemplen et al.[4] gave 94% **4b** (colorless needles); b: **4b**, THF, $CuSO_4$ (anhydrous, 7 equiv), reflux, 6 h, gave 42% **3a** (colorless crystals) after chromatography [5]; c: **3a**, DMF, NaH, benzyl bromide, 15 min, according to Bovin et al.[6] gave 61% **3b** (colorless, thin oil); d: **3b**, *m*CPBA (excess), CH_2Cl_2, reflux, 24 h, gave 54% **1** (faintly yellow oil) [7]; e: **3b**, AcOBr, CCl_4, ice bath, 25 min, gave 62% **5a** (colorless, viscous oil) [8]; f: **5a**, K_2CO_3 (2 equiv), CH_3OH/H_2O, 9/1, 3 h, gave **5b** in quantitative yield (colorless oil, slowly separating as crystals when cooled) [9]; g: **5b**, K_2CO_3, CH_3OH/H_2O 9/1, 5 d, gave 85% **2** (colorless crystals) [7].

A retrosynthetic analysis showed that the key compound 1,6-anhydro-2,3-dideoxy-β-D-*erythro*-hex-2-enose **3a**—a derivative of pseudoglucal that is generally obtained from the pyrolysis products of the ivory nut (*phytelephas macrocarpa*) or from cellulose[10]—should also be accessible from glucal **4b** by an intramolecular vinylogous substitution. We have now been able to carry out this reaction, not previously observed with the complex glucal chemistry. The primary alcohol group in glucal was activated for the intramolecular reaction in a dipolar aprotic medium in the presence of a considerable excess of anhydrous $CuSO_4$. Under these conditions compound **4b** underwent condensation with allylic rearrangement to give the bridged glucoside **3a** (42% yield). 2-(D-Glycero-1,2-dihydroxyethyl)furan was formed, as expected, as a side product (22% yield) that was easily separated from **3a** by column chromatography.[5] After subsequent benzylation in the presence of NaH in dimethylformamide (DMF) **1** and **2** could be prepared as desired by selective epoxidation of the double bond in **3b**.

The *exo* oxirane **1** was obtained easily from **3b** by a Prilezaev reaction with an excess of almost anhydrous *m*-chloroperbenzoic acid (*m*CPBA) (54% yield). This method has already proven to be reliable with similar bicyclic unsaturated acetals.[11] The isomeric *endo* oxirane **2** was formed in only

small amounts (< 5%). The *exo*/*endo* ratio did not depend on the steric requirements of the substituents on C4 ($OSiPh_3$, $OSiBn_3$, $OSitBuMe_2$). The *exo*-directing influence arose exclusively from the effect of the 1,6-anhydro configuration. This observation has been confirmed with related monocyclic pseudoglucal derivatives. The oxirane ring was preferentially oriented *trans* to the alkoxy substituent on C1.[12]

The *endo* oxirane **2** was formed stereoselectively from the same starting material if a formally analogous hypobromite was used for the electrophilic attack on the double bond in **3b** instead of a peracid. The addition of acetylhypobromite (AcOBr) to **3b** in CCl_4 gave the hitherto unknown compound **5a** with a *trans*-diaxial arrangement of the newly introduced substituents. Compound **5a** could be isolated from the reaction mixture by chromatography in 62% yield.[8] The bromohydrin **5b** was obtained quantitatively by mild, selective hydrolysis of the acetyl group with K_2CO_3 in aqueous methanol (90%). After complete reaction (about 3 h, monitored with TLC), **5b** was converted (without workup) in a slow (5 d) and clean reaction into the *endo* oxirane **2**.[9] The latter was obtained in 85% yield, based on **5a**.

In the fully analyzed ^{1}H NMR spectrum of compound **5a**[8] all vicinal ^3J couplings are less than 2 Hz, with the exception of $^3J(5,6_{exo})$, 5.8 Hz. The relatively high values for ^4J and ^5J (0.7–1.7 Hz) are quite remarkable and indicate a largely coplanar arrangement of the bonds. These results corroborate an exclusive and rigid $^1C_4$ conformation for the acetate, in which all ring protons are in equatorial positions and the substituents are in an antiperiplanar arrangement. An equilibrium with the possible $B_{0,3}$ conformation (equatorial substituents) in **5a** does not exist, at least not at room temperature. The considerable shift of the resonance frequency of proton H3 to lower field ($\Delta\delta$ ca. 2) in comparison with that in **1** and **2** is caused by the deshielding effect of the carbonyl group of the axial acetyl substituent on C3. This observation confirms the correct position of the acetyl group and our original assumption that the addition of hypobromite to **3b** takes place regio- and stereoselectively. Thus, **5a** is predestined for ring closure to the *endo* oxirane.

The most notable aspect of our new synthetic route for the Cerny epoxides is the evident simplicity of the methods employed. Laborious protecting group chemistry is not needed for preparing the synthetic building blocks **1**, **2**, **3**, and **5** from tri-*O*-acetyl-D-glucal. These compounds, which were previously unknown or could only be prepared by complicated routes, now provide an easy and generally accessible entry to hexoses selectively substituted at C2 to C4.

[1] M. Cerny, J. Stanek Jr., *Adv. Carbohydr. Chem.* **1977**, *34*, 107–164. In addition to numerous examples of the chemistry of Cerny epoxides, this review includes a more detailed explanation of the conformation nomenclature used in the text. Text books on the chemistry of sugars also provide similar information. See, for example, J. Lehmann, *Chemie der Kohlehydrate*, Thieme, Stuttgart, **1976**. The capital letters *C* (chair), *H* (half-chair), *B* (boat), etc. indicate the ring conformation of the pyranose. The indices indicate the numbers of the ring atoms (carbohydrate notation), those which lie above (in tbe direction of the observer, superscript) or those below (away from the observer, subscript) a reference plane. The corresponding reference planes for each of the conformations is formed out of four ring atoms. The index "O" designates the oxygen atom in the pyranose ring.

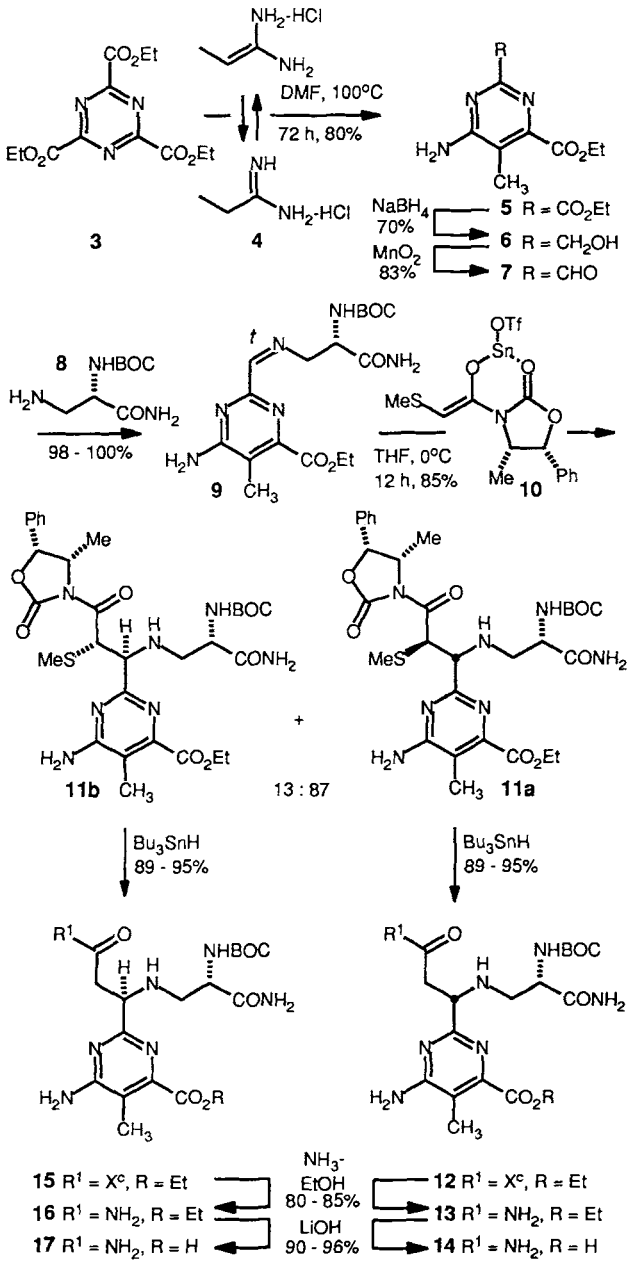
[**] This work was supported by the National Institutes of Health (CA 42056). We thank Q. Dang for the development of the synthesis of **7** (see ref. [6]) and Dr. T. Doyle of Bristol-Myers Squibb for samples of bleoxane from which an authentic sample of bleomycin A_2 and deglycobleomycin A_2 was obtained.

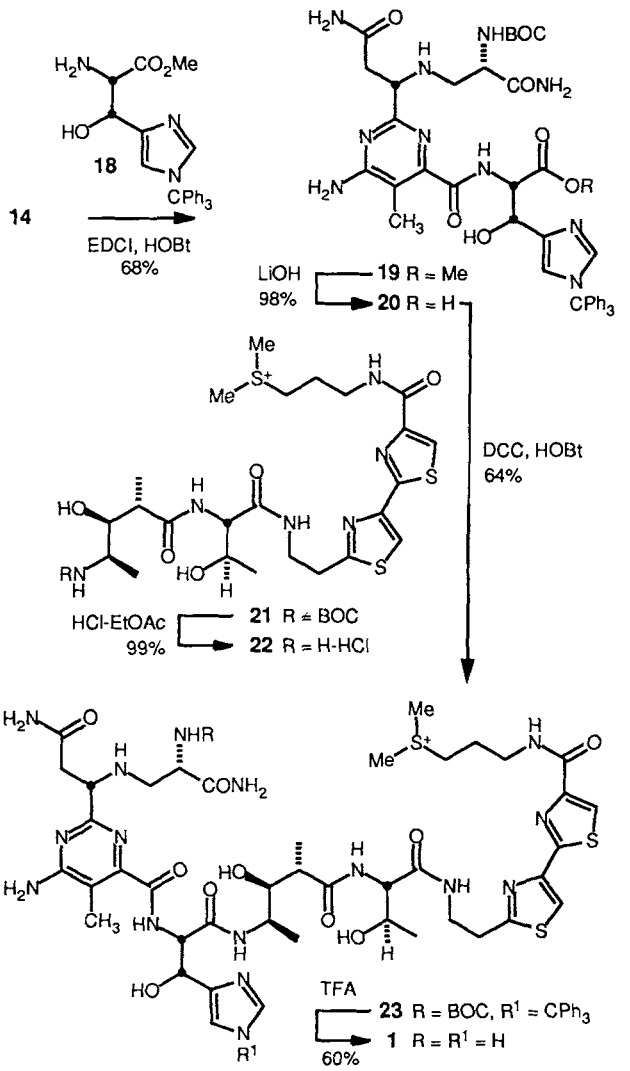
tic drug, is derived from natural sources, and is composed of a mixture of bleomycins of which bleomycin A_2 (70%) and bleomycin B_2 (20%) are the major constituents. Consequently bleomycin A_2,[2] its naturally occurring congeners,[3] its degradation products and semisynthetic derivatives,[4] and synthetic analogues[5, 6] have been the subject of extensive examination. Herein, we detail an efficient, diastereocontrolled total synthesis of (−)-pyrimidoblamic acid (**2**)[7] and deglycobleomycin A_2 (**1**)[2] by an approach applicable to the preparation of the naturally occurring bleomycins and structural analogues. The key elements of the approach to (−)-pyrimidoblamic acid include a one-step preparation of the functionalized pyrimidine nucleus **5** employing the inverse-electron-demand Diels–Alder reaction[8] of 2,4,6-tris(ethoxycarbonyl)-1,3,5-triazine (**3**)[9] with propionamidine hydrochloride (**4**), and a diastereoselective imine addition reaction constituting the first reported stereocontrolled introduction of the C2 acetamido side chain.

Treatment of **3** with **4** (100 °C, dimethylformamide (DMF), 72 h, 80%) provided pyrimidine **5** in a reaction cascade that proceeds by thermal tautomerization of **4** to 1,1-diaminopropene and its [4 + 2] cycloaddition with **3** (Scheme 1).[10] The sequential elimination of ammonia, tautomerization of the resulting imine, and retro-Diels–Alder loss of ethyl cyanoformate provide **5** directly in excellent yield. Selective reduction of the sterically more accessible and electronically more reactive C2 ethoxycarbonyl group of **5** (1.0 equiv $NaBH_4$, EtOH, 5 °C, 150 h, 70%) provided **6**.[6, 10] Oxidation of **6** (10 equiv MnO_2, CH_3CN, 84 °C, 3 h, 83%) followed by condensation of **7** with **8**[6, 10] (10 wt. equiv. 4 Å molecular sieves, CH_3CN, 25 °C, 6 h, 98–100%) afforded **9**.

Addition of the stannous (*Z*) enolate **10**, generated by treatment of the corresponding oxazolidinone[11] (1 equiv, THF, −20 °C, 1 h) with iPr_2NEt (2.2 equiv) in the presence of $Sn(OTf)_2$ (2.0 equiv), to **9** (0.5 equiv) provided a separable 87:13 mixture of the imine addition products **11a**:**11b** (THF, 0 °C, 12 h, 81–85%). The prescribed reaction conditions were derived only through considerable experimentation, and the reaction was found to proceed with a minimal number of protecting groups for the potentially reactive functionality in imine **9**. Key to the success of the diastereoselective imine addition reaction,[12, 13] which pro-



Scheme 1. Synthesis of (−)-pyrimidoblamic acid.



Scheme 2. Synthesis of deglycobleomycin A_2.

vides predominantly the *anti* adduct, was the use of the stannous enolate[14, 15] (2.0 equiv) in the presence of two additional equiv of $Sn(OTf)_2$. Under such conditions the major *anti*-**11a** adduct was found to slowly epimerize to *syn*-**11a** (0 °C, 12 h, 16:1 *anti*:*syn* **11a**; 0 °C, 24 h, 1.8:1 *anti*:*syn* **11a**).[16] Reductive desulfurization of the major diastereomer *anti*-**11a** as well as *syn*-**11a** (3 equiv Bu_3SnH, 0.3 equiv azobisisobutyronitrile (AIBN), C_6H_6, 80 °C, 45 min, 89–95%) followed by aminolysis of **12** (X^c = oxazolidinyl) (16% NH_3–EtOH, 0 °C, 1 h, 80–85%) provided **13**.[18]

Hydrolysis of the ethyl ester **13** (1.5 equiv LiOH, THF/H_2O/CH_3OH 3:1:1, 0 °C, 1 h, 90–95%) provided the well-characterized N^{α}-*tert*-butyloxycarbonyl (Boc) derivative of (−)-pyrimidoblamic acid **14**,[18] and acid-catalyzed deprotection (3 N HCl/EtOAc, 25 °C, 1 h, 100%) of **14** provided (−)-pyrimidoblamic acid (**2**).[18] Subjection of the minor diastereomer **11b** (>20:1 *anti*:*syn*) to the identical sequence provided **15**–**17** and *epi*-(+)-pyrimidoblamic acid.[18]

Direct coupling of **14** with erythro-N^{π}-triphenylmethyl-β-hydroxy-L-histidine methyl ester (**18**)[17] provided **19** (1.05 equiv 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide (EDCI), 1.0 equiv hydroxybenztriazole (HOBt), THF/DMF 2:1, 25 °C, 55 h, 68%), without protection of the primary or secondary amine of **14** (Scheme 2). Methyl ester hydrolysis (1.5 equiv LiOH, THF/CH_3OH/H_2O 3:1:1, 0 °C, 1.5 h, 98%) followed by *direct* coupling of **20** with synthetic tetrapeptide S (**22**)[17] provided **23**,[18] without additional protection of the adorning functionality (3 equiv dicyclohexylcarbodiimide (DCC), 1.0 equiv HOBt, 2.5 equiv $NaHCO_3$, DMF, 25 °C, 72 h, 64%). Final deprotection of **23** (trifluoroacetic acid (TFA), 25 °C, 45 min, 60%) afforded deglycobleomycin A_2 (**1**)[18] identical in all compared respects with authenic material[19] (^1H NMR and IR spectra, high-resolution mass spectrometry, TLC, HPLC).

[15] The stannous enolate **10** proved more effective than the titanium enolate ($TiCl_4$, 20–30% yield, 9:1, **11a**:**11b**) which provided the same products with a comparable level of diastereoselectivity. The di-*n*-butylboronyl enolate proved ineffective.
[16] The isomers *anti*-**11a** and *syn*-**11a** were correlated through their independent conversion to **12**, and the absolute configuration at the newly established amine center was determined with the conversion of **12** to natural (−)-pyrimidoblamic acid (**2**) as well as its incorporation into deglycobleomycin A_2. The assignments of the relative configurations of *anti*-**11a** and *syn*-**11a** were determined through their independent conversion to a cyclic carbamate derived by $NaBH_4$ reduction of the acyl oxazolidinone to the primary alcohol and cyclic carbamate formation through reaction with phosgene. The axial and equatorial disposition of the thiomethyl substituent was determined by ^1H NMR coupling constants, half-width values, and 2D ^1H-^1H NMR spectroscopy. The epimerization of *anti*-**11a** to *syn*-**11a** detailed occurs at the MeS center.

Iodine Azide**

By *Peter Buzek, Thomas M. Klapötke,* Paul von Ragué Schleyer,* Inis C. Tornieporth-Oetting,* and *Peter S. White**

Only four binary iodine nitrogen compounds have been described, all of which are explosive because of the very labile N–I bond[1] and the associated thermodynamic instability: IN_3,[2a, b] $I(N_3)_2^-$,[3] NI_3,[4] and $I_2N_3^+$.[5] Although iodine azide IN_3, the first example of this class of compounds,[2a] has been well known since the beginning of this

W., CRG 920034), the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft (KL 636/2-2) and the Bundesministerium für Bildung und Wissenschaft (program title "Synthesis and structural elucidation of low-molecular-weight compounds").

century, it was only in 1976 that Dehnicke succeeded in its isolation and characterization by vibrational spectroscopy.[2b] Only the $I(N_3)_2^-$ ion could be characterized structurally.[3] $[NI_3 \cdot NH_3]_n$, investigated by Jander et al.[6] by X-ray diffraction methods, consists of chains in the crystal. The N atom is surrounded by I atoms in an almost tetrahedral arrangement. The I atoms have weak covalent bonds (2.53 Å) to NH_3. $[NI_3 \cdot NH_3]_n$ is therefore not a true binary compound. We now report the synthesis of very pure crystalline IN_3, its X-ray structure analysis, and an ab initio calculation of its structure.

The preparation of IN_3 follows a modified literature method.[2a] Iodine and freshly prepared silver azide react in $CFCl_3$ according to Equation (a) to give iodine azide.

$$1.5\,AgN_3 + I_2 \xrightarrow{0\,^\circ C,\ 1\ h,\ CFCl_3} IN_3 + AgI \qquad (a)$$

After removal of AgN_3 and AgI (which are insoluble in $CFCl_3$) by decantation and subsequent evaporation of the solvent at 0 °C (14 Torr), highly pure, bright yellow iodine azide was isolated in yields up to 95% (0.5 g). Sublimation (1 h at 200 Torr N_2 pressure in the sublimation flask) gave single crystals suitable for X-ray analysis. The crude product was kept at 4 °C and the cold finger at 0 °C. The crystals, protected by careful coating with "Kel-F" $(-F_2CCFCl-)_n$, were placed on a glass fiber also coated with Kel-F and mounted immediately on the X-ray diffractometer.

According to the crystal structure analysis IN_3 forms I-N-I-N chains which are arranged along the *a* axis. The terminal N atoms of each N_3 unit (N4, N5) help comprise the chain (Fig. 1). The chains lie roughly in the IN_3 plane and form layers.[7] As expected, the N_3 units are disordered. The

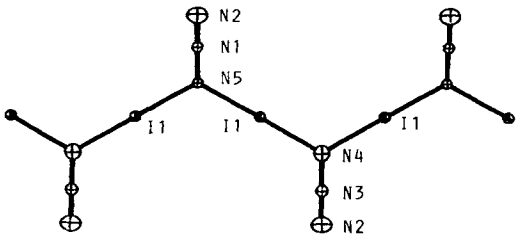

Fig. 1. Structure of IN_3 in the solid state. Selected bond lengths [Å] and angles [°], standard deviation in parentheses: I1-N4 2.264(23), I1-N5 2.30(3), N1-N5 1.19(9), N2-N3 1.05(6), N3-N4 1.28(7), N1-N2 1.09(6); N4-I1-N5 177.2(20), N2-N3-N4 174(6), I1-N4-N3 114.2(14), I1-N5-I1 121(3), I1-N5-N1 117.7(18), N2-N1-N5 171(7).

iodine atoms of different layers lie on top of each other, so that the terminal N atoms of the N_3 unit (N2) are superimposed. Thus the structure could be refined with 100% occupation probability for N2 but with only 50% for the other N atoms. The I and N2 atoms were refined anisotropically, like the remaining N atoms, the latter with only 3.5 electrons on each atom. The insignificantly larger thermal parameters of the N2 atoms are consistent with the slightly different positions of the superimposed atoms.[8f] The N–I distance (2.30 Å) in IN_3 is in remarkable agreement with that observed in the $I(N_3)_2^-$ ion (2.27 Å).[3] Furthermore both IN_3 and $I(N_3)_2^-$ appear to have bent N_3 units with clearly different N–N bond lengths.[3] Only the I-N-N bond angles vary between IN_3 (114°) and $I(N_3)_2^-$ (124°).[3]

We carried out ab initio calculations on the structure of IN_3. The results are in good agreement with the experimental bond lengths and angles of the $(IN_3)_n$ polymer (Fig. 2), as well as with the recently published results of ab initio calcu-

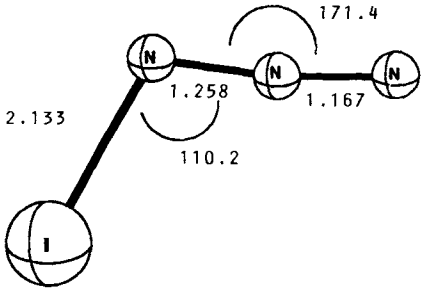

Fig. 2. MP2 optimized structure of IN_3, basis sets: see text, bond lengths in [Å] and angles in [°] [18].

lations on halogen azides.[9] While insignificant, the deviations between the experimental and theoretical values can be attributed to packing effects in the crystal as well as to the twofold coordination of the iodine atom in the chain. Calculations were carried out with the program package Gaussian 90 by using the 6-31 + G* standard basis set for N*,[10, 11] for iodine a quasi-relativistic pseudopotential[12] and a [5s5p1d]/[2s2p1d] (DZ + P) basis set[13] were employed. The geometry was fully optimized, including the effect of dynamic electron correlation, by means of second-order Møller–Plesset (MP(FU)) perturbation theory.

Vapor-pressure measurements at room temperature on solid IN_3 showed that the vapor pressure is about 2 Torr.[14] Consequently a gas-phase IR spectrum could be recorded for the first time.[15] This spectrum, as well as the solution and solid-state spectra,[2b] are in agreement with the C_s molecular symmetry and a bent I-N-N unit. Except for the I-N-N deformation vibration, which is expected to lie below the range of our measurement, all fundamental vibrations could be assigned, and a combination ($\nu_s + \nu_{as}$) and an overtone vibration ($2\nu_s$) observed.[2b, 15] An electron diffraction investigation failed because IN_3 exploded during attempted room-temperature vaporization (lower temperatures are not possible because of the relatively low vapor pressure).[16]

Caution: IN_3 is explosive.[17] The explosive nature increases with greater purity.

Nickel(III)-Promoted DNA Cleavage with Ambient Dioxygen**

By *Chien-Chung Cheng, Steven E. Rokita,** and *Cynthia J. Burrows**

Chemical modification of nucleic acids promoted by transition metal complexes sees utility in structure elucidation, gene manipulation, and chemotherapeutics. For in vivo applications, reactions involving transition metal catalyzed DNA oxidation should rely upon the physiologically available oxidant O_2 rather than hydroperoxides and peroxyacids commonly used in vitro.[1, 2] Moderate reactivity of a metal complex with O_2 is desirable since highly reactive species might be too unstable for biological use. Only a few nickel complexes are known to activate O_2.[3] Pentaaminedioxidonickel(II) complexes are excellent candidates for this chemistry; their reactivity with O_2 has been documented by Kimura and co-workers[4] and recently reinvestigated by Martell et al.[5] Although little DNA site-specificity would be expected with these simple compounds, such specificity may not be required for many applications. In fact, most DNA-targeted drugs show little or no sequence-specificity.

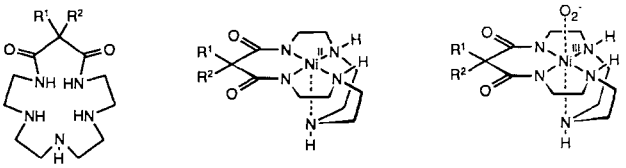
[**] Chemistry of Nickel with Nucleic Acids, Part 4. This work was supported by grants from the Stony Brook Center for Biotechnology sponsored by the New York State Science and Technology Foundation, the American Cancer Society, and the National Science Foundation (CHE-9006684). – Part 3: J. G. Muller, X. Chen, A. C. Dadiz, S. E. Rokita, C. J. Burrows, *J. Am. Chem. Soc.* **1992**, *114*, 6407.

Macrocycles **1a** and **1b** were previously reported to form pentacoordinate complexes [Ni^{II}L] (L = **1a**, **1b** − 2H) in mildly basic aqueous solutions.[4] These purple compounds turn brown on exposure to O_2 and are proposed to have the hexacoordinate nickel(III)–superoxido structure shown as **3**.[4] The complexes are stable for minutes to hours depending upon the ligand substituents. Earlier studies demonstrated the capacity of **3a, b** to oxidize benzene to phenol[4a] and hydroxylate its own ligand[5] at the R^1,R^2 position.



1 **2** **3**

a $R^1 = R^2 = H$
b $R^1 = CH_2C_6H_5$, $R^2 = H$
c $R^1 = F$, $R^2 = H$
d $R^1 = F$, $R^2 = CH_2C_6H_5$
e $R^1 = R^2 = CH_3$

Tetracoordinate nickel(II) complexes have recently been shown to display interesting DNA reactivity in the presence of monopersulfate HSO_5^-, including specific recognition of guanine units in single-stranded regions of DNA.[1] In the present study, the nickel complexes of ligands **1b**–**1e** were examined for reactivity with plasmid DNA in the presence of only O_2 as oxidant. Nickel- and O_2-dependent strand scission was observed for complexes of **1b** and **1c**. These ligands initially form green complexes with Ni^{2+} in H_2O in which only the three amine nitrogen atoms of the macrocycle are coordinated. Raising the pH to about 9 effects amide deprotonation to yield the pentacoordinate purple complexes **2b**[4b] and **2c**, which remain purple on lowering the pH back to 7.5. Complexes **2b** and **2c** have nearly identical properties: $E_{1/2}$ ($Ni^{III/II}$, pH 9.2, K_2HPO_4, vs. Ag/AgCl) = 0.28 V for **2b** and 0.31 V for **2c**; $\lambda_{max}(H_2O)$ = 350 and 520 nm for **2b**, and 344 and 512 nm for **2c**. Both form brown O_2 complexes, **3b** (λ_{max} = 270 and 290 nm) and **3c** (λ_{max} = 269 and 306 nm), on exposure to air for 15 min. Complex **3c** is stable for >1 h at pH 7.5. Most studies were carried out using **3c** because of the ease of ligand synthesis.[6]

In DNA modification studies, circular plasmids were used to monitor the amount of oxidative strand scission. Both **3b** and **3c** were equally reactive and exhibited concentration-dependent single-strand cleavage of supercoiled form I DNA to nicked form II DNA (see Fig. 1 A). Complete DNA

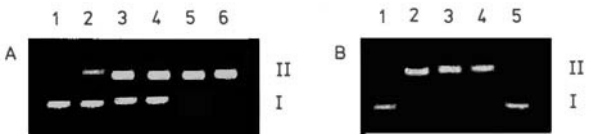


Fig. 1. A: Concentration dependence of the DNA nicking reaction (form I → form II) with complex **3c**. DNA (2.2 μM base pair) alone (lane 1) and treated with 30 μM (lane 2), 60 μM (lane 3), 120 μM (lane 4), 180 μM (lane 5), and 240 μM (lane 6) **3c**. B: Quenching studies of **3c** and comparison of the reactivity of **3d**. Lane 1, DNA only; lanes 2–4, 200 μM **3c**; lane 2, no quenching agents; lane 3, 50 mM mannitol; lane 4, 1.5 M EtOH; lane 5, 200 μM **3d**, no quenching agents.

nicking was observed after 45 min at room temperature when 180 μM **3c** was used with the plasmid pBR322. The reactivity of the precursor complex **2c** was also checked. When **2c** was added directly to a solution containing plasmid

DNA without preforming the O_2 complex, the nickel(II) complex was capable of slowly cleaving DNA under an ambient air atmosphere. The final extent of reaction in either case was the same, but the time required for reaction was 6–8 h for **2c** versus 45 min for **3c**. Higher concentrations of **2c** or **3c** led to further fragmentation of form II DNA. Subsequent reaction did not occur adjacent to the first site of modification since the accumulation of linearized DNA (form III) was not observed. A heterogeneous set of products was formed instead and detected as broad, unstructured bands of DNA derivatives by gel electrophoresis. $Ni(OAc)_2$ (180 μM) had no effect on plasmid DNA under the reaction conditions used for **2c** and **3c**.

Quenching studies were performed to help identify the oxidant responsible for nicking. The reaction was unaffected by 50 mM mannitol and by 1.7 M ethanol (Fig. 1 B, lanes 3 and 4); both typically quench reactions involving $HO^{\bullet}$ radicals. On the other hand, addition of superoxide dismutase (0.94 μM) quenched about 50% of the reaction. This effect did not arise from scavenging of an oxidant by proteins in general, but was instead specific to the catalytic activity of this enzyme. RNase A (1.16 μM), in contrast, had no effect on the reaction of **3c** and plasmid DNA. These experiments suggest that the superoxido complex **3c**, O_2^- itself, or a decomposition product of O_2^- may be involved in DNA oxidation leading to strand scission. In a subsequent study, however, incubation of 520 μM KO_2 (from a DMSO solution containing excess [18]crown-6 for initial solubilization) yielded no detectable DNA scission after 20 min. This initial examination thus suggests a crucial role for **3c**.

In an attempt to optimize the reactivity, the fluorobenzyl ligand **1d** was synthesized. Previous work [4, 5] suggested that the benzyl substituent provides a hydrophobic pocket for stabilization of the O_2 complex and that further substitution at this site might prevent the competing side reaction of ligand hydroxylation and inactivation of the complex. Both ligand **1d** and the known compound **1e** [7] formed green complexes on coordination of Ni^{2+}, but surprisingly, both failed to give stable purple complexes (**2d, e**) at higher pH, turning instead to yellow-brown. Also, both failed to induce plasmid DNA strand scission (e.g. Fig. 1 B, lane 5), indicating the high sensitivity of this overall process to substituents on the ligand. Further mechanistic studies are expected to provide insight in the design of optimum nickel complexes.[8]

Finally, the specificity of the cleavage reaction mediated by **3c** was monitored using the hairpin-forming oligonucleotide d(AGTCTATGGGTTAGACT) previously described.[1b] Strand scission occurred directly after incubation but was enhanced by a final treatment with piperidine.[1] High-resolution gel electrophoresis revealed cleavage at almost all sites and little nucleotide-, conformation-, or sequence-specificity could be discerned. This is consistent with a picture in which an octahedral Ni^{III}–O_2^- complex such as **3** is coordinatively saturated, and the metal is unable to participate in direct DNA binding and recognition. Nevertheless, site-specificity, if desired, should be possible if the standard DNA binding agents are appended to the macrocycle.[9] Such agents would be expected to increase greatly the efficiency of the nickel–superoxido complex for DNA oxidation, making lower concentrations practical.[10]

These results are significant because they show that appropriately designed nickel complexes may cause DNA scission under physiological conditions using only O_2 at ambient pressure. No additional reagents, light, or electrochemistry are required for reaction. Variation of substituents on the macrocycle will now allow careful modulation of the overall activity of the nickel complex.

Experimental Procedure

1c: A solution of diethyl fluoromalonate (6.3 mmol) and tetraethylenepentaamine (6.1 mmol) in anhydrous ethanol (200 mL) was heated to reflux for 24 h. After the reaction mixture was concentrated, the crude material was recrystallized from CH_3CN/CH_3OH to provide a white solid in 42 % yield. ^1H NMR ($CDCl_3$): $\delta = 7.27$ (br s, 2H), 5.22 (d, 1H, $J = 47.4$ Hz, exchangeable with D_2O), 3.61 (m, 2H), 3.35 (m, 2H), 2.56 - 2.86 (m, 12H), 1.65 (br s, 3H); ^{13}C NMR ($CDCl_3$): $\delta = 164.9$, 86.9 (d, $J = 196$ Hz), 48.8, 48.4, 48.3, 39.0. IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3529, 2837, 1695, 1537, 1276, 1127 cm^{-1}. Correct C, H, N analysis.

1d: Diethyl fluoromalonate (6.18 mmol) was added dropwise to excess NaH in THF at 0 °C. After 20 min benzyl bromide (7.02 mmol) was added, and the clear solution was stirred at room temperature for 6 h. Water was added to quench the reaction and the product extracted with CH_2Cl_2. The collected extracts were dried over $MgSO_4$, filtered, and concentrated. Distillation at reduced pressure provided pure diethyl benzylfluoromalonate (38% yield) and recovered diethyl fluoromalonate (60% yield). Diethyl benzylfluoromalonate was used in the same cyclization procedure reported for **1c**. The crude product was chromatographed on silica gel with $CHCl_3$:CH_3OH:NH_4OH = 10:2:0.2 to yield a white solid in 28% yield. ^1H NMR ($CDCl_3$): $\delta = 7.18$ (m, 5H), 7.09 (br s, 2H), 3.5 (m, 2H), 3.48 (d, 2H, $J = 25.5$ Hz), 3.04 (d, 2H), 2.1–2.8 (m, 12H), 1.58 (br s, 3H); ^{13}C NMR (CD_3OD): $\delta = 167.5$, 133.9, 130.1, 127.8, 126.8, 98.6 (d, $J = 202$ Hz), 47.4, 47.1, 38.6, 38.3, 38.1. FAB-MS *m/z* 366 ($M+1$).

DNA Studies: Aqueous solutions (pH 7.5) of nickel complexes **2** were exposed to air for 15 min to provide the O_2 complexes **3**. Plasmid DNA pBR322 (2.2 μM per base pair) and nickel complex (30–240 μM) in 10 mM phosphate (or tris) buffer at pH 7.48 containing 5 mM NaCl was allowed to react under ambient air at room temperature for 45 min. Conversion of form I to form II DNA was detected by gel electrophoresis on 1% agarose with ethidium bromide staining. In control experiments nickel complex was added. Superoxide dismutase from bovine erythrocytes was purchased from Sigma.

Propionyl-Aza(dethia)coenzyme A as Pseudosubstrate of the Biotin-Containing Transcarboxylase

By *Harald Martini* and *János Rétey**

The exact details of how biotin-containing carboxylases work are still a matter of dispute.[1] The ingenious experiments of Lynen et al.[2] established the intermediacy of 1′*N*-carboxybiotin in the carboxylation process. It is, however, still unclear how 1′*N*-carboxybiotin formation is coupled to ATP hydrolysis and how the carboxyl group is transferred to

[*] Prof. Dr. J. Rétey, Dr. H. Martini
Lehrstuhl für Biochemie im Institut für Organische Chemie der Universität
Richard-Willstätter-Allee, D-W-7500 Karlsruhe 1 (FRG)

the substrate, for example, propionyl-coenzyme A (CoA). Retention of configuration in the substitution of a H atom by a carboxyl group[3-7] as well as a distinct tritium transfer from one noncarboxylated substrate to the other (propionyl-CoA and pyruvate) in the transcarboxylase reaction seemed to support a concerted mechanism (Fig. 1).[8] Later results

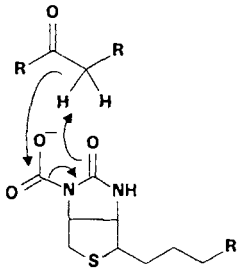

Fig. 1. Concerted mechanism of carboxyl transfer from 1'*N*-carboxybiotin to the substrate.

obtained using β-fluoropropionyl-CoA as pseudosubstrate[9] and more decisively, results from a double isotope fractionation assay[10, 11] showed, however, that the carboxyl transfer —most likely to the enolate of the substrate— is a stepwise process. Figure 2 illustrates the two remaining mechanistic possibilities. Variant *a* represents a direct nucleophilic attack by the substrate enolate on the carboxyl group of 1'*N*-carboxybiotin, whereas according to variant *b* the latter would be first decarboxylated and the CO_2 trapped in situ by the enolate.[1]

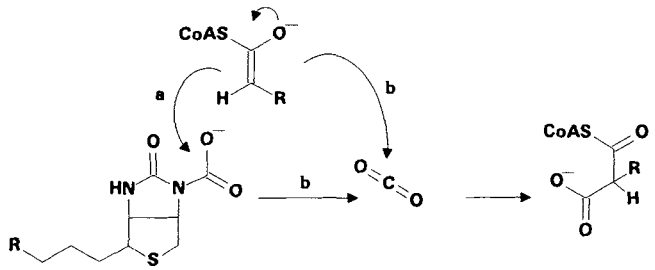

Fig. 2. Stepwise mechanisms of carboxyl transfer from 1'*N*-carboxy-biotin to the substrate. Variant *a*: direct attack of the substrate enolate; variant *b*: prior decarboxylation of 1'*N*-carboxybiotin followed by trapping the locked CO_2 by the substrate enolate.

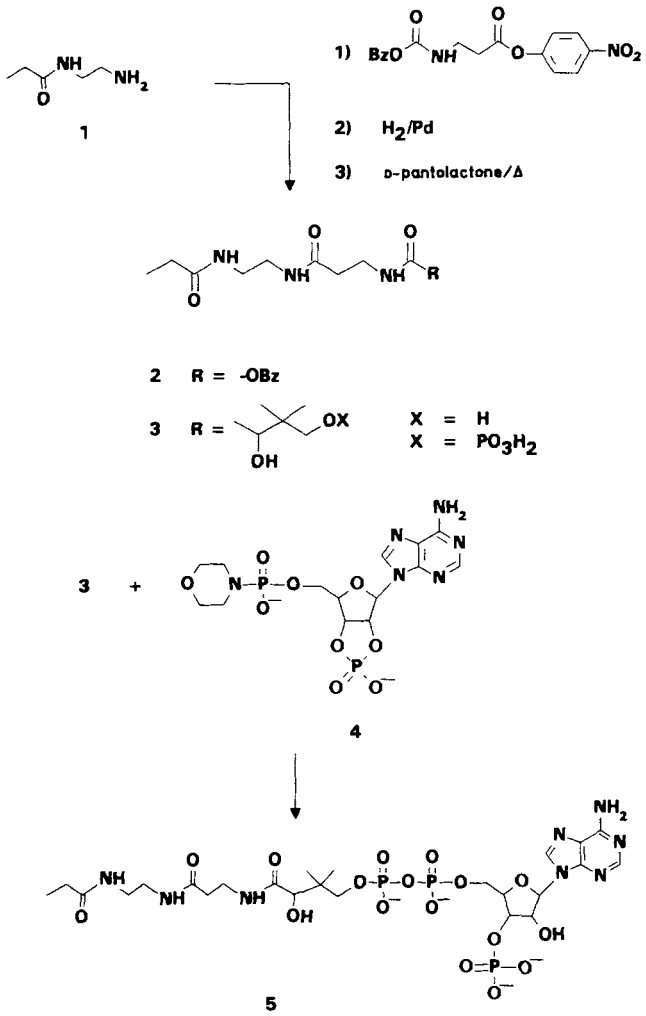
To distinguish between these two variants we synthesized propionyl-aza(dethia)coenzyme A (**5**) starting from *N*-(2-aminoethyl)propionamide (**1**). We followed essentially the same strategy that has been applied for the synthesis of propionyl-carba(dethia)coenzyme A.[12] Amide **1** was treated with the *p*-NO_2-phenyl ester of (*Z*)-β-alanine to yield **2**. After hydrogenolytic removal of the protecting group the product was condensed by melting with D-pantolactone to obtain **3** (X = H). Phosphorylation of **3** (→ X = PO_3H_2) was performed with β-cyanoethylphosphate.[13] Finally, **3** (X = PO_3H_2) was coupled with adenosine-2',3'-cyclophosphate-5'-morpholidate (**4**). After opening the 2',3'-phosphate ring by acid, the resulting propionyl-aza(dethia)coenzyme A (**5**) was separated from the 2'-phosphoisomer (iso-**5**) by chromatography and was spectroscopically characterized.[14] In a coupled optical enzyme assay **5** seemingly behaved as a substrate of propionyl-CoA-oxaloacetate transcarboxylase (oxaloacetate = 2-oxosuccinic acid) from *P. shermanii*. The kinetic constants, K_m and V_{max}, for propionyl-CoA are 0.47×10^{-4} M and 2.40 μmol min^{-1} mL^{-1}, respectively, and for **5** 1.29×10^{-4} M and 0.11 μmol min^{-1} mL^{-1}, respectively. Investigation of the product by ^{1}H NMR spectroscopy revealed, however, that no methylmalonyl-CoA was formed; that is, the carboxyl group of oxaloacetate was not transferred to **5**. Nevertheless, the coupled enzyme assay proved the formation of pyruvate. It must thus be concluded that **5** induced the enzymatic decarboxylation of oxaloacetate.



To produce a direct proof for this decarboxylation we applied instead of oxaloacetate its 3-fluoro analogue. 3-Fluorooxaloacetate is a substrate of the transcarboxylase,[15] and its decarboxylation can be monitored directly by ^{19}F NMR spectroscopy. The ^{19}F signal for fluorooxaloacetate appears at $\delta = -204$ (trifluoroacetate $\delta = -77$), that of fluoropyruvate at $\delta = -230$. Monitoring the reaction for 5 hours showed that in the presence of propionyl-aza(dethia)coenzyme A **5** (12 mM) about double as much 3-fluorooxaloacetate was decarboxylated as with transcarboxylase alone.

The induction of decarboxylation can be interpreted as follows: Binding of pseudosubstrate **5** causes a conformational change of the enzyme that is necessary to catalyze the decarboxylation of 1'*N*-carboxybiotin. On the other hand the low acidity of the α-CH_2 group does not allow enolate formation from **5**, and thus its carboxylation by the "naked" CO_2 locked at the active site cannot occur. Our results support a two-step mechanism of the carboxyl transfer: 1) formation of CO_2 from 1'*N*-carboxybiotin, 2) trapping the locked CO_2 by the enolate of the substrate (Fig. 2, variant *b*).

Whether the enolate of biotin, produced on decarboxylation, functions as base for the deprotonation of the substrate, as discussed by J. R. Knowles,[1] is unclear. In contrast to **5**, propionylcarba(dethia)coenzyme A is actually carboxylated to its methylmalonyl derivative in the transcarboxylase reaction.[12]

Ca_2PN_3: A New Phosphorus(v) Nitride with One-Dimensional Infinite Chains of Corner-Sharing PN_4 Tetrahedra**

By *Wolfgang Schnick** and *Verena Schultz-Coulon*

The systematic investigation of binary and higher phosphorus(v) nitrides has uncovered a variety of P–N substructures which, despite the comparatively small number of known compounds, show clear structural analogies to silicates and phosphates.[1–6] The characteristic structural elements found in all the phosphorus(v) nitrides are PN_4 tetrahedra which may be connected by common vertices showing differing degrees of condensation: Isolated PN_4^{7-} anions are found in Li_7PN_4,[1] whereas in $Li_{12}P_3N_9$ three PN_4 units form $P_3N_9^{12-}$ anions, analogously to cyclotrisilicates.[2] The smallest imaginable cage structure that can be formed from corner-sharing PN_4 tetrahedra has been found in $Li_{10}P_4N_{10}$,[3] which contains the $P_4N_{10}^{10-}$ anion, the nitrido analogue of molecular phosphorus(v) oxide. HPN_2, $LiPN_2$,[4, 5] and $Zn_7[P_{12}N_{24}]Cl_2$[6] each exhibit three-dimensional infinite network structures of corner-sharing PN_4 tetrahedra, $_\infty^3[PN_{4/2}^-]$, which can be considered as the topological equivalent of β-crystobalite or of the sodalite framework, respectively. Low-dimensional structures of corner-sharing PN_4 tetrahedra have not yet been proven for phosphorus(v) nitrides. Like silicate compounds with chain or layer structures the analogous phosphorus nitrides are expected to have P:N ratios of 1:3 or 2:5. In contrast, lithium phosphorus nitrides with these ratios contain "dreier" rings or $P_4N_{10}^{10-}$ cages, respectively.

By the reaction of stoichiometric amounts of the binary nitrides Ca_3N_2 and P_3N_5 [Eq. (a)] we have now successfully

$$2\,Ca_3N_2 + P_3N_5 \xrightarrow[\text{W crucible, } N_2 \text{ atm.}]{800\,^\circ C,\ 14\,d} 3\,Ca_2PN_3 \qquad \text{(a)}$$

synthesized pure calcium phosphorus(v) nitride Ca_2PN_3[7] and elucidated its crystal structure.[8] In the solid one-dimensional infinite "zweier" chains exist running parallel [100] (Fig. 1). These chains exhibit a perodicity of two PN_4 tetrahedra and an extreme stretching factor $f_s = 1.0$ similar to that found in johannsenite, $CaMn[Si_2O_6]$, ($f_s = 0.98$).[9] The P–N bond lengths to the terminal nitrogen atoms (average value: 162.5 pm) are shorter than those within the chains (167.4 pm). This finding corresponds qualitatively with the bonding in $Li_{12}P_3N_9$ and $Li_{10}P_4N_{10}$ and can be explained by an increased double bond character or by polar bonding contributions. The Ca^{2+} ions in Ca_2PN_3 are coordinated in a distorted pentagonal bipyramidal manner by the nitrogen atoms of the PN_3 chains, whereby one Ca^{2+} ion connects three chains with one another.[10] The Ca–N contact distances (242–300 pm) lie approximately in the region of the sum of the ionic radii.

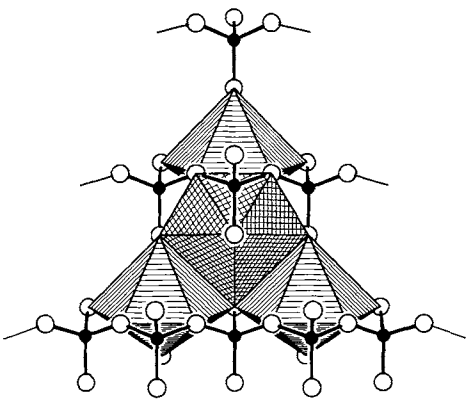

Fig. 1. Crystal structure of Ca_2PN_3 (view along [001]). The PN_3 chains along [100] are clearly visible. The two crystallographically independent Ca atoms are each coordinated in a distorted pentagonal-bipyramidal fashion by nitrogen atoms of the PN_3 chains. The coordination spheres around the Ca^{2+} ions are shown as closed polyhedra. Phosphorus: black, nitrogen: white.

Despite the observed topological similarity of the P–N substructures in this compound (as in other phosphorus(v) nitrides) with isosteric silicate anions, it appears that the structure rules as formulated by Liebau for silicates[11] cannot be applied directly to phosphorus(v) nitrides: cyclic silicate anions are less stable than chainlike arrangements due to electrostatic repulsive forces between the oxygen atoms. In the case of phosphates, this difference is leveled out due to lower charge densities on the PO_4^{3-} units. In contrast, for phosphorus(v) nitrides (PN_4^{7-}), this repulsive effect is expected to be significantly enhanced due to the higher charges. In addition, a significant destabilization of cyclic and branched silicate anions is observed due to the influence of hard electropositive counterions (Li^+, Mg^{2+}), whereas with soft cations (Ca^{2+}, Na^+, K^+) the opposite effect occurs.

Although any generalization is difficult owing to the small number of phosphorus(v) nitrides known to date, the appearance of $_\infty^1[PN_2N_{2/2}^{4-}]$ chains in the calcium compound and $[P_3N_9^{12-}]$ "dreier" rings in the lithium compound is nev-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

ertheless surprising. Also, the existence of $[P_4N_{10}^{10-}]$ cages in $Li_{10}P_4N_{10}$, for which no isosteric silicate anion is known, is a further example of the divergent structural behavior of phosphorus(v) nitrides compared to silicates. Possible reasons for this could be, in particular, in comparison to the Si–O bonds, the higher covalent character of the P–N bonds, longer P–N bond lengths and, related to this, the larger P–P distances between neighboring tetrahedral centers and a preference for smaller bond angles at the bridging nitrogen atoms. Thus, P–N bonds are on average about 10 pm longer than Si–O bonds of comparable bond strength.[12] A simple estimation of the degree of covalency of the P–N bonds based on the occurring differences in electronegativity (Pauling)[13] gives a distinctly higher value than that found for the more polar Si–O bonds (P–N: 78%, Si–O: 50% covalent). These two factors result in a smaller electrostatic repulsion between centers of neighboring tetrahedra for the phosphorus(v) nitrides. Cosequently, for the P-N-P bond angles an average value of about 120° is observed which is significantly smaller than the ideal value for the Si-O-Si bond angles in silicates (140°) as given by Liebau.[14, 15]

The coordinative requirements of the Ca^{2+} ions in Ca_2PN_3 could be responsible for the formation of the PN_3 "zweier" chains found in this compound. Likewise, in Mg_2PN_3, which crystallizes in an ordered wurtzite superstructure variant,[16] infinite chains of corner-sharing PN_4 tetrahedra are probably present. We are currently working on a more accurate determination of the structural data for this compound.

Experimental Procedure

Stoichiometric amounts of the binary nitrides Ca_3N_2 (synthesized from pure alkaline earth metal in a flow of nitrogen gas, 950°C, 1 h, heating rate 150°C h^{-1}) and P_3N_5 were homogenized in a micro-ball mill under an argon atmosphere (glove box, MBRAUN, Garching (FRG); $O_2 < 0.4$ ppm, $H_2O < 0.1$ ppm). The reaction mixture was sealed under a pure nitrogen atmosphere in a tungsten crucible in a quartz ampoule and finally allowed to react at 800°C (14 days). Under these conditions, Ca_2PN_3 was obtained in a pure form as a light beige microcrystalline powder.

[7] Elemental analyses were performed by first dissolving the product obtained in dilute H_2SO_4 at 180°C and 10 bar. The amount of calcium was determined by complexometric titration with EDTA, phosphorus photometrically as molybdovanadatophosphate, and nitrogen photometrically as indophenol. Parallel to this, the solid product was analyzed by energy dispersive and wavelength dispersive X-ray microanalyses (EDX: Ca, P and WDX: absence of oxygen). The presence of hydrogen (as N-H groups) was excluded by use of IR spectroscopy.

Reductive Ring-Opening of Oxabicyclic Compounds with Diisobutylaluminum Hydride. Application to the Synthesis of the C_{17}–C_{23} Subunit of Ionomycin**

By *Mark Lautens*,* *Pauline Chiu*, and *John T. Colucci*

The development of methodology for the construction of polypropionate and polyacetate subunits is of critical importance to the preparation of many natural products.[1–3] The aldol condensation and other carbonyl addition approaches have been widely used to address this challenge in spite of the inherently iterative nature of this strategy. We have recently reported an alternative synthetic sequence that utilizes nucleophilic ring-opening of oxabicyclic compounds to generate cyclic and acyclic fragments related to *anti* propionate aldol constructs with up to five contiguous stereocenters.[4, 5] This methodology has been applied to the synthesis of the C_{21}–C_{27} subunit of rifamycin.[6] Herein, we describe a complementary sequence using a reductive ring-opening which assembles stereochemical arrays currently prepared by acetate aldol reactions. We also highlight the efficiency of this strategy in a synthesis of a fragment of the ionophore ionomycin.

In a previous study, we found that Grignard reagents bearing β-hydrogen atoms effect the slow reductive ring-opening of oxabicyclo[3.2.1] and -[2.2.1] substrates.[7] This reaction occurred only in the presence of *excess* magnesium bromide which indicated that a Lewis acidic component was crucial to the success of the reduction. However, the scope and regioselectivity of this reaction was limited. A survey of other hydride sources identified diisobutylaluminum hydride (DIBAH) as a new and effective reagent for reducing oxabicyclic substrates.[8, 9] Cycloalkenols with up to four contiguous stereocenters are generated in one step from readily available starting materials.

In a typical reaction, oxabicyclic substrates such as **1a** were treated with excess DIBAH (1.5–6 equiv) in refluxing hexanes [Eq. (a), TBDS = *tert*-butyldimethylsilyl]. The ma-

jor product **2a** was accompanied by a minor side product **3a**. The formation of this overreduced product could be minimized by decreasing the amount of DIBAH as well as avoiding prolonged reaction times. Thus, treatment of **1b** with 1.5 equiv DIBAH for 3 h yielded only **2b** and unreacted starting materials (25%). The high yield of **2a** compared to **3a** is significant since it reveals a reversal in the usual rates of hydroalumination of cycloalkenes.[10] Additional strain in the bicyclic dihydrofuran compared to cyclopentene, or complexation of the bridging oxygen to the Lewis acidic DIBAH might be responsible for this reversal. Formation of **3a** and **3b** can also be achieved by increasing the ratio of DIBAH to substrate and the reaction time.[11]

7 [b]	 **16**	16	 **17**	80

[a] Reaction conditions: 6 equiv DIBAH in refluxing hexanes. [b] 6 equiv DIBAH in refluxing ether. [c] Yields of isolated, analytically pure material. [d] Could not be separated from the doubly reduced product, yield estimated from the ^{1}H NMR spectrum of the mixture.

The data in Table 1 shows the generality of the reaction. Substituents at all positions were tolerated, and every oxabicyclic substrate effectively underwent reductive ring-opening. Substrates included compounds with unprotected hydroxyl groups (entries 1–6), and oxabicyclo[3.2.1] compounds with substituents at the bridgehead positions (entries 3,5). The more strained oxabicyclo[2.2.1] substrate **16** was reduced under even milder conditions and in very good yield (entry 7).

Highly regioselective opening of an unsymmetrical substrate **18** was also achieved; the selectivity of this reaction could be manipulated by varying the substituent at C_3 [Eq. (b)]. Hydroalumination of the protected alcohol **18a** occurred regioselectively placing the bulky dialkylaluminum at the sterically less hindered position. Subsequent elimination of the bridging oxygen atom β to the aluminum atom provided **19a**. Treatment of **18b** with DIBAH alone resulted in virtually no selectivity. However, when **18b** was deprotonated with MeLi prior to hydroalumination, the major product was the regioisomer **20b**. These results demonstrate that the remote *endo* alkoxide group exerts a directing effect on the mode of the hydroalumination reaction. Previous work in our laboratories has established that double bonds in oxabicyclic compounds with an *endo* alkoxide function at C_3 are more reactive toward organolithium reagents.[6] We are currently investigating the stereochemistry of the hydroalumination reaction (i.e. *exo* or *endo* addition) and also examining specific applications for the observed selectivity.

5 equiv DIBAH

The following concise synthesis of the C_{17} to C_{23} subunit of ionomycin serves to highlight the efficiency of the reductive ring-opening reaction (Scheme 1).[12] Cycloheptenol **2b**, obtained from the reductive ring-opening of **1b**, was subjected to an oxidation–reduction sequence to invert the stereochemistry at C_{21}, producing **21** (>10:1 selectivity) in an overall yield of 90%. It is noteworthy that the reductive ring-opening of the less readily available oxabicyclic alcohol **14**[13] directly generated cycloheptenol **15** with the correct stereochemistry (Table 1, entry 6). Protection of the alcohol as a *p*-methoxybenzyl ether (80%), followed by ozonolysis

and reductive workup with $NaBH_4$ afforded the acyclic heptanediol **22**. Finally, treatment of **22** with DDQ under anhydrous conditions gave **23**, the product of oxidative cyclization (72%).[14] The synthesis of the fully differentiated ionomycin subunit was accomplished in six steps from the oxabicyclic substrate **1b** (31% overall yield).[15]

Experimental Procedure

The substrate was dissolved in anhydrous hexanes to make a 0.1 M solution. After the solution was cooled to 0 °C, 1–6 equiv neat DIBAH was added dropwise with stirring. Then the reaction mixture was heated to reflux and the progress followed by thin-layer chromatography. When the reaction was complete, the reaction mixture was diluted with ether, cooled to 0 °C, and quenched with a saturated solution of NH_4Cl. Stirring at room temperature for about 15 min produced a white gel which was dissolved by the dropwise addition of 10% H_2SO_4. The organic layer was separated and the aqueous layer was extracted three to five times with ethyl acetate. The combined organics were dried over anhydrous magnesium sulfate, and the solvent was removed in vacuo. The crude product was purified by flash chromatography on silica gel.

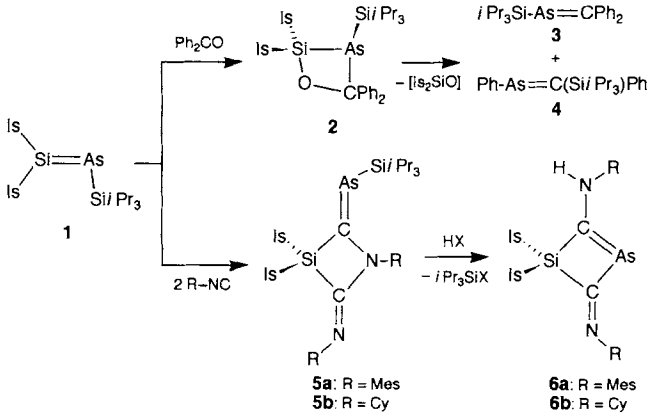
Novel Arsaalkenes from an Arsasilene Derivative and Isocyanides**

By *Matthias Driess,* Hans Pritzkow,* and *Michael Sander*

Dedicated to Professor Robert West on the occasion of his 65th birthday

Recently we reported a simple synthetic route to the first arsasilene $Is_2Si{=}AsSiiPr_3$ (**1**) (Is = 2,4,6-$iPr_3C_6H_2$).[1] The high reactivity of **1** allowed the synthesis of new arsasila heterocycles, which are suitable, for example, as synthetic equivalents for alkylidenarsanes ("arsaalkenes"). Thus, the thermolysis of 1,2,3-oxaarsasilacyclobutane **2**,[1] which is accessible from **1** and Ph_2CO, leads to the formation of the arsaalkenes **3** and **4** (Scheme 1). Bickelhaupt et al., Becker et. al, and Tzschach et al.[2] previously reported arsaalkenes, however, their structures and reactivity have been less investigated than phosphaalkenes. To our knowledge the only arsaalkene structurally characterized so far is the arsaalkenyliron complex $[(\eta^5\text{-}C_5H_5)(CO)_2Fe{-}As{=}C(OSiMe_3)tBu]$.[3] We have now found that the Si=As bond is extremely reactive towards organic isocyanides, and that these reactions open a new, unusual route to arsaalkenes.



Scheme 1. Syntheses of the arsaalkenes **3**–**6** from **1** and benzophenone or from **1** and isocyanides. Mes = 2,4,6-trimethylphenyl, Cy = cyclohexyl, Is = 2,4,6-triisopropylphenyl.

Compound **1** reacts with RNC (R = Mes, *cyclo*-C_6H_{11}) at −80 °C, independent of the chosen stoichiometry, in the molar ratio 1:2 to give the arsaalkenes **5** (Scheme 1). This reactivity of the Si=As bond towards isocyanides is similar to the behavior of the C=Si bond in silenes. Thus silenes also react with isocyanides in a 1:2 molar ratio leading to 2-alkylidene-4-imino-1-aza-3-silacyclobutanes,[4] which are isostructural with **5**. In contrast, the Si=Si bond in disilenes reacts in a different way with isocyanides depending on the substituents: tetraaryldisilenes afford *thermally* by [2 + 1] cycloaddition exclusively *C*-iminodisilacyclopropanes,[5a] whereas the *photolysis* of tetra-*tert*-butyldisilene in the presence of isocyanides leads to the formation of 3,4-diimino-1,2-disilacyclobutanes and 2,4-diimino-1,3-disilacyclobutanes.[5b]

The constitution of **5a, b** was confirmed by NMR and IR spectroscopy (Table 1) and in the case of **5b** also by X-ray crystallography (Fig. 1).[6] The SiC_2N four-membered ring is planar, and the N atom in the ring is trigonal planar coordinated. The exocyclic C=N bond (1.258(4) Å) has the

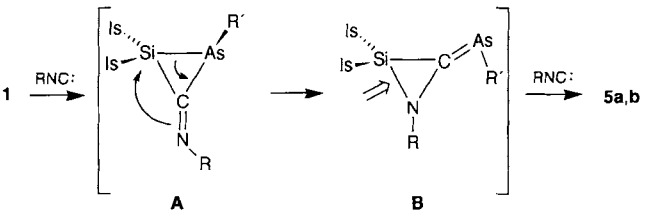
[a] NMR spectra in C_6D_6; ^{1}H: 200 MHz, ^{13}C: 50 MHz, ^{29}Si: 39.7 MHz; MS: electron impact ionization, 70 eV; IR spectra in KBr.

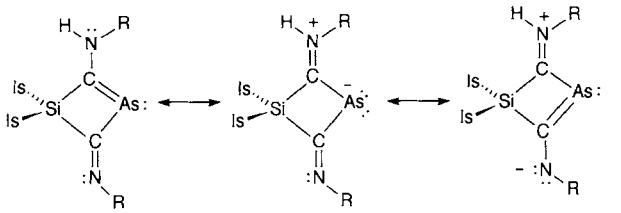
same length as the C=N bonds in methylenimine and other Schiff bases.[7] The C–As bond (1.827(3) Å) is considerably shorter than a C–As single bond (1.96 Å)[7] and corresponds to the C–As distance in the arsaalkenyl complex [(η^5-C$_5$H$_5$)(CO)$_2$Fe–As=C(OSiMe$_3$)tBu][3] (1.821(2) Å). In contrast, more conjugated C=As bonds such as those found in arsinines are longer (1.859, 1.884 Å).[8]

A reaction mechanism as given in Scheme 2 is proposed for the formation of **5**; however, no intermediate can be proven by NMR spectroscopy. Compound **1** probably reacts initially with one equivalent of isocyanide to give the intermediate arsasilacyclopropanimine **A**, which isomerizes immediately in a Peterson-like olefination to give the azasilacycloproylidenearsane **B**.[9] The insertion of a further isocyanide molecule into the Si–N bond of **B** could then finally lead to **5**. In the similar reaction of silenes with isocyanides in the molar ratio 1:2, C-alkylidenazasiliridines,[4] that is, compounds analogous to **B**, could be proven as intermediates, which supports the postulated mechanism in Scheme 2.



Scheme 2. Hypothetical mechanism for the reaction of **1** with RNC to give **5**.

The reaction of **5** in Et_2O with a stoichiometric amount of HCl etherate or aqueous 40% HF at −50 °C was carried out to investigate whether a 1,2 addition to the C=As bond and/or the exchange of the SiiPr$_3$ groups at the arsenic atom by a hydrogen atom is possible. Surprisingly, in these reactions, however, the novel cyclic arsaalkenes **6** and iPr$_3$SiX (X = F, Cl) are obtained as the only products (Scheme 1, Table 1). The existence of an intermediate could not be proven by spectroscopy, so that only assumptions could be made about the reaction mechanism. The expected low-field signals for the C atoms of the C=As bond are observed in the ^{13}C NMR spectra of **6** (δ = 235.88 (**6a**), 211.86 (**6b**)). The C atoms (positioned in the ring) of the imines also exhibit a singlet signal at very low field (δ = 201.68 (**6a**), 198.52 (**6b**)); this unusually strong deshielding in comparison to **5** (δ = 169.54 (**5a**), 169.76 (**5b**)) is produced by a higher contribution of polar resonance structures in the electronic ground state (Scheme 3).



Scheme 3. Mesomeric resonance structures of the arsaalkenes **6**.

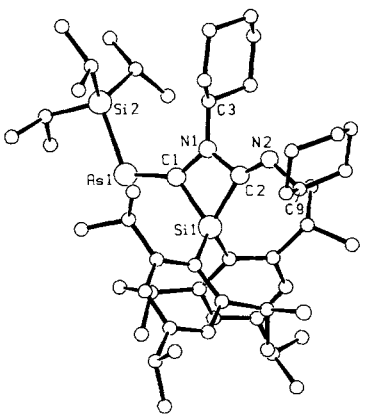


Fig. 1. Molecular structure of **5b**. Selected distances [Å] and angles [°]: As1–Si2 2.384(1), As1–C1 1.827(3), Si1–C1 1.935(3), Si1–C2 1.929(3), N1–C1 1.377(4), N1–C2 1.437(4), N1–C3 1.468(4), N2–C2 1.258(4); C1–As1–Si2 115.5(1), C2–Si1–C1 71.6(1), C2–N1–C1 106.8(2), C3–N1–C1 128.5(2), C3–N1–C2 124.7(2), C9–N2–C2 117.6(2).

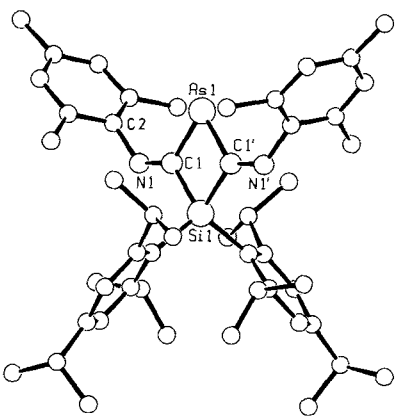

Fig. 2. Molecular structure of **6a**. Selected distances [Å] and angles [°]: As1–C1 1.921(3), Si1–C1 1.887(3), N1–C1 1.302(3), N1–C2 1.433(4); C1–As1–C1' 80.2(1), C1–Si1–C1' 81.9(1), C2–N1–C1 126.9(2), Si1–C1–As1 99.0(1), N1–C1–As1 130.8(2), N1–C1–Si1 130.0(2).

The IR spectra of **6** (Table 1) each show one band for the N–H stretching frequency in the characteristic region for secondary amines.[10] The crystal structure analysis[11] of **6a** confirmed the presence of a four-membered ring with a AsC_2Si skeleton (Fig. 2), but only gives an averaged structure in which the molecule possesses a twofold axis through As1 and Si1. The As1–C1 (1.921(2) Å) and C1–N1 (1.302(3) Å) bond lengths lie between the values for the corresponding single and double bonds,[7] which supports the formulation of **6** as given in Scheme 3.

The rearrangement of **5** into **6** poses the question of whether similar substituted phosphaalkenes lead to analogous products; this is currently under investigation.

Experimental Procedure

5a: **1** (322 mg, 0.48 mmol) in toluene (20 mL) was treated with mesitylisocyanide (139.2 mg, 0.96 mmol) at −80 °C. This caused the color of the reaction solution to change from orange to pale yellow. The solution was warmed to room temperature over 3 h, and subsequently the solvent was removed under vacuum (10^{-2} Torr). The product was obtained quantitatively as a yellow powder (m.p. 227–228 °C). Yellow crystals of the analogue **5b** were obtained from **1** (322 mg, 0.48 mmol) and cyclohexylisocyanide (104.6 mg, 0.96 mmol; m.p. 242 °C).

6a: **5a** (320 mg, 0.35 mmol) in Et_2O at −50 °C was treated with the stoichiometric amount of HCl or with aqueous 40% HF and subsequently warmed to 25 °C. Removal of the volatiles under vacuum (10^{-2} Torr), and uptake of the residue in hexane (5 mL), gave a yellow solution, from which, following filtration, orange-yellow crystals (192 mg, 0.24 mmol, 68%; m.p. 173 °C) were isolated at −30 °C (ca. 7 days). **6b** was obtained in an analogous way from **5b** (138.5 mg, 0.19 mmol, 61%) as a yellow powder (m.p. 186–188 °C).

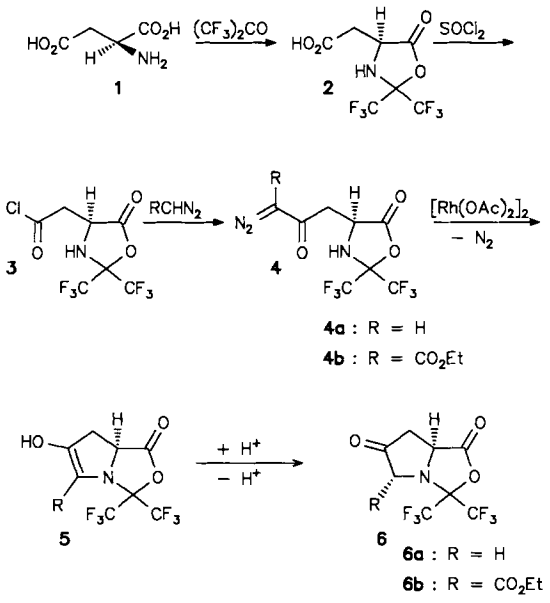
Synthesis of 4-Oxo-L-proline and *cis*-4-Hydroxy-L-proline Derivatives from L-Aspartic Acid**

By *Klaus Burger,* Martin Rudolph,* and *Susanna Fehn*

Every reaction of an amino acid that proceeds with conservation of stereochemistry is preparatively valuable, especially if the conversion can be carried out on amino acids that are readily available in both enantiomeric forms.[1] We have shown that hexafluoroacetone-protected aspartic acid derivatives **2**–**4** are interesting starting materials for the synthesis of amino acids[2] and peptides.[3]

Diazoketone **4**,[2] available in three steps from L-aspartic acid, has the complete sequence of atoms of the framework of 4-oxo-L-proline.[4] To reach the target molecule only a C–N bond must be formed (**4** → **6**). The photochemical transformation **4a** → **6a** was not successful, since the Wolff rearrangement of the α-oxocarbene is much faster than the N–H insertion to form the five-membered ring (Scheme 1).



Scheme 1.

Transition metal catalyzed reactions of α-diazocarbonyl compounds proceed via electrophilic Fischer-type carbene complexes.[5] The Wolff rearrangement is thus suppressed, and consequently the insertion takes place exclusively.[6] When a solution of **4a** in chloroform at room temperature was treated with a catalytic amount of dirhodium tetraacetate,[7] the 4-oxo-L-proline derivative **6a** is obtained in 73% yield. The conversion **4a** → **6a** could also be achieved in a mixture of 70% HF/pyridine at −20 °C.[8] Treatment of **4a** with HCl and HBr, on the other hand, yields the corresponding α-haloketones.[2]

In contrast, when α-diazoketone **4a** is treated at room temperature with a catalytic amount of dirhodium tetraacetate for a controlled decomposition, the ^{19}F NMR spectrum shows the initial formation of the single product **5b** with the

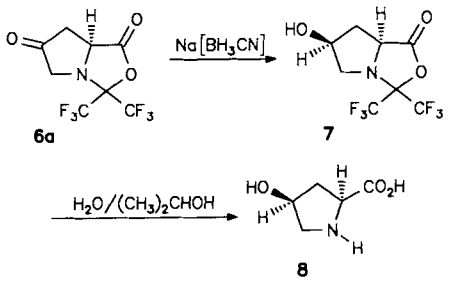
[**] Hexafluoroacetone as a Protecting Group and Activation Reagent in Amino Acid and Peptide Chemistry, Part 12. This research was supported by the Fonds der Chemischen Industrie. We thank Hoechst AG, Frankfurt/Main, for their generous donation of chemicals. – Part 11: K. Burger, M. Rudolph, E. Windeisen, A. Worku, S. Fehn, *Monatsh. Chem.*, in print.

disappearance of starting material; the NMR spectra are in accordance with an enol substructure. Crystalline **5b** can be stored at −28 °C for longer periods. At room temperature in both the solid state and in solution **5b** rearranges to give the expected oxoproline derivative **6a** (monitored by ^{19}F NMR spectroscopy).

The configuration of the newly formed stereogenic center C8 was determined with a heteronuclear NOE experiment (^{19}F–^{1}H HOESY).[9] In the 2D NOE NMR spectrum an NOE was found between the proton at C8 and only one of the trifluoromethyl groups at C2. The configuration of compound **6b** is thus established: relative to the chiral center C5 introduced by the (*S*)-aspartic acid, C8 is also *S*-configurated. The formation of the chiral center at C8 in the keto → enol rearrangement is a thermodynamically controlled self-organization of a sterogenic center.[10] Because of the accessibility of diazo compounds with diverse functionality,[11] this method allows the diastereoselective synthesis of numerous 4-oxoproline derivatives with interesting substitution patterns and may become important in peptide modification and the development of proline dehydrogenase inhibitors (Scheme 2).



Scheme 2.

Compounds **4**–**6** possess considerable potential not only with regards to the diastereoselective synthesis of 5-substituted 4-oxoproline derivatives. As a result of the concave shape of bicycle **6** whose inner face is also sterically shielded by a trifluoromethyl group,[12] nucleophilic additions to the carbonyl function should display a distinct preference for the *Re* face. This was confirmed by the reduction of the keto function of **6a** with $Na[BH_3CN]$ (*de* > 86%). The stereochemistry of the main product **7** was established by an NOE experiment and shown to correspond to that of *cis*-4-hydroxy-L-proline.

The L-proline derivatives resulting from nucleophilic addition to the keto function or from conversion of the carbonyl function are N-protected amino acids with activated carboxyl groups and can be employed directly for the functionalization of the carboxyl group. The derivatization of the carboxyl group is coupled with the deblocking of the amino function. The free amino acids are obtained in a pH-neutral mixture of 2-propanol and water.[13] The hydrolysis of **7** leads to *cis*-4-hydroxy-L-proline (**8**),[14] which is a proline antagonist in collagen biosynthesis[15] and inhibits the growth of cultured tumor cells that synthesize basal membrane collagen.[16] If the synthetic sequence starts with D-aspartic acid, then the corresponding D-proline derivative is obtained.

We will report elsewhere on other applications of compounds of the type **4**–**7** in the regio- and stereoselective functionalization of the proline framework and the transfer of the concept described here to similar heterocyclic amino acids.

Experimental Procedure

5 (R = $CO_2C_2H_5$): **4b**[2] (5.6 g, 14.8 mmol) was dissolved in $CHCl_3$ (200 mL) at room temperature under N_2 and treated with $[Rh(OAc)_2]_2$ (12 mg, 27 μmol). After 2 d the reaction was complete according to ^{19}F NMR spectroscopy. The solvent was removed under vacuum and the residue extracted with hexane (3 × 100 mL). The hexane extracts were concentrated to dryness giving **5** (4.67 g, 90%) as a crystalline substance which had already undergone partial conversion to **6b** (10%), but which did not appear to react further at −28 °C. ^{1}H NMR ($CDCl_3$): δ = 1.31 (t, J = 7 Hz, 3H; CH_3), 2.93 (dd, J = 9, 18 Hz, 1H; H-C6), 3.24 (dd, J = 10, 18 Hz, 1H; H-C6), 4.31–4.39 (m, 2H; OCH_2), 4.75 (dd, J = 9, 10 Hz, 1H; H-C5), 10.19 (brs, 1H; OH); ^{13}C NMR ($CDCl_3$): δ = 13.6 (CH_3), 33.9 (C6), 59.1 (C5), 61.5 (OCH_2), 92.7 (sept, J = 39 Hz; C2), 109.5 (C8), 119.9 (q, J = 291 Hz; CF_3), 120.2 (q, J = 286 Hz; CF_3), 165.7 (C7), 166.6, 168.7 (C=O ester, C4); ^{19}F NMR ($CDCl_3$): δ = −0.4 (q, J = 9 Hz, 3F; CF_3), 4.5 (q, J = 9 Hz, 3F; CF_3).

6a: A solution of **4a**[2] (3.05 g, 10 mmol) in CH_2Cl_2 (150 mL) was added dropwise under N_2 to a vigorously stirred solution of $[Rh(OAc)_2]_2$ (24 mg, 54 μmol) in anhydrous CH_2Cl_2 (200 mL). After 24 h the ^{19}F NMR spectrum showed the reaction to be complete. The solvent was removed under vacuum. Kugelrohr distillation of the residue (1.3 mbar, oven temperature 80 °C) provided **6a** as a colorless oil (2.02 g, 73%). $[\alpha]_D^{21}$: −168.0 (c = 1.0 $CHCl_3$). IR: $\tilde{\nu}$[cm^{-1}] = 1835, 1770. ^{1}H NMR ($CDCl_3$): δ = 2.66 (dd, J = 9, 19 Hz, 1H; H-C6), 2.83 (dd, J = 9, 18 Hz, 1H; H-C6), 3.68 (d, J = 19 Hz, 1H; H-C8), 3.82 (d, J = 19 Hz, 1H; H-C8), 4.54 (t, J = 9 Hz, 1H; H-C5); ^{13}C NMR ($CDCl_3$): δ = 37.4 (C6), 54.0 (C5), 57.2 (C8), 91.6 (sept, J = 33 Hz; C2), 120.3 (q, J = 291 Hz; CF_3), 120.4 (q, J = 286 Hz; CF_3), 168.8 (C4), 207.7 (C7); ^{19}F NMR ($CDCl_3$): δ = −3.4 (q, J = 9 Hz, 3F; CF_3), 5.0 (q, J = 9 Hz, 3F; CF_3).

6b: Compound **5** (4.67 g, 13.4 mmol) was dissolved in $CHCl_3$, and the solution was filtered through a pad of silica gel (diameter 90 mm, height 70 mm, 0.032–0.063 mm). The silica gel was washed with $CHCl_3$ (5 × 50 mL), the filtrate concentrated to dryness under vacuum, and **6b** obtained as a colorless oil (4.4 g, 94%). $[\alpha]_D^{21}$: −104.5 (c = 2.0 $CHCl_3$). IR: $\tilde{\nu}$[cm^{-1}] = 1830, 1770, 1740. ^{1}H NMR ($CDCl_3$): δ = 1.31 (t, J = 7 Hz, 3H; CH_3), 2.71 (dd, J = 9, 19 Hz, 1H; H-C6), 2.94 (dd, J = 8.5, 19 Hz, 1H; H-C6), 4.23–4.32 (m, 2H; OCH_2), 4.46 (s, 1H; H-C8), 4.77 (dd, J = 8.5, 9 Hz, 1H; H-C5); ^{13}C NMR ($CDCl_3$): δ = 13.9 (CH_3), 37.1 (C6), 56.3 (C5), 62.9 (OCH_2), 66.1 (C8), 91.3 (sept, J = 32 Hz; C2), 120.0 (q, J = 291 Hz, CF_3), 120.1 (q, J = 287 Hz, CF_3), 165.2, 167.9 (C=O ester, C4), 201.9 (C7); ^{19}F NMR ($CDCl_3$): δ = −2.3 (q, J = 9 Hz, 3F; CF_3), 5.9 (q, J = 9 Hz, 3F; CF_3).

7: A solution of **6a** (1.07 g, 3.88 mmol) in anhydrous 2-propanol (10 mL) at 0 °C was stirred and $Na[BH_3CN]$ (0.12 g, 1.94 mmol) added in portions. After the addition of glacial acetic acid (4 mL), the reaction mixture was stirred until no more starting material was evident by ^{19}F NMR spectroscopy (ca. 1 h). $CHCl_3$ was added to the reaction mixture, which was then washed twice with $NaHCO_3$ solution and water, dried over $MgSO_4$, and concentrated to dryness under vacuum. **7** was obtained as a colorless oil (0.74 g, 68%). $[\alpha]_D^{21}$: −28.4 (c = 1.2 $CHCl_3$). IR: $\tilde{\nu}$[cm^{-1}] = 3600–3200, 2960, 1815. ^{1}H NMR ([D_6]acetone): δ = 2.20 (ddd, J = 13.5, 4.5, 2 Hz, 1H; H-C6), 2.35 (ddd, J = 13.5, 9, 4 Hz, 1H; H-C6), 3.29 (dd, J = 13, 9.5 Hz, 1H; H-C8), 3.48 (ddd, J = 13, 4, 2 Hz, 1H; H-C8), 4.24 (m, 1H; H-C5), 4.40 (m, 1H; H-C7); ^{13}C NMR ([D_6]acetone): δ = 37.1 (C6), 57.7 (C5), 60.9 (C8), 69.4 (C7), 92.8 (sept, J = 32 Hz; C2), 120.2 (q, J = 288 Hz; CF_3), 122.2 (q, J = 288 Hz; CF_3), 172.7 (C4); ^{19}F NMR ($CDCl_3$): δ = −1.72 (q, J = 10.5 Hz, 3F; CF_3), 7.28 (q, J = 10.5 Hz, 3F; CF_3).

8: A solution of **7** (1.06 g, 3.79 mmol) in 2-propanol/water (20 mL/20 mL) was stirred at room temperature. After the starting material could not be detected by ^{19}F NMR spectroscopy, the reaction mixture was concentrated to dryness under vacuum and the residue recrystallized from H_2O/CH_3OH to give **8** (0.43 g, 41%). M.p. 241 °C (decomp). $[\alpha]_D^{21}$: −60.9 (c = 1.0 H_2O). ^{1}H NMR (D_2O): δ = 2.31 (m_c, 1H; H-C3), 2.56 (m_c, 1H; H-C3), 3.43 (dd, J = 2.5, 12.5 Hz, 1H; H-C5), 3.53 (m_c, 1H; H-C5), 4.28 (dd, J = 2.5, 10.5 Hz, 1H; H-C2), 4.64 (m_c, 1H; H-C4); ^{13}C NMR (D_2O): δ = 39.8 (C3), 55.6 (C5), 62.4 (C2), 71.8 (C4), 177.2 (CO_2H).

Ba[Si(OCH$_2$CH$_2$O)$_3$], a Hexaalkoxysilicate Synthesized from SiO$_2$**

By *Martin L. Hoppe, Richard M. Laine,* Jeffrey Kampf, Mark S. Gordon,* and *Larry W. Burggraf*

Anionic (pentacoordinate) and dianionic (hexacoordinate) organosilicates were first reported more than 60 years ago.[1–4] Pentacoordinate Si complexes have recently received considerable attention because of their role in sol–gel processing of silicate glasses,[4–6] their utility in organic synthesis and polymerization,[7–9] and their use as precursors to organosilicon compounds.[10–12] Pentacoordinate silicates are easily prepared from compounds with tetrasubstituted Si centers.[10–22] Although polyhalogenated anionic silicates are relatively common, only perfluorinated derivatives are found to form hexacoordinate silicate dianions, for example $[SiF_6]^{2-}$.[23] Salts of the dianion $[Si(1,2\text{-}O_2C_6H_4)_3]^{2-}$, first prepared in the early 30s, are the most common nonfluorinated hexacoordinate silicates.[2, 3, 10]

Surprisingly, these salts are thermally and hydrolytically more stable than pentacoordinate alkoxysilicates, possibly because the aromatic rings provide charge delocalization.[1c] Hexacoordinate dianionic germanium complexes $M_2[Ge(1,2\text{-}O_2C_2Me_4)_3]$ (M = K, Li; $1,2\text{-}O_2C_2Me_4$ = dianion of pinacole) have been synthesized directly from GeO_2; however, silicon analogues are still unknown.[24] Polyhedral germanates with four, five, and six oxygen donors at Ge have been prepared, but it has been suggested[25] that the ability of Ge (but rarely Si) to exhibit sixfold O-coordination is because it is a post transition metal element. Materials with sixfold O-coordinated Si atoms are limited to the rare mineral stishovite formed from a meteor impact.

Given that no examples of hexaalkoxysilicates have been described in the literature since the synthesis of the tris(benzenediyldioxido) complexes in 1931, it can be inferred that they do not form readily. However, theoretical calculations suggest that simple silicate dianions with six O ligands without supporting aromatic groups should be stable.[26] We report here the first such example.

We recently reported the synthesis of the pentacoordinate silicates $M[Si(OCH_2CH_2O)_2(OCH_2CH_2OH)]$ and $M_2[Si_2(OCH_2CH_2O)_5]$ (M = Li, Na, K, Cs) by direct reaction of one equivalent of MOH with one equivalent of SiO_2 in excess ethylene glycol.[27] Efforts to delineate the scope of this reaction led to studies of analogues with alkali metals, for example $M[Si_2(OCH_2CH_2O)_5]$ (M = Mg, Ca, Ba), whose stoichiometry would be ideal for the preparation of aluminosilicates such as $CaO \cdot 2SiO_2 \cdot Al_2O_3$ (garnet). These studies provided rather unique and unexpected results. We report here the synthesis of the first example of the heretofore unknown dianionic hexaalkoxysilicate **1** directly from silica, ethylene glycol, and barium oxide.

$Ba[Si(OCH_2CH_2O)_3]$ **1**

When mixtures of BaO (85.2 g, 0.56 mol), SiO_2 (30.0 g, 0.5 mol), and glycol (500 mL) were heated such that excess glycol and the H_2O formed in the reaction distilled off, the SiO_2 dissolved completely in 2–4 h. When the clear solution was cooled, the white microcrystalline methanol-soluble product **1** precipitated (≈ 90% yield).[28] CaO and MgO can be used in place of BaO; the yields are low with MgO because of the low reactivity of MgO with ethylene glycol. X-ray quality single crystals of the Ba complex were grown by vapor diffusion of acetonitrile into a solution of the Ba complex in glycol.

The structure determined by single-crystal X-ray diffraction (Fig. 1)[29] reveals two crystallographically independent $Ba^{2+}[Si(OCH_2CH_2O)_3]^{2-}$ formula units per asymmetric unit. ^{29}Si MAS solid-state NMR data support these findings.[30] Each Si atom has a slightly distorted octahedral coordination environment with three bidentate ethanediolato ligands. Each unit cell contains 13 glycol molecules in the crystal lattice. Coulombic Ba···O interactions and strong hydrogen bonding with the glycol molecules in the lattice[31] likely account for the stability of the complex and also modify the stereochemistry about each silicon atom. One Si atom has a Δ configuration; its three bidentate ethanediolato ligands adopt a $(\lambda\delta\delta)$ configuration. The configuration about the other Si atom is $\Delta(\delta\delta\delta)$. The crystallographic inversion center also generates Si centers with $\Lambda(\delta\lambda\lambda)$ and $\Lambda(\lambda\lambda\lambda)$ stereochemistry.

There are no chemically significant differences in any of the Si–O or C–C bond lengths or angles for the two molecules except for those imposed by stereochemistry. However, the Ba atoms occupy quite different environments in the crystal lattice. Each Ba atom has nine contacts with O atoms < 3.2 Å. For Ba1, two of these contacts are with the Si1–tris-

[**] This work was supported by the Air Force Office of Scientific Research. We would like to thank Prof. Linda Nazar, Waterloo, and Prof. Florence Babonneau, Paris, for continuing collaborations, especially for running solid-state NMR studies; and Prof. R. J. P. Corriu for numerous helpful discussions that have made this publication possible.

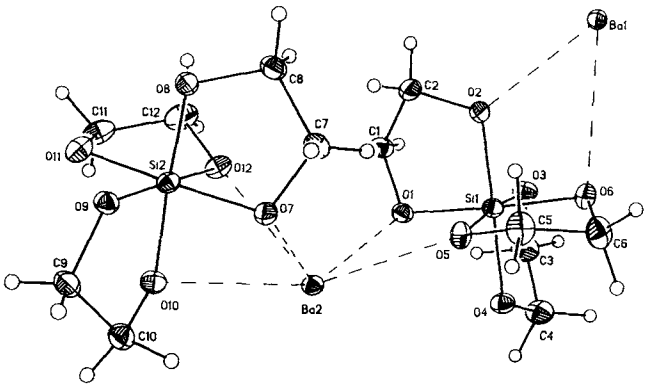

Fig. 1. ORTEP plot of the crystallographically independent formula units of $Ba[Si(OCH_2CH_2O)_3]$ (**1**) (atoms represented as 50% thermal ellipsoids). Selected interatomic distances [Å]: Si(2)-O(7) 1.835(2), Si(2)-O(8) 1.762(2), Si(2)-O(9) 1.753(2), Si(2)-O(10) 1.781(2), Si(2)-O(11) 1.809(2), Si(2)-O(12) 1.770(2), Ba(2)···O(7) 2.772(2), Ba(2)···O(10) 2.956(2), Ba(2)···O(12) 2.682(1), Ba(2)···Si(2) 3.481(1). Mean bond lengths have typical values: Si-O 1.785(1), C-O 1.419(3), C-C 1.516(4).

(ethanediolato)complex (mean distance) (2.904(2)), two are with the Si2 complex (2.739(2)), and five are with glycol molecules in the lattice (2.832(2)Å). For Ba2, two contacts are with the Si1 complex (2.739(2)), three are with the Si2 complex (2.803(2)), and four are with glycol molecules in the lattice (2.827(2)Å). The Ba···Si distances are also quite dissimilar. The Ba1–Si2 and Ba1–Si2 distances are 3.874(1) and 3.768(1) Å, respectively, while the Ba2–Si1 and Ba2–Si2 distances are 3.684(1) and 3.481(1) Å. The closest Ba···Ba distance is quite long, 4.750(1) Å.

Thermogravimetric analyses of **1** reveal the expected weight loss calculated from the chemical analysis,[28] and at temperatures greater than 800 °C lead to the formation of phase-pure $BaSiO_3$ (JCPDS File No. 26-1402).[32]

Because no chemically significant differences in the Si–O bonds are observed in the crystal structure, despite the coulombic interactions with Ba^{2+} ions, we reexamined the synthesis of the analogous hexacoordinate alkali metal silicates with two equivalents of LiOH or KOH; the reactions provided the pentacoordinate complexes in lower yields.[27] The presence of a dication may be required to stabilize dianionic hexaalkoxysilicates; however, this conclusion is not supported by preliminary theoretical studies.[26]

Preliminary ab initio calculations with a minimal basis set (STO-2G)[33] were conducted on the free, isolated $[Si(OCH_2CH_2O)_3]^{2-}$ dianion to determine if it has any inherent asymmetry. Geometry optimization using analytical gradient routines (GAMESS[34]) was conducted with C_1 symmetry. The resulting structure (which has a positive definite hessian) predicts Si–O bond lengths that are within an 0.002 Å range (1.805–1.807 Å). The semiempirical AM1 method[35] predicts all six bond lengths to be 1.794 Å. Both of these results are remarkably close to the average experimental Si–O distance of 1.785 Å in **1**. (EXAFS studies of **1** indicate that the Si–O bond lengths, which range from 1.753 to 1.809 Å, are essentially identical to those in stishovite, 1.757 and 1.809 Å.[39]). Thus, at these levels of theory the isolated dianion exhibits no bond-length distortion. The distortions seen in the X-ray structure of **4** probably result from crystal packing effects, H-bonding, and Ba–O coulombic interactions.

The monomers $M[Si(OCH_2CH_2O)_3]$ (M = Mg, Ca, Ba) and tractable polymeric derivatives may offer access to novel silicon-containing materials, including glasses and ceramics. $Mg(OR)_2/Si(OR)_4$ mixtures have been used to form novel silicates;[36] our work suggests that $Mg[Si(OR)_6]$ may be an intermediate. The Mg analogue of **1** can be used as a tractable cordierite precursor.[37] The isolation of hexaalkoxysilicates also provides support for the formation of hexacoordinate silicate anion intermediates in the nucleophilic reactions of pentacoordinated silicates.[38]

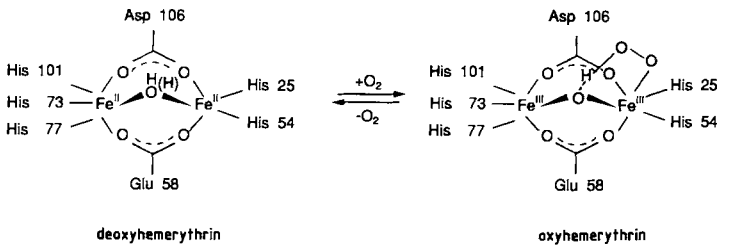
A Hemerythrin Model Complex with Catalase Activity**

By *Bert Mauerer, Jonathan Crane, Jürgen Schuler, Karl Wieghardt,** and *Bernhard Nuber*

In the past few years the structural and electronic properties of the active site of the metalloprotein hemerythrin have been modeled successfully with low-molecular-weight systems.[1] Current efforts are concentrated on the preparation of *functional* model complexes. The active form of the enzyme, deoxyhemerythrin, has one penta- and a hexacoordinate, high-spin iron(II) ion bridged by a hydroxy or aqua ligand, whereas in the O_2 containing form, oxyhemerythrin, both Fe ions are in the oxidation state + III and one Fe^{III} ion binds a hydroperoxo ligand (Scheme 1).



Scheme 1.

[**] This research was supported by the Fonds der Chemischen Industrie. J. C. thanks the Alexander-von-Humboldt-Stiftung for a stipend.

Previous attempts at modeling the active site in oxyhemerythrin proceeded logically from the synthesis of coordinatively unsaturated Fe^{II}_2 complexes, which were treated with O_2 at low temperatures in aprotic solvents in the hope of stabilizing the oxyhemerythrin form.[2] Despite some preliminary success this approach is problematic because of the extreme lability of Fe^{II} complexes. Therefore, we decided to try another approach in which more robust, coordinatively unsaturated Fe^{III}_2 complexes are treated with H_2O_2.[3] We report here on the synthesis and reactivity of a complex of this type.

The dinuclear complex **1**, which is asymmetric with respect to the two Fe^{III} ions with different coordination, was synthesized by the reaction of $[(bpy)_2Fe_4O_2(ac)_7](PF_6)$[4a] (bpy = 2,2′-bipyridine; ac = acetate) with $LFeCl_3$[4b] (L = 1,4,7-trimethyl-1,4,7-triazacyclononane) and 2,2′-bipyridine in acetonitrile. As the X-ray structure analysis[5] shows (Fig. 1 top), one Fe^{III} ion is bound to the tridentate amine L and the other to 2,2′-bipyridine and a terminal choride ion; the two metal ions are connected by an oxo and

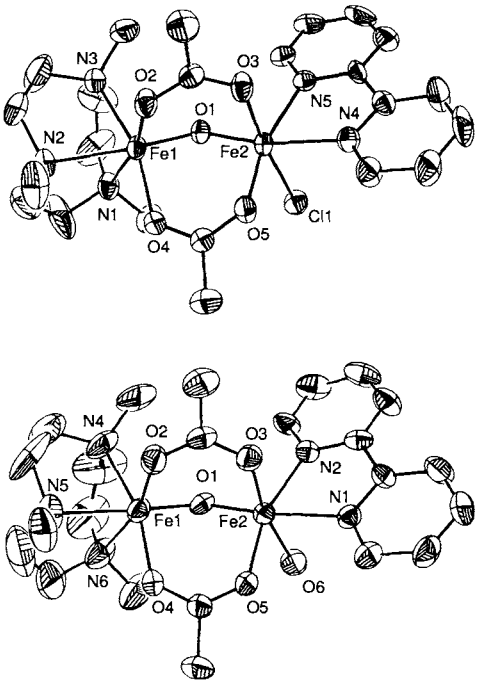

Fig. 1. Crystal structures of the cations in **1** (top) and **2** (bottom). Selected distances [Å] and angles [°]: **1**: Fe2-Cl1 2.376(2); Fe1-O1 1.786(5), Fe2-O1 1.797(5), Fe1···Fe2 3.097(2), Fe2-N4 2.206(6), Fe2-N5 2.146(7), Fe1-N1 2.184(7), Fe1-N2 2.252(7), Fe1-N3 2.211(7); Fe1-O1-Fe2 119.6(3). **2**: Fe1-O1 1.806(8), Fe1-O2 1.995(9), Fe1-O4 2.017(9), Fe1-N4 2.173(12), Fe1-N5 2.242(15), Fe1-N6 2.190(12), Fe2-O1 1.785(7), Fe2-O3 2.048(9), Fe2-O5 2.017(8), Fe2-N1 2.218(10), Fe2-N2 2.148(10), Fe2-O6 2.153(9), Fe1···Fe2 3.102(3); Fe1-O1-Fe2 119.5(4).

two symmetric acetate bridges. Thus, this is an asymmetric methemerythrin model complex. The chloro ligand in **1** can by replaced by H_2O in a reaction with $AgClO_4 \cdot H_2O$ in CH_2Cl_2 giving complex **2**, whose X-ray structure was also

$[LFe(\mu\text{-}O)(\mu\text{-}ac)_2Fe(bpy)Cl]X$ **1a**, X = PF_6, **1b**, X = ClO_4

$[LFe(\mu\text{-}O)(\mu\text{-}ac)_2Fe(bpy)(H_2O)](ClO_4)_2 \cdot CH_2Cl_2$ **2**

determined (Fig. 1 bottom).[5] The structural and electronic properties of **1** and **2** are similar to those of their sym-

metric analogues $[L_2Fe^{III}_2(\mu\text{-}O)(\mu\text{-}ac)_2]^{2+}$,[6a] $[(bpy)_2Fe^{III}_2(\mu\text{-}O)(\mu\text{-}ac)_2Cl_2]$,[4a] and $[(bpy)_2Fe^{III}_2(\mu\text{-}O)(\mu\text{-}ClCH_2CO_2)_2(H_2O)_2]^{2+}$.[6b]

When we treated **2** with an aqueous H_2O_2 solution, we observed an unexpected, vigorous evolution of O_2. Complex **2** catalyzes the disproportionation of H_2O_2 following Equation (a); the complex thus displays catalase activity. Interestingly, the symmetric complex, $[L_2Fe^{III}_2(\mu\text{-}O)(\mu\text{-}ac)_2]^{2+}$ (lacking the labile coordination site), is comparatively unreactive under the same conditions (see below).

$$2H_2O_2 \longrightarrow O_2 + 2H_2O \qquad (a)$$

To our knowledge catalase activity has not been observed for hemerythrin. It is known that deoxyhemerythrin (5×10^{-5} M) reacts with H_2O_2 (ca. 5×10^{-4} M) at pH 6.3–8.3 to give hydroxymethemerythrin,[7] but O_2 evolution was not observed (though possibly also not sought).

We examined the kinetics of the reaction of **2** with H_2O_2 in homogeneous aqueous solution more closely. Compound **2** is stable in pure H_2O for only a few minutes; the formation of $[Fe(bpy)_3]^{2+}$ can be detected by UV/VIS spectroscopy. In contrast, **2** is stable in 0.10 M acetic acid/sodium acetate buffer (1:1) for more than 24 h. We therefore decided to measure the evolution of O_2 from solutions of **2** (buffered acetic acid/sodium acetate) at 20 °C with a manometer with variation of the following parameters: 1) the concentration of **2** (1.3×10^{-5}–1.2×10^{-4} M), 2) the concentration of H_2O_2 (0.27–1.7 M), 3) the pH (3.7–5.6), and finally 4) the concentration of acetate ions (0.14–1.0 M).

Figure 2 shows the O_2 evolution as a function of time, from which the following conclusions can be drawn. From

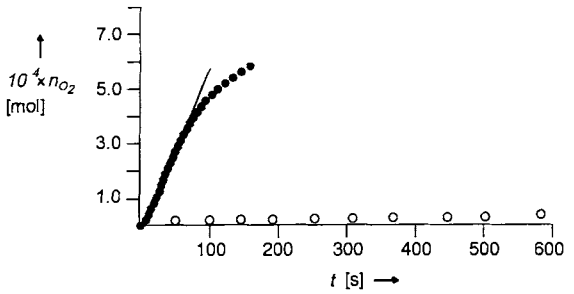

Fig. 2. Plot of the O_2 evolution versus time at 20 °C for catalyst **2** (•) and $[L_2Fe^{II}_2(\mu\text{-}O)(\mu\text{-}ac)_2](ClO_4)_2$ (○). Conditions: $[CH_3CO_2H/CH_3CO_2^-] = 0.07$ M; pH = 5.01; $[H_2O_2] = 1.03$ M; $[\mathbf{2}] = 1.2 \times 10^{-4}$ M. The region in which the plot follows the straight line has zeroth-order kinetics.

the start of the reaction until about 200–300 turnovers the reaction follows zeroth-order kinetics. The O_2 evolution is terminated by decomposition of the catalyst. Plots of the initial rates versus the concentrations of a) **2** and b) H_2O_2 indicate that the reaction is first order in both under constant concentrations of H^+ and $CH_3CO_2^-$ [Eq.(b)].

$$\text{rate} = k[\mathbf{2}][H_2O_2] \qquad (b)$$
$$([H^+] = \text{const.}, [CH_3CO_2^-] = \text{const.})$$

Experiments at constant concentrations of **2**, H_2O_2, and $CH_3CO_2^-$ demonstrate that the rate of evolution of O_2 *decreases* with increasing H^+ concentrations (Fig. 3 bottom). Acetate ions *inhibit* the evolution of O_2 (Fig. 3 top) as well. These observations allow the conclusion that the acetate ions replace the labile H_2O ligand in **2** and compete with H_2O_2 (or HO_2^-) molecules for this coordination site. The observed pH-dependence most probably arises because HO_2^- is a better nucleophile than its protonated form H_2O_2. It is noted that in the experimental pH range (4–6) the spectrum of **2** does not change, that is, protonation at the μ-oxo bridge does not occur.

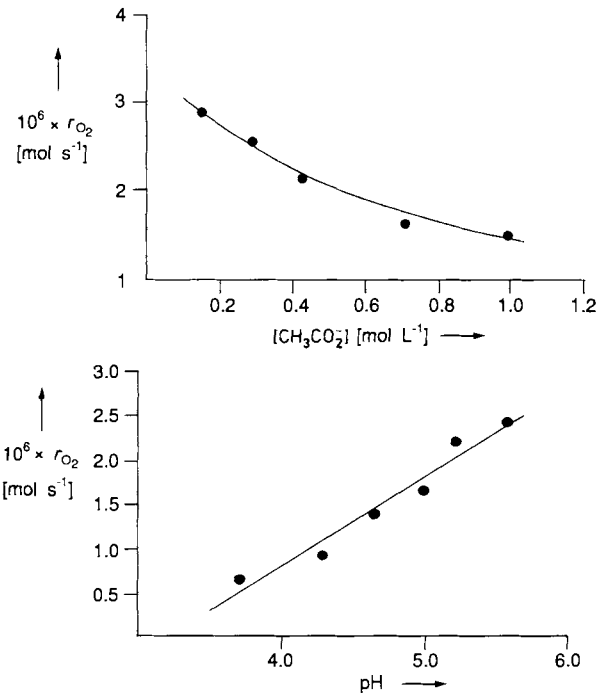

Fig. 3. Plot of the initial rate of O_2 evolution as a function of the concentration of acetate ions (pH = 5.0; $[H_2O_2] = 1.03$ M; $[\mathbf{2}] = 7.2 \times 10^{-5}$ M) (top) and the pH ($[\mathbf{2}] = 6.0 \times 10^{-5}$ M; $[CH_3CO_2^-] = 0.18$ M, $[H_2O_2] = 1.08$ M) (bottom).

A possible catalytic cycle is sketched in Figure 4 which takes into account the known chemistry of hemerythrin and its model complexes as well as the kinetic experiments described here. The rate-determining step may be the substitu-

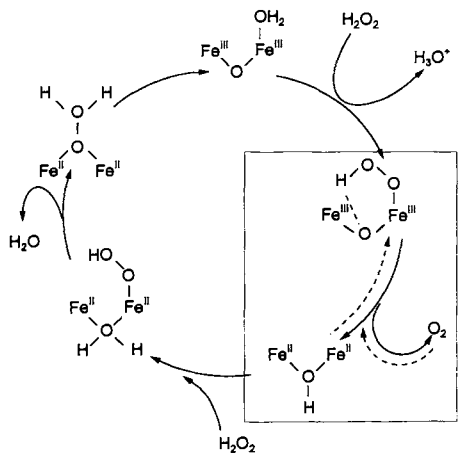

Fig. 4. Proposed mechanism for the disproportionation of H_2O_2 catalyzed by complex **2**. In the framed section hemerythrin–oxygen binding is in the direction of the dashed arrows.

tion step in the binding of H_2O_2 (or HO_2^-) to an Fe^{III} ion in **2**. This cycle is plausible, since it essentially represents steps of the back reaction in hemerythrin–oxygen binding. Finally, only the Fe^{III}/Fe^{II} redox potential of hemerythrin and its model complexes decides if the oxyhemerythrin form can be stabilized or if the coordinated HO_2^- is oxidized with concomitant formation of the deoxyhemerythrin form (Fe^{II}).

Experimental Procedure

Synthesis of the complexes: **1a**: A solution of $[(bpy)_2Fe_4O_2(ac)_2](PF_6)$[4a] (6.0 mmol) $LFeCl_3$[4b] (12 mmol) and bpy (37 mmol) in acetonitrile (200 mL) was heated for 4 h at reflux. The reaction mixture was cooled and filtered, then nBu_4NPF_6 (5.0 g) and diethyl ether (400 mL) were slowly added in portions. After 30–40 min red $[Fe(bpy)_3](PF_6)_2$ precipitated and was filtered off. Ether (100 mL) was again added to the filtrate, and the solution was filtered after 30 min. Within the next 12 h brown crystals of **1a** formed (30%). The perchlorate salt **1b** was prepared analogously by using nBu_4NClO_4.

2: A solution of **1b** (1.0 mmol) and nBu_4NClO_4 (0.50 g) in anhydrous CH_2Cl_2 (80 mL) was treated with a solution of $AgClO_4 \cdot H_2O$ (1.0 mmol) in CH_2Cl_2/toluene (3:1; 3 mL) and stirred. After 5 min AgCl was filtered off. Within 12 h brown crystals of **2** (30%) formed. **1a**, **1b**, and **2** gave satisfactory elemental analyses (C,H,N,Fe).

Physical properties[8]: UV/VIS (CH_3CN) λ_{max} [nm] (ε[$Lmol^{-1}cm^{-1}$]): **1**: 235 (2.6×10^4), 294 (1.3×10^3), 336 (8.6×10^3), 463 (1.1×10^3), 500 (970), 718 (202); **2**: 237 (2.6×10^4), 285 (1.3×10^3), 341 (7.9×10^3), 475 (1.2×10^3), 500 (sh), 766 (228). 2,3,7,8,12,13,17,18-Octamethoxyporphyrin**

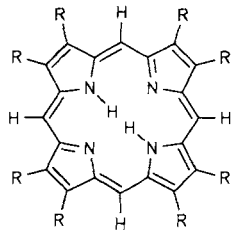
By *Andreas Merz,* Roland Schropp,* and *Johann Lex*

Dedicated to Professor Emanuel Vogel on the occasion of his 65th birthday

Porphyrins are of considerable biological importance and of interest to theoreticians as aromatic systems; nevertheless, far from all of the imaginable or desirable substitution patterns have been realized for the porphyrin system. While *meso*-tetraarylporphyrins are easily accessible from pyrrole and aromatic aldehydes,[1] the construction of even symmetric octaalkylporphyrins, for example **1c** or **1d**, is laborious,[2] primarily due to the lack of good synthetic routes to the basic pyrrole building blocks such as 3,4-disubstituted pyrroles. Porphyrins with + M substituents, in particular, are hardly known; the descriptions are limited to a few examples having one or two methoxy groups besides six alkyl substituents in the remaining β-pyrrole positions[3] as well as derivatives of octaalkylporphyrins with *meso*-amino substituents.[4, 5] We report here on the synthesis and properties of octamethoxyporphyrin **1a**, the first porphyrin with multiple donor substituents.



1a (R = OCH_3)
1b (R = H)
1c (R = CH_3)
1d (R = CH_2–CH_3)

3,4-Dimethoxypyrrole (**2**), the basic building block of **1a**, is a stable, crystalline compound that can be oxidized electrochemically to give highly conductive polydimethoxypyrrole films.[6] The facile oxididation of **2** is also reflected in its chemical behavior: treatment of a cold solution (−70 °C) of **2** in THF with *N*-bromosuccinimide leads to oxidative polymerization, not the formation of brominated derivatives. In contrast, the synthesis of porphyrin **1a** from the reaction of **2** with formaldehyde under acid catalysis and air oxidation is remarkably smooth; the best results, approximately 20% yield of **1a**, were hitherto obtained following the method of Treibs and Häberle with mixtures of glacial acetic acid and pyridine.[7] **1a** forms shiny, blue, rectangular prisms (m.p. 307–309 °C) that dissolve in many solvents to give brown solutions, thin layers of which appear red. Irradiation with a UV lamp causes an intense crimson fluorescence. Dilute solutions of **1a** are stable for several weeks without protection from air or light.

The methoxy group can function as an −I and + M substituent on aromatic systems.[8] This is evident from the comparison of the spectroscopic and structural data of **1a** with that of the parent compound porphine (**1b**), octamethylporphyrin **1c**, and octaethylporphyrin **1d**, which is isosteric and isoelectronic to **1a**. In the UV/VIS spectrum of

and dimethoxyporphyrins described in ref.[3] do not show this effect. Since −M substituents (vinyl, formyl, and carboxyl groups) in the β positions often exert a considerable *bathochromic* effect on the Soret bands,[9] the hypsochromic shift observed here is in accord with the + M character of the methoxy group. The differences in the visible part of the spectrum are not as evident. Relative to the spectrum of **1d** the Q bands of **1a** have a slight hypsochromic shift and change from the etio to the rhodo type; the Q-III band, not the Q-IV band, has the greatest intensity. This effect has been observed previously for vinyl and formyl groups, but in those cases is accompanied by a *bathochromic* shift.[9] On irradiation of **1a** at 77 K with light with a wavelength of 400 nm, its fluorescence spectrum exhibits an intense band at 622 nm, flanked by three weaker bands at longer wavelengths, 644, 666, and 683 nm, with 18, 24, and 35% intensities (relative to that of the main band). Phosphorescence was not observed below 900 nm.

The ^{1}H NMR spectrum of **1a** shows only three singlets as expected (Table 2). The resonance frequency of the *meso*

protons in **1a** relative to that of **1d** and **1c** does not indicate any particular effect of the methoxy substituents on this position: steric effects appear to cancel out the electronic effects. The downfield shift of the OCH_3 protons ($\Delta\delta \approx 1$ relative to **2** or anisole) reflects the high diatropism of the porphyrin system, but this value is $\Delta\delta \approx 0.5$ greater than that of the CH_3 groups of **1d** when the chemical shifts of both groups as benzene substituents are used as a comparison. This supports a structure of **1a** in which the OCH_3 groups are oriented more in the porphyrin plane. The upfield shift of the quadrupole-broadened NH signal is also in accord with the electron-donating effect of the OCH_3 group. For **1a** the difference in the chemical shifts of N–H and *meso*-H, $\Delta\delta = 14.47$, is greater than that of porphyrins listed for comparison (Table 2). In contrast to **1b** and **1d**, in the spectrum of the green, double-protonated form of **1a** both the *meso* protons and the N–H protons are shifted to lower fields.

In the ^{13}C NMR spectrum of dimethoxypyrrole **2** relative to that of the unsubstituted parent compound the two OCH_3 groups cause a tremendous downfield shift of the β C atoms and a simultaneous upfield shift of the α C atoms; this corresponds to the −I effect on the C atom directly bound to the oxygen atoms and the + M effect on the neighboring position. This effect is also apparent, although to a lesser degree, in the comparison of octamethoxyporphyrin **1a** and octaalkylporphyrins. Since the quadrupole effect of the ^{14}N nucleus causes the relaxation time of the neighboring C atoms to decrease, the two ^{13}C NMR signals could be assigned because of the signal broadening of the α C atoms.

The crystal structure of porphyrin **1a** has C_i symmetry (Fig. 1, Table 3).[15] Comparison of the structure of **1a** to

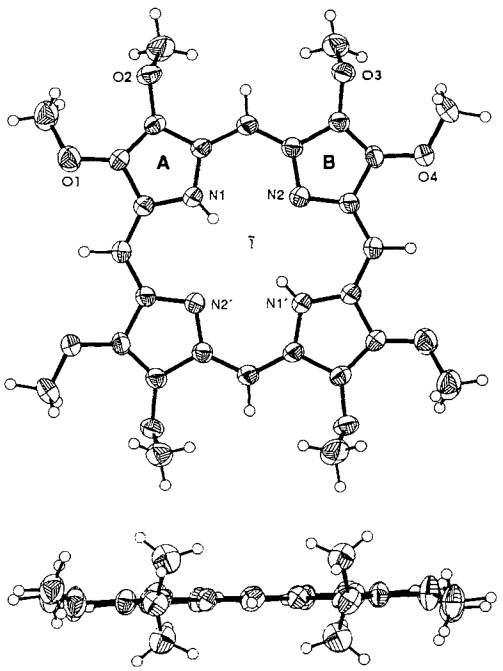

Fig. 1. Crystal structure of **1a** (ORTEP, ellipsoids at the 40% probability level[15]).

those of the other basic types of porphyrins[16] shows the bond lengths and angles to be intermediate to those of the unsubstituted parent compound **1b** and those of **1d**, which is in accord with the reduced steric demands along the

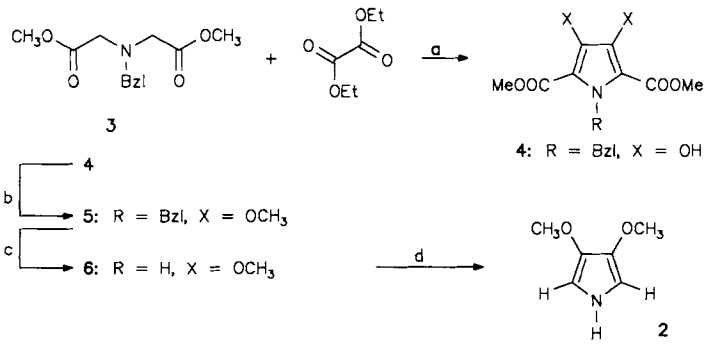
perimeter of **1a**. Since the methoxy groups require less space, one methoxy group on each pyrrole ring is almost in the porphyrin plane (i.e. its C–O bond and the porphyrin are close to coplanar). The deviation of the CH_3 carbon atoms of these "planar" methoxy groups from the best plane of the porphyrin ring is only 0.415(O1) and 2.33(O4) Å for **1a**, and 1.144(O2) and 1.068(O3) Å for those twisted out of the plane. The methoxy groups are arranged so that the "planar" methoxy groups point away from the *meso* hydrogen atoms, forcing the neighboring methoxy group on the same pyrrole ring out of the plane. Four of the eight methoxy groups are thus in conjugation with the porphyrin unit; the increased sp^2 character of the oxygen atoms results in markedly shorter porphyrin–O and methyl–O distances and in larger C-O-C bond angles at the "planar" groups.

In summary, **1a** as the first octaalkoxyporphyrin does not show principal changes in the geometry of the porphyrin core; however, all of its spectroscopic properties point to a modified π-electron system, which will certainly be the subject of future investigations.

We have also been able to improve the synthesis of starting material **2** (Scheme 1). *N*-Benzyl-3,4-dihydroxypyrrole (**4**),



Scheme 1. a: 1. CH_3ONa/CH_3OH, reflux, 2. neutralization (58%); b: $(CH_3)_2SO_4/Na_2CO_3$, acetone, reflux (80%); c: H_2/10% Pd/C, acetic acid, 10 bar (96%); d: ref.[6]. Bzl = benzyl.

obtained from the condensation of dimethyl *N*-benzyliminodiacetate (**3**) and diethyl oxalate, was methylated with dimethyl sulfate to give the dimethoxy derivative **5**. The subsequent selective debenzylation at 10 bar H_2 on Pd/C provided **6** without hydrogenation of the porphyrin core.[17] The final reactions furnishing **2** can be conducted on a 10 g scale without difficulty as already described.[6] The route via **3** also opens the way to other 3,4-dialkoxypyrroles, which may find ample application, for example, in the synthesis of porphyrins with improved solubility properties or with peripheral functionalization.

Experimental Procedure

A solution of **2** (250 mg, 1.96 mmol) in glacial acetic acid (14 mL) and pyridine (7 mL) was treated with 35% formalin solution (0.2 mL) and then heated at reflux for 30 min while air was passed through the reaction mixture. After standing several days at room temperature the reaction mixture was filtered, providing 10–15 mg of **1a**. The filtrate was evaporated to dryness and the residue extracted with hot toluene. The resulting solution was chromatographed on silica gel eluting with ether; the first faction provided another 35–40 mg of **1a**. Correct C,H,N analysis. FAB-MS: *m/z* 551 ($M + H^+$).

$[Fe_2Cl_6]^{2-}$: A Discrete Form of Ferrous Chloride**

By *Kim R. Dunbar** and *Anne Quillevéré*

The important role of iron in biological as well as catalytic processes has spurred a considerable amount of research by bioinorganic and coordination chemists.[1, 2] In order to gain a better understanding of the function of non-heme iron–sulfur proteins in fundamental biological reactions such as the transformation of N_2 into NH_3 by nitrogenase, researchers have designed synthetic analogues to compare their magnetic, spectroscopic, redox, and structural properties to those of the natural enzymes.[3] The dinuclear model compounds have the general formula $[Fe_2S_2(SR)_4]^{2-/3-}$, in which the iron centers in the oxidation states III,III or III,II are bridged by two sulfur atoms in an overall edge-sharing bitetrahedral arrangement.[4] This structural type is atypical for diiron(II) compounds, however, as evidenced by the fact that the only known representatives are $[Fe_2(SEt)_6]^{2-}$ and $[Fe_2Cl_4(OPh)_2]^{2-}$.[5, 6] All other reported fully reduced diiron complexes exhibit either a doubly or triply bridged bioctahedral geometry.[7, 8–11]

[**] This research was supported by the National Science Foundation (Grant CHE-89149) and the Camille and Henry Dreyfus Foundation. We thank G. Christou, D. Dunham, and M. Kanatzidis for helpful discussions and D. Dunham for the magnetic data. We also appreciate the help of J. Matonic in obtaining the packing diagram. The X-ray equipment was purchased with funds from the National Science Foundation (CHE-8403823 and CHE-8908088).

While studying the reactivity of ferric chloride with tris(2,4,6-trimethoxyphenyl)phosphane tmpp, we unexpectedly isolated the hitherto unknown ferrous chloride anion $[Fe_2Cl_6]^{2-}$ as the phosphonium salt **1**. In spite of the extensive literature on Fe^{II} and Fe^{III} which documents numerous structures of common units such as $[FeCl_4]^{2-}$ and $[FeCl_4]^-$,[12,13] the title complex is the first homoleptic dinuclear iron(II) chloride species, although the $[Fe_2I_6]^{2-}$ anion is known.[14,21]

$[Htmpp]_2[Fe_2Cl_6]$ **1**

The reaction of anhydrous ferric chloride with one equivalent of tmpp in benzene produced a pale yellow air-sensitive solid identified as **1** (yield 60–65%).[15] In an alternate synthesis the starting materials were dissolved separately in diethyl ether, and the $FeCl_3$ solution was passed through a filter and into the solution containing the phosphane. Single crystals were obtained by slow diffusion of hexanes into a solution of **1** in acetone.[16] The salt appears to be indefinitely stable in acetone in the absence of air, but in alcohols it decomposes to a mixture of $[Fe^{II}Cl_4]^{2-}$ and unidentifiable products. Oxidation to the well-known $[Fe^{III}Cl_4]^-$ is facile in the presence of oxygen or in halogenated solvents.[17] Thus far, no firm evidence for a mixed-valence complex has been found, although an intensely colored intermediate has been observed in O_2-saturated solutions of **1** in CH_2Cl_2 before the $[FeCl_4]^-$ compound is formed; the identity of this species is under investigation.

The X-ray structure unequivocally establishes the identity of the anion in **1** as $[Fe_2Cl_6]^{2-}$ with two phosphonium ions as counterions. An ORTEP representation of $[Fe_2Cl_6]^{2-}$ is presented in Figure 1. The structure of the dianion consists

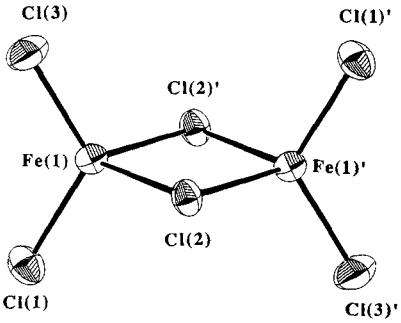

Fig. 1. Selected distances [Å] and angles [°] for the anion in **1**: Fe(1)···Fe(1)′ 3.350(4), Fe(1)-Cl(1) 2.235(2); Fe(1)-Cl(2) 2.38(5); Fe(1)-Cl(3) 2.227(2), Fe(1)-Cl(2)′ 2.409(2); Cl(1)-Fe(1)-Cl(2) 108.02(9); Cl(1)-Fe(1)-Cl(2)′, 110.57(8); Cl(1)-Fe(1)-Cl(3), 120.5(1); Cl(2)-Fe(1)-Cl(2)′; 91.36(8); Cl(2)-Fe(1)-Cl(3), 110.96(9); Cl(3)-Fe(1)-Cl(2)′, 111.50(8); Fe(1)-Cl(2)-Fe(1)′, 88.64(8).

of two edge-sharing tetrahedra with two terminal and two bridging chloro ligands per metal atom with an inversion center at the midpoint of the Fe(1)···Fe(1)′ bond. The Fe(1)···Fe(1)′ distance of 3.350(4) Å, which is much larger than the sum of the covalent radii, precludes the formation of a direct bond and is comparable to the distances of 3.32 Å found in $[Fe_2(\mu\text{-}OH)(OAc)_2(me_3tacn)_2](ClO_4)$[8] and 3.35 Å in $[Fe_2(bpmp)(OPr)_2](BPh_4)$,[9] but shorter than the corresponding value reported for $[Fe_2(biphme)_2(O_2CH)_4]$ (3.585 Å).[10] The Fe···Fe distances reported for the two closely related structures $[Fe_2(SEt)_6]^{2-}$ and $[Fe_2Cl_4(OPh)_2]^{2-}$ are somewhat shorter, 2.978(1) and 3.177(3) Å, respectively.[5,6] The average Fe^{II}–Cl bond length for the terminal chloro ligand (2.231(2)Å) is intermediate between the reported ranges for Fe^{II}–Cl (2.25–2.35 Å)[12] and Fe^{III}–Cl bonds (2.15–2.20 Å).[13] As expected, the average distance for the bridging chloro ligands is longer (2.397(2) Å) than for the terminal groups. The Cl-Fe bond angles are in the range anticipated for tetrahedral geometry (108.02(9) – 120.5(1)°) but the Cl(2)-Fe(1)-Cl(2)′ and the Fe(1)-Cl(2)-Fe(1)′ angles of 91.36(8) and 88.64(8)°, respectively, are considerably distorted from ideal geometry. A three-dimensional packing diagram of **1** (Fig. 2) viewed along the *b* axis illustrates the segregated arrangement of the $[tmpp]^+$ and the $[Fe_2Cl_6]^{2-}$ units and underscores how bulky the unusual cation is. The

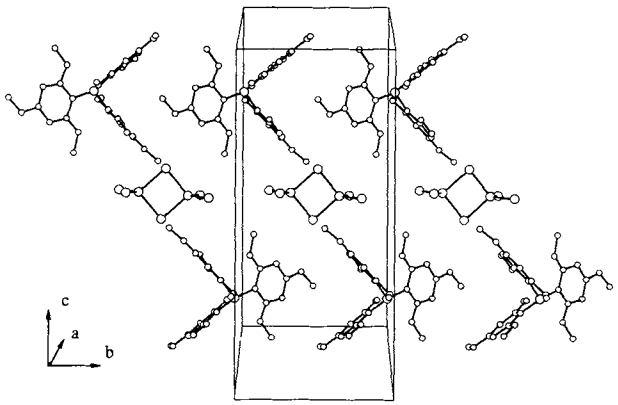

Fig. 2. Packing diagram of **1** viewed along the *b* axis.

identity of the cation and its spatial requirements may affect the structure; therefore, we have sought to prepare other salts of $[Fe_2Cl_6]^{2-}$ with more common counterions. Preliminary results indicate that the corresponding reaction of PPh_3 with $FeCl_3$ in benzene furnishes the analogous product, $[HPPh_3]_2[Fe_2Cl_6]$. We are currently working on syntheses with $FeCl_2$ and salts such as [tmpp]Cl, $[Ph_4P]Cl$, and $[Et_4N]Cl$.

The far-IR spectrum of **1** exhibits four Fe–Cl stretching bands at 360(s), 320(m), 300(m), and 230(w) cm^{-1}, as predicted by a group-theoretical treatment of a molecule with D_{2h} symmetry. The electronic spectrum of **1** ($CHCl_3$) exhibits three features (λ_{max} [nm] (ε [$M^{-1}cm^{-1}$])): 377 (1.80×10^3), 287 (sh), and 260 (6.80×10^4)). The ^1H NMR spectrum (CD_3CN) exhibits the characteristic resonances attributed to the protonated phosphane: $\delta = 3.67$ (s, *o*-OCH_3), 3.85 (s, *p*-OCH_3), 6.24 (d, *m*-H), 8.37 (d, P–H).

The magnetic exchange interactions within the $[Fe_2Cl_6]^{2-}$ unit are being examined by measuring the solid-state temperature-dependence of the magnetic susceptibility. A plot of μ_{eff} versus T[K] is shown in Figure 3. A detailed description of the magnetic behavior of **1** along with its Mössbauer spectrum will be reported in full elsewhere.

Complex **1** reacts with molecular oxygen in a variety of solvents to eventually form the very stable tetracoordinate phosphane oxide adduct (Otmpp) · $FeCl_3$ in high yield.[18] When the reaction was carried out in protic solvents such as MeOH or EtOH the tetrachloroferrate salts $[Htmpp]_2[Fe^{II}Cl_4]$ and $[Htmpp][Fe^{III}Cl_4]$ were isolated as intermediates.[19] These results indicate that the oxidation of phosphane to phosphane oxide in the presence of $FeCl_3$ proceeds by quaternarization of the phosphane and not via dioxygen adducts. We are currently extending this chemistry to other tertiary phosphanes in order to determine the role of $[Fe_2Cl_6]^{2-}$ in the catalytic oxidation of such systems.

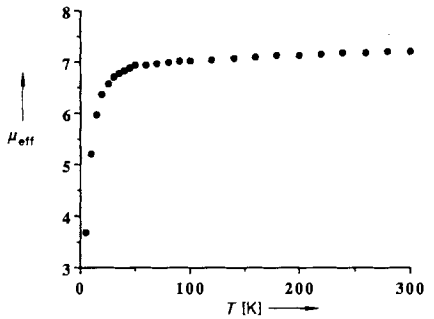

Fig. 3. A plot of μ_{eff} versus temperature for **1**. The curvature in this graph is due to the presence of zero-field splitting terms in the spin Hamiltonian.

The ionic compound reported in this paper contains the remarkably simple yet unknown anion $[Fe_2Cl_6]^{2-}$. While dinuclear complexes of the type $[Fe_2Cl_6(\mu\text{-}O)]^{2-}$ and $[Fe_2Cl_6(\mu\text{-}OR)_2]^{2-}$ are known for Fe^{III} centers [2] and Fe_2Cl_6 is the structure $FeCl_3$ adopts in the gas phase,[20] no discrete unit of $FeCl_2$ has ever been reported to our knowledge.[21] Furthermore, the title compound constitutes one of the few structurally characterized diiron(II) compounds.

Experimental Procedure

Method A: Anhydrous $FeCl_3$ (0.162 g, 0.999 mmol) was added to one equivalent of tmpp (0.532 g, 0.999 mmol) in 30 mL of deoxygenated benzene. The resulting suspension was stirred at room temperature for 24 h, after which time the solvent was decanted from a yellow solid. The product was washed with several aliquots of benzene (3 × 10 mL) and THF (3 × 10 mL) until the washings were colorless. The resulting pale yellow product was dried in vacuo (yield 0.456 g, 65%).

Method B: A solution of $FeCl_3$ (0.062 g, 0.380 mmol) in 15 mL of diethyl ether was filtered into a solution of tmpp (0.203 g, 0.380 mmol) in 25 mL of diethyl ether. The resulting yellow suspension was stirred at room temperature for 24 h. The workup was the same as described in method A. A yellow solid was obtained (yield 0.148 g, 56%).

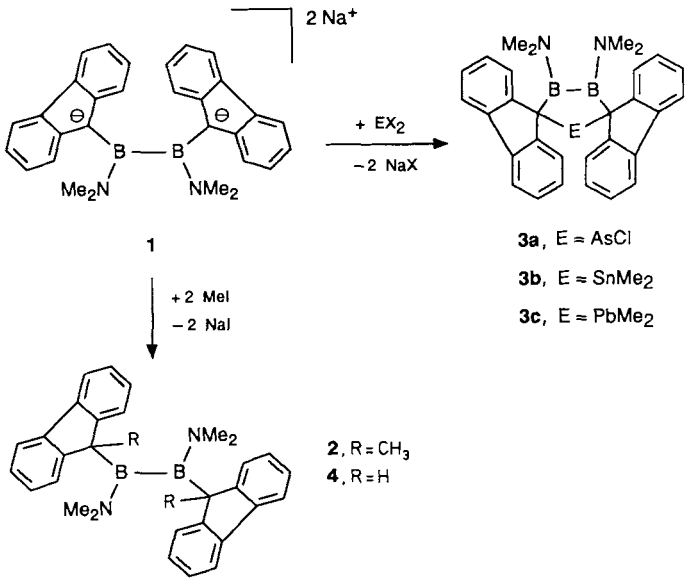
1-Hetero-3,4-diborolanes and Two New Routes to 1,2-Diboretanes**

By *Ralf Littger, Heinrich Nöth,* Martina Thomann,* and *Matthias Wagner*

The synthetic potential of boryl-substituted alkyllithium compounds (alkylideneborates) has hardly been exploited so far, although compounds of the type R_2BCH_2Li [1] and $(R_2B)_2CHLi$ [2] should allow access to other boryl-substituted organometallic compounds. An even greater variety of reactions is to be expected for the (formally) dianionic 2,3-diboratabutadienes.[3] Thus, for example, **1** should be suitable for the construction of new heterocycles. Indeed, from the reactions given in Scheme 1, not only the methyl derivative **2**, but also the 1-hetero-3,4-diborolanes **3a–c** are obtained in good yields.

For **3b** and **3c** two signals occur for the NMe_2 groups in both the ^{1}H and ^{13}C NMR spectra, in the case of **3a**, however, four signals are observed, because the pyramidal C_2AsCl group causes a decrease in symmetry. Thus, hindered rotation about the B–N bonds occurs in all compounds. Thirteen signals for the fluorenyl groups in the ^{13}C

[*] Prof. Dr. H. Nöth, Dipl.-Chem. R. Littger, Dr. M. Thomann, Dr. M. Wagner
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-W-8000 München 2 (FRG)

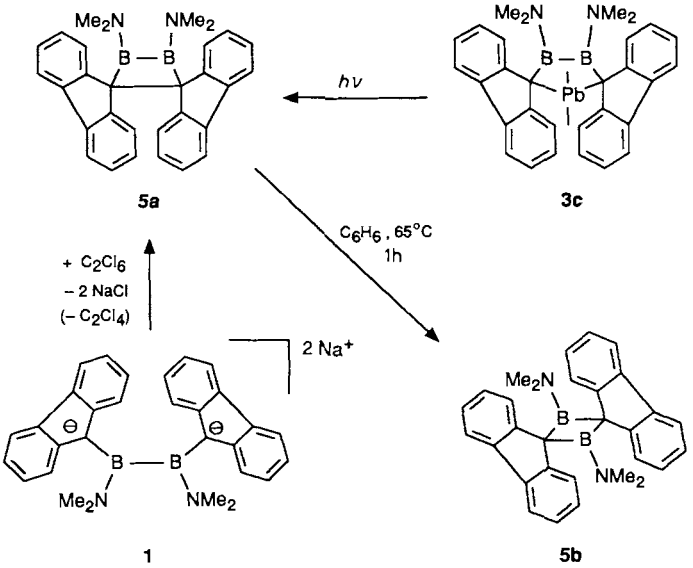


Scheme 1.

NMR spectra of both **3b,c**, and only one signal for the two methyl groups at the Sn and at the Pb atom, respectively, indicate a *twist* conformation with C_2 symmetry for the appropriate B_2C_2E ring framework. Twenty-three signals are found for the fluorenyl groups of **3a**, three of these signals show double intensity; thus two nonequivalent fluorenyl groups exist due to the lower symmetry. The ^{11}B chemical shifts of **3a** ($\delta = 48$), **3b** ($\delta = 48$), and **3c** ($\delta = 50$) lie in the expected range.[4] In the case of **3b** $\delta(^{119}Sn) = 101.4$ indicates a strongly deshielded Sn atom in an SnC_4 environment.[5] Since $\delta(^{119}Sn)$ responds strongly to a change of bond angles at the Sn atom,[5] this value indicates a considerable deviation from the ideal tetrahedral configuration. This corresponds to the "normal" coupling constant[5] to the methyl C atoms $^1J(^{119}Sn,^{13}C = 286$ Hz) and to an unusually small coupling to the endocyclic C atoms (135 Hz).

The X-ray structure analysis[6] of **3b** reveals that the C_2 symmetry deduced from NMR spectroscopy is almost retained in the solid state (Fig. 1). The twisted B_2C_2Sn five-membered ring (ring C atoms above and below the B_2Sn plane) contains Me_2NB groups, whose C_2BN planes strive for orthogonality, like all electron-precise poly(dimethylamino)boranes.[7] The B–B distance in **3b** (1.757(9) Å) is significantly longer than in **1** (1.716 Å)[3a] and the neutral compound **4** (1.697(4) Å).[4] The B–C distances in **3b** (1.606(8), 1.614(9) Å), however, are somewhat shorter than in **4** (1.618(3), 1.624(3) Å). The endocyclic Sn–C bonds are on average 0.11 Å longer than the exocyclic ones. This, and the small endocyclic C-Sn-C angle of the ring (96.1(2)°) indicate ring strain. In the mass spectrum of **3b** a fragmentation leading to $[SnMe_2]^{\cdot+}$ and $[fl{=}B{=}NMe_2]^{\cdot+}$ (fl = fluorenylidene) is dominant, which can be interpreted as a [2 + 2 + 2] cycloreversion. Also with the elimination of $SnMe_2$ the 1,2-diboretane cation is formed during the fragmentation of $M^{\cdot+}$. This contraction of the ring, however, is not achieved either by thermolysis or by photolysis of **3b**.

Since Pb–C bonds are weaker than Sn–C bonds, **3c** should be more readily accessible to elimination of $PbMe_2$ than **3b** is to expulsion of $SnMe_2$. Indeed, the reaction that was only suggested for **3b** in its mass spectrum, can be carried out for **3c**: $PbMe_2$ is eliminated photochemically from **3c** and with contraction of the ring, the 1,2-diboretane derivative **5a**[8] is obtained. The liberated $PbMe_2$ disproportionates into $PbMe_4$ and elemental lead. Compound **5a** is more readily accessible by the oxidative coupling of the disodium salt **1** with C_2Cl_6 (Scheme 2) than by photolysis.



Scheme 2.

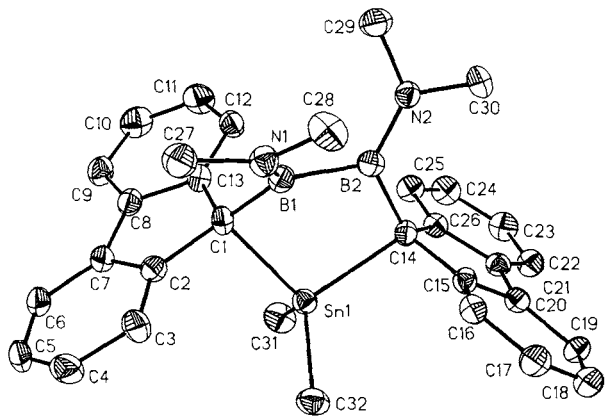


Fig. 1. Crystal structure of **3b**. Selected bond lengths [Å] and angles [°] with standard deviations in parentheses: B1-B2 1.757(9), B1-N1 1.389(8), B2-N2 1.386(6), B1-C1 1.606(8), B2-C14 1.614(9), Sn-C1 2.267(6), Sn-C14 2.225(4), Sn-C31 2.119(7), Sn-C32 2.145(6); B2-B1-N1 123.5(5), B1-B2-N2 124.3(6), N1-B1-C1 122.3(5), N2-B2-C14 119.5(5), B2-B1-C1 114.0(5), B1-B2-C14 116.1(4), Sn-C1-B1 94.9(4), Sn-C14-B2 99.7(3), C31-Sn-C32 114.8(4).

On heating to 65 °C in benzene solution, **5a** rearranges quantitatively into the isomeric 1,3-diboretane derivative **5b** within an hour. Compound **5a** is thus formed under kinetic control, whereas **5b** is thermodynamically the more stable product. This is in agreement with the theoretical prediction.[9] The corresponding rearrangement does not occur for 1,2-bis(diisopropylamino)-1,2-diboretane.[8] It remains an open question whether the rearrangement takes place via radical intermediates, an intermediary B–C double bond system, or a tetrahedral cluster transition state.

Experimental Procedure

The numbering for the fluorenyl C atoms in Figure 1 is also used for the assignment of the NMR spectroscopic data.

2: MeI (0.23 mL, 3.8 mmol) was added to a solution of **1** (0.92 g, 1.9 mmol) [7b] in THF (20 mL) at −30 °C. The orginally blood-red solution immediately brightened. After the solution had been warmed to room temperature, it was

stirred for 1 h, then concentrated to 5 mL under vacuum. The resulting paste-like suspension was treated with benzene (20 mL) and centrifuged, thereafter insoluble products (mainly NaI) were discarded. After removal of all volatiles from the solution under vacuum, the paste-like residue was dissolved in pentane (15 mL). Compound **2** (0.53 g, 60%) crystallized as a yellow solid at −78 °C, m.p. 117–120 °C; $C_{32}H_{34}B_2N_2$ (468.3), correct elemental analysis; ^{11}B NMR (64.16 MHz, C_6D_6, 25 °C, $BF_3 \cdot OEt_2$): $\delta = 52$ ($h_{1/2} = 700$ Hz); ^{1}H NMR (400 MHz, C_6D_6, 25 °C, TMS): $\delta = 7.80$ (m, 6H), 7.50 (m, 2H), 7.30 (m, 8H), 2.69, 1.92 (s, 6H, s, 6H; $N(CH_3)_2$), 1.76 (s, 6H; fl-CH_3); ^{13}C NMR (100.6 MHz, C_6D_6, 25 °C, TMS): $\delta = 155.9$, 155.8 (C2,13), 141.2 (C7,8), 127.5, 127.1 (C5,10), 125.9, 125.8 (C4,11), 125.0, 124.5 (C3,12), 120.3 (C6,9), 49.2 (C1), 47.2, 38.4 ($N(CH_3)_2$), 29.4 (fl-CH_3).

3a: $AsCl_3$ (0.71 g, 3.92 mmol) in THF (10 mL) was added dropwise to a solution of **1** (1.91 g, 3.94 mmol) in THF (15 mL) at −78 °C. After the solution had warmed to room temperature, it was stirred for 12 h. The solvent was removed under vacuum from the orange suspension. The residue was taken up in CH_2Cl_2 (20 mL) and separated from insoluble products by centrifugation, the solvent was removed under vacuum, and the nonvolatile yellow solid precipitated from hexane (15 mL). Yield: 1.42 g **3a** (66%), colorless powder, m.p. 175 °C (decomp); $C_{30}H_{28}AsB_2ClN_2$ (548.6), correct elemental analysis; ^{11}B NMR (64.16 MHz, $CDCl_3$, 25 °C, $BF_3 \cdot OEt_2$): $\delta = 48$ ($h_{1/2} = 850$ Hz); ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 7.89$, 7.58, 7.30 (m, 5H, m, 6H, m, 5H; aromatic protons) 2.97, 2.85, 2.29, 1.96 (s, 3H, s, 3H, s, 3H, s, 3H; $N(CH_3)_2$); ^{13}C NMR (100.6 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 149.7$, 145.6, 145.3, 145.2 (C2,13), 140.0, 139.7, 139.2 (C7,8), 128.5, 126.8, 126.7, 126.2, 125.8, 125.7, 125.6, 125.4, 125.1, 123.3 (C3,4,5,10,11,12), 120.8, 120.3, 119.9, 119.8 (C6,9), 61.0, 60.6 (C1), 45.7, 44.9, 41.6, 40.1 ($N(CH_3)_2$).

3b: **1** (1.63 g, 3.4 mmol) in THF (20 mL) at −78 °C was treated (as for **3a**) with a 0.44 M solution of Me_2SnCl_2 (7.6 mL, 3.3 mmol) in THF. After the solution had warmed to room temperature, it was stirred for 12 h. During this time a precipitate formed that did not settle very well and the solution remained tomato red. Following centrifugation the insoluble products were separated and all the volatiles were removed from the solution under vacuum. The remaining red resin was precipitated from hexane (10 mL), which afforded **3b** (1.75 g, 88%; m.p. 280–283 °C) as a colorless powder. Single crystals of **3b** were formed on slow evaporation of a CH_2Cl_2 solution over paraffin chips. ^{11}B NMR (64.16 MHz, $CDCl_3$, 25 °C, $BF_3 \cdot OEt_2$): $\delta = 48$ ($h_{1/2} = 880$ Hz); ^{119}Sn NMR (74.58 MHz, $CDCl_3$, 25 °C): $\delta = 101.4$; ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.04$, 7.99 (d, 2H, d, 2H; H6,9), 7.79, 7.60 (d, 2H, d, 2H; H3,12), 7.51, 7.38, 7.34, 7.29 (each pseudo-t, 2H; H4,5,10,11), 3.07, 2.26 (s, 6H, s, 6H; $N(CH_3)_2$), −0.63 (s, $^2J(^{117/119}Sn,H) = 48$ Hz, 6H; $Sn(CH_3)_2$); ^{13}C NMR (100.6 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 149.8$, 148.7 ($^2J(^{117/119}Sn,C) = 18$ Hz, $^2J(^{117/119}Sn,C) = 44$ Hz; C2,13), 136.8, 136.6 ($^3J(^{117/119}Sn,C) = 16$ Hz, $^3J(^{117/119}Sn,C) = 17$ Hz; C7,8), 125.7, 125.3 ($^4J(^{117/119}Sn,C) = 11$ Hz, $^4J(^{117/119}Sn,C)$ not resolved; C4,11), 124.6, 121.9 ($^3J(^{117/119}Sn,C) = 15$ Hz, $^3J(^{117/119}Sn,C) = 17$ Hz; C3,12), 122.4 ($^5J(^{117/119}Sn,C)$ not resolved; C5,10), 120.1, 120.0 ($^4J(^{117/119}Sn,C)$ each not resolved; C6,9), 56.3 ($^1J(^{117/119}Sn,C) = 135$ Hz; C1,14), 44.8, 42.2 ($N(CH_3)_2$), −6.9 ($^1J(^{117/119}Sn,C) = 286$, 274 Hz; $Sn(CH_3)_2$).

3c: A solution of **1** (8.13 g, 16.8 mmol) in THF (50 mL) was added dropwise to a suspension of Me_2PbBr_2 (6.66 g, 16.8 mmol) in THF (40 mL) with exclusion of light at −78 °C and continuously stirred. Workup as for **3b**. Yield: **3c** (8.85 g, 78%) as an intense yellow powder, m.p. 110 °C (decomp); $C_{32}H_{34}B_2N_2Pb$ (675.5), correct elemental analysis; UV/VIS (C_6H_6): λ_{max}[nm] = 276, 295, 366; ^{11}B NMR (64.16 MHz, C_6D_6, 25 °C, $BF_3 \cdot OEt_2$): $\delta = 50$ ($h_{1/2} = 930$ Hz); ^{1}H NMR (400 MHz, C_6D_6, 25 °C, TMS): $\delta = 8.03$, 7.96 (d, 2H, d, 2H; H6,9), 7.92, 7.60 (d, 2H, d, 2H; H3,12), 7.54, 7.33 (each pseudo-t, 2H, 2H; H4,11), 7.25, 7.21 (each pseudo-t, 2H, 2H; H5,10), 2.76, 2.09 (s, 6H, s, 6H; $N(CH_3)_2$), −0.01 (s, $^2J(^{207}Pb,H) = 35$ Hz, 6H; $Pb(CH_3)_2$); ^{13}C NMR (100.6 MHz, C_6D_6, 25 °C, TMS): $\delta = 149.7$, 149.0 ($^2J(^{207}Pb,C) = 19$ Hz, $^2J(^{207}Pb,C) = 62$ Hz; C2,13), 137.0, 136.7 ($^3J(^{207}Pb,C) = 30$ Hz, $^3J(^{207}Pb,C) = 26$ Hz; C7,8), 125.9, 125.6 ($^4J(^{207}Pb,C) = 23$ Hz, $^4J(^{207}Pb,C) = 19$ Hz; C4,11), 124.8, 122.3 ($^3J(^{207}Pb,C) = 31$ Hz, $^3J(^{207}Pb,C) = 34$ Hz; C3,12), 123.1, 122.9 ($^5J(^{207}Pb,C) = 28$ Hz, $^5J(^{207}Pb,C) = 22$ Hz; C5,10), 120.5, 120.4 ($^4J(^{207}Pb,C) = 15$ Hz, $^4J(^{207}Pb,C) = 19$ Hz; C6,9), 68.5 ($^1J(^{207}Pb,C)$ not resolved; C1), 44.2, 42.0 ($N(CH_3)_2$), 12.0 ($^1J(^{207}Pb,C) = 8$ Hz; $Pb(CH_3)_2$).

5a: a) By photolysis of **3c**: A solution of **3c** (0.53 g, 0.79 mmol) in benzene (80 mL) was solidified in a cylindrical quartz flask by using a cold finger (isopropanol-dry ice). Afterwards the reaction flask was placed in the sunlight, and the solidified solution was allowed to warm up over 2 h. During this time a black lead mirror formed, and the yellow color of **3c** completely disappeared. Subsequently, the mixture was filtered through a G4 frit, and volatile benzene and $PbMe_4$ were removed under vacuum. Pale pink **5a** was obtained by precipitation from hexane in an analytically pure form. Titration of the amount of lead deposited gave 90% of that expected theoretically. Yield of **5a**: 0.18 g, 51%. b) By oxidative coupling of **1** with hexachloroethane: **1** (2.75 g, 5.68 mmol) was suspended in benzene (70 mL) and a solution of hexachloroethane (1.34 g, 5.66 mmol) in benzene (20 mL) was added over 10 min at room temperature, and the mixture was stirred. Thereafter no undissolved **1** remained. All volatiles were removed from the clear, red-brown solution under vacuum, the residue was suspended in a little benzene and centrifuged from the slimy precipitate. The benzene was removed from the solution under vacuum and the solid residue was reprecipitated from hexane (5–10 mL). Yield of **5a**: (1.0 g, 42%), colorless powder (m.p. 159–161 °C). (The reactions described [a and b] occur quantitatively; the moderate yields of **5a** are a result of the considerable solubility of **5a** in hexane.) $C_{30}H_{28}B_2N_2$ (438.2), correct elemental analysis; ^{11}B NMR (64.16 MHz, C_6D_6, 25 °C, $BF_3 \cdot OEt_2$): $\delta = 49$ ($h_{1/2} = 820$ Hz); ^{1}H NMR (400 MHz, C_6D_6, 25 °C, TMS): $\delta = 7.77$, 7.67, 7.12 (m, 4H, m, 4H, m, 8H; aromatic protons), 2.65, 1.86 (s, 6H, s, 6H; $N(CH_3)_2$); ^{13}C NMR (100.6 MHz, C_6D_6, 25 °C, TMS): $\delta = 148.5$, 140.6 (C2,7), 126.1, 125.6, 124.5, 120.3 (C3,4,5,6), 62.0 (C1), 43.9, 39.2 ($N(CH_3)_2$).

5b: Compound **5a** (0.37 g, 0.84 mmol) was dissolved in benzene (15 mL). The red solution was held at 65 °C for 1 h and stirred. Even at this temperature a little **5b** precipitated as a colorless powder. The solution was cooled to room temperature, and the now colorless solution was concentrated to a third of its volume, and the insoluble **5b** was filtered with a G3 frit. After **5b** had been washed with a few drops of benzene, it was obtained as a colorless powder; yield: 0.23 g (62%); m.p. 245–246 °C; $C_{30}H_{28}B_2N_2$ (438.2), correct elemental analysis; ^{11}B NMR (64.16 MHz, $CDCl_3$, 25 °C, $BF_3 \cdot OEt_2$): $\delta = 46$ ($h_{1/2} = 490$ Hz); ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.02$, 7.40 (m, 8H, m, 8H; aromatic protons), 1.79 (s, 12H; $N(CH_3)_2$); ^{13}C NMR (100.6 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 150.7$ (C2), 139.7 (C7), 126.3 (C3), 123.7, 123.2 (C4,5), 120.2 (C6), 38.8 ($N(CH_3)_2$, signal of C1 not observed.

The First Octahedral Zintl Ion: Sn_6^{2-} as a Ligand in $[Sn_6\{Cr(CO)_5\}_6]^{2-}$**

By *Berthold Schiemenz* and *Gottfried Huttner**

Dedicated to Professor Hartmut Bärnighausen on the occasion of his 60th birthday

Octahedral clusters with M_6 skeletons (M = transition metal) appear very frequently in the chemistry of the d block elements.[1] In contrast, in the chemistry of the main group elements, it is only in boron chemistry that the octahedron is known as a framework pattern of clusters.[1] Octahedral clusters have so far not been proven either for Zintl ions E_6^{n-} [2, 3] (E = main group element) or for isopolycations E_6^{n+}.[4] The reason why the octahedron does not occur as a

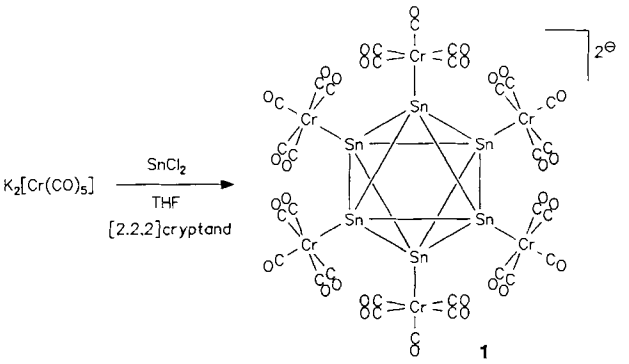
construction motif in these cases appears to be unknown.[2] Thus, for example, in the chemistry of tin, which shows a rich Zintl ion chemistry,[2, 3] an octahedral ion Sn_6^{2-} is unknown. According to Wade's rules,[5] such an ion could be stable as an octahedral cluster with 14 framework electrons; also its comparatively low charge seems to indicate that it could exist. However such clusters occur neither in the solid state nor in solution.[2, 3] Also attempts to stabilize Zintl ions by using transition metal complex fragments[6] have so far not led to the isolation of aggregates which are not members of the series of the well-known anions E_m^{n-}.[2, 3]

We report now on the synthesis of coordinatively stabilized, octahedral Sn_6^{2-} in $[Sn_6\{Cr(CO)_5\}_6]^{2-}$ (**1**). $K_2[Cr(CO)_5]$[7]



reacts with $SnCl_2$ in THF at $-70\,^{\circ}C$ to give a brown-red solution. After the addition of potassium [2.2.2]cryptand,[8] **1** can be crystallized from this solution as the [2.2.2]cryptand salt.[9] At the same time elemental tin is precipitated from the reaction solution. In addition $[K([2.2.2]cryptand)]_2[Cl_2Sn\{Cr(CO)_5\}_2]$ can be isolated as a crystalline compound.

The structure of the anionic cluster **1** is shown in Figure 1.[10] The six tin atoms form an almost regular octahedron with Sn–Sn distances ranging between 293.0 and 296.0 pm (Fig. 1). The Sn–Sn bond lengths are in the normal range.[3, 11] Each tin atom is coordinated through its "lone pair of electrons" to one $Cr(CO)_5$ fragment. The Sn–Cr bond vectors radiate outwards with Sn–Cr distances of 260.8 to 261.3 pm. The deviations from the ideal radial orientation (ideal value Sn-Sn-Cr: 135°; cf. range of angles for Sn-Sn-Cr angle, Fig. 1) result from the spatial requirement of the bulky $Cr(CO)_5$ "protective groups". On the whole, however, the distortions remain quite small (Fig. 1).

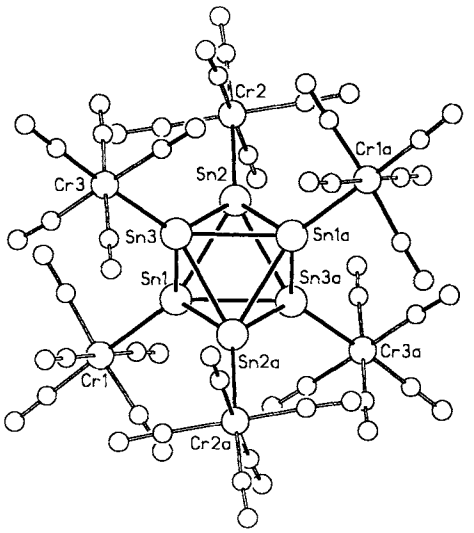


Fig. 1. The crystal structure of the anion $[Sn_6\{Cr(CO)_5\}_6]^{2-}$ (**1**). Selected distances [pm] and angles [°]: Sn1-Sn2 294.0(1), Sn1-Sn3 293.0(1), Sn1-Sn2a 294.8(1), Sn1-Sn3a 294.2(1), Sn2-Sn3 296.0(1), Sn2-Sn1a 294.8(1), Sn2-Sn3a 294.5(1), Sn1-Cr1 260.9(2), Sn2-Cr2 260.8(3), Sn3-Cr3 261.3(2); Cr1-Sn1-Sn2 148.0(1), Cr1-Sn1-Sn3 129.9(1), Cr1-Sn1-Sn2a 121.1(1), Cr1-Sn1-Sn3a 136.6(1), Cr2-Sn2-Sn1 135.1(1), Cr2-Sn2-Sn3 131.6(1), Cr2-Sn2-Sn1a 135.3(1), Cr2-Sn2-Sn3 131.6(1), Cr2-Sn2-Sn1a 135.3(1), Cr2-Sn2-Sn3a 138.7(1), Cr3-Sn3-Sn1 135.3(1), Cr3-Sn3-Sn2 130.5(1), Cr3-Sn3-Sn1a 134.7(1), Cr3-Sn3-Sn2a 139.2(1). The center of the Sn_6 octahedron is a crystallographic inversion center. The atom designators Xi and Xia stand for atoms related by inversion symmetry.

The Zintl ion **1** is not only aesthetically pleasing, but its isolation shows for the first time that octahedral element aggregates such as Sn_6^{2-}, the first octahedral Zintl ion, can exist also in main group chemistry. Evidently, apart from the correct number[5] of 14 framework electrons, a prerequisite for the synthesis of such ions is also the "correct" choice of synthetic method and protective groups.

Experimental Procedure

All experiments were carried out with freshly distilled and dried solvents under an argon atmosphere. IR spectra: Bruker IFS 66. NMR spectra: Bruker AC 200. KC_8 (270 mg, 2 mmol) [7] was suspended in THF (20 mL) and allowed to react with $[Cr(CO)_6]$ (220 mg, 1 mmol) at $-70\,^{\circ}C$. To the dirty green suspension [7] obtained after the mixture had been stirred for 3 h (1 h $-70\,^{\circ}C$, 2 h $0\,^{\circ}C$) was added anhydrous $SnCl_2$ (95 mg, 0.5 mmol) at $-70\,^{\circ}C$. The suspension turned brown immediately; after it had been stirred for 30 min [2.2.2]cryptand (126 mg, 0.3 mmol) was added. The solution was allowed to warm to $0\,^{\circ}C$ and subsequently filtered through diatomeic earth. The brown filtrate was concentrated to 5 mL under vacuum and layered first with a little diethyl ether and then with pentane at $15\,^{\circ}C$. In the course of 7 days elemental tin was deposited; in addition yellow needlelike crystals of $[K([2.2.2]cryptand)]_2[Cl_2Sn\{Cr(CO)_5\}_2]$ could be isolated. Deep red, analytically pure crystals of $[K^+\text{-}([2.2.2]cryptand)]_2$ [1] were found both on the wall of the flask and in the precipitate; they must be picked out by hand. $M = 2695.61\ g\,mol^{-1}$, $C_{66}H_{72}Cr_6K_2N_4O_{42}Sn_6$, yield: 15 mg (7% based on Sn), correct C,H,N analysis, IR (THF): ν_{CO} [cm^{-1}] = 2073 m, 1943 vs, 1918 s; ^1H NMR (293 K, [D_6]acetone: $\delta = 2.61$ (m, 24 H), 3.65 (m, 48 H).

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

New Books to Mark the Coming-of-Age of Bioinorganic Chemistry

Bioinorganic chemistry has now matured into a well established area of research and has become an essential part of the education of new chemists. This is well illustrated by the first four books reviewed below. However, a comparison of these gives a hint of a new development. Whereas three of the books treat bioinorganic chemistry from a classical standpoint which, although interdisciplinary, is predominantly based on the concepts of inorganic chemistry, the book by J. J. R. Fraústo da Silva and R. J. P. Williams strongly emphasizes the *biological* aspects. The latter viewpoint can be characterized as the "biological chemistry of the elements", a broadly based subject ranging from inorganic chemistry (i.e., the chemistry of the elements) to molecular biology; thus it includes bioinorganic chemistry in the conventional sense, but extends beyond it.

Bioanorganische Chemie. (Series: Teubner Studienbücher Chemie.) By *W. Kaim* and *B. Schwederski*. Teubner, Stuttgart, 1991. XII, 450 pp., paperback DM 44.80.—ISBN 3-519-03505-7

At last here is an up-to-date and comprehensive textbook of bioinorganic chemistry! According to the cover blurb it is intended for use by students who have already attended a basic course of lectures in chemistry. In fact, in order to use the book to full advantage it is necessary (and sufficient) for readers to have a basic knowledge of the three core areas of chemistry as well as of biochemistry. However, to suggest only students as potential readers is too restrictive.

The authors have avoided following a rigid plan of arranging the contents according to either chemical elements or biological functions, and have thus freed the readers and themselves from unnecessary restrictions—especially with regard to presenting an overall view of bioinorganic chemistry. The result is an interesting and lively book. The detailed contents mainly follow a sequence that is of proven didactic value: presenting the experimental facts, explaining these on the basis of proposed models, and drawing attention to more far-reaching relationships. The text is supported by over 400 figures, tables, structural formulas, reaction schemes, and equations.

Two introductory chapters, the first giving a historical survey and indicating the present importance, and the second introducing some basic principles, are followed by 17 chapters devoted to special topics such as photosynthesis, hemoproteins, nickel-containing enzymes, biomineralization, and chemotherapy. Practically all the areas of bioinorganic chemistry are covered. The book concludes with a bibliography, a glossary of terms, and a good keyword index.

Particular attention has been given to providing up-to-date literature references, citing publications up to and including 1991. Readers are likely to have different views on whether or not the large number of literature references (over 700) is appropriate—probably those engaged in research will say that it is, whereas students will be less inclined to agree.

The glossary explains just under a hundred terms very briefly, typically in two lines. In view of the assumed previous knowledge of the readers, the extremely short definitions seem unnecessary in many cases; examples are diamagnetism, entropy (" a thermodynamic quantity measuring the degree of disorder in a system"), extinction coefficient, Lewis base, Lewis acid, molecular orbital, and the primary, secondary, and tertiary structure of a protein. Instead of these it would have been better to include expressions that are less familiar to chemists, such as "fakultativ aerob" (facultatively, or optionally, aerobic) on page 326.

A similar difficulty arises with some of the special sections inserted into the text, typically one or two pages in length and distinguished by a gray background, that deal with physical methods or theoretical models. Some of the explanations of complicated measurement and evaluation procedures are too superficial. Expressions such as "data sets", "the phase problem" (in the determination of structures by X-ray diffraction), "a method that is not unambiguous" (in connection with X-ray absorption spectroscopy), and "quadrupole splitting" (in Mössbauer spectroscopy) are used with little or no explanation. However, there are other such sections (e.g., those on the entatic state—catalysis by enzymes, electron spin resonance I + II, mirror image isomers in octahedral complexes) that are well presented.

Factual errors and inaccuracies are very few in relation to the wealth of information contained in the book. Although it is true that thiolates *can* stabilize high oxidation states of metal centers (p. 123), the authors should certainly have mentioned that for this to occur it is necessary for the normal reaction yielding the organic disulfide (with reduction of the metal ion) to be blocked. In Equation (7.11) the reducing agent needed to form $[Fe_4S_4(RS)_4]^{2-}$ is not shown. In Equation (10.10) the formula of the *ortho*-quinone is incorrect. In the catalytic cycle of the Cu,Zn-superoxide-dismutase (p. 218) the imidazole ring coordinated at stages 3 and 4 must be neutral, not anionic. The statement on page 237 that a bridging by N_2 between two metal centers in the nitrogenase is not possible is at least misleading, since an Mo–N_2–Fe configuration has in fact been discussed in the literature for the actual cluster model shown (Eq. (11.23)). Changes in bone structure in cases of chronic cadmium poisoning are probably caused not so much by direct replacement of Ca by Cd as by the indirect effects of kidney damage (through interference with the calcium and phosphate metabolism). On page 348 the impression is given that carcinogenic effects of chromate in humans have not yet been proven. In fact, however, zinc chromate is classified as a human carcinogen (see the MAK register). I found about 30 printing errors in the book.

These minor defects do not alter the favorable overall impression of the book. As already indicated above, the potential readership is not confined to students. The book is of interest to everyone who wishes to obtain an overview of bioinorganic chemistry and already has an adequate knowl-

edge of general chemistry. Advanced chemistry students should definitely have a copy, and the relatively low price should help to make that possible.

It is desirable that an English language edition should be made available very soon, and the book should then have an excellent prospect of gaining a reputation beyond the German-speaking world as a standard work on bioinorganic chemistry.

The Biological Chemistry of the Elements. The Inorganic Chemistry of Life. By *J. J. R. Fraústo da Silva* and *R. J. P. Williams*. Clarendon Press, Oxford, 1991. XXI, 561 pp., hardcover £ 60.00.—ISBN 0-19-855598-9

A preliminary thumbing through this book already reveals some unusual features in form and content. The text is arranged in short sections with headings that stand out clearly, and a liberal use is made of space, all of which makes for excellent clarity. A wide margin occupies the left-hand third of each page, and is frequently used for figures and tables. Quite a number of the figures present biological information; for example, there are diagrams of a hepatocyte and a nerve cell, organelles (mitochondrion, chloroplast, etc.), the skeleton of a lizard, and many schematic diagrams of cells of a wide variety of types, showing cell membranes with material and energy flows.

The interconnections between inorganic chemistry, (bio)-physical chemistry, biochemistry, and molecular biology are emphasized in a wealth of examples. The program of the book can be illustrated by three quotations. Page 147: "The function of an element or a compound in biology has to be seen in the context of where and when it combines and how it moves, is used, and is removed." Page 155: "The complexity of the uses of energy, the fact that the whole system is constantly multiplying and growing or repairing, that it can maintain shape or alter it, and that the several operations are timed require a continuous monitoring, feedback, communication and energy network." Page 527: "The central hypothesis is that the evolving nature of living systems... is a product of an interaction between the properties of inorganic elements... and an ever-evolving organic chemistry dependent on these properties."

The book is divided into three sections containing altogether 22 chapters. The first section is concerned mainly with coordination chemistry and physicochemical and biochemical aspects. Some of the topics discussed are the relative abundance, bioavailability, and speciation of different elements, compartmentelation in biological systems, kinetic and energetic aspects, the special role of hydrogen, and biological macromolecules. The second section is the bioinorganic core of the book, consisting of 12 chapters dealing with individual elements, groups of elements, and the forms in which each element can occur (e.g., iron in the form of heme). The third section is concerned with biominerals and biological shapes, homeostasis, morphogenesis, and evolution, and lastly with the use of the elements by man (ecological, toxicological, and medical aspects). A detailed index completes the book. The lists of references given at the end of most of the chapters have deliberately been kept short, with a high proportion of review articles.

There are about 450 figures and tables, plus many reaction equations and structural formulas. The consistently high quality of the figures and the commendably low incidence of printing errors show that the book has been carefully prepared. Some errors worth pointing out are as follows: on page 44 "1 pm = 100 Å" is wrong; on page 45 the sulfide S-atoms of the Fe_4S_4 cluster cannot have free terminal bonds; on pages 152 and 522 an incorrect formula is given for the anion of shikimic acid; in the formula for glutathione on page 455 the positions of the glycine and cysteine groups should be interchanged.

"The Biological Chemistry of the Elements" is an attractive book and is a pleasure to read. The authors have sought to present a comprehensive picture, including both the biochemical states *and* the processes, covering both the spatial *and* the temporal (e.g., evolutionary) aspects. From the reader's standpoint a broad background knowledge is desirable as a starting basis. This work is not suitable as a student textbook, and is presumably not intended as such; in any case, the high price alone will deter students from buying it. The book should be of great interest to those engaged in research and teaching in chemistry and biology, especially in the areas of complex chemistry, bioinorganic chemistry, biochemistry, and molecular biology. Other books suitable as introductions and accompaniments to the study of this work are: *Bioanorganische Chemie*, by W. Kaim and B. Schwederski (see above) and *Molecular Biology of the Cell*, by B. Alberts, D. Bray, J. Lewis, M. Raff, K. Roberts, and J. D. Watson.

Bioinorganic Chemistry. (Series: Progress in Inorganic Chemistry, Vol. 38.) Edited by *S. J. Lippard*. Wiley, New York, 1990. XV, 535 pp., paperback £ 28.30.—ISBN 0-471-52945-1

This volume contains eight review articles on current areas of research in bioinorganic chemistry, based on contributions to the Fourth International Conference on Bioinorganic Chemistry held in 1989 in Cambridge (USA).

In the first article R. H. Holm, S. Ciurli, and J. A. Weigel begin with a short introduction to the chemistry of iron–sulfur clusters, then go on to describe studies with model compounds aimed at mimicking the effects of the protein matrix on Fe_4S_4 centers. Special attention is then devoted to Fe_4S_4 cubane-type clusters with nonequivalent iron atoms.

O. Hayaishi, O. Takikawa, and R. Yoshida contribute a review of the heme-containing enzyme indoleamine-2,3-dioxygenase. Here, unfortunately, inorganic aspects only receive marginal attention, and therefore a more appropriate place for this article would be in a series on biochemistry.

Iron and manganese proteins containing (μ-oxo)dimetal centers take part in a variety of biochemical processes. Perhaps the best known of these proteins is the dioxygen carrier hemerythrin. L. Que, Jr., and A. E. True describe these metalloproteins and numerous smaller complexes that serve as models for their active centers. This is the longest chapter (104 pp.), and also contains the greatest number of literature references. The authors have succeeded in giving a very clear account of the combined use of spectroscopic, X-ray crystallographic, magnetochemical, and electrochemical methods to study proteins and model complexes.

An article by P. Hendry and A. M. Sargeson deals with biologically important reactions of phosphate derivatives and discusses their mechanisms. Complexes formed by inert metal ions have proved to be especially useful for such mechanistic studies. The central theme is the intramolecular attack of metal-coordinated nucleophiles such as OH^- or NH_2^- on neighboring phosphate ligands.

B. E. Bowler, A. L. Raphael, and H. B. Gray discuss theoretical and experimental aspects of long-range electron transfer (ET) in donor–acceptor complexes and proteins. The ET rate is shown to depend on various factors, such as the electronic coupling, the distance between donor and acceptor,

and the reorganization energy. The authors also discuss ET processes between proteins and inorganic complexes, in modified proteins, and between different proteins.

J. G. Wright, M. J. Natan, F. M. MacDonnell, D. M. Ralston, and T. V. O'Halloran present a detailed review of the state of mercury(II)-thiolate chemistry. As a closely related topic they describe the receptor MerR, which is specific for Hg^{II}; this DNA-binding protein controls the mechanism of the detoxification of Hg^{II} ions in certain bacteria.

Transition metal complexes can be used as probes for investigating nucleic acids, for example as a way of recognizing different types of DNA, or in sequencing. Metal complexes are especially suitable for this purpose since they can react in many different ways, have useful spectroscopic and electrochemical properties, and can if necessary have rigid structures with defined symmetry. This fascinating subject is covered by A. M. Pyle and J. K. Barton.

In the final article S. L. Bruhn, J. H. Toney, and S. J. Lippard discuss the structure and biochemistry of DNA molecules that have been modified by the action of platinum compounds. As expected the main emphasis is on the antitumor agent cisplatin, but the properties of the corresponding *trans* compound are also discussed.

The experiment mentioned in the preface whereby the usual proofreading has been omitted, so as to produce a more up-to-date text, is not without its adverse effects. Even without a systematic search, more than 30 printing errors were noticed, of which more than 20 were in the article by J. G. Wright et al. However, most of these were not very serious. The figures are, with only a few exceptions, of good quality, and the index is adequate.

The potential readership should particularly include advanced students. The idea of publishing the book in a (relatively!) cheap paperback version at the outset was a good one, not only with students in mind. The advanced level of treatment could present problems for the average student, but despite this some of the chapters may be suitable as a basis for student seminar discussions. In any case, however, the students will first need to be familiar with the fundamentals of bioinorganic chemistry, for example through an introductory lecture course or from a textbook such as that by Kaim and Schwederski (see above).

To summarize, everyone interested in the latest developments in bioinorganic chemistry is strongly recommended to buy this book. It is, in any case, a must for every departmental library.

Perspectives on Bioinorganic Chemistry, Volume 1. Edited by *R. W. Hay, J. R. Dilworth*, and *K. B. Nolan*. JAI Press Ltd., London, 1991. XI, 284 pp., hardcover \$ 78.50 (in North America).– ISBN 1-55938-184-1

The new series "Perspectives on Bioinorganic Chemistry" aims to present the current state of research in this field. The first five volumes are already planned, and will appear at approximately yearly intervals, as implied by the subtitle of Volume 1: "A Research Annual". This first volume contains seven review articles varying in length from 26 to 51 pages. The fact that the individual chapters are short and not very broad in scope is perhaps a justification for the absence of an index.

The first topic is the formation of complexes between metal ions and peptides, reviewed by L. D. Pettit, J. E. Gregor, and H. Kozlowski. The article is arranged according to the various metals, with particular emphasis on copper, and the authors limit their treatment essentially to a factual account in the style of the "Specialist Periodical Reports". However, this is not typical of the book as a whole. Surprisingly, there is no mention of the phytochelatins, a class of plant peptides with an important role in the homeostasis of metal ions.

In the second article T. H. Fife describes the action of metal ions in catalyzing the hydrolysis of esters and amides, starting with simple small-molecule systems and then going on to the example of carboxypeptidase A. The author discusses kinetic and mechanistic aspects which are, of course, intimately related to the structures of the complexes, substrates, and ligands.

There are already numerous reviews on the topic of "blue copper proteins", and the article here by S. K. Chapman is therefore to be seen as updating the position. A description of the structural and spectroscopic properties of the blue copper centers is followed by a list of the individual proteins. Lastly several special topics are covered, such as ruthenium-modified proteins.

F. A. Armstrong contributes an article on voltammetry of metal centers in proteins. The versatile capabilities of this technique, which has hitherto been viewed with some skepticism, are well described. Among other aspects, the special importance of the electrode surfaces is emphasized. Of the systems that have been investigated, iron–sulfur proteins receive particular attention.

W. E. Smith and J. Reglinski report on the use of gold compounds for the treatment of rheumatoid arthritis. After briefly describing the nature of the disease and the clinical aspects, the authors discuss the chemistry of gold compounds, especially complexes with sulfur-containing ligands. The distribution of gold in living organisms, reactions with enzymes and cells, clinical trials, and the mechanism of the therapeutic action are also discussed.

R. C. Hider and A. D. Hall deal with iron chelating agents that can be used for therapeutic applications. The discussion centers mainly on derivatives of 3-hydroxypyridin-4-one. The first clinical tests on compounds of this class have yielded promising results. The work reported includes studies on the mobilization of iron from proteins with transport and storage functions.

In the final article R. R. Eady collects together information on nitrogenases that do not depend on molybdenum. The aspects reported on include the genetics of nitrogen fixation, the biochemistry of the nitrogenase, and the iron proteins, VFe proteins, and FeFe proteins.

Some of the figures and formulas are unsatisfactory in their quality and size. However, this criticism definitely does not apply to the chapters by T. H. Fife and by R. C. Hider and A. D. Hall. The incidence of factual and printing errors is tolerably low. Some particularly noticeable examples are as follows: on page 10 rubredoxin has an Fe_2S_2 core; the formulas given for the lysine side-chain on page 21 and for serine on page 274 contain errors; on page 28 "Glu–Cys–Gly" for glutathione is not strictly correct; in the discussion of CH_3Hg^+ complexes on page 30, the stability constants given are for Cd^{2+}; in Figure 5 on page 198 no unit is given for the ordinate axis; Ref. [47] on page 208 gives the names of the authors but not the journal; on page 280 the text refers to Table 5, but this cannot be found.

On the basis of the quality of the contributions in this first volume, the series "Perspectives on Bioinorganic Chemistry" should find a place in every relevant library. Research groups with interests in bioinorganic chemistry are also recommended to buy the series.

Natural Products. A Laboratory Guide. 2nd Edition. By *R. Ikan*. Academic Press, New York, 1991. XIV, 360 pp., hardcover $ 54.95.—ISBN 0-12-370551-7

Most specialist books are either cheaply produced or too expensive or, in the worst cases, both. The one reviewed here is not cheaply produced; it is typeset in a clear style, printed on good paper, and solidly bound. But what purpose does it serve? More on this later.

The main content of the 17 chapters (about 350 pages altogether) consists of descriptions of 33 isolations of natural products, of which 26 are from the plant kingdom, five from the animal kingdom, and two others. In addition 15 conversion or breakdown reactions and five total syntheses are described. Also included are experimental data on 24 chromatographic separations and six other laboratory processes (color reactions, formation of inclusion complexes, separation of racemates, etc.).

The contents are arranged under four main compound classes: acetogenins, carbohydrates, isoprenoids, and nitrogen compounds. These are further subdivided; for example, the acetogenins are divided into flavones, lipids, lignans, quinones, and phloroglucinols. Each chapter begins with an introduction and ends with questions and a list of recommended books. The middle part describes the individual experiments relating to the subject of the chapter.

Each introduction describes the relevant group of natural products and explains its subdivisions. For example, steroids are subdivided into sterins, bile acids, steroid hormones, compounds with cardiac activity, and sapogenins. On the whole these introductions are very detailed and well illustrated with formula diagrams, although regrettably these are often shown as "flat" structures that are stereochemically ambiguous. These introductions are, of course, no substitute for reading up on natural products chemistry in the relevant textbooks, especially since they do not deal at all with the important aspect of biosynthesis. Nevertheless, they are suitable as a first introduction or for revision, and are presumably meant to be no more than that.

The questions are intended to serve as revision of what has been learnt, but the chemical aspects are not adequately covered. Only rarely does one find questions about reactions or understanding of the principles; instead the emphasis is on names and definitions ("What is ...?" or "Describe ..."). It is doubtful whether this style is suitable as a preparation for examinations.

The descriptions of experiments contain many old favorites, such as Gattermann's methods for the isolation of caffeine from tea and of heme from blood. However, some micropreparations are also included, where the emphasis is not so much on isolating significant quantities as on chromatographic investigations, as in the isolation of pteridines from fruit-flies. Finally, to complete the picture, there are some examples of conversions (e.g., cholesterol to cholestenone, which again is old hat) and total syntheses (e.g., mescalin—was this really necessary?). These experimental descriptions again follow a consistent pattern under standard headings: introduction, principle of the method, apparatus, materials, time required, and execution. The latter usually also includes information on yield, physical properties, test reactions and derivatives, spectroscopic data, and literature references. The latter especially makes it evident that the original edition is now 25 years old.

Some important items that have been added since the first edition are the spectroscopic data given for most of the end products, and details of the flash chromatography of essential oils, HPLC of carotenoids, RP-HPLC of amino acids, HPTLC of carbohydrates, experiments on geoporphyrins, yeast RNA, and the synthesis and breakdown of alkaloids and steroids.

Time and again one asks "Is this necessary?" Not because of the errors, which are very few—for example, in the formula diagrams on pages 201 and 252, in nomenclature (the correct names are citral, not geranial, and sabinene, not sabonene), and on page 240 where the impression is given that strychnine can be extracted from ground-nuts. These are pardonable sins, but more serious faults to my mind are the unnecessarily detailed descriptions of experiments (pp. 280f., preparation of silica gel layers on glass rods and test-tubes for thin-layer chromatography), and sketches of apparatus whose poor print quality alone indicates that they have probably been simply photocopied (p. 197, apparatus for UV irradiation, and p. 200, where the flash chromatography sketch is clearly identical to that in Still's original publication).

Who should buy this book? Obviously it tries to achieve too much. The whole of natural products chemistry, from isolation and structure determination through conversions to the total synthesis of natural products—a subject that should certainly also include biosynthesis—cannot be compressed into 350 pages. If the subtitle "A Laboratory Guide" is intended seriously, a good deal of this could be left out, and perhaps also some of the old familiar stuff could be sacrificed in favor of up-to-date procedures. At this price students are hardly likely to buy the book, and natural products chemists will find in it little that they do not already have in other sources; however, interested scientists from neighboring disciplines can obtain from it a concise impression of the variety of natural products chemistry.

Nucleophilic Aromatic Displacement. The Influence of the Nitro Group. (Series: Organic Nitro Chemistry Series). By *F. Terrier*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1991. XI, 460 pp., hardcover DM 239.00.—ISBN 0-89573-312-9/3-527-26746-8

The attention of modern organic chemistry is directed mostly towards control of the stereochemistry of organic reactions, synthesis of natural products, and especially towards life processes. The chemistry of aromatic compounds, particularly nucleophilic substitution in aromatic rings, is presently "out of fashion" in academic research. There are some reasons for such an attitude; nevertheless, since the majority of products of organic chemical industry contain aromatic carbo- or heterocyclic rings, the chemistry of arenes is still of great importance. Moreover, contrary to the common opinion, it also offers a significant intellectual challenge and an interesting field for discoveries.

In this situation the appearance of the monograph by François Terrier is very timely and welcome. In a relatively short volume the author discusses many important effects of the nitro group on the reactivity of aromatic compounds with nucleophilic agents. Thus, such problems as the kinetics and thermodynamics of the formation of σ-adducts, classical nucleophilic aromatic substitution of leaving groups, and many variants of nucleophilic substitution of hydrogen, photosubstitution, etc., are thoroughly discussed, and a rich selection of examples and references is given. As one might expect, the author's own preferences and interests flavor the book to a noticeable extent. Physicochemical and mechanistic problems are discussed in more depth than practical

aspects; nevertheless, the usefulness and applicability of the various reactions in organic synthesis is discussed at an adequate level.

Although I am very favorably impressed by the concept of this book and its content, I cannot refrain from some critical remarks.

The first objection concerns terminology. Although it is commonly accepted to use the term "complexes" for the adducts of nucleophiles to nitroarenes, this is somewhat misleading. It implies a specific nature for the bonds formed in the addition process, whereas they are normal σ-bonds to sp^3 carbon atoms. The term "σ-adduct" should perhaps be used instead of "complex", and in fact the former term is also used occasionally by the author.

The second objection is more important. In the present state of knowledge, it is evident that nucleophilic addition to a carbon atom bonded to hydrogen (to form a σ^H-adduct) takes place more rapidly than to one with another substituent (σ^x-adduct formation), when these carbon atoms are in equally activated positions of the aromatic ring. This fact is well presented in the book, and also in the author's own original papers and earlier reviews. From this one can draw the general conclusion that nucleophilic substitution of a leaving group in the nitroaromatic ring is usually preceded by fast and reversible formation of the isomeric σ^H-adducts. The author justifiably claims that π-complexes are formed in the course of the S_NAr reaction, but does not mention the more important pre-equilibrium of the formation of σ^H-adducts. Such a conclusion would undoubtedly stimulate the search for new reactions, and would give this very interesting book an additional value.

In a relatively concise book such as this, it is necessary to select material, and thus some omissions are unavoidable. However, I think that the important, although not very general, method of converting σ^H-adducts into nitroso compounds should be mentioned as another variant of the nucleophilic substitution of hydrogen.

The general appearance of the book is pleasing, and the high quality of typography and artwork makes reading it not only an interesting, but also an enjoyable excursion into the chemistry of nitroarenes.

There are very few typographical errors; for example, in structure **10** (p. 162), in the side chain NO_2 should instead be Me; on page 179, second line from the bottom, 5% should instead be 50%; on page 163, "dimethylation" (with HMPA) should read dimethylamination. The most serious error can be seen on the back cover!: *neu*cleophilic substitution.

In general, this is a very valuable, interesting, and important book, and I strongly recommend it for all libraries of academic and industrial chemical research laboratories. In spite of the relatively high price, it will undoubtedly also be purchased by many individual chemists. I certainly hope that it will promote a greater interest in the fascinating chemistry of nitroarenes.

Microbial Degradation of Natural Products. Edited by *G. Winkelmann*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. XII, 420 pp., hardcover DM 248.00.—ISBN 3-527-28354-4

Molds and bacteria play a central role in the mineralization of all organic compounds. This book presents an overview of microorganisms and their enzymes that are involved in the degradation of natural products. The importance of such enzymes extends far beyond degradation in the narrower sense. They are involved in many biotechnological processes, and are also present as supplements in various products. Interest in natural products as renewable raw materials has increased in recent years. In Germany, for example, research on renewable raw materials has been supported by grants of about DM 50 million from the Federal Ministry for Research and Technology alone. Therefore the book fills a gap and is likely to be welcomed with considerable interest. No survey of the degradation of natural products has previously been available in this form.

The editor, G. Winkelmann, has succeeded in recruiting a team of expert authors from universities and industry. In twelve chapters they report on the breakdown of starch, pectin, cellulose, hemicellulose, lignin, proteins, nucleic acids, and arenes. In nature these substrates undergo degradation by a wide variety of microorganisms, of which molds play a central role. These organisms synthesize a great variety of amylases, glucoamylases, pectinases, and other enzymes. The current state of knowledge on the microorganisms and enzymes that take part in degradation is brought together here, both in the text and in the numerous tables. The chapters have a clear arrangement of subject matter, and for each substrate there are sections on the physiology and genetics of the microorganisms, and on the properties of the enzymes and methods for their purification and assay. There are also applications-related sections explaining the importance of the enzymes in biotechnology. Enzymes such as amylases, glucose-isomerase, and proteases, which are manufactured on a large scale and are used in the saccharification of starch, in the food industry, and in detergents are described, but the spectrum of applications is much broader, ranging from medicine (collagenases) through fine chemicals manufacture (thermolysin, lipases) to molecular biology (nucleases). Whereas it is not yet clear how or whether lignin-peroxidases will be adopted in biotechnology, the use of P-450 enzymes for selective biotransformations is continually being extended to new processes. Everyone interested in such enzymes will find in this book a wealth of possible organisms for producing them. However, whether or not a particular one is actually obtainable is another question, since many organisms have not been deposited in the available collections, and some of those mentioned in publications are not even accessible through the groups reporting them.

Most of the enzymes involved in the degradation of natural products are exoenzymes, and their synthesis and secretion is therefore reviewed in the first chapter. Two other chapters of special importance are those on arenes, which occur in nature during the breakdown of lignin, and are also present in amino-acids, lignin precursors, antibiotics, flavonoids, phytoalexins, and melanins. One of these chapters is devoted to metabolization in molds, and the other to anaerobic breakdown of arenes. As well as being potentially useful for the detoxification of water and soil, these reactions also offer possibilities for manufacturing fine chemicals by biotransformations that are environmentally friendly and selective.

The book gives the reader an insight into the gaps in present knowledge and the directions of future research. For example, we do not yet have a complete picture of anaerobic degradation. Progress is hampered especially by the slow growth rate of the microorganisms concerned and by the small cell mass per unit volume of the fermentation medium. An important advance in the understanding of lignin break-

down came with the discovery of lignin-peroxidase in 1983, but the fate of the phenoxy radicals that are formed after the initial oxidation step is not yet understood. The topic of how microorganisms interact during degradation raises more questions than answers. Most investigations are carried out using pure cultures, but this book shows very clearly that there are many different isolated strains that can use a given substrate as a carbon source. In contrast to the understanding of the functions of individual microorganisms, little is known about the cooperative functioning of several specialized microorganisms, nor about the ecology of the functionally redundant types. The first insights into these questions are now coming from studies of the degradation of wood in soil and of cellulose in the digestive systems of ruminants. However, studies of the "communication" between microorganisms and their metabolic interactions are only just beginning.

The main emphasis of the book is on microorganisms and their enzymes, whereas there is in general relatively little theoretical discussion of the chemistry and mechanisms of degradation. The book is essentially a literature survey and a work of reference, and the detailed bibliographies citing material for further reading, as well as an index of microorganisms and enzymes at the end, are consistent with this purpose. It can be recommended for everyone interested in studies of microbial degradation, and also especially for users of such processes.

Bernhard Hauer
BASF AG, Ludwigshafen (FRG)

Transition Metal Oxides. An Introduction to their Electronic Structure and Properties. (International Series of Monographs on Chemistry, Vol. 27.) By *P. A. Cox*. Oxford University Press, Oxford, 1992. IX, 284 pp., hardcover £ 37.50.—ISBN 0-19-855570-9

As the author mentions in the preface to this book, interest in the oxides of the transition metals can be traced far back into antiquity. These compounds are nowadays of enormous importance in chemical technology, for example as magnetic pigments, white pigments, laser materials (e.g., garnets), and X-ray fluorescent materials (e.g., $BaWO_4$). They are also an important subject of basic research, which has led to a deeper understanding of many physical properties of the solid state. One of the most significant recent discoveries is that of the new high temperature superconductors (the oxocuprates), the study of which provides a good illustration of the close connection between structure and properties in the solid state.

This book is not so much concerned with describing the great variety of transition metal oxides as with discussing their widely varying electronic properties. The first chapter starts by briefly explaining some basic concepts of solid state chemistry, such as oxidation levels, nonstoichiometric compounds, the phase rule, and phase diagrams. This is followed by an equally concise treatment of the coordination of metal atoms by oxygen, the resulting polyhedral crystal structures, the occurrence of defects in these, and an overview of electronic properties.

Chapter 2 describes the essential features of various models for interpreting electronic structures, ranging from the purely ionic picture of the ligand field theory, through the molecular orbital (MO) theory, to the band structure model. Intermediate models such as the Hubbard model and the Anderson localization theory are also discussed. Chapter 3 begins by discussing band gaps in relation to spectroscopic properties, based on examples of nonconducting oxides of metals with d^0, d^8, or d^{10} electronic configurations. The author then deals with the question of the assignment of bond energies in doped and undoped transition metal oxides, and the various types of magnetic interactions that can occur in these materials. Chapter 4 is concerned with physical effects in semiconducting oxides, such as the properties of the charge carriers, point defect models, carrier binding energies, spectroscopic studies of free and bound charge carriers, and transitions to the metallic state. The fifth and last chapter deals with band structures and with the transport and optical properties of metallic transition metal oxides, and ends with a brief discussion of the new high temperature superconductors and the problems of developing a theoretical understanding of their properties.

A praiseworthy attempt is made in this book to treat the chemistry of transition metal oxides from the standpoint of their physical properties. Although the descriptions of the various theoretical models are brief and sketchy, the understanding of them is helped by numerous tables and diagrams. However, the reader whose interest in the subject goes beyond a superficial level is not well served. Also anyone who hopes for an overview of the whole field of transition metal oxides will be disappointed. Moreover, the treatment of the subject is incomplete insofar as oxides with localized metal–metal bonds, such as reduced oxomolybdates and oxoniobates, are not covered.

Despite these criticisms, the book can be recommended for all whose work is concerned with the structure and properties of solids. The many literature references provide an excellent starting point for more advanced reading in this area.

Jürgen Köhler
Max-Planck-Institut für Festkörperforschung
Stuttgart (FRG)

Oxygen Chemistry. By *D. T. Sawyer*. Oxford University Press, Oxford, 1991. 223 pp., hardcover £ 30.00.—ISBN 0-19-505798-8

Within the *International Series of Monographs on Chemistry* Donald Sawyer has provided a new book on different aspects of the chemistry of oxygen. In a one-page preface, R. J. P. Williams mentions that molecular oxygen is one of the major constituents of the atmosphere and that life depends on the kinetic barriers to oxygen reactions, in the presence of a very strong thermodynamic drive. This stimulating book is an attempt to show how the entire chemistry of oxygen (molecular oxygen and its reduced forms) in aqueous and non-aqueous media can be treated in a unified way, leading to a comprehensive understanding of all the different reaction pathways involving oxygen.

The book is divided into eight chapters. After an introductory chapter dealing with fundamentals such as the central role of oxygen in chemistry, and O_2 as a unique natural product, Chapter 2 describes the redox thermodynamics for oxygen species (ozone, molecular oxygen, $HOO\cdot$, $O_2^-\cdot$, HOOH, HOO^-, O, $O^-\cdot$ and HO^-). This chapter contains useful tables on reduction potentials in aqueous or aprotic solvents which are generally widely scattered throughout the literature. The chemical versatility of dioxygen species (oxido-reduction, atom transfer, or dismutation) is mainly influenced by the reaction medium. Chapter 3 describes the nature of the chemical bonds in oxygen species, on the basis of

electronegativities of elements and valence bond theory. This first half of the book provides the necessary background for the second half, which is focussed more on the chemical reactivity of the different oxygen species. Chapter 4 describes the reactivities of hydrogen peroxide, alkyl hydroperoxides, and peracids. The Lewis acid activation of HOOH and the monooxygenation reactions induced by iron(III) salts in aprotic solvents are described in great detail. The following chapters, 5 and 6, are concerned with the reactivity of oxygen radicals ($HO\cdot$, $RO\cdot$, $HOO\cdot$, $ROO\cdot$ and $RC(O)O\cdot$) and the activation of dioxygen for selective oxygenation reactions, respectively. Biological systems are mentioned in a small section. Chapter 7 is entirely devoted to the reactivity of superoxide ion, a favorite topic of the author ("How super is superoxide?"), and finally Chapter 8 is concerned with the reactivity of oxy-anions (HO^-, RO^-, HOO^-, ROO^-, and $O_2^-\cdot$). References are listed at the end of each chapter. All in all, this book is useful for readers involved in oxygen chemistry. However, it must be noted that some aspects of this monograph are rather controversial by deliberate intent of the author ("the electron is the ultimate nucleophile"). High-valent metal-oxo complexes are usually considered by the author as being not well substantiated, despite the growing evidence provided by various physicochemical methods on several species isolated at low temperatures.

In summary, this book is a good choice for chemists and electrochemists who want to enter the field of oxygen chemistry, and it is recommended for anyone who is not convinced that oxygen chemistry is highly versatile.

Bernard Meunier
Laboratoire de Chimie de Coordination du CNRS
Toulouse (France)

HPLC of Proteins, Peptides and Polynucleotides. Contemporary Topics and Applications. By *M. T. W. Hearn*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1991. XV, 776 pp., hardcover DM 225.00.—ISBN 1-89573-295-5/3-527-26951-7

The great importance of modern high performance liquid chromatography (HPLC) for the analytical and preparative scale separation of peptides, proteins, and polynucleotides has led to the development of many new stationary phases, and these are comprehensively reviewed in this book. Many different chromatographic media are described, for example, those based on agarose, silica, and polyethyleneimine. The capabilities of the method are illustrated by examples, and a wealth of literature references is provided. Also the importance of models for describing the interactions between the peptide or protein and the stationary phase, from which one can predict the retention behavior, is recognized. The author also describes strategies for achieving an optimal separation by progressively changing the composition of the mobile phase. Several of the chapters contain very detailed descriptions of techniques such as reversed phase, ion exchange, exclusion, and hydrophobic interaction chromatography, and combinations of these. In analogy to 2-D electrophoresis, two-dimensional or multidimensional HPLC can be used for protein or peptide mapping. Another chapter is devoted to the use of chromatography for investigating protein–protein interactions. The various methods for determining equilibrium constants using exclusion or affinity chromatography are described in detail. Much attention is also given to preparative techniques. Variants of affinity chromatography using a variety of immobilized ligands, such as dyes, antibodies, lectin, and heparin are thoroughly discussed. Further chapters deal specifically with the separation and purification of individual groups of substances; these include protein hormones, membrane proteins, viral proteins, monoclonal antibodies, physiological amino-acids, oligonucleotides, plasmids, and DNA restriction fragments. The book ends with a chapter on the separation of peptides and proteins by capillary electrophoresis, an alternative to HPLC which combines the high efficiency and ease of automation of HPLC with the special separation mechanisms of electrophoresis.

To summarize, this book gives an excellent survey of the latest developments in the analysis of peptides and proteins, bringing together information that would otherwise be available only by an extensive study of the original literature. Each chapter is supplemented by numerous literature references. The book is definitely intended not for beginners, but for HPLC users interested in extending their knowledge. It does not contain laboratory recipes for particular separations, but instead discusses general relationships and optimization strategies. Every one of the 22 chapters is of a very high standard and contains a wealth of information. Even chromatographers with long experience in the field will gain a lot of useful knowledge from the book.

Christine Schwer
Max-Planck-Institut für Biochemie
Martinsried (FRG)

Phase Diagrams of the Elements. By *D. A. Young*. University of California Press, Berkeley, CA (USA), 1991. XI, 291 pp., hardcover $ 39.95.—ISBN 0-520-07483-1

Our understanding of the chemical bonding in solids and its influence on the properties of materials has, in the past, been greatly helped by structural studies in which the pressure and temperature are systematically altered. The results of such investigations, including the interconversion of different modifications of a substance under conditions of thermodynamic equilibrium, can be displayed especially clearly in the form of p–T phase diagrams, which have a high information content. The structures of the elements in the solid state, and their dependence on pressure and temperature, are of fundamental interest to the chemist, and there is now a wealth of information on these for the majority of elements. By bringing together a comprehensive collection of phase diagrams for the elements that have been investigated up to now, accompanied by brief descriptions of the structures that occur, this book fills an important gap.

The comprehensiveness of the results presented here has been made possible through the considerable developments that have recently taken place in experimental techniques for work at high temperatures and pressures. Most important among these developments is the diamond anvil cell (DAC). This has now made it possible to carry out X-ray crystallographic and spectroscopic studies at pressures up to about 1.1 TPa, or at temperatures up to 5000 K (at 100 GPa pressure). There have also been improvements in theoretical methods for understanding and predicting the occurrence of high pressure or high temperature phases, for example the application of the band theory of solids through the "local density approach" (LDA).

The book begins with a short introduction to modern experimental techniques used in high-pressure studies. This is followed by an equally brief summary of the theoretical methods for predicting the occurrence of phases and inter-

preting the results (band structure calculations, Monte-Carlo methods, molecular dynamics, and the thermodynamics of phase transformations and melting processes).

The main part of the book presents the phase diagrams for the individual elements, arranged according to the groups of the Periodic Table. Experimental results and relevant theoretical studies published between 1960 and 1990 are included; the main emphasis is on results published in the last ten years, stressing the most recent developments. This is followed in each case by a summary of the results in graphical form, in which the high-pressure phases of each element as a function of pressure are shown alongside each other for easy comparison. Each chapter ends with a comprehensive list of literature references. As all the elements of the Periodic Table are covered in barely 190 pages, this usually leaves only a little space for discussing the structures and special physical properties of the modifications that occur. Often the discussion is limited to a brief mention of theoretical considerations to explain the electronic structure and the different crystal structures found, together with literature references. Consequently the book should be regarded not as a comprehensive work of reference, but rather as a concise up-to-date summary of results, with particular emphasis on theoretical approaches to understandig the phase transformations that occur.

Although the book contains much information that should make interesting reading even for students, only certain parts of it are suitable for use as teaching material (in particular the p–T phase diagrams and the structural diagrams). Some of the abbreviations used are rather misleading: for example, the cubic primitive structure of α-Po is described as being of the α-sc(1) type, while the structure of black phosphorus is described as eco(8), and that of solid Cl_2 as eco(4). Thus, the structures are classified according to their Bravais types and the number of atoms per unit cell.

The author (a theoretical physicist) has written the book for a readership that includes solid state chemists with structural interests, but not all of these will find it meets their needs. Despite the brevity of the individual sections, all the important modifications of the elements are mentioned. A particularly interesting feature is that gaps in present knowledge are pointed out in many cases (for example, in the phase diagram for boron, or with regard to experimental evidence for the occurrence of a semimetallic modification of carbon at pressures of 1.1 TPa or greater).

This book is a valuable compilation of p–T phase diagrams and crystal structures of the elements in the solid state, containing information not hitherto available, and with special attention to the theoretical understanding of solids.

Wolfgang Schnick
Institut für Anorganische Chemie
der Universität Bonn (FRG)

Fascinating Molecules in Organic Chemistry. By *F. Vögtle*. Wiley, Chichester, 1992. IX, 304 pp., hardcover £ 80.00. – ISBN 0-471-93147-0

The author is an internationally renowned organic chemist whose diverse research interests include cyclophanes, crown compounds, and supramolecular chemistry. His love for exotic molecules is particularly evident in this volume. Like the companion book, *Supramolecular Chemistry*, this volume is based principally on lectures given at the University of Bonn. Although "fascinating" is a subjective term and beauty truly lies in the eye of the beholder, few modern enthusiasts of organic chemistry would find fault with the selection of organic molecules covered in this book. Key aspects of each parent system or class of molecules are described, including history, synthesis, properties and applications. The book is an excellent source of material for enlivening lectures on introductory organic chemistry and for special topics courses at the graduate level.

The book is organized in five chapters, and Chapter 1 is an introduction to fascinating natural structures and symmetry. Highly symmetrical structures have intrinsic aesthetic appeal. "The Platonic Solids" introduces a discussion that interweaves chemistry with cosmology. The result is not New Age chemistry; rather it is an exploration of the way in which symmetry can excite imagination concerning the structure of the universe as well as structural chemistry. Chapter 2, entitled "Alicyclic Compounds", ties into the previous chapter by beginning with a discussion of the fundamental Platonic hydrocarbon derivatives that are currently known: tetra-*t*-butyltetrahedrane, cubane and dodecahedrane. Icosahedral C_{60} (buckminsterfullerene), while not a Platonic hydrocarbon, should rightly follow dodecahedrane in this discussion of carbon clusters. Unfortunately, most fullerene research is too recent to be included in this book, except for some brief notes at the end of the first chapter. Chapter 2 continues with lively discussions on adamantane, pagodane, and [1.1.1] propellane. The alicyclic compounds presented in this chapter represent milestones in synthetic and structural organic chemistry. In addition to the now classical syntheses of the parent systems, more recent synthetic approaches and commercial applications are also described, including the Idemitsu process for the production of adamantane and pharmaceutical applications of adamantane derivatives.

Chapter 3 presents the highlights of research on fascinating aromatic compounds, including the triphenylcyclopropenylium cation, azulene, biphenylene, circulenes, cycloarenes, and the helicenes. Coverage of these aromatic compounds is somewhat uneven and clearly reflects the author's personal perspective. For example, 25 pages are devoted to the history, synthesis and properties of azulene, whereas kekulene is all but omitted from the interesting discussion on circulenes and cycloarenes. The section on helicenes on the other hand is a very good review and it is an excellent introduction to helically chiral compounds. In Chapter 4 triptycenes, 1,8-methanonapthalene, [2.2.2]phanes, and superphane are grouped together as "aralicyclic compounds". These discussions are just as interesting as those of the preceding sections. Finally Chapter 5, entitled "Heterocycles and Biologically Active Compounds", is more or less a grab bag of interesting molecules that do not clearly fit into the previous categories. It includes excellent discussions of Tröger's base, acetylsalicylic acid, vitamin B_6 (pyridoxine), and phthalocyanines. The discussion on phthalocyanines can be viewed as a bridge between this volume and the companion book (*Supramolecular Chemistry*) since it describes the properties of molecular materials derived from phthalocyanines, including electronic conduction and photochemical hole burning. Also included is a short epilogue on new tetrapyrrole macrocycles concerning porphacenes and other expanded porphyrins of current interest.

Overall, "Fascinating Molecules in Organic Chemistry" is a masterful compilation of challenging synthetic targets, theoretical puzzles, and molecular templates for practical applications. The English is remarkably smooth for a translation from German and there are very few errors. Rare mistakes include the misnumbering of structures on page 197 (duplication of **60**), redundant description of Landa's first isolation of adamantane (pp. 44, 45, 46), and misnaming of [1.1.1]-

propellane as [1.1.1]cyclopropane (p. 69). Good author and subject indexes enhance the utility of this book for reference purposes. This book is a necessary acquisition for relatively complete academic and industrial libraries. It would also be useful as a reserve book and as a source of interesting material in introductory and advanced organic chemistry courses. It could also serve as a textbook in special topics courses, but unfortunately it is priced as an import in the United States. Every effort should be made to reduce the price of this and the companion volume, *Supramolecular Chemistry*, in order to make them useful as textbooks, in accord with the apparent intention of their author.

Thomas W. Bell
Department of Chemistry
State University of New York, Stony Brook, NY (USA)

Properties of Chemically Interesting Potential Energy Surfaces. (Series: Lecture Notes in Chemistry, Vol. 56.) By *D. Heidrich, W. Kleisch,* and *W. Quapp.* Springer, Berlin, 1991. VIII, 183 pp., paperback DM 44.00.—ISBN 3-540-54286-8

The calculation of molecular structures using quantum-chemical computer programs has now become almost a routine procedure in modern theoretical chemistry. The enticing possibilities offered by these methods are not limited to the ability to calculate energy minima on the potential energy hypersurface (PHS), giving results that may be compared with experimental values and are increasingly being used as a substitute for them; one can also determine any other kinds of extrema such as first-order saddle points, which represent transition states and provide the chemist with information that cannot be obtained experimentally. Volume 56 in the excellent series "Lecture Notes in Chemistry" gives an overview of the mathematical basis of calculations on potential hypersurfaces. The main emphasis is on a discussion of the search procedures for determining extrema and of methods for predicting reaction pathways on the PHS. As an example of the application of these techniques, proton transfer processes are treated in detail.

The book is divided into four chapters. Chapter 1 (25 pp.) starts by discussing the concept of the PHS. This chapter is recommended reading for everyone interested in obtaining a brief introduction to current ideas on molecular structure based on the PHS model, and a survey of the most important published work. Conventional theories of molecular structure are based on the Born–Oppenheimer approximation, the validity of which is usually taken to be self-evident. However, there are growing indications that this approximation has its limitations, for example from studies of systems such as the NH_3 molecule. The authors propose some tests of the validity of the Born–Oppenheimer approximation, and suggest that this could lead to a fundamental change in the understanding of molecular structures. However, having put forward these somewhat heretical views, the authors are content to leave it at that, and the rest of the book proceeds along conventional lines within the Born–Oppenheimer approximation. The first chapter is completed by an explanation of some fundamental principles in the theoretical treatment of chemical reactions.

Chapters 2 and 3 (66 and 35 pp., respectively) are devoted to mathematical aspects. Two of the three authors (Kleisch and Quapp) are mathematicians, and these two chapters essentially contain a summary of the mathematical basis of the optimization procedures used in many quantum-mechanical calculations. This is the most important part of the book from the specialist's standpoint, and the comprehensive presentation of so many techniques, such as those for updating the Hesse matrix, is especially valuable since it is the only such compilation available. The fundamentals of these quantum-mechanical methods can be found in many textbooks, but the mathematical details of the computer programs used are often difficult to find. These two chapters are, unavoidably, written in the language of a mathematical textbook. However, this reviewer found that, after a short period of getting accustomed to the style, most of the derivations could be understood without much difficulty. The authors also deserve praise for having taken the trouble to give the mathematical expressions in terms of quantities understandable to chemists, at least pictorially, and to avoid losing the link with the chemical problem. Perhaps we see here the influence of the chemist member of the author team (Heidrich).

The fourth and last chapter (38 pp.) deals with the calculation of potential hypersurfaces and reaction pathways in proton transfer. Here again particular attention has been given to the question of the visualization of the numerical results. To the despair of many theoreticians, chemists respond better to pictorial than to numerical information, and it is found again and again that more attention is paid to a diagram of dubious accuracy than to a good numerical calculation that is difficult to interpret. The fashionable subject of "molecular modeling" provides enough disturbing examples of this. The authors have succeeded very well in bridging this difficult gap; Chapter 4 is not only understandable to the average chemist but is also well worth reading.

The book is a must for all chemists with theoretical interests, while Chapters 1 and 4 can be recommended for reading by chemists from all backgrounds. It should certainly be held by every departmental library. That should be possible even in these times of severe cost-cutting in view of the commendably low price.

Gernot Frenking
Fachbereich Chemie
der Universität Marburg (FRG)

Transition Metal Organometallics for Organic Synthesis. By *F. J. McQuillin, D. G. Parker* and *G. R. Stephenson.* Cambridge University Press, Cambridge, 1991. XX, 594 pp., hardcover £ 100.00.—ISBN 0-521-33353-9

Transition metal organometallics have made very important contributions to the success of organic synthesis in recent years. Nevertheless, many of the available methods are not yet employed as widely as their effectiveness justifies. To remedy this situation, the authors have provided a work of broad scope which describes the various synthetic methods based on transition metal organometallic reactions. Its main purpose is to assist newcomers to the field.

A brief introduction to the basic concepts needed for describing the structure and reactivity of transition metal organic compounds is given, and this is then followed by discussions of major reaction types, such as isomerization and rearrangement reactions, oxidations of multiple bonds, nucleophilic and electrophilic additions to coordinated ligands, carbonylation, and coupling reactions. The chemistry of transition metal-complexed π-ligands as well as σ- and car-

bene complexes is examined in detail and illustrated by a multitude of well selected examples. Catalytic and non-catalytic processes are explained with equally great care, and even enantioselective methods are not neglected. The two concluding chapters deal with "organometallic" strategies for the synthesis of natural products and heterocycles, providing striking illustrations, in the context of specific synthetic problems, of the usefulness of the methods previously introduced. Here, if not earlier, it also becomes evident that "habitual retrosynthetic thinking" must be thrown overboard if one really wants to use the opportunities of transition metal chemistry.

The text is written in a concentrated but very readable style, and is interlarded with valuable information and references. Preparative aspects clearly dominate throughout the book, but are always complemented and connected by mechanistic considerations. The scope and limitations of the individual methods generally become clearly evident, which is of great interest for potential "users".

The impressive wealth of material is backed up by more than 2000 literature references, which are grouped (sorted by chapters) at the end of the book. The literature is continuously covered up to 1988, and partly even up to 1990. It should be mentioned that the appealing quality of the book is also reflected in its appearance (binding, paper, printing, harmony of typesetting and formula diagrams). The book is also provided with an extensive subject index, which, together with the well structured table of contents, facilitates quick orientation even during the search for single facts.

A safety bibliography warns of potential risks associated with the handling of organometallic reagents. However, there is a possibility of an immediate danger of a different kind to the reader of the book, insofar as some misunderstandings could occur. Some readers, especially those not completely well versed in stereochemistry, could possibly be misled by the fact that a clear distinction is not always made between absolute and relative configuration. For instance, not all racemic target compounds are indicated as such, and the diagrammatic representation of stereochemical details (particularly of π-complexes) in many structural formulas could certainly be improved. But these are more or less minor matters: on the whole, the formula diagrams are clearly arranged, and also the number of misprints and other mistakes is small.

Of course, one is tempted to rate the book as overexpensive. However, if one takes into account the excellent quality of its appearance and contents, the enormous wealth of up-to-date, well selected, and conscientiously processed information on almost 600 pages, the price seems reasonable. To the publisher one could make an appeal to also provide a cheaper paperback edition, which would enable a larger circle of private individuals (e.g., students!!) to buy this important work.

To summarize, this generally excellent book entirely fulfills its intention, and is well worth its (high) price. On the back cover is the claim: "This book stands as an invaluable reference work as well as a source for initiating the design of new organometallic procedures, and as such will be of great value to organic chemists and research workers in both universities and industry". I can only agree with this statement and I hope this book will be well received by a wide readership.

Hans-Günther Schmalz
Institut für Organische Chemie
der Universität Frankfurt/M. (FRG)

Chemical Equilibria in Solution. Dependence of Rate and Equilibrium Constants on Temperature and Pressure. (Physical Chemistry Series). By *M. J. Blandamer*. Ellis Horwood/Prentice Hall, Chichester, 1992. 144 pp., hardcover $ 68.50.—ISBN 0-13-131 731-8

This monograph (142 pages) uses a thermodynamics theme to provide arrays of suitable equations which can be used to analyze data from solution equilibrium and kinetics experiments in which pressure or temperature, or both, are varied. It does not purport to, and does not discuss experimental methods or provide interpretative discussion of activation parameters derived from the various treatments. A pleasing feature, and one making for easier reading, is the separation of sets of equations from the narrative.

The author presents a literature survey in addition to contributions from his group, and successfully manages, almost without fault, the unenviable task of providing an orderly and consistent set of symbols throughout. References are cited for each subsection of a chapter, a convenient approach. However, the lack of lists of chapter-end references or of a cumulative reference list could be bothersome for some. There is an index of essential terms and named equations.

Chapters 1, 2, and 3 develop standard thermodynamics in terms of symbolism and application to solution chemistry into the repertoire of needs for the heart of the book (Chapters 4–6). Of these latter chapters, the first examines methods for treatment of pressure dependence results, while Chapters 5 and 6 consider, at length, methods for treating equilibrium and kinetics temperature dependence results. In the seventh and final chapter the dependence of equilibrium composition and rate constants on temperature and pressure is covered. The reader is given a lucid account of recent contributions to characterization of the isochoric condition and to calculations of isochoric activation parameters.

Overall the writing style is direct. There are some minor errors, such as missing words, for example in the first sentence of Section 4.14, and in the second sentence of the first complete paragraph of page 91, a missing letter as in pentaamminecobalt(III) (p. 69), and occasional confusing use of units; in this latter category an enthalpy change $\Delta_r H^\infty$ is given in $J\,mol^{-1}$ on page 102, and in $kJ\,mol^{-1}$ on page 105, and the volume parameter $\Delta_r V^\infty$ is expressed in cm^3mol^{-1} on page 71 but is given (erroneously) as $-35.9\ m^3mol^{-1}$ on page 66. The Tait equation, introduced in Chapter 1 and used again on page 72, contains lower case c, but when it is applied in the context of the Benson–Berson approach (pp. 73–74) a capital C appears.

Given that the author is a renowned thermodynamics expert one might expect that only other thermodynamics specialists will be attracted to this book. This would not be an accurate assessment, since the book can appeal in total, or in selected parts, to chemists and other scientists who have an undergraduate or more advanced knowledge of physical chemistry. It is likely that it could form part of the recommended reading for a graduate student lecture course on solution thermodynamics. The promotional material on the back cover cites among others "researchers in medicinal chemistry and medically related subjects..." as potential readers. While the broad appeal of the text can be lauded, it is not clear why these groups were selected.

Because of its focus only on development of thermodynamics equations for treatment of data, there is, at times, a sense of lack of connection with actual chemical equilibria and various chemical reactions. This is a disappointing aspect, and for some experimentalists could have the effect of

reducing the scope of use of the book. An emphasis could have been placed on the limitations which are not so much a lack of will or skill to fit data, but of suitable instrumentation, time, or amenable reacting systems. Obtaining data of sufficient quality to justify pursuit of calculation of the pressure and temperature derivatives of ΔV^* and ΔH^* respectively is seldom possible. Again, although this would have broadened the purpose of the book, it would have benefited from the inclusion of a section devoted to interpretation of derived parameters, and explaining how this contributes to understanding the chemical processes being studied. However, all the treatments experimentalists require are collected together here in one convenient source with each method easily accessible and referenced. This alone merits a place for this book in chemistry libraries and in the personal collections of thermodynamicists and kineticists.

The new 18-volume series "Materials Science and Technology" covers the properties, manufacture, and processing of materials, and their specific areas of use. It brings together the know-how of chemists, physicists, and engineers, and shows how fundamental research and applications-orientated research can be made to interact most effectively and fruitfully.

The first volume to appear, in 1991, was Volume 5, "Phase Transformations in Materials", and has already been reviewed in the context of the series as a whole (*Angew. Chem.* **1992**, *104*, 245; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1521). Up to now Volumes 2A, 3A, 4, 5A, 7, 9, 14, and 15 have been published, and four of these (3A, 4, 7, 15) are reviewed here.

During the planning of Volume 3 ("Electronic and Magnetic Properties of Metals and Ceramics") it already became clear that it would hardly be possible to treat all the necessary aspects and phenomena of this subject in a single volume, and it was decided to have two volumes. The second of these (Vol. 3B) has not yet appeared, but the chapter titles have already been given as: "Magnetic Properties of Spinel Ferrite"; "Electronic Properties of Liquid, Amorphous, and Quasicrystalline Alloys"; "Invar Alloys"; "Magnetic Recording Materials"; "Hydrogen in Pure Metals and Solid Solutions"; "Ternary Hydrides"; "Soft Magnetic Metallic Materials"; "Permanent Magnet Materials"; "Magnetostrictive Materials".

The first chapter of Volume 3A deals with the calculation of electronic structures. The ability to perform such calculations for the highly complex systems of interest to materials science has come with the availability of very fast computers. Chapter 2 is concerned with the magnetooptical properties of metals, alloys, and compounds. After an introduction to the fundamentals (theory and measurement techniques), some special materials are described and their properties discussed (alloys and compounds of 3d metals, materials based on lanthanoids and actinoids, and mixed 3d–4f and 3d–5f compounds). Chapter 3 is devoted to electron transport properties of "normal" metals, including the behavior of electrons in magnetic fields, electrical resistivity, the Hall effect, thermoelectric power, etc. Chapter 4 covers superconductivity, with discussions of the Bardeen–Cooper–Schrieffer (BCS) and Ginzburg–Landau (GL) theories; the oxide high-temperature superconductors are also described, of course. In Chapter 5 the focus of interest turns to the magnetic properties of metallic systems, then Chapter 6 deals with ultrathin films and superlattices (epitaxy). The book concludes with Chapter 7 on Fermi surfaces in strongly coupled electronic systems. This, like Chapter 1, treats the topic in a fundamental way, and includes instructive comparisons of experimental results with band structure calculations.

Volume 4 ("Electronic Structure and Properties of Semiconductors") presents the basic concepts of modern semiconductor physics, starting from the fundamentals of ideal semiconductors and continuing through the physics of defects and heterostructures (artificial semiconductors) to amorphous semiconducting systems. Chapter 1 ("Band Theory Applied to Semiconductors") and Chapter 2 ("Optical Properties and Charge Transport") are of an introductory nature. They cover the basic theory needed to understand the formation of energy bands in solids with three-dimensional structures and structures of lower dimensionality and in amorphous materials, the investigation of band structures by measuring intrinsic optical properties, charge transport, and nonlinear optics. Chapter 3 deals with the simplest types of point defects, the intrinsic defects that occur in crystal structures where some atoms have changed their positions or are missing altogether; essentially one is concerned here with vacancies, interstitial sites, and sites at which anions or cations have been changed ("antisites"). As examples of different types the chapter discusses silicon (an elemental semiconductor), ZnSe (a II–VI semiconductor), and GaAs (a III–V semiconductor). In Chapter 4 ("Deep Centers in Semiconductors") the discussion moves on from intrinsic defects to doped materials (e.g., with nitrogen and transition metals as dopants in silicon or compound semiconductors, chalcogens in silicon, and DX centers—in which D represents a donor and X an unknown effect—in the mixed crystal system $Al_xGa_{1-x}As$). Silicon and gallium arsenide are nowadays the most important semiconducting materials used in the manufacture of electronic and optoelectronic components, and Chapter 5 ("Equilibria, Nonequilibria, Diffusion, and Precipitation") is concerned particularly with these materials and the behavior of their point defects (whether intrinsic or produced by doping). Moving on from point defects, Chapters 6 ("Dislocations") and 7 ("Grain Boundaries in Semiconductors") deal with these more extended types of defects and their effects on the physical properties of semiconductor materials, from both the phenomenological and theoretical standpoints. Newer manufacturing techniques, including the now highly developed methods of epitaxial growth, make it possible to produce artificial materials and components with special properties that depend on the presence and concentration of interfaces. Chapter 8 gives the

reader an insight into basic concepts whereby one can describe the structural characteristics of such interfaces and understand how they confer special electronic properties on these materials. The tendency towards increasing miniaturization has also resulted in a move from two-dimensional to one-dimensional systems. Lithographically produced heterostructures such as those of the system GaAs–$Al_xGa_{1-x}As$ are suitable for studying the quantum Hall effect in a quasi-one-dimensional electron gas, as described in Chapter 9 ("The Hall Effect in Quantum Wires").

For nearly twenty years now there has also been much interest in the possibilities of using amorphous silicon (e.g., for photovoltaic devices). However, the pure phase contains such a high concentration of defects that it is unsuitable for electronic components. It was accidentally found during the manufacture of amorphous silicon from silane that the concentration of defects could be considerably reduced by introducing hydrogen to saturate the proportion of free silicon valences that are present, and this proved to be the breakthrough needed. The interesting material thus obtained is described in Chapter 10 ("Material Properties of Hydrogenated Amorphous Silicon"). Lastly Chapter 11 contains an up-to-date review of the doping of silicon with 3d elements (see also Ch. 5). The unusual and interesting physical properties that this gives are, however, accompanied by some disadvantages. Aspects of the behavior of 3d elements in the host structure that are discussed here are solubility, diffusion, electronic structure (at high temperatures), and separating out by nucleation.

Silicon is undoubtedly one of the most important materials in the present "silicon age". A metallic material that still continues to be of great importance to human activities and is produced in vast quantities worldwide is the system that we loosely call "steel", and this is the subject of Volume 7 ("Constitution and Properties of Steels").

The world production of steel in 1989 was 783 million tonnes. The plentiful natural occurrence and availability of iron ores is enough in itself to guarantee this class of materials a long-term future, let alone the unique properties that make steel suitable for such a wide variety of uses. The subject of metallography covers many aspects: chemical constitution, phases, alloys, equilibria and nonequilibria between phases, structure and microstructure, precipitation processes, and many more. Chapter 1 ("Microstructure and Transformations in Steel") introduces the basic tools for understanding the subject: phase diagrams for the iron–carbon system, microstructures such as cementite, ferrite, pearlite, martensite, and bainite, precipitation reactions in ferrite and austenite, etc. Chapter 2 ("Structure–Property Relationships in Steels") is concerned mainly with microstructures (dimensions of the matrix–grain structure, crystallographic texture, and grain size distribution). This provides the essential key to understanding and controlling the mechanical properties. Chapter 3 ("Steelmaking and Non-Metallic Inclusions") describes steel production, then Chapter 4 ("Processing—Conventional Heat Treatments") deals with the heat treatment stages (annealing, normalizing, quenching, tempering, case-hardening) that are used to control the microstructure and phase composition. Thermomechanical processing, which is the subject of Chapter 5, also has an important role in determining the microstructure and phase composition of steels, and the same applies to cold-working and work-hardening, as described in Chapter 6. The factors influencing the malleability of steels and methods for controlling it are discussed in Chapter 7. The following chapters are devoted to steels with special properties and uses, as follows. Chapter 8: high strength low-alloyed steels (building and construction steels with small amounts of vanadium, niobium, or titanium); Chapter 9: steels with medium to high carbon contents (≥ 0.30 wt.% C), used for railway tracks, for example; Chapter 10: heat-treated forging steels (0.45 wt.%C, 1.5 wt.% Mn); Chapter 11: creep-resistant steels for applications at high pressures and temperatures; Chapter 12: stainless steels containing 11 wt.% or more of chromium; Chapter 13: tool steels with especially high strength and hardness; Chapter 14: high temperature resistant "superalloys" with iron, nickel, or cobalt as the main constituent; Chapter 15: cast iron, i.e. iron-based alloys containing C, Si, Mn, S, and P as the main alloying elements, with Al, Bi, and Sb as minor additives, and further additives to influence the matrix structure (Mo, Cu, Ni, Sn) and/or the graphite morphology (Mg, Ce, Ti). To complete and round off Volume 7, Chapter 16 deals with the welding of steel and Chapter 17 with surface treatments.

Volume 15, the last of the four reviewed here, is entitled "Processing of Metals and Alloys". Practical aspects are closely linked to results from basic research, but the main emphasis throughout is on applications. The first task facing the editor of this volume, R. W. Cahn, was to decide which topics to include and which to leave out, since this was to be a concise treatment. Among the aspects excluded was mechanical shaping; Cahn explains this in the preface as follows: "I took the view that these topics have become part of the province of mechanical engineering, of continuum mechanics in particular (just as extractive metallurgy is virtually part of chemical engineering today)". In Chapter 1 ("Solidification Processing") the various types of structures that can result from solidification (dendritic, cellular, planar, single phase or multiphase, etc). are described and are discussed in the context of particular process conditions. Important variables influencing the outcome include the solidification rate and the heat flow. Chapter 2 is devoted exclusively to rapid solidification processes. Methods range from those based on spraying and on falling droplets to atomization and the quenching of molten films. Chapter 3 is concerned with the surface treatment of metals and alloys using laser beams, e.g. from a CO_2 laser. Chapter 4 deals with powder metallurgy (the production, characterization, granulation, and sintering of powders, and molding at high temperatures). Chapter 5 describes how high energy ball-milling can be used not only for uniform mixing but also to produce special alloys not obtainable in any other way. For example, oxide particles can be finely dispersed in metallic systems to give oxide dispersion strengthened (ODS) alloys. This method can be used to significantly increase the mechanical strength of an alloy matrix, as the mobility of dislocations is thereby reduced. Chapter 6 is concerned with ion implantation and mixtures produced using ion beams. The particular interest of this method is that it can be used to form metastable alloys not obtainable in other ways, new compositions and structures, and (not least) new intermediate phases. From Chapter 7 ("The Epitaxy of Metals") and Chapter 8 ("Metallic Multilayers") it becomes evident that the uses of epitaxy and multilayer methods are by no means confined to the semiconductors field, but also extend to metals and alloys. Chapter 9 deals with recrystallization and recovery (the "healing" of defects), and Chapter 10 with the measurement and control of texture. Other aspects that arise here are the growth and migration of grain boundaries, nucleation, deep drawing and molding, and ferromagnetic anisotropy. The last three chapters of Volume 15 are concerned with special processes and materials. Chapter 11 ("Electrodeposition of Metals and Alloys") describes new developments in the surface treatment of metallic materials (coating, etc.). Chapter 12 ("Solidifica-

tion Processing under Microgravity") examines the topical question of whether the modification of solidification processes under weight loss conditions (microgravity) can be usefully applied to make new materials or to optimize properties. Chapter 13 ("Cluster Assembly of Nanophase Materials") describes the preparation, characterization, and properties of materials in which a very high proportion of the atoms are in "grain boundary" type situations (i.e. with "ordered" regions and "grain" dimensions of less than 100 nm).

Despite the fact that the "Materials Science and Technology" series involves over 200 authors from all parts of the world (about 50 in these four volumes alone), the editors have succeeded well in guiding their contributions so as to present a unified overall picture. This in itself is an achievement that should not be underestimated. Moreover, the quality of the contributions is very high, and represents the current state of the art in every case.

It was certainly a good decision on the part of VCH to publish this series. The time was ripe for it; to quote the preface: "This bold new field (Materials Science and Technology) is now in need of an all-inclusive reference source—one that meets the demands of theorists and practitioners from every area of materials research, in research institutes and universities as well as in industrial research and development".

It is this reviewer's conviction that materials science and fundamental research are not opposites but form a unified whole. It is not sufficiently recognized that the problems and questions of basic research are very close to those of materials science, as this series impressively demonstrates. The volumes published so far deserve to reach a wide readership, and one can confidently predict that this assessment will also hold for the series as a whole.

Kinetics and Mechanism of Reactions of Transition Metal Complexes. 2nd Edition. By *R. G. Wilkins*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1991. XV, 465 pp., hardcover DM 148.00.—ISBN 3-527-28253-X/1-56081-125-0; Softcover DM 68.00.—ISBN 3-527-28389-7/1-56081-198-6.

The author has thoroughly revised and updated the first edition of this book published in 1974, thereby maintaining its position as one of the classic textbooks dealing with the reaction mechanisms of transition metal complexes. Noticeable changes from the first edition mainly involve recent developments in this area, such as the application of photochemical, NMR, and high pressure techniques to elucidate the intimate details of reaction mechanisms. In addition, more information on biological aspects of coordination chemistry (bioinorganic kinetics) is given and a few examples from organometallic chemistry are included. With this book the author has fulfilled a serious need for a textbook dealing with inorganic reaction mechanisms that is suitable for students up to graduate level.

The approach used in the revised edition is similar to that of the first edition. The first three chapters are devoted to the acquisition of experimental data in order to determine the empirical rate law, and the formulation of theoretical mechanisms that are in agreement with the experimental findings. In these chapters many chemical examples are used to illustrate the meaning of the formal mathematics. The following four chapters present a systematic treatment of the mechanisms of substitution, oxidation–reduction and isomerization reactions, as well as the reactivity of coordinated ligands in transition metal complexes. The last chapter includes a systematic summary of the mechanistic features of complexes of different transition elements. Each chapter contains a detailed list of references (between 96 and 370) and selected bibliography (between 2 and 18), and a set of stimulating and illustrative problems (between 10 and 34). Hints to solutions of these problems are given in a separate chapter.

This is the first mechanistic textbook in which the application of pressure as a kinetic parameter in the study of transition metal complexes is described at an appropriate level. Significantly, the author states on page 65 that "the rate law gives the composition of the activated complex (transition state)—nothing more nor less—but yields no clue about how it is assembled". He emphasizes on page 110 that "a careful compilation of as many kinetic parameters as possible can lead to overwhelming support for a mechanism"; thus all activation parameters ($\Delta H^{\neq}$, $\Delta S^{\neq}$, and $\Delta V^{\neq}$) should be considered. This general philosophy will find strong support from students and researchers in this area.

Highlights of the textbook include an attractive balance between theoretical aspects and real chemical systems, a compact but complete treatment of ligand substitution processes, and a well presented chapter on oxidation–reduction reactions. The numerous references to biochemically-related systems will attract the attention not only of inorganic chemists, but also of biochemists interested in the role of transition metal complexes in biological systems. The book really has something for everyone, and should be well accepted by students.

To summarize, the publication of this textbook has fulfilled the longstanding need for such an updated book in the general area of inorganic reaction mechanisms. The experience of the author in research and teaching on the kinetics and mechanisms of reactions of transition metal complexes has resulted in a well-balanced and well presented textbook. The presentation is of a high technical quality, and the text is easy to follow. The price of the paperback copy is very reasonable and should fit the average student budget. It is highly recommended to students and researchers in this field. Ralph Wilkins will receive a sincere appreciation from many inorganic kineticists for providing this thoroughly revised edition.

A Wandering Natural Products Chemist. (Series: Profiles, Pathways, and Dreams.) By *K. Nakanishi*. American Chemical Society, Washington, D.C., 1991. XXIII, 230 pp., hardcover $ 24.95.—ISBN 0-8412-1775-0

Seventy Years in Organic Chemistry. (Series: Profiles, Pathways, and Dreams.) By *T. Nozoe*. American Chemical Society, Washington, D.C., 1991. XIX, 267 pp., hardcover $ 24.95.—ISBN 0-8412-1769-6

With the appearance of the autobiographies of Nakanishi and Nozoe the series "Profiles, Pathways, and Dreams" is now half completed. Looking at the half-time score in this 22-volume series, the verdict so far is that the excellent first impression has not diminished in any respect. Gradually the pieces of this mosaic are beginning to fit together to form a

multicolored picture of modern chemistry. These latest two volumes again show how sensible it was of the series editor Jeffrey I. Seaman to construct this "living history" of chemistry on international lines right from the start.

Comparing these two autobiographies one notices another attractive feature, in that they are complementary to each other. Whereas Nozoe represents the old "imperial" Japan, which was obliged to open itself up to the outside world (and indeed wished to do so), Nakanishi is the citizen of the world who has overcome the language and cultural barriers (partly as a result of his unusual upbringing) and has become the archetypal example of the modern scientist. Readers whose acquaintance with the Japanese culture is only superficial, and is nonexistent at the psychological and emotional levels, cannot easily appreciate the importance and sometimes considerable power of the forces of tradition. It is slightly disappointing that Nozoe is reticent on this point, and does not allow the reader an insight into how he overcame his initial language isolation, for example. (At first he spoke no English, and lectures to be given abroad were first translated by a colleague and then learnt by heart—a common situation at that time, and one that does not appear to have been completely overcome even today.) One would also have liked to be told more about the political background, as the author began his scientific career at the Taihoku Imperial University in Formosa (now Taiwan), an island that still belonged to Japan in the thirties. The Japan of the pre-war years and of World War II is only spoken of rarely by Japanese people, and that also applies to this book. Nozoe's main area of research, the chemistry of seven-membered ring compounds derived from tropone and tropolone, is described in great detail—a very suitable title for the book might have been "Seven Decades of Seven-Ring Chemistry". Here the editor could well have intervened with a little tightening up without adversely affecting the book as a whole. On the other hand, this part could well serve as an excellent and sound introduction to the field, on which the now 92-year-old chemist is currently writing a definitive monograph.

Of all the autobiographies that have appeared in the series so far, the Nakanishi volume is the one I like best. The author gives a lively account of a scientific life that can have few equals with regard to its variety. This ranges from the isolation of natural products (on which there is much thought-provoking comment here), through the characterization of products using all kinds of physical methods, to synthetic chemistry, in which very few classes of substances are absent. Moreover, this varied nature is by no means confined to the scientific aspects of Nakanishi's experience. Parochial thinking, a common fault among chemists, is unknown to this author. He is more of a natural philosopher than a chemist, and the word "wandering" in the title could just as well have been spelled with an "o" instead of "a". The two authors are in stark contrast in the breadth of their choice of research topics, but Nakanishi is also well aware of the risks that can come from covering too broad a range. But what a lively and interesting man he turns out to be—whether he is expressing his curiosity about new eating habits and foods, or discussing his hobbies, including his well known skill as a magician, or his shortcomings. His views on policies towards research and education in Japan (and in his host country, the USA), on the relationship between teacher and student, or on choosing research topics that deserve attention, are all well worth reading, not least because they bear the stamp of Nakanishi's human point of view.

Like other books in the series, these are both illustrated by many evocative photographs and by formula schemes. Nozoe also includes extracts from his famous autograph books; these are guest books in which scientific colleagues from all parts of the world have recorded their good wishes, notes, or sketches of their favorite molecules or reactions. This "book within a book" can be read separately, and is a very personal miniature illustrated history of the (mainly organic) chemistry of the last forty years.

Defect Chemistry: Composition, Transport, and Reactions in the Solid State; Part I: Thermodynamics**

By Joachim Maier*

Dedicated to Professor Hermann Schmalzried on the occasion of his 60th birthday

Within the last few decades—though its foundations were laid over 60 years ago—a direction of research has developed almost unnoticed by the classical chemical disciplines, such that one can now recognize a chemistry *within* the solid state that is analogous to the long-familiar chemistry in the liquid state. It arises from those departures from the ideal structure that are thermodynamically unavoidable, the point defects, and is referred to as defect chemistry. It includes the description of ionic and electronic effects, and it considers diffusion as a special step of the overall reaction. This area of chemistry enables one to describe and treat in a unified way many widely different phenomena such as ionic conduction in crystals, doping effects and p–n junctions in semiconductors, color centers in alkali metal halides, image development in photography, passivation and corrosion of metals, the kinetics of synthesis and sintering of solid materials, problems of rock formation during the earth's evolution, the mechanisms of gas sensors and high temperature fuel cells, the performance of photosensitive electrodes, variations of the electron balance in high-temperature superconductors, elementary processes of heterogeneous catalysis, nonequilibrium transitions and oscillations in semiconductors in electric fields, and many more. In such phenomena the equilibrium concentration of defects has an important double role: it not only determines the disorder and the departure from the Dalton composition in the equilibrium state, but also, together with the mobility as the kinetic parameter, is the key parameter concerning the rates of physicochemical processes. Accordingly, in this first part of the review the emphasis will be on the equilibrium thermodynamics of point defects, whereas the second part will be specifically concerned with the kinetic aspects. Both parts will emphasize the fact that the defect chemistry of solids, as well as being the counterpart of solution chemistry in the liquid state, also provides a unifying approach in which electronic and ionic charge carriers are treated by analogous methods, both in the bulk and in boundary layers, and allows diffusion to be incorporated naturally into the overall kinetics of reactions as an elementary chemical process.

1. Introduction

Whereas the solid state has traditionally always played a prominent role in physics, the chemist still continues to regard it as a special case, despite its importance in everyday life. The importance of structure and bonding in solids is very well acknowledged, as is that of solid-state reactions on a global scale; however, the notion of solid-state chemistry in the sense of a chemistry of processes taking place *within* the solid phase, and being studied as successfully as "wet chemistry" before it, still seems rather fanciful.

[*] Prof. Dr. J. Maier
Max-Planck-Institut für Festkörperforschung
Heisenbergstrasse 1, D-W-7000 Stuttgart 80 (FRG)

[**] Part II: Kinetics will appear in the April issue of *Angewandte Chemie*.

Nevertheless, this chemistry of the solid state is a key discipline on which the fundamental insights and considerable achievements of modern materials science largely depend, and it affords a unified description of the thermodynamics and kinetics of a whole range of important phenomena in such varied fields as catalysis, battery research, corrosion, sensors, and electronics.[1] This review aims to show that "defect chemistry" is in fact a natural extension (and generalization) of chemistry in solutions. Defect chemistry is essentially the study of the nature of point defects in the solid state and of their interactions (but it also includes higher dimensional defects, such as dislocations, interfaces, or pores). The central role of point defects, that is essentially the role of extra particles and of missing particles, is illustrated in Figure 1a, which shows a small region of the structure of water. The successes that have been achieved in understanding the chemistry of water and in modifying its properties depend not so much on a precise knowledge of the basic structure and bonding (which influence phenomenological parameters such as equilibrium constants and rate constants) but on the ability to relate these properties to relevant "particles," such as H_3O^+ and OH^- ions, and foreign molecules or ions. If we formally subtract the underlying perfect water phase (Fig. 1a), we are left with the two "defects" (shown on the right-hand side in Fig. 1a), namely an "extra" proton and a "missing" proton (proton vacancy). This can be described in terms of the formation reactions in Equations (1a)–(1c).

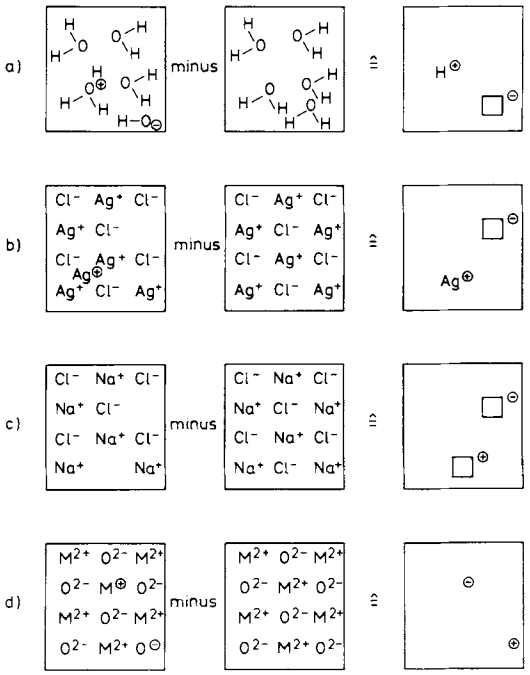

Fig. 1. By "subtracting" the ideal structure (middle column) from the actual structure (left-hand column), the defects remain as the "particles" that determine the behavior.

$$2H_2O \rightleftharpoons H_3O^+ + OH^- \quad | - H_2O \qquad (1a)$$

$$H_2O \rightleftharpoons H^+ + OH^- \quad | - H_2O \qquad (1b)$$

$$\text{nil} \rightleftharpoons H^+ + |H|^- \qquad (1c)$$

From the standpoint of defect chemistry the particles appearing in Equation (1c) (in which the underlying phase has completely disappeared from the description) are the defects in the water structure, namely an extra proton (H^+) and a vacant proton site ($|H|^-$). These particles, together with any dissolved substances, determine the acid-base and redox chemistry in water, and make ionic transport possible.

Figure 1b shows AgCl, a typical solid phase. Here also, the occupation of the sites in the rock salt structure is not perfect at finite temperatures; a small number of the silver ions have left their regular sites to occupy interstitial positions, leaving (in the case of the pure material) an equal number of vacant sites in the crystal lattice [Eq. (2)].[3, 14, 15]

$$\text{nil} \rightleftharpoons Ag^{\bullet} + |Ag|' \qquad (2)$$

In this sense the vacant silver ion site can also be regarded as a negative $Ag^{\bullet}$ particle (or better as a complementary particle). It can be seen that this class of defects, which are said to be formed by a Frenkel reaction (F), corresponds to the autoprotolysis reaction [Eq. (1c)]. In both cases the "defect concentration" is an inevitable consequence of the thermodynamics due to entropy considerations. These internal equilibria can also be treated, as we shall see again later, by using mass action laws, and here too dissolved particles have to be considered. As in the later examples, the existence of the same relevant particles leads to an internal mobility, thus allowing ionic conduction, either by an interstitial lattice mechanism or by a vacancy mechanism (similar to the Grotthus mechanism of proton conduction). The defect chemistry of solids is fundamentally more general than the chem-

Joachim Maier was born in 1955 in Neunkirchen, Saarland. He studied chemistry at the Universität des Saarlandes and received his doctorate there in 1982 in physical chemistry. At the Max-Planck-Institute für Festkörperforschung in Stuttgart he devoted himself to the questions of mass and charge transport in the solid state. In 1988 he completed his habilitation at the Universität Tübingen about "ionic conduction in boundary layers". After a visiting professorship at the Massachusetts Institute of Technology, where he is still a faculty member today, he worked at the Pulvermetallurgischen Laboratorium des Max-Planck-Instituts für Metallforschung on ceramic materials. Since 1991 he has been scientific member of the Max-Planck-Gesellschaft and Director at the Max-Planck-Institut für Festkörperforschung in Stuttgart. Among his awards the Chemidozentenstipendium and the Carl-Duisberg-Gedächtnispreis are particularly worthy of mention. His interests include the thermodynamics and kinetics of the solid state, in particular questions of the boundary layers and of ionic transport.

istry of ions in water, as can be seen from the following features:

1) Since many solids are built up of ions,[16] it is necessary to distinguish between real and relative charges. For example, a vacant cationic site has an effective negative charge relative to the background of the perfect structure. In Equation (2), as commonly used in the literature, this relative charge has been indicated by deliberately using dots and primes instead of plus and minus signs. The systematic notation is explained in the next section.

2) In the solid the particles are assigned fixed positions, and one therefore has to distinguish between several different types of disorder. In addition to Frenkel (F) defects, and anti-Frenkel ($\bar{F}$) disorder, as the corresponding defects in the anion structure (e.g., in halides of alkaline earth metals) are called, there are Schottky defects (S). (See Fig. 1c). Schottky defects occur particularly in the closely packed alkali metal halides;[2, 14] in NaCl this involves the formation of a sodium vacancy and a chlorine vacancy ($|Na|'$ and $|Cl|^{\cdot}$) with the removal of an NaCl molecule [Eq. (3)].

$$nil \rightleftharpoons |Na|' + |Cl|^{\cdot} + NaCl \tag{3}$$

Anti-Schottky defects ($\bar{S}$), believed to occur in yellow lead(II) oxide,[17] conversely involve the incorporation of a lattice molecule PbO with the formation of Pb^{2+} and O^{2-} ions ($Pb^{\cdot\cdot}$ and O'', respectively) in the interstitial lattice [Eq. (4)].

$$PbO \rightleftharpoons Pb^{\cdot\cdot} + O'' \tag{4}$$

In principle, of course, the thermodynamic treatment of a given phase must simultaneously take into account all these equilibria. For water in the liquid state this variability does not exist. In this case no regular and interstitial lattice sites are defined, and therefore the reaction desribed by Equation (1) can be regarded with equal validity as generating Schottky defects (vacant OH^- and H^+ sites), anti-Schottky defects (extra H^+ and OH^- ions), or anti-Frenkel defects (missing OH^- ions and extra OH^- ions).

3) In contrast to the usual situation in chemical kinetics, the low mobility in the solid state means that diffusion processes always constitute an important part of the overall process, and in many cases represents the rate-determining step. This point will be considered in detail in Part II of the review,[97] where it will also be shown that chemical reactions and transport processes can be treated by formally similar methods (see also Fig. 5, and Figs. 2 and 3 in Part II).

4) The thermodynamic and kinetic treatment of the solid state is of a more general nature than that of most liquids since, in addition to ionic defects, one always has to consider electronic charge carriers, which include both conduction electrons (e') and electron holes ($h^{\cdot}$). This leads not only to internal redox processes (which also occur in aqueous systems), but also, more importantly, to an intrinsic electronic conductivity which often predominates. Frequently ionic and electronic conduction are present simultaneously. This general case of a mixed conductor leads to interesting properties, and requires a generalized treatment of electrical transport phenomena. For many ionic compounds, and especially for transition metal oxides, the transfer of a valence electron into the conduction band can often be described as an internal redox reaction of the form shown in Equation (5). In more general terms this again can be considered as the formation of one extra particle, the conduction electron (e') and one vacancy, the electron hole ($h^{\cdot}$) [Eq. (6)].

$$O^{2-} + M^{m+} \rightleftharpoons O^- + M^{(m-1)+} \tag{5}$$

$$nil \rightleftharpoons e' + h^{\cdot} \tag{6}$$

Figure 1d illustrates this in a simplified way by showing a localized picture. As the notation already suggests, the thermodynamics and kinetics for electronic defects can be treated analogously at sufficiently high temperatures.

5) Because of the restricted space in the solid and the associated selective solubility, an aliovalent doping of the ionic crystal nearly always results in a pattern of substitution that involves both an acid-base effect (a change in the concentration of ionic defects) and/or a redox effect (a change in the concentration of electronic defects), whereas this is normally not the case in the aqueous phase as the anions and cations are normally dissolved simultaneously (see Section 2).[18]

2. Notation

The notation introduced here is based on a relative notation; in other words, it describes the changes that take place as one goes from the perfect to the real solid. The notation used in Section 1 (the "building elements" notation[4, 6, 8]) is a precise relative notation with regard to matter and electric charge, and is the most rigorous from a thermodynamic standpoint, but it fails to convey a clear structural picture. The "structural elements" description[19] is a compromise

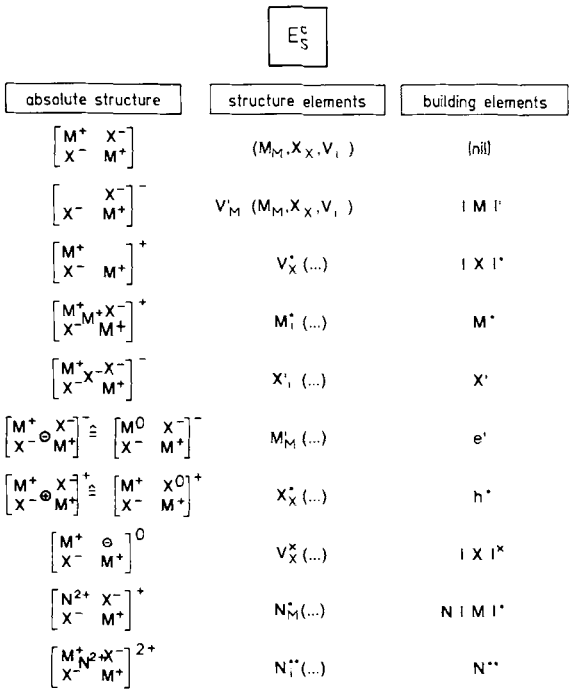

Fig. 2. Simple point defects represented in the form of the absolute structure (left), the structure elements (middle), and the building elements (right).

that comes closer to a chemical representation; it takes the structural picture into account,[20] but is still a relative notation with regard to electric charge. Here, as Figure 2 illustrates, the symbol E_s^c represents a general structural element; E defines the chemical species, for example Ag, Cl, or V for a vacancy. As explained previously, it is important to define the crystallographic site (s); for example, s is Ag, Cl, or i (i denotes an interstitial site). The term c gives the relative charge (the charge in the real state minus the charge in the perfect state); the superscripts ′ and • are used to denote positive and negative charges, respectively. Where the relative charge is zero, the superscript is often omitted or written as "×". Thus Ag_{Ag} or Ag_{Ag}^{x} represents a regular silver ion, V'_{Ag} represents a vacant silver site, $Ag_i^{\bullet}$ a silver ion at an interstitial site, and $Cd_{Ag}^{\bullet}$ a Cd^{2+} ion that has replaced a regular Ag^+ ion. For a compound whose ideal composition is M^+X^-, the formation equations for the different types of defects as discussed previously now take on the clearly descriptive form shown in Equations (7)–(10).

$$M_M + V_i \rightleftharpoons V'_M + M_i^{\bullet} \qquad \text{(Frenkel, F)} \qquad (7)$$

$$X_X + V_i \rightleftharpoons V_X^{\bullet} + X_i' \qquad \text{(anti-Frenkel, } \bar{F}\text{)} \qquad (8)$$

$$M_M + X_x \rightleftharpoons MX + V'_M + V_X^{\bullet} \qquad \text{(Schottky, S)} \qquad (9)$$

$$MX + 2V_i \rightleftharpoons M_i^{\bullet} + X_i' \qquad \text{(anti-Schottky, } \bar{S}\text{)} \qquad (10)$$

For simplicity no distinction has been made between the interstitial lattice sites of anions and cations. It can be seen that the reactions S and $\bar{S}$ result in a coupling between the anion and cation lattices, and involve the uptake or release of a "lattice molecule", which can only take place if dislocations or interfaces are present. In the reactions of defect chemistry, not only must the particles and charges on the two sides of the equation balance, as in conventional chemical reactions, but the lattice sites must also balance.

Although the electronic defect-forming reaction in structure element notation could be described as the transfer of an electron from the valance band to a vacant site in the conduction band, which would generate an electron in the conduction band and a hole in the valence band (in analogy to the Frenkel reaction F), the notation used in Equation (6) will be retained for this case, as the electron shell is already understood as being included in the ionic defects. Moreover, in this way the extent of localization is not specified (Fig. 2).

By rearranging Equations (7)–(10) it can be seen that each of the building elements [see Eqs. (2)–(4)] corresponds to a combination of the structure elements; for example, $Ag^{\bullet} \equiv Ag_i^{\bullet} - V_i$ and $|Ag|' \equiv V'_{Ag} - Ag_{Ag}$. These combinations denote structure elements that can be introduced into the crystal (leaving aside charge effects). For example, the introduction of an extra Ag^+ ion leads to both the loss of a vacant lattice site and the creation of a vacancy by the removal of a regular ion. When the regular constituents Ag_{Ag}, Cl_{Cl}, and V_i are present in large numbers, which provides a virtually inexhaustible supply, the two notations are thermodynamically equivalent.[20, 21]

Since both ionic and electronic defects can occur in a crystal, it is possible to have deviations from the ideal composition M^+X^- (non-stoichiometry). According to the Gibbs phase rule, in thermodynamic equilibrium at a given temperature and pressure the degree of non-stoichiometry is determined by the activities of the components M or X, and therefore by the partial pressures of M or X (or X_2). The interaction can then be derived from a relationship such as, for example, Equation (11a), which represents the incorporation of X, in the form of the X^- anion, into a vacant X site. The effect of this on the other defects, such as $M^{\bullet}$ or $h^{\bullet}$, is then given by Equations (7) to (10). This can, of course, also be obtained directly by expressing the insertion reaction [Eq. (11a)] in appropriate alternative forms. For example, the effect on the concentration of metal vacancies (hole concentration) may be obtained from Equations (11b) or (11c).

$$\tfrac{1}{2}X_2 + V_X^{\bullet} + e' \rightleftharpoons X_X \qquad (11a)$$

$$\tfrac{1}{2}X_2 + M_M + e' \rightleftharpoons MX + V'_M \qquad (11b)$$

$$\tfrac{1}{2}X_2 + M_M \rightleftharpoons MX + V'_M + h^{\bullet} \qquad (11c)$$

However, Equations (11b) and (11c) are redundant if the equilibria expressed by Equations (7) to (11a) are established. Similarly, the effect of an impurity ion N^{2+}, which is usually treated as an irreversible introduction, is sufficiently described by only *one* structure element combination, for example the acid-base reaction given in Equation (12a).

$$NX_2 + 2M_M \rightarrow N_M^{\bullet} + V'_M + 2MX \qquad (12a)$$

(The replacement of an M^+ ion by an N^{2+} ion is compensated by generating a vacancy at an M site.) It can be seen that the greater charge of the N-impurity ion results in an increase in the concentration of M vacancies. As can be seen by combining this with the Schottky reaction [Eq. (9)], the establishment of the equilibrium is accompanied simultaneously by a reduction of the concentration of anion vacancies. Instead of Equation (12a) one could, of course, have chosen to go directly to Equation (12b), which is in fact redundant if the above equilibria apply; here X is introduced into an anion vacancy. Furthermore, combining this with Equation (11a) shows that the e′ concentration is also affected; it is increased as a result of the introduction of N^{2+}. Here again one could have chosen to write the doping reaction immediately as a redox reaction [Eq. (12c)], in which the incorporation of the N^{2+} ion is accompanied by a reduction of the crystal.

$$NX_2 + V_X^{\bullet} + M_M \rightarrow N_M^{\bullet} + MX + X_X \qquad (12b)$$

$$NX_2 + M_M \rightarrow MX + \tfrac{1}{2}X_2 + N_M^{\bullet} + e' \qquad (12c)$$

All this can be summarized as follows: as one can easily see from general considerations that are based ultimately on the irreversibility of Equations (12) and the electrical neutrality of the reactions given, the introduction of an impurity with an effective positive charge causes an increase in the concentrations of all negatively charged defects and a reduction in the concentrations of all positively charged defects, and vice versa. This generalization is very important for materials research, and may be described as the "rule of homogeneous doping", expressed by Equation (13).

$$\frac{z_k}{z_{dop}} \frac{\delta c_k}{\delta c_{dop}} < 0 \qquad (13)$$

Here z_k is the effective charge of the intrinsic crystal defect, z_{dop} is the effective charge of the dopant species, and c is the concentration. (It will be shown in Section 3.2 that a similar relationship can also be derived for "heterogeneous doping".) For example, the doping of AgCl with $CdCl_2$, which involves the formation of $Cd^{\bullet}_{Ag}$ defects, raises the numbers of silver vacancies, and of conduction electrons and lowers the concentrations of interstitial silver ions and of electron holes. The introduction of S^{2-} ions by doping AgCl with Ag_2S, with consequent formation of S'_{Cl} defects, has exactly the opposite effect (see Section 3.1.1, homogeneously doped silver halide).[115]

Here it must be briefly mentioned that in addition to these simple point defects one can have complex defects formed by association between them. An example is the association of two vacancies that neutralize each other electrically [Eq. (14)]; such a pair can be regarded as a preliminary stage in the

$$V'_M + V^{\bullet}_X \rightleftharpoons (V_M V_X)^{\times} \qquad (14)$$

formation of a pore. Another example is the capture of electronic charge carriers by ionic defects, as in Equations (15) or (16).

$$V'_M + h^{\bullet} \rightleftharpoons V^{\times}_M \qquad (15)$$

$$N^{\bullet}_M + e' \rightleftharpoons N^{\times}_M \qquad (16)$$

Ion-electron associates of this kind are of considerable significance when their electronic energy levels lie within the band gap.

Other important examples are color centers, such as those observed in NaCl when subjected to high partial pressures of sodium.[122] These arise from the capture of electrons (e') by Cl^- vacancies, as in Equation (17) (cf. Fig. 2). Such color

$$V^{\bullet}_{Cl} + e' \rightleftharpoons V^{\times}_{Cl} \qquad (17)$$

centers can be described surprisingly well by using the simple quantum mechanical model of an electron in a box with atomic dimensions, and optical absorption measurements can therefore be used to assess the dimensions of the anion vacancy sites.[123]

Evidently, because of the gain in Coulomb energy and the reduction of configurational entropy, such association reactions will usually take place preferentially at low temperatures and high concentrations.

All this occurs within the one phase "MX"—thus it can be seen that the chemistry of the solid state is just as richly varied as the chemistry of the aqueous phase. A characteristic feature is the variation in the M:X ratio, which results from the simultaneous occurrence of electronic and ionic defects, and is determined by the partial pressures of M and X. The defect concentrations are normally very small, and very often their contribution to the total energy of the crystal is negligible, but they are of crucial importance for many properties (equilibrium partial pressures of the M and X components, transport phenomena, and reactivity). The following sections will begin by discussing the thermodynamic equilibrium. If the notation presents difficulties initially, the reader is recommended to always bear in mind the absolute structure (as in the left-hand column of Fig. 2).

3. Thermodynamics

3.1. Behavior in the Bulk Material

The thermodynamic treatment takes a simple form in cases where the defects can be regarded as behaving independently of each other.[23b] This condition is most likely to be satisfied for low defect concentrations and high temperatures.[2] Let us consider, as the simplest example, the formation of vacancies in an elemental crystal (Fig. 3). Since the

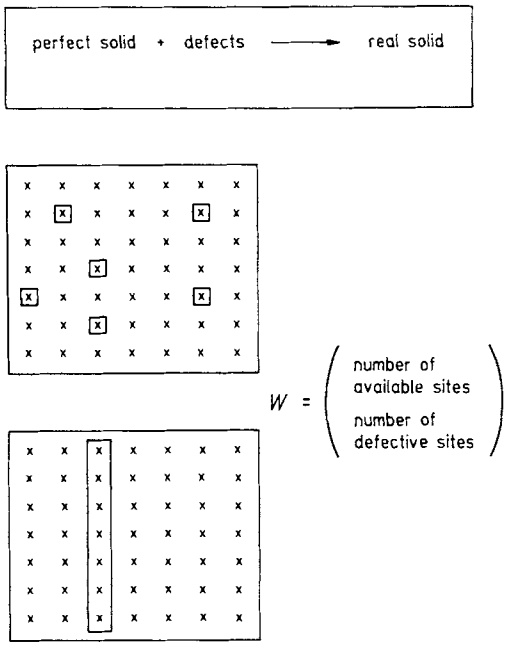

Fig. 3. The introduction of point defects (in this case vacancies) into an elemental crystal.

relevant bonds must be broken in this case, some energy must always be expended. Moreover, the resulting deficit cannot be fully made up by structural changes in the immediate environment that minimize the "damage", nor by any possible increase of the vibrational entropy. Despite this, any crystal in thermodynamic equilibrium at a finite temperature contains a finite number of point defects, because the introduction of such defects makes an enormous number of new configurations possible. The macrostate specified in Figure 3 (six vacancies in a total of 49 sites) can be achieved by any one of W microstates, where W is given by Equation (18).

$$W = \binom{\text{number of available sites}}{\text{number of defective sites}} = \binom{49}{6} = 49!/\{6!(49-6)!\} \qquad (18)$$

The resemblance of Figure 3 to a completed lottery slip (six out of 49) is not accidental. In the German national lottery the probability of winning the top prize ($1/W$) is discouragingly small due to the size of W (about 14 million), and in view of the state's cut of the profits this has led to the lottery being sourly described as a "special tax on fools".

The gain in configurational entropy, ΔS_{conf}, follows directly from the calculation above (see [Eq. (19)]). The total Gibbs energy of the real solid (where N_{def} is the number of point defects) can be broken down into several contributions, as shown in Equation (20).

$$\Delta S_{conf} = k \ln W_{real} - k \ln W_{ideal} = k \ln W_{real} \tag{19}$$

$$\begin{aligned} G_{real}(N_{def}) &= G_{perf} + \Delta G_{def}(N_{def}) \\ &= G_{perf} + N_{def} g^0_{def} - T\Delta S_{conf}(N_{def}) \end{aligned} \tag{20}$$

Here G_{perf} is the Gibbs energy of the perfect solid; this consists essentially of the bonding energy at absolute zero together with the contributions from thermal activation, which is mainly determined by the vibrational specific heat.[5, 13] The quantity g^0_{def} represents the free enthalpy change caused by the introduction of each defect, arising mainly from a bonding enthalpy contribution and a change in vibrational entropy. As already mentioned, structural relaxation processes make the value of g^0 considerably more favorable than the naive picture (Fig. 3) would suggest, but nevertheless it is always positive. Typically it is of the order of 1 eV per defect, which corresponds to 100 kJ mol^{-1} [24] Provided that the point defects do not interact, the factor g^0_{def} is independent of N_{def}, and thus the second term is proportional to the number of defects. However, this is not the case for the negative term $-T\Delta S_{conf}$. As Figure 4 shows, the decrease of this term at small N_{def} values is very pronounced; as a result the curve of free enthalpy against number of defects has a minimum at a small but finite defect number $\hat{N}_{def}$, which is the equilibrium defect number and increases with increasing temperature.[23b]

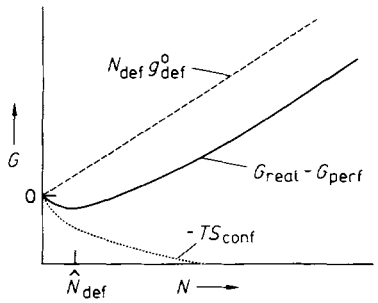

Fig. 4. The main contributions to the free enthalpy G of a real crystal (with a low concentration of defects). The minimum corresponds to the equilibrium concentration of point defects, $\hat{N}_{def}$. [23b] N = number of point defects.

This equilibrium value is given by the condition $\partial G_{real}/\partial N_{def} = 0$. Furthermore, up to the Avogadro number N_A, the partial derivative $\partial G_{real}/\partial N_{def}$ is identical to the chemical potential μ_{def}, which can be regarded as a measure of how much the particles (i.e. the defects) are "disliked" in the phase. This is obtained from Equation (20), in the form that is already familiar for dilute states, as a linear function of the logarithm of the defect concentration [Eq. (21)].

$$\mu_{def} = \mu^0_{def} + RT \ln c_{def} \tag{21}$$

The standard potential μ^0_{def} is given by $N_A g^0_{def}$ and the defect concentration c_{def} by N_{def}/N, where N is the total number of available sites. It will be noticed that N_{def} and N are the same terms as in the expression for W (cf. [Eq. (18)]. The equilibrium concentration $\hat{c}$ can be derived readily, and is given by Equation (22). It is not difficult to see that this is equivalent to the simplest case of a mass action equation, corresponding to the formation reaction [Eq. (23)] (Fig. 5).

$$\hat{c}_{def} = \exp - \left(\frac{\mu^0_{def}}{RT}\right) \equiv K(T) \tag{22}$$

$$\text{nil} \rightleftharpoons \text{defect (vacancy)} \tag{23}$$

The equilibrium constant $K(T)$ contains the standard value of the chemical potential, whereas the contribution arising from the configurational entropy is taken into account by the concentration term [left-hand side of Eq. (22)]. The above result can be easily generalized for the formation of several defects (for example, via a Schottky or Frenkel defect). Because of conservation of the elements, a minimum in G requires that the sums of the chemical potentials on the two sides of the reaction equation cancel each other.[25] From Equation (21) we can obtain the mass action law in its usual form. The mass action constant is then given by the corresponding linear combination of the standard potentials (e.g. $\mu^0_B - \mu^0_A$ in Fig. 5).[25] Provided that, as assumed here, we are concerned with dilute states, it does not matter

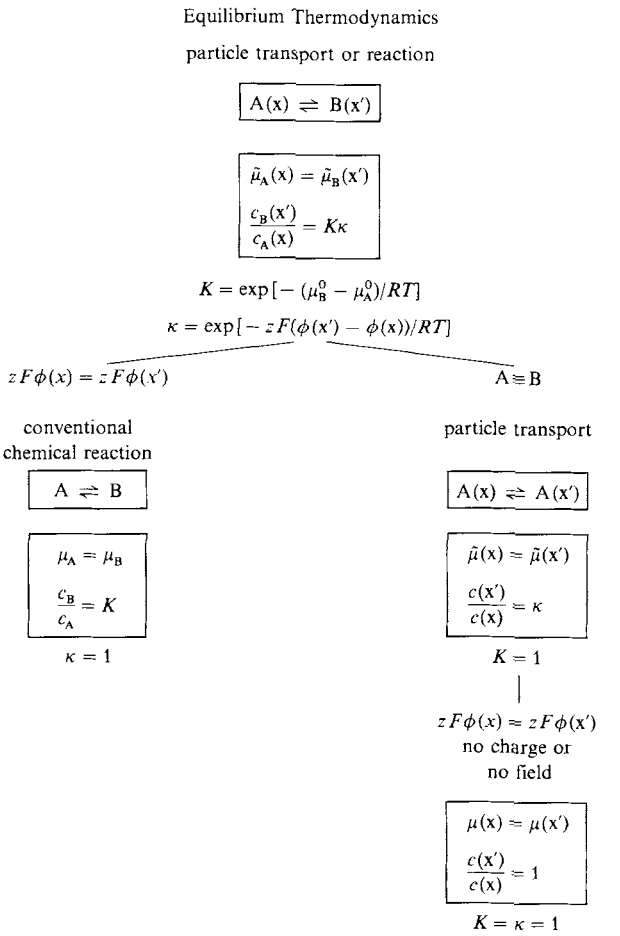

Fig. 5. Diagram summarizing equilibrium thermodynamics. Both the reactions of particles and their transport are included in the general description, so that (conventional) chemical reactions and particle transport appear as two special cases.

whether we use the thermodynamically correct building elements notation, or whether we use the structure element notation and introduce individual virtual potentials for each of the species involved.[20, 21] This is because the virtual chemical potentials of the regular particles remain constant due to their high concentration. For convenience, in the following discussions molar concentrations will be used for c unless otherwise stated. With this convention the mass action constants become dimensional quantities.

Table 1 lists the relevant mass action relationships for the defect equilibria discussed previously. It is well known that

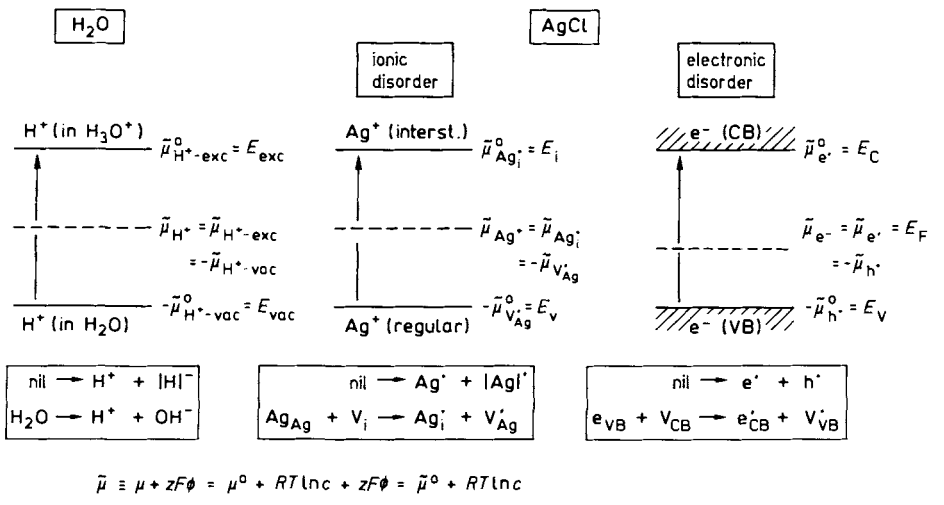
Table 1. Defect reactions, mass action equations, and electroneutrality conditions for the simple bulk defect chemistry of an ionic crystal "M^+X^-" (or $M_{1+\delta}X$).

Simple defect chemistry in $M_{1+\delta}X$	
Reaction (r)	Mass action equation
internal	
Schottky (S)	$[V_X^{\cdot}]\,[V_M'] = K_S$
anti-Schottky ($\bar{S}$)	$[M_i^{\cdot}]\,[X_i'] = K_{\bar{S}}$
Frenkel (F)	$[M_i^{\cdot}]\,[V_M'] = K_F$
anti-Frenkel ($\bar{F}$)	$[V_X^{\cdot}]\,[X_i'] = K_{\bar{F}}$
band-to-band (B)	$[h^{\cdot}]\,[e'] = K_B$
$K_r(T) \propto \exp + \left(\frac{\Delta_r S^0}{R}\right) \exp - \left(\frac{\Delta_r H^0}{RT}\right)$	
external	
reaction with the gas phase (X)	$[h^{\cdot}]\,[V_M'] \, P_{X_2}^{-1/2} = K_X$
electroneutrality condition	
$[V_X^{\cdot}] + [M_i^{\cdot}] + [h^{\cdot}] = [V_M'] + [X_i'] + [e'] \; (\pm D)$	

this formalism can also be applied to electronic defects in solids.[26] These relationships form the basis of a large part of semiconductor physics. Provided that the concentration of defects is sufficiently low and the temperature sufficiently high, the conduction electrons or holes are assumed to be distributed over a large reservoir of available states, as in the previous examples. Again the configurational entropy is as given earlier, resulting in an expression of the same form as Equation (21) for the potential (Boltzmann approximation). However, owing to the band character of the states in this case, the total number of available sites is replaced by an effective density of states. In Table 1 these terms have been included in the mass action constants, wherever electronic concentrations are involved. Also, at lower temperatures and high electron concentrations, Fermi–Dirac statistics must be applied. These corrections can be formally incorporated into the activity coefficients.[27] As shown in Figure 6, the energy levels used in semiconductor physics, namely E_F (Fermi level), E_v (upper edge of valence band), and E_c (lower edge of conduction band), here expressed as molar quantities for convenience, correspond in thermochemical terms to the electrochemical potentials (chemical potential + electrical potential term) or to the electrochemical standard potentials.[28] In particular, bearing in mind Equation (21), one can immediately understand why it is usual in semiconductor physics to determine the concentrations of electrons and holes from the energy differences $E_c - E_F$ and $E_F - E_V$. It can also be seen that the difference between E_V and E_L, the band gap E_g, is almost identical to the expression in Equation (24), in other words to the change of the standard free

$$\mu_{h^{\cdot}}^0 + \mu_{e'}^0 = -RT \ln K_B \qquad (24)$$

energy of the electron-hole reaction in Table 1.[29] It is also evident that the Fermi level for a "pure semiconductor", in which $[e'] = [h^{\cdot}]$, lies approximately in the middle of the band gap. To emphasize the similarities between the two representations, in Figure 6 level schemes for the ionic disorder in AgCl (see also Fig. 7) and for water (with the energy levels E_{exc}, E_{reg}, E_F') have been constructed. The electrochemical potentials of H^+ and Ag^+ lie in the middle between the upper and lower levels, which indicates equal concentrations of negative and positive ionic defects. This condition is fulfilled for both pure H_2O and pure AgCl so far as the ions are concerned, but—as shown by Example 1 (Section 3.1.1) – it is in these compounds normally not fulfilled for electronic defects (E_F lies in the middle of the band gap only in very special cases). Figure 7 shows the level scheme for AgCl at a higher resolution,[31] emphasizing an important characteristic of ion transport in solids: The transport of the interstitial defects (Fig. 7, top) and the transport of vacancies (Fig. 7, bottom) are both affected by free activtion energies for the periodic hopping process ($\Delta_i G^{\neq}$ and $\Delta_v G^{\neq}$), which refer to the transition states in conventional chemical reactions, and are determined by the "bottleneck" (more precisely: saddle-point) associated with the diffusion path or the reaction coordinates.



$$\tilde{\mu} \equiv \mu + zF\phi = \mu^0 + RT \ln c + zF\phi = \tilde{\mu}^0 + RT \ln c$$

Fig. 6. The construction of a band diagram and analogous energy level diagrams for the electrons and the Ag^+ ions in AgCl [66] and for the protons in water ($H_{exc}^+ \triangleq H^+$; $H_{vac}^+ \triangleq OH^-$). CB = conduction band, VB = valence band.

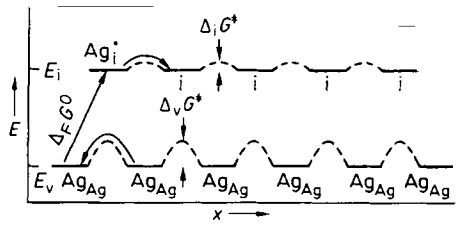


Fig. 7. The generation and transport of ionic defects in silver halides, shown in the form of an energy level diagram (cf. Fig. 6), x = spatial coordinate [66].

Let us, as shown in Figure 3, impose restrictions on the distribution of the defects, in demanding for example that all the defects must form a column as in Figure 3 (bottom), we obtain a crude way of simulating the extended defects such as grain boundaries with respect to the configurational behavior. The probability of the configuration, and consequently also the configurational entropy, are then enormously reduced; in the above case there is a reduction from 14 million to 6 (or to 7 in the example chosen). In the three-dimensional arrangement, and with particle numbers of macroscopic magnitudes, the reductions are even more extreme.[32] From this one can immediately conclude that the equilibrium probabilities for internal surfaces in real crystals are completely negligible. Despite this, such internal boundaries are of great importance due their metastable existence.[33] In summary, the equilibria involved in the chemistry of simple internal defects for a pure compound $M_{1+\delta}X$ are described by the mass action equations given in Table 1.

A closer inspection of the equations in Table 1 reveals that one of them is redundant (for example, one can write $K_{\bar{F}} = K_S K_{\bar{S}}/K_F$). The only additional relationship needed to solve the system with variable defect concentrations (treating P_{X_2} as a parameter) is the local electrical neutrality condition[34] given by Equation (25a), which can also be written in the form of Equation (25b) by using the mass action equations.

$$[V_X^{\bullet}] + [M_i^{\bullet}] + [h^{\bullet}] = [V_M'] + [X_i'] + [e'] \tag{25a}$$

$$[M_i^{\bullet}](K_s/K_F + 1) + [h^{\bullet}] = [V_M'](K_{\bar{S}}/K_F + 1) + [e'] \tag{25b}$$

If aliovalent impurities of fixed valency are present, these must be taken into account by including their doping concentrations (D, normally constant) in Equation (25). The mathematical treatment of systems with a large number of mass action equations (linear when reduced to logarithmic form) also presents no difficulties, nor does that of systems involving association reactions. Complications arise only when we come to the electrical neutrality relationship, (or equations for element conservation) which is not logarithmically linear. However, in many cases, depending on the X_2 partial pressure and also on the temperature, one of the two terms in Equation (25b) can be neglected, so that Equation (25b) becomes linear when expressed in logarithmic form (Brouwer approximation).[30] In such cases one can derive sectional solutions, yielding the equilibrium concentration for each defect species as a function of the controlling parameters $P \equiv P_{X_2}$ (X_2 partial pressure), T (temperature), and D (dopant concentration) in the form of Equation (26).

$$\hat{c}_k(P,T,D) = \alpha_k P^{N_k} D^{M_k} \Pi_r K_r^{\gamma_{rk}}(T) \tag{26}$$

Here α_k, N_k, M_k, and γ_{rk} are characteristic constants, and the mass action constants are given by the usual expressions in terms of the reaction enthalpies and reaction entropies for the reaction r (Table 1). Thus, Equation (26) represents the fundamental solution of the (bulk) problem of defect chemistry in the equilibrium case. The characteristic exponent N_k (not to be confused with the number of particles), is of particular importance, as it represents the dependence of the activity of the components on the partial pressure [Eq. (27a)], and yields valuable information about the defect model on which the theory is based.

$$N_k = \partial \ln \hat{c}_k / \partial \ln P \tag{27a}$$

$$M_k = \partial \ln \hat{c}_k / \partial \ln D \tag{27b}$$

Figure 8a shows schematically the dependence of $\lg \hat{c}_k$ on $\lg P$ in the Brouwer approximation for the case where there is negligible disorder in the anion lattice ($K_s = K_{\bar{s}} = 0$). Thus,

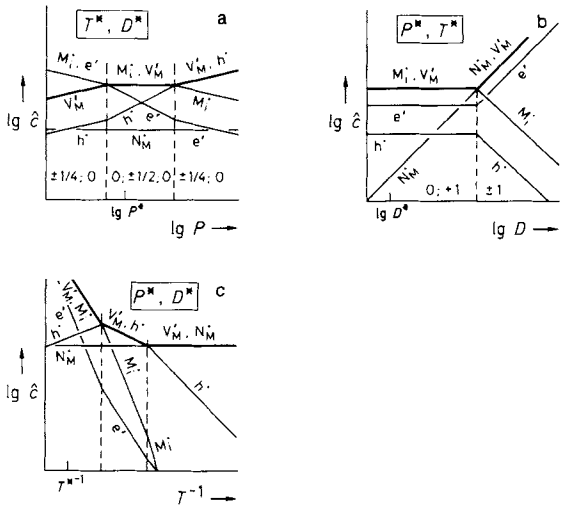

Fig. 8. Defect concentration as a function of the partial pressure (a), dopant concentration (b), and temperature (c) in the Brouwer approximatio (P^*, T^*, D^* are the values at the working point).

Figure 8a describes the "chemistry of the solid state" as one moves through the homogeneous region of the phase in the phase diagram. The straight-line sections correspond to constant values of N, with slopes equal to N_k (in the example chosen here, the exponents have the values 0, $\pm 1/4$, $\pm 1/2$). For very high values of the X_2 partial pressure (high [X]/[M] ratio, right-hand side of Fig. 8a), the concentrations of metal site vacancies are correspondingly high [see Eq. (11c)] and, owing to the oxidizing conditions, the holes predominate, so that the electrical neutrality condition simplifies to that given in Equation (28).

$$[h^{\bullet}] = [V_M'] \tag{28}$$

Equation (11c) then leads directly to Equations (29), and similarly from Equations (7)–(10) we obtain Equations (30),

$$[h^{\bullet}] \propto P^{1/4};\ [V_M'] \propto P^{1/4} \tag{29}$$

$$[e'] \propto P^{-1/4};\ [M_i^{\bullet}] \propto P^{-1/4} \tag{30}$$

as shown in Figure 8a. Provided that the dopant concentration ($[N_M^{\bullet}]$) remains small compared with those of the majority charge carriers ($h^{\bullet}$, V_M'), its effects, even on the minority charge carriers, can be neglected. Analogously for the region of low partial pressures (in which $[e'] = [M_i^{\bullet}]$), the straight-line sections shown in the left-hand side of Figure 8 are obtained. Similarly, for the intermediate regime ionic defects often predominate, as has been assumed in Figure 8a, so that $[M_i^{\bullet}] = [V_M'] =$ constant (constant $= K_F^{1/2}$ according to Table 1), leading to Equations (31). In general the width of the phases is usually insufficient to cover the whole of the defect range shown in the diagram.

$$[h^{\bullet}] \propto P^{1/2};\ [e'] \propto P^{-1/2} \tag{31}$$

The dependence of defect concentration on the degree of doping for constant values of P and T can be derived in an analogous way (Fig. 8b). For the fixed dopant level $D = D^*$ and partial pressure P^* assumed in plotting Figure 8a, the degree of doping is insufficient to cause a detectable effect, as is confirmed by the left-hand half of Figure 8b. Only when the defect concentration D becomes comparable with the concentration of the majority charge carriers (in this case $M_i^{\bullet}$, V_M') does it have a controlling influence on defect chemistry (right-hand side of Fig. 8b). Here, in agreement with the doping rule [Eq. (13)], the concentrations of the metal ion vacancies and of the conduction electrons increase with increasing doping, while those of the interstitial metal ions and electron holes decrease. In this example the resulting values of the exponent M (see Eq. (27b)) are 0, +1, and −1.

The temperature dependence is given in terms of the standard reaction enthalpies of the equilibria involved from Equation (22). This results in Equation (32), in which the

$$W_k \equiv -\partial \ln \hat{c}_k/\partial(1/RT) = +\sum_r \gamma_{rk} \Delta_r H^0 \tag{32}$$

value of $\Delta_r H^0$ for the formation of electron–hole pairs is, to a good approximation, equal to the band gap ($\Delta_B H^0 \simeq \Delta_B G^0 = E_g$), and the factors γ_{rk} are again simple rational numbers. Thus the temperature dependence yields information about the corresponding energy values, and $\ln c$ should be a linear function of T^{-1} over limited temperature ranges. Figure 8c illustrates the chemistry within the solid at different temperatures. The example chosen shows that also in this case a succession of different regimes are possible as the temperature is altered. If we start from the point (T^*, P^*, D^*), we are initially in the ionic-dominated region, as shown by Figure 8a. Since the various reaction enthalpies have different values ($\Delta_F H^0 > \Delta_X H^0 > \Delta_B H^0$ in the example chosen here), the boundaries of the regimes indicated in Figure 8a vary with temperature. In the example shown, reducing the temperature with fixed P results in a shift into the "high-pressure region" ($[V_M'] = [h^{\bullet}]$). Further cooling causes the thermally generated defect concentrations to become less and less, so that eventually the defect chemistry is determined by the level of doping.

A few examples illustrating the behavior in real situations will be described in the following sections. For this we first need to anticipate a result that will be arrived at in Part II of this review, namely that the observed electrical conductivity provides a convenient measure of the (equilibrium) defect concentration, and conversely the conducting properties of solid materials are determined by the (equilibrium) defect chemistry. Although slight departures from equilibrium are unavoidable when measuring the conductivity σ, provided that these are small the conductivity due to a defect k can be expressed in the form given in Equation (33). Here z_k is the

$$\sigma_k(T,P) = |z_k| F u_k(T) \hat{c}_k(T,P) \tag{33}$$

charge number, F is the Faraday constant, u_k is the mobility, and $\hat{c}_k$ is the equilibrium molar concentration. Since u_k is essentially independent of the composition, and therefore of P, for small defect concentrations, σ_k is proportional to the equilibrium concentration. Thus, by measuring the conductivity as a function of the partial pressure and dopant concentration the values of the important exponents N_k and M_k are obtained directly [Eqs. (34)].

$$\partial \ln \sigma_k/\partial \ln P = N_k;\ \partial \ln \sigma_k/\partial \ln D = M_k \tag{34}$$

The temperature dependence is a little more complicated, since the mobility also varies with the temperature. For ionic defects, and also for electronic polaron states, the activation energy controlling the value of u is the migration threshold $\Delta H^{\neq}$ (see Fig. 7 and the more detailed discussion in Part II of this review), and consequently the temperature dependence of the specific conductivity σ is given by a thermodynamic term ($\sum \gamma_{rk} \Delta_r H^0$) and a kinetic term ($\Delta H_k^{\neq}$), as indicated in Equation (35).

$$E_k \equiv -R\partial \ln \sigma_k/\partial(1/T) = W_k + \Delta H_k^{\neq} \tag{35}$$
