Figure 7 illustrates very clearly the two contributions that are needed for ionic charge transport to occur. In the first place the necessary defects must be formed (e.g. by generating interstitial ions and lattice vacancies, as controlled by $\Delta_F G^0$), and these must then be transported from their original sites to the nearest equivalent sites over the corresponding migration thresholds (e.g. $\Delta_i G^{\neq}$ for the interstitial lattice mechanism or $\Delta_v G^{\neq}$ for the vacancies mechanism). If band conduction occurs, and k refers to an electronic defect, the mobility of the electronic charge carriers normally decreases slowly with temperature according to a power law (typically $T^{-3/2}$).[26] In such cases the temperature dependence of the concentration term predominates, and Equation (35) is still approximately valid for $\Delta H^{\neq} \simeq 0$. In general the conductivity is the sum of the partial contributions, and this can be separated into an ionic term and an electronic term, as in Equation (36).

$$\sigma = \sigma_{ion} + \sigma_{eon} = \sum \sigma_k \tag{36}$$

An experimental procedure for determining the separate contributions is indicated in Section 3.2.1. The overall changes N, E, and M can be formally expressed as weighted summations of the individual changes by using the transport numbers $t_k \equiv \sigma_k/\sigma$, as in Equation (37).[35]

$$N = \sum_k t_k N_k;\ E = \sum_k t_k E_k;\ M = \sum_k t_k M_k \tag{37}$$

3.1.1. Example 1: Silver Chloride – A Typical Ionic Conductor

Due to the rather low concentration of crystal defects combined with relatively high mobilities, silver chloride is an excellent model substance for studying ionic conduction. Furthermore, it is also a solid of practical interest. One need only mention the importance of silver halides in photography, and the Ag/AgCl electrode that is so useful in electrochemistry, for example, as a reference electrode in water analysis or in gas sensor technology, applications which all depend on its defect chemistry.

Pure silver chloride

In pure silver chloride Frenkel disorder predominates. The conduction is predominantly ionic, involving silver ions. Accordingly, there is a much higher concentration of ionic defects than of electronic defects.[15] Thus the electrical neutrality (EN) relationship is simply given by Equation (38).

$$[V'_{Ag}] = [Ag^{\bullet}_i] \tag{38}$$

The interaction with the adjacent phase can be described by Equations (39). From the Frenkel equilibrium (F) ex-

$$\tfrac{1}{2}Cl_2 + Ag_{Ag} \rightleftharpoons AgCl + V'_{Ag} + h^{\bullet} \tag{39a}$$

$$K_{Cl} = [h^{\bullet}]\,[V'_{Ag}]\,P^{-1/2} \tag{39b}$$

pressed by Equations (40) and the condition of electroneutrality [Eq. (38)] the simple result follows that both ionic defect concentrations are determined by the square root of

$$Ag_{Ag} + V_i \rightleftharpoons Ag^{\bullet}_i + V'_{Ag} \tag{40a}$$

$$K_F = [Ag^{\bullet}_i]\,[V'_{Ag}] \tag{40b}$$

the Frenkel constant [Eq. (41)]. Combining this with Equation (39) gives the more complex expressions in Equations (42) for the concentrations of electronic defects.

$$[Ag^{\bullet}_i] = [V'_{Ag}] = K_F^{1/2} = \exp\left(\frac{\Delta_F S^0}{2R}\right)\exp-\left(\frac{\Delta_F H^0}{2RT}\right) \tag{41}$$

$$[h^{\bullet}] = (K_{Cl}K_F^{-1/2})\,P^{1/2} \tag{42a}$$

$$[e'] = (K_B K_{Cl}^{-1} K_F^{+1/2})\,P^{-1/2} \tag{42b}$$

The concentrations of all the charge carriers are highly temperature dependent, but only those of the electronic charge carriers are also strongly influenced by the chlorine partial pressure, that is by the exact position in the phase diagram. The dependence of the partial pressure of the ionic and electronic contributions on the conductivity is shown in Figure 9. As the abscissa one can use either the logarithm of the chlorine partial pressure or that of the silver activity (a_{Ag}), which are related to each other through the reaction constant for the formation of AgCl. Figure 9 shows the behavior of defect chemistry within the AgCl phase as one moves across the phase diagram. The window accessible in this way corresponds to the middle section of Figure 8a. At the extreme left of Figure 9 AgCl is in equilibrium with silver metal ($a_{Ag} = 1$). This defines the lowest possible Cl_2 partial pressure, whereas the right-hand edge of the diagram is fixed by the chlorine partial pressure of 1 bar.[37] Changes in defect chemistry are thus accompanied by a change of about 12 orders of magnitude in the chlorine partial pressure!

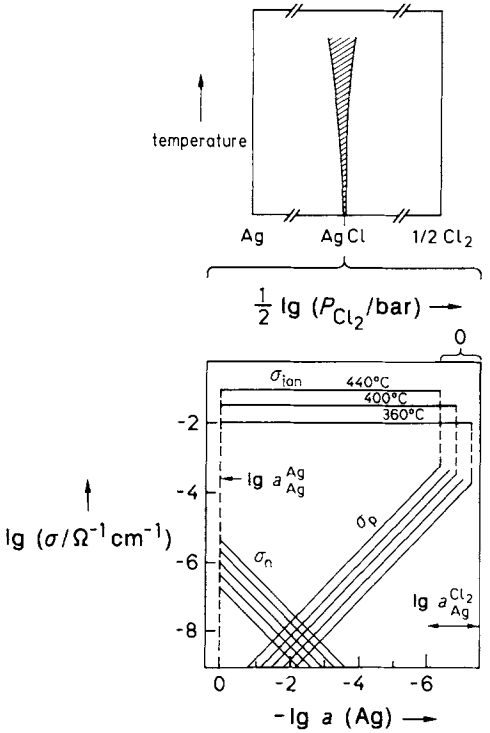

Fig. 9. The ionic and electronic conductivities in AgCl as functions of the silver activity (a_{Ag}) or of the chlorine partial pressure give a picture of the defect chemistry on passing through the width of the phase (data from ref. [36]). The superscripts Ag and Cl_2 denote the boundaries of the phase width (i.e. contact with Ag or with pure Cl_2).

Curve 1 in Figure 10 shows the conductivity (which is entirely ionic) of nominally pure AgCl as a function of temperature.[38] As will be shown later, the interstitial ions are the most mobile, so that $\sigma \simeq \sigma_{ion} \simeq \sigma_{Agi}$. The slope at higher temperatures in Figure 10 is therefore determined by half the

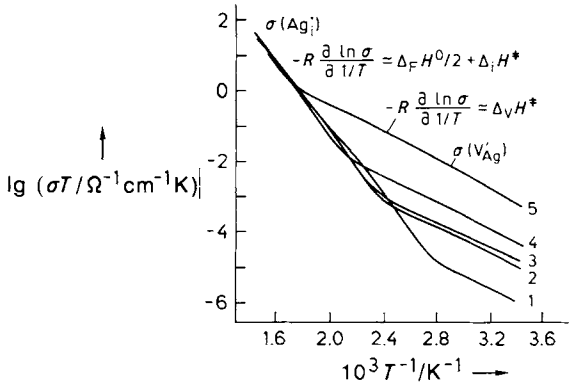

Fig. 10. Ionic conductivity of AgCl with various dopant levels as a function of temperature. Curves 1 and 2: nominally pure AgCl, with calculated dopant concentrations of 0.3 and 0.6 ppm, respectively; curve 3: with 6.9 ppm Mn; curve 4: with 31 ppm Cd; curve 5: with 1200 ppm Cd [38].

Frenkel enthalpy together with the activation energy for transport from one interstitial site to the next [Eq. (43)].

$$E = E_{A_{gi}} = \Delta_f H^0/2 + \Delta_i H^+ \quad (43)$$

Simulations and doping experiments have shown (see next section) that $\Delta_i H^+$ is small, thus the value of 1.45 eV obtained by doubling the slope gives the standard enthalpy of the Frenkel reaction with a good degree of accuracy.[39]

Any real material, even though nominally pure, contains impurities. Since the degree of thermal disorder decreases exponentially on reducing the temperature, the behavior at sufficiently low temperatures is *always* determined by extrinsic conditions (see Fig. 8c). This accounts for the reduced slope of the conductivity curves at low temperatures (curves 1 and 2) in Figure 10.

Homogeneously doped silver halides

If AgCl contains cationic impurities of higher valency such as Cd^+ or Mn^+, (as in curves 3–5 of Fig. 10), an additional term such as $D = [Cd^{\bullet}_{Ag}]$ must be included on the right-hand side of Equation (38). The concentrations of ionic defects are then given by the solution of a quadratic equation [Eq. (44)].

$$[V'_{Agi}] = D + [Ag^{\bullet}_i] = \frac{D}{2} + \sqrt{\frac{D^2}{4} + K_F} \quad (44)$$

For $D \ll \sqrt{K_F}$ (where $\sqrt{K_F}$ = intrinsic ionic defect concentration) the compound effectively behaves like the pure material ($[V'_{Ag}] = [Ag^{\bullet}_i] = \sqrt{K_F}$), whereas in the other extreme case of high defect concentrations one obtains a (high) concentration of vacancies that is independent of partial pressure and temperature ($[V'_{Ag}] \simeq D$), and the concentration of interstitial ions [see Eq. (45)] is reduced to a very low value, which is strongly temperature dependent due to the effect of $\Delta_F H^0$.

$$[Ag^{\bullet}_i] = K_F(T)/D \quad (45)$$

If instead the material is doped with Ag_2S (giving S'_{Cl}), these relationships are expected to be exactly reversed. Figure 11 shows the changes in the ionic conductivity for AgBr with temperature.[15] The minimum in the right-hand half of the figure corresponds to the change from interstitial type conduction to vacancy conduction. The fact that this does not occur at the zero point (pure AgBr) is due to the lower mobility of the vacancies: For very low Cd^{2+} concentrations, even though there is already a greater concentration of vacancies the conduction is still of the interstitial type, and the conductivity is therefore less than that of the pure material. On the other side of the minimum the higher value of $[V'_{Ag}]$ more than compensates for the lower mobility, and vacancy conduction predominates.

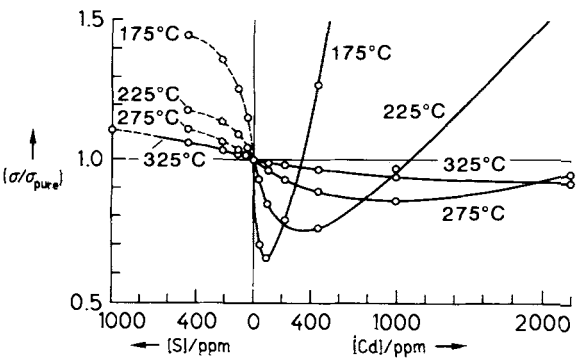

Fig. 11. Ionic conductivity of AgCl as a function of dopant concentration [15].

In Figure 10 the lower (right-hand) part of the conductivity curve corresponds to vacancy conduction, in contrast to the high temperature (left-hand) side. For the reason already explained, there is a characteristic knee in the curve corresponding to the transition region. The slope of the right-hand portion corresponds to 0.3 eV, and since $[V'_{Ag}]$ is constant this can be attributed to the enthalpy of migration of the silver ion vacancies. Thus it can be seen that measurements of this kind allow one to determine thermodynamic quantities such as enthalpies and entropies of formation, and also the enthalpies and entropies of migration that are relevant to kinetic studies. Table 2 summarizes some results.[13, 24]

Table 2. Thermodynamic parameters for the formation and migration of point defects.

Crystal	Disorder type	Enthalpy of formation [MJ mol^{-1}]	Entropy of formation [a]	Migration enthalpy [kJ mol^{-1}]	Migration entropy [a]
LiF	S	0.23	9.6	70 (V'_{Li})	1 (V'_{Li})
LiCl	S	0.21		40 (V'_{Li})	
LiBr	S	0.18		40 (V'_{Li})	
LiI	S	0.11		40 (V'_{Li})	
NaCl	S	0.24	9.8	70 (V'_{Na})	1–3 (V'_{Na})

BaF_2	$\bar{F}$	0.19		40–70 ($V^{\bullet}_F$)	
				60–80 (F'_i)	

[a] In units of R.

Two further comments on this example should be added:

1) Because Equations (2) and (6) both have the same form, exactly analogous considerations apply for a purely electronic (dilute) solid system such as pure silicon, or silicon doped with boron or phosphorus. Detailed descriptions can be found in textbooks on solid-state physics, and these cases are covered by the formalism given above.

2) One type of homogeneously doped ionic conductor of considerable practical importance is ZrO_2 doped with CaO or Y_2O_3. Oxygen vacancies are formed in the material in such a concentration as to give a high oxygen conductivity, which is used in high-temperature fuel cells and in electrochemical oxygen sensors (Fig. 12).[40] If different oxygen partial pressures P_1 and P_2 exist on the two sides of the doped zirconium oxide (to which electrodes are attached as in Fig. 12), a voltage is generated which, according to the Nernst equation, is proportional to $\ln(P_1/P_2)$. This can be used to determine the partial pressure P_1 (e.g., the oxygen

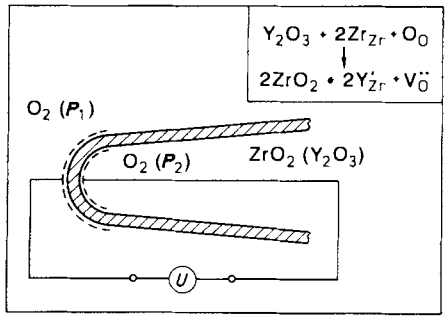

Fig. 12. Schematic arrangement of an oxygen concentration cell based on the ceramic solid electrolyte $ZrO_2(Y_2O_3)$, as used in oxygen sensors, pumps, and fuel cells. (In the latter, the oxygen partial pressure on the anode side is kept very low by a gas such as hydrogen.)

partial pressure in automobile exhaust gases) if P_2 is known, or can even be used to control it (as in the automobile λ-probe). Alternatively, a very large difference in the oxygen potentials, and thus a high cell voltage, can be achieved (by supplying hydrogen to one side[41]) corresponding to an electrochemical conversion of H_2 and O_2 to water. In this way chemical energy can be converted to electrical energy efficiently. Such fuel cells with ceramic solid electrolytes attain an efficiency that is not limited by the conditions of the Carnot cycle, since no heat energy stage is involved. Furthermore, they have the advantage that they can be operated at high temperatures. At these temperatures the electrode reactions are reversible, and this also allows other fuels such as CH_4 or CH_3OH to be electrochemically converted.[42]

3.1.2. Example 2: Tin(IV) Oxide—A Semiconducting Oxide

As a second example of bulk equilibrium thermodynamics the semiconductor SnO_2 is considered.[43,44] The dependence of the conductivity on the oxygen partial pressure (Fig. 13), indicates that n-type conduction predominates, thus "SnO_2" is better described as $SnO_{2-|\varepsilon|}$. The oxygen

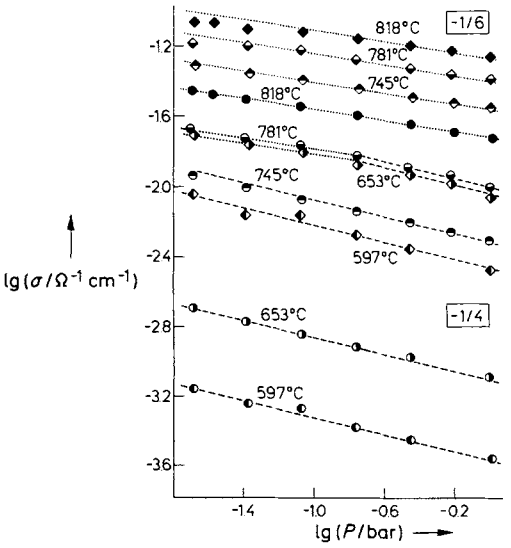

Fig. 13. Electronic conductivity of SnO_2 as a function of the oxygen partial pressure at various temperatures. Circular symbols: nominally pure material which, however, contains high levels of acceptor impurities, mainly Fe^{3+}; square symbols: materials in which this is partly counteracted by additional doping with small amounts of the donor Sb (as Sb^{5+}) [43].

incorporation or removal at high temperatures is understood by oxygen vacancies $V_O^{\cdot\cdot}$ as compensating defects. This is indicated in Equation (46), with Equation (47) as the electroneutrality condition.

$$\tfrac{1}{2}O_2 + V_O^{\cdot\cdot} + 2e' \rightleftharpoons O_O \tag{46}$$

$$2[V_O^{\cdot\cdot}] = [e'] \tag{47}$$

Applying the mass action equation leads directly to the value $-1/6$ for the exponent $N_{e'}$. Figure 13 shows that for nominally pure SnO_2 (circular symbols) these slopes are only found at very high temperatures and/or low partial pressures.[43] This is due to the effects of (acceptor) impurities, in this case Fe^{3+} ions resulting in Fe'_{Sn} defects [see Eq. (13)]. At low temperatures (negative reaction enthalpy for Eq. (46)) and at high oxygen partial pressures (see Eq. (46) and compare with the isotherm for 781 °C in Fig. 13), the e' concentration is suppressed below the impurity level (see Fig. 8c), and the electroneutrality condition is then given by Equation (48), with $N_{e'} = -1/4$, in agreement with the experimentally observed value (see Fig. 13).[46]

$$[Fe'_{Sn}] = 2[V_O^{\cdot\cdot}] = \text{const.} \tag{48}$$

The impurity-controlled range can be extended by doping SnO_2 with In_2O_3 as an acceptor.[43] If SnO_2 containing Fe as an impurity, as described previously, is lightly doped, with a donor $Sb^{\cdot}_{Sn}$ (i.e. Sb^{5+} replacing Sn^{4+}), this reduces the effective acceptor concentration, and thus also the extrinsically determined vacancy concentration, as given by Equation (49).

$$[V_O^{\cdot\cdot}] = [Fe'_{Sn}] - [Sb^{\cdot}_{Sn}] \tag{49}$$

As expected, the transition from the impurity-controlled region to that of virtually pure material then occurs at a lower temperature (the critical isotherm in Fig. 13 is that for 653 °C, square symbols), but at the same conductivity value (i.e. the same electron concentration).[43] An example in which the donor effect predominates is described in reference [44]; here SnO_2 prepared from SnF_4 was studied. Residual fluorine impurities act as donor centers $F^{\cdot}_O$ (F^- replacing O^{2-}), which increases the electron concentration. This results in an electronic conductivity at low temperatures and high partial pressures (due to the electroneutrality condition $[F^{\cdot}_O] = [e']$), whose value is almost independent of partial pressure and temperature. Transitions between the different disorder regimes can also be recognized from the temperature dependence of the conductivity: since the mobility makes only a small contribution, a plot of $\ln \sigma$ vs. T^{-1} yields the slopes $-\Delta_O H^0/3R$ for pure SnO_2, $-\Delta_O H^0/2R$ for acceptor-compensated SnO_2, and zero for donor-compensated SnO_2.[43,44] Here $\Delta_O H^0$ is the reaction enthalpy for Equation (46). At lower temperatures the effects of association between ionic and electronic defects [Eq. (50)] become

$$V_O^{\cdot\cdot} + 2e' \rightleftharpoons V_O^{\cdot} + e' \rightleftharpoons V_O^{\times} \tag{50}$$

important, and these then determine the changes observed in the conductivity.[47] From the energy data obtained in this way a fairly detailed band scheme can be constructed.[43]

Here it must again be noted that in no case does the band gap control the temperature dependence.

3.1.3. Example 3: The High Temperature Superconductors Lanthanum Copper Oxide and Yttrium Barium Copper Oxide

Pure La_2CuO_4, the archetype of the family of high-temperature superconductors,[49] is in one sense the opposite of SnO_2, since it exhibits an excess of oxygen, which results in a p-type conduction. Studies of defect chemistry are generally concentrated on the non-superconducting state for the following reasons. First, at temperatures below 40 K the stoichiometric changes are so slow that equilibrium studies are not possible. More importantly superconducting ceramics are prepared at very high temperatures, where the defect chemistry attains partial equilibrium. The concentrations of ionic and electronic point defects are thus established at these high temperatures according to the relationships discussed previously, and due to the extreme temperature dependence of the kinetic parameters in the superconducting region they remain essentially frozen in (apart from ordering and association processes).[57] To emphasize this point yet again, defect chemical relationships that apply at high temperatures are determined by the quantitative correlation between charge carrier concentration and parameters such as the oxygen partial pressure as discussed previously.

Chemical analysis and neutron scattering studies show that oxygen can be incorporated at interstitial sites.[50, 51, 52] For pure La_2CuO_{4+x} this is expressed by Equation (51), with the electroneutrality condition given by Equation (52).

$$\tfrac{1}{2}O_2 + V_i \rightleftharpoons O_i'' + 2h^{\bullet} \tag{51}$$

$$2[O_i''] = [h^{\bullet}] \tag{52}$$

These two equations lead directly to the value of $+1/6$ for the exponent in the case of hole conduction, in agreement with experiment.[56] As is well known, La_2CuO_4 with a sufficient proportion of excess oxygen is superconducting.[52] Alternatively, the degree of oxidation (generating holes) is raised by the method originally reported,[49] namely by doping with an acceptor, for example by exchanging Sr^{2+} for La^{3+}, as in Equation (53a).

$$2\text{“SrO”} + 2La_{La} + 1/2\,O_2 \rightleftharpoons \text{“}La_2O_3\text{”} + 2Sr'_{La} + 2h^{\bullet} \tag{53a}$$

According to the homogeneous doping rule [Eq. (13)], incorporating Sr not only reduces the oxygen concentration in the interstitial lattice but also (in greater numbers as it turns out) generates oxygen vacancies [Eq. (53b)].

$$2\text{“SrO”} + 2La_{La} + O_O \rightarrow \text{“}La_2O_3\text{”} + 2Sr'_{La} + V_O^{\bullet\bullet} \tag{53b}$$

Only one of these two equations is needed to define the thermodynamic situation, provided the disorder equilibria given in Table 1, which refer to the anion substructure, are established, namely Equation (46) and the anti-Frenkel equilibrium Equation (54). This example provides a very nice

$$O_O + V_i \rightleftharpoons O_i'' + V_O^{\bullet\bullet} \tag{54}$$

illustration of the relationship between the equilibrium concentration and the (fixed) concentration of dopant introduced, which follows directly from the above relationships [cf. M_k in Eq. (27b)].[50] Figure 14 shows how the concentration of defects in $(La,Sr)_2CuO_{4+x}$ varies with the dopant concentration (with constant T and P_{O_2}). In the region of

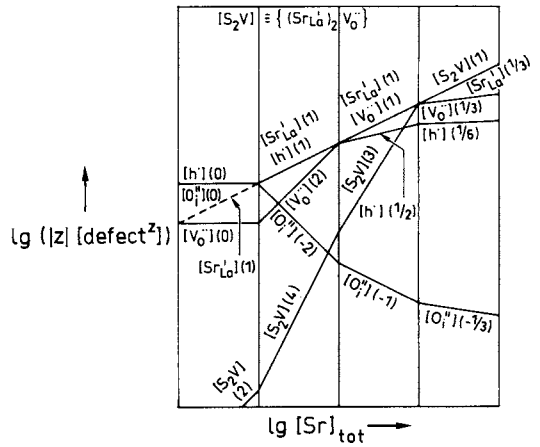

Fig. 14. Defect concentrations in La_2CuO_4 as a function of Sr dopant concentration [50].

negligibly low Sr concentrations (left-hand region), $[Sr'_{La}]$ does not appear in the electroneutrality equation, and $[h^{\bullet}]$, $[V_O^{\bullet\bullet}]$, and $[O_i'']$ do not depend on $[Sr'_{La}]$. With increasing Sr concentration the concentration of the excess oxygen ions is reduced, whereas that of the holes is increased. Eventually a region must be reached in which the impurity concentration is compensated by the hole concentration (inner left region), so that the gradient of the holes curve is given by $M_{h^{\bullet}} = 1$. This can be confirmed experimentally by measurements of the conductivity. The dependence of the concentration of interstitial oxygen ions on the dopant concentration, and the slopes of $M_{O_i''} = -2$ and $M_{V_O^{\bullet\bullet}} = +2$ follow from Equations (55–57).

$$M_{O_i''} = (\partial \ln [O_i'']/\partial \ln D) \tag{55}$$

$$K_O P^{1/2} = [O_i''][h^{\bullet}]^2 \tag{56}$$

$$2M_{h^{\bullet}} + M_{O_i''} = 0 \tag{57}$$

Since $M_{V_O^{\bullet\bullet}} > M_{h^{\bullet}}$, the concentration of vacancies increases very steeply, and a regime is reached in which the impurity concentration is compensated by that of the oxygen vacancies (inner right region). By analogous derivations the remaining quantitative relationships shown in Figure 14 are obtained. It is also found that in this impurity-controlled region the dependence of the hole concentration on oxygen partial pressure is given by $N_{h^{\bullet}} = +1/4$ (since $[V_O^{\bullet\bullet}]$ and $[O_i'']$ are constant), and in the hole-compensated region by $N_{h^{\bullet}} = 0$ ($[h^{\bullet}]$ constant). Both these relationships can be tested by experiment. With regard to the ionic contributions, an analogous transition from the interstitial mechanism to the vacancy mechanism occurs, as confirmed by tracer diffusion and ionic conductivity measurements (see Part II of this reviews). In all the measurements it is found that at very high

Sr concentrations the high temperature conductivity falls off rapidly with increasing Sr content. In this region the simple concept of point defects, in which defect chemistry is treated as a perturbation of the perfect structure, becomes unreliable; structural changes assume an important role, and the equilibrium constants and mobilities discussed above become concentration-dependent. Even if randomly distributed association complexes between Sr'_{La} and $V_O^{\cdot\cdot}$ (or between Sr'_{La} and $h^{\cdot}$) are assumed, this does not explain the behavior adequately, as Figure 14 shows. Although the postulated formation of Sr'_{La}–$V_O^{\cdot\cdot}$ complexes causes a flattening of the curve (right-hand regime), it does not reduce the concentrations of the free charge carriers. The situation here is further complicated by the probable existence of vacant La sites.

The defect chemistry of $YBa_2Cu_3O_{6+x}$ can be described in a similar way, but in this case the high defect concentrations result in interactions between ionic and electronic point defects even at high temperatures [Eq. (58)],[53] so that a significant proportion of the holes are localized.

$$O_i'' + 2h^{\cdot} \rightleftharpoons O_i' + h^{\cdot} \rightleftharpoons O_i^{\times} \tag{58}$$

(The O_6 compound has the appropriate reference composition.)[48] On reducing the temperature, significant ordering effects are observed. It is possible that localization phenomena (which are also expected to occur in La_2CuO_4 at lower temperatures) play an important role in superconductivity. Whether or not that is the case, a high concentration of point defects is a common feature of all high-temperature superconductors, and this must also influence their dynamic properties.[54]

A striking feature of $YBa_2Cu_3O_{6+x}$ (and also of the more complex high-temperature superconductors with higher critical temperatures) is the high degree of disorder in the cationic partial structure, leading to entropy effects which partly compensate for the generally poor stability of these compounds.[55]

These considerations have provided the basis for a quantitative rationalization[53] of the empirical relationships observed between equlibrium partial pressure, composition, and temperature for $YBa_2Cu_3O_{6+x}$.

It is also worth mentioning that for $YBa_2Cu_3O_{6+x}$ in contrast to La_2CuO_4, a transition to n-type conduction at low oxygen partial pressures has been observed.[56]

3.1.4. Example 4: The Transition from n- to p-Type Conduction in $SrTiO_3$

Figure 15 shows a set of conductivity isotherms for $SrTiO_3$.[58] Here again the defect chemistry in the dense perovskite structure can be considered very simply in terms of oxygen vacancies and electronic defects. Any Sr and Ti defects that may be present are immobile at the temperatures used for the measurements. The slopes of $\pm 1/4$ observed in Figure 15 are as expected for a fixed $V_O^{\cdot\cdot}$ concentration, as is the flattening out to an $N_{e'}$ value of $-1/6$ at lower oxygen partial pressures (see the previous Section). Whether the compensation occurring here is mainly due to immobile Sr vacancies or to acceptor impurities is unimportant. The transition from n- to p-type conduction can be clearly seen. At low temperatures it is superposed by the accompanying ionic

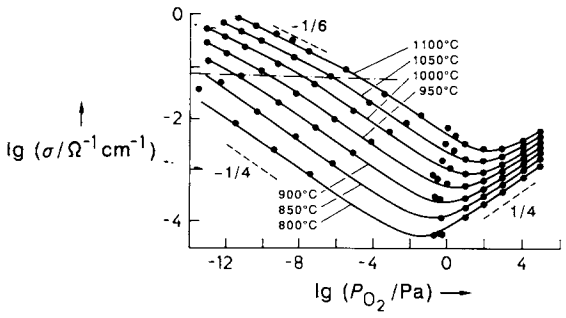

Fig. 15. Electronic conductivity of $SrTiO_3$ as function of the oxygen partial pressure [58].

conduction (see Fig. 8a). From the temperature dependences observed in the different regions of the conductivity curves one can calculate the standard reaction enthalpies for the reactions shown in Equations (59a) and (59b), then from their difference one obtains that of the electronic defect-forming reaction [Eq. (60)], which corresponds to the thermal band gap ($\Delta_B H^0 \simeq E_g$).

$$\tfrac{1}{2}O_2 + V_O^{\cdot\cdot} + 2e' \rightleftharpoons O_O \tag{59a}$$

$$\tfrac{1}{2}O_2 + V_O^{\cdot\cdot} \rightleftharpoons O_O + 2h^{\cdot} \tag{59b}$$

$$\text{nil} \rightleftharpoons e' + h^{\cdot} \tag{60}$$

An alternative way of determining the thermal band gap is to measure the temperature dependence of the conductivity minimum in Figure 15. From Equation (61), and the fact

$$\sigma_{min} = 2\sigma_{n,min} = 2\sigma_{p,min} \tag{61}$$

that the conductivity increases with increasing concentration, and also taking into account Equation (60), the temperature dependence of the minimum yields the band gap directly [Eq. (62)].

$$-R\frac{d \ln \sigma_{min}}{d(1/T)} \cong \tfrac{1}{2}\Delta_B H^0 \simeq \tfrac{1}{2}E_g \tag{62}$$

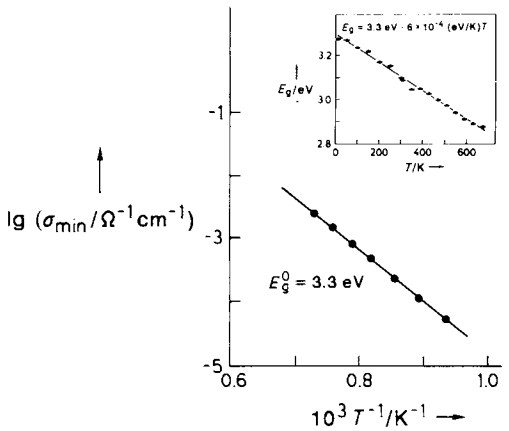

Fig. 16. a) A determination of the thermal band gap at absolute zero for $SrTiO_3$, from the conductivity values at the minima in Figure 15. b) Inset: Temperature dependence of the optical band gap from absorption measurements [59].

A determination by this method is shown in Figure 16.[58] However, it must be noted here that the band gap is temperature dependent, as is evident from the data obtained by in situ optical measurements[59, 60] shown in the inset of Figure 16. The value of E_g yielded by Equation (62) is that for $T = 0$ K, and the same value is obtained by extrapolation of the optical data.

The sensitive and reproducible dependence of the conductivity on the oxygen partial pressure indicated here is of considerable interest and promise as the basis for an oxygen sensor in automobiles, especially as $SrTiO_3$ is stable at high temperatures and less affected by temperature changes than $ZrO_2(Y_2O_3)$.

3.1.5. *Example 5: Proton Conduction in Oxides of the Perovskite Type*

This conduction phenomenon, which has only recently begun to be investigated in detail, provides an excellent example of the importance of foreign elements in ionic conduction.[61] Evidence for proton conduction is found in a number of perovskite materials, particularly in acceptor-doped perovskites such as $(Sr,Fe)TiO_3$,[62] and possibly also in the structurally similar $(La,Sr)_2CuO_4$.[63] The most interesting of these materials is ytterbium-doped $SrCeO_3$.[64a] In all these cases acceptor doping increases the concentration of vacant oxygen sites. It is conceivable that through contact with a moist atmosphere these oxygen vacancies become occupied by OH groups, the remaining proton being taken up by regular O^{2-} ions to form a further hydroxyl group. Such effects at surfaces are already well known. The incorporation reaction can be expressed in the form of Equation (63), in

$$H_2O + O_O + V_O^{\bullet\bullet} \rightleftharpoons 2OH_O^{\bullet} \tag{63}$$

which $OH_O^{\bullet}$ can also be regarded from a phenomenological standpoint as $(O_O + H_i^{\bullet})$. It is not yet clear to what extent this mechanism is in agreement with the observed conductivity phenomena, or how important a role it plays.[64b]

3.2. Boundary Layers

The foregoing thermodynamic description is inadequate for the boundary layers of the M^+X^- crystal. The condition for phase equilibrium, namely that the neutral components must have a constant chemical potential, when combined with the electroneutrality condition, was entirely adequate for understanding the behavior within the bulk material. However, in the boundary regions some limited deviations from electrical neutrality can occur. This means that even the expanded formula $M_{1+\delta}X$ is no longer sufficient and must be replaced by $[M_{1+\delta'}X]^{\varepsilon+}$, in which δ' and ε are position-dependent variables.[65] At the boundary surfaces the distribution of particles is no longer uniform, and the concentrations of the charged constituents differ from those in the bulk material in ways that depend on the chemical nature of the adjacent phase. Local deviations from electrical neutrality can result from an excess or deficiency of any of the ionic or electronic defect centers involved. Electrical neutrality is, of course, retained in a global sense; thus the corresponding opposite charge may be either in the boundary layer itself or in the boundary regions of the adjacent phase. In addition to the condition for phase equilibrium, which requires that the chemical potentials of the neutral components M and X must be spatially invariant [Eq. (64)], for complete contact equilibrium the electrochemical potentials of the ions and electrons must also be spatially invariant, as expressed by Equation (65) (see the general scheme shown in Fig. 5).

$$(\partial/\partial x)\mu_M = (\partial/\partial x)\mu_X = 0 \tag{64}$$

$$(\partial/\partial x)\tilde{\mu}_{M^+} = (\partial/\partial x)\tilde{\mu}_{X^-} = (\partial/\partial x)\tilde{\mu}_{e^-} = 0) \tag{65}$$

It can be shown that the electrochemical potentials of the defects also have zero gradient. This means that only the sum of the concentration and field contributions is required to be spatially invariant. In other words, an adjacent phase (such as A in Fig. 17) which exerts attractive or repulsive forces on cations, anions, or electrons, causes a separation of charges. This chemical effect generates gradients in the chemical potential, and therefore concentration gradients (see Fig. 5), but only up to the point where it is balanced by the opposing charge separation effect (i.e. a gradient in the electrical potential). Since the standard potential in Equation (21) is constant, this condition is expressed quantitatively by Equation (66), in which k refers to the (dilute) defect species.

$$(\partial/\partial x)\mu_k = RT(\partial/\partial x)\ln c_k = -z_k F(\partial/\partial x)\phi \tag{66}$$

Figure 17 shows this both from the thermochemical standpoint (a), and in the form of an "energy level Diagram" (b) which is constructed in analogy to the level schemes of semiconductor physics (see Fig. 6). It is seen that although the (free) energy profiles for the charged defects show a curved region, those for μ_M and $\Delta_F G^0$ (i.e. the difference between E_i and E_v) are spatially invariant.[67]

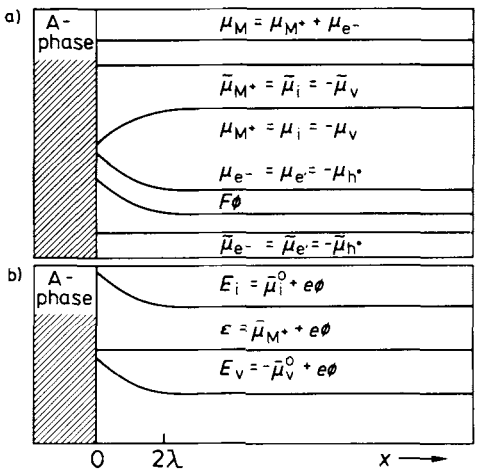

Fig. 17. a) Thermochemical representation of the boundary layer thermodynamics for a mixed conductor (A is the adjacent phase). Both the chemical potential of the neutral component and the electrochemical potential of the charged particles must be spatially invariant. The chemical potentials of the charged species are seen to have gradients (i.e. a gradient of the electrostatic potential ϕ). b) Boundary layer thermodynamics of the ions in the form of an energy level diagram analogous to that for a semiconductor. The separations between the "Fermi level" ε and the energies E_i or E_v correspond to the defect concentrations (i: $M_i^{\bullet}$; v: V_M') [66].

Integration of Equation (66) from the bulk (∞) of the material up to the position x in the boundary layer yields the increase in concentration as a function of the field effect [Eq. (67)].

$$\left(\frac{c_k(x)}{c_k(\infty)}\right)^{1/z_k} = \exp\{-F(\phi(x) - \phi(\infty))\} = \Xi(x) \qquad (67)$$

This can also be seen directly from Figure 5 ($\Xi^{z_k} \equiv \kappa$). As the expression on the right-hand side of Equation (67) is independent of the nature of the defect, it follows from this equation (and is also shown graphically in Fig. 18) that the defect concentrations in the boundary layer are either raised or lowered, depending on the charge of the defect (particle), by a factor $\Xi(x)$ that is independent of the type of defect.

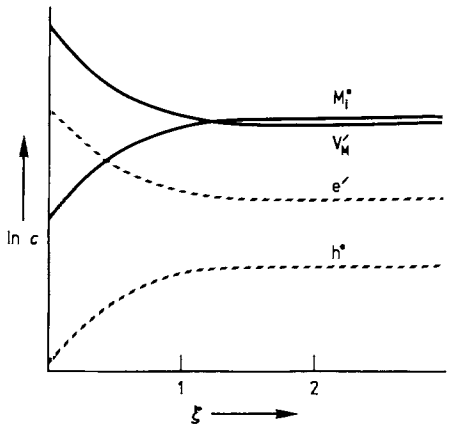

Fig. 18. Defect concentration profiles in the boundary layer for a mixed conductor with Frenkel disorder and a positive charge at the boundary (adsorption of cations) [66]. ξ = spatial coordinate normalized relative to the Debye length.

Taking AgCl as an example, for positive boundary layer potentials ($\phi - \phi_\infty$) the concentrations of the silver ions in the interstitial lattice and of the electron holes must be increased by the factor Ξ, whereas those of the silver lattice vacancies and the conduction electrons must be reduced by the same factor. A comparison with Table 1 will confirm that this behavior is entirely consistent with the conditions for equilibrium between the particles. However, this does not solve the problem for the chemist, since first the space charge potential is not independent of the defect concentrations, and second the chemistry of the adjacent phase needs to be taken into consideration.

The condition of local electroneutrality has, according to electrostatics, to be replaced by Poisson's equation. This takes the form of a relationship [Eq. (68)] between the electric field gradient (the curvature of the electrical potential) and the defect concentrations.

$$(\partial^2/\partial x^2)\phi = \frac{1}{\varepsilon\varepsilon_0}\sum_k z_k F c_k \qquad (68)$$

(In the bulk material $\partial^2\phi_\infty/\partial x^2 = 0$ on grounds of symmetry, and therefore $\sum z_k F c_{k\infty} = 0$, which is the electroneutrality condition.) By taking into account the dependence of the electrical potential on the defect concentrations as given by Equation (67), a parametric solution of Equation (68) is obtained. The concentration profile is then given by an expression of the form shown in Equation (69), where f represents a function of position which has a steep increase or decrease in the boundary layer region. The analytical form of the function is given in reference [65].

$$c_k = f(x;\lambda,\theta) = f(x;c_0,c_\infty) \qquad (69)$$

In a similar way to the Brouwer approximation, this solution is only valid when the charge density depends on only two types of charge carriers (here those with charge numbers $+1$ and -1). For the silver halides these are the defect pair $[Ag_i^{\bullet}]$ and $[V_{Ag}']$ (or, in the heavily Cd-doped material, $[V_{Ag}']$ and $[Cd_i^{\bullet}]$, in silicon they are $h^{\bullet}$ and e', and in SnO_2 $V_O^{\bullet\bullet}$ and e'.

Equation (69) introduces two quantities that are of great importance for the chemist. The first of these is the Debye length λ, which is directly proportional to the square root of the dielectric constant and inversely proportional to the square root of the concentration (for pure AgCl; $c_\infty = [Ag_i^{\bullet}]_\infty = [V_{Ag}']_\infty = \sqrt{K_F}$). The second is the parameter θ,[68] which describes the extent to which the adjacent phase influences the defects under investigation, and is defined by Equation (70). Evidently this quantity varies between $+1$ and -1, that is between the extremes of a greatly increased concentration ($c_0 \gg c_\infty$) and a greatly reduced concentration ($c_0 \ll c_\infty$). The case where $\theta = 0$, corresponding to $c_0 = c_\infty$, is the point of zero charge, where the boundary effect vanishes. In semiconductors this is referred to as the case of a flat band potential. Thus, the chemistry of the boundary layer is determined entirely by the two parameters c_∞ and c_0, namely the concentration in the bulk and that in the atomic layer directly adjacent to the interface where the opposing charge is situated. The solution of the problem in the bulk material, as discussed in the preceding section, corresponds to the state of the art, in contrast to the boundary layer problem considered here. The parameter c_0 contains the interaction with the adjacent phase, and thus describes the contact chemistry. However, the problem of relating c_0 to the properties of the adjacent phase is complicated. It involves considering the potential jump between $x = 0$ and the actual interface, the condition of global electroneutrality (the dielectric displacement must be continuous), and the electrochemical equilibrium at the interface. The procedure is complex, and is described in reference [69]. In such a way c_0 can ultimately be related to the controlling parameters of temperature, dopant content, and partial pressure (in the adjacent phase!).

$$\theta \equiv \frac{(c_0/c_\infty)^{1/2} - 1}{(c_0/c_\infty)^{1/2} + 1} \qquad (70)$$

Although these space charge effects are very important in relation to the electronic states in semiconductor physics, when considering ions in solids—and therefore the composition of the solids!—they are scarcely taken into account. The brief description of boundary layer phenomena that is given here, as well as that of the bulk thermodynamics, is independent of the nature of the defects; it includes the general case of a mixed conductor, and therefore also that of a purely electronic conductor. We start by considering an ionic conductor.

3.2.1. Example 1: The Junction between an Ionic Conductor and a Surface-Active Adjacent Phase: "Heterogeneous Doping"

Of the ionic conductor junctions that have been studied, those between AgCl and ("inert") oxides have yielded most information.[66, 68, 72] The nature of the oxide surface determines whether, and to what extent, silver (or chloride) ions are preferentially accumulated at the interface. Results from detailed electrochemical and spectroscopic studies show that the mechanism of defect formation at the interface is as in Equation (71) (see Fig. 19c).

$$[\text{Oxide}] - \text{OH} + \text{M}_\text{M} \rightleftharpoons [\text{Oxide}] - \text{OHM}^+ + \text{V}'_\text{M} \qquad (71)$$

According to this, cations from the crystal are adsorbed internally at the oxide surface, mainly by OH groups. An analogous reaction is known to occur when aqueous solutions are in contact with oxides such as Al_2O_3 or SiO_2; there it is an expression of the Brønsted acid–base interaction with the solid surface. In that case, the proton of the OH group may also become detached under strongly basic conditions. The pH value for which the surface appears neutral is called the pH of zero charge. This value is reduced as one goes from Al_2O_3 to SiO_2, or from γ-Al_2O_3 to α-Al_2O_3, and this is accompanied by the corresponding reduction in the basicity expressed by Equation (71), and thus in the adsorption effect. However, if the OH groups of γ-Al_2O_3 are deactivated with $(CH_3)_3SiCl$, the above reaction [Eq. (71)] no longer takes place.[66] The use of a silver chloride melt as the contacting phase even allows the study of the effects of different crystallographic orientations of α-Al_2O_3 on the wetting contact angle and the calculation of interaction enthalpies and entropies.[73] It is evident from Figures 18 and 19 that at the junction between (crystalline) AgCl and γ-Al_2O_3 the concentration of silver vacancies must be increased and that of the interstitial ions reduced by the same amount. This means that at very high temperatures, at which according to Section 3.1.1 the ion transport in the bulk is determined by the Ag_i ions, the average conductivity in the boundary layer should be reduced compared with that in the bulk (depleted boundary layer, Fig. 20a). At moderate temperatures, because the boundary layer effect varies only slightly with temperature, and also because vacancy conduction becomes increasingly important as a result of impurity effects, the vacancy conduction in the boundary layer is dominant compared with the interstitial ion conduction characteristic of the bulk (inversion layer, Fig. 20b). Thus, there is a local transition from interstitial ion conduction (i) to vacancy conduction (v); this i–v transition[69] is entirely analogous to an electronic n–p transition. Finally, even in nominally pure AgCl close to room temperature the extrinsic vacancy conduction (caused by impurities with cations of higher valency) is almost always dominant; the vacancy conduction that predominates in the bulk is then further enhanced near the boundary (accumulation with respect to V'_{Ag} layer, Fig. 20c). It is shown in reference [68] that the effective conductivity due to the boundary layer (in the direction parallel to the interface) is given by Equation (72).

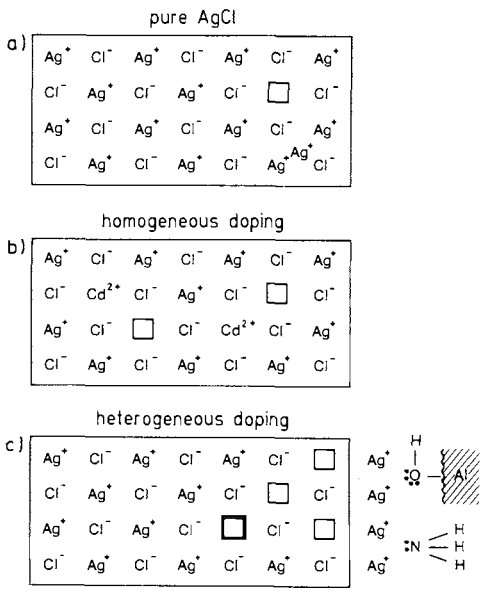

Fig. 19. Comparison of the effects of conventional (homogeneous) doping (b) (with $CdCl_2$ as the dopand), and of heterogeneous doping (c) (with Al_2O_3 or NH_3 as the active adjacent phase), when applied to pure AgCl (a).

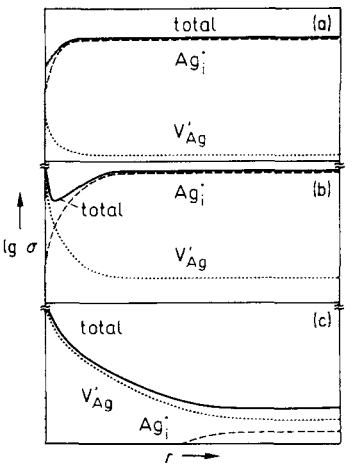

Fig. 20. Ionic conductivity σ in silver halides at the junction with Al_2O_3. At high temperatures (a) an insulating space charge zone is formed, whereas at low temperatures (c) the space charge zone has a higher conductivity than the bulk. At intermediate temperatures (b) an inversion layer is formed, which is characterized by a v–i transition (the ionic equivalent of a p–n transition).

$$\langle\sigma\rangle = \varphi_\text{L} F \sum_{\text{v},i} u_{\text{v},i} \left(2c_\infty \frac{\theta_{\text{v},i}}{1-\theta_{\text{v},i}} \right) \simeq F u_\text{v} (2\lambda)(c_0 c_\infty)^{1/2} \propto u_\text{v} c_{\text{v}0}^{1/2} \qquad (72)$$

Here φ_L is the contribution of the boundary layer to the measured volume, and is determined by the effective thickness of the boundary layer (2λ). For large effects ($|\theta| \to 1$) we obtain the simple expression on the right-hand side, which shows that the conductivity is determined by the effective thickness 2λ and the effective charge carrier concentration, given by the geometric mean of the concentrations in the bulk and in the first layer adjacent to the neighboring phase. Since λ is proportional to $c_\infty^{-1/2}$, the bulk contribution cancels out, and the conductivity is therefore a direct measure of the boundary effect. In particular it is seen that, to a good approximation, impurities do not enter into the calculation; the resulting increase in the bulk concentration, and thus

increase in the effective charge carrier concentration, is compensated by increased screening, resulting in a decreased effective thickness of the boundary layer.

Despite the large increase in charge carrier concentration, the overall effect of a single interface in typical samples is too small to be detected. Thus, measurements must be carried out using a two-phase mixture of the ionic conductor and the oxide. This is best prepared by dispersing a fine Al_2O_3 powder into the melt of an ionic conductor, for example AgCl, which is then cooled. This produces a large number of interfaces. The very small oxide particles are deposited in the AgCl grain boundaries, leading to a network of continuous conduction pathways. A moderate increase of Al_2O_3 content leads to an increase of the interfacial contact area by decreasing the AgCl grain size. It is only at very high Al_2O_3 concentrations (typically above 10%) that the conduction paths gradually become blocked by excess oxide, and the conductivity of the mixture is drastically reduced.

Figure 21 shows the results of conductivity measurements on $AgBr/Al_2O_3$ composite solid electrolytes.[71] These data

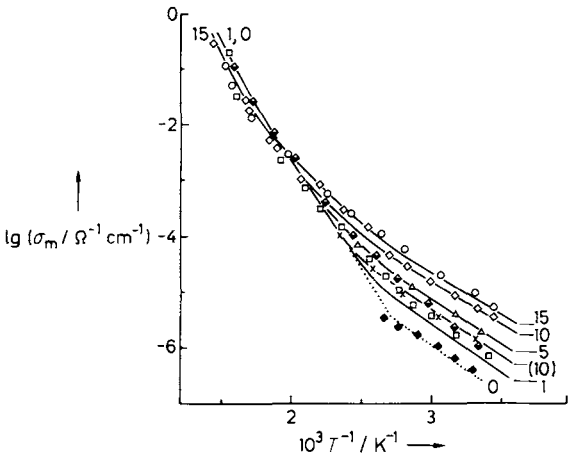

Fig. 21. Total conductivity of two-phase mixtures of AgBr with γ-Al_2O_3 as a function of temperature for various volume ratios (the numbers give the volume percentage of Al_2O_3) and different particle sizes [10: 10 vol% Al_2O_3, 0.03 μm; (10): 10 vol%, 0.05 μm]. The symbols represent experimental data and the solid lines the results of theoretical calculations [71].

indicate that the conductivity increase of one to two orders of magnitude (relative to pure AgBr) that occurs in the low temperature region has an activation energy of about 0.3 eV, a value which corresponds to the migration enthalpy of the vacancies [see Eq. (72)], and results from the fact that $c_{v0}^{1/2}$ varies only slightly with temperature.[68] As is shown by the solid curves in Figure 21, together with detailed discussions,[66, 71] the observed conductivities for the entire range of experimental conditions investigated, variation of the temperature, volume fraction, and γ-Al_2O_3 particle size) can be quantitatively described by assuming the maximum disorder in the first layer of the halide adjacent to the oxide.

A comparison with Figure 11 confirms that there is a similarity to the behavior with conventional (homogeneous) doping. As in that case, here too one has a means of influencing the concentration of defects, and here too it is controlled by the effective charge. Apart from the presence of an electric field, the most important difference from conventional doping is the absence of spatial homogeneity. For this reason insulating regions (e.g., in the moderate- or high-temperature regions for AgBr, see Fig. 20a, b) can be bypassed by using more readily conducting paths in the bulk material, and the knee observed in the case of homogeneous doping is now absent (compare Figs. 21 and 10).[75] It is legitimate to talk of „heterogeneous doping" as an alternative way of modifying the conducting properties of a given phase,[66] and this term is now becoming established in the literature. An example is discussed in reference [76] in which the simultaneous effects of homogeneous and heterogeneous doping were investigated. In an analogous way it is possible to improve the conduction properties of a whole range of similar ionic conductors with moderate defect concentrations (CuCl, CuBr, AgBr, β-AgI, etc.).[66, 72] A system of historical interest is LiI/Al_2O_3, in which such effects were first discovered.[77] Another important system is $TlCl/Al_2O_3$, in which the heterogeneous doping effect of Al_2O_3 converts an anionic conductor into a cationic conductor.[76] Furthermore, in analogy to the fundamental rule of homogeneous doping [Eq. (13)], we can state a rule of heterogeneous doping [Eq. (73)].

$$\frac{\delta(z_k c_{0k})}{\delta \Sigma} < 0 \qquad (73)$$

This expresses the fact that for a positive surface charge Σ the concentrations of all positive mobile defects in the space charge layer are reduced, whereas for a negative surface charge the concentrations of all negative defects are increased. Figure 19b, c illustrates the two basic methods for influencing the defect concentration in the example of the model substance AgCl.

Recently the electrochemical behavior of a single boundary layer of this type has been successfully investigated.[79] This study made use of the depletion effect that is expected at higher temperatures (see Fig. 20) and which can be calculated from Equation (69). The experiments were carried out using sufficiently basic, but electronically conducting, oxides, such as RuO_2 and $(La,Sr)CoO_3$, which could simultaneously serve as electrodes. By impedance spectroscopic measurements in series with the boundary layer it was possible to detect these as layers with a high resistance and, at the same time, a high capacitance (i.e. small thickness). The results showed that, in agreement with quantitative calculations,[79] the activation energy for the space charge resistance is $\Delta_f H^0/2$ and that for the boundary layer capacitance is $\Delta_f H^0/4$.

A question of fundamental interest is that of the behavior of the electronic charge carriers in these materials,[74] since we are then considering the general case of defect thermodynamics of a mixed conductor of the type M^+X^- (provided the behavior of the boundary layer is dominated by no more than two defect concentrations). As already mentioned, the n and p concentrations are expected to react to the electric field in a similar way as $Ag_g^{\bullet}$ and V'_{Ag} [see Eq. (67) and Fig. 18]. In silver halides the ionic defects predominate by several orders of magnitude. Therefore, since only the defects that determine the charge density enter into Poisson's equation, the boundary layer effect and the associated electric field are determined by the interaction of these defects with the adjacent phase. Consequently, the behavior of the electronic charge carriers is determined not by the redox

interaction of the silver halides with the adjacent phase but by the acid-base properties (interaction with the ions). Thus the electronic charge carriers in the boundary layer are under ionic control or better under acid-base control, a fact that may be of considerable importance for many semiconducting materials with high concentrations of ionic point defects (see next Section). In the case of Al_2O_3/AgCl dispersions one can predict from Equation (73) or more quantitatively from Equation (67) in the space charge zones there will be an increase in n-type conduction and a decrease in p-type conduction. Experimental studies are possible by using the Wagner–Hebb method,[80] in which one of the reversible silver electrodes that are normally used for the measurements is exchanged for a graphite electrode which blocks the Ag^+ ions. In the steady state the ion current is completely blocked, so that the minority electronic conduction can be measured and even resolved into its n and p components from the current vs. voltage curve. Furthermore, a quantitative extension of the experiment to inhomogeneous systems[74] allowed the separate measurement of the bulk and boundary layer values for all these contributions. The results agree with the theoretical predictions within the limits of experimental error. Extensive thermodynamic calculations have been carried out for AgCl as a prototype, and up to now the only example;[74] this yields a complete set of data for the defect concentrations as functions of temperature, Ag activity (or Cl_2 partial pressure), and spatial coordinates, and is thus a complete solution of the thermodynamic problem for this case.[69, 74] Figure 22 shows these important results for two of the charge carriers (V'_{Ag} as a majority charge carrier and e' as a minority charge carrier) as a function of the silver activity (or chlorine partial pressure) at a given temperature. A silver activity of 1 corresponds to the left-hand coexistence line in the phase diagram (Fig. 9) that is in contact with silver.

The extremely high defect concentrations that can be obtained by heterogeneous doping also exhibit catalytic activity, as will be described in Part II of this review.[81] Last but not least it is worth mentioning that the very high defect concentrations expected in the space charge regions may possibly lead to phase transformations immediately at the contact.[23b]

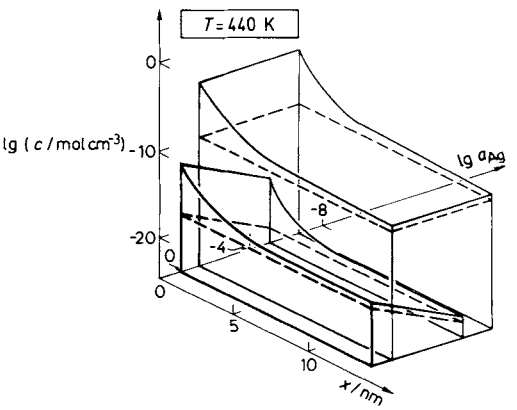

Fig. 22. Defect chemistry in the boundary layer and the bulk for pure AgCl (γ-Al_2O_3 as the adjacent phase) as a function of silver activity of 1 (i.e. exact position in the phase equilibrium). The larger graph gives the concentration of the vacancies and the smaller graph the concentration of the conduction electrons [74]. The dashed lines represent the values for the bulk.

3.2.2. *Example 2: Conductivity Anomalies in Ionic Conductor–Ionic Conductor Systems and in Ceramics*

Here we consider a junction between two ionically conducting phases, such as occurs for mixed silver halide systems in the miscibility gaps of the relevant phase diagram (e.g., β-AgI:AgBr, Fig. 23,[82] or β-AgI:AgCl[83]). In analogy to semiconductor junctions, the equilibrium at the interface results in a transfer of mobile ions from one phase to the adjacent phase, in order to achieve a constant electrochemical potential.[84] This leads to a double space charge effect, associated with an increase in vacancy conduction in one phase and an increase in interstitial ion conduction in the other phase (see Fig. 23). The situation is entirely analogous to the behavior of a semiconductor–semiconductor junction, in which the need to build up a constant Fermi level causes a transfer of electrons at the interface (Fig. 23). Evidently an

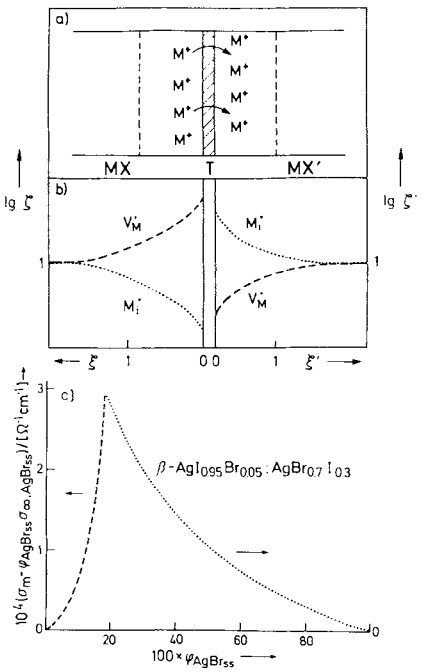

Fig. 23. Boundary effects at the junction between two ionic conductors MX and MX': a) establishment of equilibrium at the junction by redistribution of M^+ ions; b) the resulting defect distribution; c) anomalous increase in conductivity relative to the corresponding boundary phases for the AgI/AgBr system in the miscibility gap (φ = volume fraction, ζ = concentration normalized to the bulk value, ξ = spatial coordinate normalized relative to the Debye length) [66,82].

overall contact equilibrium is only possible if a constant electrochemical potential is maintained for each defect (ionic and electronic). A quantitative treatment of the thermodynamics, concentration profiles, and conductivity behavior is also possible in this case.[84] The conductivity anomalies in the miscibility gaps of the β-AgI:AgCl system can be understood quantitatively in the light of the foregoing discussion.[83] Here the free standard reaction enthalpy of the heterogeneous Frenkel reaction [Eq. (74)] plays a key role.

$$Ag_{Ag}(\text{phase 1}) + V_i(\text{phase 2}) \rightleftharpoons Ag_i^{\bullet}(\text{phase 2}) + V'_{Ag}(\text{phase 1}) \quad (74)$$

More interesting and instructive is the fact that at temperatures above the transition to the superconducting α phase (i.e. in the miscibility gap of the α-AgI/AgCl system) the conduction mechanism shows the classical percolation behavior;[79] this means that the transport of charge occurs by α-AgI_{ss} particles in contact with each other, and not as a result of boundary effects.

Another type of junction that is of fundamental importance in ceramics is the grain boundary itself, that is a contact between two grains of the same chemical composition (a homojunction, in contrast to the heterojunctions discussed above). Since the structure at the (metastable) grain boundaries differs from that of the bulk, thermodynamics requires that there should be a stabilization of cations or anions, in addition to possible electronic effects, associated with a symmetrical space charge zone (Fig. 24).[85, 86, 88] A particularly important result for ceramics is the observation that grain boundaries can act both as blockers and as efficient conductors in the same ceramic material. This is connected with their anisotropy: Owing to the sandwich-like structure of alternating core regions and space charge regions, and to the significant profile character of the space charges, there is a large difference depending on whether the movement of the ions is along the grain boundaries or perpendicular to them.[85] In polycrystalline samples, in priciple, a distinction can be made between the two types of conduction paths: on the one hand, transport through the bulk, interrupted at points where the path crosses grain junctions in a perpendicular direction, and on the other hand bypass conduction, in which the paths lie entirely within grain boundaries. In varistor materials, which are the basis of some important electronic components, the grain boundaries have a blocking function.[90] In the electronic conductor ZnO the grain boundaries determine the observed (DC) resistivity; the energy barrier, and therefore the resistivity (electronic in this case), can be conveniently altered by an externally applied voltage. In the case of SiC, which is a good electronic conductor in its monocrystalline form, the grain boundaries in an SiC ceramic material increase the resistivity to such an extent that these materials have applications as insulators. In studies of silver halides by impedance spectroscopy it was shown that both functions of the grain boundaries (highly conducting and blocking) are present simultaneously, and the reduction of these effects during sintering was monitored.[85] More interestingly, it was found that for AgCl ceramics the greatest increases in conductivity observed occurred for materials prepared from the diammonium complex of AgCl. Traces of NH_3 are adsorbed at the grain boundaries, and these evidently serve to capture Ag^+ ions, in a manner similar to the action of the OH groups in Al_2O_3 in the composite electrolyte, which leads to an enhanced vacancy conduction in the grain boundaries (see Fig. 19c).[66] This behavior is very interesting from the chemist's standpoint. The main difference in comparison with the Al_2O_3 dispersions is that the surface potential in the heterogeneous solid electrolytes has a higher absolute value and is less temperature-sensitive.

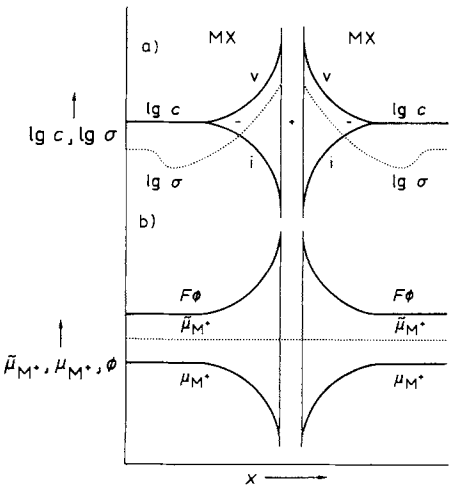

Fig. 24. Interfacial effects at a grain boundary [66]. x = spatial coordinate.

3.2.3. *Example 3: The Interface between an Electrical Conductor and a Gas*

As one might expect, a gaseous phase too not only influences the behavior within the bulk, but also has a direct effect on the space charge potential. From the above example the NH_3/AgCl interface suggests itself as a suitable system for investigation. As anticipated, it is found that under suitable conditions there is an increase in the concentration of vacancies. This effect gives rise to a new sensor principle that can be used to detect (acid–base active) gases through the change in surface conductivity (Fig. 25, bottom).[91]

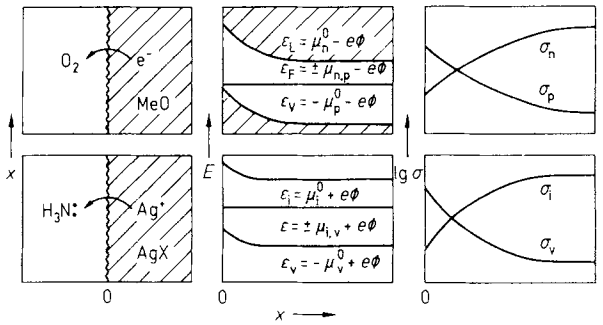

Fig. 25. Top: The interfacial influence of a redox-active gas on the electron distribution in a semiconductor. Bottom: The interfacial influence of an acid–base active gas on an ionic conductor [91]. x = spatial coordinate, E = potential.

This ionic phenomenon again has its electronic counterpart. The change in the surface electronic conductivity in SnO_2 (close to room temperature) has long been used for detecting redox-active gases. Let us first recall the example in the previous section, in which it was shown that the bulk conductivity in SnO_2 or the $SrTiO_3$ is dependent on the oxygen partial pressure. This effect can be used advantageously for measuring oxygen concentrations. Bulk conductivity sensors of this kind could eventually replace the λ-probe used currently in automobiles.[92] (Boundary layer effects are relatively insignificant at these high temperatures owing to the shortness of the Debye length.) In addition SnO_2 can be used conveniently as a gas sensor at room temperature, or better still at slightly elevated temperatures. In

this case the kinetic conditions do not allow a bulk equilibrium (see Part II of this review). On the other hand, the electronic interaction within the space charge zones is rapid enough.[93] The chemical properties of the oxygen adsorbed at the surface cause it to capture electrons, resulting in the band bending shown in the upper half of Figure 25.[67] The surface region of the SnO_2 (an n-type conductor) suffers a depletion of charge carriers, considerably reducing the surface conductivity. Figure 25 shows only the effect on the electronic charge carriers. However, within certain limits determined by the kinetics, the oxygen vacancies [see Eq. (67)] can also migrate in response to the electric field, or at least there may be some ionic charge carrier gradients that have become frozen in during the preparation of the ceramic material. This becomes especially important when the ionic point defects are the majority charge carriers, as is the case in acceptor-doped SnO_2, and usually also in nominally pure SnO_2 at low temperatures. If the interaction of the oxygen with the oxygen vacancies is a significant factor in the formation of the space charge potential, the depletion of the vacancies at the boundary may cause a complete reversal of the field relative to the direction, leading to an enrichment of only the electronic charge carriers. This is one explanation why donor-doped SnO_2 has been found to be preferable in applications as a boundary layer gas sensor.[69]

A further comment is appropriate here: As shown earlier, within the range of validity of the Brouwer approximation, the dependence of the defect concentration in the bulk material on the oxygen partial pressure can be described by a power law with an exponent $N_{k\infty}$. If the behavior in the boundary layers can be described by a power law, it cannot be assumed that the exponents will have the same values. Furthermore, it should be noted that, owing to the proportionality to $\sqrt{c_0}$, the observed boundary layer conductivity does not correspond to $N_{k\infty}$ as in the bulk, nor to N_{k0}, but to $N_{k0}/2$. This explains in a very simple way the observation that the surface conductivity for ZnO[93] follows a power law with an exponent of approximately 0.15 ± 0.03 (about 1/8), whereas N_∞ has the value 1/4.[69]

3.2.4. *Example 4: Nanosystems*

Boundary layer phenomena become very important in cases in which the dimensions are no longer large compared with the Debye length, as in very thin films and ceramics with crystallites of nanometer dimensions. In addition to the obvious reason that the boundary layers then occupy a larger fraction of the total volume, a further aspect of a more fundamental nature is involved.[94] The left-hand part of Figure 26 shows the behavior of the boundary layer as the specimen thickness is reduced. Since the value of c_0 is determined by the interaction with the adjacent phase, the defect concentration profile for nanosystems no longer corresponds to the bulk properties anywhere in the sample. This means that the specimen behaves like a single boundary layer with a single space charge zone, and the properties are determined essentially by the adjacent phase. Thus, much greater conductivity effects are expected to be found than in normal boundary layers. The problem of calculating the profiles is more complicated than before, and can only be solved by numerical

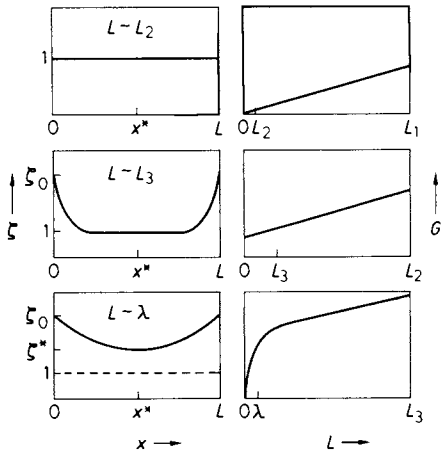

Fig. 26. Left-hand column: defect concentration distribution in thin films of different thicknesses (ζ = concentration normalized relative to the bulk value). Right-hand column: the dependence of the conductance G (parallel to the interface), on film thickness L [66].

methods.[94] The right-hand part of Figure 26 shows that for macroscopic specimens with negligible space charge effects the conductance G (the reciprocal of the resistance) increases in proportion to the thickness, whereas when the space charge effects become appreciable (while remaining independent of the thickness), they show up as a finite intercept on the conductance axis. However, as Figure 26 indicates the behavior in cases in which such size effects (mesoscopic effects) are significant is more complicated. The resulting additional increase in the conductivity (i.e. above that expected from Eq. (72)) can be calculated numerically, but exactly, by introducing a "size effect factor",[94] which in simple cases is approximately $4\,\lambda/L$; thus, for $L \simeq \lambda/2$ the additional effect is an increase by nearly an order of magnitude. There is no doubt that these phenomena can sometimes have appreciable effects even for the heterogeneous solid electrolytes discussed previously, as well as for ceramics with microcrystalline structures of nanometer dimensions. It has been shown that by applying the above relationships together with data on the dependence of the ionic and electronic conductivities on the thickness, various important thermodynamic parameters for the bulk and for the boundary layer can be determined.[94] Some surprises are also possible regarding our knowledge of structures, as illustrated by the observation that LiI layers on SiO_2 can be obtained with a hexagonal structure.[95] For systems with electronic charge carriers the reduction of the specimen dimensions leads to additional quantum-mechanical effects.[96] Apart from these phenomena, the discussion presented here leads to a unified description of ionic and electronic effects. This discussion has concentrated mainly on ionic boundary layer effects, since the corresponding electronic effects (p–n transitions, Schottky barriers) behave in an analogous way and are treated in detail in textbooks on solid-state physics.

[32] Also in this case the probability can be calculated from: (number of positions for lines or planes) over (number of lines or planes present). In a cube with n atoms along each edge the number of possible planes in any given direction is $n^{1/3}$. If the value of g^o for one such defect plane containing $n^{2/3}$ individual defects is estimated to be $n^{2/3}g^0_{def}$, we obtain an extremely small equilibrium probability (per particle), given by $\hat{c}^{n^{2/3}}/n^{2/3}$, where $\hat{c}$ is the equilibrium fraction of point defects whose free enthalpy of formation would be g^0_{def}.
[33] In contrast to this, the surface areas of phases are determined by the limited mass. However, here too the equilibrium morphology, as specified by the Wulff conditions, is usually not estblished (see for example C. Herring, *Phys. Rev.* **1951**, *82*, 87).
[34] The electrical neutrality condition is a consequence of electrostatics for the special case of the interior of an extended homogeneous body (in general Poisson's equation applies, see Section 3.2).

[39] In the case of α–AgI, [23b] in which all the Ag^+ ions can be regarded as disordered, the enthalpy of formation term $\Delta_R H^0$ is negligible, and only the (small) migration energy is significant. At lower temperatures this modification is unstable and it becomes converted to the "normal" β phase.
[40] The usual dopant levels of around 10% are well above the regime of low defect concentrations, and interactions between the defects play an important role [9].
[41] If we consider the partial pressure of water vapor in a typical atmosphere, it is seen that an appreciable H_2 partial pressure of 1 atm corresponds to an extremely small oxygen partial pressure, given by $P_{O_2} = K^{-1}P_{H_2}^{-2}P_{H_2O}^2$ (where K is the equilibrium constant for the formation of H_2O).

[45] An alternative possibility in principle would be Sn ions in the interstitial lattice, but this is refuted by density measurements, and is also inconsistent with the observed slopes of the isotherms. The Schottky equilibrium only becomes important at very high temperatures.
[46] The occupation of singly charged oxygen vacancies by oxygen would also explain the slope of 1/4 at lower temperatures, but would result in a critical isotherm of a completely different shape [43].
[47] For kinetic reasons the main electron source or sink at low temperatures is no longer the interaction with the gas phase, but is instead the transfer of electrons to or from the vacant sites, as in Equation (50). However, the gas phase still has an effect on the boundary regions, as discussed later (Section 3.2.3).
[48] The transition from n-type to p-type conduction occurs near the composition corresponding to O_6. It is therefore appropriate (except in very complex situations) to choose this composition as the reference point. Thus, any additional oxygen is regarded as being in the interstitial lattice. If ionized, it is compensated by holes. The choice of O_7 for the reference composition leads to an inconsistency, since a lower oxygen content would then correspond to vacancies ($V_O^{\cdot\cdot}$, $V_O^{\cdot}$, $V_O^{\times}$), which would be compensated by conduction electrons. This would then lead (assuming comparable mobilities) to n-type conduction, rather than the p-type conduction that is observed (n and p mobilities are comparable).

Carbohydrates as Chiral Auxiliaries in Stereoselective Synthesis

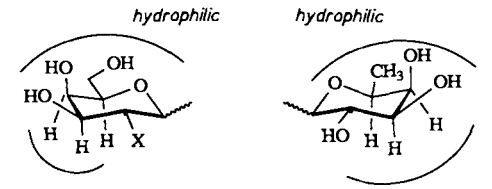
New Synthetic Methods (90)

By Horst Kunz* and Karola Rück

Carbohydrates are inexpensive natural products in which numerous functional groups and stereogenic centers are combined in one molecule. By directed regio- and stereoselective formation of derivatives they can be converted into efficient chiral auxiliaries for controlling asymmetric syntheses. Stereoelectronic effects and pre-orientation of the reactive and shielding groups through formation of complexes can often be used for effective diastereofacial differentiation. In aldol reactions and alkylations on carbohydrate ester enolates intramolecular complexation promotes simultaneous elimination with formation of ketene. The steric, stereoelectronic, and coordinating properties of carbohydrate templates can also be used selectively to attain high levels of asymmetric induction in processes such as Diels–Alder reactions, hetero-Diels–Alder reactions, [2 + 2] cycloadditions, cyclopropanations, and Michael additions. It was possible with bicyclic, strongly stereodifferentiating carbohydrate auxiliaries to achieve a diastereoselective synthesis of carboxylic acid derivatives branched in the β position by a new 1,4-addition of alkylaluminum halides to α,β-unsaturated *N*-acylurethanes, in which methylaluminum halides and higher alkyl- or arylaluminum compounds behave mechanistically in a strikingly different manners. As complex ligands in chiral reagents and promoters, carbohydrates allow highly stereoselective reductions and aldol reactions that lead, amongst others, to chiral alcohols and β-hydroxy-α-amino acids in excellent enantiomeric excesses. Glycosylamines offer the possibility of versatile stereoselective applications: in the presence of Lewis acids the corresponding aldimines permit high-yielding syntheses of enantiomerically pure α-amino acids by Strecker and Ugi reactions, controlled by steric and stereoelectronic effects and by complex formation. They can be used with equal efficiency for asymmetric syntheses of chiral homoallylamines and for asymmetric Mannich syntheses of β-amino acids and chiral heterocycles, for example alkaloids.

1. Carbohydrates in Natural Selection Processes

Carbohydrates are widespread chiral natural products. Many are produced continuously in considerable quantity in nature, for example in sugar cane, sugar beets, and trees, and in chitin. They are cheap and frequently easy to obtain in the pure form. As a result of these useful qualities, carbohydrates have been transformed into diverse, interesting chiral products in ex-chiral pool syntheses. However, carbohydrates were not used for a long time as chiral auxiliaries in stereoselective syntheses. For this purpose they were regarded as too complex, constructed of too many chiral centers, and with too many functional groups. The chiral information they contain could not be exploited in stereodifferentiating selection processes in an organized and surveyable fashion. In addition, carbohydrates long had the reputation of fulfilling more general, less selective roles in biological processes. In analogy to the main representatives of the polysaccharides, starch and cellulose, they were regarded largely as biological stores of energy and as skeletal components. Only during the last two decades has it been increasingly recognized that the carbohydrate portions of glycoconjugates play a decisive role in processes of biological selection – in particular those pertaining to biological recognition on membranes.[1] Selective interactions of carbohydrates with receptors regulate, for example, the uptake of serum proteins into cells[2] and the intracellular transport of enzymes;[3] they are of decisive importance for infection[4] and numerous immunological processes,[5] cell adhesion,[6a] and the regulation of cell growth.[6b] These highly interesting findings from research in cell biology, immunology, and biochemistry have strongly stimulated chemists' interest in glycoconjugates. These results have made researchers aware that carbohydrates contain a considerable amount of regio- and stereochemical information,[7] which nature employs in diverse selection and directed distribution processes in multicellular organisms. Apparently, it is not just chirality or the functional groups capable of forming hydrogen bonds that are responsible for this selection potential. Lemieux has pointed out the amphiphilic character of those monosaccharides frequently involved in recognition processes, D-galactose **1**, D-galactosamine **2**, and L-fucose **3**.[8]



1: X = OH
2: X = NHAc

3

It is obvious that saccharide structures with peripheral galactose, galactosamine, and/or fucose units can undergo not only polar but also hydrophobic interactions. In consideration of biological selection processes of this type it may be

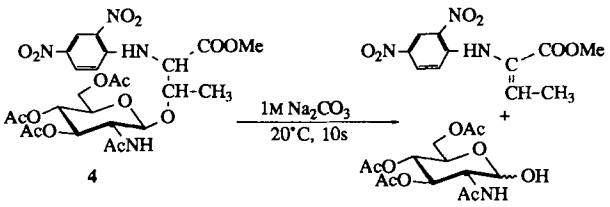
[*] Prof. Dr. H. Kunz, Dr. D. K. Rück
Institut für Organische Chemie der Universität
Johann-Joachim-Becher-Weg 18–20
D-W-6500 Mainz (FRG)

more appropriate, in view of the high pressure under which organic molecules exist in a biological, aqueous environment, to speak of the ability to minimize the hydrophobic volume instead of simply the hydrophobic interaction. In this context saccharides **1**–**3**, in which the arrangement of the hydrophobic and hydrophilic groups divides the molecules into sections, fit much better into a hydrophobic receptor counterpart than, for example, glucose or mannose.

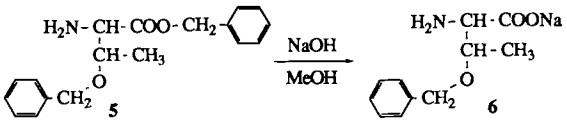
This faculty for recognition displayed by oligosaccharides in glycoconjugates, further magnified by formation of antenna- or clusterlike accumulations, has induced considerable interest in the synthesis of glycoconjugates, which are of enormous importance for immunology, infection processes, and the development of directed pharmaceuticals that are more stable toward proteases. They have also stimulated our efforts in the synthesis of glycopeptides.[9] In these syntheses of *O*-glycosylserine- and -threonine-glycopeptides, a major problem is the facile β-elimination of the carbohydrate portion, for example when the protecting groups are removed.[10] The explanation of this reaction directs attention to a further property of carbohydrates that in addition to chirality and polyfunctionality is also of interest for stereoselective processes: their ability to form complexes. According to recent findings, the complex-forming ability of carbohydrates is also important for processes of biological recognition, for example, in the interaction of the calcium-dependent carbohydrate-recognizing domains of mammalian lectines with saccharides.[11]

2. Carbohydrates—Chiral Matrices Able to Form Complexes

The β-elimination of carbohydrates derived from *O*-glycosylserine and -threonine derivatives takes place even under mildly basic conditions, as shown by the example of glucosaminylthreonine ester **4**.[12] Seen from the viewpoint of peptide chemistry, this smooth, base-catalyzed elimination, long known in carbohydrate chemistry,[13] is surprising.



Usually serine and threonine esters protected in the side chain as benzyl or *tert*-butyl ethers can be saponified under much more forcing conditions without β-elimination. The reaction of *O*-benzylthreonine benzyl ester **5** underlines this difference.[14]



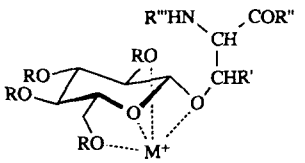
Confronted with these contradictory experiences from carbohydrate and peptide chemistry, we explained the greater tendency of carbohydrates of *O*-glycosylserine and -threonine derivatives to undergo elimination by the complex-forming properties that carbohydrates can display towards cations.[9]

Complexation of the cation in **7** increases the ability of the carbohydrate to function as a leaving group, because the

Karola Rück was born in 1963 in Hargesheim near Bad Kreuznach (Rhineland-Palatinate). She started her chemistry studies in 1983 at the University of Mainz and received her Ph.D. in 1992 for her work with Horst Kunz on stereoselective reactions of organoaluminum compounds. In 1989 she received the Adolf-Todt-Preis of the University of Mainz and a doctoral stipend from the Fonds der Chemischen Industrie. Since October 1992 she has been working with Steven Ley at the University of Cambridge in Great Britain as a postdoctoral fellow supported by the Deutscher Akademischer Austauschdienst.

Horst Kunz was born in 1940 in Frankenhausen near Zwickau (Saxony). He studied chemistry at the Humboldt University in (formerly East) Berlin and at the University of Mainz. He received his Ph.D. in 1969 for his work with Leopold Horner on the synthesis of organophosphorus compounds. He acquired his "Habilitation" in 1977 for his work on ester analogues of acetylcholine and their application in protecting group chemistry. He was appointed Associate Professor for Organic Chemistry in 1979 at the University of Mainz and was promoted to Full Professor for Bioorganic Chemistry in 1988. His research centers on stereoselective synthesis, methods in peptide and carbohydrate chemistry, and the synthesis, elaboration, and development of glycopeptides, for which he recieved the Max-Bergmann-Medaille in 1992.

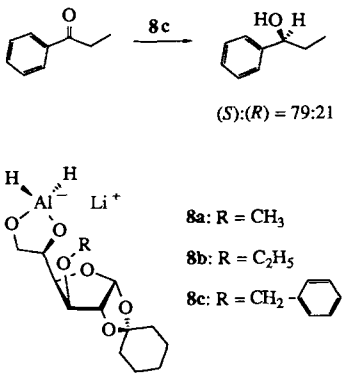
developing charge is neutralized. This complex-forming ability of carbohydrates is also reflected in the considerably higher rate of saponification of carbohydrate esters compared with that of analogous alkyl esters.[15] By complexation carbohydrate esters gain the properties of active esters to a certain extent, which could be developed into a new process for the synthesis of peptides.[16] It should be noted that anomeric selection effects in glycoside synthesis by alkylation of carbohydrates not protected at the anomeric position could also be explained by complexation.[17]



7

For us the explanation of the rapid β-elimination of the carbohydrate component of glycosylserine and -threonine derivatives by formation of complex **7** was the starting point for the development of a concept, according to which inexpensive carbohydrates can be employed in stereoselective syntheses as chiral matrices organized by complexation.[18] This is even more promising, as a diverse spectrum of methods is now available for the regioselective modification of the functional groups and the stereochemistry of carbohydrates.

At this point some studies had already appeared in which carbohydrate components were used for stereodifferentiation.[19] The early experiments of Landor et al.[20] are representative: lithium alkoxyaluminum hydrides were prepared from $LiAlH_4$ and used as enantioselective reducing agents. This strategy was employed for the stereoselective reduction of propiophenone to 1-phenylpropanol by means of reagent **8**, which was prepared from 3-*O*-alkyl-1,2-*O*-cyclohexylidene-α-D-glucofuranose. Whereas the 3-*O*-methyl (**8a**) and 3-*O*-ethyl (**8b**) derivatives showed little induction, the 3-*O*-benzyl derivative **8c** gave an enantioselectivity of 79:21 in favor of the (*S*) alcohol.



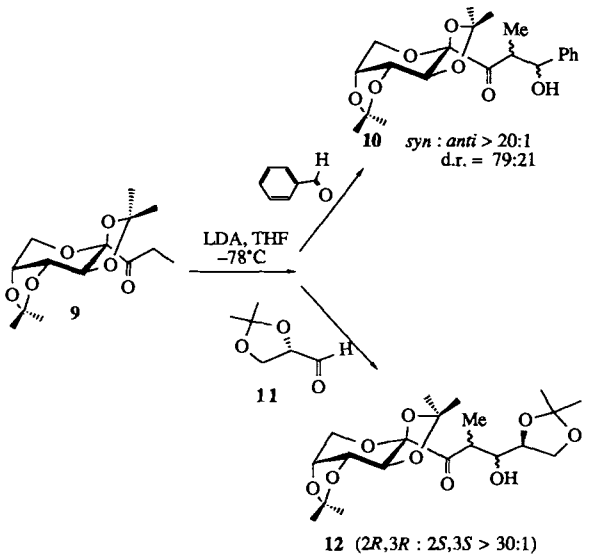
Although the role of the carbohydrate ligands was difficult to explain in most cases, very interesting effects could be observed. For example, addition of one equivalent of ethanol to **8c** gave a less reactive, apparently monohydrido complex that reacted with propiophenone with reversal of the direction of selectivity to give the (*R*) alcohol [(*R*):(*S*) = 73:27].

Other individual examples of the use of carbohydrates for stereoselection involve, for example, aldol reactions, cycloadditions, and 1,2- and 1,4-additions of Grignard reagents and will be discussed in the following sections. Nevertheless, it should be mentioned here that in 1,3-dipolar cycloadditions of *N*-(α-mannofuranosyl)nitrones, for example, considerable stereoselectivity was observed without the addition of complex-forming reagents.[21] An influence of the carbohydrate complexation on aldol reactions and related processes must certainly be assumed; consequently, these will be discussed first.

3. Stereoselective Reactions of Carbohydrate Ester Enolates

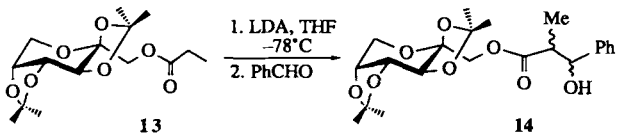
In order to keep this review a reasonable length, the scope must be restricted to stereoselective reactions in which the carbohydrate serves as a chiral auxiliary removed at the end of the process. The extensive investigations in which carbohydrates have been used in ex-chiral pool syntheses[22]—2,3-*O*-isopropylideneglyceraldehyde alone has been applied on countless occasions in this regard[23–25]—cannot be treated here. As early as 1981 Heathcock et al.[26] investigated enolates of carbohydrates both in chiral pool syntheses and also in auxiliary-supported stereoselective reactions. The lithium enolate of ketone **9** (prepared from D-fructopyranose) reacted with benzaldehyde in the first sense (i.e. ex-chiral pool) to give the diastereomeric aldols **10** with high, simple diastereoselectivity but modest asymmetric induction (Scheme 1). This example is the best of a whole series of analogous cases.

The same enolate reacted with (*S*)-*O*-isopropylideneglyceraldehyde (**11**) with double diastereodifferentiation to give aldol **12**, which was formed with high selectivity as one of the two *syn* diastereoisomers (presumably 2*R*,3*R*). In contrast, the analogous reaction with the (*R*) glyceraldehyde gave three diastereomers in the ratio 5.5:2.5:1. In other examples,



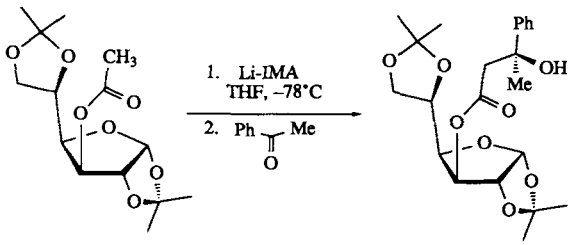
Scheme 1. LDA = Lithium diisopropylamide.

as already seen in the reaction of benzaldehyde, even less stereodifferentiation was observed. All in all, the results of Heathcock et al.[26] provide an interesting picture, but one that is nevertheless complicated and difficult to interpret and tends to confirm the preconceived view expressed earlier that carbohydrates are too chiral and too polyfunctional for directed stereoselection. This impression is reinforced by the results obtained in the same work on ester enolates with carbohydrates as removable auxiliaries, as shown by the example of propionate **13** derived from D-fructopyranose.[26] Apart from a small *anti*/*syn* preference, practically no diastereodifferentiation was found with the enolate, and a mixture of all four diastereomeric aldol adducts **14** resulted.



13 **14**
syn (17+10) : *anti* (37+36) = 27 : 73

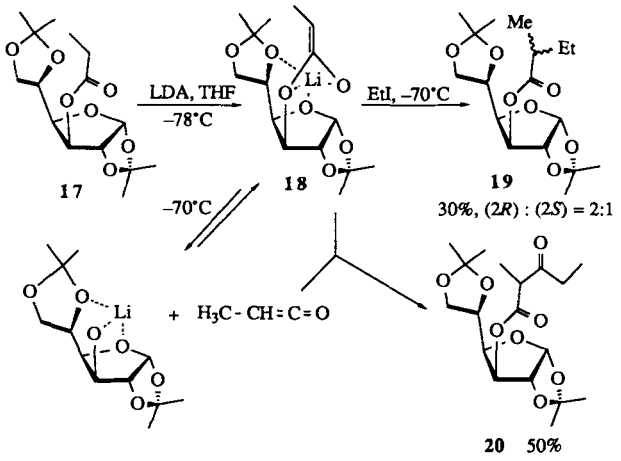
In another early example of the use of carbohydrates as chiral auxiliaries Brandänge et al.[27] subjected the 3-*O*-acetate of diacetoneglucose (**15**) to aldol reactions under various conditions. The highest diastereoselectivity was obtained by deprotonation of **15** with lithium *N*-isopropyl-(−)-menthylamide (Li-IMA) and reaction with acetophenone as the prochiral partner.



15 **16** (3*S* : 3*R* = 3:1)

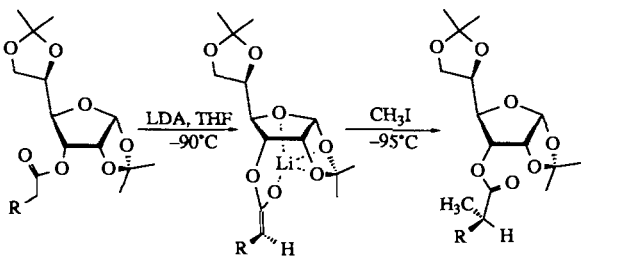
The influence of the complexation of Li^+ in these processes is evident, since addition of magnesium chloride to the enolate of **15** (generated with LDA) with acetophenone favored the (*R*) diastereomer of **16** with lower selectivity. In contrast, an analogous Reformatsky reaction starting from the bromoacetic acid ester corresponding to **15** (with zinc in refluxing THF) gave predominantly the (*S*) diastereomer **16**.

The complex-forming ability of the carbohydrate auxiliary strongly affects the alkylation of the prochiral ester enolate of 3-*O*-propionyl diacetone glucose **17**. Reaction of the enolate **18** (formed with LDA) with ethyl iodide at −70 °C gave 2-methylbutyrate **19** with low selectivity and yield. In addition, an O-alkylation product and **20**, surprisingly the product of an apparent ester condensation, were formed.[28] Closer investigation of the unexpected reaction revealed that enolate **18** starts to decompose reversibly into ketene and carbohydrate alkoxide even at −70 °C, a reaction that is otherwise only observed with ester enolates at considerably higher temperatures.[29] With this behavior the carbohydrate once again shows its ability to form intramolecular complexes, which increases its tendency to function as a leaving group. The ketene formed reacts with the intact enolate **18** to give the condensation product **20**. As a consequence of the reversibility of the enolate decomposition, **18** exists as a mixture of *E*/*Z* isomers, which was demonstrated by NOE measurements on the corresponding silylketene acetals. The slow alkylation of enolate **18** at −70 °C and the competing isomerization of **18** by the reversible decomposition account for the low stereoselectivity observed.



17 **18** **19**
30%, (2*R*) : (2*S*) = 2:1
20 50%

In contrast to enolate **18**, the enolates of esters of 3-epimeric 1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose (**21**) are considerably more reactive.[28] Deprotonation at −90 °C led to (*Z*) enolates **22** (proven by silylketene acetals), which reacted with methyl iodide even at −95 °C to give the chiral α-methylcarboxylic acid esters **23**. At such a low temperature formation of ketene was not observed. In comparison with that of **18** both the yield and the stereoselectivity of the alkylation of **22** are considerably higher. High yields and stereoselectivities were found in particular with bulky substituents R. The different reactivity and selectivity of carbohydrate ester enolates like **18** and **22** indicate not only the complex-forming effect of the carbohydrate function, but also the steering influence of the lithium ion during attack of the electrophile.[28]



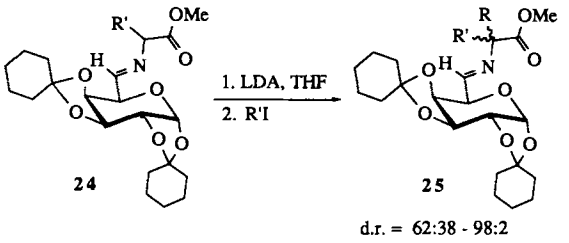
21 **22**
23a: R = Et, 65%, (*R*):(*S*)=82:18
23b: R = *t*Bu, quant., (*R*):(*S*)=91:9

Intramolecular complexation that does not promote decomposition into ketene and an alcohol might exist in enolates that are formed by deprotonation of Schiff bases **24**, themselves prepared from protected galactodialdehyde and

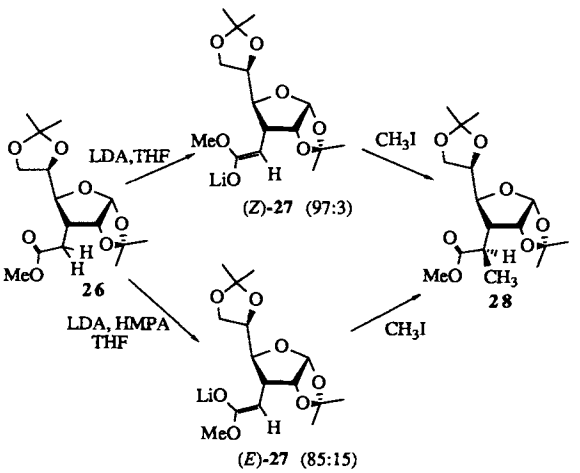
Table 1. D-Galactodialdehyde as a chiral auxiliary in the stereoselective synthesis of methyl esters of α-alkylamino acids [30].

Amino acid residue R	R'-I	Yield (**25**)	*de*
$CH(CH_3)_2$	$CH_2C_6H_5$	91%	80
$CH(CH_3)_2$	$CH_2CH{=}CH_2$	91%	>95
$CH_2CH(CH_3)_2$	$CH_2C_6H_5$	93%	75

amino acid esters (Table 1).[30] For these reactions the configuration of the enolate formed was not given, however.[31] Moreover, the ratios of the diastereomers of the alkylation products **25** could not be determined directly, but were obtained by ^{1}H NMR measurements in the presence of chiral shift reagents after hydrolysis to give the free amino acids. Interpretation of the results regarding the complexation and the stereodifferentiating factors was therefore not possible.



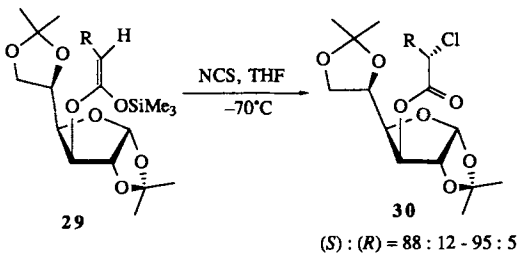
On the other hand, for the alkylation of ester enolates of branched carbohydrate carboxylic acids, which belong, strictly speaking, to ex-chiral pool syntheses, a transfer of chirality was postulated that is not effected by chelation.[32] Following the principles of stereoselective enolate formation,[33] ester **26** (obtained from the corresponding 3-ulose by Horner olefination and subsequent hydrogenation) reacted with LDA/THF to give the (*Z*) enolate (*Z*)-**27** (*Z*/*E* = 97:3) and with LDA/hexamethylphosphoric triamide (HMPA)/THF to give predominantly the (*E*) enolate (*E*)-**27** (*Z*/*E* = 15:85).



Both enolates reacted selectively with methyl iodide to give the (*R*)-α-methyl derivative **28**. From this and the even higher induction observed in alkylation of analogous ester enolates containing 5-deoxy- or 2,5-dideoxyfuranose structures, the authors[32] concluded that chelate formation with the carbohydrate functions cannot be responsible for the stereoselectivity in these reactions. As the intramolecular complexation of Li^+ in the (*Z*) enolate (*Z*)-**27** is sterically unfavorable, this enolate should form aggregates. Complexation with the ring oxygen atom in (*E*)-**27** cannot be ruled out, so that the alkylations of (*Z*)-**27** and (*E*)-**27**, which lead to product **28** with high selectivity, could have a different cause in each case. In the reaction of (*E*)-**27** chelate control could exist, whereas in the reaction of the other enolate this is clearly not the case. Intramolecular complexation of these enolates at least does not promote decomposition into ketene and alcohol.

The intramolecular chelation and formation of ketene characteristic of O-bound carbohydrate ester enolates considerably limit the range of application of carbohydrates as removable auxiliaries in the reactions of enolates. As a result, asymmetric reactions of enolates with carbohydrates as auxiliaries can compete only in isolated cases with the well-known, very successful concepts for asymmetric syntheses based on ester and amide enolates.[34]

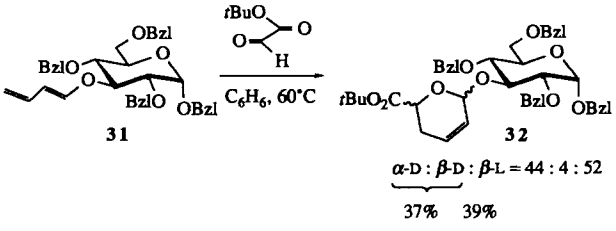
This limitation is not, however, valid for silyl derivatives of carbohydrate ester enolates attached to diacetone glucose,[35] as shown by recent results in the synthesis of α-chlorocarboxylic acid esters **30** from silylketene acetals **29**.



The sterically more favorable frontal attack of *N*-chlorosuccinimide (NCS) on **29** effected the preferential formation of the (*S*) diastereomer of 2-chlorocarboxylic acid ester **30** with notable stereoselectivity.

4. Cycloadditions

Cycloadditions in which the carbohydrate unit itself acts as the cycloaddition component will not be treated here, although such ex-chiral pool transformations can lead to interesting products.[36–38] However, the role of the carbohydrate in de novo disaccharide syntheses from 1-butadiene ethers of monosaccharides such as **31** and reactive carbonyl

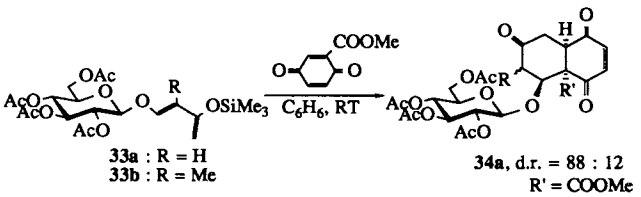


compounds such as esters of glyoxylic acid[39] could also be regarded as that of an auxiliary.

In spite of the elevated reaction temperature the carbohydrate-bound diene component **31** reacted with high diastereofacial differentiation (96:4), although with only a low *endo*/*exo* selectivity, to give a mixture of epimeric and anomeric disaccharides **32**. The diastereomeric ratios were determined by chromatographic separation (sometimes after chemical transformation). 2,3,4-Trideoxy-L-glycerohexopyranoses could be obtained from the β-L diastereomers of **32** by reduction of the ester with lithium aluminum hydride, hydrogenation of the double bond, and subsequent acidic hydrolysis. The product contains no carbon atoms from the carbohydrate auxiliary employed.[39]

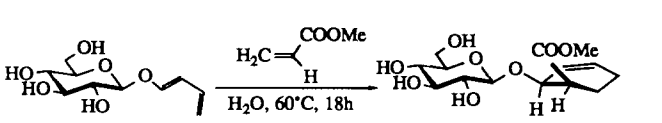
4.1. Diels–Alder Reactions

As in the reaction described above with a heterodienophile, carbohydrate-bound dienes have also been used successfully in asymmetric Diels–Alder reactions. In connection with tetracycline syntheses it was shown that the electron-rich 1-glucosyloxydiene **33a** reacts, for example, with 2-methoxycarbonyl-*p*-benzoquinone with considerable stereoselectivity to give the hydrolysis product **34a** via the Diels–Alder adduct.[40,41] From NOE experiments the authors[41] deduced a preferred conformation of the glucosyloxydiene, which is in agreement with the *exo*-anomeric effect and which corresponds to the transoid conformation of **33a**. The higher selectivity observed in the reaction of the analogous 2-methyldiene **33b** proves that the cisoid form of **33a** is not decisive. On the assumption that an *endo* addition occurs, the dienophile must in this case preferentially attack from the front side, that is, from that direction in which the steric interaction with the 2-acetoxy group must be overcome.[40]



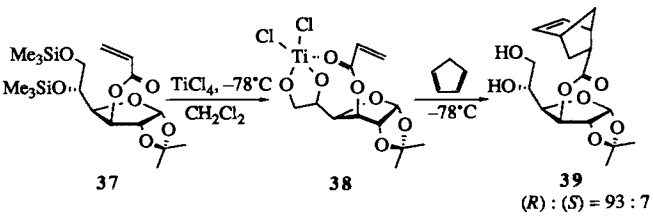
High stereoselectivities were reported for the asymmetric Diels–Alder reactions of 1,4-naphthoquinone with cyclohexanedienols bound to diacetone glucose.[42]

Anomeric glucosyloxy-butadienes such as **35** with unprotected hydroxyl groups enable interesting Diels–Alder reactions to be carried out in water. Compound **35** reacted with methyl acrylate with complete *endo* selectivity but modest diastereofacial differentiation to give the diastereomeric cyclohexenol ethers **36**.[43] The corresponding α-anomeric diene reacted with methacrolein to give the cycloadduct with lower and opposing *Re*/*Si* facial differentiation. On the assumption that the cisoid conformation of **35** is preferred, the predominant attack of the dienophile would be from the *Re* side (C1), again with approach from the front side.[43] When an *O*-benzyl ether protecting group was introduced selectively to the 2-position of **35**, the cycloaddition with methacrolein proceeded with reversal of the direction of induction but also with lower selectivity (34:66).[44]

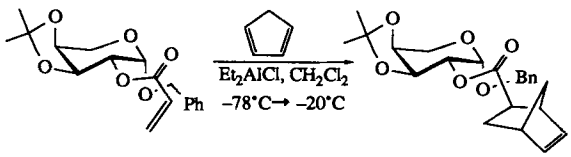


A stereoselective Claisen rearrangement of an allyl vinyl ether attached to an unprotected glucose is related to these Diels–Alder reactions. This process also showed a selectivity of only 60:40.[45]

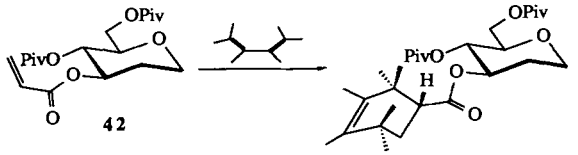
Diels–Alder reactions of dienes attached to carbohydrates have been carried out without Lewis acid catalysis, which may be one reason for the generally modest asymmetric inductions observed. When the dienophile was attached to a carbohydrate auxiliary, the reactivity was increased by Lewis acid catalysis and the Diels–Alder reaction could be conducted at a lower temperature. Results obtained to date show that the dienophile can be shielded by coordinative fixing to the carbohydrate framework to give effective diastereodifferentiation. Intermediate **38**, formed from the 3-*O*-acryl-glucofuranose derivative **37** and titanium tetrachloride at −78 °C, contains both the dienophile and the Lewis acid catalyst bound to the carbohydrate matrix. The dienophile is oriented by intramolecular coordination in the chiral matrix in such a manner that it reacts with cyclopentadiene preferentially on the *Si* side.[46] Thus, the *endo* adduct **39** was formed with high stereoselectivity as the (*R*) diastereomer. The analogous reaction with a 5-*O*-trimethylsilylxylofuranose derivative gave the diastereomeric (*R*) adduct exclusively.[46] The reactions of dienes with lower reactivity must be conducted at ambient temperature and are thus less selective.



2-*O*-Acrylates derived from β-L-arabinopyranosides were used by Shing et al.[47] in Et_2AlCl catalyzed Diels–Alder reactions. The reason for the moderate inductions observed, compared with those from the titanate complexes **38** mentioned above, may be that the functional groups in the carbohydrate residue in **40** carry protecting groups which exhibit a reduced coordination tendency towards the Lewis acid catalyst.



In agreement with this conclusion it was possible, using another concept, to coordinate the Lewis acid with great effect to the carbohydrate matrix by acyl protecting groups. In this case it is possible to vary the strength of the Lewis acid over a wide range, thus permitting the stereoselective reaction of less reactive dienes.[48] Compound **42**, an acrylate bound to a dihydroglucal template (Scheme 2), reacted with cyclopentadiene under $TiCl_2(OiPr)_2$ catalysis at $-30\,^{\circ}C$ to give the cycloadduct **43a** in high yield and stereoselectivity (98:2). However, cycloaddition of **42** with anthracene required activation from the stronger Lewis acid $TiCl_4$ at $0\,^{\circ}C$. Adduct **43d** was then obtained as almost exclusively one diastereomer (Table 2). The examples in Table 2 show that reactive as well as less reactive dienes can be converted to chiral cycloadducts according to this flexible principle with efficient stereoselectivity and in high yield.



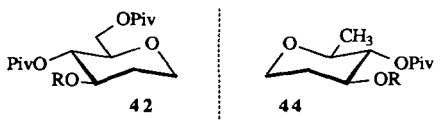
Scheme 2. Piv = Pivaloyl. For products of analogous reactions see text and Table 2.

Table 2. Stereoselective Diels–Alder reaction of acrylate **42** bound to dihydro-D-glucal [48].

Diene (10 equiv)	Lewis acid (3 equiv)	T [°C]/ t [h]	Adduct	Yield [%]	$(R):(S)$
cyclopentadiene	$TiCl_2(OiPr)_2$	−30/1.5	**43a**	92	98:2
isoprene	$TiCl_3(OiPr)$	0/48	**43b**	94	95:5
buta-1,3-diene	$TiCl_3(OiPr)$	0/6	**43c**	90	92:8
anthracene	$TiCl_4$	0/4	**43d**	87	99:1

The range of application of this stereoselection method has been extended considerably, since cycloadducts of the opposite configuration could also be prepared with high selectivity. In the case of dienophile **44** a dihydro-L-rhamnal unit served as the chiral template, to which the acrylate function was attached as an ester.[48]

Comparison of the two auxiliaries **42** and **44** illustrates that the structural and functional versatility of the carbohydrates provides a flexible concept for the alternative stereoselective synthesis of both enantiomeric configurations of a chiral target molecule, even though most sugars do not exist naturally in both enantiomeric configurations. The essential coordinating and shielding groups of the auxiliaries obtained from glucose and L-rhamnose mirror each other perfectly (Scheme 3). The trick of using quasi-enantiomeric carbohydrate templates was employed earlier in amino acid syntheses for selective formation of either the D or the L enantiomer (see Section 7.1).[18]



Scheme 3. R = Acryloyl.

Compound **44** (R = acryloyl) reacted with dienes to give (*S*)-configurated cycloadducts such as **45**, again in high selectivity and yield (Table 3); the strength of the Lewis acid and the reaction temperature were varied.

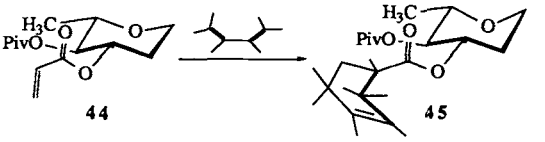


Table 3. Stereoselective Diels–Alder reaction of acrylate **44** bound to dihydro-L-rhamnal [48].

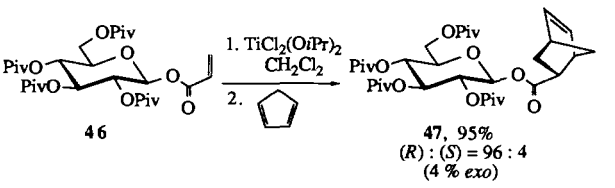
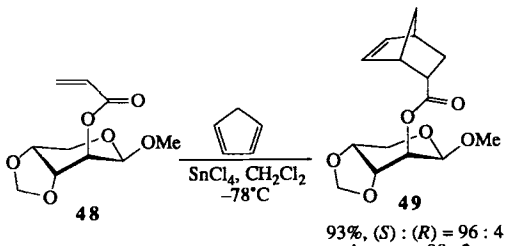
Diene (10 equiv)	Lewis acid (3 equiv)	T [°C]/ t [h]	Yield [%]	$(R):(S)$
cyclopentadiene	$TiCl_2(OiPr)_2$	−30/2	80	6:94
isoprene	$TiCl_3(OiPr)$	−30/18	60	10:90
butadiene	$TiCl_4$	−30/4	68	5:95
anthracene	$TiCl_4$	0/18	52	1:99

The anomeric acrylate **46** could be converted into the corresponding adduct (here **47**) at $-30\,^{\circ}C$ only with more reactive dienes such as cyclopentadiene. $TiCl_2(OiPr)_2$ was sufficient as Lewis acid; stronger Lewis acids such as $TiCl_4$ caused cleavage of the anomeric ester.[49] In contrast to the reactions of dienes attached to carbohydrates, attack on the back side clearly dominates in this Lewis acid catalyzed Diels–Alder reaction of the carbohydrate-bound dienophile. An *endo/exo* selectivity of 96:4 and stereoselectivity in favor of the (*R*) diastereomer of **47**, also 96:4, were obtained.[49] The α-anomeric acrylate corresponding to **46** reacted more slowly with cyclopentadiene and with a lower selectivity. Interestingly, in this case the diastereomeric (*S*) adduct was formed preferentially.[49]



Methyl-3,4-*O*-methylene-β-D-arabinopyranoside, in which the 2-hydroxyl group was esterified with acrylic acid to give **48**, was recently used as auxiliary in a Lewis acid catalyzed Diels–Alder reaction.[50] Compound **48** reacted with cyclopentadiene and 2,3-dimethylbutadiene in the presence of $TiCl_4$ or $SnCl_4$ to give adducts such as **49** with high stereoselectivity and *endo* preference. Only modest or low induction was achieved when the reaction was conducted with boron trifluoride or ethylaluminum dichloride as the catalyst and with isoprene as the diene. Nevertheless, the authors[50] traced the diastereofacial differentiation in favor of the *Re* face in **48** back exclusively to the steric shielding caused by the β-methoxy group.

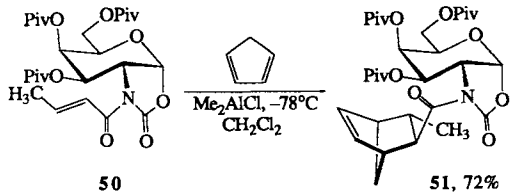


48 49

93%, (*S*) : (*R*) = 96 : 4
endo : *exo* = 98 : 2

The crotonates corresponding to the acrylates **42**, **44**, and **46** do not generally react at sufficiently low temperature to give the cycloadducts stereoselectively. However, crotonates were successfully employed in diastereoselective Diels–Alder reactions with various auxiliaries not derived from carbohydrates.[51]

Crotonate **50**, containing a bicyclic oxazolidinone unit (developed for another purpose, see Section 5.2) derived from galactosamine, underwent Diels–Alder reactions with high *endo* preference and practically complete diastereoselectivity.[52] The reaction required catalysis by Lewis acids like



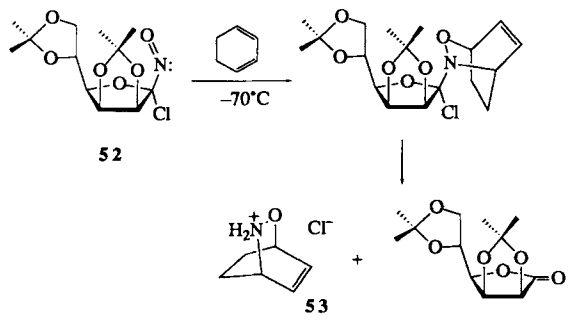
50 **51**, 72%

dimethylaluminum chloride and gave the *endo* adduct **51** (*endo*:*exo* = 20:1). The *endo* adduct was detected as only a single diastereoisomer by capillary GC.[52]

4.2. Heteroanalogous [4+2] Cycloadditions

The α-chloronitroso compound **52**, formed by reaction of the hydroxyimino-γ-lactone of the isopropylidene-protected mannonic acid with *tert*-butylhypochlorite, reacted with dienes at −70 °C with high stereoselectivity to give 3,4-dihydro-2*H*-1,2-oxazines such as **53**.[53] The configuration of **52** was determined by X-ray analysis. The intermediate adduct was hydrolyzed during the reaction or the subsequent workup to give the free oxazine hydrochloride **53**.

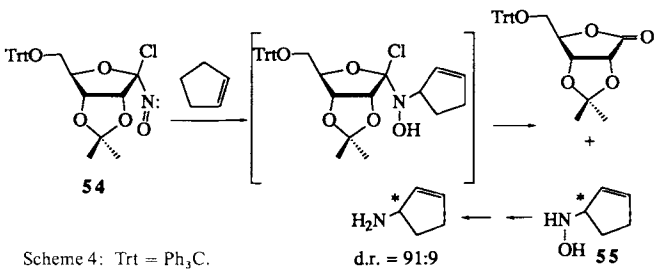
Stereoselectivities of more than 98:2 have been attained in numerous examples. Heterodienophile **52** is characterized by



52 **53**

a high reactivity at low temperature. It seems that, as in the solid state, a conformation of **52** is preferred that is stabilized by $n \rightarrow \sigma^*$ delocalization of the lone pair on the nitrogen atom into the C1–O bond. The result is a very effective stereofacial differentiation in favor of attack on the sterically more accessible back side of the N=O bond, while the *anti* orientation of the diene relative to the furanose ring is preferred.

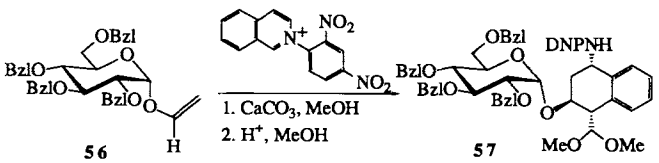
These favorable properties could also be employed in a stereoselective ene reaction. When the chloronitrosoribose derivative **54** was used instead of the mannose compound, the alternative enantiomeric series could be prepared (Scheme 4).[54] The enantiomeric ratios for both **53** and **55** were determined after chemical transformation.



54 **55**

Scheme 4: Trt = Ph_3C. d.r. = 91:9

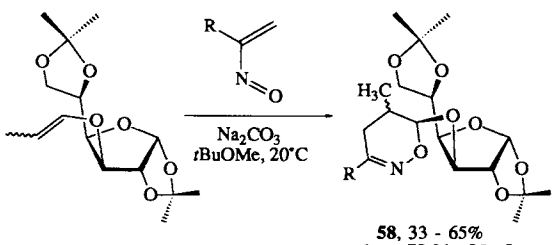
Isoquinolinium salts have been used as heterodienes in Diels–Alder reactions with inverse electron demand with vinyl glycosides.[55] In one case, the reaction of **56**, a high induction was observed. The given diastereomeric ratios of products **57** (DNP = dinitrophenyl) were obtained after isolation of the diastereomer mixtures. As neither reaction nor



56 **57**

70%, d.r. > 98 : 2

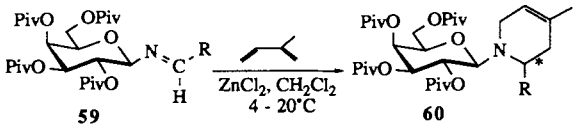
workup conditions were given, enrichment effects cannot be excluded. The synthesis offers, after conversion of acetal **57** into a dithiane and cleavage of the carbohydrate unit with trimethylsilyl iodide, an interesting route to homochiral trisubstituted tetralines. Diacetone glucose enol ethers reacted stereoselectively with nitrosoalkenes (generated in situ) as heterodienes to give chiral 1,2-oxazine derivatives **58**.[56] The



58, 33 - 65%
d.r. = 79:21 - 95 : 5

reported results allow the conclusion that the (*E*) enol ethers generally react with greater selectivity than the (*Z*) analogues.

The stereoselective synthesis of 2-substituted piperidine derivatives was achieved by the hetero-Diels–Alder reaction of *N*-galactosylimine **59** with dienes such as isoprene.[57] The reaction required catalysis by zinc chloride, as imines are usually too unreactive for cycloadditions.



59 **60**

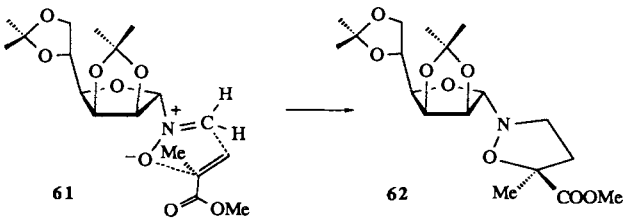
Although the absolute configuration of the major diastereomers of didehydropiperidines **60** has not been clarified, the NMR data for the imine and its zinc complexes[18] for R = aryl indicate that a (2*S*) configuration is probable. A few examples of these stereoselective syntheses of didehydropiperidines are listed in Table 4. Although the diastereomeric ratio reaches a value of 10:1 in only a few cases, the process offers the advantage that most of the products **60** can be obtained in good yield and diastereomerically pure by recrystallization or by flash chromatography.

Table 4. Aza-Diels–Alder reaction of Schiff bases **59** with isoprene; stereoselective synthesis of 2-substituted piperidine derivatives [57]. RT = room temperature.

R	*T* [°C]/*t*	Yield [%]	Diastereomeric ratio	Pure diastereomer
p-ClC_6H_4	+4/12 h	95	87:13	60%
p-FC_6H_4	+4/12 h	90	91:9	52%
2-furyl	RT/4 d	98	80:20	65%
2-thienyl	RT/4 d	95	84:16	56%

According to recent results the reaction can also be catalyzed by tin tetrachloride. Imines of D-arabinopyranosylamine, which are quasi-mirror images of **59**, can be used for the synthesis of chiral piperidines that, in comparison to **60**, have the opposite configuration.[58]

In the 1,3-dipolar cycloaddition of *N*-manno- and *N*-ribofuranosylnitrones to alkenes, Vasella et al.[59, 60] found an interesting stereoselective route to isoxazolines with a chiral center at C5. As an example, the addition of nitrone **61** (prepared from *O*-isopropylidene-protected *N*-mannofuranosylhydroxylamine and formaldehyde) to methyl methacrylate is given.



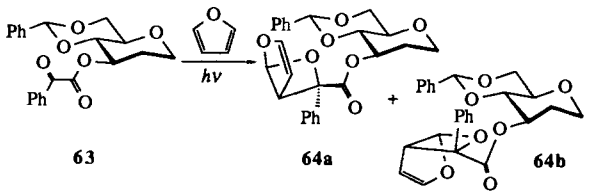
61 **62**

98%, (5*S*) : (5*R*) = 87.5 : 12.5

The preferred formation of the (5*S*) diastereomer was explained,[60] in that **61** reacts from a predominantly O-*endo* conformation. Moreover, a methyl-*endo* geometry in the approach to the methacrylate was concluded from similar reactions of other nitrones[61]. Attack of the dipolarophile follows with high selectivity from the back side, that is, from the direction of the furanose C1–O bond, because delocalization of the *n* orbital developing on the nitrogen atom (in **62**) into the σ^* orbital of the ring C–O bond can occur at an early phase and in the transition state (kinetic *exo*-anomeric effect). In analogous cycloadditions prochiral nitrones of type **61**, for example that of acetaldehyde, were not very diastereoselective with regard to the configuration at C3 of the isoxazolidine. This effect could be traced back to the low configurative stability of the nitrone itself. Nitrone **61** and its pseudo-enantiomeric ribofuranosyl analogues with N-protected L-vinylglycine esters were employed in a double diastereodifferentiation.[60] Whereas **61** gave the diastereomeric isoxazolidines in a ratio of only 3:1, L-vinylglycine esters and the D-ribose analogue apparently form a "matching pair" and react to give a single stereoisomer, which was subsequently transformed into the antibiotic acivicin.[62]

4.3. [2 + 2] Cycloadditions

In addition to [2 + 2] cycloadditions in which the carbon atoms of the carbohydrate unit are incorporated into the ring structure,[38, 63] syntheses of four-membered rings have recently been reported in which carbohydrates act as chiral auxiliaries. For the purpose of this review, stereoselective Paterno–Büchi reactions should also be included here,[64] although such photochemical processes are not concerted but take place via 1,4-diradicals. Irradiation of the carbohydrate phenylglyoxylic acid ester **63** and furan gave the diastereomeric dioxabicycloheptenes **64a** and **64b** in the ratio 9:1. An interesting observation in this reaction was that a somewhat higher diastereoselectivity was found with increasing reaction temperature.[64]

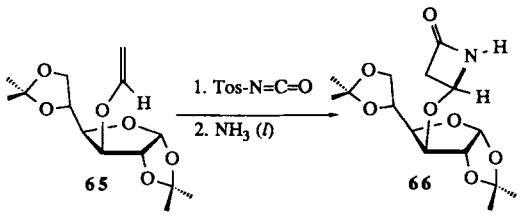


63 **64a** **64b**

80%, 64a : 64b = 9 : 1

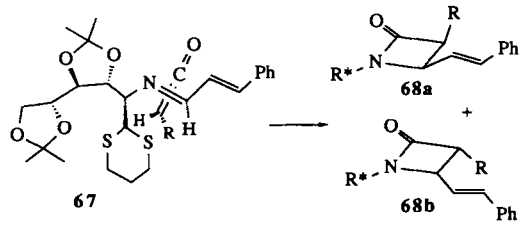
Asymmetric [2 + 2] cycloadditions that permit access to chiral β-lactams are of particular interest. In this context the vinyl ether of diacetone glucose **65** was treated with tosyl isocyanate in ether at room temperature.[65] The (4*R*) diastereomer of β-lactam **66** was obtained predominantly with a diastereoselectivity of 86:14.

The yields in these and similar processes are moderate.[65] In several other cases the (4*S*) diastereomer of the lactam was formed, albeit with lower selectivity. *N*-Trichloroacetyl isocyanate underwent almost exclusively [4 + 2] cycloaddi-



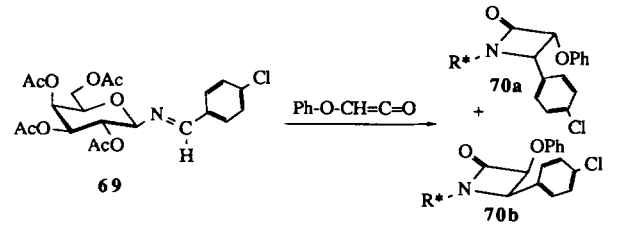
tion with vinyl ethers like **65** and showed only little or no diastereofacial differentiation.[65]

Another route to chiral β-lactams is provided by the Staudinger reaction of ketenes with imines prepared from chiral amines. Imine **67**, derived from glucosamine and cinnamic aldehyde, reacted with ketenes generated in situ to give the *cis* β-lactams **68**.[66] Whereas *N*-phthalimidoketene gave the (3*S*,4*S*) adduct in high yield and complete stereoselectivity, the analogous reaction of the methoxyketene (R = MeO) showed hardly any selectivity. The glucosamine auxiliary was cleaved by abstraction of the dithianyl proton with butyllithium and β-elimination of the lactam (yield: 35%).



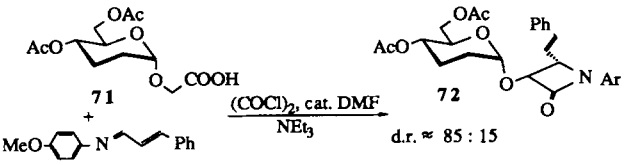
R = PhtN, 92%, **68a**
R = OMe, 94%, **68a** : **68b** = 65 : 35

Galactosylimines[18, 57] display only slight stereodifferentiation in the Staudinger reaction with aryloxyketenes according to the observations of G. Georg et al.[67] As shown, for instance, in the reaction of imine **69**, obtained from *p*-chlorobenzaldehyde, both *cis* products **70a** and **70b** were formed in good yield. The *cis* α,α-diastereomer **70a** generally predominated in the ratio 3:2.[67b]



85%, **70a** : **70b** = 60 : 40

Recently, a stereoselective Staudinger reaction with the chiral, carbohydrate-bound ketene from *O*-glycosylglycolic acid **71** was described.[68] Both *cis* β-lactam diastereomers were formed selectively; the *cis* α,α-diastereomer **72** dominated in a ratio of about 85:15. The reason for the observed facial differentiation could be the unhindered attack on the *Re* side of the ketene formed in situ as a result of the 2-deoxy structure of **71**. The importance of stereoselective β-lactam syntheses does not need to be underlined here; a large number of important types of antibiotics belong to this group of compounds.



d.r. ≈ 85 : 15

4.4. Cyclopropanations

Cyclopropanations by addition of carbenes (or carbenoids) can be regarded as [2π + 2ω] or [2π + 2σ] processes and are thereby categorized as [2 + 2] cycloadditions.[69, 70] The geometric and stereoelectronic factors in these reactions are so different from those of the [2s + 2a] additions of compounds with cumulated double bonds discussed previously that the stereodifferentiating influence of auxiliaries in these reactions may be quite different.

An interesting and efficient asymmetric synthesis of chiral cyclopropyl compounds was described by Charette et al.[71] in the reaction of allyl β-D-glucopyranosides **73** with diethyl zinc/diiodomethane. The chiral cyclopropylmethylglucosides **74** were obtained in high yields and generally with excellent diastereoselectivity (ca. 100:1). Some appropriate examples are given in Table 5.

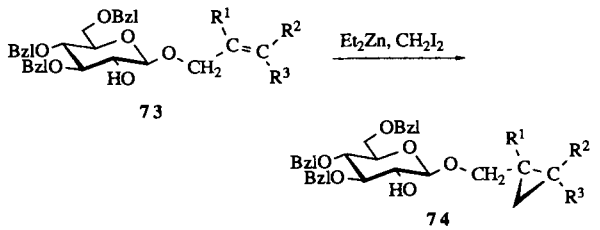


Table 5. Cyclopropanation of allyl-2-hydroxyglucopyranosides **73** [71].

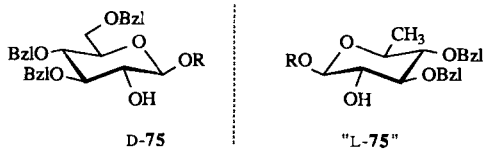
R	*T* [°C]	Diastereomeric ratio [a]
-OCH$_2$-(Pr)	−35 → 0	>50:1 (124:1)
-OCH$_2$-(Me)	−35 → 0	>50:1
-OCH$_2$-(Ph)	−35 → 0	>50:1 (130:1)
-OCH$_2$-(Ph)	−35 → 0	>50:1 (114:1)
-OCH$_2$-(Me, Me)	−35 → 0	>50:1 (111:1)

[a] Values in brackets refer to ratios obtained from the ^{13}C NMR spectra.

The unprotected 2-hydroxyl group is important for the diastereofacial differentiation in **73**. This group reacts with diethyl zinc and forms a coordinative anchor for the Simmons–Smith intermediate with the iodomethyl zinc unit.

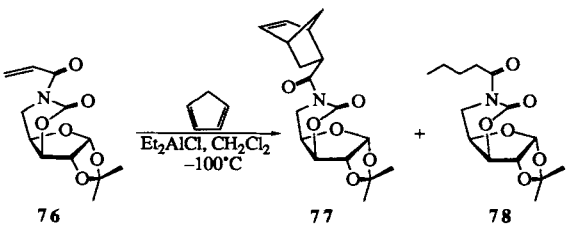
When diethyl zinc was used in only equimolar amounts rather than a tenfold excess, the diastereomeric ratio dropped to about 60:40. In addition, allylglucopyranosides in which the 2-position is protected showed only a modest asymmetric induction in cyclopropanation under standard conditions.[71a]

When this reaction was conducted with the auxiliary "L-**75**", which is pseudo-enantiomeric to D-glucose (D-**75**; see Section 4.1, **42**/**44**) and easily accessible from L-rhamnal, cyclopropanes with the opposite configuration were obtained stereoselectively. Similarly, in the reaction with the α-anomeric allyl glucosides corresponding to **73**, preferential formation of the cyclopropylmethylglucoside with the opposite configuration to that of **74** was observed.



The examples described above show that because of their steric and chelating potential carbohydrates are effective agents for the asymmetric shielding of the diastereotopic sides of components in cycloadditions. Initial results of hetero-Cope rearrangements of derivatives of diacetone glucose show that this selection principle can be successfully extended to other types of pericyclic processes.[72] The structure of the selected auxiliary must, of course, fit the reaction to be stereochemically controlled. Otherwise, the induction will be unsatisfactory. High selectivity is generally always obtained when unequivocal facial differentiation can be guaranteed by the regio- and stereoselective attachment of both the reacting functionality and the shielding groups. Without additional means this is frequently attained by attachment of the substrate structure to a secondary hydroxyl group of the carbohydrate auxiliary, and indeed especially when spatial requirements clearly favor a preferred conformation of the substrate. Fixing the reactive and shielding groups by complexation frequently leads to decisive increases in the stereoselectivity. This is particularly the case for substrates that are attached to the auxiliary at the anomeric position. Moreover, in this type of attachment, stereoelectronic effects (anomeric effects) also promote selectivity in the cycloaddition.

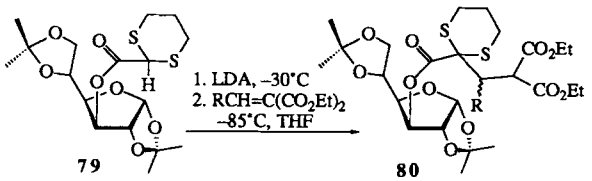
Nevertheless, in some cases the reaction takes an unexpected course. It makes sense to clarify the structures of unexpected products, as their formation could provide stimulus for further investigations. This is illustrated by work on the Diels–Alder reaction of the *N*-acryloxazinone **76** derived from xylofuranose.[73] The cycloaddition catalyzed by diethylaluminum chloride[51] was not only slow and incomplete, but also showed disappointingly low stereoselectivity. In addition to the Diels–Alder adduct **77** a side product **78** was isolated. The latter emerged[73] as a 1,4-adduct (a "Michael" adduct) of the catalyst and the acceptor **76**. The formation of this adduct led to a new route to the synthesis of β-branched carboxylic acids, which will be discussed in the following section.



5. Michael Additions

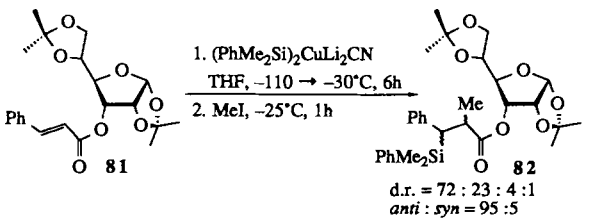
5.1. Michael Additions of Enolates and Cuprates

Carbohydrate derivatives can also be applied successfully for stereodiscrimination in Michael additions. Thus, chiral 1,3-dithian-2-carboxylic acid ester **79** (derived from diacetone glucose) was added, after deprotonation with LDA (at −30 °C), to benzylidenemalonic ester at −85 °C as a prochiral component. The diastereomeric ratios for the resulting ketoglutaric acid derivatives **80** lie between 90:10 and 93:7.[18, 73]



R = *m*-ClC$_6$H$_4$, (*S*):(*R*) = 90:10
R = Ph, (*S*):(*R*) = 93:7

In a sequence of reactions, consisting of a 1,4-addition of the silylcuprate $(PhMe_2Si)_2CuLi_2CN$ to the α,β-unsaturated ester derivative **81** of diacetone allose and subsequent methylation of the intermediate enolate with methyl iodide, a mixture of four diastereomeric products **82** was formed in the ratio 72:23:4:1.[74] After the carboxylic acid products were cleaved from the auxiliary, a 95:5 ratio of the *anti* and *syn* isomers was found. This result indicates that although the alkylation indeed takes place with high *anti* selectivity, the preceding Michael addition of the cuprate occurs with only moderate diastereoselectivity.



The Cu^{I}Cl catalyzed conjugate addition of Grignard reagents to the corresponding α,β-unsaturated esters was first considered in an early study on stereodifferentiation

with carbohydrates.[75] The reaction of the 3-*O*-crotonic ester prepared from 1,2;5,6-di-*O*-cyclohexylideneglucofuranose with phenylmagnesium iodide gave, after removal of the auxiliary, 3-phenylbutyric acid in 74% optical and 58% chemical yield.

Conjugate addition of organocuprates to Michael acceptors bound to carbohydrates, giving good yields and with a diastereoselectivity of 79:21 to 95:5 (Table 6), could be achieved by suitable modification of the carbohydrate structure.[76] Steric shielding by the benzyl group is apparently the sole factor responsible for the selectivity of the addition to **83**.

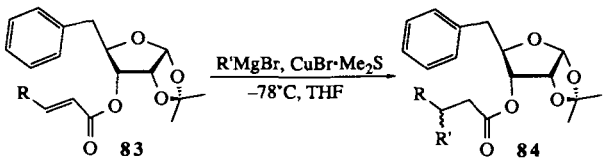


Table 6. Conjugate addition of cuprates to substrate **83** [76].

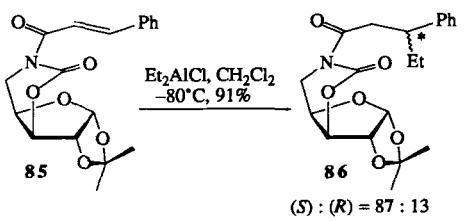
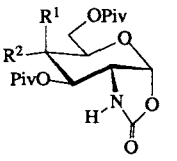
R	R′	Yield (**84**) [%]	Diastereomeric ratio
Me	Ph	74	(*S*):(*R*) = 97.5:2.5
Me	Et	65	(*R*):(*S*) = 95:5
Me	*i*Pr	72	(*S*):(*R*) = 95:5
Ph	Et	89	(*R*):(*S*) = 79:21
Ph	*i*Pr	69	(*S*):(*R*) = 87.5:12.5

5.2. 1,4-Additions of Alkylaluminum Compounds to Carboxylic Acid Derivatives

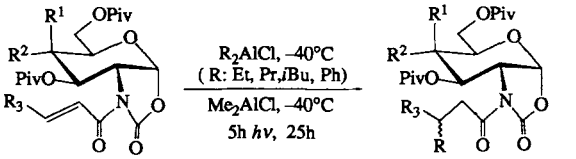
A new route to β-alkyl-substituted carboxylic acid derivatives has been provided by the 1,4-addition of diorganoaluminum chlorides to α,β-unsaturated *N*-acylurethanes. This route was developed based on the analysis of the by-products formed in the Diels–Alder reaction of oxazinone dienophiles catalyzed by aluminum Lewis acids (see Section 4.4, reaction of **76**). The cinnamic acid derivative **85** reacted in this new synthesis to give, when at least two equivalents of Et_2AlCl were employed, exclusive 1,4-addition and the 3-phenylvaleric acid derivative **85** in high yield and with a diastereoselectivity of 87:13.[77]



Further investigations into the preparative applicability of the reaction and its extension to other diorganoaluminum chlorides were first carried out on achiral[77] and chiral *N*-acyloxazolidinones (derived from the amino acid (*S*)-phenylalanine).[78] Whereas the higher homologues nPr_2AlCl, iBu_2AlCl, and Ph_2AlCl reacted smoothly at low temperature to give the 1,4-adduct exclusively, the transfer of a methyl group from Me_2AlCl was possible only with photochemical initiation or in the presence of atmospheric oxygen.[78] This unexpected contrast between the mode of reaction of methylaluminum compounds and that of higher alkylaluminum compounds is a striking characteristic of this 1,4-addition. Because of the moderate diastereoselectivity obtained with auxiliaries such as oxazinones like **85** or oxazolidinones derived from (*S*)-phenylalanine, bicyclic oxazolidinones **87** from 2-aminodeoxy sugars were developed in order to attain effective steric shielding of one side of the α,β-unsaturated acceptor and thereby higher diastereoselectivity in the 1,4-addition. After deprotonation of the nitrogen atom, the oxazolidinones **87** were treated with acid chlorides to give Michael acceptors **88** and **89**. The examples of the reactions



87a: R^1 = OPiv, R^2 = H
87b: R^1 = H, R^2 = OPiv



88: R^1 = OPiv, R^2 = H
89: R^1 = H, R^2 = OPiv
R_3 = CH_3,C_6H_5

90: R^1 = OPiv, R^2 = H
91: R^1 = H, R^2 = OPiv

carried out with these acceptors listed in Table 7 illustrate the stereodifferentiating efficiency of the carbohydrate auxiliaries derived from galactosamine and glucosamine. The β-branched carboxylic derivatives **90** and **91** were formed with excellent diastereoselectivity, in particular with the galactosamine auxiliary **87a**; both configurational series are accessible by choice of the groups R^3 and R.[79] The selectivity in the case of the glucosamine-oxazolidinone derivatives **89** is somewhat lower.

Table 7. Stereoselective Michael addition of diorganoaluminum chlorides with bicylic carbohydrate-oxazolidinones **87** as chiral auxiliaries [79].

R^1	R^2	R^3	R_2AlCl	*T* [°C]/ *t* [h]	Yield [%]	(*R*):(*S*)

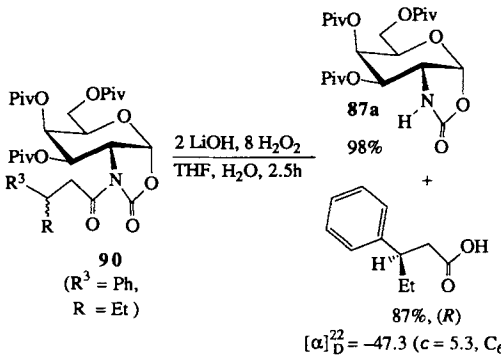
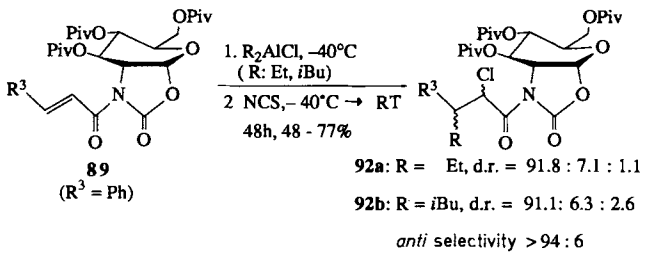
[a] Activation with 1 equiv Me_2AlCl. [b] Photochemical initiation.

As in the Diels–Alder reactions already discussed, the sterically demanding pivaloyl protecting group also offers an advantage. This group is inert towards strong aluminum Lewis acids and, in addition, permits the desired, pronounced steric control of the reaction. The diastereomerically pure β-branched carboxylic acid derivatives can generally be isolated in good yields after flash chromatography or by recrystallization. For substrate **90** (R^3 = Ph), for example, cleavage of the acid from the auxiliary with $LiOH/H_2O_2$ in THF/water proceeded in high yield (> 87%) and with almost quantitative recovery of the carbohydrate template.



Trapping the intermediate aluminum enolate formed in the 1,4-addition of higher organoaluminum compounds with *N*-chloro- or *N*-bromosuccinimide gave chiral β-branched α-halocarboxylic acid derivatives such as **92** with high *anti* selectivity.[80]

Based on the results obtained so far, the high diastereofacial selection potential of the bicyclic carbohydrate-oxazolidinone **87** provides a number of routes to chiral β-branched carboxylic acid derivatives. The use of various electrophiles

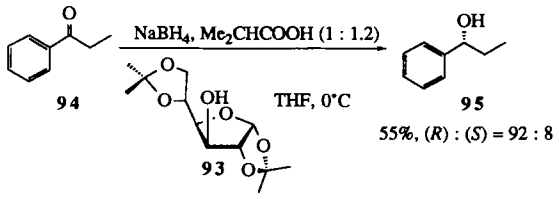


for the subsequent reaction with the enolates formed permits access to a wide spectrum of interesting products.

6. Carbohydrates as Components of Chiral Reagents and Promoters

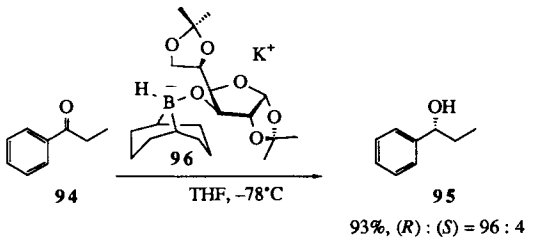
6.1. Complex Hydrides

Carbohydrates were employed quite early as chiral ligands for complex organoaluminum reducing agents.[20] In reactions with carbohydrate alcohols, preferably diacetone glucose **93**, modified complex borohydrides also proved to be efficient in the enantioselective reduction of prochiral ketones.[81] These reactions are influenced by temperature, molar ratios, solvent, and other additives in a complex way. Addition of Lewis acids such as zinc chloride raises the level but reverses the direction of induction.[82] The addition of carboxylic acids such as butyric acid was found to be of value;[83, 84] the direction of induction did not change but a higher enantiofacial differentiation was attained. The reduction of propiophenone (**94**) is a favorable example.[84]



Since several of the species formed from the reaction components could be responsible for the asymmetric induction,[83] interpretation of the steric course of the process is hardly possible. The use of dicyclohexylideneglucofuranose instead of **93** and of chiral carboxylic acids failed to bring about an increase in the stereoselectivity.[85]

Sterically demanding complex borohydrides of defined structure such as **96**, capable of reducing ketones even at –78 °C, were obtained from 9-borabicyclo[3.3.1]nonane, diacetone glucose, and potassium hydride in THF.[86] Propiophenone (**94**) was reduced to (*R*)-1-phenylpropanol (**95**) by **96** with excellent enantioselectivity. Under the same conditions the sterically demanding *tert*-butyl phenyl ketone gave practically pure (*R*)-carbinol. α-Keto esters could also be reduced with **96** to give the corresponding α-hydroxycarboxylic acids with high enantioselectivity.[87] α-Aminoketones were converted with **96** into chiral 2-aminoalcohols with the same direction of induction, but nevertheless with significantly lower enantiofacial differentiation.[88]



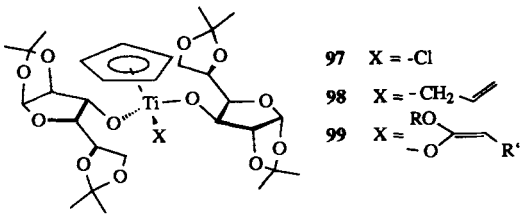
Phosphines and phosphinites[89–91] derived from carbohydrates have been used on numerous occasions as chiral ligands in asymmetric hydrogenations. For reasons of space, we are unable to consider this application in this review.

6.2. Chiral Titanates as Promoters in Aldol Reactions

As is the case for reductions with complex hydrides, it is also an advantage in other stereoselective syntheses when the inducing chirality of the auxiliary resides in the reagent, which, during the reaction, transfers a group diastereoselec-

tively to the substrate, but itself does not appear in the enantioselectively formed product. This is particularly the case for processes in which the covalent attachment of a chiral auxiliary is difficult to realize or causes undesired side reactions, as shown, for example, in the case of the carbohydrate enolate reactions (see Section 3).

A good solution to this problem, precisely for aldol reactions and related processes, was provided by Riediker, Duthaler, et al.[92-94] with the introduction of dialkoxy(chloro)cyclopentadienyltitanate **97**. In reactions with allyl Grignard reagents in ether/THF at 0 °C, **97** was converted into the chiral allyltitanate **98**. This complex reacted with



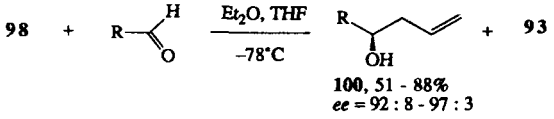
aldehydes at −78 °C in high yield and enantioselectivity to give the (*R*)-homoallylic alcohols **100**.[92, 95] Some examples of this reaction are listed in Table 8.

Table 8. Enantioselective syntheses of homoallylalcohols **100** using chiral allyltitanium reagent **98**[92].

R [a]	Yield (**100**)	*ee*	Config.	R [a]	Yield (**100**)	*ee*	Config.
phenyl	85%	90	(*R*)	*n*-propyl	78%	93	(*S*)
1-naphthyl	83%	88	(*R*)	isobutyl	55%	85	(*R*)
vinyl	61%	86	(*R*)	cyclohexyl	78%	92	(*R*)

[a] R (aldehyde).

Substitution in the cyclopentadienyl ligand of complex **98** had hardly any effect on the selectivity of the reaction. In contrast, exchange of the diacetone glucose ligand **93** for other carbohydrate alcohols always led to considerable loss of stereoselectivity. When diacetone-L-idose (5-epimer of **93**) was employed as the ligand, the (*S*)-configurated homoallylic alcohol was indeed formed preferentially, but with a diastereomeric ratio of only about 70:30.[96]



The diacetone glucose titanate complex also displays a high stereoselection potential in aldol reactions of ester enolates. The lithium enolate of the *tert*-butylacetate was treated with **97** to provide titanium enolate **99a** (R = *t*Bu, R' = H; DAG = diacetone glucose), which reacted with aldehydes to give chiral β-hydroxycarboxylic acid esters in enantiomeric ratios of 95:5 to 98:2 at −78 °C.[93, 95] A few examples demonstrating the efficiency of this process are given in Table 9.

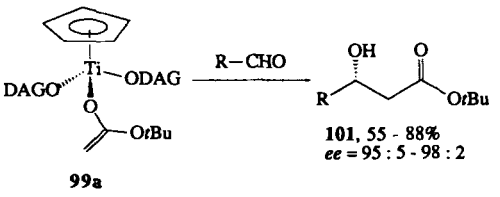


Table 9. Enantioselective aldol addition with titanium ester enolates **99a** [93].

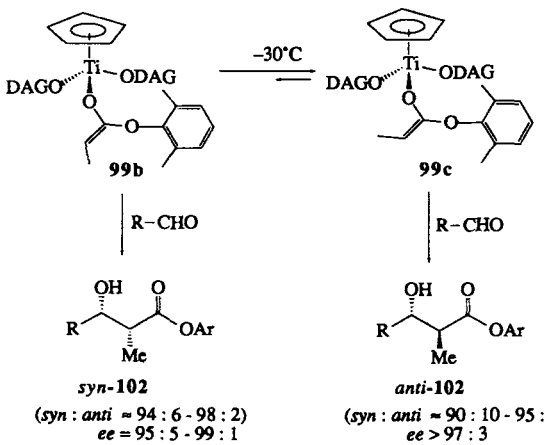
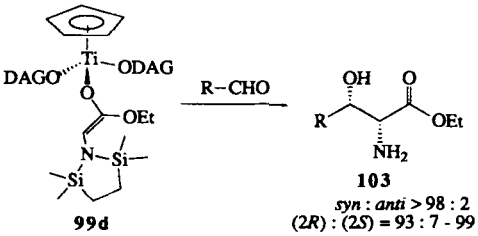
R [a]	Yield (**101**)	*ee*	R [a]	Yield (**101**)	*ee*
n-propyl	51%	94	cyclohexyl	70%	92
isobutyl	81%	94	α-styryl	64%	96
isopropyl	66%	95	phenyl	62%	95

[a] R (aldehyde)

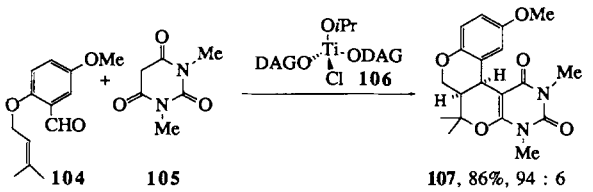
The preparative range of this aldol addition could be extended since both the (*Z*) and (*E*) series of titanium propionyl ester enolates (**99b** and **99c**, respectively; R = $C_5H_3Me_2$, R' = Me) are available. These complexes reacted with aldehydes with high diastereo- and enantioselectivity to give α-methyl-β-hydroxycarboxylic acid esters **102**.[93, 94]



The aldol reaction with titanium enolate **99d** (R = Et, R' = $C_6H_{16}NSi_2$), obtained from the N-protected glycine ethyl ester, gave β-hydroxy-α-amino acid esters **103** with high enantioselectivity .[94, 96] In some cases the reaction provided one of the four possible stereoisomers almost exclusively. β-Hydroxyamino acids are of interest for synthesis of drugs.

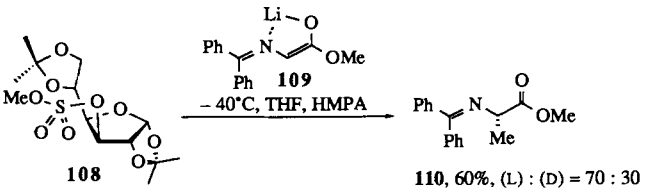


The modified diacetone glucose titanate **106** has recently been described as an effective Lewis acid catalyst in a tandem Knoevenagel–Diels–Alder reaction sequence.[97] The tetracyclic product **107** was formed with considerable enantioselectivity from aldehyde **104** and *N,N'*-dimethylbarbituric acid (**105**) via the Knoevenagel condensation product followed by its intramolecular cycloaddition.

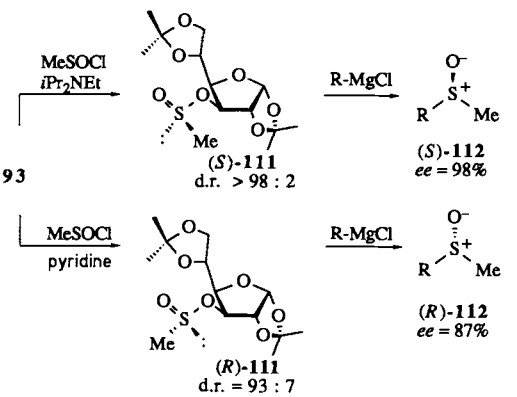


6.3. Electrophilic Reagents Bound to Carbohydrates

In contrast to the titanium and complex hydrido complexes, the mixed sulfate **108** from diacetone glucose reacts as a chiral electrophile. Lithium enolate **109** (obtained from the glycine methyl ester protected as a Schiff base) was alkylated with **108** to give the corresponding alanine derivative with predominant formation of the L enantiomer **110** (70:30).[98]



A powerful synthesis of chiral sulfoxides was attained by using diacetone glucose **93**, which was treated with methylsulfinyl chloride either in the presence of diisopropylethylamine to give the (*S*) diastereomeric product, sulfinate (*S*)-**111**, or in the presence of pyridine to give (*R*)-sulfinate (*R*)-**111**. As both diastereomeric sulfinates react with Grignard reagents with inversion at sulfur, one could obtain both enantiomeric series of the chiral sulfoxides **112**.[99]



Finally, we should mention that, in addition to other chiral compounds, carbohydrates also have been employed in experiments aimed at enantioselective protonation.[100, 101] In these and related[102] protonations with chiral proton sources, however, enantiomeric ratios of 80:20 have rarely been exceeded.

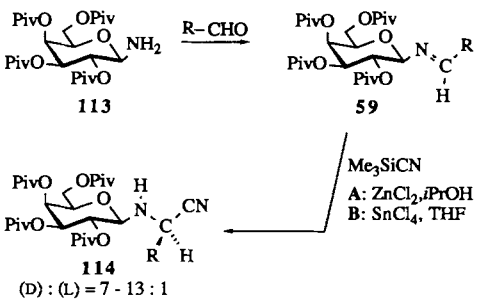
7. Stereoselective Syntheses with Glycosylamines

Glycosylamines are chiral cyclic aminoacetals, the nitrogen atom of which can be carried into the product being synthesized. Since the N-glycosidic bonds in these products are easy to cleave, separation of the selectively prepared chiral compound from the chiral carboxhydrate matrix can generally be achieved under mild conditions. As previously discussed in Section 4.2, glycosylamine Schiff bases **59** can act as heterodienophiles in aza-Diels–Alder reactions, thereby providing a stereoselective route to chiral nitrogen-containing heterocycles.[57] Even before these investigations, glycosylamines had been examined as chiral templates in the asymmetric synthesis of amino acids.

7.1. Strecker and Ugi Syntheses of α-Amino Acid Derivatives

The increasing importance of biomimetic drugs during the last few years has stimulated interest in the stereoselective synthesis of enantiomerically pure natural and non-natural amino acids.[103, 104] Among the known amino acid syntheses, the Strecker synthesis offers the advantage that it does not require the use of organometallic reagents and that only inexpensive components are employed.

In the stereoselective Strecker synthesis, tetra-*O*-pivaloyl-β-D-galactosylamine (**113**) has been shown to be the best of those derived from glycosylamines.[105] It could be converted with aldehydes to *N*-galactosylimines **59**, which reacted with trimethylsilylcyanide in the presence of either zinc chloride in isopropanol or tin tetrachloride in THF in a few hours to give nearly quantitative yields of *N*-galactosyl-α-aminonitriles **114**. The D-aminonitriles were thus formed in excess



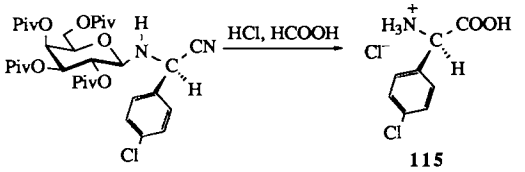
in the ratio 87:13 to 93:7.[106, 107] Still more fundamental for the preparation of enantiomerically pure amino acids was the discovery that pure D-aminonitrile diastereomers **114** can be obtained in high yields (75–90%) by simple recrystallization from *n*-heptane. As bases are not used, D-phenylglycine derivatives can be efficiently produced in this fashion (Table 10).

Table 10. Stereoselective Strecker synthesis of D-aminonitriles **114** with galactosylamine **113** as chiral auxiliary [106,107].

R	Method [a]	T [°C]/ t [h]	Yield [b] [%]	D:L
$CH(CH_3)_2$	**B**	−18/5	74	8:1
$C(CH_3)_3$	**B**	−18/3	86	13:1
C_6H_5	**A**	0/1.5	70	4:1
C_6H_4-4-CH_3	**A**	−18/8	87	12:1
C_6H_4-4-Cl	**B**	−18/6	84	11:1

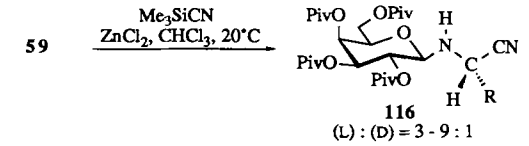
[a] **A**: $ZnCl_2$, isopropanol; **B**: $SnCl_4$, THF. [b] Yield of pure D diastereomer.

The free D-amino acids were obtained by treating the diastereomerically pure aminonitriles **114** with HCl/formic acid or HBr/acetic acid/dichloromethane. As shown with the example of 4-chlorophenylglycine **115**, the carbohydrate matrix could be removed without measurable racemization.[107]



115

An interesting characteristic of the Strecker synthesis with galactosylimines **59** is that the direction of induction can be reversed by a change in solvent. Reaction of **59** with trimethylsilylcyanide in the presence of zinc chloride in chloroform led to preferential formation of L-aminonitrile **116**.[108] Moreover, Strecker synthesis with imines **59** in chloroform showed a remarkable dependence on the temperature; the (*S*) selectivity (for R = *i*Pr) increased from 60:40 at −20 °C to 84:16 at +20 °C.[109]

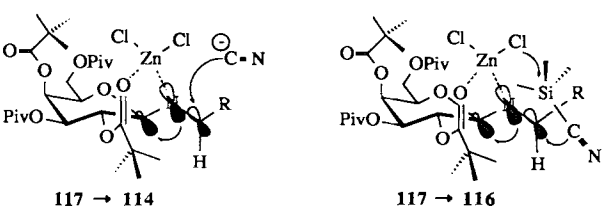


116

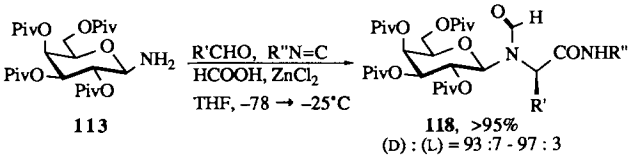
(L) : (D) = 3 - 9 : 1

The stereoselectivity in these Strecker syntheses of **114** and **116** and the opposing inductions observed in isopropanol and chloroform have been explained with the aid of zinc complex **117**. As a result of the delocalization of the π electrons in the C=N bond into the σ^* orbital of the C1–O bond, the Schiff bases **59** adopt the conformation illustrated in **117**. This was shown by a significant NOE in the ^{1}H NMR spectrum between the aldimine proton and 1-H. According to the NMR measurements this conformation is retained in the zinc complex (in both $[D_8]$THF and $CDCl_3$).

In polar media the cyanide released from the silylcyanide reacts with complex **117** preferentially by attack on the free back side to give D-aminonitriles.[106,107] In chloroform, however, free cyanide is not formed. In this case the nucleophilicity of the CN group must first be developed by interaction between the *exo* chloro ligand on zinc and the silyl group. After completion of this electronic circuit, which can only take place on the front side of the C=N bond, the CN group is sufficiently electron-rich to react with the imine, which in turn is activated by complexation. This geometry favors formation of L-aminonitriles **116**.[108] This alternative mode of reaction was confirmed in several other reactions. This process depends on whether a free nucleophile, or one that must first be developed during the process, reacts with the zinc complex of imines such as **59**.



117 → **114** **117** → **116**



113

118, >95%

(D) : (L) = 93 :7 - 97 : 3

Another amino acid synthesis in which galactosylamine acts as chiral template is the Ugi reaction.[110] When galactosylamine **113** was allowed to react with an aldehyde, an isocyanide, and a carboxylic acid (preferably formic acid) in the presence of zinc chloride in THF, *N*-galactosyl-amino acid amide derivatives **118** were obtained almost quantitatively. At −25 °C (for aliphatic imines −78 °C) the D-amino acid diastereomers **118** were formed with a diastereoselectivity of about 95:5.[110,111]

Phenylglycine derivatives **118**, even those containing electron-withdrawing groups, were furnished with high stereoselectivity. Diastereomerically pure D-amino acid amides **118** could be isolated in yields of 75–95% by simple recrystallization from heptane or heptane/dichloromethane. Aliphatic amino acid amides were recovered in diastereomerically pure form by recrystallization from methanol/water or by flash chromatography. A few examples are listed in Table 11.

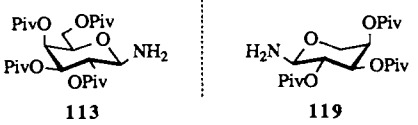
Table 11. Diastereoselective Ugi synthesis of amino acid amides **118** using D-galactosylamine **113** as the chiral auxiliary and *tert*-butyl isocyanide [110, 111].

R'	T [°C]/ t	D:L	Yield [%] [a]
n-propyl	−78/2 d	94:6	80
isopropyl	−78/2 d	95:5	86
tert-butyl	−25/3 d	96:4	80
phenyl	−25/24 h	95:5	80
styryl	−25/24 h	95:5	75

[a] Yield of pure 2-D-**118**.

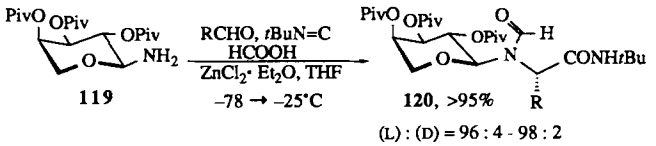
Similarly high stereoselectivities were observed in Ugi reactions with *O*-acetyl-protected galactopyranosylamine.[111] The high differentiation in this one-pot reaction can also be explained with the aid of the zinc complex of the intermedi-

ate imine (**117**). The free isocyanide nucleophile attacks this complex with a strong preference for the back side, where it encounters no steric repulsion. Thus, the D-amino acid amide diastereomers **118** are formed with high selectivity. In agreement with this interpretation, no reversal of the direction of induction was obtained when this Ugi reaction was carried out in chloroform. Nevertheless, in order to obtain the interesting L-amino acid derivatives by the stereoselective Ugi reaction, the pivaloyl-protected D-arabinopyranosylamine **119** was used as a chiral template, quasi-enantiomeric to **113**.[112]



113 **119**

The comparison shows that **119**, although belonging to the D series, is almost the mirror image of galactosylamine **113** used hitherto. The Ugi reaction of D-arabinopyranosylamine **119** with aldehydes, *tert*-butyl isocyanide, and formic acid in the presence of zinc chloride in THF gave the L-amino acid amide derivatives **120** in excellent diastereoselectivity and in high yield. Diastereomerically pure compounds **120**



119

were recovered in yields of 85–95% by recrystallization or flash chromatography.[113] The examples given in Table 12 illustrate that diastereomerically pure aliphatic, branched, aromatic, and heteroaromatic L-amino acid derivatives **120** can be prepared according to this process with high efficiency.

Table 12. Diastereoselective Ugi synthesis of L-amino acid amides using D-arabinopyranosylamine **119** as chiral matrix [112,113].

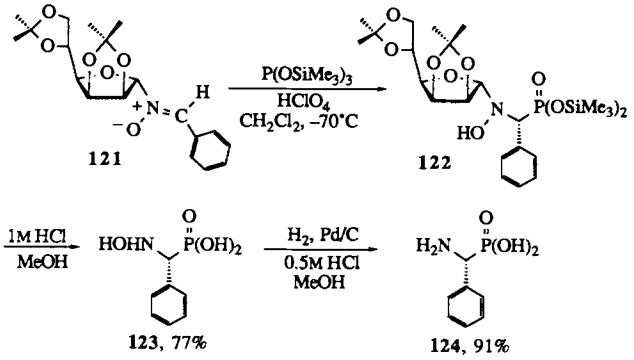
R	T [°C]/t [h]	L:D	Yield [%] [a]
tert-butyl	–25/72	97:3	85
benzyl	–78/24	97:3	87
4-chlorophenyl	–25/24	98:2	91
2-furyl	–25/24	96:4	85
2-thienyl	–25/24	4:96	85 (2*D*)

[a] Yield of pure 2-L-**120**.

Exchange of the *O*-acyl protecting group in the glycosylamine for an *O*-methyl protecting group generally leads to a reduction in the stereoselection in this Ugi reaction.[114] This observation indirectly confirms the importance of the mechanism of differentiation via complexes such as **117**.

7.2. Stereoselective Syntheses of α-Aminophosphonic Acids

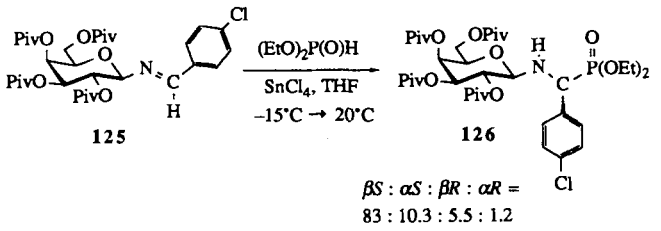
Chiral α-aminophosphonic acids are drawing increasing attention as enzyme inhibitors and building blocks for drugs. Stereoselective synthesis of such compounds by means of carbohydrate auxiliaries was achieved by Vasella et al.[115] These authors treated *N*-mannofuranosylnitrones such as **121**, already employed in 1,3-dipolar cycloadditions,[59] with phosphites like tris(trimethylsilyl)phosphite.



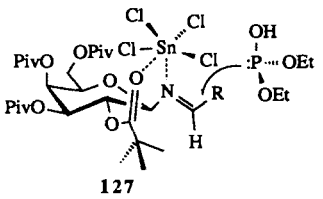
121 **122** **123, 77%** **124, 91%**

When the reaction was catalyzed with $HClO_4$, (*R*)-*N*-hydroxyphenylphosphaglycine (**123**) was obtained in high yield and with an optical purity of 87.5% after acidic workup. The latter could be increased to 95% by recrystallization. Hydrogenolysis of **123** (optical purity 95%) gave (*R*)-phenylphosphaglycine (**124**), the optical purity of which amounted to 88%.[115] For another aromatic aldehyde and three aliphatic aldehydes similar stereoselective syntheses of the corresponding aminophosphonic acids have been described. The reaction, the stereochemistry of which can be explained under the conditions given above by a kinetic *exo*-anomeric effect, shows a striking dependence on the Lewis acid catalyst employed, the amount of catalyst, and on the solvent. For example, **121** reacted selectively with the phosphite with catalysis by 0.01 equivalents of zinc chloride in benzene (78 °C) to give (*S*)-*N*-hydroxyphosphaglycine (*S*)-**123** (enantiomeric ratio 94:6). When the amount of zinc chloride was increased to 1 equivalent, the (*R*) enantiomer was again obtained in excess (o.p. > 83%).[115] To explain this effect it was assumed that the catalyst can influence both the conformational equilibrium of the nitrone and also the direction of approach of the phosphite. Based on NMR spectroscopic measurements on the nitrone **121**, it was concluded that zinc chloride can form a complex with both the *N*-oxide oxygen and with the O2 atom of the furanose component, in spite of the 1,2-*trans* arrangement of the ligands on the five-membered ring.

Complexation of a Lewis acid exerts an unmistakable influence on the facial differentiation in the formation of α-aminophosphonic acid esters from diethylphosphite and the Schiff bases **59** derived from galactosylamine **113**.[116] In the presence of catalytic amounts of tin tetrachloride in THF the four diastereomeric *N*-galactosyl-4-chlorophenylphosphaglycine esters **126** were formed from *N*-galactosylimine **125**. The β diastereoisomer **126** (83%) clearly predominated,

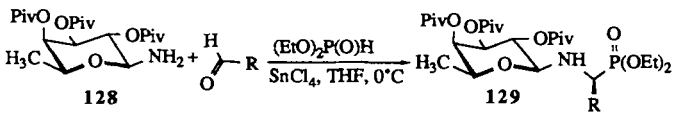


and overall a ratio of (*S*)/(*R*) diastereomers of 93:7 was found. The preferential formation of β-*S*-**126** is apparently due to tin complex **127**, in which the *Re* side of the imine **125** is effectively shielded. The phosphite attacks this complex as a free nucleophile (see the interpretation of the Strecker synthesis, Section 7.1) from the back side (*Si* side).



127

The reaction could also be carried out as a one-pot process, almost without loss of stereoselectivity, starting from galactosylamine **113**, the respective aldehyde, and phosphite. In addition, with fucosylamine **128** as a quasi-enantiomeric auxiliary, it was possible to prepare the series of (*R*)-diastereomeric α-aminophosphonic acid esters **129** with similar efficiency.[116] In reactions with the fucosyl derivatives



R = 4-MeC$_6$H$_4$: 81%
βR : αR : βS : αS = 85 : 4 : 10 : 1

the major diastereomers ((*R*) configuration) crystallized slowly. Since the corresponding *N*-glucosylaminophosphonic acid esters show a stronger inclination to crystallize, the major diastereomers, with (*S*) configuration, could be obtained in pure form.[116] This tendency to crystallize is effected largely by the pivaloyl protecting group.[117] The utility of this group for the isolation of enantiomerically pure α-amino acids[105–113] has already been documented.

7.3. Chiral Homoallylamines

Although the utility of the quasi-enantiomeric pair D-galactose and L-fucose had already been demonstrated in earlier stereoselective syntheses of (*S*)-[118,119] and (*R*)-homoallylamines,[120] the reaction of aldimines with allyltrimethylsilane had not yet been described for the simple, achiral case. The achievement of the reaction with *N*-glycosylimines such as **59** with Lewis acid catalysis can probably be traced back to the higher electrophilicity of these Schiff bases of semiaminal ethers such as **113** and **128**. In THF, however, the reaction must be initiated with 2.2 equivalents of tin tetrachloride and conducted at 0–25 °C. Nevertheless, high to excellent stereoselectivity was attained, and the (*S*)-homoallylamine derivatives **130** were preferentially formed from galactosylimines **59** in a ratio of 7–27:1. In this manner, however, the process was possible only with imines **59** derived from aromatic aldehydes. Some examples are listed in Table 13.

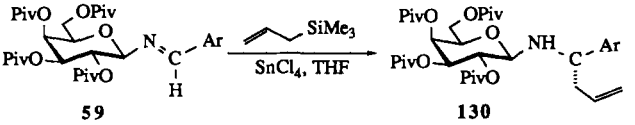


Table 13. Diastereoselective synthesis of *N*-galactosyl-1-arylhomoallylamines **130** [119].

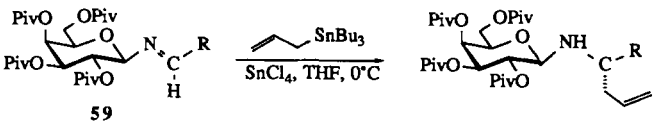
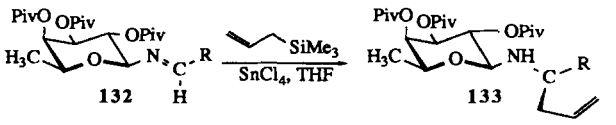
Ar	*t* [d]	Yield [%]	(*S*):(*R*)
4-ClC$_6$H$_4$	2	49	22:1
C$_6$H$_5$	3	65	14:1
4-O$_2$NC$_6$H$_4$	2.5	73	8:1
4-MeC$_6$H$_4$	4.5	55	22:1
4-NCC$_6$H$_4$	3	49	15:1

Under these conditions the analogous imines **59** of aliphatic aldehydes undergo anomerization and decomposition. Their conversion to homoallylamines **131** was achieved, however, at −78 °C with allyltributylstannane instead of allylsilane, again in the presence of $SnCl_4$ (1.2 equivalents). Thus, (*R*)-homoallylamines **131** were obtained selectively with the same direction of induction.[118,119] The α anomers of **131** appeared as side products, formation of which occurred with lower stereoselectivity.



131a: R = *n*-C$_3$H$_7$, 32%, (*R*) : (*S*) = 24 : 1
131b: R = *n*-C$_9$H$_{19}$, 37%, (*R*) : (*S*) = 8 : 1

If these reactions are conducted with the *O*-pivaloyl-protected L-fucosylimines **132** instead of the quasi-enantiomeric *N*-galactosylimines **59**, then selective formation of the (*R*)-configurated homoallylamines **133** (R = aryl) and the (*S*)-homoallylamines (R = unbranched alkyl group) is possible.[120] The (*R*)-homoallylamines **133** were formed with high selectivity from imines derived from aromatic amines, whereas the aliphatic compounds again reacted only with allyltributylstannane to form **133** at −78 °C in low yields



and in this case with only moderate selectivity. A few examples can be found in Table 14.

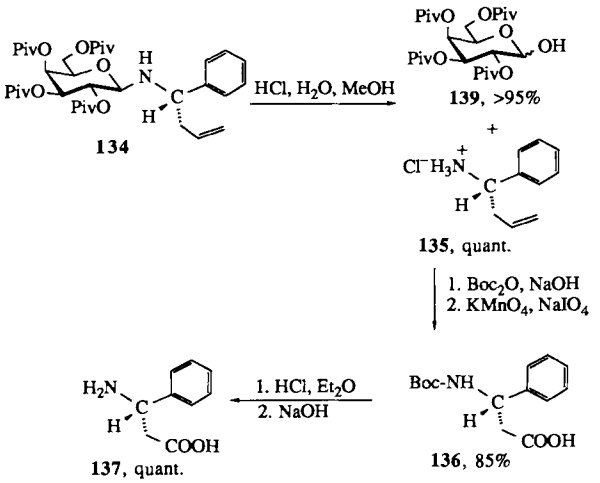
Table 14. Stereoselective synthesis of *N*-(L-fucosyl)-homoallylamines **133**[120].

R	*T* [a]/*t*	Yield [%]	(*R*):(*S*)
4-ClC$_6$H$_4$	RT/36 h	66	9:1
C$_6$H$_5$	RT/4 d	44	23:1
4-O$_2$NC$_6$H$_4$	RT/2 d	68	20:1
4-MeC$_6$H$_4$	RT/60 h	43	49:1
4-NCC$_6$H$_4$	RT/2 d	56	13:1
n-C$_3$H$_7$	−30 °C/36 h	26	4.5:1

[a] RT = room temperature.

Most *N*-fucosylhomoallylamines **133** are crystalline and can be obtained as the pure (*R*) diastereomer or as a strongly enriched mixture simply by recrystallization. The homoallylamines **130**, **131**, and **133** can be converted in a variety of ways into other chiral products.

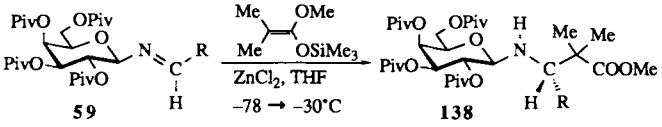
1-Phenylhomoallylamine **135** was released quantitatively from the carbohydrate auxiliary by treatment of the phenyl derivative **134** with aqueous methanolic hydrochloric acid. After introduction of the Boc protecting group (Boc = *tert*-butoxycarbonyl) and oxidation of the double bond, the Boc-protected *β*-phenyl-*β*-alanine **136** was obtained; acidolysis provided free (*S*)-*β*-phenyl-*β*-alanine (**137**).



After its removal the carbohydrate auxiliary was recovered almost quantitatively. (*S*)-*β*-Phenyl-*β*-alanine (**137**), a precursor to Winterstein's acid,[121] was thus obtained from galactosamine **113** in six steps with an overall yield of 41%. In contrast, a 15-step synthesis from L-diethyltartrate provided (*S*)-**137** in 4.3% yield and with a lower optical purity.[122] This comparison illustrates the utility of allylsilane additions to *N*-glycosylimines.[118–120]

7.4. Syntheses of Chiral *β*-Amino Acids

Glycosylimines, for example those of type **59**, offer an alternative, direct, and highly stereoselective synthesis of chiral *β*-amino acids. They react with silylketene acetals in THF under catalysis by zinc chloride in the fashion of a Mannich reaction to give *N*-glycosyl-*β*-amino acid esters **138**, as shown by the reaction with the silylketene acetal of isobutyric acid methyl ester.[123] The reaction proceeded with high

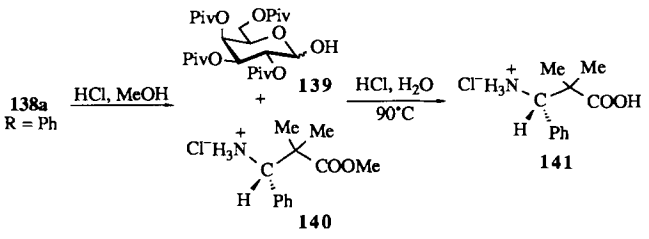


stereocontrol and frequently produced products with a diastereomeric ratio of over 100:1. An effective stereoselection was observed even at room temperature. Some examples are listed in Table 15.

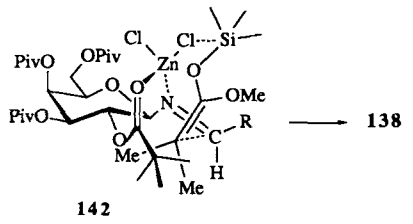
Table 15. Diastereoselective synthesis of *N*-galactosyl-*β*-amino acid esters **138** using an asymmetric Mannich reaction[123].

R	*T* [°C]/*t* [h]	Yield [%]	L:D
3-ClC$_6$H$_4$	−30/24	90	68:1
C$_6$H$_5$	−30/24	89	150:1
4-FC$_6$H$_4$	−30/24	88	105:1
2-naphthyl	+30/72	90	10:1
n-C$_3$H$_7$	−30/24	83	250:1

The preferred formation of the (*S*)-diastereomeric *β*-amino acid ester **138** was proven by conversion of the phenyl derivative **138a** into free *β*-phenyl-*α*,*α*-dimethyl-*β*-alanine (**141**), the (*R*) enantiomer of which is known in the literature.[124] Treatment of **138a** with HCl in methanol led to quantitative cleavage of the N-glycosidic bond. The auxiliary **139** was completely recovered. Warming the *β*-amino acid ester **140** in aqueous HCl gave the free (*S*)-amino acid **141**. This procedure is generally applicable for the synthesis of free enantiomerically pure *β*-amino acids from diastereomers **138**.



Attack on the *Re* side of the *N*-galactosylimine–zinc complex **117** is a prerequisite for the highly selective formation of the (*S*)-configurated *β*-amino acid diastereomers **138**. This result can be explained by an initiatiating interaction of the silyl group in the silylketene acetal with one of the chloro ligands on the zinc atom (**142**) similar to the case of the (*S*)-selective Strecker synthesis in chloroform (see **117** → **116**, Section 7.1). Attaching the reaction partners steers the approach such that it occurs selectively on the *Re* side of the imine (front side in **142**). This interaction between Cl and Si, illustrated for **142**, generates the required nucleophilicity of

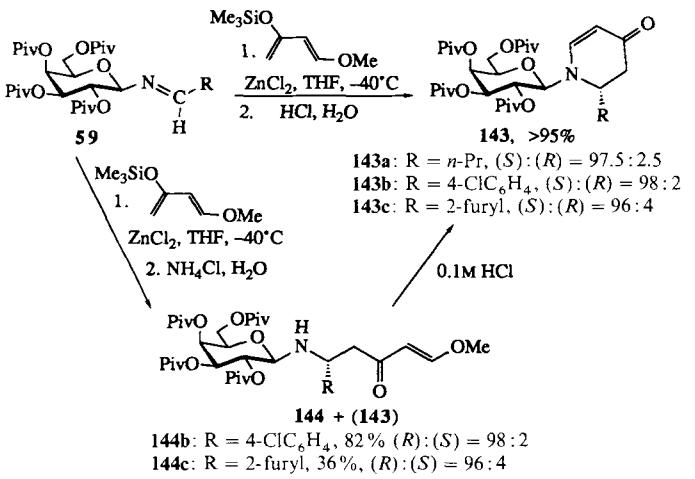


142 → 138

the ketene acetal and leads the way to the C–C bond forming electron transfer. This interpretation was prompted by the stereochemistry observed in presumed hetero-Diels–Alder reactions between galactosylimines **59** and silyloxydienes (see Section 7.5).[125]

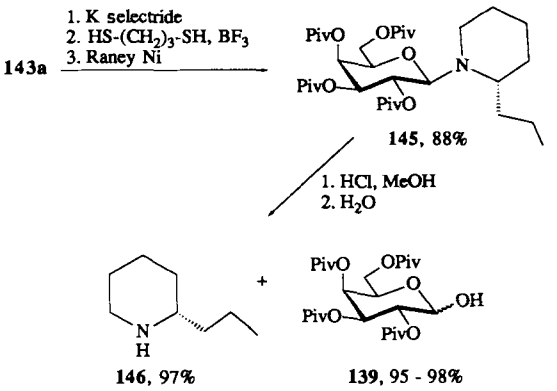
7.5. Chiral 2-Substituted Piperidines and Mannich Bases

In the course of investigations on the hetero-Diels–Alder reaction of *N*-galactosylimines **59**[57] (see Section 4.2), 1-methoxy-3-trimethylsiloxybuta-1,3-diene[126] was employed as an electron-rich diene. As a result of the high reactivity of the latter, the reaction proceeded under catalysis by zinc chloride in THF at low temperature (−40 to −20 °C). After hydrolysis with dilute hydrochloric acid, *N*-galactosyl-2,3-dehydropiperidin-4-one derivatives **143** were obtained in high yield and excellent stereoselectivity. The reaction does not proceed as a concerted cycloaddition, as only shown when the products were hydrolyzed with ammonium chloride solution. The initially formed Mannich base **144** could then be isolated and characterized. The diastereomeric ratios

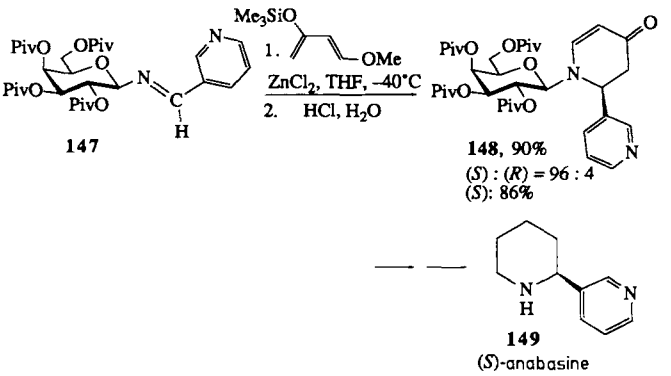


were obtained by analytical HPLC of the hydrolyzed reaction solution and gave the same values for **143** and **144**.[125] According to this, the formation of the chiral piperidinones **143** proceeds as a tandem Mannich–Michael addition, which is terminated by the elimination of methanol in the condensation step. The major diastereomers of the chiral heterocycles **143** were obtained in pure form in yields of 60–90% by recrystallization or flash chromatography.[125]

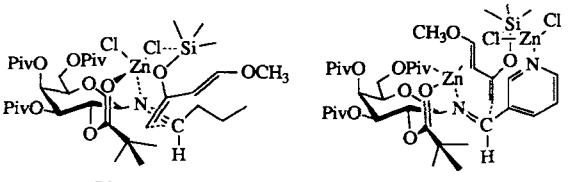
Piperidinones are starting materials for further transformations. In this context reduction and deoxygenation of **143a** gave *N*-galactosylconiine **145**. After the straightforward removal of the carbohydrate matrix, (*S*)-coniine (**146**) was obtained in enantiomerically pure form. The absolute configuration of the Mannich bases **144** and the piperidinones **143** were thereby clarified at the same time.



The Schiff base (**59**) of 3-pyridinaldehyde **147** underwent the tandem Mannich–Michael process with 1-methoxy-3-silyloxybutadiene with similarly high stereoselectivity (96:4). Two equivalents of zinc chloride were required, however, and the opposite direction of induction was shown with formation of (*S*)-piperidinone **148**.



The pure major diastereomer **148** was again isolated in high yield by simple flash chromatography. By means of an analogous reaction series as that used for coniine, compound **148** was converted into enantiomerically pure (*S*)-anabasine (**149**). This process brought to light the surprising opposing direction of induction and initiated the more detailed investigation of the presumed cycloadditions. The opposite diastereofacial selectivity in the preliminary Mannich reaction leading to **145** and **148** was explained by the reaction of the zinc complexes **150** and **151** with the silyldienol ether.[125]



The reactions of the Schiff bases **59** with the silyloxydiene required only one equivalent of zinc chloride. The stereochemistry of the products **143** formed can be explained by a reaction pathway (**150**) analogous to that of the silylketene acetal reaction (**142**). In the reaction with 3-pyridylaldimine **147** the first equivalent of zinc chloride coordinates to the more nucleophilic nitrogen atom of the pyridine. This equivalent of zinc chloride is thus no longer available for activation of the imine, but carries the more nucleophilic chloro ligands that favor the interaction with the silyloxydiene molecule in **151** and effect the alternative introduction of the nucleophile to the *Si* side (back side) of the imine. These interpretations of the course of the reaction are working hypotheses, which nevertheless permit systematic conclusions to be made regarding the selection processes taking place on carbohydrate auxiliaries, and which also stimulate new experiments. In this fashion, concepts have been developed, in particular for the reactions of glycosylamines, that permit predictions to be made concerning the stereochemistry expected from the envisaged processes involving carbohydrate auxiliaries.

8. Characteristics of Stereoselection with Carbohydrates

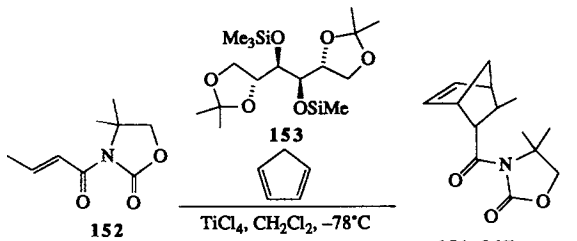
As stereodiscriminating auxiliaries carbohydrates offer a variety of possibilities for spatial differentiation at a reactive group. In principle, numerous parameters are provided for adjustment of a desired stereoselectivity—the choice of carbohydrate, the regioselective attachment of the substrate unit, the selected introduction of sterically shielding groups, the epimerization at chiral centers, and the organization of reactive groups and the functional groups on the carbohydrate by formation of complexes. Steric shielding predominantly characterizes, for example, the function of diacetone glucose in chiral complex borohydrides,[81-88] and in the chiral titanium Lewis acids,[92-96] which sterically control aldol reactions and the nucleophilic transfer of allyl groups to carbonyl compounds very effectively. The stereoselectivity of cycloadditions is also sterically controlled in the absence of coordinating Lewis acids; the effects of attachment at, for example, the 3-position of diacetone glucose[45, 56] are generally greater than those obtained by attachment at the anomeric center.[40, 41, 43-45]

If steric and complexation effects can be combined to give a strong facial differentiation, then high stereoselectivity can be attained, as has been shown, for example, for Diels–Alder reactions[46-48, 50] and cyclopropanations.[71]

A particular characteristic of carbohydrate auxiliaries is provided by the striking stereoelectronic effects, in particular those that involve the anomeric substituents. Thus, the excellent stereoselectivity in the cycloaddition to anomeric chloronitroso-mannofuranoses[53] can be traced back to an *exo*-anomeric effect that fixes the heterodienophile spatially. If steric, stereoelectronic, and complexing influences can be cooperatively combined, an effective stereoselection can be established, especially for attachment of the reacting species at the anomeric center. This is underlined by the Strecker and Ugi syntheses of α-amino acid derivatives and [105-113] the Mannich reactions to give β-amino acid esters[123] and chiral piperidine derivatives, which open up routes to stereoselective syntheses of alkaloids.[125] The high stereoselectivities of the reactions of allylsilanes and -stannanes with glycosylimines result from the same sources.[118-120] Bicyclic carbohydrate auxiliaries generate a particularly effective facial differentiation that permits, for example, the 1,4-addition of alkylaluminum compounds to unsaturated carboxylic acid derivatives to be steered with high selectivity.[79] Furthermore, carbohydrates offer the possibility of synthesizing both series of enantiomers of a chiral product alternatively and selectively, as was demonstrated for the pair galactosylamine and D-arabinosylamine in the Strecker and Ugi syntheses[110-113] and later also in cycloadditions.[48, 71]

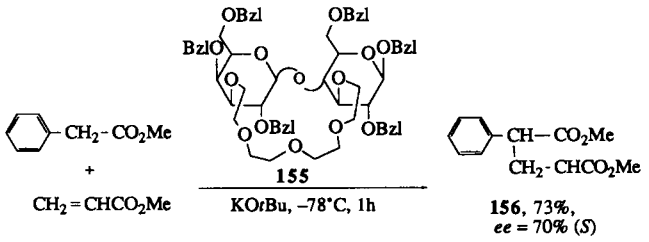
A multitude of interesting chiral products are accessible in diastereo- or enantioselective fashion, either with carbohydrate auxiliaries or with carbohydrate reagents. These include chiral carbocycles, heterocycles, branched carboxylic acids, secondary alcohols, β-lactams, and α- and β-amino acids. The interest in the stereodifferentiating potential of carbohydrates may continue to increase, so that in addition to the well-developed ex-chiral pool syntheses, in which carbohydrate units are built into chiral products, the use of carbohydrates as versatile and easily modified chiral auxiliaries in stereoselective synthesis will be established as an independent research area. In the field of enantioselective catalysis[127] the hitherto rarely considered carbohydrates (neglecting hydrogenation catalysts) also appear to bear interesting potential.[128] In an early study Inch et al.[129] employed diacetone glucose **93** as an equimolar solvent additive to steer a Grignard–carbonyl reaction stereoselectively. In the addition of MeMgBr to cyclohexyl phenyl ketone the corresponding methylcarbinol was obtained in 70% optical and 95% chemical yield.

Chiral Lewis acids such as **153**, derived from D-mannitol, were used successfully as equimolar additives in asymmetric Diels–Alder reactions of cyclopentadiene with *N*-crotonyl-4,4-dimethyloxazolidin-2-one (**152**).[130]



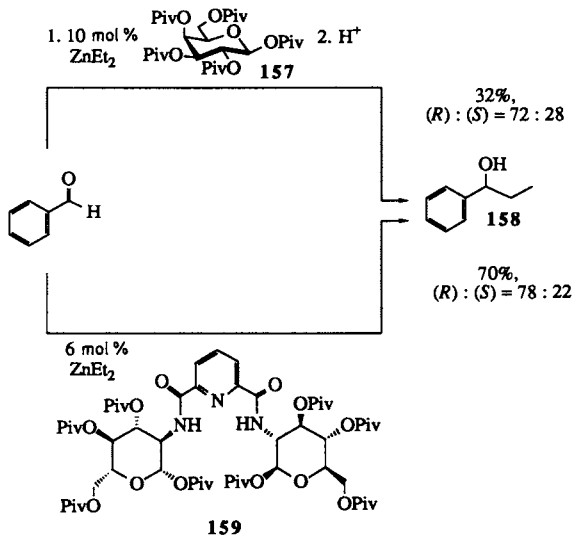
In the field of catalytic enantioselective processes, application of macrocyclic lactose derivatives leads to asymmetric Michael additions. Thus, phenylacetic acid methyl ester underwent smooth addition to methyl acrylate at −78 °C in the presence of potassium *tert*-butylate and catalyst **155** to give **156** in 70% optical and 73% chemical yield.[131]

Catalysis of the addition of diethyl zinc to aldehydes such as benzaldehyde can be influenced enantioselectively by carbohydrate catalysts. Addition of penta-*O*-pivaloyl-β-D-galactopyranose (**157**) to the reaction of benzaldehyde with



diethyl zinc in toluene gave 1-phenylpropanol with considerable excess of the (*R*) enantiomer **158**.[132] It is remarkable that **157** is not only relatively planar but also contains no acidic functional groups, as usually required for catalysis of reactions of diethyl zinc.

When the more complex diamide **159**,[133] obtained simply from pyridine-2,6-dicarboxylic acid and glucosamine, was employed in this reaction as catalyst, a completely chemoselective reaction was observed. No benzyl alcohol was formed by hydride transfer. The transfer of an ethyl group



proceeded with an enantioselectivity of 4:1 in favor of the (*R*) enantiomer **158**.[133] It is easy to see that carbohydrates can be converted into highly selective catalysts for enantioselective synthesis and that these generally inexpensive, naturally occurring, regenerable compounds will open up a further, attractive field of application.

We thank the Deutsche Forschungsgemeinschaft, the Bundesminister für Forschung und Technologie, and the Fonds der Chemischen Industrie for the financial support of our work. K. R. thanks the Adolf-Todt-Stiftung of the University of Mainz for a stipend and the Fonds der Chemischen Industrie for a doctoral stipend. H. K. expresses his gratitude for the stimulating teamwork of all those co-workers whose ability and enthusiam have helped to further the cause of stereoselective syntheses with carbohydrates. In addition to the coauthor these include Joachim Weissmüller, Bernd Müller, Jürgen Mohr, Wilfried Sager, Klaus-Jürgen Pees, Waldemar Pfrengle, Matthias Decker, Wolfgang Stähle, Dirk Schwanzenbach, Sabine Laschat, Stefan Engel, Ingo Ganz, Michael Puhl, Helmut Haning, Dominique Hebrault, Andreas Burgard, Markus Weymann, and Arnim Stamm.

Dynamic Solvent Effects on Electron-Transfer Reactions

By Hans Heitele*

Electron-transfer processes in solution are among the most important reactions in chemistry and biology. The huge number of redox reactions of transition metal ions and complexes, many preparatively important oxidations and reductions of organic compounds, photosynthesis, and metabolism are only a few examples where electron-transfer reactions play a pivotal role. This ubiquity, as well as their relative simplicity, makes them excellent models for the study on a molecular level of chemical reactions in solution. A particularly important question in chemical reaction dynamics in solution is the influence of the solvent on the reaction rate. In this context one distinguishes between static and dynamic solvent effects. Static effects refer to the stabilization of reactants, transition state, and products, that is, how the solvent affects the free energies of these species and the energy of activation. This interpretation of solvent effects on all kinds of chemical reactions is well established. A more recent development is the investigation of the influence of solvent dynamics on the rate of a reaction. The transfer of an electron is usually thought to be triggered by a fluctuation of the dielectric polarization in the surrounding solvent. The dynamics of such fluctuations is determined by the finite response time of the orientational polarization of the solvent. Under certain conditions this dielectric response time can become the rate-determining factor of the reaction. In this article I intend to give a review of these modern developments in the theory and experimental study of electron-transfer processes. We shall see that solvent dynamics may lead to a whole plethora of phenomena in reaction dynamics. The concepts needed for their description are not limited to electron transfer but bear relevance to many other chemical reactions in solution.

1. Introduction

Electron-transfer (ET) reactions in solution have been one of the most thoroughly investigated subjects in chemical reaction dynamics over the last decade.[1-12] Advances in the synthesis of tailor-made, artifical electron donor–acceptor systems and the availability of spectroscopic techniques for dynamic measurements with high temporal resolution have led to a wealth of new experimental results. Major progress has been made on the dependence of ET rates on the free energy of reaction (driving force),[13-17] on the donor–acceptor distance,[14, 18-26] as well as on the static properties of the solvent.[27-32] Some elements of ET research such as energetic control of ET rates or the Marcus cross-relation have already become part of textbook chemistry.[33]

More recently, the development of ultrafast optical spectroscopy and intensive theoretical research have shifted interest on effects of solvent dynamics on ET. It has become increasingly evident that many basic assumptions in ET theory will no longer obtain when the actual transfer step occurs on a shorter time scale than the dynamics of the surrounding solvent. In this case the solvent dynamics during the reaction has to be taken into account explicitly. Because of the many-body nature of the interaction between the reacting species and a large number of solvent molecules, this dynamics is essentially stochastic in character. Although stochastic barrier crossing has been a well-known concept in reaction dynamics at least since Kramers's work in 1940,[34] its application to ET reactions is a fairly recent development. An additional complication here is that there are adiabatic as well as nonadiabatic reactions involving one or two potential energy surfaces (PESs). The proper description of a reaction will crucially depend on the intimate relationship between stochastic motion across the activation barrier and hopping between PESs.

On the other hand the comparatively advanced degree of understanding of electron-transfer processes promises a very detailed insight into the basic mechanisms of the dynamic interaction of reacting species with the surrounding solvent. Thus the more general importance of these ET studies is as a test case for some of the most fundamental concepts of reaction dynamics in solution.

Progress in the study of dynamic solvent effects is extensively documented (see refs [35-55] for theory and refs. [56-77] for experiment). In addition to many research papers, a number of reviews of the subject have appeared recently. Maroncelli et al.[78] and Simon[79] focus on time-resolved studies of polar solvent dynamics. Weaver and McManis[80] discuss recent results on bimolecular electron self-exchange (i.e., symmetrical) reactions. Barbara and Jarzeba[81] extensively review their own work on ultrafast intramolecular electron-transfer reactions and solvation of the excited state. Bagchi[82] summarizes mostly theoretical developments in the dynamics of polar solvation and briefly discusses charge-transfer reactions.

However, despite these authoritative accounts of the state of progress of dynamic solvent effects an experimentalist or an interested nonexpert might look for a more general presentation of fundamental theoretical aspects, as well as a critical assessment of the present state of experimental verification. This does not require a rigorous derivation of these effects. Instead, the following article will focus on qualitative arguments using characteristic length and time scales.[39-41, 83-85] In this respect it borrows heavily from the seminal paper by Frauenfelder and Wolynes[83] on the

effects of friction and nonadiabaticity on barrier crossing phenomena.

The organization of this paper is as follows: Section 2 develops general concepts of ET reactions and their description within a transition-state (TS) theory. How dielectric friction effects on ET reactions arise and how they affect the reaction rate is discussed next. This is shown in terms of the two basic theoretical models used in this context. Section 3 presents the fundamental ideas of Kramer's approach to barrier crossing in the presence of friction and modifications due to nonadiabaticity of the reaction. Section 4 explains the physical aspects of the (apparently) very different model of Sumi and Marcus.[45] These theories require a detailed knowledge of the dynamic dielectric response of the solvent used. Recent results on the characterization of the dielectric relaxation of polar liquids are briefly discussed in Section 5. Section 6 finally gives a critical, although necessarily incomplete review of recent experiments and how they fit into the predictions of Sections 3 und 4.

In ET reactions accompanied by bond breaking, bond formation, or by a significant conformational change ("large amplitude motion"), the overall reaction rate is very often limited by the progress of these structural changes and not by the actual electron transfer. In order to avoid such complications we shall focus on ET reactions of the outer-sphere type[2, 4-6, 8] with the reactants kept at a fixed distance in a well-defined geometry.

2. Transition-State Theory of Electron Transfer

In TS theory the system is assumed to be in (quasi-) equilibrium between the reactant state and the activation maximum. ET is described as the crossing of the activation barrier along a specific coordinate in a straight trajectory. It must be borne in mind that the electronic change itself may be a rate-limiting factor.

2.1. Potential Energy Surfaces in Electron Transfer

Like most other chemical reactions, ET processes can be discussed as motions on, and transitions between, potential energy surfaces (PESs).[1-7, 54] These PESs represent the potential energy of the nuclei of the entire system consisting of electron donor, acceptor, and solvent environment, as a function of the nuclear coordinates. Reactants or products in (quasi-)equilibrium correspond to local minima on PESs.

In general the potential energy of the entire system is a complex function of a very large number of these coordinates specifying bond lengths and bond angles within the donor and acceptor themselves (intramolecular coordinates), as well as the position and orientation of the surrounding solvent molecules (solvent coordinates). An explicit inclusion of all these coordinates in a theoretical treatment is impossible. In most cases they are summarily combined into one or a small number of high-frequency (intramolecular) vibrational coordinates to be treated by quantum mechanics and a one classical (solvent) coordinate. The choice of the solvent coordinate is explained in Section 2.2. However, this reduction of the degrees of freedom necessitates a reinterpretation of PESs as free energy surfaces (FESs) as will be argued in Section 2.2.

It is customary to distinguish diabatic and adiabatic PESs (or FESs) (see Fig. 1). The motivation is as follows. In order to speak of reactants and products at all, these states must be metastable for a short time. The idea is that the total Hamiltonian $\boldsymbol{H}$ of the system can be partitioned into a zeroth-order part $\boldsymbol{H}_0$ and a weak perturbation $\boldsymbol{V}$. Reactants or products are eigenfunctions (stable states) of $\boldsymbol{H}_0$ in which the electron to be transferred is localized either on the donor or the acceptor.[86]

A Born–Oppenheimer approximate wave function to these zeroth-order Hamiltonians gives the diabatic PESs U_R and U_P for the two states. The shift of the minima for reactants and products takes account of the change in the solvent and

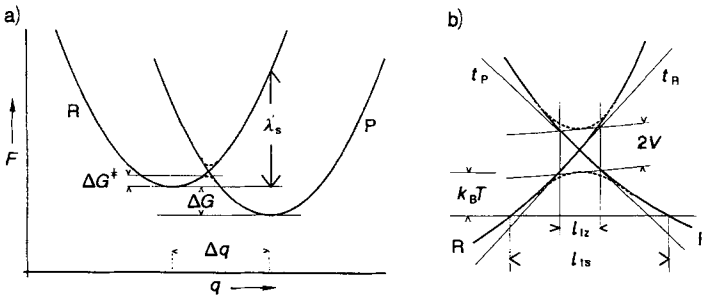

Fig. 1. a) Free energy surfaces (FESs) F used in the discussion of electron-transfer reactions as functions of a generalized solvent coordinate q. Solid lines: diabatic FESs of reactants R and products P: $F_R = 1/2 f_s q^2$, $F_P = 1/2 f_s (q - \Delta q)^2 + \Delta G$; dashed lines: adiabatic FESs in the Landau–Zener (LZ) region. λ_s = solvent reorganization energy. b) Definition of LZ and transition state (TS) regions and estimate of the corresponding lengths l_{Iz} and l_{Is} (t_R, t_P: tangents to the diabatic FESs R and P at the intersection).

Hans Heitele was born in Friedrichshafen am Bodensee in 1956. He studied chemistry at the University of Constance and later at the Technical University in Munich where he earned his Ph.D. in 1986 for research on photoinduced electron-transfer reactions under the supervision of Prof. M. E. Michel-Beyerle. Since 1986 he has been working on his habilitation in physical chemistry.

intramolecular equilibrium coordinates upon oxidation and reduction of the reacting species. Motion on a diabatic surface does not change the electronic state of the system. In the diabatic picture ET is induced by the perturbation term V, which couples reactant and product electronic states ($|R\rangle$ and $|P\rangle$). The strength of this coupling is characterized by the matrix element $V = \langle P|V|R\rangle$.

On the other hand adiabatic PESs are Born–Oppenheimer approximate solutions to the full Hamiltonian of the system. In contrast to the diabatic PES, on the adiabatic PES the electronic state changes smoothly from that of the reactants to products upon the proper change of the nuclear coordinates. Adiabatic states can be constructed as linear combinations of diabatic states coupled by the perturbation. In the two-state approximation of Figure 1b this perturbation leads to an avoided crossing and a splitting of the diabatic PESs by about $2V$.

A useful criterion in the discussion below is the extent of the region with significant interaction between the diabatic PESs of reactants and products. A crude estimate of this Landau–Zener (LZ) region is obtained with simple geometric arguments (see Fig. 1b). The diabatic PESs in the vicinity of the activation maximum are approximated by their tangents at the crossing. Sizable mixing of reactant and product electronic states occurs where the energies of the respective diabatic PESs differ by less than $2V$. As is evident from Figure 1b this is the case on a length l_{lz} [eq. (1)] near the top of the barrier. U_R' and U_P' denote the slopes of the diabatic PESs of reactants and products at the crossing point. The derivatives for the determination of the tangents are taken along the coordinate to be defined in the next section.

$$l_{lz} = \frac{2V}{|U_R' - U_P'|} \tag{1}$$

2.2. Definition of the Reaction Coordinate q

We begin with a simplified description of ET ignoring high-frequency vibrations. In general, electronic motion is much faster than nuclear motion, which confines the actual ET step to a narrow region on the PES where the nuclear momenta and the potential energy are nearly conserved (Franck-Condon principle). Consequently, an adjustment of the nuclear configuration prior to the ET reaction is required to achieve a situation where the PESs of reactants and products intersect (see Fig. 1). This process gives rise to the activation barrier. The narrow reaction zone is nothing but the LZ region of Section 2.1.

A crucial step is the identification of the mode of nuclear rearrangement—the reaction coordinate q—by which this intersection is effected. Usually the reaction coordinate is constructed by finding the minimum energy path between the minima for reactants and products on the multidimensional PESs.[37] A very convenient alternative approach[54, 55, 87–95] is to define the reaction coordinate q directly as the vertical energy gap [eq. (2)]. $U_R(X)$ and $U_P(X)$ denote the values on

$$q(X) = U_R(X) - U_P(X) \tag{2}$$

the microscopic, multidimensional, diabatic PESs of reactants and products for a solvent arrangement (the solvent configuration) characterized by the set of coordinates X. In general there exists a huge number of different configurations leading to the same value of $q(X)$. The energy gap q is the difference in the collective, mainly electrostatic interaction of many solvent molecules with reactants or products and depends on the position and orientation of these solvent molecules. The temporal change of q [that is, $q(X(t))$] reflects the very complex dynamics $X(t)$ of the solvent environment. Motion within the potential wells along q away from the minima essentially corresponds to a (nonequilibrium) dielectric polarization fluctuation. Yet, nonequilibrium only exists with respect to that part of the polarization which is due to the orientation of permanent dipoles; electronic polarization is always at equilibrium with the momentary charge distribution on electron donor and acceptor.

The reaction coordinate defined according to equation (2) changes its sign at the intersection of the diabatic PESs and intuitively is a useful parameter for the characterization of processes that occur near this intersection. Yet, the definition in equation (2) reveals its usefulness and full power only in explicit multibody molecular dynamics calculations.[54, 55, 87–95]

A change in the description of the potential energy from the microscopic coordinates X to the reaction coordinate q does not merely correspond to a simple one-dimensional profile of the multidimensional PESs $U_{R,P}(X)$. Instead it implies a statistical weighting of all the solvent configurations X that give the same value of $q(X)$. This procedure leads to the FESs mentioned in Section 2.1, which we shall denote by the symbols $F_{R,P}(q)$.

The microscopic construction of the diabatic FESs $F_{R,P}(q)$ can be carried out as follows: For a fixed charge distribution on the reacting species (corresponding to either reactants or products) a molecular dynamics calculation for the solvent environment generates an equilibrium probability distribution $p_{R,P}(X)$ of the solvent configurations and, on application of equation (2), one of $q(X)$, namely $p_{R,P}(q)$.[54, 55, 87–95] Use of these distributions enables the functions F of the diabatic FESs to be defined according to equations (3a) and (3b), where k_B = Boltzmann's constant and T = absolute temperature; for ΔG see Section 2.3. Very often no clear distinction is made between the PESs $U_{R,P}$ and the FESs $F_{R,P}$.[96]

$$F_R(q) = -k_B T \ln [p_R(q)] \tag{3a}$$
$$F_P(q) = -k_B T \ln [p_P(q)] + \Delta G \tag{3b}$$

2.3. Characterization of the Activation Barrier

For simplicity it is usually assumed that the diabatic FESs $F_{R,P}(q)$ are quadratic functions of the reaction coordinate with equal force constants f_S for reactants and products.[97] Recent Monte Carlo simulations in model systems have shown this approximation to be surprisingly accurate.[88]

Several parameters characterizing $F_{R,P}(q)$ are shown in Figure 1. The free energy of reaction ΔG is the difference in the free energies between the minima of products and reactants. In general a polar medium provides better solvent stabilization of a more polar species. Thus a polar environment increases the driving force of a charge-separation reaction, but reduces it for charge recombination.[31] Another

useful quantity is the solvent-reorganization energy $\lambda_S = 1/2 f_S \Delta q^2$ where Δq is the shift between the free energy minima. It is approximately given by equation (4),[98,99] where $r_\pm$ are the effective radii of the reactants at distance d, n is the refractive index, and ε_S the static dielectric constant of the solvent. The energy parameter λ_S in equation (4) has the same form as that part of the solvation energy (of an ion pair) that results from the *orientational* polarization of the solvent. The free energy of activation $\Delta G^{\neq}$ can be expressed in terms of the free energy of reaction ΔG and the solvent reorganization energy λ_S [(5)], by solving the quadratic equation for the point of intersection of two parabolas. The splitting V is often neglected in $\Delta G^{\neq}$.

$$\lambda_s = e^2 \left(\frac{1}{2r_+} + \frac{1}{2r_-} - \frac{1}{d} \right) \left(\frac{1}{n^2} - \frac{1}{\varepsilon_s} \right) \tag{4}$$

$$\Delta G^{\neq} \approx \frac{(\Delta G + \lambda_s)^2}{4\lambda_s} - V \tag{5}$$

In the following we shall distinguish the transition-state (TS) region from the LZ region of Section 2.1. The TS region denotes the neighborhood of the activation maximum differing in energy by less than $k_B T$ (see Fig. 1b). For many purposes the TS region can be considered as (energetically) flat. On the other hand, once the system has left the TS region on either side it can be considered as thermally stabilized. We characterize its extent by the length l_{ts}. Its estimate depends on the strength of the electronic coupling V (see Fig. 2). A

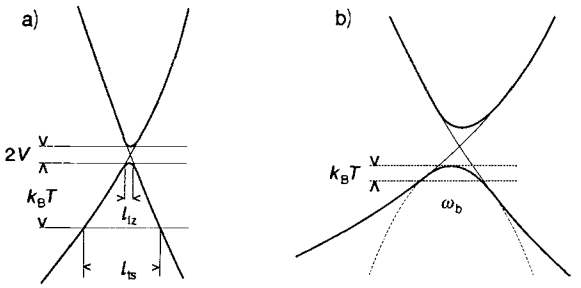

Fig. 2. Shape of the barrier top for different electronic couplings V. a) Nonadiabatic reaction for $V \ll k_B T$ (cusped barrier). A stepwise linear approximation gives $l_{ts} = k_B T(1/|F_R'| + 1/|F_P'|) \approx 4k_B T/\sqrt{2\lambda_s M\omega_0^2}$ and $l_{lz} = 2V/\sqrt{2\lambda_s M\omega_0^2}$. Here we assume that $F_{R,P}' \approx U_{R,P}'$. b) Strongly adiabatic reaction. For the inverse parabolic barrier with the force constant $f_b = M\omega_b^2$, the length l_{ts} is defined by $l_{ts} = \sqrt{8k_B T/M\omega_b^2}$.

small splitting of the diabatic FESs leaves the adiabatic FESs rather sharp (cusped barrier) on the length scale l_{ts}. Strong electronic coupling leads to a broad maximum, which is often described by an inverse parabola.

2.4. The Electron-Transfer Rate k in Transition-State Theory

Interpreted as a motion on FESs, the picture of electron transfer is the following: Most of the time the reactants are at or near equilibrium with the solvent environment; that is, the system moves near the minimum of the reactant FES. Once in a while a solvent fluctuation drives the system up the activation barrier where reactant and product FESs intersect. Within the LZ region near the intersection an electron may hop from the electron donor to the acceptor; with a certain probability the system changes to the product FES and subsequently relaxes to the bottom of the well. Thus we have to take account of changes in the nuclear coordinates as well as of the electronic structure.

The derivation of the reaction rate in the framework of conventional TS theory presupposes the validity of the following assumptions:

a) Throughout the course of the reaction the system maintains a quasi-equilibrium distribution along the reaction coordinate on the reactant FES up to the TS region. This in general requires that vibrational and solvent relaxation in the reactant FES are much faster than ET.

b) Upon crossing the activation barrier along the reaction coordinate the system moves uniformly through the TS region. Reactive trajectories on the FES cross the barrier top once and only once.

c) Once the system has crossed the TS region and a reaction (with probability P) has occurred, excess energy is dissipated fast enough to trap the system on the products side.

The ET rate k is then given by the product of three factors [eq. (6)]: firstly the occurrence probability of the system in the TS region moving in forward direction, secondly the (average) inverse time it takes to cross the TS region "in straight flight", and thirdly the electronic transition probability P for a transition from reactant to product FESs whenever the system traverses the TS region.[100-102]

$$k = P \frac{k_B T}{h} \frac{1}{Z_0} e^{-\frac{\Delta G^{\neq}}{k_B T}} \approx P \frac{\omega_0}{2\pi} e^{-\frac{\Delta G^{\neq}}{k_B T}} = P k_{ts} \tag{6}$$

Z_0 is the partition function of a classical, one-dimensional motion in the initial well with the oscillation frequency $\omega_0 = \sqrt{f_s/M}$; M is the effective mass associated with the motion near the well bottom[97] (h = Planck's constant). A typical value of ω_0 is $10^{13}\ s^{-1}$[103].

The preexponential factor $\omega_0/2\pi$ is somewhat misleading in the sense that it seems to count the number of attempted barrier crossings per unit time. Yet, equation (6) does not hold when the system undergoes a simple oscillation on the FES as will be argued in Section 3. The factor $\omega_0/2\pi$ is just the ratio $k_B T/hZ_0$.

2.5. Estimate of the Electronic Transition Probability P

It is intuitively obvious that the likelihood of a successful electronic transition increases the longer the system remains in the LZ region and the faster an electronic transition takes place there. Thus, P depends on the ratio of the traversal time τ_{lz} of the system through the LZ region to the duration τ_{hop} of the change of the electron distribution from that of the reactants to that of the products.[1] The traversal time is the ratio l_{lz}/v_{th} where v_{th} is the thermal velocity of the motion along the reaction coordinate through the LZ region. The duration of an electronic transition is about $\hbar/V$. When using l_{lz} from equation (1) the ratio τ_{lz}/τ_{hop} thus is directly proportional to the square of the electronic coupling V and inversely proportional to the average thermal velocity v_{th} along the reaction coordinate [eq. (7)].

$$\frac{\tau_{lz}}{\tau_{hop}} \approx \frac{l_{lz}/v_{th}}{\hbar/V} = \frac{2V^2}{\hbar v_{th}|U_R' - U_P'|} := \gamma_{lz} \tag{7}$$

where $v_{th} = \sqrt{2k_B T/\pi M}$ and γ_{lz} is the (Landau-Zener) adiabaticity parameter[104].

For a sufficiently small electronic coupling V we have a nonadiabatic reaction with $\gamma_{lz} \ll 1$, where P is proportional to γ_{lz} ($P = 2\pi\gamma_{lz}$).[105] If l_{lz} is used for the cusped barrier (Fig. 2a), the explicit expression is equation (8). Alternative-

$$k_{na} = \frac{2\pi}{\hbar} \frac{1}{\sqrt{4\pi\lambda_s k_B T}} V^2 e^{-\frac{(\Delta G + \lambda_S)^2}{4\lambda_S k_B T}} \tag{8}$$

ly, equation (8) can be derived in the framework of nonadiabatic ET theory based on time-dependent perturbation theory[107-109] (see also the semiclassical trajectory approach in ref. [55]). The characteristic feature of ET reactions with small couplings is the proportionality of the rate to V^2. In the nonadiabatic case the system moves too fast through the LZ region for the electrons to form the product state. It will most likely stay on the diabatic FES of the reactants. A successful reaction is a rare jump to the product FES among many futile crossings of the LZ region.

In the opposite case of a large electronic coupling $\gamma_{lz} \gg 1$, $P = 1$ (adiabatic reaction). Every crossing of the LZ region leads to products. The traversal time is long enough to form the electronic state of lowest energy; the reaction can be discussed on the lower adiabatic FES alone. For arbitrary values of γ_{lz}, P is a geometric series[1, 110] in the Landau-Zener probability p_{lz} [eq. (9)] where $p_{lz} = 1 - e^{-\pi\gamma_{lz}}$.[106]

$$P = \frac{2p_{lz}}{1 + p_{lz}} \tag{9}$$

2.6. Concluding Remarks

The free energies of reaction and activation [eq. (5)] depend on the relative stabilization of the reactants, the transition state, and the products by the solvent environment. This stabilization of charged species is mainly determined by static properties of the solvent such as the polarity and the refractive index. The force constant f_S and the effective mass M for the frequency ω_0 are equilibrium properties as well[97] (see also eq. (25) in Section 5.1). Thus the rate in equation (6) as a whole is determined by the static properties of the solvent. Solvent dynamics can be completely ignored.

3. Kramers's Theory of Barrier Crossing and Beyond

The rapidly fluctuating, collective interaction between the reacting species and the solvent environment may have a profound influence on the rate of energetic (de)activation of the system and on the character of the trajectories over the activation barrier. Under certain circumstances the basic assumptions of TS theory in Section 2.4 are no longer fulfilled and corrections to the ET rate in TS theory are necessary.

3.1. Electron Transfer as a Problem of Random Walk and Solvent Dielectric Response

We immediately recognize the importance of solvent dynamics if we remember that the reaction coordinate $q(X)$ is itself a function of a great number of coordinates X characterizing the position and orientation of mutually interacting solvent molecules. The projection of the highly irregular dynamics of many solvent molecules onto a single reaction coordinate results in the occurrence of frictional and random forces in the equation of motion for q.

Two consequences of frictional and random forces on the dynamics along the reaction coordinate are important: 1) They provide a mechanism for the exchange of energy between the reaction coordinate and the other degrees of freedom (mostly of the solvent) functioning as a heat bath. Without such an energy flow the system could neither acquire the necessary energy along the reaction coordinate to overcome the activation barrier nor get rid of excess energy to become stabilized on the products' side once it has crossed the barrier. 2) They change the character of the motion along the reaction coordinate. They are able to effect a crossover from deterministic to stochastic motion which resembles a random walk (or Brownian motion) on the FESs.

In view of the complexity of this motion its dynamics is usually described phenomenologically by a Langevin equation[111] for the reaction coordinate [eq. (10)].[37, 112] The

$$M\frac{\partial^2 q}{\partial t^2} = -\frac{\partial F_{R,P}(q)}{\partial q} - \zeta\frac{\partial q}{\partial t} + R(t) \tag{10}$$

first term on the right hand side is the potential force in the relevant FES $F_{R,P}$ (for parabolic FESs $\partial F_R(q)/\partial q = M\omega_0^2 q$), the second the dielectric friction with the microscopic friction constant ζ, and the third the random force $R(t)$ exerted by the rapidly fluctuating solvent environment. The many-body aspect of the solvent dynamics is incorporated into the friction constant ζ and the random force $R(t)$ which is defined by its stochastic properties, that is, its moments and autocorrelation functions.[111-113] The fluctuation–dissipation theorem shows these two quantities to be closely related.[111-113] In the treatment below they are used as input information known from experiments or other theories. This is discussed further in Section 5.

It has to be kept in mind, however, that friction along the reaction coordinate is, a priori, unrelated to the hydrodynamic friction that is exerted on a molecule rotating or drifting in a liquid. Motion along the reaction coordinate reflects the dynamics of polarization fluctuations; that is, it is governed by the dielectric response of the solvent.

In much of the following we assume that the second derivative on the left hand side of equation (10) is negligible. This neglect of inertial effects in solvent dynamics is reasonable in the presence of strong friction and results in overdamped motion (of a harmonic oscillator, for example). In dielectric relaxation it corresponds to the important special case of a Debye liquid in which the frequency-dependent dielectric constant is defined by equation (11),[114, 115] where ε_S is the static and ε_∞ the high-frequency dielectric constants of the solvent (very often $\varepsilon_\infty \approx n^2$). The resulting dielectric response

exhibits a single-exponential time dependence with the Debye relaxation time τ_d. Nevertheless, the characteristic time scale of interest here is the longitudinal (or constant charge) dielectric relaxation time τ_l, related to τ_d by equation (12).

$$\varepsilon(\omega) = \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + i\omega\tau_d} \tag{11}$$

$$\tau_l = \frac{\varepsilon_\infty}{\varepsilon_s}\tau_d \tag{12}$$

Thus in polar solvents τ_d can exceed τ_l by more than an order of magnitude (see Table 1)! Both refer to the same underlying molecular relaxation mechanisms; they differ by the boundary condition under which the response of the medium is measured. The dielectric relaxation time τ_d is the response

Table 1. Selection of representative dielectric relaxation times τ_d and τ_l (in ps) in common solvents from [67, 69]. The values τ_1 and τ_2 and the corresponding amplitudes in parentheses are biexponential fits to the function $C(t)$ in equation (26) from TDSS experiments [81, 144].

Solvent	τ_d	τ_l	τ_1	τ_2	τ_s
acetonitrile	3.3	≃0.2	0.07 (80) [b]	0.2 (20)	
CH_2Cl_2	1.5	≃0.4			
methanol	48 [a]	8.2 [a]	1.2 (40)	9.6 (60)	6.2
propanol	390 [a]	42 [a]	14 (30)	40 (70)	33
acetone	3.3	0.3	0.3 (47)	1.0 (53)	0.7
water		0.2	0.25 (50)	1.0 (50)	0.6
DMSO		2.4	0.3 (57)	2.3 (43)	1.2

[a] τ_d and τ_l for methanol and propanol refer to the dominant slowest component of the dielectric response. [b] The data for acetonitrile in [139] were fitted by the sum of a Gaussian with a fwhm = 120 fs and an exponential with a decay time of 200 fs.

time when a fixed electric field is suddenly turned on (E-jump) whereas τ_l characterizes the response when a fixed (external) charge is added (D-jump).[116] As defined in equation (2), the reaction coordinate describes the change in the solute–solvent interaction upon an instantaneous (virtual) change of the charge distribution on the reacting species. Consequently τ_l is taken as the relevant relaxation time.[117] For most common liquids τ_l falls in the range from 250 fs to 10 ps (see Table 1) and is identified with the relaxation time of the overdamped harmonic motion resulting from equation (10) for a parabolic FES.[50] This gives the simple relationship $\zeta = M\omega_0^2\tau_l$ between the friction constant ζ and τ_l in a Debye liquid.

3.2. Adiabatic Reactions

The influence of friction on the dynamics along the reaction coordinate and on the adiabaticity of the reaction leads to corrections to the TS value k_{ts} to yield the ET rate $k(\zeta)$. We define $k(\zeta)/k_{ts}$ as a measure of frictional effects. At first we shall focus on intrinsically adiabatic reactions where the motion is confined to the lower adiabatic FES in Figure 1 leading continuously from reactants to products. This is the realm of Kramers's theory[34] and its more recent generalizations;[102, 112, 118–120] its results are illustrated in Figure 3 and explained in the following.

For weak frictional or random forces the system will undergo several oscillations between the reactant and product wells before finally settling down in one of them. The reaction rate is limited by how fast the necessary activation energy is acquired and how fast excess energy in the reaction coordinate is dissipated to trap the system in either well (regime of energy diffusion, Fig. 3a). This is achieved by an exchange of energy between the reaction coordinate and the heat bath. The energy dissipation of a weakly damped oscillator, which is directly proportional to the friction constant ζ serves as a crude estimate of this flow of energy, that is, $k(\zeta)/k_{ts} \propto \zeta$. This is the equivalent of the low-pressure regime of unimolecular reaction theory. The proportionality constant[102] need not concern us here. A consequence of slow energy exchange is that, in contrast to TS theory, a quasi-stationary Boltzmann distribution in the initial state is never achieved. The distribution is significantly depleted well below the TS region.

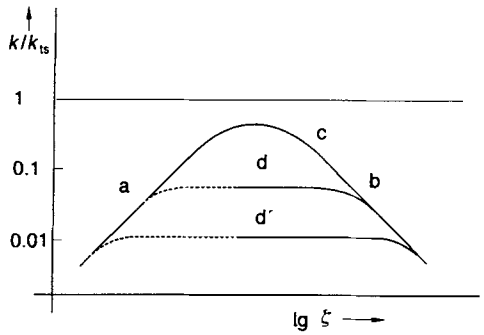

Fig. 3. Qualitative dependence of the ratio $k(\zeta)/k_{ts}$ as a function of the microscopic dielectric friction constant ζ experienced by the system upon barrier crossing. a) Regime of energy diffusion, b) regime of spatial diffusion, c) adiabatic reaction ($P \approx 1$); d) and d') indicate the influence of nonadiabaticity ($P < 1$) on the rate. The dashed sections are not treated here but were added for completeness.

With increasing frictional and random forces the motion in q becomes steadily more statistical; it changes direction on a shorter length scale (characterized by the mean free path l_f) and in a random fashion resembling a diffusive motion. This will lead to a rapid equilibration of the reactants to a Boltzmann distribution. On the other hand, once the mean free path l_f of the motion is shorter than l_{ts}, such a randomly moving system will change direction several times even within the TS region and recross the barrier top repeatedly before finally settling on the products' side (see Fig. 4).

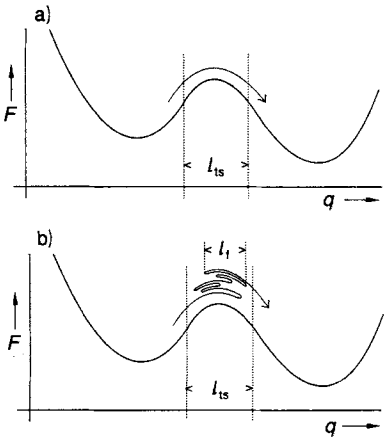

Fig. 4. Influence of frictional and random forces on the barrier-crossing dynamics: a) uniform or ballistic crossing for weak frictional forces, b) repeated back scattering of the system within the TS region in the presence of strong frictional and random forces ($l_f \ll l_{ts}$).

This "back scattering" reduces and finally dominates the rate.[121] The ratio $k(\zeta)/k_{ts}$ then approximately equals the inverse ratio of the traversal times $\tau_{ts,diff}$ of diffusive and $\tau_{ts,uni}$ of uniform or ballistic motion through the TS region [spatial diffusion limit, Fig. 3b, eq. (13)]. The diffusive traversal time

$$\frac{k(\zeta)}{k_{ts}} \approx \left(\frac{\tau_{ts,diff}}{\tau_{ts,uni}}\right)^{-1} \tag{13}$$

$\tau_{ts,diff}$ can be estimated as the time a random walker (with diffusion constant D) needs to cover a distance equal to the length of the TS region l_{ts}: $\tau_{ts,diff} = l_{ts}^2/2D$[111]. Thus one derives equation (14) using $\tau_{ts,uni} = l_{ts}/v_{th}$ and the Einstein relation $D = k_B T/\zeta$.[111] This simple estimate with l_{ts} from Figure 2 reproduces the correct ratio $k(\tau_1)/k_{ts} = \sqrt{\pi \lambda_s/4 k_B T}\,1/\omega_0\tau_1$ for the cusped barrier (Fig. 2a) and yields the exact result $\omega_b/\omega_0^2\tau_1$ for the parabolic barrier (Fig. 2b) up to a factor of $2/\sqrt{\pi} \approx 1.13$. The important point is that the rate is *inversely* proportional to the friction constant ζ or the relaxation time τ_1: $k(\zeta)/k_{ts} \propto 1/\zeta,\ 1/\tau_1$.

$$\frac{k(\zeta)}{k_{ts}} \approx \left(\frac{\tau_{ts,diff}}{\tau_{ts,uni}}\right)^{-1} = \left(\frac{l_{ts}^2/2D}{l_{ts}/v_{th}}\right)^{-1} = \frac{2k_B T}{v_{th} l_{ts}}\frac{1}{\zeta} = \frac{2k_B T}{v_{th} l_{ts}}\frac{1}{M\omega_0^2}\frac{1}{\tau_1} \tag{14}$$

The crossover from the energy diffusion to the spatial diffusion regimes results in the nonmonotonic dependence of the rate on friction in Figure 3. The limit predicted by TS theory of $k(\zeta)/k_{ts} = 1$ is never achieved but is approached in a region of intermediate friction (Kramers turnover). TS theory is thus a useful approximation when friction is strong enough for rapid equilibration in the initial state but still weak enough to allow a quasi-uniform or ballistic crossing of the TS region.

To assess what kind of motion is realized in any specific case is a major problem. Yet, at present it appears unlikely that the energy diffusion limit is ever achieved in ET reactions in solution. It would imply a collective oscillatory motion of many solvent molecules in a system as disordered as a liquid. Current estimates[41, 103] indicate that most liquids belong either to the turnover or spatial diffusion regimes. Henceforth the energy diffusion regime can be omitted.

3.3. Inclusion of Nonadiabaticity

3.3.1. A Modified Landau–Zener Parameter

Let us next turn to a nonadiabatic reaction where $V \ll k_B T$. This in general implies a cusped barrier with $l_{ts} \gg l_{lz}$ (Fig. 2a). A thorough discussion would require a case distinction depending on the relative size of l_f, l_{ts}, and l_{lz} and p_{lz}; this has been done,[39–41, 84] but since from an experimentalist's point of view several of these cases are practically indistinguishable, we shall focus on the gross features instead.

As long as TS theory is approximately valid, weak electronic coupling reduces the rate by a factor equal to the electronic transition probability P [eq. (6)]. Its effect in the spatial diffusion regime is a priori not clear since the derivation of P assumes uniform a motion through the LZ region. Yet, the interpretation of the adiabaticity parameter γ_{lz} as the ratio of the residence time τ_{lz} and the hopping time τ_{hop} in equation (7) indicates that, in the end, not the character of the motion but the total time spent in the LZ region is the crucial aspect.[39]

In order to obtain the analogous adiabaticity parameter κ for diffusive motion along the reaction coordinate we have to remember two important differences from the uniform case: 1) The residence time in the LZ region has to be estimated by using random walk arguments. 2) Since by assumption $l_{ts} \gg l_{lz}$, the system will leave and reenter the LZ region many times before it finally drifts out of the TS region and settles in either the reactant or the product well. The total residence time τ_{lz} in the LZ region is, therefore, the fraction of the residence time τ_{ts} in the TS region given by equation (15a), from which follows (15b) and (15c). Inserting l_{lz} and l_{ts} for the cusped barrier (Fig. 2a) we obtain equation (16).[41] The factor of 2π is included with a view to the later derivation of equation (18).

$$\tau_{lz} = \frac{l_{lz}}{l_{ts}}\tau_{ts} \tag{15a}$$

$$\tau_{lz} = \frac{l_{ts} l_{lz}}{2k_B T}\zeta \propto V\tau_1 \tag{15b}$$

$$\frac{\tau_{lz}}{\tau_{hop}} \propto V^2\tau_1 \tag{15c}$$

$$\kappa(\tau_1) = \frac{4\pi V^2}{\hbar\lambda_s}\tau_1 \approx 2\pi\frac{\tau_{lz}}{\tau_{hop}} \tag{16}$$

3.3.2. Interpolation of the Transfer Rate

As long as $\kappa \ll 1$, a transition from one diabatic FES to the other during a crossing of the TS region is an improbable event, and the reaction is nonadiabatic, be the motion uniform or diffusive.[39] Although the number of traversals of the TS region is greater for uniform motion (because the system moves faster) the system stays in this region longer *per traversal* for diffusive motion. The fraction of time the system spends in the LZ region is given by the Boltzmann distribution and is the same in both cases. On the other hand if $\kappa \gg 1$, the system always stays in the LZ region long enough for a change of electronic states to occur. Once the system drifts out of the TS region on the product side it will, for energetic reasons, always do so on the lower FES leading to products. The rate of the reaction is no longer limited by the change of electronic states as in a normal nonadiabatic reaction but by the escape rate from the TS region! Thus we return to the adiabatic case where Kramers's theory is valid (solvent-controlled adiabatic reaction)! For the cusped barrier equations (6) and (14) give equation (17) when $\kappa \gg 1$. In practice A will most likely be of the order of 0.1 to 1. Thus, equation (17) sets an upper limit of $1/\tau_1$ to the rate for all reactions!

$$k(\tau_1) = \sqrt{\frac{\lambda_s}{16\pi k_B T}}\frac{1}{\tau_1}e^{-\frac{(\Delta G + \lambda_S)^2}{4\lambda_s k_B T}} = \frac{A}{\tau_1}e^{-\frac{\Delta G^{\ddagger}}{k_B T}} \tag{17}$$

To estimate the rate between these extremes we simply interpolate between the nonadiabatic rate constant k_{na} [eq. (8)] and Kramers's prediction $k(\tau_l)$ [eq. (17)] for a Debye liquid. In fact, the proportionality constant in equation (16) was defined in such a way that $\kappa = k_{na}/k(\tau_l)$, from which we derive (18).[41]

$$k = \left(\frac{1}{k_{na}} + \frac{1}{k(\tau_l)}\right)^{-1} = \frac{1}{1+\kappa(\tau_l)} k_{na} = \frac{1}{1+\frac{4\pi V^2}{\hbar \lambda_S}\tau_l} k_{na} \quad (18)$$

The result is depicted in Figure 3 as well. At first the rate is practically independent of friction, but it finally merges with Kramers's prediction for a friction-limited adiabatic reaction. Another essential feature of equation (18) is that the reaction rate may be proportional to V^2 for fast relaxation [eq. (8)], but with increasing τ_l finally becomes independent of the electronic coupling.

3.4. Generalizations

3.4.1. Inclusion of (Intramolecular) Quantum Modes

So far we have ignored intramolecular degrees of freedom. The excitation of intramolecular vibrations provides a way for the system to dispose of large amounts of energy.[55, 108, 122] We can easily include them into our described framework when we remember that their frequencies in general satisfy the condition $\hbar\omega_i \gg k_B T$; that is, in contrast to solvent dynamics, intramolecular motion has a quantum-mechanical nature. The appropriate description of these degrees of freedom is not in terms of position and momentum on a FES, but as discrete quantum states enumerated by quantum numbers. For most practical purposes a single intramolecular mode will suffice; that is, we specify its vibronic state by the number of phonons in this mode. Instead of a single FES for reactants and products each, we get two sets of FESs where every FES is characterized by the electronic state (reactant or product) *and* the phonon number defining the vibronic state with respect to the intramolecular high-frequency mode (see the nested FESs in Fig. 11). Since by physical argument $\hbar\omega_i \gg k_B T$, only the vibronic ground state of the reactants is occupied. We then define individual reaction rate constants $k_{0,n}$ between the reactant ground state and every vibronic substate of the set of product states [eq. (19)].[39, 44, 51]

$$k_{0,n} = \frac{1}{1+\frac{4\pi\tau_l}{\hbar\lambda_S}V_{0,n}^2} \frac{2\pi}{\hbar} \frac{1}{\sqrt{4\pi k_B T \lambda_S}} V_{0,n}^2 \, e^{-\frac{(\Delta G + \lambda_S + n\hbar\omega_i)^2}{4\lambda_S k_B T}} \quad (19)$$

The individual rate constants differ in two ways from equations (8) and (18) which ignore high-frequency intramolecular vibrations: 1) The effective free energy of reaction $\Delta G_{0,n} = \Delta G + n\hbar\omega_i$ corrects for the part of the driving force taken up by the intramolecular mode. 2) Since a transition from the reactant FES to a product FES involves a change of the electronic state as well as of the intramolecular vibronic state, the purely electronic transition matrix element V has to be multiplied by the vibronic overlap matrix element $\langle 0|n\rangle$ between the vibronic ground state of the reactants $|0\rangle$ and the nth vibronic product state $|n\rangle$; that is, the square of the effective matrix element $V_{0,n}^2$ is the product of the purely electronic coupling V^2 times the Franck–Condon factor for the transition between the respective vibronic states: $V_{0,n}^2 = V^2 |\langle 0|n\rangle|^2$.

$|\langle 0|n\rangle|^2$ is a function of the intramolecular reorganization energy $\lambda_i = 1/2\, f_i \Delta x^2$ where f_i is the force constant and Δx the shift of the equilibrium position of the intramolecular mode from reactants to products. The overall rate constant is the sum over all these rate constants for the different vibronic channels: $k = \sum_n k_{0,n}$. For $\tau_l \to 0$ we recover the rate in the nonadiabatic limit[108, 109] and thereby generalize equation (8) in the presence of high-frequency intramolecular vibrations.

Very often one of the channels predominates. This is particularly important for reactions with a very high driving force (reactions in the inverted region with $-\Delta G > \lambda_s + \lambda_i$). In these cases nuclear tunneling in the high-frequency modes favors the transition to that electronic–vibronic state whose FES intersects the reactant FES in the minimum resulting in an almost activationless reaction[122] (see for example Figure 11) but with a considerably lower rate!

In addition to the well-established quantum effects in intramolecular vibrations, potential quantum effects in solvent motion have recently attracted increasing attention.[55, 93, 103, 123] Current estimates predict only small or mutually compensating corrections to classical solvent dynamics.[103] Possible exceptions are protic solvents where the motions of hydrogen atoms can be dominated by tunneling.[123]

3.4.2. Influence of Frequency-Dependent Friction

So far, we have assumed a single characteristic time scale of dielectric response. Yet, the description of the dielectric relaxation dynamics of most liquids requires a whole spectrum of relaxation times. The underlying molecular mechanisms are usually discussed in terms of the two extremes of polar media, those with static and those with dynamic disorder.

In a medium with (pure) dynamic disorder, solvent dielectric relaxation is the same in the microscopic environment of every electron donor–acceptor pair but nevertheless nonexponential. In the Langevin equation of the reaction coordinate this implies a finite correlation time of the random force $R(t)$ and a memory effect of the friction [eq. (20)].[112, 113, 124] Fourier transformation converts $\zeta(t)$ into a frequency-dependent friction constant $\zeta(\omega)$ or relaxation time $\tau_l(\omega)$.[50]

$$\zeta \frac{\partial q}{\partial t} \to \int_0^t \zeta(t-\tau) \frac{\partial q}{\partial \tau} \, d\tau \quad (20)$$

The barrier top for many ET reactions with weak electronic coupling, especially of those with a high activation barrier, is rather sharp (cusped barrier) and l_{lz} and l_{ts} small. As a consequence the required solvent fluctuation to traverse the TS region is also small. In these cases the short but finite correlation time of the frictional force could be important. In a molecular picture, the underlying relaxation mechanism could involve small amplitude motions of individual solvent molecules that will experience only weak friction with the

surrounding liquid.[112] The strong curvature of the barrier top therefore probes the short time dynamics of solvent relaxation, which accelerates the transition of the system over the barrier top but does not necessarily assist in acquiring the activation energy or in the deactivation on the products' side.[112]

The quantitative formulation of this problem is still a matter of active research. A theoretical treatment by Hynes et al.[50, 124] predicts that the actual crossing of the activation maximum in ET reactions with a cusped barrier is determined by a friction constant $\zeta(\omega \gg \omega_0)$ at high frequencies that is small and not rate-determining, whereas energetic (de)activation is somewhat slowed by dielectric friction. Altogether a weak dependence of the rate on the relaxation properties is expected.[50] This finding is in contradiction to numerical simulations by Straub, Borkovec, and Berne[125] and more recent theoretical treatments of Kramers's problem by Pollack, Grabert, and Hänggi,[126] which give a rather strong dependence of the overall barrier-crossing rate on frequency-dependent friction. Yet, the latter results rest very much on specific assumptions on the shape of the barrier which may or may not be justified in ET reactions. This problem was also discussed by several other groups[36, 41, 52, 127–129] who arrive at different conclusions. In summary, the influence of frequency-dependent dielectric friction on barrier crossing in general, and ET reactions in particular, is still an open question.

In a solvent with (pure) static disorder, the dielectric relaxation of the microscopic solvent environment of any electron donor–acceptor pair is exponential but the relaxation times τ_l in the environment of different pairs are not identical. This corresponds to an inhomogeneous medium with a distribution of relaxation times $g(\tau_l)$. The observed survival probability of the reactants $P(t)$ is an ensemble average of systems with individual reaction rate constants $k(\tau_l)$ over $g(\tau_l)$ [eq. (21)].[43, 47] This averaging can result in a strongly nonexponential time-dependence. An example is given in ref. [43].

$$P(t) = \int_0^\infty \mathrm{e}^{-k(\tau_l)t} g(\tau_l)\, \mathrm{d}\tau_l \qquad (21)$$

3.4.3. Nonequilibrium Effects

Another mechanism leading to a nonexponential time dependence comes into play when the crossing of the activation barrier is able to compete effectively with equilibration to a quasi-steady-state distribution on the reactant FES. This is expected for adiabatic reactions with a very low activation barrier or when the initially prepared distribution of the reactants is far from an equilibrium distribution. In this case the concept of a (time-independent) reaction rate constant is no longer meaningful. In general, the kinetics of the reaction has to be determined by explicit numerical solution of a Langevin or an equivalent equation for the motion along the reaction coordinate.[130]

3.5. Additional Remarks

The interplay of electronic coupling, dielectric friction, and the character of the motion along the reaction coordinate is illustrated in the triangle in Figure 5 formed by the extreme cases of a uniform adiabatic, a nonadiabatic, and a solvent-controlled adiabatic reaction. Transitions between these limiting cases are governed by the respective adiabaticity parameters κ and γ_{lz}, and the ratio l_{ts}/l_f. A closed interpolation formula encompassing all three limits was proposed by Rips and Jortner.[131]

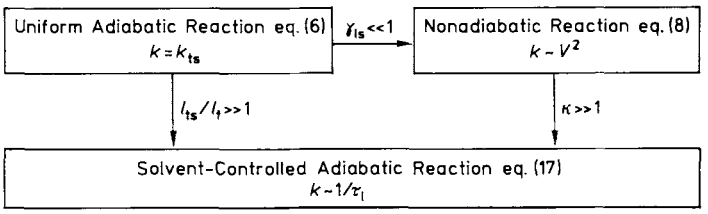

Fig. 5. Schematic representation of the relationship between uniform adiabatic, nonadiabatic, and solvent-controlled adiabatic electron-transfer reactions based on the extension of Kramers's one-dimensional approach as described in Section 3. Transitions between these limiting cases are controlled by the Landau–Zener adiabaticity parameter γ_{lz} for uniform motion [eq. (7)], the adiabaticity parameter κ for diffusive motion [eq. (16)], and the ratio of the width l_{ts} of the TS region and of the mean free path l_f of the motion along the reaction coordinate (see Fig. 4).

The formal treatment of the influence of solvent dynamics on ET has been attempted in many different ways, for example,

- in the framework of quantum-mechanical propagators by path integral calculations for a two-level system coupled to a heat bath of harmonic oscillators by Garg et al.[38] and Onuchic,[39] or to a dielectric by Rips and Jortner[41]
- by the solution of a stochastic Liouville equation for a two-level system where the reaction coordinate is described by a Smoluchowski equation (Zusman,[35] Rips and Jortner[42])
- with Greens function methods for the Liouville equation of the density matrix reminiscent of optical line-shape theory by Mukamel and coworkers[52]
- with Greens functions for the solution of a Fokker–Planck equation for the reaction coordinate by Cukier et al.[53] and
- within the mean first passage times approach by Friedman and Newton.[49]

The comparability of these approaches is difficult to assess. Except for minor corrections they seem to agree in the gross features of the effect of solvent dynamics and in particular in the crossover from nonadiabatic to solvent-controlled adiabatic behavior. The interested reader is referred to the original papers.

4. Two-Dimensional Approach of Sumi and Marcus

An essential feature of Kramers's model is the assumption that the barrier crossing is overwhelmingly undertaken along or close to the minimum energy path on the PES, and thus an essentially one-dimensional treatment of the motion is sufficient. This approximation may break down when the curvature of the PES at the barrier perpendicular to the reaction coordinate is weak or the motions along the reaction coordinate and perpendicular to it are characterized by

very different time scales. In this case the system may follow a trajectory over the barrier with a higher energy of activation, that for reasons of dynamics, however, is more easily accessible than the minimum energy path.

4.1. Basic Assumptions

This possibility of an alternative route across the activation barrier is the basis of the model for dynamic solvent effects suggested by Marcus, Sumi, and Nadler,[45, 46] which is related to earlier work of Agmon and Hopfield.[132] In this approach it is assumed that in addition to solvent fluctuations a low-frequency intramolecular vibration mode ($\hbar\omega_{i,cl} \leq k_B T$) exists, along which the activation barrier can be overcome. Thus, the FES is a two-dimensional function of an intramolecular (Y) and a solvent coordinate (X) (Fig. 6). The solvent motion is taken to be purely diffusive.

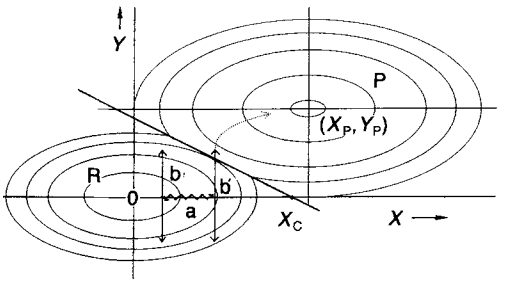

Fig. 6. Contour plot of the two-dimensional FES as a function of a diffusive solvent coordinate X and a low-frequency intramolecular coordinate Y. The diagonal line marks the intersection between the diabatic FESs. a) Diffusive motion along the solvent coordinate X; b), b') classical oscillation and barrier crossing along the intramolecular coordinate Y.

Furthermore, the relaxation along Y is assumed always to be fast enough compared to that along X to maintain thermal equilibrium with respect to Y. In contrast to the situation in Sections 2 and 3, the barrier is surmounted along the nondiffusive, intramolecular coordinate. Nevertheless, diffusive motion along the solvent coordinate changes the barrier height $\Delta G^{\neq}(X)$ of the reaction, which has to be overcome by intramolecular vibration. Again, if a (step wise) parabolic dependence of the FES on X and Y is assumed, a simple calculation shows that $\Delta G^{\neq}$ is given by equation (22). The reorganization energies λ_s and $\lambda_{i,cl}$ are for the solvent and the low-frequency intramolecular mode, respectively. They are defined by $\lambda_s = 1/2 f_s (X_R - X_P)^2$ and $\lambda_{i,cl} = 1/2 f_{i,cl} (Y_R - Y_P)^2$, where $f_s (= M\omega_0^2)$ and $f_{i,cl}$ are force constants and $X_{R,P}$ and $Y_{R,P}$ the appropriate equilibrium positions for reactants and products. X_c is the position of the barrier top on the X axis (see Fig. 6). A crucial quantity in this approach is the ratio $r = \lambda_{i,cl}/\lambda_s$. For $r \gg 1$, $\Delta G^{\neq}(X)$ is only weakly dependent on X; the barrier can be overcome for a wide range of X (wide reaction window), whereas for $r \ll 1, \Delta G^{\neq}(X)$ rapidly increases with the distance $(X - X_c)$ and confines the actual barrier crossing to a narrow gate near X_c (narrow reaction window).

$$\Delta G^{\neq}(X) = \frac{1}{2}\frac{\lambda_s}{\lambda_{i,cl}} f_s (X - X_c)^2 = \frac{1}{2r} f_s (X - X_c)^2 \qquad (22)$$

The quantitative formulation of this combination of diffusive and reactive motion leads to the Smoluchowski equation (23) for the time-development of the probability distribution $P(X,t)$ of the system along the solvent coordinate X.[45]

$$\frac{\partial P}{\partial t} = \frac{k_B T}{M\omega_0^2 \tau_l}\frac{\partial^2 P}{\partial X^2} + \frac{1}{M\omega_0^2 \tau_l}\frac{\partial}{\partial X}\left(P\frac{\partial F}{\partial X}\right) - k(X)\,P \qquad (23)$$

The first two terms on the right-hand side describe one-dimensional diffusion in a potential $F(X)$, that is taken as the cross section through the FES at $Y = Y_R$. The last term simulates the actual ET along Y. Since the distribution along Y is (by assumption) always at quasi-equilibrium, it need not be treated explicitly. $k(X)$ is taken from TS theory; its dependence on X refers to the fact that the activation barrier that the system has to overcome along the low-frequency mode is a function of X [eq. (22)].

4.2. Some Predictions

The details of the solution of the basic equation (23) are beyond the scope of this paper. Qualitatively the reaction dynamics is an interplay of two processes: 1) The system crosses the activation barrier along the low-frequency intramolecular mode Y into the product well at a rate $k(X)$. This reaction depletes the distribution $P(X, t)$ in the reactants' well for values of X that have a low activation barrier. 2) Diffusive motion along the solvent coordinate X repopulates the distribution for depleted values of X. This situation is illustrated in Figure 6.

Depending on r and on the initial preparation of the system, a very rich dynamic behavior is expected. The two limiting cases for very fast and very slow relaxation (fast and slow diffusion) are immediately obvious. In the first case the equilibrium distribution in X is always maintained; the effective rate k_{eq} is a thermal average of $k(X)$ over the equilibrium distribution $P_{eq}(X, t)$ and corresponds to the TS limit in equation (6). In the slow diffusion limit, the dynamics can be considered an ensemble average over a frozen distribution of X. More general cases have to be treated numerically. In general, the predicted time dependence of the reaction is nonexponential. Nevertheless, approximate relationships can be derived for the average survival time τ_a and the first moment τ_b of the survival probability $P(t)$ [$P(X, t)$ integrated over X] of the reactants. For large τ_l, both survival times τ_a and τ_b of the reactants are proportional to a (fractional power of) τ_l [eq. (24)].[46]

$$\tau_a = \int_0^\infty P(t)\,dt \propto \tau_l^\alpha \qquad (24a)$$

$$\tau_b = \frac{1}{\tau_a}\int_0^\infty t\,P(t)\,dt \propto \tau_l^\beta \quad \text{with} \quad 0 < \alpha, \beta \leq 1 \qquad (24b)$$

The exponents α and β decrease with increasing r. In the narrow reaction-window limit ($r \to 0$, meaning predominant influence of solvent reorganization), α and β approach 1; in the wide reaction-window limit α and β approach 0 for very large r. This is a plausible but important finding: Low-frequency intramolecular degrees of freedom may dampen the

influence of friction. They widen the range of X that has a low activation barrier and thereby reduce the need for sizable polarization fluctuations along X. In the narrow reaction-window limit the functional dependence on τ_l is very much like that in equation (18) in Section 3.3.2.

4.3. Generalizations

High-frequency intramolecular vibrational modes can be incorporated into the scheme in an analogous way to that discussed in Section 3.4.1. Instead of a single adiabatic FES or a pair of diabatic FESs one considers a set of FESs each characterized by a particular vibronic state (with index n) with respect to the high-frequency mode and defines vibronic reaction channels with individual rate constants $k(0 \rightarrow n,X)$. As in equation (19), high-frequency modes are important as accepting modes for large reaction energies.

In the original Sumi–Marcus approach, the classical low-frequency mode is thought of as an intramolecular vibration. Such vibrations often exist in transition metal complexes but not necessarily in rigid organic donor–acceptor molecules. Yet, another interpretation of this degree of freedom is as a fast relaxation mode of the solvent. In fact, under certain simplifying assumptions the Langevin equation (10) with memory friction [eq. (20)] characterized by two relaxation times can be cast into the form of equation (23).[133] Thus the Sumi–Marcus approach can be interpreted, too, as an alternative way to incorporate more than one time scale for the dielectric response.

4.4. Further Comments

In the preceding sections we have seen that effects of dielectric relaxation on ET reactions are the result of an interplay of three factors: 1) the degree of electronic coupling between reactant and product states as described by the parameter V; 2) the dynamics of dielectric response of the solvent and its effect on the nature of the motion along the reaction coordinate; and 3) the relative importance of intramolecular and solvent reorganization during the reaction.

Although the two theoretical models discussed so far differ in important assumptions, they agree in several qualitative predictions.

1) For fast relaxing solvents the reaction rate is independent of the relaxation properties of the solvent. With increasing relaxation time the system undergoes a continuous crossover and the rate finally becomes inversely proportional to (a fractional power of) τ_l.

2) The relaxation time at which this transition occurs depends on the electronic coupling V.

3) Unless the activation barrier is high, nonexponential kinetics are likely.

4) The overall dependence of the rate on the dielectric response of the solvent is sensitive to details of the dielectric relaxation spectrum as well as to intramolecular vibrational modes.

A general deficiency of most theoretical models is that they treat the solvent as an unstructured continuum and include molecular aspects of the solvent and its interaction with the solute insufficiently. Solvent properties enter the theory as empirical input parameters. Some progress towards a molecular theory has been made by using a description of the solvent beyond the simple continuum model.[134] One approach is the mean spherical approximation;[135, 136] another is molecular dynamics simulations of model charge-transfer reactions.[54, 55, 87–95]

5. Characterization of Solvent Dielectric Relaxation

Dielectric response enters the theories in Sections 3 and 4 as necessary input information. Although considerable progress has been achieved lately, the lack of reliable data in particular on the short-term behavior of dielectric relaxation is one of the main sources of uncertainty and ambiguity in the interpretation of possible dielectric relaxation effects on electron-transfer processes.

5.1. Qualitative Description

Historically, dielectric relaxation has been attributed to rotational diffusion of permanent dipoles[114, 115] or clusters of dipoles (region (a) in Fig. 7). This is the mechanism related to the Debye relaxation time τ_d. As a purely dissipative process, rotational diffusion represents a strongly overdamped motion with an exponential (possibly multiexponential) response function. In many cases the relevant time scale is correlated with the shear viscosity of the liquid[114, 115] and can vary by orders of magnitude (see Table 1). Additionally, translational diffusion of polar molecules (region (b) in Fig. 7) surrounding an electric charge was found to speed up dielectric relaxation considerably in solvents such as methanol.[82, 137] As long as these diffusional mechanisms dominate the dielectric response, the neglect of the second derivative in equation (10) is a valid approximation. More recently, however, inertial motion turned out to be important in simple liquids such as acetonitrile.[138–140] This motion is mainly associated with free rotation of individual solvent molecules (region (c) in Fig. 7) in the cage formed by surrounding molecules. Its characteristic time scale is the inverse well frequency ω_0^{-1} of Section 2. As is shown in equation (25), ω_0 is related[50, 103] to the thermal free rotational frequency ω_f given by $\omega_f^2 = 2k_BT/I$. I is the solvent molecular moment of inertia I. The prefactor to ω_f^2

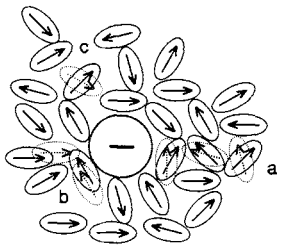

Fig. 7. Schematic representation of different mechanisms of dielectric response in a polar liquid: a) (strongly hindered) rotational diffusion, b) translational diffusion, and c) free (inertial) rotation of polar molecules.

in equation (25) accounts for the effect on the free rotation of the local electric field induced by the surrounding dielectric. The Kirkwood correlation parameter g is of the order of 1 in many solvents.[115] An ensemble average over many molecules leads to a Gaussian time dependence for the inertial part of the dielectric response function. There is also some speculation about a weak oscillatory contribution to the response function.[138-140]

$$\omega_0^2 = \frac{2\varepsilon_s + \varepsilon_\infty}{3g\varepsilon_\infty}\frac{2k_B T}{I} \tag{25}$$

5.2. Measurement of Dielectric Response

The most common experimental method for the determination of dielectric relaxation times is based on the measurement of dielectric loss spectra[141] in a macroscopic sample of the dielectric. Numerous experiments of this kind have shown that dielectric relaxation in many liquids—especially in alcohols[142, 143]—occurs on a whole distribution of time scales. Nevertheless, there are major disadvantages of these methods: a) They measure bulk properties; structural changes of the solvent and short-range correlation effects around the solute are ignored. b) In general the achievable microwave or millimeter wave frequency is insufficient to probe the dielectric response on the relevant time scale of a few picoseconds and below. Fortunately, progress is being made to extend the frequency range into the far infrared.[141] c) In liquids with nonexponential dielectric response, the relationship between resonances in dielectric loss spectra and microscopic relaxation times is not as simple as in equation (12), but requires a model for the coupling of the various relaxation components to the microscopic charge distribution.

More recent experimental methods are based on time-dependent shifts of fluorescence[144-147] or absorption[148] spectra of molecules undergoing a considerable change in dipole moment upon emission or optical excitation. The principle of these measurements is illustrated in Figure 8.

When a fluorophor is excited from a weakly polar ground state in equilibrium with the solvent environment to a strongly polar excited state, the electronic polarization of the solvent will instantly adjust to the new charge distribution on the solute. On the other hand the orientational polarization immediately after excitation will be the same as before, which represents a nonequilibrium situation in the excited state. The solvent will respond by dielectric relaxation to the equilibrium configuration with respect to the excited state. Analogously, fluorescence from the excited state will preserve the orientational polarization of the excited state present at the instant of the transition. The time-resolved fluorescence spectrum consequently experiences a time-dependent red-shift (see Fig. 8), which is usually cast into the normalized function $C(t)$ [eq. (26)].

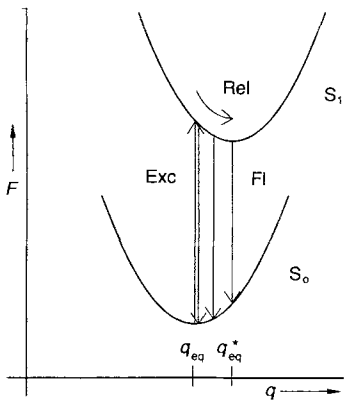

Fig. 8. Schematic representation of the influence of solvent relaxation (Rel) on the time-dependent red-shift of the fluorescence (Fl) of molecules undergoing a large change of dipole moment upon optical excitation (Exc).

$$C(t) = \frac{\nu(t) - \nu(\infty)}{\nu(0) - \nu(\infty)} \tag{26}$$

The frequencies $\nu(0)$, $\nu(t)$, and $\nu(\infty)$ represent the intensity maximum of the fluorescence spectrum immediately after excitation, at time t, and for the fully relaxed spectrum. The advantages of time-dependent spectral shift (TDSS) measurements are threefold: 1) These solutes are direct microscopic probes of the solvent environment. 2) The temporal resolution of these experiments is as high as 100 fs. 3) $C(t)$ directly mirrors the motion along the solvent coordinate on the excited state FES. In fact, $C(t)$ can be considered the (properly normalized) solvent coordinate q[149] [see eq. (2) and Fig. 8]!

A great number of such investigations allow some generalization to be made. a) With the exception of strongly associated liquids such as higher alcohols, dielectric relaxation in many common solvents occurs on a time scale of 10 ps and less. A number of representative results is compiled in Table 1. b) The dynamics is nonexponential in most cases. For simplicity an average solvation time τ_s is then introduced as an approximate time constant of dielectric relaxation. c) At least in acetonitrile there is indeed a very fast relaxation component with a characteristic decay time of about 100 fs, which constitutes almost 80% of the overall dielectric response of the solvent.[139] This is strong evidence for the kind of inertial motion depicted in Figure 7 (c).

Nevertheless, any attempt to translate experimental data into molecular mechanisms is rather speculative at present. In this context, molecular dynamics simulations of solvation[140] constitute a powerful and very promising tool. Although numerical difficulties in these calculations require serious simplifications, these techniques offer several advantages. First, such simulations achieve a theoretical temporal resolution that is still far beyond experimental means. This is particularly important for the short-time behavior of dielectric relaxation. Second, they provide a very detailed picture of the microscopic molecular motion of the solvent. Different types of motion such as rotation of dipoles, translation of molecules, and diffusional motion can be distinguished, and their relative importance in different stages of relaxation can be evaluated.

6. Experiments on Dielectric Relaxation Effects

Most relevant experiments measure the dependence of the ET rate on the longitudinal dielectric relaxation time τ_l (or τ_s). A glance at Table 1 and equation (17) shows that such an

experiment will either require a temporal resolution on a (sub)picosecond time scale or a reaction with a sizable activation barrier. The relaxation time τ_l is varied either by the use of different solvents, or in the same solvent by a change of temperature or external pressure.[150] This procedure leads to additional complications since other solvent parameters such as dielectric constant, refractive index, and density cannot be kept constant. Several of these parameters affect the rate through the free energy of activation. This dependence has to be eliminated experimentally or theoretically before a meaningful comparison with theoretical predictions can be made.

6.1. Evidence for Solvent-Controlled Adiabatic Electron Transfer

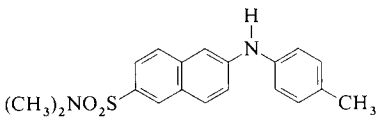
A popular method is the investigation of intermolecular electron exchange between molecules and their anions or cations:

$$A^{\bullet -} + A \rightleftharpoons A + A^{\bullet -} \quad \text{or} \quad C^{\bullet +} + C \rightleftharpoons C + C^{\bullet +}$$

A small fraction of the molecules in solution is oxidized or reduced chemically or electrochemically. These species are expected to form precursor complexes $A/A^{\bullet -}$ or $C/C^{\bullet +}$ within which the electron exchange, which is investigated with ESR[72] and NMR techniques[68] or electrochemical methods, occurs.[65, 66] The electron exchange leads to a broadening of ESR or paramagnetic NMR lines, which can be measured as a function of solvent, temperature, etc. Typical examples are TMPD/TMPD$^{\bullet +}$ (TMPD = *N,N,N',N'*-tetramethylphenylenediamine), TCNE/TCNE$^{\bullet -}$ (TCNE = tetracyanoethylene), and $[Cp_2Co]/[Cp_2Co]^{\bullet +}$ (Cp = cyclopentadienyl). Grampp et al.[72] and Weaver et al.[65, 68] have indeed found some cases where the rate of exchange is inversely proportional to τ_l as is expected for a solvent-controlled adiabatic reaction [eq. (17)]. Great care was taken to correct the data for solvent effects on the barrier height $\Delta G^{\ddagger}$.

A characteristic feature of most electron-exchange reactions is that they are processes with weak electronic coupling and a high activation barrier (of the order of 0.2 eV); that is, a steady-state distribution in the reactants is likely. In fact, the latter is a necessary condition to slow the reaction down sufficiently to make it accessible to magnetic resonance methods. Although these systems constitute good models for a verification of the above theoretical predictions, ESR and NMR methods have serious drawbacks. 1) They are limited to practically thermoneutral reactions. 2) The rate is indirectly inferred from the linewidth; no explicit time dependence is monitored. 3) On the time scale of the electron-transfer reaction in many of these systems, other processes occur, potentially obscuring or in any case complicating the interpretation of experimental data,[151, 152] among them decay and reformation of the precursor complex of the reactants and structural changes within it.

Some of these disadvantages were avoided in a few time-resolved fluorescence experiments of photoinduced charge-transfer reactions. Among the first examples were fluorescence measurements by Kosower et al.[56] with the *N*-arylaminonaphthalenesulfonate derivative **1**.



1

The reaction is initiated by optical excitation of the naphthalenesulfone-*N,N*-dimethylamide. In polar solvents the fluorescence of the excited state is quenched by intramolecular ET from the arylamino residue to the excited sulfonamide to form a charge-separated state. Back ET from the sulfonamide anion to the arylamino cation to form the ground state of the molecule completes the reaction cycle. The charge-separated state is fluorescent, too. Time-resolved measurements of the fluorescence decay from the excited state and the charge-separated state reveal the kinetics of charge-separation and recombination. Measurements were carried out in the series of alkanols from methanol to decanol as solvent. The dielectric response of these linear alcohols is best described by a sum of three exponentials where the slowest relaxation component covers a range of τ_l from 3 to 500 ps. The intramolecular charge separation was nonexponential but the average electron-transfer time τ_{et} was found to be about the same as τ_l within 30% when τ_l was calculated with this longest dielectric relaxation component of the alkanols. Obviously the faster components are irrelevant in this case. ET reactions on such a short time scale are necessarily processes with a low activation barrier.

In another series of experiments Huppert et al.[57] focus on the explicit time dependence of the charge separation in **1** and related derivatives in several pentanediols. They found that the fluorescence intensity is well fitted by a stretched exponential function and attribute it to a perturbation of the local solvent structure by the presence of the fluorophor.

Still, electron transfer in many of these systems is expected to be accompanied by the rotation of part of the molecule. Such conformational changes are known to exhibit a dependence on the viscosity of the solvent,[153] which may be difficult to distinguish from dielectric relaxation effects. In fact, much of the formalism in Section 4 was originally developed[132] as a model for an intramolecular reaction accompanied by slow conformational changes!

6.2. Evidence for the Crossover from Nonadiabatic to Solvent-Controlled Adiabatic Transfer

Evidence for the transition from nonadiabatic to solvent-controlled adiabatic behavior is still scarce. Weaver et al.[68] investigated a series of electron-exchange reactions between metallocenes with different metal atoms and with substituents of different size and their cations. The different substituents and central atoms influence the intermolecular electronic coupling V between the reactants in the precursor complex. In the solvents used, τ_l increased from about 250 fs to 10 ps. The qualitative dependence of the rate was similar to that defined in equation (18) with a regime with practically constant rate that then falls off roughly as $1/\tau_l$. Furthermore, the larger the substituents on the ferrocene the later this crossover occurred. This is consistent with a weaker donor–acceptor coupling V the further apart the reactants are kept by bulky ligands.

Higher alcohols exhibit a very strong temperature dependence of τ_l. This property was utilized by several groups[58, 73, 74, 76] to test equation (18) with intramolecular donor–acceptor compounds that exhibit photoinduced nonadiabatic ET at room temperature. Upon lowering the temperature, τ_l increases sufficiently to effect a crossover from nonadiabatic to solvent-controlled adiabatic behavior. An example of this kind is shown in Figure 9 where the

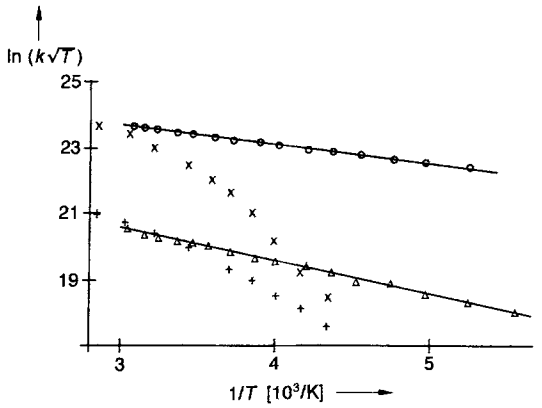


Fig. 9. Temperature-dependent electron-transfer rates in **2** in propionitrile (o, Δ) and propylene glycol (x, +). o,x: $n = 1$; Δ, +: $n = 2$.

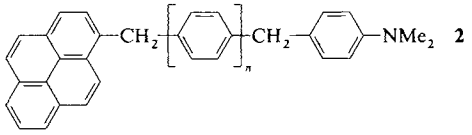
temperature-dependent rates of the photoinduced intramolecular ET in the two compounds (**2**, $n = 1$, 2) are compared in propylene glycol and propionitrile.[74]



2

Optical excitation of the pyrene moiety induces an ET from the dimethylanilino residue to the excited acceptor. The kinetics of the ET is inferred from the increased fluorescence decay rate relative to that of a reference compound lacking the electron donor. The longer bridge between the donor dimethylaniline and the acceptor pyrene in **2** ($n = 2$) results in weaker electronic coupling V than in **2** ($n = 1$). The temperature dependence of the rates determined by $\Delta G^{\neq}$ is expected to be quite similar in both solvents and is empirically corrected in the ratio of the rates in both solvents, k_{diol}/k_{nitr}. On the other hand, in contrast to propionitrile, dielectric relaxation in propylene glycol is enormously slowed down at lower temperatures. Furthermore, it exhibits a broad distribution of relaxation times of the Davidson–Cole type.[143] The data in Figure 9 show that at elevated temperatures the rates for each compound are about the same in the two solvents. At lower temperatures they rapidly diverge. The temperature at which this deviation sets in increases, that is, the corresponding τ_l decreases, the stronger the electronic coupling V. This is predicted by equation (18). The strong temperature dependence of the ratio k_{diol}/k_{nitr} translates into $k_{diol} \propto 1/\tau_l^{\alpha}$, $\alpha = 0.3-0.6$. This exponent is possibly related to the distribution of relaxation times in propylene glycol.[43, 47, 48]

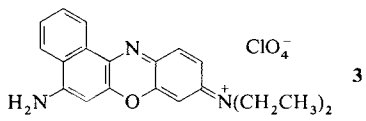
A similar qualitative change in behavior was observed in other experiments.[58, 76] However, as with **2**, all these donor–acceptor systems are rather flexible molecules undergoing conformational changes, which in turn can overlay the actual ET reaction and lead to a dependence on temperature and viscosity not unlike the one predicted by equation (18). Nevertheless, no systematic study seems to have been undertaken with rigid compounds yet.

6.3. Examples of an Unexpected Absence of Solvent Control

Despite such examples of reasonable agreement between experiment and theory there is a significant number of apparent failures, in the sense that very little correlation was found between charge-transfer rates and published relaxation times. These examples include intermolecular electron-exchange reactions, charge transfer in certain intramolecular systems with a twisted charge-transfer state (TICT), and fairly rigid intramolecular donor–acceptor compounds. In many of these cases k_{et} is much faster than the inverse of τ_l or τ_s, although according to equation (17), $1/\tau_l$ is an upper bound for the rate!

In several of their measurements on bimolecular electron exchange Weaver et al.[67, 69–71] explain this discrepancy with a predominant coupling of the charge transfer to fast relaxation components of the solvents that are even now difficult to measure and were left out in older relaxation data. According to Hynes[50] these components can speed up the rate significantly (see Section 3.4.2). Yet it is less than obvious what distinguishes these systems from similar ones such as those in Sections 6.1 and 6.2 that do behave as expected. A major drawback for attempts at clarification is the insufficient knowledge of the relevant intramolecular and solvent parameters of most ET systems, which allows no detailed comparison with existing theories without additional ad hoc assumptions.

Kobayashi et al.[77] measured the intermolecular ET rate in a solution of nile blue (**3**) in *N,N*-dimethylaniline. In this

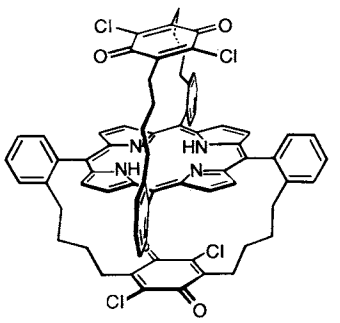


3

system *N,N*-dimethylaniline is both solvent and electron donor, which quenches the fluorescence of nile blue. The reaction is thought to occur in a close face-to-face configuration of donor and acceptor. The kinetics of the reaction is biphasic; the dominant decay time is 100 fs (95%) and the second component 2.5 ps (5%). The faster component implies an ET rate of 10^{13} s^{-1}, which is about 50 times faster than the inverse of the (estimated) τ_l of about 5ps in *N,N*-dimethylaniline! On the grounds of estimated reorganization energies of $\lambda_s \approx \lambda_i \approx 0.3$ eV, the authors classify their system as belonging to the intermediate reaction-window regime ($r \approx 1$, see Section 4.2). In the Sumi–Marcus model intramolecular vibrations offer an "escape route" over the activation barrier independent of frictional effects. Results of nu-

merical calculations for the average survival times τ_a and τ_b of equation (24) in this regime are indeed consistent with experimental decay times in this case (assuming $k_{eq} = 2 \times 10^{14}\ s^{-1}$). Yet their estimate of the intramolecular reorganization energy[77] yields only the high-frequency part of λ_i, whereas, strictly speaking, the ratio r in Section 4 refers to low-frequency vibrations. Thus the straightforward application of the Sumi–Marcus theory appears somewhat questionable.

Similar behavior was revealed for the cyclophane-like compound **4** containing a porphyrin and two dichloroquinone units in a cofacial orientation.[75] The optically excited



4

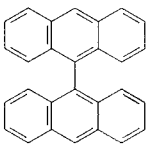
porphyrin acts as the electron donor, the quinones as acceptors. The kinetics is again monitored by the fluorescence quenching of the porphyrin. The reorganization energies λ_s and λ_i in this compound are comparable to those of system **3**.[154] The intramolecular ET rate is about $10^{12}\ s^{-1}$ and almost independent of solvent polarity in solvents ranging from hexane to acetonitrile and those with dielectric relaxation times as large as $\tau_l \approx 100-300$ ps such as glycerol triacetate and octanol. The very fast ET even in the nonpolar solvent hexane indicates that the reaction coordinate does not necessarily involve significant polarization fluctuations.

In addition to these cases of "missing" frictional effects there are several examples where initially a good correlation of ET rates and dielectric relaxation was postulated, which later turned out to be a simple effect of solvent on the barrier height ΔG^{+} (a static solvent effect)[155, 156] or were questioned for other reasons.[157] A general problem in this context is that the accessible range of τ_l (or other parameters) in most systems is rather narrow because of experimental difficulties. This leads to small variations of the rate which can be fitted by any theory showing the same qualitative behavior (and vice versa).

6.4. Recent Results from Ultrafast Spectroscopy

A significant step forward towards a sufficient characterization of the system under investigation was recently made by Barbara et al. at the University of Minnesota in a series of experiments in which solvent and intramolecular parameters could be determined independently. One example is the photoinduced charge separation in bianthryl (**5**, A–A)[59, 60] (see Fig. 10).

An ultrashort light pulse excites the molecule into a nonpolar locally excited (excitonic) (LE) state (A–A $\rightarrow$A*–A $\leftrightarrow$A–A*). In a polar liquid an asymmetric fluctuation in the solvent environment breaks the symmetry of the system



5

and induces an intramolecular charge separation leading to one of two possible dipolar charge-transfer (CT) states (A*–A $\leftrightarrow$A–A* $\rightarrow$A$^+$–A$^-$,A$^-$–A$^+$). The stronger solvent stabilization of the polar CT state compared to the nonpolar LE state leads to self-trapping of the CT state.

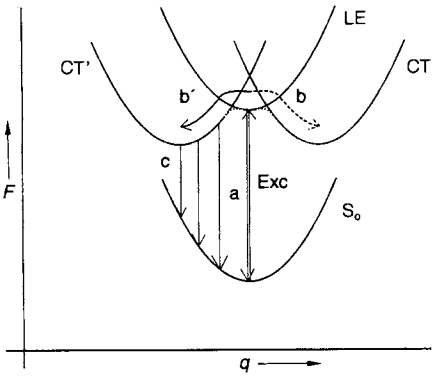


Fig. 10. Schematic representation of diabatic and adiabatic FESs for **5** in a polar solvent in the ground state S_0 (A–A), the nonpolar LE state (A*–A $\leftrightarrow$A–A*), and the two polar charge-transfer states CT (A$^-$–A$^+$) and CT' (A$^+$–A$^-$). a) Fluorescence from the LE state, b), b') intramolecular charge separation to the CT states and solvent relaxation, c) time-dependent red-shift of the charge recombination fluorescence from CT'.

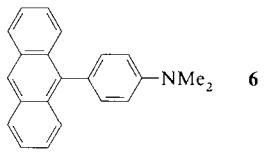
The kinetics of this system was extensively investigated by the time dependence of the fluorescence spectra of the LE state (A*–A $\leftrightarrow$A–A* $\rightarrow$A–A) and of the CT states (A$^-$–A$^+$, A$^+$–A$^-$ $\rightarrow$A–A) in many solvents with very high temporal resolution.[59] The average electron-transfer times τ_{et} of the reaction LE $\rightarrow$ CT vary from 0.85 ps in acetone to 450 ps in pentanol at 273 K and agree with average solvation times τ_s within 40%. As in the system depicted in Figure 8, the temporal change of the fluorescence spectrum from the charge-separated state directly mirrors the motion on the FES. This motion was simulated[60] with a Langevin equation and a frequency-dependent friction term determined in TDSS experiments (see Section 5.2). The agreement between experimental spectra and numerical simulations was surprisingly good. The experimental data show that the charge-separation reaction is adiabatic, practically activationless, and nonexponential in most cases. Yet one distinctive feature of this system should be kept in mind: Sizable solvent fluctuations are indispensible for creating the asymmetry necessary in the system if a charge separation is to occur. Otherwise there is no reaction; that is, polarization fluctuation dynamics is necessarily rate-determining. It is hard to see how some intramolecular vibration could have the same effect.

A very similar analysis was performed by the Minnesota group on the photoinduced charge separation in the (unsymmetrical) molecule 9-(4-*N*,*N*-dimethylaminophenyl)anthracene (**6**).[61] The ET in this compound can be considered as a two-step process. The first step comprises most of the change of the electronic charge distribution on **6**, occurs on a time scale of less than 150 fs, and is independent of solvent

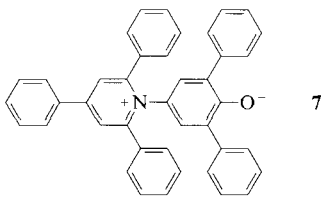


6

relaxation properties. The second one essentially mirrors the time-dependent solvent stabilization of the resulting charge-separated state with the characteristic time constant τ_s and involves only a minor further separation of the total charge transferred. Thus the ET reaction as a whole is only weakly affected by dynamic solvent effects.

A common feature of systems **5** and **6** is that the explanation of the ET dynamics requires the explicit simulation of the time dependence of the probability distribution of the reactants along the reaction coordinate. A discussion in terms of rate constants is clearly insufficient.

A very different behavior was found[62-64] for the photo-induced charge separation in the compound betaine-30 (**7**).



7

This molecule is directly excited from a charge-separated ground state into a higher, weakly polar state (see Fig. 11).

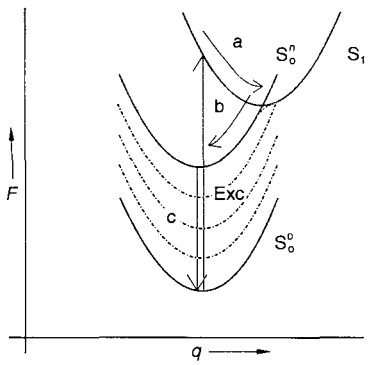


Fig. 11. FESs representing the vibronic ground state S_0^0 and the manifold of nth vibrationally excited states S_0^n of the charge-separated ground state S_0 and the weakly polar, optically excited state S_1 of **7**. The various states S_0^n are vertically shifted by the phonon energy $\hbar\omega_i$. Note: The classical coordinate q refers to two different degrees of freedom for step a and b: a) dielectric relaxation of the solvent in the excited state, b) charge-transfer reaction induced by a low-frequency (intramolecular) vibration, c) vibrational relaxation to the ground state with respect to high-frequency modes.

The large change in dipole moment will necessarily lead to a nonequilibrium initial polarization in the excited state. The reverse reaction from the weakly polar excited state to the charge-separated ground state was monitored by the recovery of the ground-state absorption (temporal resolution of about 100 fs). Room temperature measurements in simple solvents such as acetonitrile and methyl acetate cover a range of average solvation times τ_s between 250 fs and about 10 ps.[62, 63] Temperature-dependent measurements in glycerol triacetate from 228 to 318 K extend the upper limit of τ_s from 10 ps to μs.[64] A drawback of the experiments on temperature dependence is that the dielectric response of glycerol triacetate is less well characterized than that of the other solvents. The reliability of the data for fast and slow relaxation is therefore not strictly comparable.

The relevant solvent parameters and intramolecular parameters were estimated by fitting model band-shape functions to stationary ground-state absorption spectra in many solvents.[158] The band shape is statisfactorily reproduced if, in addition to a structureless continuous dielectric, an effective high-frequency ($\hbar\omega_i \approx 1600\ cm^{-1}$) intramolecular mode and a low-frequency ($\hbar\omega_{i,el} \leq 200\ cm^{-1}$) mode are included. The nature of the latter mode is not yet understood, however. Furthermore, the band-shape analysis yields estimates of the energies λ_s, λ_i, and $\lambda_{i,el}$ (see Sections 2.3, 3.4.1, and 4.1) referring to solvent continuum and high-frequency and low-frequency mode reorganization. The electronic coupling V was estimated at about $2500\ cm^{-1}$, which guarantees an adiabatic reaction under all circumstances.

The overall dependence on relaxation properties is as follows: In solvents with solvation times τ_s of less than 3 ps, the survival time of the excited state rapidly rises with τ_s from 0.2 to about 2 ps, but then remains almost constant at 2–5 ps in "slower" solvents with solvation times greater than 10 ps (even by several orders of magnitude). This kind of crossover of the ET rate with increasing dielectric relaxation time of the solvent is the exact opposite of the one in equation (18)!

The interpretation offered by the authors[63] is the generalized Sumi–Marcus model including a classical and a high-frequency, quantum-mechanical intramolecular mode. The high-frequency mode serves as an accepting mode for the high driving force and enables an almost activationless course of this ET reaction in the inverted regime. The low-frequency mode of the band-shape analysis is taken as the Y coordinate in Figure 6. Furthermore, the initial nonequilibrium polarization prepared upon optical excitation is explicitly taken into account.

The qualitative explanation of the biphasic dependence of the rate on τ_s is as follows: Optical excitation of the betaine initially prepares a state within a range of the diffusive solvent coordinate X that has a sizable activation barrier in $k(X)$. In "fast" solvents ($\tau_s \leq 3$ ps) the solvent polarization will at first "diffuse" to a solvent configuration for which the activation barrier is lower, and then the system reacts to form products very rapidly along the classical nondiffusive coordinate. The rate-determining step is the polarization diffusion, and the survival time of the excited state is therefore proportional to τ_s. In "slow" solvents ($\tau_s \geq 10$ ps), the system will react over the barrier that it experiences in its initial solvent configuration before it can diffuse to another configuration characterized by a lower barrier. Naturally the rate will be almost independent of τ_s in this limit. Although the time scale is only 10 ps, this already corresponds to the frozen limit of Section 4.2.

On comparison of **5**, **6**, and **7**, a very specific dynamic solvent effect is found in each compound. Nevertheless, these systems represent only the special case of an almost barrierless reaction with an intrinsically very strong donor–acceptor interaction. The crossover between the nonadiabat-

ic/solvent-controlled adiabatic/uniform adiabatic cases has not yet been treated in the same detail.

7. Conclusions and Prospects

In general, the finite dielectric response time of a polar solvent exerts a retarding influence on the change of the charge distribution on a solute that is a reactant of an ET reaction. Such a reaction is described as the crossing of a particle (the "system") over an activation barrier between two wells on a FES. The rapidly fluctuating interaction with many solvent molecules is modeled by frictional and random forces and results in a highly stochastic motion of the particle over the barrier.

A fairly general consequence of diffusive barrier crossing is that the retardation in the rate of crossing is proportional to the longitudinal dielectric relaxation time τ_l of the solvent. Thus for a long time the proportionality of the rate to $1/\tau_l$ has been considered the trademark of dielectric relaxation effects, and early experimental results seemed to confirm this picture. In fact, theory suggested that dynamic solvent control of ET can be attained in every reaction if it is carried out in solvents with sufficiently slow dielectric relaxation. Yet, this early enthusiasm may have been premature. It has become increasingly evident that reality is much more complex. This behavior results from an interplay of electronic coupling (nonadiabaticity), stochastic barrier crossing, and the possibility of several time scales for dielectric response and intramolecular reorganization. Nevertheless, current theoretical models are still too crude to offer reliable criteria in practical cases. In this respect a lot remains to be done to develop a truly molecular theory.

On the other hand it is precisely the uncertainty of relaxation data and the lack of reliable molecular information in combination with the flexibility of current theories that has hitherto allowed researchers to declare agreement of theory with practically every experimental outcome. Consequently, the crucial question is: What are the conditions an ideal experiment has to fulfill to remedy this somewhat unsatisfactory state of affairs?

First, fixed distance and orientation of electron donor and acceptor are highly desirable. This condition is realized in rigidly bridged intramolecular donor–acceptor compounds and ensures a well-defined electronic coupling and excludes conformational and other structural changes likely to interfere with the ET.

Second, a full characterization of intramolecular and static solvent parameters independent of the measurement of dynamic solvent effects on ET is indispensible. The electronic coupling can be estimated from a global analysis of the dependence of the rate on the driving force and the distance[14] and in some cases from static charge-transfer absorption spectra.[18, 159, 160] Band-shape analysis of charge-transfer transitions can provide estimates of relevant reorganization energies and vibronic frequencies.[158, 161] Raman studies of these systems[162] could further improve our knowledge on these parameters.

Third, detailed information on the time scales and mechanisms of dielectric response and its coupling to the reacting species is essential. In this context, ultrafast optical spectroscopy has reached a stage where one is beginning to understand solvent dynamics on a molecular level.

Fourth, there is important information in the explicit time depencence of ET. This necessitates a time-resolved measurement of ET kinetics on a time scale comparable to dielectric response. In summary, only a combination of several static and dynamic measurements will provide the necessary information to construct the relevant FESs of the system and the motion thereon.

Fortunately, the enormous progress in spectroscopic instrumentation and the synthesis of suitable donor–acceptor systems have brought these ambitious goals within reach. Furthermore, advances in computer power are beginning to enable realistic simulations of ET reactions in solution, which promise to close the gap between experiment and theory.

This encouraging prospect is of far-reaching importance for reaction dynamics in solution as a whole. Although the general ideas of dynamic solvent effects such as diffusive barrier crossing and adiabaticity have been discussed in the context of ET, they are of a much wider validity and pertain to other reactions such as proton transfer, isomerizations,[163] ligand binding in enzymes,[83] ionic and radical association/dissociation,[164] and to nucleophilic substitution[117, 165] as well.

Most of all I would like to thank my academic teacher Prof. M. E. Michel-Beyerle, Technische Universität München (TUM). Her enthusiasm has been a source of inspiration over many years. Without her ceaseless commitment I would have had neither the means nor the conceptual background for my work on electron-transfer reactions. It was at her instigation that I began writing this review. It is also with great pleasure that I acknowledge the continuous support and encouragement by Prof. J. Jortner, Tel Aviv University. He introduced me to the subject and has generously shared his comprehensive knowledge and latest results with me ever since. Much of the success in our work at the TUM is a direct result of his advice. Without the enormous synthetic effort and the close cooperation with Prof. H. A. Staab and his co-workers at the Max-Planck-Institut in Heidelberg, we could not have carried out our most recent measurements with the porphyrin–quinone compounds. Furthermore, I have benefited much from the critical reading of the manuscript and many stimulating discussions with Prof. M. Bixon, Tel Aviv University, and Prof. N. Rösch, Technische Universität München. I would also like to thank Prof. P. F. Barbara, University of Minnesota, for making available several preprints prior to publication. The financial support by the Deutsche Forschungsgemeinschaft and the Bundesministerium für Forschung und Technologie is gratefully acknowledged. Last but not least, I am heavily indebted to Prof. G. L. Hofacker, TUM, for the kind hospitality I have experienced at his institute.

[96] A difficult question is whether the equilibrium averaging in equation (3) of the solvent configurations (X) remains meaningful even in a dynamic process far from equilibrium. Eventually, nonequilibrium dynamics has to be treated explicitly on higher dimensional (free) energy surfaces, for example, along the lines of Section 4.
[97] A harmonic free energy surface $F(q)$ corresponds to a Gaussian probability distribution $p(q)$ in equation (3). Its force constant f_s is determined by the width of the Gaussian $f_s = k_B T/\langle (q - \langle q \rangle)^2 \rangle$; the effective mass M is defined through the equipartition theorem $M = k_B T/\langle (\partial q/\partial t - \langle \partial q/\partial t \rangle)^2 \rangle$, where the brackets $\langle\ \rangle$ indicate equilibrium averages [95].

[104] There are other conventions for γ_{1L} differing from equation (7) by factors of 2, $\pi/2$, $\sqrt{\pi/2}$ etc.

[105] The justification of the factor of π requires an explicit quantum-mechanical calculation of the transition probability for a single crossing of the LZ region [100, 106]. The factor of 2 accounts for the fact that in a nonadiabatic reaction the system usually crosses the LZ region twice: once on the way up the reactant PES and, unless a transition has occurred during the first crossing, once on the return trip, each contributing $\pi\gamma_{lz}$ to the overall transition probability P for a successful reaction.

[108] R. P. Van Duyne, S. F. Fischer, *Chem. Phys.* **1974**, *5*, 183; N. R. Kestner, J. Jortner, J. Logan, *J. Phys. Chem.* **1974**, *78*, 2148; J. Ulstrup, J. Jortner, *J. Chem. Phys.* **1975**, *63*, 4358; J. Jortner, *ibid.* **1976**, *64*, 4860.

[109] Practically all analytical results in quantum-mechanical ET theory were derived only for reactions with a negligible entropy change. In applications, however, entropy effects are included in rate expressions by simply substituting free energies for ordinary energies. For equation (8) this substitution is discussed in R. A. Marcus, *J. Chem. Phys.* **1984**, *81*, 4494. In general, this procedure is only justified by the lack of alternatives. In simulations, free energies enter in a more natural way [55].

[110] The Landau–Zener probability p_{lz} is the transition probability upon a single crossing of the LZ region for arbitrary γ_{lz}. The derivation of the geometric series is a generalization of the argument in [105]: After an unsuccessful crossing of the LZ region on the way up the reactant PES the system may be trapped above the crossing point by repeated hopping between the diabatic PESs on the way down. The overall transition probability is the sum over all transition probabilities for an arbitrary number n of hops: $P = p_{lz} + (1\text{-}p_{lz})p_{lz}(1\text{-}p_{lz}) + \cdots + (1\text{-}p_{lz})p_{lz}^{2n-1}(1\text{-}p_{lz}) + \cdots = 2p_{lz}/(1 + p_{lz})$. See for example, [1] and T. Holstein, *Ann. Phys. (N.Y.)* **1959**, *8*, 343. Yet, the LZ transition probability is only valid between one-dimensional PESs. Its application to FESs must be seen in the spirit of the remark in [109].

[117] This statement tacitly ignores an important aspect: In an adiabatic reaction the solvent "sees" a gradual shift of the charge from the donor to the acceptor in the LZ region, which leads to an additional coupling between the dynamics of the solvent and of the change of the electronic structure [55]. This observation seems to have been overlooked in practically all analytical treatments of dynamic solvent effects on ET. Yet, the coupling was explicitly taken into account in computer simulations of S_N2-reactions (J.-K. Hwang, G. King, S. Creighton, A. Warshel, *J. Am. Chem. Soc.* **1988**, *110*, 5297; J.-K. Hwang, S. Creighton, G. King, D. Whitney, A. Warshel, *J. Chem. Phys.* **1988**, *89*, 859) and in the simulation of the model ET reaction in [94].

Nitric Oxide, NO, an Intercellular Messenger

By *Hans-Joachim Galla**

Nitric oxide, NO, is a colorless, relatively stable gas. It is not very reactive chemically, even though it has an unpaired electron and thus shows radical character. This can be equated with the fact that the ground state of the molecule at low temperatures is diamagnetic because of the interaction between the orbital moment and the spin moment of 1/2. Since the energy difference between the ground state and the excited paramagnetic state is around $1/2\,kT$ at room temperature NO exists as a gaseous highly paramagnetic free radical. NO reacts readily with oxygen in the air to form NO_2. NO is thermally unstable and under high pressures breaks down to yield N_2O and NO_2. In contrast to NO_2, pure NO evokes no physiological irritation. It is, however, able to convert hemoglobin to methemoglobin by oxidizing Fe^{2+} to Fe^{3+}. Since methemoglobin is unable to bind and transport oxygen NO is potentially toxic. The solubility of NO in water is low and is of the same order of magnitude (about 1 mM) as that of O_2 and CO_2. NO can, however, easily diffuse across the cell membrane. In physiological media the NO radical has a half-life of only a few seconds. Although it could not be deduced from its chemical and physical properties, we know today that NO is one of the most important and widely used messenger molecules in biological systems.[1] Endogenous NO is synthesized enzymatically in various mammalian cells by so-called NO synthases, during this process the amino acid L-arginine reacts with oxygen to give citrulline. This pathway is a shortened version of the urea cycle (Fig. 1). Hitherto the amino acid arginine has not been considered to be important in signal transduction, however, as a precursor of NO it takes on a completely new role. This is particularly interesting when one considers the role of the urea cycle in the brain; here two key enzymes of the urea cycle have so far not been found, namely ornithine carbamoyl transferase and carbamoyl phosphate synthase.[2] This is despite the fact that all the imtermediates of the urea cycle including citrulline, which is synthesized from carbamoyl phosphate and ornithine, have been identified in brain tissue. This finding can be explained partly by the shortened cycle through NO synthase. However, how arginine is transported into the brain remains unclear.

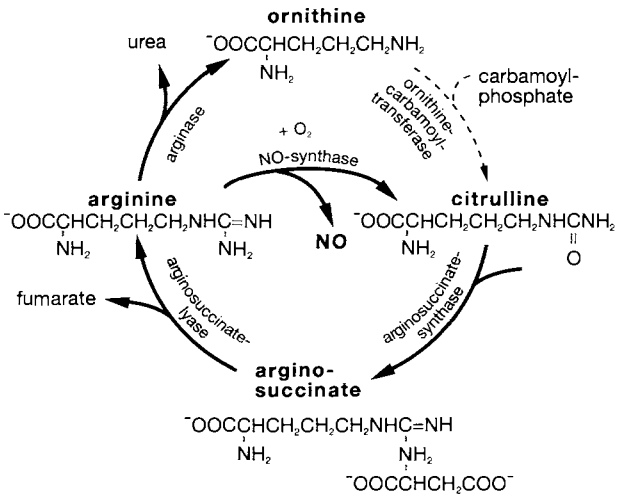

Fig. 1. Urea cycle and NO synthesis (taken from [2]).

The first indications that NO is a new kind of messenger molecule came from studies on the cell-mediated immune response. About ten years ago it was established that the expression of the cytotoxicity of activated macrophages on tumor cells can be induced and is dependent on L-arginine.[3] It has been known even longer that the activated macrophages inhibit DNA replication and the mitochondrial respiratory chain as well as the citrate cycle in their tumor target cell. The inhibited enzymes such as the proximal oxidoreductases of the mitochondrial membrane or the enzyme aconitase of the citrate cycle all contain 4Fe4S clusters as prosthetic groups. Therefore it was proposed that intracellular iron was the site of the attack. The identification of nitrosyl–iron–sulfur complexes two years ago supported the hypothesis that the arginine NO pathway is involved in the immune response. It is now known that in addition to the cytotoxicity on mammalian cells, NO possesses antimicrobial activity. It has therefore been proposed that the NO synthesis induced by cytokines or lipopolysaccharides (LPS) is an important biochemical defense mechanism against intracelluar microorganisms and pathogens.[4] An inducable NO synthase occurs in neutrophilic granulocytes.

Vascular endothelial cells[5, 6] release a wide variety of vasoactive substances, of these the so-called endothelial-derived relaxing factor (EDRF) is believed to be the most important. The EDRF is very unstable with a half-life of around 5 s. It activates a soluble guanylate cyclase in vascular smooth muscle cells and in blood platelets. This activation results in an increased level of the concentration of cyclic 3',5'-guanosine monophosphate (cGMP), which in turn inhibits the contraction of smooth muscles and the activation of blood platelets by a reduction in the level of intracellular free calcium. A number of well-known vasoactive substances, among them the platelet-derived compounds ADP, ATP, and serotonin (5-hydroxytryptamine), or the neurotransmitter substance *P*, bradykinin, acetylcholine, and histamine exert their dilatory effect by causing the endothelial release of the EDRF. This in turn leads to a relaxation of the smooth muscle surrounding the blood vessel by increasing the level of cGMP. In 1986, after years of intensive research into the chemical structure of EDRF, it was first proposed by Furchgott during a conference that EDRF is in fact nitric oxide.[7] Although other nitrogen compounds such as dinitrosyl Fe^{2+} complexes, S-nitrosothiols, or hydroxylamine remain in contention as the EDRF, it is now accepted that NO is the primary and direct product formed from the guanidino nitrogen of L-arginine. This was estab-

Institut für Biochemie der Universität
Wilhelm-Klemm-Strasse-2
D-W-4400 Münster (FRG)

lished by Mülsch and Busse[5] using electron paramagnetic resonance (EPR) spectroscopy. They were able to trap any NO produced in the form of a ferrous diethyldithiocarbamate mononitrosyl complex, which exhibits a characteristic EPR signal. The presence of a nitrosyl-Fe^{2+}–S complex in macrophages activated by cytokines was also established by EPR spectroscopy. In addition to the effect NO has on muscle cells, it also plays an important role in the regulation of the blood flow by the blood platelets. Mediated by cGMP, NO acts as an endogenous antithrombic substance by preventing the adhesion and the aggregation of the thrombocytes on the endothelium.

The identification of NO as EDRF stimulated experiments on brain tissue, in which likewise NO was liberated from L-arginine.[8, 9] The highest levels of NO synthesis were observed in the cerebellum, in which the excitatory neurotransmitter glutamate increases the level of cGMP by binding to the *N*-methyl-D-aspartate (NMDA) receptor. The addition of glutamate or NMDA leads to a threefold increase of the NO synthase activity, addition of NO synthase inhibitors prevents the increase in NO synthase activity and cGMP concentration. This clearly shows that NO plays a role in the effect of the neurotransmitter glutamate. Interestingly, in the brain the NO synthesis occurs preferably in populations of neurons that are selectively resistant to neurotoxic damage, for example in Huntington's disease (St Vitus'dance) or in a stroke. Since glutamate stimulates the formation of NO it seems paradoxical that those neurons which contain NO synthase are resistant to the neurotoxicity of the glutamate. This finding only makes sense if we assume that glutamate stimulates the production of NO in neurons but that then NO diffuses out of these cells and affects neighboring cells. This is supported by the fact that the destruction of neurons due to the neurotoxic activity of NMDA, which is for example released in the case of a stroke, can be prevented effectively by the use of NO synthase inhibitors, such as nitroarginine. A significant level of NO synthesis has been found in the peripheral nervous system in populations of neurons that regulate peristalsis in the intestine, in the nerves to erectile organs, and in neurons to the posterior pituatory gland and to the adrenal medulla. In these systems NO acts as a neurotransmitter: the synthase enzyme causes NO release upon nerve stimulation.

The NO-synthesizing enzyme, NO synthase, is a NADPH-dependent dioxygenase, which requires tetrahydrobiopterin as a cofactor. The enzyme is widely distributed and its activity is linked mostly to the activation of a soluble guanylate cyclase in the NO-producing cell itself or in other target cells (Fig. 2). This means that NO is both an intercellular messenger and an autocrine signal. The synthase occurs in at least two isoforms. The basal level of NO synthase activity in macrophages or in neutrophilic granulocytes is low. After stimulation of the macrophages by lipopolysaccharides or γ-interferon there is a drastic increase in NO synthesis.[10] At the same time oxygen free radicals are formed, that can combine with NO to form, for example, peroxynitrite, which is broken down to yield hydroxyl and nitrogen dioxide radicals. These are the actual cytotoxic substances (Fig. 2).

In endothelial cells a constitutive Ca^{2+}/calmodulin-dependent NO synthase occurs.[5] This enzyme produces physiological amounts of NO, which regulates the resting blood

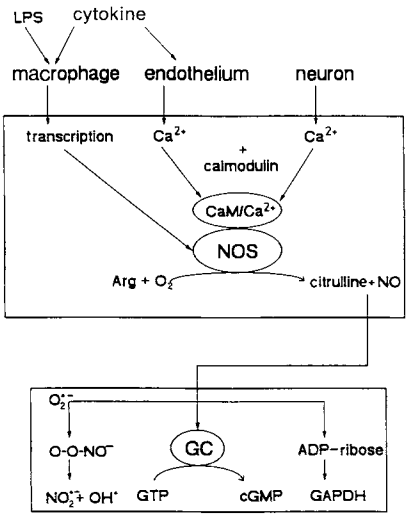

Fig. 2. Overview of the production and effects of NO on macrophages, endothelium, and neurons. Abbreviations: CaM, calmodulin; LPS, lipopolysaccharide; NOS, NO synthase; GC, guanylate cyclase; Arg, arginine; GAPDH, glycerine aldehyde-3-phosphate dehydrogenase (taken from [1]).

pressure through the smooth muscle of the blood vessel walls. The constitutive NO release can be divided up into continuous basal release and stimulated release. The stimulated NO synthesis can be increased by a factor of 2 to 3 receptor-dependent by agonists like acetylcholine, ATP, or bradykinin, or receptor-independent by Ca^{2+} ionophores, polycations, or Ca^{2+} ATPase inhibitors. This leads, however, to a short release of NO for only a few seconds. Both receptor-dependent and receptor-independent pathways require an increase in the intracellular Ca^{2+} concentration for NO synthesis. This transmembrane calcium flux remains little understood. Well understood, on the other hand, is the process in which the binding of an agonist to a receptor leads to the release of inositol-1,4,5-trisphosphate (IP_3) by the action of a membrane-bound phospholipase C on phosphatidylinositol-4,5-bisphosphate. IP_3 causes the release of Ca^{2+} from intracellular storage, as well as an influx of Ca^{2+} through voltage-independent Ca^{2+} channels. The resulting Ca^{2+}/calmodulin complex activates the NO synthase. Apart from this constitutive isoform, the endothelial cells, as well as granulocytes, and macrophages contain a NO synthase which can be induced in response to immune stimulation. A cardiovascular collapse which sometimes occurs after the application of cytokines such as tumor necrose factor (TNF) or interleukin-2 is in all probability caused by a pathological overproduction of NO. The same also applies to septic shock during which the endogenous level of cytokines drastically increases.

In the central nervous system, nerve stimulation leads to an increase in the cGMP level. Glutamate is released from the presynaptic terminal and affects the excitatory amino acid receptors, namely the NMDA and the AMPA receptors, which are named after their selective antagonists, *N*-methyl-D-aspartate and α-amino-3-hydroxy-5-methyl-4-isoxazole propionate. Both receptors are classed as ionotropic receptors, that is, they contain an integral ion channel. The NMDA channel of the glutamatergic synapse is normally blocked by Mg^{2+}. If, however, the postsynaptic membrane becomes sufficiently depolarized, the Mg^{2+} is released from

the NMDA channel and the channel is then open for an influx of Ca^{2+}. The Ca^{2+}, which enters the postsynapse, is complexed by calmodulin and activates the NO synthase. NO can then diffuse into neighboring cells, for example astrocytes, or diffuse back to the presynaptic nerve ending and activate the guanylate cyclase present there. The cGMP formed can in turn affect ion channels, stimulate phosphorylation by cGMP-dependent kinases, lower the cAMP level through cGMP-stimulated phosphodiesterases, and raise the level of cAMP through cGMP-inhibited phosphodiesterases (Fig. 2). A coherent overall picture of these interactions is not available at present.

Since the successful cloning of the cDNA of the neuronal NO synthase by Bredt et al.[11] much information has come to light about the structure and regulation of this enzyme. The NO synthases from brain tissue, endothelial cells, and macrophages show a 50% homology in their amino acid sequences, although the neuronal NO synthase is longer at both the C and N terminal than the endothelial and macrophage NO synthase. Cytochrome P_{450} reductase shows a significant sequence homology with NO synthase. Cytochrome P_{450} reductase transfers electrons to cytochrome P_{450}, which plays an important role in the detoxification of xenobiotic compounds. The NO synthases have the same binding sites for the coenzymes nicotinamide adenine dinucleotide phosphate (NADPH), flavin adenine dinucleotide (FAD), and flavin mononucleotide (FMN).[12] Such flavonucleotide binding sites are typical of the family of electron transfer proteins. In cytochrome P_{450} reductase these flavin nucleotides together with NADPH form an electron tranport chain through the isoalloxazine rings. It is assumed that electron transfer between the flavins also plays a role in NO synthase. The fact that the purified enzyme binds heme groups tightly and that after binding of carbon monoxide light is absorbed at 450 nm, leads to the conclusion that NO synthase must be a cytochrome P_{450} enzyme.

All three synthases have binding sites for calmodulin, however, the macrophage NO synthase is insensitive to Ca^{2+}. It is also interesting that the NO synthases have consensus sequences for cAMP-dependent phosphorylation sites. The neuronal NO synthase is phosphorylated by cAMP-dependent protein kinase A, protein kinase C, and by a Ca^{2+}/calmodulin-dependent protein kinase. Each of these three enzymes phosphorylates different serine residues in the NO synthase. Phosphorylation by protein kinase C leads to a drastic reduction in the catalytic activity of the NO synthase.

Bredt et al.[12] postulated an interesting mechanism for the regulation of the NO synthesis and deduced a connection between the IP_3 signal chain and the signal chain of NO as a messenger in neurons and endothelial cells. The receptor-controlled hydrolysis of phosphatidylinositolbisphosphate yields two messengers IP_3 and diacylglycerine (DAG). IP_3 causes an increase in the concentration of intracellular Ca^{2+}, leading to the formation of a Ca^{2+}/calmodulin complex which then activates NO synthase. The down regulation could then take place through DAG which activates protein kinase C, and decreases the rate of NO synthesis by phosphorylation of the NO synthase.

The physiological importance of the NO system is emphasized by a further consideration. Based on the sequence homology with cytochrome P_{450} reductase, which only applies to the C terminal of NO synthase, and the observation that NO synthase also exhibits cytochrome P_{450} properties, Lowenstein and Snyder[1] concluded that both enzymatic functions are present in NO synthase. One function of cytochrome P_{450} reductase is electron transfer to hemoxygenase, which breaks down the heme group into biliverdin and carbon monoxide. CO could function as a messenger in a very similar way to NO.[13] This idea is supported by the fact that hemoxygenase has the same distribution in neurons in the brain as guanylate cyclase. This could indicate that CO also regulates the endogenous cGMP level, so that the question has to be asked whether CO instead of NO is really the physiological regulator of guanylate cyclase activity in the brain. This naturally leads to the question of whether other target molecules exist for NO. In the meantime many other regulatory effects of NO have come to light, for example an increase in ADP-ribosylation of proteins in blood platelets. A further possible metabolic target is glycolysis. In this case NO increases the ADP-ribosylation of glycerine aldehyde-3-phosphate dehydrogenase (Fig. 2), which leads to an inhibition of the enzyme. This is also a possible explanation for the neurotoxicity of NO.

In view of the enormous increase in popularity of messenger NO, (it was for example voted "Molecule of the Year 1992" by *Science*),[14] it is not surprising that much effort has been directed towards developing a direct method for determining NO in situ. The way ahead has been shown by Malinski and Taka[15] who have taken advantage of the ease of oxidation of NO for the determination of its concentration. The authors used polymeric porphyrins with nickel as the central metal ion. By coating the polymer with a substance which is permeable to NO but blocks the diffusion of nitrite they created a detector specific for NO and able to measure a concentration down to 10 nM in solution. The authors successfully applied their method to the measurement of NO in blood vessels. Such a sensor will certainly help to answer questions about the intracellular localization of NO synthase and the nature of the target molecules for NO in the not too distant future.

Heterogeneous Catalysis—Still Magic or Already Science?**

By *Robert Schlögl**

The optimization of industrial heterogeneous catalytic processes with respect to the minimization of energy consumption and pollution is of increasing importance. Although the results of these efforts may be put into operation only slowly because of the high capital costs, the scientific efforts required for these optimizations, though rewarding, are very substantial. The underlying problem is understanding the operation of a catalytic system at an atomic level; it is not adequate to have only a model. In the historic approach to catalysis research the complexity of a practical reaction system is reduced to a level that can be adequately described. This approach was very successful in the analysis of a large number of details of heterogeneous catalysis, giving rise to the hope that someday entire processes may be understood. This was thought to be possible by extrapolations of experimental details from model investigations to the real world of an operating system.

Studies on ammonia synthesis, the traditional testing ground for catalysis science, are the best known examples of this strategy.[1] The culminating success of decades of research was a kinetic theory that allowed the precise prediction of the yield of ammonia under technical conditions using as parameters experimentally determined properties and a set of experimentally verified elementary reaction steps.[2]

Unfortunately, this strategy was not successful in any other practical application as yet. Actual heterogeneous catalytic processes could not be designed up to now. All of the catalytic processes vital to industry were developed by purely empirical methods and countless screening experiments. This heuristic approach has led to the opinion that catalysis research is not a science but rather "black magic". Industrial chemists tend to be rather skeptical towards inductive-scientific strategies in heterogeneous catalysis, since it is evident that our understanding of the relationships between structure and reactivity is inadequate.

One significant obstacle to understanding structure–reactivity relationships is the complexity of the solid catalyst. Active materials are multiphase compounds with dynamic behavior with respect to both surface and bulk structure. These dynamics were recognized only recently and relate to geometric structure, composition, and the local electronic state[1] of the active center. The analyst of a catalyst should thus not be preoccupied with a priori distinctions between important and unimportant components of the system but should consider all constituents (active components, support, impurities, poisons, promotors) of a practical catalyst. The long history of catalyst characterization should have taught the lesson that all analysis should be done in situ; all monographs on the subject repeat this statement.[3] Nevertheless only a fraction of the analyses are conducted under in situ conditions, since only few techniques can be used for such investigations and even then the technical reaction conditions must be modified.

Thus these experiments place certain technical constraints on the reaction conditions. A realistic description of an in situ experiment may be that a property of a catalyst is investigated as a function of reaction conditions characteristic of the practical application under simultaneous observation of the reaction kinetics (conversion, selectivity). Only then is it ensured that the active state of the catalyst is characterized and that the data are relevant to the reaction mechanism.

Knowing the mechanism is crucial to understanding the catalyst operation, which in turn is central to the scientific approach towards catalyst optimization. Extrapolations from experimental to real operation conditions must be limited, as the mechanism is dependent on interconnected sets of parameters whose quantitative relations are unknown (Fig. 1). Quantitative knowledge of these interconnections allows the full understanding of the mode of catalyst operation.

Activity and selectivity data do not allow conclusions concerning the reaction mechanism. The kinetics are determined by chemisorption processes (only a part of the mechanism) and by the micro- and macrotexture of the catalyst. The limitations of mass- and energy-exchange processes and noncatalytic consecutive reactions tend to obscure the relationship between kinetics and mechanism. The same holds for the relationship between the elementary steps and the microkinetics composed of them.

Analytical in situ experiments and all non in situ studies require deviations from the empirically optimized reaction conditions which affect the four groups of parameters in Figure 1 simultaneously. These deviations cause parameter gaps. If the gaps are closed by inadequate extrapolations the interconnection of all factors may lead to possibly dramatic

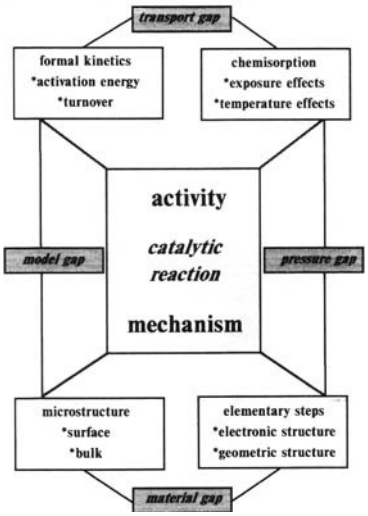

Fig. 1. Relationships between the catalytic performance of a solid (middle) and the main determining factors. The gaps arise from simplifications in the parameter sets that are required for catalysis experiments. Extrapolations from the data obtained from the simplified model to the actual catalytic reaction may endanger the relevance of a whole mechanistic reconstruction.

mechanistic errors. This is the reason for the failure of catalysis research as a science which has to prove its validity in the industrial application. As an example, much information has been accumulated on the elementary steps of chemical reactions on single crystals under high-vacuum conditions. Yet the "pressure gap" and "material gap" have been bridged inadequately, and an interpretation of the formal kinetics is not possible. As a further illustration for this point, the famous prediction arising from surface science of a theoretical limit for the selectivity of ethylene epoxidation was proven false in industrial practice.

The gaps shown in Figure 1 are all relevant in the design of in situ experiments. The transport gap describes the influences of mass- and energy-transport limitations on the kinetics. These phenomena are different for a catalyst in a fixed-bed reactor, for transparent wafers of the same material, and for catalysis experiments with single crystals. The pressure gap describes differences in the total pressure in experiments. The reaction mechanism frequently changes profoundly in a pressure range between millibars and ultrahigh-vacuum conditions because of threshold limits in the chemical potential of the gas-phase species.[4] The material gap[5] describes the difference in local microstructure and defect properties between single crystals (well-defined, easy to analyse, low dynamics) and polycrystalline materials (ill-defined, highly reactive, difficult to analyze). The model gap finally addresses the problem of finding the physical relevance of parameters obtained in a formal mathematical analysis of catalyst performance. Typically, gradients of specific activity, chemical transformations, and structural modifications are assumed to exist along the reactor tube or within a single grain of catalyst. Their experimental verification is in most cases, however, not possible.

In a fashionable approach to understanding a process a model system whose complexity is intermediate to that of a single crystal and a real system is defined and examined. Although this approach is partly successful, experimental verification of the relation between model and reality is very difficult.

This list of interconnected problems was addressed in a recent study of the methanol synthesis catalyst,[7] in which the authors describe their attempts at determining the nature of the active material of the catalyst experimentally. It is not known if in the hydrogenation of CO the active copper surface is metallic or oxidic. This reaction is the present testing ground in catalysis research, in analogy to the ammonia synthesis.[8] Certainly if the chemical nature of the active species is not known,[9] the mechanism of this reaction cannot be worked out scientifically.

For the difficult task of determining the valence state of the active copper species, which was attempted frequently before, a new spectroscopic technique has been developed which can provide information concerning the catalyst surface in situ. The results of the method are compared to and calibrated against the results obtained by more traditional techniques. The crucial experiment is a variation of the well-known extended X-ray absorption fine structure spectroscopy (EXAFS) experiment. This method allows the determination of the local geometric structure of a solid for a specific element without requiring long-range order as in conventional diffraction experiments. For metal atoms the specific X-ray radiation is hard enough to penetrate a gas atmosphere and the windows of a reaction cell, allowing in situ experiments on supported metal catalysts. In these studies of the Cu catalyst for the hydrogenation of CO the bond lengths determined allowed the differentiation between copper metal and copper oxides.

The experiment was conducted with a technical, polycrystalline, supported catalyst at ambient pressure in a gas atmosphere typical for industrial conditions (ca. 60 bar pressure). The bulk-sensitive EXAFS data clearly show that the catalyst is present in the metallic form under the conditions chosen. This was confirmed in a similar in situ experiment with conventional X-ray diffraction. The two sets of complementary structural information indicate that neither crystalline nor amorphous oxide are present in the catalyst.

Nothing has been said so far about the state of the copper surface, the essential interface for catalytic operation. The new experiment helped here: X-ray absorption was detected by measuring the yield of secondary electrons caused by the photoabsorption process, which converted the method from bulk-sensitive to surface-sensitive (information from a few monolayers instead of several micrometers). This technique also showed very convincingly that no copper oxide was present on the surface.

The nature of the active catalyst would have been clarified at this point if the experiments had been truely in situ. Unfortunately, as the authors did not determine the activity and selectivity of their catalyst, they describe an arbitrary state of the catalyst and give no evidence that the catalyst was indeed active. This point is not trivial (in the light of the gas phase applied), as the complexity of a working catalyst system outlined in Figure 1 does not permit this far-reaching extrapolation. It is frequently observed that the top layer of a catalyst bed is deactivated by poisons from the feed. In the experiments discussed only the top layer of the catalyst bed was investigated. No information on the gas purity, the shape of the catalyst bed, and the influence of the catalyst geometry (differential flow reactor) on the kinetic performance was given. Because of this lack of experimental information the investigation is not an in situ experiment, and the nature of the active copper species is open for further discussion.

At this stage the question arises of which other methods may be used to obtain information relevant to catalysis. Instationary conversion experiments are often suitable. In such truely in situ experiments the catalytic performance is analyzed as function of a process variable that changes with a defined time profile. The determination of dissolved atomic nitrogen in the catalysts used in the technical ammonia synthesis serves as an example.[10] Its interpretation required, however, a detailed knowledge of the surface chemistry of elemental iron.[11]

Such detailed chemical information is a prerequisite for a mechanistic analysis of a catalytic process and can only be obtained with certain reliability if several complementary methods are used for their determination. Only then can misinterpretations occurring as internal inconsistencies within one dataset be recognized and possibly corrected. An example of the erroneous overinterpretation of a single analytical method is the theory of paracrystallinity in catalysis. Carefully measured X-ray powder diffraction data of ammo-

nia synthesis catalysts revealed characteristic anomalies in the lineprofiles.[12] These were correlated with molecular dispersions of promoter oxides within the bulk iron, and special catalytic effects were ascribed to this unusual state of matter. Today we know[13] that the lineprofile anomalies were caused by special crystallographic artifacts which were known to exist then but were not considered. No correlation exists between the bulk X-ray diffraction data and the catalytic performance.

A further example of incorrect structural data from an in situ experiment on the active phase of the ammonia synthesis catalyst was caused by the inadvertant activation of the catalyst within the X-ray diffraction system. The resulting amorphous state was concluded[14] to be the active principle in ammonia synthesis, again without testing the catalytic activity during the diffraction experiment. Today we know that the activated catalyst contains highly oriented, crystalline iron metal particles.[10]

As outlined in Figure 1 the detailed knowledge of microstructure alone is inadequate for a complete understanding of the mode of operation of a catalyst; information about its surface constitution is essential. Unfortunately, all surface science techniques require ultrahigh-vacuum conditions because of the nature of the information-bearing particles (photoelectrons, ions, atoms). Real on-line in situ experiments with these techniques are thus not possible. The most adequate solution to this dilemma is the combination of a high-pressure microreactor with a surface analytical instrument. The suitable design of the transfer system between the high-pressure and ultrahigh-vacuum sections ensures that the working catalyst surface is frozen.[15] Any reactive chemisorbed molecular species will, however, be lost in the evacuation process. This technique was used for the investigation of the nature of the active phase[16] of the iron oxide catalyst used for the dehydrogenation of ethylbenzene to styrene. A published model of the catalyst operation[17] predicted that the conversion should increase with the surface abundance of potassium (an essential promoter) and should decrease as the surface becomes covered with carbon (from the products). A summary of X-ray photoelectron spectroscopic data collected from catalysts operated at various levels of conversion in a steady state prior to analysis[18] is given in Figure 2. It can be seen that both predictions from the catalyst model are incorrect. The parameter controlling the conversion is the abundance of hydroxyl ions indicating the presence of potassium in the deactivated form of KOH, which results from disintegration of the active ternary iron oxide $KFeO_2$.[16] A number of other promoters that are added to technical catalyst systems to improve the selectivity and stability of the catalyst are either not abundant at the surface or their bulk concentration does not appear to correlate with the surface catalytic process. This example demonstrates the value of an in situ experiment including simultaneous characterization of the catalyst performance. Its results were corroborated by a variety of complementary experiments probing both the bulk and the surface of the catalyst.[16]

In consideration of this discussion if we try to answer the question asked in the title the realistic reply must be—still magic. The obstacles to a scientific understanding of heterogeneous catalysis are considerable. The perspectives of penetrating the magic of catalysis by scientific means is, however, promising owing to the increasingly frequent attempts at circumventing these obstacles. Catalysis research today is on its way to becoming an interdisciplinary science incorporating in a rational way the knowledge from surface science, solid-state physics, and chemical engineering. Its progress will be measured by its contribution to the efficient solution of the strategies problems of future catalyst applications.

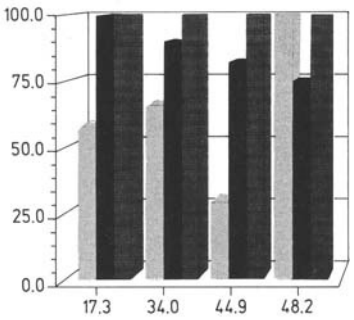

Fig. 2. Results of quantitative XPS analyses on an iron oxide catalyst active in the dehydrogenation of ethylbenzene to styrene. The data were measured at given steady-state conversion levels. The conversions were carried out under technical conditions (873 to 893 K, 6:1 mixture of water ethylbenzene, 1 bar total pressure, liquid hourly space velocity (LHSV) 0.5 Lh^{-1}). XPS data were obtained after rapid transfer of a fraction of the catalyst sample into ultrahigh vacuum. All numbers are normalized to 100. *x* Axis: Conversion to ethylbenzene in %. *y* Axis: Spectroscopic parameter in arbitrary units. Light gray columns: carbon abundance, dark gray columns: potassium to iron ratio, black columns: hydroxyl abundance.

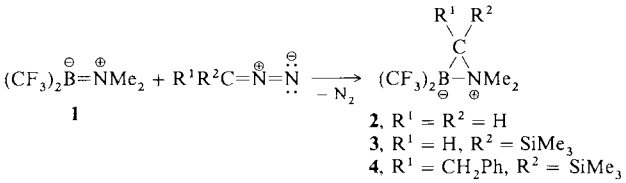
BNC Isosteres of Cyclopropane and a Borylated Diazoester from Diazo Compounds and (Dimethylamino)bis(trifluoromethyl)borane**

By *Andreas Ansorge, David J. Brauer, Hans Bürger,* Thomas Hagen,* and *Gottfried Pawelke*

Dedicated to Professor Dietrich Mootz on the occasion of his 60th birthday

The electron-withdrawing effect of the CF_3 groups is responsible for the reactivity of the BN bond of (dimethylamino)bis(trifluoromethyl)borane (**1**), which is significantly different from that of other aminoboranes.[1] Compound **1**, like other aminoboranes, adds H-acid compounds such as hydrogen halides and H_2O;[2] furthermore, like isosteric alkenes, **1** is capable of [2 + 2] cycloadditions with isocyanates and isothiocyanates,[3] [2 + 4] cycloadditions with dienes and enones,[4] and ene reactions with carbonyl compounds and nitriles.[5] Consequently, it was also to be expected that **1** would react with carbenes and thus, we investigated its reaction with diazomethane and two derivatives. We found that **1** reacts readily with diazoalkanes $R^1R^2C{=}N{=}N$ to give the novel azoniaboratacyclopropanes **2**–**4** in high yields.



1 → (− N_2) → **2**, $R^1 = R^2 = H$; **3**, $R^1 = H$, $R^2 = SiMe_3$; **4**, $R^1 = CH_2Ph$, $R^2 = SiMe_3$

The products **2**–**4** are sublimable and stable up to about 90 °C. Their constitution was derived from the NMR spectra (Table 1). We carried out an X-ray crystal structure investigation for **4**.[6] This shows (Fig. 1) that the B–N bond in the three-membered ring is the shortest found so far between tetracoordinated boron and nitrogen atoms.[4] Several short contacts occur between the ring substituents; as a result the exocyclic valency angles are below the tetrahedral value, despite the small angles in the three-membered ring. The substituent planes B,C(1),C(2) and C,C(5),Si do not bisect the corresponding angles in the three-membered ring, but, as a result of steric interactions between the B and C substituents, are twisted by 9.5(5)° and 8.3(5)°, respectively, in the direction of the NMe_2 group. This strain has different effects on the distances in the three-membered ring. Whereas the N–C bond is 0.08(1) Å longer than the average $N–CH_3$ distance, the B–C bond (1.595(5) Å)) is as yet the shortest in a ring system containing $(CF_3)_2B$ (cf. $B–CH_2$ in 1,1,4,5-tetramethyl-2,2-bis(trifluoromethyl)-1-azonia-2-borata-4-cyclohexene: 1.599(3) Å[4]). The similarity of the lengths of different bonds in the three-membered ring is remarkable, as is the fact that the Si–C bond is 0.072(7) Å longer than the average $Si–CH_3$ distance.

Ethyl diazoacetate, in contrast, reacts in an entirely different way with **1**. The borylated ethyl diazoacetate **5** is formed at −120 °C in almost quantitative yield. Compound **5** is as

Table 1. Selected spectroscopic data of **2**–**5** [a].

2: ^1H NMR: $\delta = 2.01$ (s, 2H; CH_2), 2.78 (s, 6H; CH_3); $^{13}C\{^1H\}$ NMR: $\delta = 40.7$ (broad), 47.18 (sept, $^4J(C,F) = 2.1$ Hz); ^{11}B NMR: $\delta = -16.3$ (sept. $^2J(B,F) \approx 30$ Hz); ^{19}F NMR: $\delta = -59.4$ (q, $^2J(F,B) \approx 30$ Hz); IR(gas): $\tilde{\nu}$[cm^{-1}] = 1140, 1100 (C–F).

3: ^1H NMR: $\delta = 0.20$ (s, 9H; CH_3), 1.35 (s, 1H; CH), 2.82 (s, 3H; CH_3), 2.84 (s, 3H; CH_3); $^{13}C\{^1H\}$ NMR: $\delta = -0.15$ (q, $^5J(C,F) = 1.7$ Hz), ≈44.4 (broad), 45.46 (q $^4J(C,F) = 2.6$ Hz), 50.14 (q, $^4J(C,F) = 2.4$ Hz); ^{11}B NMR: $\delta = -15.3$ (sept, $^2J(B,F) \approx 34$ Hz); ^{19}F NMR: $\delta = -57.3$ ("d", −60.5 ("d"); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1108, 1085 (C–F).

4: ^1H NMR: $\delta = 0.08$ (s, 9H; CH_3), 2.83 (s, 3H, CH_3), 3.00 (s, 3H; CH_3), 3.30 (d, 16.6 Hz, 1H; CH_2) 3.54 (d, 16.6 Hz, 1H; CH_2), 7.20–7.33 (m, 5H; C_6H_5); $^{13}C\{^1H\}$ NMR: $\delta = 2.64$ (q, $^5J(C,F) = 1.9$ Hz), 34.65 (q, $^4J(C,F) = 2.1$ Hz), 43.27 (q, $^4J(C,F) = 2.4$ Hz), 47.94 (q, $^4J(C,F) = 2.8$ Hz), ≈50.5 (broad), 126.4(s), 128.1(s), 128.6(s), 138.1(s); ^{11}B NMR: $\delta = -14.2$(s); ^{19}F NMR: $\delta = -55.7$(s), −56.1(s); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1100, 1076 (C–F).

5: ^1H NMR: $\delta = 1.31$ (t, $^3J(H,H) = 7.1$ Hz, 3H; CH_3), 2.78 (d, $^3J(H,H) = 5.6$ Hz, 6H; CH_3), 4.22 (q, $^3J(H,H) = 7.1$ Hz, 2H; CH_2), 7.18 ((broad), 1H; NH); $^{13}C\{^1H\}$ NMR: $\delta = 14.69$(s), 40.50 (sept, $^4J(C,F) = 1.4$ Hz), ≈44.9 (broad), 62.06(s), 133.18 (q,q $^1J(C,F) = 306$ Hz, $^1J(C,B) = 78$ Hz), 172.04 (s); ^{11}B NMR: $\delta = -8.4$(s); ^{19}F NMR: $\delta = -63.8$ (q, $^2J(B,F) \approx 33$ Hz); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2100, (C=N=N); 1650, (C=O); 1091, (C–F).

[a] ^1H NMR: 250 MHz, $CDCl_3$, 25 °C, $\delta(CHCl_3) = 7.27$; ^{13}C NMR: 62.9 MHz, **2**–**4**: $CDCl_3$, 25 °C, $\delta(CDCl_3) = 77.0$, **5**: CD_3CN, 25 °C, $\delta(CD_3CN) = 1.30$; ^{11}B NMR: 25.52 MHz, $CDCl_3$, 25 °C, $BF_3 \cdot OEt_2$ external; ^{19}F NMR: 84.67 MHz, $CDCl_3$, 25 °C, $CFCl_3$.

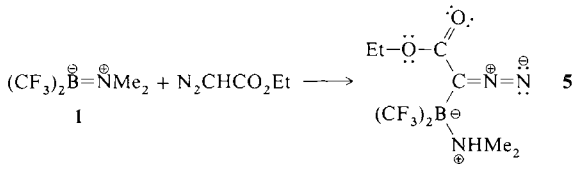
thermally stable as diazoacetate itself and melts at 84 °C without decomposition. The constitution of **5** is deduced



from the IR and NMR spectra as well as from an X-ray structure analysis.[8] The latter shows (Fig. 2) that the ethoxycarbonyldiazomethane group including the B atom is planar within ±0.06 Å. This planarity and the short C(3)–C(4) bond length (1.441 Å) are characteristic for a delocalized π-electron system in this part of the molecule. The B–C(3) distance is normal.[7] Noteworthy is the intramolecular hydrogen bonding.

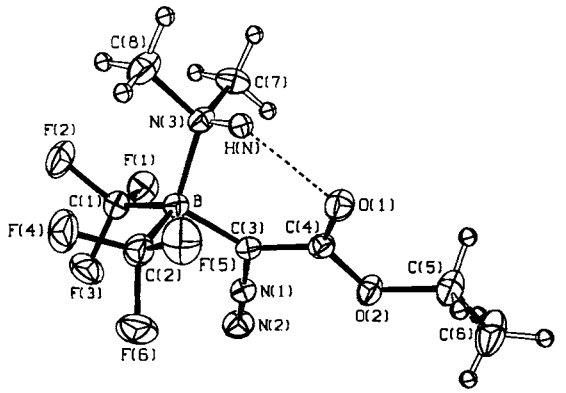


Fig. 2. Crystal structure of **5** (in perspective). Selected distances [Å] and angles [°] with standard deviations in parentheses: B-N(3) 1.612(4), B-C(1) 1.615(5), B-C(2) 1.624(5), B-C(3) 1.608(4), C(3)-C(4) 1.441(4), C(3)-N(1) 1.321(4), N(1)-N(2) 1.123(3), C(4)-O(1) 1.217(3), C(4)-O(2) 1.341(3), H(N)-O(1) 2.18(3); C(3)-B-N(3) 107.0(2), C(1)-B-C(2) 109.0(3), B-C(3)-C(4) 124.6(3), B-C(3)-N(1) 120.2(3), C(4)-C(3)-N(1) 115.0(2), C(3)-N(1)-N(2) 178.6(3), N(3)-H(N)-O(1) 141(3).

The azoniaboratacyclopropanes **2**–**4** are the first BNC three-membered rings in which boron and nitrogen occur with the coordination number four. Thus, they are the first BN isosteres of cyclopropane, whereas the corresponding isosteres of the cyclopropene have been known for some time.[9] The cyclopropanation of the B–N double bond is unprecedented, since with diazomethanes, boranes usually insert CH_2 into the boron–element bonds with retention of the coordination number three for the boron atom.[10] The inductive effect of the two trifluoromethyl groups makes a boron atom so electronically poor that it strives for saturation by increasing its coordination number to four. The reaction that **1** undergoes with ethyl diazoacetate follows the same principle and corresponds to the known reaction with carbonyl compounds $R^1CH_2COR^2$, during which dimethylamino-stabilized bis(trifluoromethyl)boranes of the type $(CF_3)_2B(R^1CHCOR^2)\cdot HNMe_2$ are formed.[5] In contrast, borylated diazomethane derivatives with boron with the coordination number three are well known.[9]

Experimental Procedure

2–**4**: An ethereal solution of diazomethane (11.8 mmol), trimethylsilyldiazomethane, or benzyl(trimethylsilyl)diazomethane (for the synthesis of **2**, **3**, and **4**, respectively) was added dropwise to **1** (2.0 g, 10.3 mmol), dissolved in dry pentane (15 mL), at −10 °C. **2**, **3**: The reaction mixture was stirred for 1 h at room temperature and subsequently condensed in a high vacuum fractionating apparatus. Compounds **2** and **3** were frozen out in a trap at −10 °C. **4**: The reaction mixture was stirred for 1 h at room temperature and subsequently the solvent was removed under vacuum. Compound **4** was isolated from the remaining black residue by sublimation at 40 °C in a high vacuum apparatus and recrystallized from CH_2Cl_2/petroleum ether.

5: Ethyl Diazoacetate (11.0 mmol) was added dropwise to **1** (2.0 g, 10.3 mmol), dissolved in dry CH_2Cl_2 (15 mL), at −120 °. The solvent was removed under vacuum while the reaction mixture was warmed from −70 °C to room temperature, and the residue recrystallized from acetone/petroleum ether. Yields/m.p.: **2**: 95%/30 °C; **3**: 97%/35 °C; **4**: 56%/74 °C; **5**: 98%/84 °C. Spectroscopic data of **2**–**5** are given in Table 1.

Stereochemistry of Norbornyl → Norpinyl Rearrangements

By *Wolfgang Kirmse** and *Dirk Minkner*

The ionization of *exo*-2-norbornyl derivatives **1b** occurs with the participation of the C1–C6 bond (**1b** → **3**).[1] For *endo*-2-norbornyl derivatives **1a** corresponding participation of the C1–C7 bond (**1a** → **4**) should likewise be possible. However, the ring strain thereby increases,[2] so that the k_c process **1a** → **2** → **3** is often preferred over the k_Δ route **1a** → **4**[3] (Scheme 1). Charge destabilizing groups at C3[4] or C2, and similarly, charge stabilizing groups at C1[5] or C6[6] can cause (partial) rearrangement to give norpinyl derivatives, particularly when nitrogen ($X = N_2^+$) serves as the leaving group. To date it remains unclear whether the

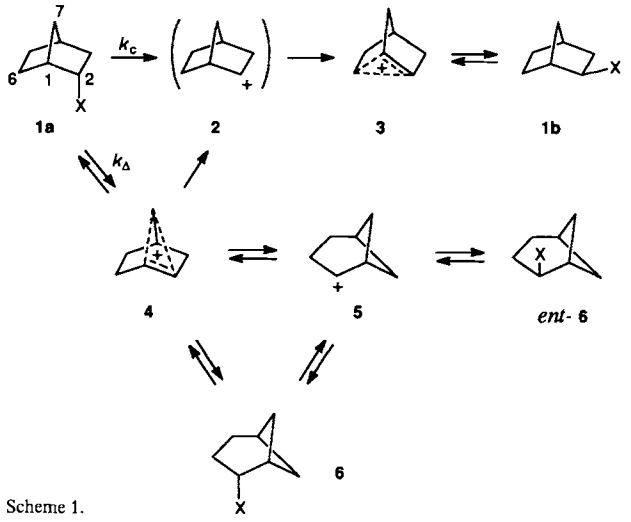
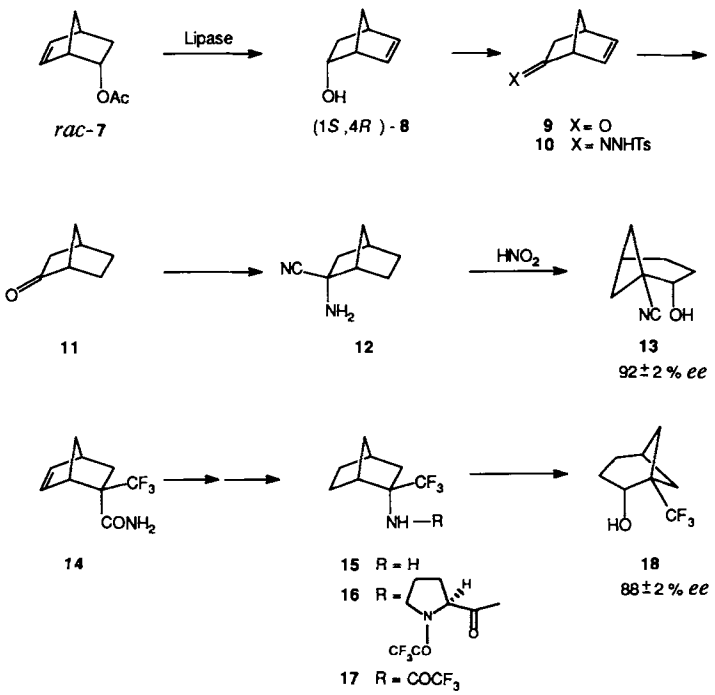
norpinyl derivatives **6** arise from the bridged cation **4** or the open cation **5**. However, since **4** is chiral, but **5** is achiral, we have now answered this question by stereochemical investigations.



Scheme 1.

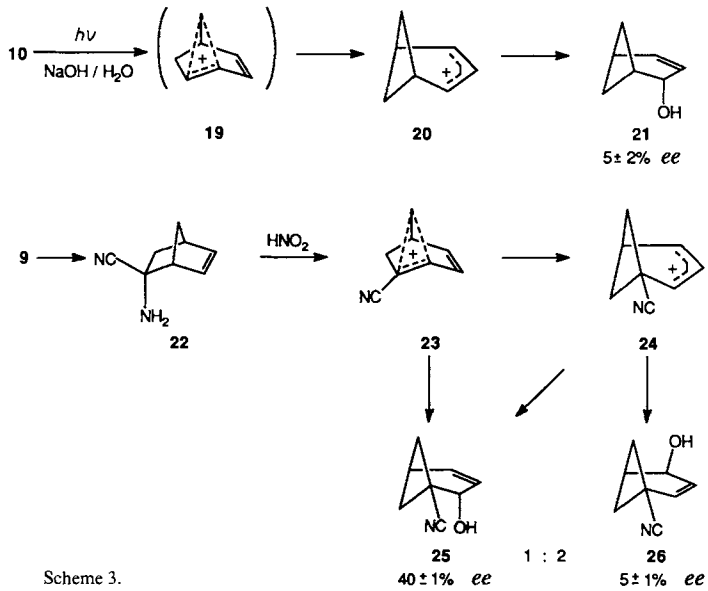
The deamination of *endo*-2-aminobicylo[2.2.1]heptan-*exo*-2-carbonitrile **12** ($NaNO_2$, $H_2O/HClO_4$, pH4) gives among other products, 2-hydroxybicyclo[3.1.1]heptan-1-carbonitrile **13** in 9% yield.[7] For the synthesis of optically active **11** we used the enzymatic cleavage of bicyclo-[2.2.1]hept-5-en-*endo*-2-yl-acetate **7** by lipase from *Candida cylindracea*.[8] From **8** we obtained the desired starting material by oxidation (→ **9**), hydrogenation (→**11**), and Strecker synthesis[7] (Scheme 2). The enantiomeric purity (*ee* values) of **11**, **12** (88 ± 1%), and **13** (81 ± 2%) was determined by gas chromatography (GC) on a chiral phase.[9] During the rearrangement **12** → **13** the enantiomeric purity is retained (92 ± 2%).



Scheme 2. Ts = *p*-toluenesulfonate

Among other products, 1-trifluoromethylbicyclo[3.1.1]-heptan-2-ol **18** is obtained in 11% yield from the deamination of *exo*-2-trifluoromethylbicyclo[2.2.1]heptyl-*endo*-2-amine **15**.[10] The starting material **15** was synthesized by a Diels–Alder reaction of cyclopentadiene with 2-trifluoromethylacrylamide, followed by hydrogenation and Hofmann degradation.[10] HPLC of the *N*-trifluoroacetyl-(*S*)-prolylamides **16** allowed the resolution of **15**, whose *ee* value (92 ± 1%) was determined by GC of the trifluoroacetamide **17**. From this starting material, **18** (81 ± 2% *ee*) was obtained with 88% retention of the enantiomeric purity. The formation of **13** and **18** thus results predominantly from bridged ions of the type **4**.

As an example demonstrating the contrary we investigated the photolysis of optically active bicyclo[2.2.1]hept-5-en-2-one-tosylhydrazones **10** in 0.5 N NaOH. The protonation of the initially generated diazo compound occurs nonselectively; however, bicyclo[3.1.1]hept-3-en-2-ol (**21**) (6%) is formed only from the *endo*-diazonium ion.[11, 12] The formation of predominantly racemic **21** (5 ± 2% *ee*) indicates that the achiral allyl cation **20** is a product-determining intermediate. The bridged structure **19** is only a transition state on the way to **20** (Scheme 3).



Scheme 3.

Particularly interesting is the combination of structural elements with opposite effects (CN group and C–C double bond) in **22**, which was obtained from optically active **9** (91 ± 1% *ee*) by Strecker synthesis. The achiral allyl cation **24**, which is derived from **22**, affords the isomeric allyl alcohols **25** and **26**, of which only **25** can be formed from the bridged ion **23**. Whereas almost racemic **26** (5 ± 1% *ee*) was obtained as expected, for **25** (37 ± 1% *ee*) the enantiomeric purity of the starting material was partially retained (40 ± 1%). Evidently, in addition to **24** also **23** participates in the formation of **25**.

As our results show, the stereochemistry of norbornyl → norpinyl rearrangements is strongly influenced by the choice of substituents. In contrast to the *exo*-selective 2-norbornyl cations, 2-norpinyl cations have no inherent stereopreference. The effects observed here genuinely reflect

the σ or π delocalization of the cationic intermediates. In favorable cases (**23**, **24**), both structural types can appear successively in one rearrangement and can be trapped by nucleophiles.

Synthesis, Properties, and Structure of $[L_xLi_2Pt(CH_2CH_2CH_2CH_2)_2]$—A New Type of Pt^{II} Metallacyclopentane Complexes**

By *Hans-Otto Fröhlich,* Ralf Wyrwa,* and *Helmar Görls*

Metallacycles containing d-block elements are of great significance as intermediates of numerous catalytic reactions such as the [2 + 2] cycloaddition of olefins,[1-3] the oligomerization of 1,2- and 1,3-dienes,[4-8] the isomerization of strained cyclic hydrocarbons,[9] and olefin metathesis.[10] Mechanistic and structural investigations, in particular on Pt^{II} and Pt^{IV} metallacyclopentanes of the known types $[L_2Pt(CH_2CH_2CH_2CH_2)]$ and $[L_nXYPt(CH_2CH_2CH_2CH_2)]$ (L = neutral ligand; X = CH_3, I; Y = Cl, Br, I; n = 1, 2), have contributed considerably to a better understanding of the catalytic behavior and the reasons behind the fact that these metallacycles are thermally more stable than noncyclic compounds of corresponding composition.[11-15] These investigations, particularly those on the platinum(II) compounds, show the influence of the neutral ligands L on the structure and thermal stability of the platinacyclopentane system. Thus, it was of interest to prepare Pt^{II} metallacycles in which exclusively butane-1,4-diyl ligands are bound to the central atom. Herein we report on the first synthesis of complexes of the type $[L_xLi_2Pt(CH_2CH_2CH_2CH_2)_2]$ (L = diethyl ether, x = 1: **1**; L = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA), x = 2: **2**) as well as on the results of ^1H and ^{13}C NMR spectroscopic investigations, differential thermal analyses (DTA), and X-ray structure analyses of these substances.

Compound **1** is obtained from the reaction of dichloro(1,5-cyclooctadiene)platinum(II) with 1,4-dilithiobutane [Eq. (a)]. By substituting the diethyl ether in **1** for other neutral mono-, bi-, and terdentate ligands, derivatives such as **2** are easily obtained [Eq. (b)].

$$[(cod)PtCl_2] + 2\,Li_2(C_4H_8) \xrightarrow[-78 \rightarrow 25\,^\circ C]{Et_2O} [(Et_2O)Li_2Pt(CH_2CH_2CH_2CH_2)_2] + cod + 2\,LiCl \quad \mathbf{1},\ 75\% \qquad (a)$$

$$\mathbf{1} + 2\,TMEDA \xrightarrow[-Et_2O]{} [(tmeda)_2Li_2Pt(CH_2CH_2CH_2CH_2)_2] \quad \mathbf{2},\ 82\% \qquad (b)$$

According to DTA studies,[16] the decomposition temperatures of **1** and **2**, surprisingly vary considerably. Whereas **1** decomposes already at 85 °C, **2** decomposes at 249 °C. Evidently, bidentate tertiary amines such as TMEDA contribute particularly to the stabilization of these platinum(II) complexes.

After the DTA measurements, the gas phases above the solid decomposition residues of compounds **1** and **2** were analyzed. The hydrocarbon mixtures were found to have the following compositions (percentage in parentheses): Sample of **1**: ethene (18), but-1-ene (66), (*Z*/*E*)-but-2-ene (4), butane (12); sample of **2**: ethene (10), but-1-ene (13), (*Z*/*E*)-but-2-ene (38), butane (39). Neither the presence of cyclobutane nor butadiene could be proven. A comparison of these results with those of the thermal decomposition (under similar conditions) of Pt^{IV} metallacyclopentanes[14] shows that in the gaseous decomposition products of the latter no ethene is present, which indicates that their decomposition occurs without cleavage of the C–C bond.

Compound **2** was characterized by ^1H and ^{13}C NMR spectroscopy (Table 1) and by an X-ray structure analysis (Fig. 1).[17]

[+] Crystal structure analysis

[**] Contributions to the chemistry of organometallic metallacyclic compounds of the d block elements, Part 7. This work was supported by the Fonds der Chemischen Industrie, the Volkswagen-Stiftung, and the Buna AG. Part 6: [16]

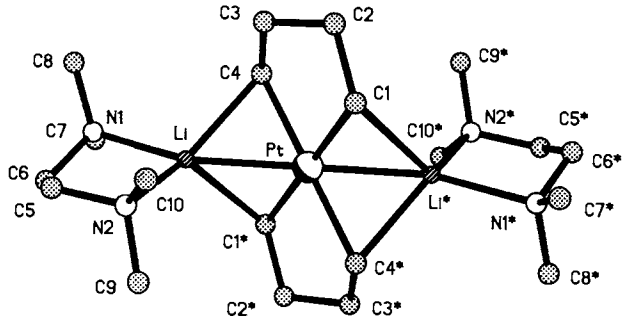

Fig. 1. Crystal structure of **2**. Selected distances [Å] and angles [°]: Pt-C1 2.114(4), Pt-C4 2.141(4), C1-C2 1.543(7), C2-C3 1.487(7), C3-C4 1.489(7), Pt-Li 2.453(7), Li-C4 2.302(8), Li-C1* 2.455(8), Li-N1 2.136(8), Li-N2 2.100(8); C1-Pt-C4 81.8(2), C1*-Pt-Li 64.5(2), C4-Pt-Li 59.7(2), Pt-C1-C2 110.0(3), C1-C2-C3 110.3(4), C2-C3-C4 109.8(4), Pt-C4-C3 108.9(3), Pt-C4-Li 66.9(2), Pt-Li-N1 161.6(4), Pt-Li-N2 112.6(3).

The molecule is centrosymmetric. The platinum atom occupies the center of symmetry. The central atom is surrounded in a planar manner by four anionic centers C1, C4, C1*, and C4*. The average Pt–C distance is 2.128 Å and the angle of inclination of the axis Li–Pt–Li* toward the coordination plane 44.3(2)°. The distances Li–C4 (2.302(8) Å) and Li–C1* (2.455(8) Å) differ significantly, showing that the Li atom interacts more strongly with one of the adjacent C atoms. This is also shown by the longer Pt–C4 distance. The shorter of the two Li–C distances, Li–C4, is similar to the one in $(LiCH_3)_4$ (2.28 Å[18]). The Li–Pt distances are 2.453(7) Å, and are thus shorter than the sum of the covalent radii Pt–Li (2.53 Å). By binding one tmeda ligand at each lithium atom the coordination number is increased to five. The intensive interaction of the lithium atoms, which are extensively shielded by the tmeda ligands, with the bis(butane-1,4-diyl)platinum(II) system apparently contributes to the thermal stabilization of the complex, as does the fact that the distances of the hydrogen atoms of the tmeda ligands from the platinum are ≥ 3.5 Å. Thus, an oxidative addition of C–H groups of the diamine at the Pt^{II} center, which would enhance the thermal decomposition, as for the thermal decomposition of bis(tricyclopentylphosphane)platinacyclopentane (in this case it is C–H groups of the cyclopentyl moieties) is probably made more difficult.[11]

Experimental Procedure

All operations were carried out under an argon atmosphere.

1: 1,4-dilithiobutane (35.8 mmol) was dissolved in diethyl ether (250 mL) and stirred at −78 °C in a Schlenk flask. Over 30 min [(1,5-cod)$PtCl_2$] (6.7 g, 17.9 mmol) was added to this solution. The reaction mixture was stirred for 2 h at −40 °C and subsequently slowly warmed to room temperature. Lithium chloride was separated, the pale yellow filtrate concentrated to 50 mL under vacuum, and finally cooled to −78 °C. The colorless crystals formed were washed with cold diethyl ether and dried under vacuum at room temperature. When required the compound can be purified by recrystallization from diethyl ether. Compound **1** was obtained in the form of colorless crystals (5.3 g, 74.9%).

2: **1** (2 g) was dissolved in diethyl ether (75 mL) cooled to −20 °C. The solution was stirred and TMEDA (3.5 mL) was added. The mixture was allowed to warm to 20 °C and then left to crystallize at −78 °C. The colorless crystals were collected on a frit and dried. Yield of **2**: 2.3 g (82.1%).

An Al–Al One-Electron π Bond**

By *Christian Pluta, Klaus-R. Pörschke,* Carl Krüger,* and *Knut Hildenbrand*

For several years we have been interested in coordination compounds of (alkene)nickel(0) complexes with main group metal alkanides (LiR,[1a, 1b] MgR_2,[1c] SnR_2,[1d]) and hydrides [M_AH,[2] $M_AH_nM_BR_{4-n}$,[3] (M_A = Li, Na; M_B = Al, Ga), $HAlMe_2$[4]]. These studies were prompted by the "nickel effect" observed by Ziegler et al.,[5a] which according to Wilke et al. is founded in an interaction between nickel(0) and trialkylaluminum compounds.[5b] However, till today no compounds with defined nickel–aluminum bonds have been synthesized.[6] Thus, in a further attempt at this goal, we treated the dialane(4) **1** prepared by Uhl[7] with $[Ni(C_2H_4)_3]$[8] or $[\{(tmeda)Li\}_2Ni(C_2H_4)_3]$ (tmeda = tetramethylethylenediamine).[9] Whereas $[Ni(C_2H_4)_3]$ did not react, a dark red solution was obtained with the lithiated complex, from which, however, no uniform product could be isolated. We therefore treated **1** directly with lithium.[10]

The dialane **1** reacts with one lithium atom in ether at −30 °C to give a blue-violet solution,[11] from which large black-violet crystals of **2** precipitate slowly at −78 °C. If the

[**] The title implies a close relation between this work and ref.[25]. We thank Prof. Dr. H. Sabrowsky, Ruhr-Universität Bochum, for the magnetic susceptibility measurements and the Fonds der Chemischen Industrie for support.

reaction solution containing **2** is treated with tmeda at 0 °C, fine, black-violet crystals of the ionic compound **3** form. Both compounds are *extremely* air-sensitive and decompose with decoloration.

$$\underset{\mathbf{1}}{Al_2\{CH(SiMe_3)_2\}_4} + Li \xrightarrow[Et_2O]{-30\,^\circ C} \underset{\mathbf{2}}{[(Et_2O)_3Li][Al_2\{CH(SiMe_3)_2\}_4]^\bullet}$$

$$\xrightarrow[tmeda]{0\,^\circ C} \underset{\mathbf{3}}{[Li(tmeda)_2]^+[Al_2\{CH(SiMe_3)_2\}_4]^{\bullet -}}$$

Solid **2** decomposes slowly with decoloration at 20 °C. Apparently the ether ligands are easily cleaved to form the starting materials **1** (colorless) and Li. In contrast, solid **3** is stable at 20 °C; the shielding of the lithium ion by two tmeda ligands precludes a reverse reaction as in **2**. The complexes behave similarly in aromatic solvents.[12] Compounds **2** and **3** afford blue-violet solutions in THF that appear unchanged after several weeks at room temperature. Presumably the ionic compound $[Li(thf)_4]^+[Al_2\{CH(SiMe_3)_2\}_4]^{\bullet -}$ **4** is present. It may be deduced from these findings that the radical ion pair $Li^+[Al_2R_4]^{\bullet -}$ is stabilized by a strong solvent coordination of the lithium ion.

On protolysis of **2** with 2-propanol (undiluted, −78/20 °C), 1.46 H_2 per two Al is released,[13] which is in accord with an oxidation of aluminum from the formal oxidation state 1.5 to Al^{III}. Compounds **2** and **3** cannot be vaporized without decomposition; their mass spectra (70 eV, 100 °C) correspond to that of dialane **1**. Informative NMR spectra have not been obtained.[14] Magnetic measurements on **3** revealed a paramagnetism that displays a temperature dependence in accord with the Curie-Weiss law.[15]

The ESR spectrum of **4** obtained at 60 °C[16] (Fig. 1a, $g = 2.0035 \pm 0.0005$) comprises eleven signal groups 1.19 mT apart. The 11-fold splitting is explained by a coupling of the unpaired electron with the two magnetically equivalent ^{27}Al nuclei ($I = 5/2$; abundance 100%; $a^{Al} \approx 1.19$ mT, 60 °C). Each of the eleven signals is flanked by ^{29}Si sidebands ($I = 1/2$; abundance 4.67%; $a^{Si} = 0.4$ mT, 60 °C). A coupling of the unpaired electron with the four β-AlCH protons does not occur, because of its predominant occupation of a π orbital, the SOMO, which forms a dihedral angle of 90 °C with the C–H bonds that lie in the nodal plane of the SOMO[17] (see molecular structure of **3**).

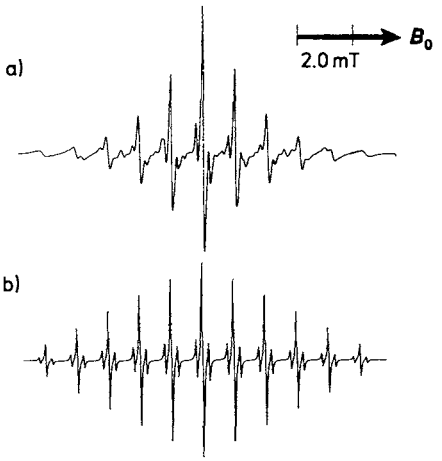

Fig. 1. a) ESR spectrum of **4** in THF at 60 °C; b) sum of the simulated ESR spectra for two isotopomeric forms of the radical anion in **4**, one with only magnetically inactive Si nuclei and one with a ^{29}Si nucleus. A complete averaging of the anisotropy was assumed. Based on the binomial distribution the following isotopic abundance is calculated: molecules with only magnetically inactive Si, 68.2%; molecules with one ^{29}Si, 26.7%. The others have two or more ^{29}Si (not taken into account in the simulaton).

The width of the signals of the high-temperature ESR spectrum is about 0.09 mT in the middle of the spectrum and increases with increasing distance from the center. The signal broadening is attributable to the anisotropy of the Al coupling, which is particularly noticeable in the outer regions of the spectrum. The effect is enhanced by lowering the temperature: at −30 °C only five and at −70 °C three signal groups may still be distinguished; the rest are very broad. One possible explanation is the decrease in the rate of the molecule's rotation in solution which therefore renders the averaging of the anisotropy less feasible (similar line-broadening is observed for an Al–ethyne adduct in neon matrix[18]). The result of a simulation of the spectrum in which anisotropy effects were not taken into account is depicted in Figure 1b.

Whereas **2** appears amorphous, the structure of **3** was determined by X-ray crystal structure analysis.[19] Its ionic structure is composed of a $[Li(tmeda)_2]$ cation and an $[Al_2\{CH(SiMe_3)_2\}_4]$ radical anion $\mathbf{1}^{\bullet -}$ (Fig. 2). Two independent molecules of the radical anion (Mol 1 and Mol 2) are arranged centrosymmetrically about an inversion center in the unit cell ($C_i \equiv \bar{1}$); the anions contain ideally planar C_2Al–AlC_2 units. Molecules 1 and 2 have similar bond lengths and

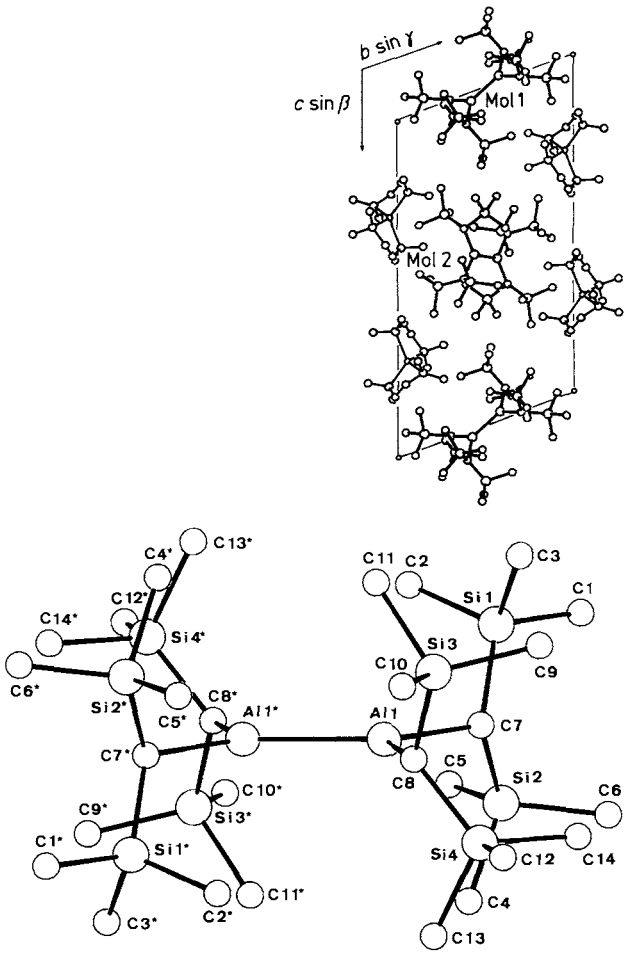

Fig. 2. Top: Unit cell of **3**. Bottom: Structure of the radical anion in **3** in the crystal (H atoms omitted). Averaged bond lengths [Å] and angles [°]: Al1*–Al1 2.53(1), Al1–C7 2.042(5), Al1–C8 2.038(6); Al1*-Al1-C7 127(1), Al1*-Al1–C8 121(1), C7-Al1-C8 111.9(2); interplanar angles Al1,C7,C8/C7,Si1,Si2 88.9/85.0; Al1,C7,C8/C8,Si3,Si4 79.3/83.3.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1993 0570-0833/93/0303-0389 $ 10.00+.25/0

angles, but their torsion and interplanar angles for the SiCSi groups differ marginally because of packing effects. The four $CH(SiMe_3)_2$ substituents in each molecule are so positioned that the H atoms at C7 and C8 (situated at idealized calculated positions) lie approximately in the C_2Al–AlC_2 plane, pointing in the same direction. The structure of the anion $\mathbf{1}^{\bullet-}$ thus corresponds to that of the neutral dialane **1**,[7] but in detail the structures of $\mathbf{1}^{\bullet-}$ and **1** reveal significant differences. In anion $\mathbf{1}^{\bullet-}$ the angle C-Al-C of 111.9(2)° is smaller than in neutral **1** (116.7(1)°); the remaining angles at the trigonal-planar aluminum atom are 127(1)° for Al1*–Al1–C7 and 121(1)° for Al1*–Al1–C8. The Al–C bond lengths of the anion (2.040(5) Å) are distinctly elongated (by 0.06 Å) relative to those of the neutral dialane (1.982(5) Å), and the central Al–Al bond in $\mathbf{1}^{\bullet-}$ of 2.53(1) Å is considerably shortened (by 0.13 Å) from the 2.660(1) Å of the same bond in **1**.[20]

The change in the structural parameters on one-electron reduction of the neutral dialane **1** to the radical anion $\mathbf{1}^{\bullet-}$ is in accord with an Al–Al π bond of partial multiple bond character in $\mathbf{1}^{\bullet-}$. On the transformation $\mathbf{1} + e \rightarrow \mathbf{1}^{\bullet-}$, the unoccupied p_z orbitals of the sp^2 hybridized aluminum atoms in **1** take up the electron, which becomes delocalized in a *bonding* orbital. The center of gravity of the charge lies between the aluminum nuclei, as their equivalence in the ESR spectrum shows. The reaction of **1** with lithium accordingly leads to a *strengthening of the Al–Al bond*.[21] The results of MO calculations agree with the experimental findings.[22] The bonding situation of the one-electron π bond[23, 24] in $\mathbf{1}^{\bullet-}$ is analogous to that in the very stable anions $[R_2B{-}BR_2]^{\bullet-}$[25] and $[R_2B{=}BR_2]^{2-}$[26] (MO calculations[27]). Furthermore, the radical anion $\mathbf{1}^{\bullet-}$ is isoelectronic with a $[R_2C{-}CR_2]^{\bullet+}$ ion. In view of the lower tendency of the main group elements of the third and higher periods to form multiple bonds, the existence of this bonding type for aluminum is surprising.

Experimental Procedure

2: A solution of **1** (1.38 g, 2.0 mmol) in ether (60 mL) was treated with an excess of lithium (50 mg) at −78 °C. The reaction mixture was stirred while it warmed slowly (2 h) to −30 °C. The color changed to dark blue-violet. After the excess lithium was filtered off, large black-violet crystals formed at −78 °C in about 24 h. After removal of the mother liquor with a capillary tube, the crystals were dried in vacuum. Yield: 1.2 g (65%); correct elemental analysis.

3: The reaction solution of **2** was treated at 0 °C with tmeda (2 mL) in ether (10 mL). Fine, black-violet crystals separated, which were filtered off, washed in 10 mL ether, and dried under high vacuum at 0 °C. Yield: 875 mg, (47%); correct elemental analysis.

[11] The cyclic voltammogram of **1** in THF (0.1 M NBu_4ClO_4) at 20 °C shows only one wave in the potential range from +1.6 to −3.2 V (glassy carbon electrode) with a peak potential at $E_p = -2.85$ V vs. SCE. This current overlaps with that from the decomposition of the electrolyte, the former resulting in a weak shoulder. In fact the corresponding electrode process (reduction) is irreversible at a sweep rate of 200 Vs^{-1}; the subsequent reaction (decomposition) of the reduction product must be extremely fast. Cyclic voltammetry thus shows that the dialane is reduced, but no deduction about whether it is a one- or two-electron reduction is possible.

[12] On dissolving **2** in benzene an immediate decolorization is observed; besides the evolution of ether, **1** is again formed. However, a suspension of **3** in benzene is stable over a long period. A suspension of **3** in toluene, stirred at 20 °C, decolorizes completely within one day, which we attribute to a radical reaction with the solvent.

[13] With MeOD, 90% D_2 was formed besides 10% HD (determined by mass spectrometry).

[14] The signals of the ^1H NMR spectra of the solutions of **2** and **3** in [D_8]THF (they contain **4**) are broad at −80 °C, and the $CH(SiMe_3)_2$ groups have only about 10–20% of their potential intensity relative to the ether or tmeda signals. With increasing temperature the signals become sharper and increase in intensity, but cannot be interpreted in more detail up to 27 °C. Probably these NMR signals arise from (diamagnetic) decomposition products of the highly reactive (paramagnetic) radical ion in **4**.

[15] Gouy method; temperature range 81–293 K; the magnetic moment is largely temperature-independent. At 293 K, $\mu = 1.85\ \mu_B$.

[16] Spectrometer: Varian E-9; X band, 100 kHz modulation.

[17] This is valid on the assumption that the β-AlCH hyperfine constant a^H can be explained by a hyperconjugation mechanism, and its value is thus dependent on the angle ($a = a_0 + a_1 \cos^2\theta$). C. Heller, H. M. McConnell, *J. Chem. Phys.* **1960**, *32*, 1535.

Superexchange through Orthogonal Magnetic Orbitals in π-Type Organic Triradicals: Quartet Ground State in Ga(3,5-dtbsq)$_3$**

By *David M. Adams, Arnold L. Rheingold, Andrea Dei,* and *David N. Hendrickson**

The design of molecular ferromagnets is a topic of considerable interest.[1] Paramagnetic building blocks must be connected together in such a way that their magnetic orbitals[2] are effectively orthogonal. This has been achieved with Cu^{II}–V^{IV} chains,[3] polycarbenes,[4] and a Ti^{IV} complex with two tridentate ligands analogous to semiquinone anion.[5] We report here that ferromagnetic exchange interactions between the three *ortho*-semiquinone ligands exist in [Ga(3,5-dtbsq)$_3$] (**1**), where 3,5-dtbsq$^-$ = 3,5-di-*tert*-butyl-1,2-benzosemiquinone anion, a ligand with $S = 1/2$.

Gallium metal (0.570 g) and 3,5-di-*tert*-butyl-1,2-benzoquinone (1.00 g) were added to 50 mL of degassed toluene under an atmosphere of argon. The heterogeneous reaction mixture was refluxed for 3 h. A noticeable color change from the yellow-green of the quinone to the blue-green of the semiquinone was noted. After the mixture was allowed to cool to room temperature and left for 24 h, the excess gallium was filtered off and the mother liquor subjected to slow evaporation under a steady flow of N_2 for two days to give black-green cubic crystals of **1** (0.30 g). The X-ray crystal structure of **1** is shown in Figure 1.[6] The gallium is octahedrally coordinated by three 3,5-dtbsq$^-$ ligands, which are related by a crystallographic C_3 axis. The bond lengths in complexed *ortho*-quinone units are characteristic of the various oxidation states of the ligand.[7] In **1** the C–O distances are 1.271(12) and 1.315(10) Å and the C–C bond length between the chelating oxygen atoms is 1.439(12) Å; all of these indicate that the three ligands are *ortho*-semiquinones. In isostructural [Cr(3,5-dtbsq)$_3$] the C–O distances are 1.280 and 1.299 Å, and the central C–C distance is 1.433 Å.[8]

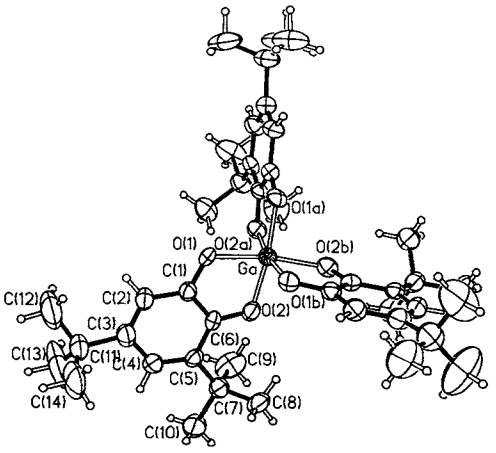

Fig. 1. Crystal structure of **1**. Important bond lengths [Å] and angles [°]: Ga-O(1) 1.963(8), Ga-O(2) 1.992(6); O(1)-Ga-O(2) 82.6(3), O(1)-Ga-O(1a) 92.6(3), O(1)-Ga-O(2a) 95.8(3), O(1)-Ga-O(2b) 170.4(3), O(2)-Ga-O(2a) 89.7. The torsion angle between the GaO_2C_2 planes is 95.7° clockwise around the threefold axis.

Ferromagnetic exchange interactions between 3,5-dtbsq$^-$ ligands in **1** are evident from the magnetic susceptibility data obtained for a polycrystalline sample in a 10.0 kG field (Fig. 2). As the temperature is decreased the effective magnetic moment per molecule increases from 2.95 μ_B at 320 K to a maximum of 3.58 μ_B at 9 K and then drops to 3.26 μ_B at 2 K. The magnetic moment at 320 K is slightly less than the value of 3.00 μ_B expected for three noninteracting, unpaired electrons. There may be a small diamagnetic impurity (the bulk sample smells of toluene). Only the data in the 60–320 K range could be fit to the Curie–Weiss equation with a Curie constant $C = 1.048$ emu K mol^{-1} and $\theta = +8.94$ K. The data from 9 to 320 K were fit by least-squares refinement to the susceptibility expression derived by assuming pairwise magnetic exchange interactions between the three $S = 1/2$ ligands on each complex with the spin Hamiltonian $\hat{H} = -2J\sum\hat{S}_i \cdot \hat{S}_z$. The C_3 site symmetry of **1** dictates one exchange parameter J; this gives one quartet and two accidentally degenerate doublet states. An expression for the molar paramagnetic susceptibility for such a complex is given in Equation (a).

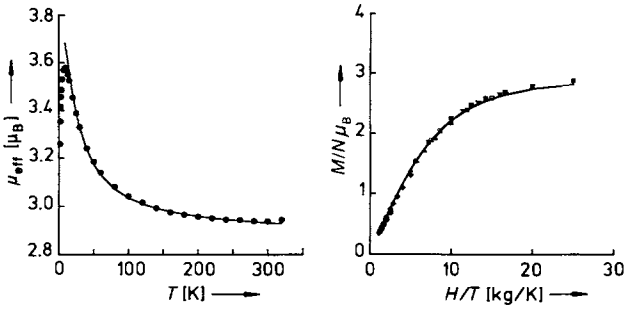

Fig. 2. Left: Plot of effective magnetic moment versus temperature for a polycrystalline sample of **1** in a magnetic field of 10.0 kG. Solid line: theoretical fit of the data in the 9–320 K range. Right: Plot of reduced magnetization, $M/N\mu_B$ (N is Avogadro's number and μ_B is the Bohr magneton), versus H/T. Data were collected at field strengths of 5.00 kG (●), 10.0 kG (♦), 20.0 kg (Δ), 30.0 kG (□), 40.0 kG (▼), and 50.0 kG (■) in the range of 2.0–4.0 K. For measurements at 10.0 and 50.0 kG data were collected in the 2.0–9.0 K range.

$$\chi_M = \frac{Ng^2\beta^2}{4kT}\left[\frac{1 + 5\exp(3J/kT)}{1 + \exp(3J/kT)}\right] \qquad (a)$$

Fitting the susceptibility data to Equation (a) gives $J = 7.8$ cm^{-1} and $g = 1.92$. The solid line in Figure 2 left shows that the data in the 9–320 K range are accommodated by Equation (a). The relatively low g-value reflects the small diamagnetic impurity and does not affect the accurate determination of J. Thus, **1** has a $S = 3/2$ ground state with two $S = 1/2$ states at an energy of 23.4 cm^{-1}.

The $S = 3/2$ ground state was confirmed by variable-field (5.00, 10.0, 20.0, 30.0, 40.0, and 50.0 kG) magnetization data in the 2.0–4.0 K range (Fig. 2). The solid line is a theoretical fit of the data accounting for Zeeman interactions in an isolated $S = 3/2$ state with $g = 1.92$ and where there is no zero-field interaction. This fit was obtained by assuming that only the $S = 3/2$ ground state is thermally populated; on each iteration of the fit the full spin Hamiltonian matrix including the Zeeman interaction was diagonalized. These data clearly indicate a $S = 3/2$ ground state experiencing a small zero-field splitting.

[**] This work was supported by the U.S. National Science Foundation (CHE-9115286 to D. N. H.).

In order to fit the full range of data collected from 2 to 320 K at a field strength of 10.0 kG it would be necessary to set up the full Hamiltonian matrix for **1** including magnetic exchange, and Zeeman and zero-field interactions and then diagonalize the matrix on each iteration. Such an effort is in progress. Simulations with full-matrix diagonalization of the Hamiltonian for an isolated $S = 3/2$ state show that most of the decrease in μ_{eff}/molecule occurring below 9 K at 10.0 kG is attributable to saturation effects. Thus, at temperatures below 9 K the Zeeman interaction is strong enough so that only the $M_s = -3/2$ component of the $S = 3/2$ state is thermally populated. Comparison with the experimental data suggests there may be very weak intermolecular exchange interactions present, which will be examined in the full report.

The ferromagnetic ligand–ligand interactions in **1** can be rationalized by proposing a dominant ferromagnetic superexchange interaction that is propagated by empty 4p orbitals on the Ga^{III} ion. The magnetic orbital of each semiquinone anion ligand is a π^* antibonding orbital. It is known[7] that the spin density of each unpaired electron is delocalized over each 3,5-dtbsq$^-$ ligand; however, there is little leakage onto the metal ion. A schematic representation of how the three Ga^{III} 4p orbitals interact with the p(π) orbitals on the six oxygen atoms of the three ligands is shown in Figure 3. It is possible to see that the orbital overlap that

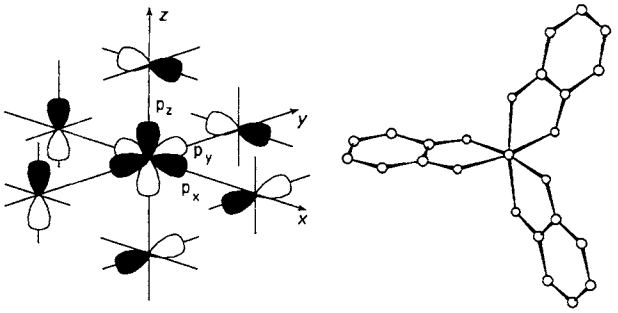

Fig. 3. Schematic drawing showing the overlap of the π^* orbitals of the three 3,5-dtbsq$^-$ ligands containing unpaired electrons with the three 4p orbitals of the Ga^{III} ion. For the ligand π^* orbitals only the 2p orbital contributions from the oxygen atoms are shown.

determines a (3,5-dtbsq$^-$) $\cdots$ (3,5-dtbsq$^-$) exchange interaction is orthogonal if the 4p orbitals of the Ga^{III} ion provide the main superexchange pathway. From the perspective of a configuration interaction, this pathway involves a virtual excited state in which the bridging gallium ion is reduced by the semiquinone anion ligand. This shows that when diamagnetic metal ions are octahedrally coordinated by *ortho*-semiquinone anion ligands paramagnetic building blocks may be assembled so that ferromagnetic spin alignments are maintained.

[6] Crystal data for **1**: $C_{42}H_{60}GaO_6$, $M_r = 730.6$, rhombohedral, $R\bar{3}$, $a = 16.419(2)$, $c = 13.899(3)$ Å, $V = 3244(9)$ Å^3, $Z = 3$, $\rho_{calc} = 1.122$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 6.71$ cm^{-1}, $T = 298$ K. Of 1070 independent reflections collected ($2\theta_{max} = 45^\circ$, Siemens P4 diffractometer, $Mo_{K\alpha}$), 886 were observed ($4\sigma F_0$). Systematic absences in the reflection data supported all of the rhombohedral space groups except for $R3c$ and $R\bar{3}c$. The E-statistics ($|E^2 - 1| = 0.727$) suggested one of the noncentrosymmetric space groups $R3$, $R3m$, or $R32$. As the only anticipated molecular symmetry element was a three-fold rotational axis, the first of the alternatives was chosen initially, and later confirmed by the results of refinement. The structure was solved by a Patterson synthesis. All non-hydrogen atoms were refined with anisotropic thermal parameters, and hydrogen atoms were placed in idealized locations. $R(F) = 0.049$ (0.0631 for all data), $R(wF) = 5.43$ for 148 refined parameters. The maximum/minimum residual electron density was less than ± 0.3 eÅ^{-3}. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Center, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the complete journal citation.

Synthesis and Structure of a Trimeric Cyclometalated Coordination Compound with a Hydrophobic Cavity**

By *Stéphane Rüttimann, Gérald Bernardinelli,* and *Alan F. Williams**

The rapidly developing field of supramolecular coordination chemistry offers synthetic routes to complex molecular structures formed by the combination of structured ligands with cations showing clear stereochemical requirements. Although particular attention has been paid to the synthesis of helical systems[1] and molecular knots,[2] in principle a wide variety of structures may be generated by suitable choice of ligands and metal ions. We report here on the synthesis and structure of a trinuclear complex with a hydrophobic cavity formed by a cyclometalation reaction followed by self-assembly.

Palladium(II) readily undergoes cyclometalation reactions,[3] and cyclometalation of the ligand 1,3-bis(1-methylbenzimidazol-2-yl)benzene mbzimpH **1**[4] could give rise to two products corresponding to the closed system (2-metalation, **2a**) or the open system (6-metalation, **2b**), in which the product possesses a free benzimidazole group which may complex another cation and thereby allow the construction of a larger supramolecular unit. Reaction of **1** with $Pd(OAc)_2$ in acetic acid gives a yellow solution from which a yellow solid **3** may be isolated in 88% yield. The chemical analysis of **3** is consistent with its formulation as the cyclometalated product [Pd(mbzimp)(OAc)], and the ^{1}H NMR spectrum (400 MHz, [D$_6$]DMSO) shows 11 different aromatic protons, confirming the loss of one hydrogen in the cyclometalation reaction, and excluding structure **2a** in which the ligand would be symmetrically coordinated.

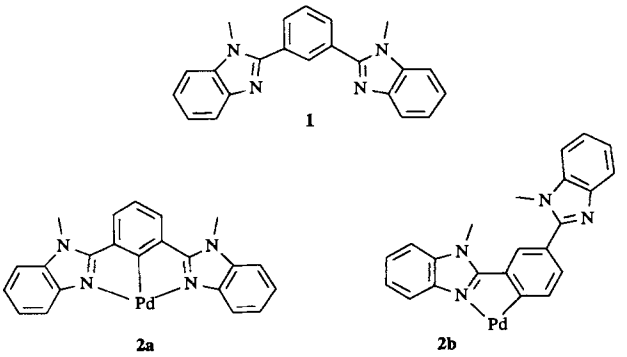

Scheme 1. The ligand mbzimpH **1** and the two possible modes of cyclopalladation: in the 2-position (**2a**) and the 6-position (**2b**).

Crystals of **3** could be grown from acetonitrile solution and were shown by X-ray crystallography to have the composition $[Pd_3(mbzimp)_3(OAc)_3]\cdot 9CH_3CN$, containing the cyclic complex $[Pd_3(mbzimp)_3(OAc)_3]$. This complex may be regarded as a trimer of the 6-metalated product **2b** in which the acetato ligands occupy the fourth coordination site of each palladium atom. The trimer may be described crudely as an equilateral triangle with a palladium atom at each vertex and a ligand making up each side (Fig. 1). The coordination sphere of each palladium atom is approximately square planar and is made up of the N–C chelate ring formed by the cyclometalation reaction, the free benzimidazole group of a second ligand (*trans* to the nitrogen of the chelate ring), and a monodentate acetato ligand (*trans* to the carbon of the chelate ring) (Fig. 2). The four atoms bound to Pd are not perfectly coplanar, but show a slight distortion of approximately 0.1 Å out of the least-squares plane towards a tetrahedral geometry; the palladium atom lies within 0.1 Å of this plane. The Pd–O bonds (average 2.15 Å) are significantly longer than the Pd–C (average 1.98 Å) and Pd–N (2.03 Å) bonds, presumably as a result of the strong *trans* influence of the Pd–C *T* bond. The chelate bite angle (81.1°) and Pd–N and Pd–C bond lengths are comparable to those previously reported for cyclopalladation of 6-phenyl-2,2′-bipyridine.[5] The three palladium sites are essentially identical within experimental error; the greatest deviations are observed for the weakly bound acetato ligands (Table 1).

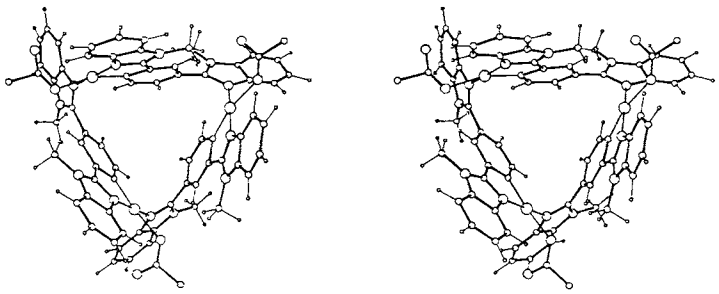

Fig. 1. ORTEP[11] stereoview of the trimer. The guest molecule of acetonitrile has been removed for clarity.

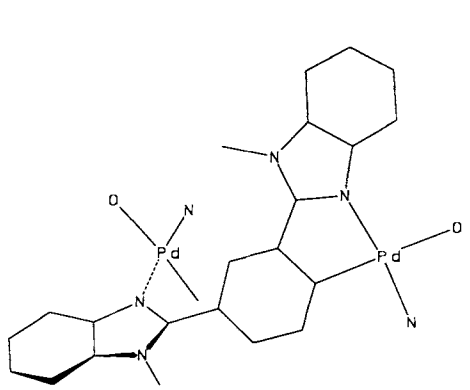

Fig. 2. View of one ligand unit of **3** showing the coordination sphere of the palladium atom and the conformation of the ligand.

Table 1. Structural data for **3**[a].

Parameter	Position A	Position B	Position C	Average

ligand deviation [Å] [b]	0.19	0.12	0.15	
Pd deviation [Å] [c]	0.11	0.06	0.07	
ph-bzim$_{chelate}$ [°]	1.6(4)	7.5(6)	6.9(5)	5.3
ph-bzim$_{pendant}$ [°]	47.7(5)	49.2(6)	48.5(5)	48.5

[a] N1: nitrogen donor in chelate ring; N2: nitrogen donor of the free benzimidazole unit; ph-bzim$_{chelate}$: angle formed by the planes of the phenyl ring and the benzimidazole unit of chelate ring; ph-bzim$_{pendant}$: angle formed by the phenyl ring and the second benzimidazole unit. [b] Maximum deviation of the four coordinated atoms from the least-squares plane. [c] Deviation of the Pd atom from the least-squares plane of the coordinated atoms.

The benzimidazole and phenyl rings of the ligands show no significant deviations from planarity. The phenyl ring and the benzimidazole unit of the chelate ring are almost coplanar (average angle between planes 5°), while the free benzimidazole is inclined at an average angle of 48.5° toward the phenyl group. The similarity of the three coordination sites and of the three ligand conformations results in a non-crystallographic C_3 symmetry for the trimer, which is chiral, although the enantiomers have not been separated. Figure 1 shows the trimer to possess a cavity at its center, which is occupied in the crystal by an acetonitrile molecule, as shown in the MOLCAD[6] view in Figure 3. The methyl group of the acetonitrile molecule lies at the bottom of the cavity, but the Pd–C_{methyl} distances are all greater than 4 Å, and agostic Pd–H interactions may therefore be excluded.

The apparent specificity for 6-metalation is probably caused by the steric hindrance of the second benzimidazole group; the only available crystal structure of a complex of mbzimpH shows the hydrogen atom on C6 to be closest to the metal ion coordinated to the benzimidazole.[4] Although the tridentate coordination mode arising from 2-metalation would be expected to be more favorable, the second chelate ring can only form after the metalation; if metalation takes place irreversibly at the 6-position, then **2a** will not be formed. The initial product of metalation will thus be **2b**, which possesses a pendant benzimidazole group able to act as a donor and two labile coordination sites on palladium; an oligomerization reaction is therefore possible. The assembly in high yield to give only the trimer presumably results from the rather rigid spatial arrangement of the donor and acceptor sites: **2b** has only one degree of internal freedom,

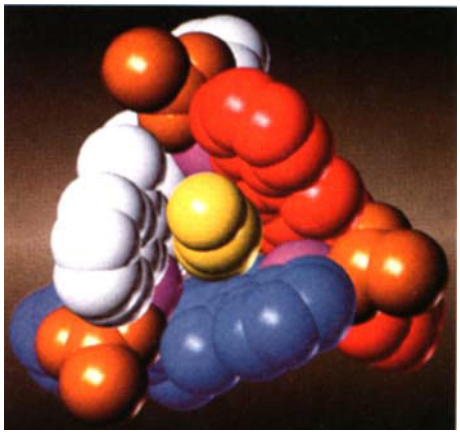

Fig. 3. MOLCAD[6] view of the trimer. The individual three ligand units are colored red, white, and blue respectively, the palladium pink, the acetato ligands brown, and the guest acetonitrile yellow.

that of torsion about the bond joining the phenyl ring and the nonchelating benzimidazole. It should be noted that the pendant benzimidazole occupies the site *trans* to the chelating nitrogen rather than the activated site *trans* to the aromatic carbon atom.

The chiral nature of the cavity in this complex offers the prospect of an interesting host–guest chemistry which is currently being investigated in solution. Further details, including the verification of the trimeric structure in solution, will be published elsewhere.[7]

Experimental Procedure

Palladium(II) acetate[8] and mbzimpH[4] were prepared according to literature methods. A solution of 0.112 g (0.5 mmol) of palladium(II) acetate in acetic acid (5 mL) was added to a solution of 0.169 g (0.5 mmol) of mbzimpH in acetic acid and refluxed for 26 h. The yellow mixture was cooled and filtered to remove a lemon-yellow precipitate (40 mg). The filtrate was evaporated to give 220 mg of **3** as a yellow-green powder (88%). Yellow crystals suitable for X-ray diffraction were obtained by slow evaporation of a solution of **3** in acetonitrile at 40°C. Analysis correct for $PdC_{24}H_{20}N_4O_2$.

A yellow crystal ($0.20 \times 0.20 \times 0.35$ mm) was sealed in a capillary with some of the mother liquor. $M_r = 626$, triclinic, space group $P\bar{1}$, $a = 14.241(2)$, $b = 16.962(2)$, $c = 19.467(4)$ Å, $\alpha = 82.40(1)$, $\beta = 84.73(1)$, $\gamma = 70.94(1)^\circ$ based on 25 reflections ($14^\circ < 2\theta < 26^\circ$), $V = 4400(1)$ Å^3, $Z = 2$. Intensity data were collected at room temperature on a Philips PW100 diffractometer with $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $6^\circ < 2\theta < 40^\circ$, 8174 unique reflections measured. Structure solved by direct methods[9], other calculations made using the XTAL system[10] and ORTEP[11] programs. Full matrix refinement was performed successively on a third of the atoms in the asymmetric unit (maximum number of variables = 280). All non-hydrogen atoms other than solvent molecules were refined with anisotropic thermal displacement parameters. One carbon atom of one of the nine solvent molecules could not be located. Final R factor = 0.072 ($R_w = 0.050$, $w = 1/\sigma^2(F_o)$), for 5704 observed reflections ($|F_o| > 4\sigma(F_o)$). Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK) on quoting the full journal citation.

Stereodivergent Enantioselective Synthesis by Exploiting Unusually Large Kinetic H/D Isotope Effects on Deprotonation**

By *Dieter Hoppe,** *Mario Paetow,* and *Folker Hintze*

We report here a new strategy in enantioselective synthesis that is based on the discrimination by a base between protons and deuterons in an otherwise identical chemical environment. Primary kinetic H/D isotope effects on the deprotonation of C–H acids usually fall within the range $k_H/k_D = 2-7$.[1] Only in exceptional cases are higher values obtained, which are attributed to the participation of quantum mechanical tunnel effects.[2] For example, for the deprotonation of 2-nitropropane with 2,6-dimethylpyridine a value of $k_H/k_D = 24$ is given.[3] The larger effective radius predicted by the Heisenberg Uncertainty Principle for the lighter proton should be particularly noticeable as a pronounced isotope effect at low temperature, for sterically shielded centers, and in aprotic media.

In an attempt to lithiate the (*S*)-(1-deuterioethyl) carbamate (*S*)-**3**, prepared by the deprotonation of **1** with *sec*-butyllithium/(−)-sparteine[4, 5] in ether (4 h, −78 °C) and subsequent deuteration with [D$_1$]methanol, for a second time under the same conditions, we noticed that the reaction was extremely slow: the product (*S*)-**5**, anticipated on capture of the lithium carbanion (*S*)-**2** with chlorotrimethylsilane, was obtained in only 6% yield, while the sample of (*S*)-**5** prepared in the same manner from **1** was formed in 86% yield and greater than 96% *ee*[6] (Scheme 1).[7, 8] Since the deuterium atom in (*S*)-**3** occupies a sterically more favorable position than the 1-H atom for abstraction by the chiral base,[9] the low rate of the reaction has its origin in an unusually high isotope effect.

In the next experiment the configurational restraint was removed by treating (*S*)-**3** (> 99% D)[10] in the presence of the achiral complex-forming agent *N*,*N*,*N*′,*N*′-tetramethylenediamine (TMEDA) instead of (−)-sparteine. The isotope effect alone then determined the rate of the abstraction of 1-H and 1-D in (*S*)-**3**, and the product (*R*)-**7** was obtained with greater than 95% *ee*[6, 7] after silylation. The content of 1-H was 1.3%.[11] Therefore the quotient k_H/k_D

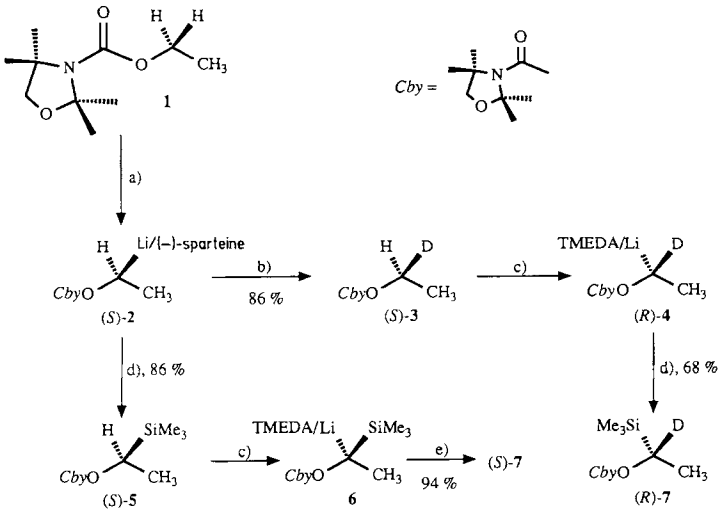
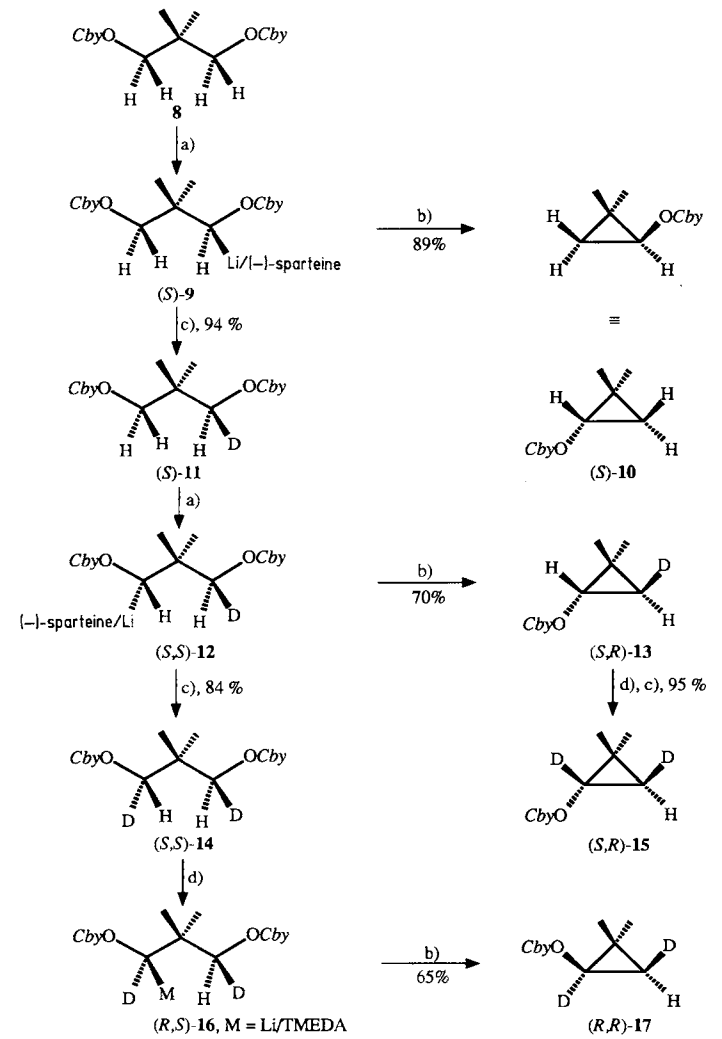


Scheme 1. a) 1.4 equiv *s*BuLi/(−)-sparteine, ca. 0.2 M in ether, −78 °C, 4 h; b) 1.6 equiv CH_3OD at −78 °C; c) 1.4 equiv *s*BuLi/TMEDA, −78 °C, 4 h; d) 1.6 equiv Me_3SiCl at −78 °C; e) 1.6 equiv CH_3COOD at −78 °C.

must be at least 70. For comparison, the enantiomer (*S*)-**7** was formed on deprotonation and deuterolysis of the isotopomer (*S*)-**5** via the anion (*S*)-**6** (95% *ee*).[7, 12–14]



Scheme 2. a) 2.0 equiv *s*BuLi/(−)-sparteine, in ether, −78 °C, 2.5 h; b) 2.2 equiv Me_3SiCl at −78 °C; c) 3.0 equiv CH_3OD at −78 °C; d) 2.0 equiv *s*BuLi/TMEDA, −78 °C, 2.5 h, in ether.

Propanediyl dicarbamates such as **8**[15] bear two homotopic methylene groups each with enantiotopic protons (Scheme 2). In a series of experiments we demonstrate how the achiral starting material **8** can be used for the synthesis of almost enantiomerically pure, specifically deuterated cyclopropanes. The (−)-sparteine complex (*S*)-**9**, generated in the usual way,[15] reacts under the influence of chlorotrimethylsilane by 1,3-elimination to form cyclopropyl carbamate (*S*)-**10**,[15, 16] while deuterolysis yields the labeled dicarbamate (*S*)-**11** (97% D_1).[17] The second deprotonation of (*S*)-**11**, followed by cyclization, affords the *trans*-cyclopropane (*S,R*)-**13**[16] with 97% *ee*[18] and 96.1% D.[17] After the correction for the original degree of deuteration, the ratio of the lithiation of the 3-CH_2 to the 1-CHD group in (*S*)-**11**, which gives (*S,S*)-**12** and (*S*)-**9**, respectively, is calculated to be about 70:1. (*S,R*)-**13** was converted into the deuteriocyclopropane (*S,R*)-**15**[16] by lithiation and deuterolysis (93% D_2).[17] The epimer (*R,R*)-**17**[16] (96.1% D_2)[17] is distinguished from (*S,R*)-**15** only in the configuration of the isotope pattern; we synthesized it by deuterolysis of (*S,S*)-**12** to give (*S,S*)-**14** (96.7% D_2)[17] followed by TMEDA-assisted lithiation and subsequent 1,3-cycloelimination. (*S,R*)-**15** and (*R,R*)-**17** have the same numerical value for the optical rotation, but opposite signs.[16]

We have therefore discovered a simple method for the stereodivergent synthesis of almost enantiomerically pure and stereospecifically labeled alcohol derivatives. It is based on the following prerequisites, which are excellently fulfilled in the chosen system:

1. possibility of generating the carbanion by deprotonation at low temperature,
2. large H/D isotope effects, amplified by tunneling,
3. configurational stability of the carbanionic intermediate.

General Experimental Procedure

(See also the legends to the schemes.)

To a stirred solution of (−)-sparteine (1.4 equiv) or TMEDA (2.0 equiv) in ether (10 mL) at −70 to −78 °C was injected a solution of *s*BuLi in cyclohexane/isopentane (1.4 N, 2.0 equiv); the solution was treated at this temperature with the carbamate (2 mmol) dissolved in ether (2–4 mL) and stirred for 4 h (2.5 h for TMEDA) below −70 °C. Thereafter the required amount of CH_3OD, Me_3SiCl, or CH_3COOD was added, and the solution was stirred for 24 h, while it warmed to room temperature. After an aqueous workup, the product was purified by chromatography on silica gel (ether/pentane)[4].

[6] Determined by ^1H NMR spectroscopy (300 MHz) in the presence of 3.3 mol% of tris[3-(heptafluoropropylhydroxymethylene)-(+)-camphorato]praseodymium(III). Because of line broadening a more precise value cannot be obtained.

[7] $[\alpha]_D^{19}$: (*S*)-**5** −26.6 (c = 1.7, CH_2Cl_2), (*R*)-**7** + 26.0 (c = 1.2, CH_2Cl_2); $[\alpha]_D^{16}$: (*S*)-**7** −27.4 (c = 1.1, CH_2Cl_2).

[8] At the same time this finding presents the proof for the following assumptions: The selection by the chiral base system *s*Bu/(−)-sparteine is kinetically controlled. The incoming deuteron takes up the position of the abstracted proton as a result of double stereoretention and the configurational stability of the carbanion.

[9] For all the deprotonations of the achiral alkyl carbamates assisted by (−)-sparteine observed till now, a strong preference for the selection of the *pro-S*-proton was noticed [4, 5, 15].
[10] A complete monodeuteration (> 99% D_1, determined by mass spectrometry) was achieved by performing the procedure twice.
[11] Determined by ^1H NMR spectroscopy (300 MHz).
[12] Degree of deuteration 98.4% (^1H NMR, 300 MHz). Some of the product (*S*)-**7** decomposed on use of CH_3OD. Yield 55–58%.
[13] This is also the first proof of a configurationally stable 1-oxy-1-silyl carbanion persisting in solution [14].

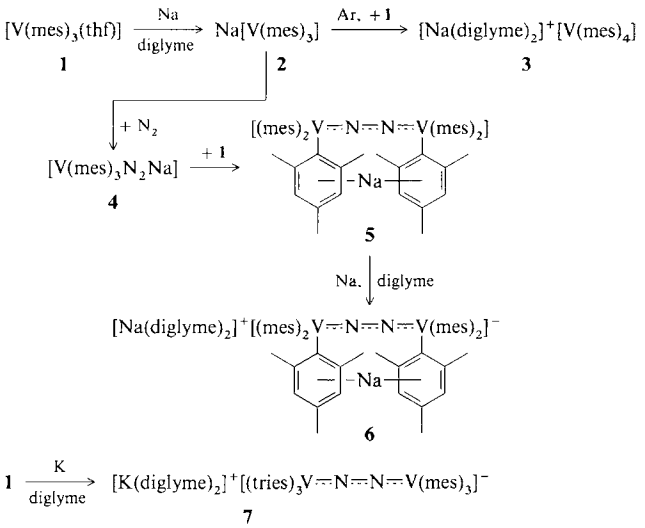
[17] Determined by GC-MS, chemical ionization with NH_3 and integration over the whole peak area. We thank Dr. F. Luftmann, Münster, for these measurements.
[18] Determined by ^1H NMR spectroscopy in the presence of tris[3-(heptafluoropropylhydroxymethylene)-(+)-camphorato]europium(III) (5.3 mol-%) after conversion into the corresponding methyl 1-carbamoyloxy-1-cyclopropanecarboxylate via the configurationally stable 1-anion of (*S,R*)-**13**.

under argon, **3** is obtained. This is the pathway followed by the reduced species **2** in the absence of an appropriate concentration of N_2. The reduction of **1** in presence of N_2 produces **6** nearly quantitatively (97%). The stepwise formation of **6** through the intermediacy of the ion pair **4** and complex **5** is suggested mainly by the product from the reduction with potassium.



Scheme 1. Reduction of **1** with sodium and potassium. diglyme = $MeOCH_2CH_2OCH_2CH_2OMe$.

Fixation and Reduction of Dinitrogen by Vanadium(II) and Vanadium(III): Synthesis and Structure of Dinitrogenmesitylvanadium Complexes**

By *Richard Ferguson, Euro Solari, Carlo Floriani,* Angiola Chiesi-Villa*, and *Corrado Rizzoli*

Reduction of homoleptic alkyl- and arylmetal compounds should produce very reactive low-valent, bifunctional ion pairs, having exclusively σ-donor ligands incapable of accommodating electron density from the metal. With this in mind we approached dinitrogen activation by early transition metals. This is a preliminary report on vanadium–nitrogen chemistry, which is a field of major interest for several reasons: 1) The first widely known bifunctional system for converting N_2 into NH_3 and N_2H_4 is based on a V^{II}/Mg^{II} system;[1, 2] 2) a vanadium-containing nitrogenase was recently discovered;[3] 3) vanadium model compounds in this area are very rare.[4] Some significant precedents in the use of low-valent homoleptic aryliron compounds in dinitrogen reduction exist, though no dinitrogeniron species has been clearly identified.[5]

The results on reductions of $[V(mes)_3(thf)]$ (**1**)[6] [mes = 2,4,6-$Me_3C_6H_2$] by alkali metals are summarized in Scheme 1. When the reaction of **1** with Na is carried out

With potassium the reaction affords complex **7** in good yield (68%). Reduction of **7** with sodium did not give the complex analogous to **6** as expected. Also, when the reduction of **1** is carried out with only 0.5 equivalents of Na, the product is still **6**. The sodium ion pair **4** is expected to be much more stable than an analogous potassium intermediate in presence of oxygen donors (e.g. diglyme), and the reduction of the neutral species **5** much easier than the reduction of the anion in **7**.

Some of the hypotheses outlined above have been greatly supported by the X-ray analysis on **3**, **6**, and **7**. Structural details are reported only for the anion in complex **6** (Fig. 1).[7] The anion has an imposed crystallographic C_2 symmetry. The V–N distance [1.763(15) Å] is very short and shows multiple-bond character, while the N–N bond [1.280(21) Å] is significantly longer than the N–N bond in free dinitrogen [1.0968 Å]. The bond lengths of all the V–N_2 complexes reported[4] to date, including **6** and **7**, should be compared, since these few complexes represent a series where dinitrogen is either simply coordinated to the metal, or significantly polarized or reduced by the metal.[4] The sodium cation is inserted into a cavity formed by two bent phenyl rings and the dinitrogen molecule. A close resemblance exists between the structure of **6** and the intermediate in the V^{II}/Mg^{II} system proposed by Shilov.[1] The structural parameters of **7**[8] are very close to those of **6**, and strongly support a significant degree of reduction of N_2.

The magnetic properties of **6** and **7** are unexpected[4c, 9] and give information on the degree of reduction of N_2 and the formal oxidation state of the metal. Coordination of N_2 usually does not change the magnetic properties of the original vanadium ion;[4c] however, in complexes **6** and **7** the magnetic moments do not correspond to a pair of d^3–d^3

Symmetry transformation: ′ = − x, y, −1/2 − z. The disordered Na1′ position has been omitted for clarity.

(complex **6**) or a d^3–d^2 (complex **7**) ions. Complex **6** (magnetic moment of 1.69 BM per vanadium at 293 K) has two unpaired electrons while **7** (μ_{eff} of 1.83 BM at 293 K) contains a single unpaired electron per two vanadium atoms. These reduced magnetic moments can be the consequence of either a strong electronic coupling of the two vanadium atoms through the N_2 bridge or a change in the oxidation state of vanadium. That the electron density on the N_2 unit is increased is additionally supported by the results from its protonation in **6** and **7**. The reaction of **6** with 0.1 M HCl (see Experimental Procedure) gave reproducible results which revealed on average of 49% N_2, 36% N_2H_4, and 11% NH_3, as decomposition products from the bridging N_2 unit, whereas with **7** the results were 70% N_2, 22% N_2H_4, and 7% NH_3.[10]

Experimental Procedure

3: A large excess of Na sand (0.430 g, 18.7 mmol) was added to a solution of **1** (4.089 g, 8.49 mmol) in diglyme (200 mL) under argon, and stirred for two hours. The brown filtrate was concentrated under vacuum to 50 mL to give, upon cooling to 0 °C, a microcrystalline solid that was recrystallized from hot diglyme. Correct elemental analysis for $C_{48}H_{72}NaO_6V$, $\mu_{eff} = 2.84$ BM at 293 K.

6: Diglyme (200 mL) and **1** (3.277 g, 6.82 mmol) were combined in a 1000 mL round-bottomed flask. The mixture was cooled to −5 °C, and then solid Na spheres (av. diameter 1.2 mm) (0.142 g, 6.18 mmol) were added. This mixture was stirred vigorously under 1–2 atm N_2 in a closed system for 14 h at −5 °C, then for 4 hr at room temperature. The black microcrystalline substance (97%, extremely air- and water-sensitive, pyrophoric) was recrystallized from benzene at about 60 °C. Correct elemental analysis for $C_{72}H_{100}N_2Na_2O_6V_2$. The N_2 content of **6** determined by reaction with iodine in THF was 98% of the expected value.

7: The procedure for **6** was used for the preparation of **7**, with 100 mL of diglyme, 4.29 g (8.92 mmol) of **1**, and a single ball of potassium (0.42 g, 10.8 mmol, excess recovered at end) (yield 68%). Correct elemental analysis for $C_{66}H_{94}KN_2O_6V_2$. The N_2 content determined as for **6** was 95% of the expected value.

Reaction of **6** and **7** with HCl: A 250 mL round-bottomed flask was charged with 0.1 M HCl (100 mL), and then degassed with N_2. A thin glass vial containing the sample (0.5–1.0 g) was placed in the flask, and the flask connected to a device for measuring gas evolution. The vial was broken by stirring and the volume of N_2 evolved measured. The solution containing decomposition products (typically light-blue) was filtered to remove bits of glass. The solution was analyzed spectrophotometrically for NH_2NH_2 on addition of Kovac's reagent [11] at μ = 42 nm and as a check at μ = 482 nm. The mixture was then distilled over KOH into a flask containing 0.1 M HCl. This distillation eliminated NH_2NH_2, while liberating NH_3. The distillate was analyzed spectrophotometrically for NH_3 after addition of Nessler's reagent [12] at μ = 524 nm.

[7] Crystal structure analysis of **6**, $C_{54}H_{66}N_2NaV_2 \cdot C_{12}H_{28}NaO_6 \cdot C_6H_6$, M = 1237.5, orthorhombic, space group $C222_1$, a = 11.823(4), b = 21.651(2), c = 28.696(6) Å, V = 7346(3) Å^3, Z = 4, ρ_{calcd} = 1.119 g cm^{-3}, $Cu_{K\alpha}$ radiation (λ = 1.54178 Å), $\mu(Cu_{K\alpha})$ = 26.24 cm^{-1}, crystal dimensions 0.16 × 0.26 × 0.35 mm. For 851 unique observed structure amplitudes [$I > 2\sigma(I)$] collected on a Rigaku AFC6S diffractometer in the range $5 < 2\theta < 120°$, corrected for absorption, the current R value is 0.081 (R = 0.093 for the incorrect enantiomorph). The structure was solved by the heavy atom method. The low percentage of observed reflections and the consequent low accuracy of the analysis could be related to the intrinsic low scattering power of the crystal due to the presence of three different molecular species. Only vanadium, nitrogen, oxygen, and non-disordered sodium atoms [Na(2)] were allowed to vary anisotropically. Na(1) was found to be statistically distributed over two positions about a twofold axis. All hydrogen atoms were placed in calculated positions prior the last stage of refinement (U_{iso} = 0.12 Å^2). The collection of the Friedel's pairs would have given a better overdetermination ratio and smaller esd.'s for all parameters. However, the presence in the structure of an element (vanadium) showing a remarkable dispersive effect with the $Cu_{K\alpha}$ wavelength enables the determination of the absolute configuration with a high degree of confidence, as indicated by the final R factors resulting from the refinement carried out on the enantiomers: R = 0.081, R_G = 0.083 for one and R = 0.093, R_G = 0.094 for the other. (W. C. Hamilton, *Acta Crystallogr.* **1965**, *18*, 502). All calculations were carried out with SHELX-76. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

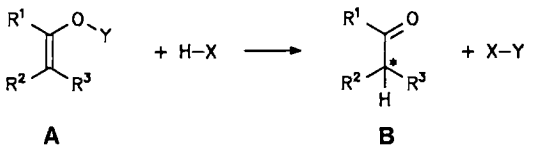
Stereoselective Protonation of Boron Enolates**

By *Thomas Haubenreich, Siegfried Hünig,** and *Hans-Joachim Schulz*

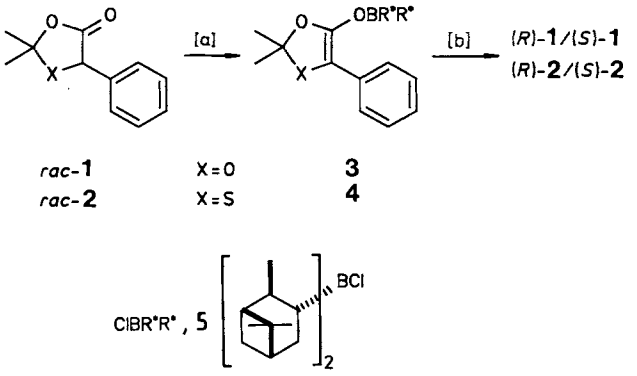
In most enantioselective protonations of formal carbanions a chiral protonic acid HX* attacks a prochiral C atom.[1] Noncovalent interactions between the substrate, which occur in the unknown, strongly variable ion aggregates, and HX* have a decisive influence on the (diastereomeric) transition states, and thus on the stereochemical course of the protonation. On the one hand, numerous possibilities exist which can influence the outcome of the protonation (temperature, choice of solvent, additives, and auxiliaries, etc.), on the other hand, the lack of knowledge about the true nature of the reacting aggregate necessitates a great deal of experience when carrying out the experiment.

Thus, we decided to extend the stereoselective protonation to enol derivatives of the type **A** according to the principle formulated in Scheme 1. As a first example we describe the



Scheme 1. Stereoselective protonation of the enol derivatives **A**. X and/or Y are chiral.

protonation of **A**, with the loss of a chiral auxiliary Y*, by achiral proton sources. For this we generated the boron enolates **3** and **4** in situ from *rac*-**1** and *rac*-**2** (Scheme 2).



Scheme 2. [a] 1. lithium hexamethyldisilazane (0.2 mmol), THF, 30 min, −40 to −50 °C; 2. ClBR*R* **5** (0.3 mmol) 2–3 min, −70 °C. [b] 1. addition, 30 min, −70 °C; 2. HX (0.4 mmol), 30 min, −70 °C; 3. AcOH or TFA (0.2 mL), −70 °C.

A boron-containing auxiliary should be able to bind (achiral) OH and NH acids coordinatively, and thus generate a defined, though transient compound between substrate and proton source. With a similar approach stereoselective C–C couplings between enol borates[2] as well as enol borinates[3] and carbonyl compounds have been well established. As a model for the planned protonations we chose chiral boron enolates, produced from commercially available (−)-*B*-chlorodiisopinocampheylborane (**5**) and ketones, which undergo stereoselective aldol reactions.[3a]

For **1** and **2**, however, it was not possible to produce the boron enolates **3** and **4** by direct reaction with **5** and the aid of tertiary amine. This commonly used method fails if the proton abstraction should occur at a tertiary carbon atom.[4] In contrast, the roundabout way via the lithium or potassium enolates of **1** and **2** was successful. Their reaction with **5** at approximately −50 °C yielded the desired chiral boron enolates, which were protonated in situ with the acids listed in Table 1.

Table 1. Protonations of the boron enolate **4**, produced in situ, in THF at −70 °C. Abbreviations are explained in [a].

Entry	Addition (equiv)	Proton source	Reaction stopped by	2% *ee* [b] (config.)
1	–	AcOH	–	54 (*R*)
2	–	TFA	–	32 (*S*)
3	–	TClA	–	40 (*S*)
4	–	MeOH	AcOH	0
5	–	MeOH	TFA	0
6	–	F_3EtOH	AcOH	0
7	–	*t*BuOH	AcOH	56 (*R*)
8	–	*t*BuOH	TFA	34 (*S*)
9	–	PhOH	TFA	4 (*S*)
10	–	$(MeCO)_2CH_2$	AcOH	46 (*S*)
11	–	$MeCOCH_2CO_2Et$	TFA	19 (*R*)
12	(*S*)-PEA (5)	AcOH	–	43 (*R*)
13	(*S*)-PEA (5)	TFA	–	19 (*S*)
14	(*R*)-PEA (5)	AcOH	–	2 (*R*)
15	(*R*)-PEA (10)	AcOH	–	5 (*R*)
16	(*S*)-EPEA (4)	AcOH	–	57 (*R*)
17	(*S*)-EPEA (4)	TFA	–	37 (*S*)
18	Pip (4)	AcOH	–	41 (*R*)
19	TMP (4)	AcOH	–	76 (*R*)
20	TMP (4)	TFA	–	39 (*S*)
21	Et_3N (10)	AcOH	–	47 (*R*)
22	*i*Pr(NEt_2) (4)	AcOH	–	51 (*R*)

[a] AcOH = acetic acid, TFA = trifluoroacetic acid, TClA = trichloroacetic acid, F_3EtOH = trifluoroethanol, PEA = α-phenylethylamine, EPEA = *N*-ethylphenylethylamine, Pip = Piperidine. [b] HPLC (Merck, ChiraSpher), reproducibility ±1%.

The boron enolate produced in situ was proven by ^{11}B NMR spectroscopy.[5] Since the measurements were to be carried out at +5 °C, the somewhat more thermostable boron enolate **3** was used. In addition to the signal for the reagent **5** (used in excess) at $\delta = 70.4$ ($\delta = 74$ in THF/Et_2O, 0 °C[6]), a new peak occurs at $\delta = 53.9$ which must be assigned to **3**. This signal lies within the range typical for dicyclohexylboron enolates ($\delta = 50–54$ in CCl_4).[7] Thus, the generation of optically active **1** or **2** for the subsequent protonation can be attributed to the attack of HX on the boron enolates **3** and **4**, respectively.

To avoid racemizations of the product formed from the protonation with weak acids, each reaction was stopped by neutralization with acetic acid (in some cases with trifluoroacetic acid). The enantiomeric excess of (*R*)- or (*S*)-enriched **1** and **2** was determined by chromatography with a chiral column (Merck, ChiraSpher), without further workup of the reaction mixture.

Since almost the same *ee* values were obtained for the products from *rac*-**1** and *rac*-**2** (AcOH and TFA as HX), only the results for the lactone **2** are listed in Table 1 and will be discussed in the following.

Interestingly, the results in Table 1 show that the protonation of **4** with acetic acid leads to an enrichment of (*R*)-**2** (entry 1), whereas the reaction with the stereochemically

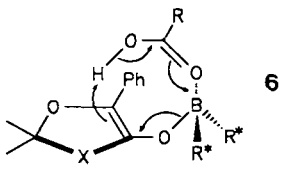
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

very similar trifluoroacetic acid favors the formation of the (*S*)-isomer (entry 2). Evidently, the lactone is protonated by two different reaction mechanisms. Thus, this is a further example of a reversal of stereoselectivity on changing from a methyl to a trifluoromethyl group in a reaction partner.[8]

The results can be explained if it is assumed that owing to the nucleophilicity of the carbonyl oxygen atom, the acetic acid forms a dative bond with the boron atom. This adduct transfers the acidic proton to the enol in a cyclic transition state, for example **6**, whereby the (*R*)-isomer is formed. A similar cyclic transition state was also postulated by Brown et al. for the protolysis of *B*-crotyl-9-borabicyclo-[3.3.1]nonane.[9]



6

In contrast, trifluoroacetic acid (TFA) protonates the enolate without prior binding at the boron atom. The reason for the reduced capability for coordination of TFA is the reduced nucleophilicity of the carbonyl oxygen atom due to the accepting ability of the trifluoromethyl group. Thus, in contrast to the IR spectra of trifluoroacetoxydibutylborane, the IR spectra of acetoxydibutylborane indicate an intramolecular coordination of the carbonyl oxygen atom to the boron atom.[10] Interestingly, the reaction rates for the protolytic cleavage of the B–C bond are less influenced by the acidity of the acid than by its nucleophilicity. Thus, the protolyses with trifluoro- and trichloroacetic acid occur extremely slowly, whereas carbonic acids which can coordinate to the boron atom cause cleavage very rapidly.[11] Indeed, after the protonation of **4** with trichloroacetic acid, (*S*)-**2** is enriched even more (entry 3).

Evidently, noncoordinating acids directly attack the enol β-C atom of **4** preferably from the less shielded *si* side. In contrast, proton sources capable of coordinating at the boron atom form an adduct with **4**, from whose *re* side the proton is transferred. Thus, different protonation mechanisms can be used in such a way that with the same chiral auxiliary opposite stereoselectivities are achieved.[12]

Sterically less demanding alcohols (methanol, trifluoroethanol) protonate **4** unselectively. The stopping of the reaction with acetic acid and with TFA both produce the same result—a racemic mixture (entries 4,5). Thus, the protonation has occurred before the addition of the acids. The same applies for the more acidic trifluoroethanol (entry 6). In contrast, the bulky *tert*-butyl alcohol is inert towards **4**. This is revealed by the change in configuration on addition of TFA and AcOH (entries 7,8). Thus, if a reaction is stopped with acetic or trifluoroacetic acid this allows a simple examination of the effect of a proton source. Stereoselective protonation of **4** is observed with β-dicarbonyl compounds. Strangely, the configuration of the product changes with the transfer from acetylacetone ((*S*)-**2**, 46% *ee*) to acetoacetic ester ((*R*)-**2**, 19% *ee*, entries 10,11).

The experiments with amines (entries 12–22) reveal that primary and secondary amines influence the stereoselective protonation considerably (tertiary amines have no or only a weak effect), without functioning as a proton source. The different effects of the antipodes of chiral amines indicate that amines are inserted—probably via noncovalent interactions—in the transition state. Direct coordination of amines with the boron enolate **4**, however, seems ruled out: Particularly highly shielded 2,2,6,6-tetramethylpiperidine (TMP) shows the strongest effects (76% *ee*, entry 19). For the protonation of **3** with acetic acid, under the addition of TMP, (*R*)-**1** could be enriched to almost 80% *ee*! A reaction with chlorodiisopinocampheylborane **5** in excess cannot serve as an explanation for the amine effect. It is already known that **5** does not add sterically hindered amines.[6]

A further optimization of the auxiliary-induced stereoselective protonation via boron enolates can be expected from the variation of the chiral boron moiety. Thus, the conformatively flexible boron diisopinocampheyl group could be substituted by cyclic, chiral, C_2 symmetrical boron ligands, as has already proved successful for stereoselective aldol reactions.[3b, c]

Protonation of the boron enolates **4** applied can be described as an auxiliary-induced stereoselective reaction. Normally, in such reactions the auxiliary is only removed in a subsequent reaction. Thus, for example, in the previously mentioned aldol addition[3] the boron-containing auxiliary is first seized by the alcoholate function formed and subsequently removed by hydrolysis.

The protonation described herein, however, belongs to the rare examples in which the construction of the new stereocenter is coupled with the removal of the auxiliary—an important step of enantioselective catalytic synthesis.

DBU and DBN are Strong Nucleophiles: X-Ray Crystal Structures of Onio- and Dionio-Substituted Phosphanes**

By *Robert Reed, Régis Réau, Françoise Dahan*, and *Guy Bertrand**

Base-induced intra- or intermolecular dehydrohalogenation reactions play a key role in organic and inorganic chemistry. Since the 1970s the efficiency of DBU (1,8-diazabi-

[*] Dr. G. Bertrand, Dr. R. Reed, Dr. R. Réau, Dr. F. Dahan

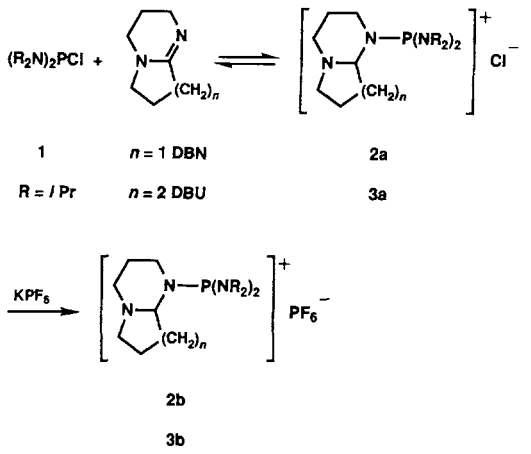
cyclo[5.4.0]undec-7-ene) and DBN (1,5-diazabicyclo[4.3.0]-non-5-ene) has been widely demonstrated,[1] although many authors have reported unexplained phenomena.[2] In this paper we report that these bicyclic amidines, known as "non-nucleophilic strong bases"[1, 3] can behave as strong nucleophiles; X-ray crystal structures of onio- and dionio-substituted phosphanes (Weiss-type compounds)[4] are presented.

In dichloromethane solution chlorobis(diisopropylamino)phosphane (**1**) and DBN or DBU are in equilibrium with the cationic phosphanes **2a** or **3a**. This equilibrium is shifted towards the products in acetonitrile, or by exchanging the chloride for hexafluorophosphate to yield **2b** and **3b**.[5]



Scheme 1.

The ^{31}P NMR chemical shifts observed for these compounds [$\delta = +108$ (**2b**), $+107$ (**3b**)] are consistent with triaminophosphanes; furthermore in the ^{13}C NMR spectra, phosphorus coupling to the bridgehead carbons [$^2J_{C,P} = 31.1$ (**2b**) and 21.1 Hz (**3b**)] confirms that the bicyclic amidines are bound to the phosphorus. To establish the exact nature of the interaction between the amidine and the phosphorus atom, a single crystal X-ray diffraction study was performed on **2b**.[6] The ORTEP view (Fig. 1) reveals the phosphorus atom in a pyramidal environment in which the three substituents are arranged in a propeller fashion to minimize the steric interactions. The P1–N3 and P1–N4 bond lengths [1.666(4) and 1.661(4) Å] are classical, longer than those observed in phosphanylium ions where 2pπ–3pπ interaction between the phosphorus and the nitrogens atom takes place.[7] Of particular interest are the very long P1–N1 bond [1.796(3) Å] and the almost equal C1–N1 [1.322(5) Å] and C1-N2 [1.298(5) Å] bond lengths. The structure of this cationic phosphane is comparable to that of borylium ions in which a cationic bivalent boron atom is stabilized by an electron pair donor and the positive charge is delocalized on the cluster.[8]

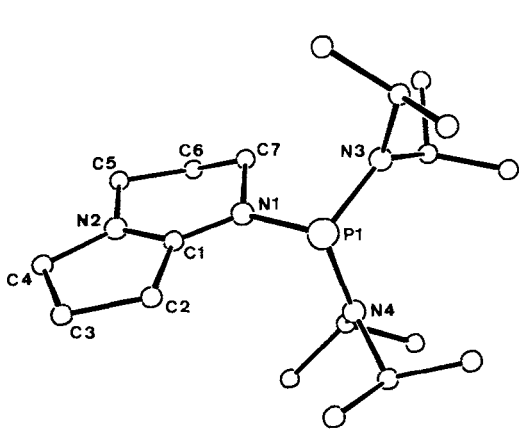


Fig. 1. Structure of cation **2b** (ORTEP). Selected bond lengths [Å] and angles [°]: P1-N1 1.796(3), P1-N3 1.661(4), P1-N4 1.666(4), N1-C1 1.322(5), C1-N2 1.298(5); N1-P1-N3 101.6(2), N1-P1-N4 99.1(2), N3-P1-N4 109.3(2), P1-N1-C1 120.3(3), P1-N1-C7 124.0(3), C7-N1-C1 114.9(3), N1-C1-C2 123.7(4), N2-C1-C2 110.0(4), N1-C1-N2 126.2(4), C1-N2-C5 123.7(4), C1-N2-C4 115.3(3), C4-N2-C5 120.9(4).

As expected, a similar ionic adduct **2c** can be obtained by treating bis(diisopropylamino)phosphanylium tetrachloroaluminate[9] with DBN. In addition, the free bis(diisopropylamino)phosphanylium salt can be cleanly regenerated by the addition of one equivalent of borontrifluoride-etherate complex to **2b**.

Most importantly, the nucleophilic behavior of DBU and DBN is very general (Table 1) and also allows the preparation of dionio-substituted phosphanes **6**–**9**, which formally result from the interaction of two DBU or DBN molecules with monocoordinated phosphorus dications (RP^{2+}).

Table 1. Spectroscopic data of the compounds $(R^1R^2R^3P)^+PF_6^-$ **2b**–**5b** and $(R^1R^2R^3P)^{2+}2PF_6^-$ **6b**–**9b** [a].

7b	Cy_2N [d]	DBU	DBU	100	163.5	10	43	212–216
8b	Ph	DBN	DBN	102	171.5	38	14	214–217
9b	Ph	DBU	DBU	98	173.2	31	[e]	[e]

[a] The spectroscopic data of compounds **2a**–**9a** (isolated as viscous oils, Cl^- as counter anion) and **2c** ($AlCl_4^-$ as counter anion) are essentially identical to **2b**–**9b** (PF_6^- as counter anion). [b] Spectra of cations in $CDCl_3$ solution, dications in CD_3CN solution. Coupling constants are in Hz. [c] Yields after recrystallization. The yields determined by ^{31}P NMR spectroscopy are essentially quantitative; no other phosphorus products were observed. [d] Cy = cyclohexyl. [e] Compound not isolated.

The X-ray crystal structure of **6b** is shown in Figure 2.[10] The P1–N1 and P1–N3 bonds are rather long [1.766(5) and 1.752(4) Å], and the C–N bond lengths of the NCN moieties [1.339(6), 1.304(8) and 1.334(7), 1.290(7) Å] are between single and double bonds. Here also, the positive charges are strongly delocalized.

This new understanding of the behavior of DBU and DBN towards halogenated derivatives of main group elements[11] led us to reconsider the mechanism of dehydrohalogenation in the presence of these cyclic amidines. For example, addition of DBU to a mixture of chlorodiphenylphosphane and diphenylphosphane gives the tetraphenyldiphosphane. In fact, no reaction between diphenylphosphane and DBU is observed by ^{31}P NMR spectroscopy, whereas adduct **5a** reacts with diphenylphosphane to yield the diphosphane quantitatively.

In contrast to what is generally admitted, these results show that DBU and DBN can act as strong nucleophiles. This new understanding will help to clarify the superior utility and frequently observed unexplained behavior of these highly popular reagents in "base-induced" dehydrohalogenation reactions.

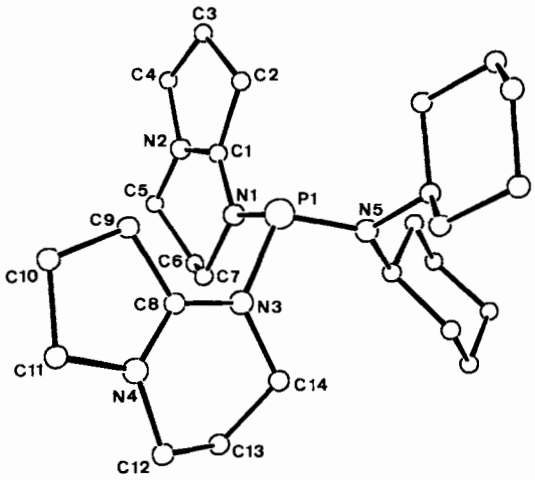

Fig. 2. Structure of cation **6b** (ORTEP). Selected bond lengths [Å] and angles [°]: P1-N1 1.766(5), P1-N3 1.752(4), P1-N5 1.628(5), N1-C1 1.339(6), C1-N2 1.304(8), N3-C8 1.334(7), C8-N4 1.290(7); N1-P1-N3 95.9(2), N1-P1-N5 104.7(2), N3-P1-N5 106.5(2), P1-N1-C1 117.2(4), P1-N1-C7 125.1(3), C1-N1-C7 116.3(5), N1-C1-N2 123.9(5), N1-C1-C2 125.6(6), C2-C1-N2 110.5(5), C1-N2-C4 113.6(5), C1-N2-C5 125.3(4), C4-N2-C5 121.1(5).

Experimental Procedure

Representative synthesis of compounds **2a–9b**, example **2a** and **2b**: An acetonitrile solution (20 mL) of DBN (5.6 mL, 45 mmol) was added dropwise at room temperature to an acetonitrile solution (20 mL) of chlorobis(diisopropylamino)phosphane **1** (12.0 g, 45 mmol) to afford **2a** as an extremely hygroscopic, viscous oil. ^{31}P NMR (32 MHz, CH_3CN, 35 °C): $\delta = 106.7$; ^{13}C NMR (50 MHz, $CDCl_3$, 25 °C): $\delta = 18.8$ (s, CH_2), 19.5 (s, CH_2), 23.8 (t, $^3J(C,P) = 7$ Hz, CH_3), 31.2 (d, $^2J(C,P) = 27$ Hz, CH_2), 42.5 (s, CH_2), 43.6 (s, CH_2), 47.5 (d, $^2J(C,P) = 12$ Hz, CH), 53.8 (s, CH_2), 165.1 (d, $^2J(C,P) = 31$ Hz, NCN). This solution was added slowly at 0 °C to an acetonitrile solution (20 mL) of KPF_6 (8.5 g, 46 mmol) and stirred for 24 hrs. The precipitated KCl was filtered off, and the solvent removed under vacuum. Compound **2b** was crystallized at −40 °C from CH_2Cl_2/Et_2O (14.5 g, 64%). ^{31}P NMR (32 MHz, $CDCl_3$, 35 °C): $\delta = 108.4$, −143.6 (sept, $^1J(P,F) = 709$ Hz); ^{13}C NMR (50 MHz, $CDCl_3$, 25 °C): $\delta = 18.7$ (d, $^3J(C,P) = 4$ Hz, CH_2), 19.3 (s, CH_2), 23.8 (t, $^3J(C,P) = 7$ Hz, CH_3), 31.2 (d, $^2J(C,P) = 27$ Hz, CH_2), 42.5 (d, $^3J(C,P) = 3$ Hz, CH_2), 43.1 (s, CH_2), 47.9 (d, $^2J(C,P) = 14$ Hz, CH), 53.5 (s, CH_2), 165.4 (d, $^2J(C,P) = 31$ Hz, NCN).

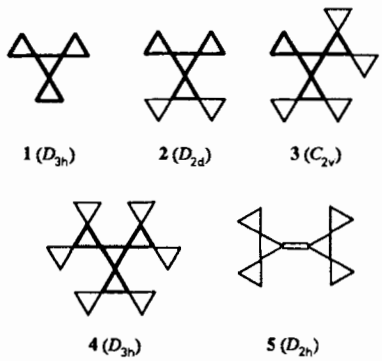
[11] Preliminary experiments show that DBU and DBN can act as nucleophiles towards a variety of halogenated compounds of main group elements.

Perspirocyclopropanated [3]Rotane—A Section of a Carbon Network Containing Spirocyclopropane Units?**

By *Sergei I. Kozhushkov, Thomas Haumann, Roland Boese,* and *Armin de Meijere**

Dedicated to Professor Emanuel Vogel on the occasion of his 65th birthday

Twenty years ago the synthesis[1, 2] of [3]rotane (**1**)[3] may have been seen as the end of the development of highly strained cyclopropane derivatives with unusual structural[4–8] and spectroscopic properties.[9] However, more recent reports on branched [*n*]triangulanes[10] like **2**[11–13] and **3**[12, 13] containing a [3]rotane subunit show that **1** is actually the starting point of a larger group of star-shaped, branched hydrocarbons with nothing but spirocyclic linkages between three-membered rings. Accordingly, the perspirocyclopropanated [3]rotane **4**,[14] a [10]triangulane[10] with D_{3h} symmetry, which we describe here, is also just another peak on a possible route to higher summits.



The starting material for the successful route[15] to **4** (Scheme 1, Table 1) was the recently described bi(dispiro-[2.0.2.1]heptylidene) **5**.[12] Cyclopropanation of **5** with two

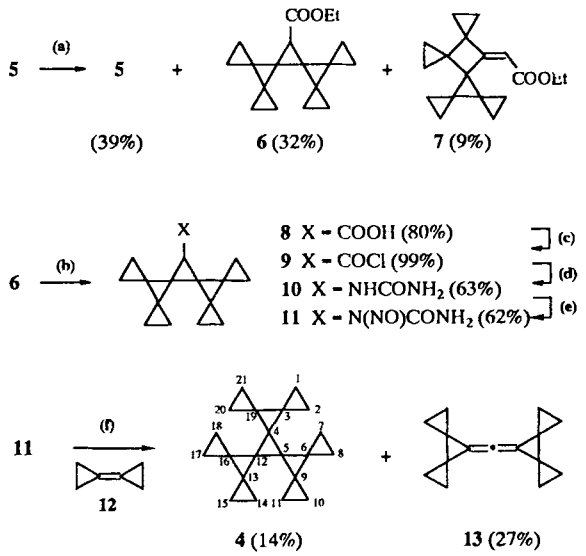

Scheme 1. a) 2 equiv $N_2CHCOOEt$, CH_2Cl_2, $[\{Rh(OAc)_2\}_2]$ (1 mol%), 0 °C, 12 h. b) 1.2 equiv NaOH, H_2O, 100 °C, 6 h. c) $SOCl_2$, 80 °C, 2 h. d) 1) NaN_3, Me_2CO, 0 °C, 2 h; 2) C_6H_6, 80 °C, 2 h; 3) NH_3, 5 °C. e) N_2O_4, Et_2O, 0 °C, 2 h. f) 10 equiv NaOMe, 0 °C, 10 h.

equivalents of ethyl diazoacetate in the presence of dirhodium tetraacetate[18] yielded, besides the desired carboxylate **6**[19] (32%), also 9% of the rearranged product **7**.[20] The products **6** and **7** were separated by chromatography over silica gel. The hydrolysis of the ester **6** afforded the acid **8** (80% yield), which was transformed into the acid chloride **9** (99%) with thionyl chloride. Analogous to the synthesis of *N*-nitroso-*N*-cyclopropylurea,[21] the nitrosourea **11** was obtained from **9** in 39% yield. The crucial step—the in situ generation of the diazo[7]triangulane from **11**—was achieved with ten equivalents of solid sodium methyl alcoholate at 0 °C[22] in a large excess of bicyclopropylidene (**12**).[23] The perspiro-cyclopropanated [3]rotane **4** could be separated from the allene **13**[19] (see ref. [15]) by chromatography on silica gel and was isolated in 14% yield.

[3]Rotane **4** precipitated on slow concentration of a dilute solution in ethanol in the form of crystals suitable for X-ray structure analysis (Fig. 1).[24] Comparison of the structural parameters of **4** (averaged over D_{3h} symmetry) with those of **1**,[4c] **2**,[8b, 11] and **3**[12] shows, on one hand, the known effects for branched triangulanes:[8a, c] the difference in length between the distal [1.525 (**1**), 1.532 (**2**), 1.516 and 1.512 (**3**), 1.529 Å (**4**)] and proximal bonds [1.477 (**1**), 1.483 (**2**), 1.475 and 1.472 (**3**), 1.481 Å (**4**)] in the outer cyclopropane rings, as well as the shortening of all C–C bonds in the trispiro-annelated rings [for the central rings: 1.475 (**1**), 1.477 and 1.481 (**2**), 1.471 and 1.483 (**3**), 1.484 Å (**4**)].[4c, 8b, 11, 12] The reason is to be found in hybridization changes involving an increased angular strain.[4c, 12, 25] To this extent the bond lengths of branched [*n*]triangulanes can be estimated according to an empirical increment system.[26] On the other hand, the bonds in the central three-membered ring of **4** (1.484 Å with a standard deviation of 0.001 Å) are significantly longer than those in the central ring of [3]rotane **1** [1.475(2) Å].[4c] This might be attributable to an additional electronic interaction in terms of a spiro conjugation between the six outer rings and the central three-membered ring.[27]

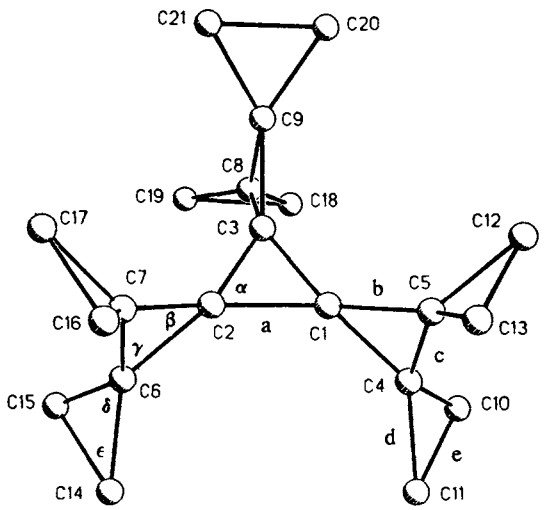

Fig. 1. Structure of **4** in the crystal. The numbering in this figure is not the same as the systematic numbering according to IUPAC nomenclature. Bond lengths [Å] and angles [°] (averaged over D_{3h} symmetry): a = 1.484(1), b = 1.479(1), c = 1.476(2), d = 1.481(1), e = 1.529(1); α = 60.0(1), β = 59.9(1), γ = 60.1(1), δ = 62.2(1), ε = 58.9(1).

Table 1. Physical and spectroscopic data of important new compounds [16]. NMR spectra: $CDCl_3$, 250 MHz (^1H); 62.9 MHz (^{13}C, additional DEPT).

4: White solid, m.p. 200–201 °C. ^1H NMR: δ = 0.69, 0.75 (AA'BB', 24H); ^{13}C NMR: δ = 6.52 (12 CH_2), 18.24 (6 C), 28.82 (3 C); high resolution MS: *m/z* calcd for $C_{21}H_{28}N$ ($M^+ + NH_4$), 294.4601, found 294.4374 (100%).

6: White solid, m.p. 80–82 °C. ^1H NMR: δ = 0.52–0.63 (m, 2H), 0.63–0.91 (m, 12H), 0.91–1.0 (m, 2H), 1.22 (t, J = 7.0 Hz, 3H), 2.09 (s, 1H), 4.05 (q, J = 7.0 Hz, 2H); ^{13}C NMR: δ = 3.51, 4.98, 6.64, 6.99 (2 CH_2), 14.08 (CH_3), 25.59 (CH), 59.88 (CH_2), 18.07, 18.49 (2 C), 172.49 (C).

7: White solid, m.p. 66–68 °C. ^1H NMR: δ = 0.05–0.12 (m, AB, J = 5.0 Hz, 2H), 0.45–0.54 (m, 2H), 0.64–0.73 (m, 4H), 0.75–0.87 (m, 4H), 0.95–1.05 (m, 4H), 1.25 (t, J = 7.1 Hz, 3H), 4.11 (q, J = 7.1 Hz, 2H), 5.20 (s, 1H); ^{13}C NMR: δ = 2.78, 4.12, 6.23, 14.36 (2 CH_2), 14.57 (CH_3), 26.45 (2 C), 29.60, 31.99, 39.10, 165.33, 175.55 (C), 59.27 (CH_2), 104.11 (CH).

8: White solid, m.p. 204–206 °C (decomp.). ^1H NMR: δ = 0.53–0.62 (m, 2H), 0.67–0.76 (m, 6H), 0.76–0.93 (m, 6H), 1.01–1.10 (m, 2H), 2.03 (s, 1H), 10.50 (s, 1H); ^{13}C NMR: δ = 3.33, 5.11, 6.69, 7.06 (2 CH_2), 25.39 (CH), 18.08, 18.65, 32.46 (2 C), 179.68 (C).

9: Clear oil. ^1H NMR: δ = 0.58–0.71 (m, 4H), 0.71–0.79 (m, 8H), 1.12–1.29 (m, 4H), 2.55 (s, 1H); ^{13}C NMR: δ = 3.42, 5.35, 6.70, 7.30 (2 CH_2), 18.23, 19.05, 36.34 (2 C), 36.10 (CH), 172.42 (C).

10: White solid, m.p. 176–178 °C (decomp.). ^1H NMR: δ = 0.60–1.12 (16H), 2.93 (s, 1H), 4.70 (s, 1H), 4.79 (s, 2H); ^{13}C NMR: δ = 3.76, 4.48, 6.55, 6.79 (2 CH_2), 17.54, 18.70, 28.71 (2C), 34.03 (CH), 160.62 (C).

11: Yellow solid, m.p. 124–125 °C (decomp.). ^1H NMR: δ = 0.55–1.15 (m, 16H), 3.21 (s, 1H), 5.20 (s, 2H); ^{13}C NMR: δ = 5.04, 6.13, 6.59, 6.71 (2 CH_2), 18.72, 19.29, 29.54 (2 C), 36.12 (CH), 175.14 (C).

13: White solid. ^1H NMR: δ = 0.97, 1.18 (AA'BB', 16H); ^{13}C NMR: δ = 8.38 (8 CH_2), 20.99 (4 C), 95.27 (2 C), 165.02 (C).

On comparison of the ^{13}C NMR data of **1**–**4**, a shift to lower field for the signals of the central C atoms is observed for each addition of two spiroannelated three-membered rings onto [3]rotane: δ = 18.3 for **1**,[1a] 23.1 for **2**,[11–13] 25.9 for **3**,[12] and 28.8 for **4**.[28]

Particularly notable is the high thermal stability of the [10]triangulane **4** with D_{3h} symmetry. Although its total strain of at least 1130 kJ mol^{-1}[29] makes **4** more highly strained than cubane,[30] it is stable for a long time even at its melting point of 200–201 °C. As the DSC curve shows,[31] a thermal transformation or decomposition occurs only above 250 °C. Accordingly, from the point of view of stability, higher aggregates of spiropentane units should be no

problem. Model calculations show that four spirocyclopropane units can be linked to construct a cyclic [8]triangulane without significant angular distortion; two [8]triangulanes in turn linked in a spiro fashion by four three-membered rings form a sort of cube ([20]triangulane), and five such cubes can be linked through common triangular faces (Fig. 2). A carbon network comprising only spiro-

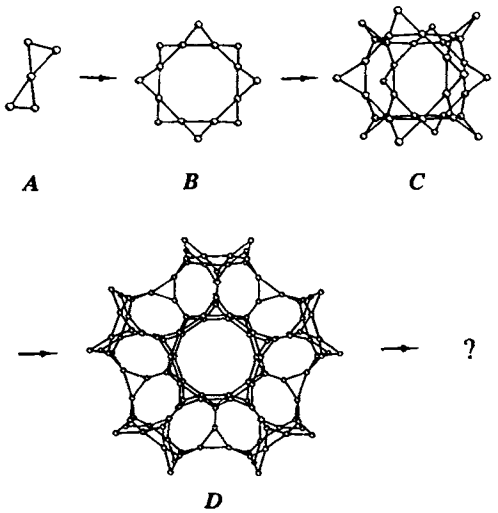

Fig. 2. *A*: spiropentane C_5H_8. ***B***: [8]cyclotriangulane $C_{16}H_{16}$. ***C***: [20]triangulane $C_{36}H_{24}$. ***D***: [80]triangulane $C_{135}H_{60}$.

linked three-membered rings is therefore conceivable.[32] Whether such a network can actually be realized is a different matter.

[14] Systematic name: nonaspiro[2.0.0.0.2.0.2.0.0.0.2.0.2.0.0.0.2.0]henicosane.

[15] Four other attempted routes did not yield **4**: 1) 7-diazodispiro[2.0.2.1]-heptane generated in situ did not react with **5**, but with bicyclopropylidene **12** instead. In the presence of **5** only bis(cyclopropylidene)methane formed while in the presence of **12** the cyclopropanation product **2** was obtained in 28% yield. 2) The alkene **5** did not react with 1-chloro-1-(2-alkoxyethyl)carbene in analogy to ref. [11]. 3) The dibromocarbene adduct of **5** was, in fact, obtained in 94% yield, but the carbenoid formed by treatment with methyllithium in the presence of bicyclopropylidene (**12**) [17] was not trapped by this adduct [16], but reacted under ring opening via the corresponding carbene to afford exclusively the allene **13**. 4) The reaction of **6** with ethylmagnesium bromide/titanium tetra(isopropyl alcoholate) according to Kulinkovich indeed furnished the 1'-hydroxycyclopropyl derivative (93% yield) [17], but it could not be converted into the bromide, and thus the prerequisite for elimination and subsequent further cyclopropanation was not attained.

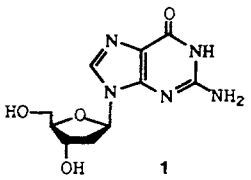
Activation of the C2 Position of Purine by the Trifluoromethanesulfonate Group: Synthesis of N^2-Alkylated Deoxyguanosines**

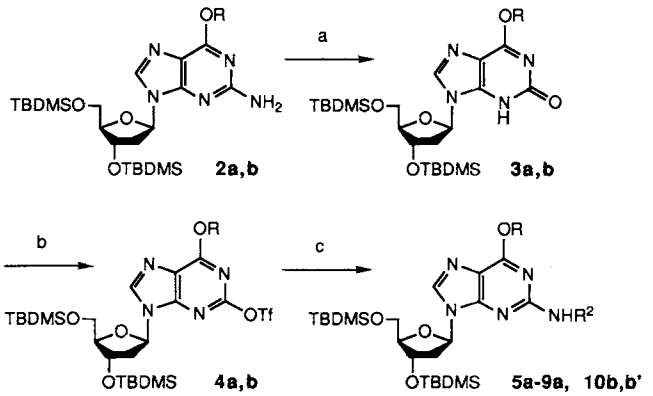
By *Thomas Steinbrecher, Christa Wameling, Franz Oesch,* and *Albrecht Seidel**

The covalent bonding of electrophilic metabolites to nucleophilic centers of pyrimidine and purine bases in DNA plays a central role in the biological activity of chemical carcinogens.[1] For carcinogenic epoxides, which are formed in the cell predominantly under catalysis of the cytochrome P450 enzymes from olefinic or aromatic structures, often attack the exocyclic amino group of deoxyguanosine (**1**) in vivo.[2] In contrast, N^2-alkylated deoxyguanosines are accessible selectively only with difficulty through a direct reaction with electrophilic reagents.[3] They are therefore usually synthesized through transformation of the appropriate substituted amines with 2-halohypoxanthines.[4] An alternative approach was recently described by Casale and McLaughlin.[5] They employed the chemoselective alkylation of 2'-deoxy-4-demethylwyosine at the N^5 position and subsequently transformed the products into N^2-alkyldeoxyguanosine derivatives. We now report on a very efficient general synthesis of fully protected N^2-alkylated deoxyguanosines. The protecting groups are chosen so that the deoxyguanosine derivatives can be used in an oligonucleotide synthesis.



1

Deoxyguanosine (**1**) is transformed into O^6-(*p*-nitrophenylethyl)-3',5'-bis(*tert*-butyldimethylsilyl)deoxyguanosine (**2a**). For this purpose the hydroxyl groups are protected by silylation with *tert*-butyldimethylsilyl chloride (TBDMS-Cl) and the O^6 position of the purine moiety through a Mitsunobu reaction with 2-(*p*-nitrophenyl)ethanol (NPE-OH)[6] or with allyl alcohol (→ **2b**). Till now **2b** was considerably more laborious to prepare by nucleophilic displacement of the mesitylenesulfonate residue, used to activate the C6 position, with allyl alcohol.[7] Allyl ethers can be cleaved under mild conditions.[7, 8] The deoxyxanthosine derivatives **3a,b** are obtained from **2a** and **2b** by a deamination with *n*-pentyl nitrite. Compounds **3a** and **3b** are transformed into **4a** and **4b**, respectively, with trifluoromethanesulfonyl chloride (Tf-Cl). Derivative **4a** reacts with the amines **5**–**7** and the amino alcohols **8** and **9** in dimethylformamide (DMF) under mild conditions and in excellent yields to give the corresponding N^2-substituted deoxyguanosines **5a**–**7a** and **8a** and **9a** (Table 1).



Scheme 1. a) *n*-$C_5H_{11}ONO$; b) CF_3SO_2Cl, NEt_3, CH_2Cl_2; c) R^2NH_2, DMF; **a**: R = *p*-nitrophenylethyl; **b**: R = allyl.

The reaction of **4a** with 1-aminomethylpyrene **6** and (*S*)-(+)-2-amino-2-phenylethanol **9** affords the protected N^2-deoxyguanosine adducts **6a** and **9a** in 81% and 88% yields, respectively. In contrast, Lee et al. reported[9a] a yield of 70% for the reaction of **6** with O^6-NPE-2-fluorodeoxyinosine under comparable conditions, while for a similar transformation of a partially protected 2-fluorodeoxyinosine with *trans*-configurated 1-amino-2-hydroxy-1,2,3,4-tetrahydrophenanthrene, Zajc et al.[9b] recently reported a yield of 55%.

Table 1. Experimental conditions and yields of the reaction of **4a** and **4b** with amines and amino alcohols according to Scheme 1. Selected physical data of the products are given in Table 2.

Amine (R^2NH_2)	Product	*T* [°C]	Yield [%]	R^1
	**5**	25	75	NPE
	**6**	25	81	NPE
	7	25	81	NPE
$HO\text{-}CH_2\text{-}CH_2\text{-}NH_2$	**8**	25	82	NPE
	(+)-**9**	25	88	NPE
	(±)-**10**	60	5	allyl

The structures **6a** and **9a** are derivatives of deoxyguanosine adducts proven to be products of the DNA alkylation by 1-pyrenylmethylsulfate[10] and 1-styreneoxide,[11] respectively. The reaction of **4b** with the acetylated *trans* amino alcohol (±)-**10**[12] of benzo[*a*]pyrene, which is only weakly nucleophilic due to the axially oriented amino group in the bay region,[13] yields a diastereomeric mixture of the N^2-deoxyguanosine adducts **10b** and **10b'**. These

[**] Chemistry of Carcinogenic Metabolites, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft (SFB 302). We thank the company Boehringer Mannheim for gifts of chemicals. T. S. is indebted to the German National Scholarship Foundation for a postgraduate fellowship. Part 1: W. Bochnitschek, A. Seidel, H. Kunz, F. Oesch, *Angew. Chem.* **1985**, *97*, 703; *Angew. Chem. Int. Ed. Engl.* **1985**, *24*, 699.

compounds are fully protected derivatives of the adducts formed in vivo from (±)-*r*-7,*t*-8-dihydroxy-*t*-9,10-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene [(±)-*anti*-BPDE], which is metabolically produced by cyctochrome P450-dependent monooxygenases.[14] Both diastereomers **10b**/**10b′** can be separated by preparative HPLC on a silica gel column. The absolute configuration of **10b** and **10b′** was confirmed by a qualitative comparison with the known CD spectra of the *trans*-configurated adducts[14] that were prepared by in vitro transformations of (+)- and (−)-*anti*-BPDE with calf thymus DNA, followed by enzymatic degradation and separation of the resulting *cis*/*trans* products. While the diastereomer eluted first (**10b** which has a 10*R* configuration) is ascribed to the *trans*-opened adduct of (−)-*anti*-(7*S*,8*R*,9*R*,10*S*)-BPDE, the more polar diastereomer **10b′** (10*S* configuration) corresponds to the analogous adduct of the ultimate carcinogenic (+)-*anti*-(7*R*,8*S*,9*S*,10*R*)-BPDE.[14]

The synthetic strategy described here enables the preparation of deoxyguanosines specifically alkylated at the exocyclic amino group. N^2-deoxyguanosine derivatives of epoxides with a defined structure are thus accessible. This method using the trimethanesulfonate group provides advantages over the common method using fluoro substituents with regard to reactivity and the use of inert silyl protecting groups at the deoxyribose moiety. The orthogonality of the protecting groups opens the possibility of sequence-selective incorporation of these adducts into oligonucleotides,[9a, 9b] which can serve as interesting tools for mechanistic studies of the mutation events in DNA initiated by adducts with defined structures.

Table 2. Selected physical data of the N^2-alkylated deoxyguanosines **5a**–**9a** and **10b**,**b′**.

Experimental Procedure

3a: **2a** (2.00 g, 3.1 mmol) was stirred in portions into *n*-pentyl nitrite (25 mL) at 0 °C. On warming to room temperature the solid went into solution, accompanied by nitrogen evolution. The solution was immediately evaporated to dryness under high vacuum and the crude product purified by flash chromatography (SiO_2; ethyl acetate/petroleum ether, 1:1). The product **3a** was obtained as viscous oil. Yield: 0.95 g (50%), $[\alpha]_D^{20} = +4.5$ (*c* = 0.3, methanol; NMR (400 MHz, $CDCl_3$): δ = 8.12 (d, 2H,Ph), 7.89 (s, 1H, purine), 7.46 (d, 2H, Ph), 6.33 (pseudo-t, 1H, $H_{1'}$), 4.84 (t, 2H, CH_2-C_6H_4-NO_2), 4.55–4.51 (m, 1H, $H_{3'}$), 3.94 (m, 1H, $H_{4'}$), 3.89 (dd, 1H, $H_{5'}$), 3.77 (dd, 1H, $H_{5'*}$), 3.25 (t, 2H, OCH_2), 2.52–2.49 (m, 1H, $H_{2'}$), 2.48–2.26 (m, 1H, $H_{2'*}$), 0.80 (s, 18H, *t*Bu), 0.03 (s, 12H, $SiCH_3$); MS(FD): *m*/*z* 646 (M^+).

4a: **3a** (0.50 g, 0.77 mmol) was dissolved in CH_2Cl_2 (25 mL) and treated with triethylamine (1 mL). The solution was stirred at 0 °C, and trifluoromethanesulfonyl chloride (130 mg, 0,77 mmol) was added. After 15 min the reaction mixture was concentrated and purified by flash chromatography (SiO_2, ethyl acetate/petroleum ether, 1:2). The initially oily product **4a** crystallized at −20 °C within 24 h. Yield: 510 mg (85%), m.p. 72 °C, $[\alpha]_D^{20} = +5.9$ (*c* = 2.6, methanol); ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.31 (s, 1H, purine), 8.15 (d, 2H, Ph), 7.46 (d, 2H, Ph), 6.35 (pseudo-t, 1H, $H_{1'}$), 4.81 (t, 2H, CH_2-C_6H_4-NO_2), 4.57 (m, 1H, $H_{3'}$), 4.00 (m, 1H, $H_{4'}$), 3.84 (dd, 1H, $H_{5'}$), 3.75 (dd, 1H, $H_{5'*}$), 3.30 (t, 2H, CH_2-CH_2-C_6H_4-NO_2), 2.59–2.54 (m, 1H, $H_{2'}$), 2.45–2.41 (m, 1H, $H_{2'*}$), 0.89 (s, 9H, *t*Bu), 0.87 (s, 9H, *t*Bu), 0.08 (s, 6H, $SiCH_3$), 0.06 (s, 6H, $SiCH_3$); MS(FAB): *m*/*z* 778 (M^+, 65%).

General procedure for the treatment of **4a**,**b** with amines and amino alcohols: **4a**,**b** (0.13 mmol) and amines **5**–**7** or amino alcohols **8**–**10** were stirred in DMF (10 mL) (for reaction temperatures see Table 1) until no more **4a**,**b** could be detected by thin-layer chromatography. The DMF was distilled off under high vacuum. The crude products were purified by flash chromatography (SiO_2, ethyl acetate/petroleum ether, 1:3 for the amine derivatives and 1:1 for the amino alcohol derivatives); the separation into diastereomeric adducts **10b** and **10b′** was achieved by preparative HPLC (5 µm, SiO_2) with a solvent mixture of dichloromethane/acetone (98.5:1.5) as eluent (**10b** is the product eluted first).

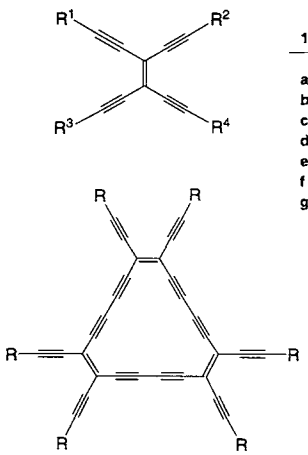
Stable [12]- and [18]Annulenes Derived from Tetraethynylethene**

By *John Anthony, Carolyn B. Knobler,* and *François Diederich**

In memoriam Franz Sondheimer

We recently described the synthesis of tetraethynylethene (**1a**)[1] along with geminally bisdeprotected (**1b**, **c**),[1] monodeprotected (**1d**),[2] and *trans*-bisdeprotected (**1e**)[2] derivatives and now wish to report the completion of the series with the first synthesis of a *cis*-bisdeprotected tetraethynylethene (**1f**).[3] Compound **1f** with a free *cis*-enediyne unit is of special interest because it could lead, by oxidative cyclization, to the hexaethynylhexadehydro-[18]annulene **2a** and after deprotection to **2c**, to the planar all-carbon network **3**.[4] Here, we report that Hay coupling of **1f** leads not only to the [18]annulene **2a** but also to the [12]annulene **4a** and discuss the very different properties of these macrocycles.



1	R^1	R^2	R^3	R^4
a	H	H	H	H

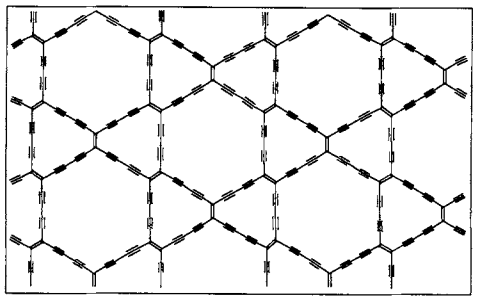
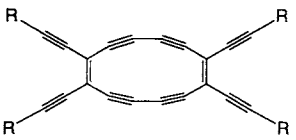
2a R = TIPS
2b R = TMS
2c R = H

TIPS = $Si(iPr)_3$, TMS = $SiMe_3$

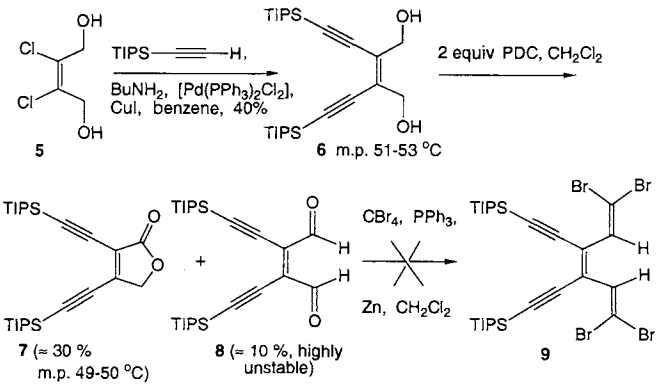


3



4a R = TIPS
4b R = TMS

cis-Enediyne **1f** proved to be far more difficult to prepare than the tetraethynylethene derivatives **1b–e** previously synthesized. The simplest route to **1f** started from *cis*-2,3-dichloro-2-buten-1,4-diol (**5**), obtained by exhaustive reduction of mucochloric acid,[5] and followed the pathway previously used for the synthesis of the *trans* derivative **1e** (Scheme 1).[2] However, this route was abandoned after oxidation of *cis*-diol **6** led preferentially to the dialkynyl lactone **7**[6] and since dialdehyde **8** could not be transformed into tetrabromide **9**.



Scheme 1. Attempted direct synthesis of *cis*-enediyne **1f** from precursor **9**. TIPS = triisopropylsilyl, PDC = pyridinium dichromate.

To avoid the problems associated with the preparation and reactivity of dialdehyde **8**, a route to **1f** was chosen by which the key intermediate **9** was prepared by sequential introduction of the two dibromomethylene residues (Scheme 2). The key steps in this synthesis are the preparation of orthoester **11** and its selective reduction to the monoprotected diol **12**.[7] Since compound **13** and all other intermediates with dibromomethylene groups on the way to **1f** underwent facile *cis–trans* isomerizations in the presence of acid, acidic reaction and workup conditions had to be strictly avoided. As an example, removal of the methoxy-

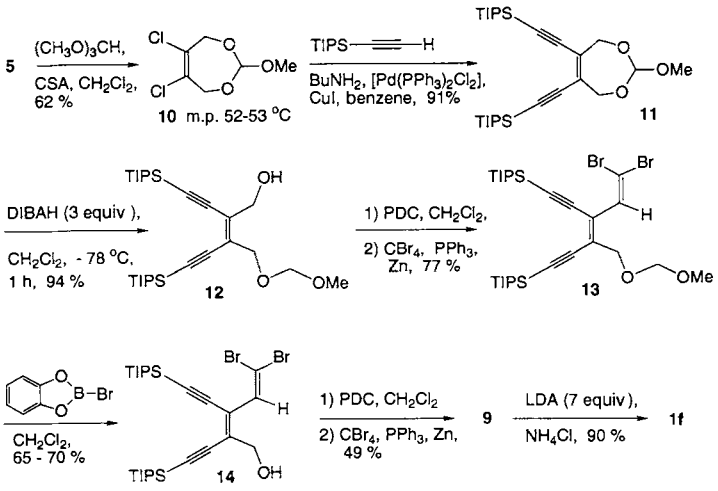
[**] We thank the U.S. National Science Foundation, the American Chemical Society (A.C.S. graduate student fellowship to J. A.) and the ETH (set-up funds) for support of this work. According to IUPAC nomenclature tetraethynylethene should be called 3,4-diethynyl-3-hexene-1,5-diyne. The trivial name tetraethynylethene is easier to remember, however, and equally unambiguous.



Scheme 2. Synthesis of *cis*-enediyne **1f**. Except for **10**, all compounds are oils. CSA = camphorsulfonic acid, DIBAH = diisobutylaluminum hydride, LDA = lithium diisopropylamide.

methylene protecting group in **13** with bromotrimethylsilane[8] afforded **14** in addition to a significant amount of the corresponding *trans*-enediyne, whereas no isomerization of **14** was detected with *B*-bromo-1,3,2-benzodioxaborole ("*B*-bromocatecholborane") as the deprotecting agent.[9]

Tetrabromide **9** was obtained as a yellow oil which, upon standing on the lab bench, yielded pale yellow crystals. Surprisingly, X-ray analysis of these crystals showed them to be *trans*-tetrabromide **15** (m.p. 78 °C, Fig. 1)![10] Further study showed that *cis*-tetrabromide **9** can be stored safely for several days in solution in the dark at −20 °C when traces of acid are strictly eliminated.

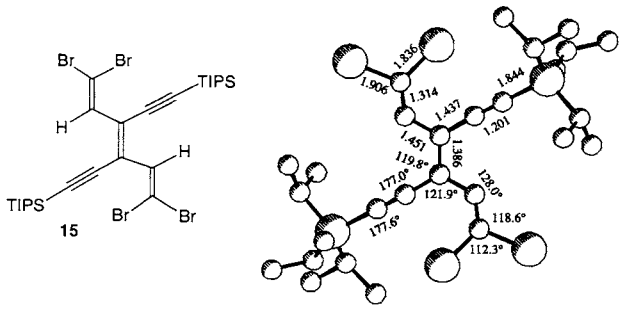


Fig. 1. X-ray crystal structure of **15**.

Upon treatment of **9** with an excess of LDA at −78 °C, a deep purple solution of the *cis*-di(lithium acetylide) formed, which was quenched at 0 °C with saturated NH_4Cl. The free *cis*-enediyne **1f** was obtained as a yellow oil which is quite stable at room temperature in dilute solution. When a solution of **1f** in benzene was heated at reflux for 6 h, 80 % of the compound was recovered; heating the neat oil to 60 °C gave immediate decomposition. Whether intramolecular Bergman cyclizations[11] or intermolecular processes are responsible for the decomposition of **1f** is currently under investigation.[12]

Hay coupling of **1f** (0.002 M in acetone) yielded the [12]annulene **4a** (28 %) and the [18]annulene **2a** (12 %) as readily separable and isolable compounds.[13] The 18-membered cycle **2a** is a stable yellow solid (m.p. 215 °C decomp.), and its ^{13}C and ^1H NMR data strongly support the cyclic trimeric structure. In addition, the characteristic electronic absorption spectrum of **2a** (Fig. 2) closely resembles those of other hexadehydro[18]annulenes with planar aromatic perimeters.[14] Based on this strong spectral correlation, we also assign aromatic character to the cyclic [4n + 2] π-electron system in **2a**.

The [12]annulene **4a** (m.p. 200 °C, decomp) crystallizes readily from pentane to give dark red needles suitable for X-ray crystallography (Fig. 3).[10] Except for the isopropyl groups, **4a** is planar with a mean out-of-plane deviation of the conjugated 20-carbon framework of 0.089(6) Å. Considerable strain in the 12-membered ring is expressed by the

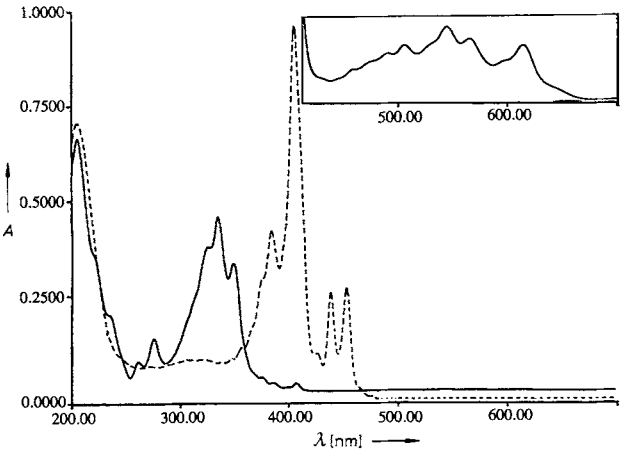

Fig. 2. Electronic absorption spectra of **2a** (----) and **4a** (——) recorded in pentane, $T = 298$ K, $d = 1$ cm, $c = 4.23 \times 10^{-6}$ M for **2a** and $c = 1.024 \times 10^{-5}$ M for the shorter wavelength and 2.56×10^{-6} M for the longer wavelength absorptions (insert) of **4a**. Inset is scaled up 25 ×. A = Absorbance.

strong bend in the two butadiyne units[4, 15b] and by the reduction of the inner C–C≡C bond angles to 117.6 and 118.5°. Despite this ring strain, the molecule is quite stable. At room temperature, dilute pentane solutions remain unchanged over weeks and crystals can be kept in air for several days without decomposition. However, if a solution of **4a** is concentrated without crystallization, significant decomposition occurs.

Both [18]annulene **2a** and [12]annulene **4a** have planar rigid chromophores, and correspondingly, their electronic absorption bands show considerable vibrational fine struc-

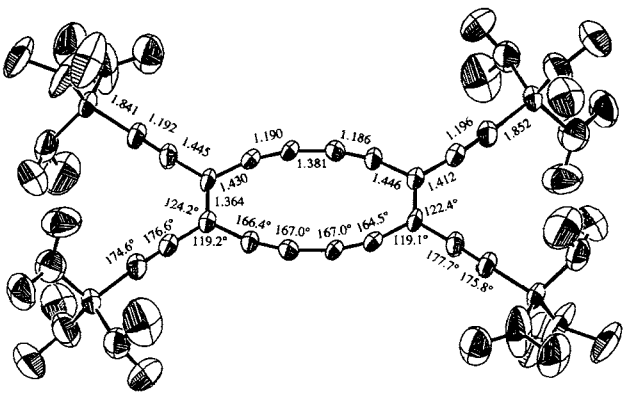

Fig. 3. X-ray crystal structure of **4a**.

ture. The spectra of the two compounds are otherwise strikingly different (Fig. 2). The end absorption in **2a** occurs near 480 nm (2.57 eV), while **4a** shows a characteristic weak absorption band at longer wavelengths which extends to 660 nm (1.87 eV) (Fig. 2). Solutions of **2a** are bright yellow, whereas compound **4a** gives purple solutions that, when dilute, look remarkably similar to solutions of buckminsterfullerene C_{60}.

Although the absence of protons in proximity to the [12]annulene perimeter of **4a** prevents a direct experimental determination of its paratropic character by ^{1}H NMR spectroscopy, a comparison of optical properties suggests that **4a** is antiaromatic. The strong redshift of the end absorption in the UV/VIS spectrum of **4a** as compared to **2a**, can be explained by the smaller HOMO–LUMO gap in an antiaromatic system. The spectrum of **4a** is indeed extremely similar in shape and structure to the spectrum of [12]annulene **16** which has an end absorption at approximately 620 nm (1.99 eV) and is paratropic according to its ^{1}H NMR spectrum.[16, 17] In contrast, [12]annulene **18** does not exhibit a paramagnetic ring current as a result of the benzannelation and shows optical properties that differ entirely from those of **4a** and **16**.[15a] Compound **18** is pale yellow and its end absorption in the UV/VIS spectrum already occurs at 450 nm (2.74 eV).[18] Together with the results of previous comparative studies on [18]- and [24]annulenes[4, 14, 19] these findings suggest that in series of planar, structurally related annulenes, careful correlations of electronic absorption spectra can be used to evaluate their aromatic or antiaromatic character.

18

The deprotection of **2a** to give compound **2c** and the preparation of planar all-carbon networks by oxidative polymerization are now under investigation.

Experimental Procedure

12: To a solution of 7.35 g (15.0 mmol) of **11** in CH_2Cl_2 (150 mL) at $-78\,^\circ$C was added slowly 45 mL of a 1.0 M solution of DIBAH in hexanes (45 mmol). After 15 min, the solution was warmed rapidly to $0\,^\circ$C and stirred at that temperature for 15 min. The solution was quenched by careful addition of water until the entire mixture solidified. The product was dissolved in 50 mL of CH_2Cl_2, and the resulting solution was dried over $MgSO_4$. The grainy solid was removed by filtration, and the product-containing solution was concentrated to yield crude (96% pure) **12** (7.0 g, 94% yield) as a pale yellow oil which was used in the next reaction without further purification. Analytically pure **12** was obtained as a colorless oil by flash chromatography (SiO_2, CH_2Cl_2): IR (neat): $\tilde{\nu}$[cm^{-1}] = 3440 (O–H), 2146, 2127 (C≡C); ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.07 (s, 42H), 3.38 (s, 3H), 4.24 (s, 2H), 4.66 (s, 2H); ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 11.40, 18.86, 55.70, 62.04, 66.15, 95.86, 99.48, 101.02, 105.63, 106.55, 126.80, 132.49. MS (EI, 20 eV) *m/z* 492.3 (M^+).

2a/4a: To a solution of **1f** (0.89 g, 0.002 mol) in 500 mL of acetone was added 1 mL of Hay catalyst (prepared by stirring CuCl (2.5 g) and TMEDA (1.25 mL) in acetone (45 mL) for 30 min). After 1 h, the black solution was poured into pentane and extracted first with 0.1 N HCl, then with water and saturated NaCl solution. The solution was filtered with pentane through a short silica gel plug. The rapid elution of the deep purple fraction of **4a** (0.24 g, 28%) was followed by elution of the bright yellow fraction of **2a** (0.104 g, 12%). Compound **4a**: dark red needles (pentane), m.p. ≈ 200 °C (decomp); IR (KBr) $\tilde{\nu}$[cm^{-1}] = 2107 (C≡C); ^{1}H NMR (360 MHz, $CDCl_3$) δ = 1.00 (s, 84H); ^{13}C NMR (90.6 MHz, $CDCl_3$): δ = 11.06, 18.51, 87.80, 94.05, 99.67, 106.79, 124.37; MS (Desorption Electron Impact (DEI)), 20 eV) *m/z* 868 (M^+): UV/VIS (pentane) λ_{max} (ε) = 614 (270), 598 (sh) (190), 564 (300), 546 (370), 531 (sh) (290), 506 (290), 491 (254), 477 (225), 461 (195), 407 (1540), 402 (sh) (565), 385 (1690), 374 (sh) (3110), 349 (32650), 335 (44700), 326 (36900), 276 (13200), 262 (7210), 233 (sh) (19600), 220 nm (sh) (35200). Compound **2a**: m.p. 215 °C (decomp). IR (neat): $\tilde{\nu}$[cm^{-1}] = 2122 (C≡C); ^{1}H NMR (360 MHz, $CDCl_3$) δ = 1.17 (s, 126H); ^{13}C NMR (90.6 MHz, $CDCl_3$); δ = 11.31, 18.69, 83.81, 85.09, 102.25, 107.38, 118.00. MS (DEI, 20 eV) *m/z* = 1303.7 (M^+). UV/VIS (pentane) λ_{max} (ε) = 453 (56000), 438 (53700), 425 (sh) (22500), 405 (189700), 383 (84300), 375 (59400), 367 (35400), 356 (sh) (24100), 323 nm (17600).

[12] The TMS-protected *cis*-enediyne **1g** was also obtained as a colorless oil following the synthetic route shown in Scheme 2. The TMS-protected [12]annulene **4b** (ready decomposition) and [18]annulene **2b** (m.p. 170 °C, decomp) have also been prepared and their spectral properties closely resemble those of the two TIPS derivatives **4a** and **2a**, respectively; J. Anthony, F. Diederich, unpublished results.

[13] The yield of the oxidative cyclization reaction is strongly dependent on concentration as was shown in more systematic studies with the TMS-protected *cis*-enediyne **1g**: Whereas a 0.006 M solution of **1g** in acetone gave a product ratio of 12:5:1 (**4b**:**2b**: larger macrocycles), a 0.045 M solution led to a higher yield of the larger cycles [product ratio: 1:4:2 (**4b**:**2b**: larger macrocycles)]. Generally, the overall yield of isolable cyclic products increased with increasing concentration of **1g**. In the coupling of the TIPS derivative **1f**, higher cyclic oligomers beyond **2a** are not formed presumably for reasons of steric crowding of the TIPS groups in the larger macrocycles.

$[Mo_2(CCH)_4(PMe_3)_4]$, the Parent Dimetallapolyyne**

By *Timothy C. Stoner, Steven J. Geib,* and *Michael D. Hopkins**

We are presently exploring the syntheses, structures, bonding, and properties of transition metal complexes and transition metal-containing polymers with conjugated electron systems.[1–3] As part of this work, we recently reported the preparation of alkynyl-substituted complexes with quadruple bonds of the types $[M_2(CCR)_4(PMe_3)_4]$ (M = Mo, W; R = alkyl, C_6H_5, $SiMe_3$)[1] and $[1,1\text{-}W_2(CCMe)_2Cl_2(PMe_3)_4]$,[2] and we noted that the electronic absorption spectra of these dimetallapolyynes manifest δ(MM)–π(CC) conjugation. Unfortunately, we were neither able to characterize the $[M_2(CCR)_4(PMe_3)_4]$ class by X-ray crystallography,[4] nor to prepare the parent $[M_2(CCH)_4(PMe_3)_4]$ derivatives by the otherwise general synthetic route to these compounds. The study of the parent ethynyl compounds, which possess the electronically simplest alkynyl R group with the highest symmetry, is crucial to understanding the dimetallapolyyne class as a whole, since their bonding and properties provide benchmarks against which the symmetry and inductive effects of organic and inorganic R groups can be evaluated. We now wish to report the synthesis and crystal structure of the dimetallapolyyne **1**, as well as spectroscopic evidence that **1**

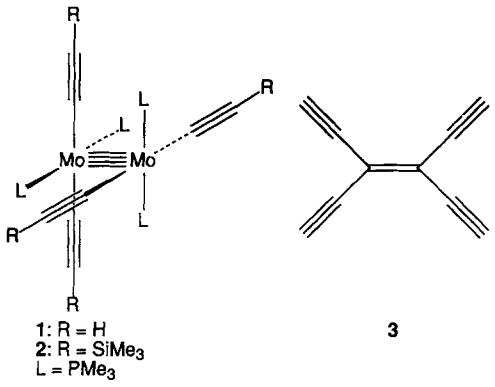
$[Mo_2(CCH)_4(PMe_3)_4]$ **1**

is, in fact, electronically distinct from other $[Mo_2(CCR)_4(PMe_3)_4]$ complexes.

We have successfully prepared a variety of $[M_2(CCR)_4(PMe_3)_4]$ complexes from the reaction between $[M_2Cl_4(PMe_3)_4]$ and LiCCR (4 equiv).[1, 2] In contrast, no tractable products were obtained under comparable conditions from the reactions between $[Mo_2Cl_4(PMe_3)_4]$ and either $LiCCH \cdot (H_2NCH_2CH_2NH_2)$ or MgCl(CCH). Given that protodesilylation of alkynylsilanes is a standard synthetic route to terminal alkynes,[5] it seemed plausible to us that **1** might be similarly generated from **2**.[1] Although the use of

$[Mo_2(CCSiMe_3)_4(PMe_3)_4]$ **2**

this method to generate transition metal ethynyl complexes has not, to our knowledge, been reported,[6] and there is scant precedent in the chemistry of complexes with quadruple bonds for ligandlocalized reactivity,[7] the reaction of **2** with $[nBu_4N][HF_2]$[8] in dimethoxyethane at room temperature affords **1** cleanly in high yield. The use of $[nBu_4]F \cdot 3H_2O$ as the protodesilylation reagent slows down the reaction, and lowers the yield of **1**. Compound **1** was identified by elemental analyses, ^{1}H, ^{13}C, and ^{31}P NMR spectroscopy, and X-ray crystallography.



Crystals of **1** are free of disorder, unlike those of all other $[M_2(CCR)_4(PMe_3)_4]$ compounds that we have examined,[4] allowing the first high-quality single-crystal X-ray diffraction study for this class of compounds.[9] The structure of **1** (Fig. 1) is typical of those of the $[M_2X_4(PMe_3)_4]$ class:[7, 10] it possesses idealized D_{2d} symmetry, and the bond lengths and angles of the $Mo_2C_4P_4$ core lie within the expected ranges. The C≡C (1.18 Å) and C–H (0.93 Å) bond lengths of **1** are similar to those of $[Fe(\eta^5\text{-}C_5Me_5)(CO)_2(CCH)]$ (1.17

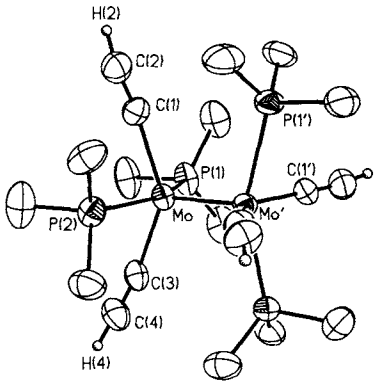


Fig. 1. Molecular structure of **1** (ORTEP, thermal ellipsoids at the 50% probability level). For clarity, all hydrogen atoms are omitted except H(2) and H(4), which are represented by spheres of arbitrary size. Selected bond lengths [Å] and bond angles [°] (standard deviations in parentheses): Mo-Mo' 2.134(1), Mo-P(1) 2.509(1), Mo-P(2) 2.515(1), Mo-C(1) 2.153(4), Mo-C(3) 2.161(4), C(1)-C(2) 1.183(6), C(3)-C(4) 1.174(6), C(2)-H(2) 0.950(39), C(4)-H(4) 0.909(35); Mo'-Mo-P(1) 103.2(1), Mo'-Mo-P(2) 103.1(1), Mo'-Mo-C(1) 110.5(1), Mo'-Mo-C(3) 110.1(1), Mo-C(1)-C(2) 171.7(3), Mo-C(3)-C(4) 171.9(4), C(1)-C(2)-H(2) 172.1(24), C(3)-C(4)-H(4) 166.7(24), Mo-Mo' torsion angle = 1.1.

[**] This research was supported by the National Science Foundation, the Camille and Henry Dreyfus Foundation, and the David and Lucile Packard Foundation (M. D. H.), and by an Andrew W. Mellon Graduate Fellowship (T. C. S.).

and 0.87 Å, respectively),[11] the only other related metal complex for which both lengths are known, and to those of acetylene.[12] The Mo–C≡C (ca. 172°) and C≡C–X (172, 167°) units in **1** are slightly bent, which may reflect the fact that relatively little energy is necessary to bend a C≡C–H unit.[13] The difference of 5° between the two crystallographically independent C≡C–H bond angles is not statistically significant, although the ethynyl groups do lie in very different environments in these chiral crystals: C(1)≡C(2)–H(2) is pointed at the ethynyl β-carbon atom of an adjacent molecule, forming a T-shaped structure, while the ethynyl ligand of a third molecule is directed similarly at C(4) of C(3)≡C(4)–H(4). This interesting arrangement is reminiscent of one found in crystalline[12] and surface-bound[14] acetylene, as is the CCH ··· C distance (2.99 Å for **1**, 3.05 Å for C_2H_2).[12]

We have proposed previously that the structural parameter most sensitive to π(CC)–δ(MM)–π(CC) conjugation in dimetallapolyynes is the M–C bond length.[2] The difference between the Mo–C bond lengths of **1** and $[Mo_2Me_4(PMe_3)_4]$[10] is 0.09 Å, which can be attributed solely to the difference (0.08 Å) between the single-bond covalent radii of sp- and sp^3-hybridized carbon atoms. Thus, the structure of **1** does not manifest a π(Mo–C) bonding interaction. In contrast, the more sensitive ^{1}H NMR and electronic spectroscopic probes of such interactions strongly support the formulation of **1** as a system with π(CC)–δ(MM)–π(CC) conjugation. Specifically, the signal of the proton of the C≡C–H unit in **1** appears as a complex multiplet in the ^{1}H NMR spectrum and as a singlet in the $^1H\{^{31}P\}$ spectrum, indicative of long-range spin-spin coupling between these nuclei and phosphorus; this coupling is facilitated by π(CC)–δ(MM) electron delocalization.[2] Moreover, the $^1(\delta \rightarrow \delta^*)$ absorption band in the electronic spectrum of **1** ($\tilde{\nu}_{max} = 15150\ cm^{-1}$, $\varepsilon = 4550$) is red shifted by about 1800 cm^{-1} from that of $[Mo_2Me_4(PMe_3)_4]$,[1] and is nearly 2.5 times as intense, consistent with π–δ–π conjugation.

Although the properties of **1** are largely similar to those of other $[Mo_2(CCR)_4(PMe_3)_4]$ compounds, there also appear to be electronic differences between the parent compound and the substituted derivatives, as evidenced by the distinctive vibronic structure that the $^1(\delta \rightarrow \delta^*)$ band of **1** displays at low temperature. Whereas all other $[Mo_2(CCR)_4(PMe_3)_4]$ derivatives that we have examined display a prominent 360-cm^{-1} progression as the major vibronic feature, **1** displays a 400-cm^{-1} progression (Fig. 2). We have suggested that the 360-cm^{-1} progression corresponds to the excited-state ν(Mo–C) mode, based on the ground-state vibrational frequencies for **2** (ν(Mo–Mo) = 362, ν(Mo–C) = 397 cm^{-1}).[1] While we have not been able to obtain Raman data for **1** due to its photochemical instability (see below), this conclusion applies to **1** better still, given the closer match in frequency between its vibronic progression and ν(Mo–C), and we thus conclude that the 360-cm^{-1} progression observed for other dimetallapolyynes is a combination of the vibrations of both ν(Mo–Mo) and ν(Mo–C), and that the 400-cm^{-1} progression for **1** is almost exclusively based on ν(Mo–C). Since the $\delta(M_2)$ and $\delta^*(M_2)$ orbitals are nonbonding with respect to the σ(CCR) orbitals, the different relative vibronic activities of the ν(Mo–C) and ν(Mo–Mo) modes for **1** as compared to other $[Mo_2(CCR)_4(PMe_3)_4]$ compounds would appear to reflect fundamental differences in ground- and/or $^1(\delta\delta^*)$ excited-state M–C π bonding among these complexes. That **1** is electronically distinct from other dimetallapolyynes is also borne out by its reactivity in the excited state; while solutions of **2** are indefinitely stable towards irradiation into the $^1(\delta \rightarrow \delta^*)$ band, **1** decomposes rapidly under comparable conditions. The question of whether these differences between **1** and substituted $[Mo_2(CCR)_4(PMe_3)_4]$ derivatives arise from σ or π effects of the R group is under investigation.

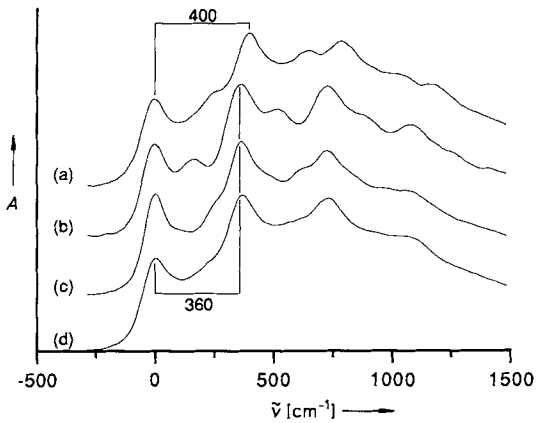

Fig. 2. Electronic absorption spectra (in the region of the $^1(\delta \rightarrow \delta^*)$ band) of compounds of the type $[Mo_2(CCR)_4(PMe_3)_4]$ at 77 K in 2-methylpentane, normalized to the energies of their 0–0 vibronic transitions: a) R = H, b) R = Me, c) R = *t*Bu, d) R = $SiMe_3$. *A* = absorbance. Vibronic spacings are in cm^{-1}.

In closing, it is interesting to compare the structure, spectra, and bonding of **1** with those of the recently reported tetraethynylethene (**3**),[15] its closest organic analogue and archetype of the tetraalkynylethene class of compounds.[16] Aside from the lack of planarity among the ethynyl groups of **1**, these cross-conjugated tetraethynyl compounds differ largely in the elemental and frontier-orbital composition of their dinuclear cores; the δ(Mo≡Mo) fragment of **1**[17] is replaced by a π(C=C) subunit in **3**. Spectroscopic similarities between **1** and **3** include the fact that they exhibit identical ^{1}H NMR chemical shifts for the proton of the C≡C–*H* unit ($\delta = 4.38$), well downfield from that of acetylene ($\delta = 1.80$), and that the energies of the lowest lying electronic transitions of the $[Mo_2(CCR)_4(PMe_3)_4]$ and $C_2(CCR)_4$ classes both stand in the order H > $SiMe_3$ > Ph.[1, 15, 16c] In addition, the molecular structures of these classes both display distinct bond-order alternation along their conjugated backbones. These similarities support our earlier suggestions[1–3] that the electronic structures of conjugated organic and transition metal compounds parallel each other, and they encourage us to believe that other physical properties common to dimetallapolyynes and tetraalkynylethenes will track each other as well. Work is in progress to explore these analogies further.

Experimental Procedure

1: A dimethoxyethane solution of $[nBu_4N][HF_2]$ [8] (excess) was added to a solution of **2** [1] (5.08 g, 5.73 mmol) in the same solvent at 25 °C. The color of the resulting solution changed little over the course of the reaction; monitoring by UV/VIS spectroscopy revealed that the reaction was complete within about 30 min. The volatile components of the reaction mixture were removed under vacuum, yielding a viscous liquid; this was extracted with pentane, which was then decanted from the reaction mixture, filtered, and evaporated under vacuum. Recrystallization of the resulting blue powder by slow addition of acetonitrile to an ether solution at room temperature gave 3.19 g (93%) of **1** as blue needles. Crystals suitable for single-crystal X-ray diffraction were obtained by slow cooling of a hexamethyldisiloxane solution of **1** to −35 °C. ^{1}H NMR (500 MHz, C_6D_6, 25 °C): $\delta = 4.38$ (m, C*CH*), 1.72 (virtual t, ^2J(H,P) + ^4J(H,P) = 7.65 Hz, PMe_3); $^1H\{^{31}P\}$ NMR (500 MHz): $\delta = 4.38$ (s, 4H, CCH), 1.72 (s, 36H, PMe_3); ^{13}C NMR (75.4 MHz): $\delta = 133.8$ (d, ^1J(C,H) = 219 Hz, *C*CH), 133.4 (br, *C*CH), 15.3 (q, ^1J(C,H) = 129 Hz, PMe_3); $^{31}P\{^1H\}$ NMR

(202 MHz): $\delta = -4.39$ (s). UV/VIS (*n*-hexane): λ_{max} [nm] (ε) = 660 (4550), 520 (290), 362 (5140). Correct C, H analysis.

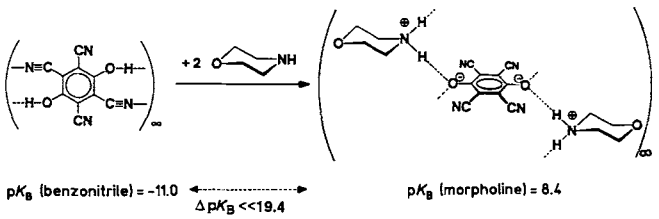
Tetracyanohydroquinone and its Dimorpholinium Salt: Hydrogen Bonds O–H···N or $O^{\ominus}\cdots H\text{–}^{\oplus}N$ to Nitrogen Bases of Different Strengths**

By *Hans Bock,* Wolfgang Seitz, Zdenek Havlas,* and *Jan W. Bats*

Dedicated to Professor Meir Lahav

Multiple hydrogen bonding in[1] and between[2–4] molecules exert a structure-determining influence especially if their usually small individual energy contributions are increased by cooperative effects. Furthermore, the H-bond dynamics $(A\text{–}^{\oplus}H\cdots B)\leftrightarrow(A\cdots H^{\oplus}\text{–}B)$ within the time domain of about 10^{-9} s allows, through molecular recognition, the fast and biochemically important[2] optimization of self-organization processes, which is presently topic of extensive studies on selected suitable model compounds.[2, 3] The morphology of molecules and molecular aggregates containing structure-determining hydrogen bonds can also be modified by the relative electron densities at their proton donor and acceptor centers:[1–4] Thus the exchange of chloride anions as *external*, electron-rich H-bond acceptors ($Cl^{\ominus}\cdots H\text{–}^{\oplus}N$) in tetrapyridylpyrazine dihydrochloride by non-protonatable tetraphenylborate anions produces a flattened molecular skeleton with extremely short *intramolecular* $N\cdots H\text{–}^{\oplus}N$ bridges between adjacent pyridine rings[1]. Here we report drastic structural changes (Fig. 1) caused by reorganization of hydrogen bonds on treatment of tetracyanohydroquinone with the considerably stronger nitrogen base, morpholine [Eq. (a)].



(a)

According to the general reaction scheme between Brønsted acids AH and bases B via proton transfer—$AH + B \rightleftharpoons (A\text{–}H\cdots B) \rightleftharpoons (A^{\ominus}\cdots H\text{–}^{\oplus}B)$—the acidic hydroquinone AH_2 crystallizes in a form containing four H bonds to its weakly basic cyanogen substituents, the H acceptors (Fig. 1a, b). After addition of the almost 20 pK_B units stronger (!) base, morpholine,[5] a double proton transfer generates the dimorpholinium salt $(HB^{\oplus})_2A^{2\ominus}$ under formation of its energetically favorable dianion $A^{2\ominus}$. In this process, four O–H···N hydrogen bonds, two on either side of the six-membered rings, are each substituted by $O^{\ominus}\cdots H\text{–}^{\oplus}N$ bonds outside of the planes of the rings (Fig. 1c, d).

A search of the literature for known hydrogen bonds to nitrile acceptors[8] yielded almost a thousand references in which the shortest O(H)···NC distances of 279 pm were found for both cyanoacetic acid[8g] and for hexacyanocobalt(III) dihydrate.[8h] The O(H)···NC distances of only 277 pm in tetracyanohydroquinone (Fig. 1b) are therefore the shortest O–H···NC hydrogen bonds observed so far. Remarkable are also the enlarged angles CCO of 125° and COH of 115°, which result in an approximately linear O(H)···NC arrangement (angle at H of about 162°). The O–H bond lengths have to be corrected (based on neutron diffraction data[1, 2, 4]) to about 100 pm; the H···N distances should therefore amount to about 180 pm (Fig. 1b).

On recrystallization of tetracyanohydroquinone in the presence of the stronger nitrogen base, morpholine,[5] a double proton transfer produces the tetracyanohydroquinone dianion and two morpholinium cations [Eq. (a)], which again form a hydrogen-bonded aggregate. Its low-temperature crystal structure analysis (Fig. 1c, d) proves that polar bonds $O^{\ominus}\cdots H\text{–}^{\oplus}N$ are now present below and above the planes of the six-membered rings. At both participating centers, the hydroquinone dianion oxygen and the

[**] Structures of Charge-Perturbed and Sterically Overcrowded Molecules, Part 19. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the State of Hesse. – Part 18: Z. Havlas, S. Nick, H. Bock, *J. Int. Quantum Chem.* **1992**, *44*, 449.

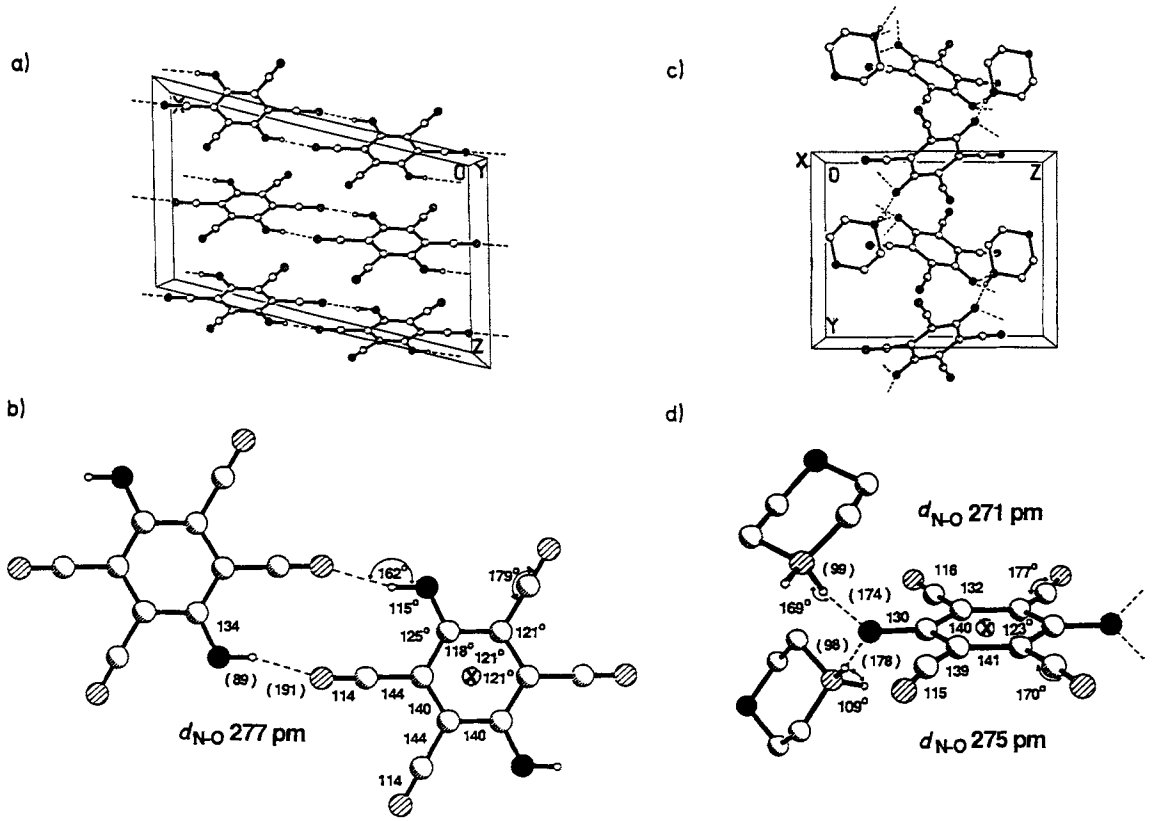

Fig. 1. Single crystal structures of tetracyanohydroquinone [6] and its dimorpholinium salt [7]: a) Unit cell of hydroquinone showing strings in the (110) direction ($Z = 4$; shortest interchain distance 308 pm) and b) section with four O–H ··· NC hydrogen bonds and the essential structural data. c) Packing of the morpholinium salt in the x direction showing unit cell ($Z = 2$) and d) section with four $O^{\ominus} \cdots H\text{–}{}^{\oplus}N$ hydrogen bonds and the essential structural data. (● = O, ▨ = N; ⊗: crystallographic inversion center.)

morpholinium nitrogen, bifurcation[2–5,9] ($H \cdots O^{\ominus} \cdots H$) and ($\cdots H\text{–}{}^{\oplus}N\text{–}H \cdots$) is observed. The $O^{\ominus} \cdots H\text{–}{}^{\oplus}N$ distances of 271 and 275 pm are shorter than in tetracyanohydroquinone (Fig. 1b,d); the same holds for the average $O^{\ominus}$–C ($\Delta d_{OC} = -4$ pm) and (N)C–C distances ($\Delta d_{CC} = -9$ pm). Eye-catching is also the decrease in the benzene *ipso* angle by 114° caused by the $O^{\ominus}$ donor substituent.[10]

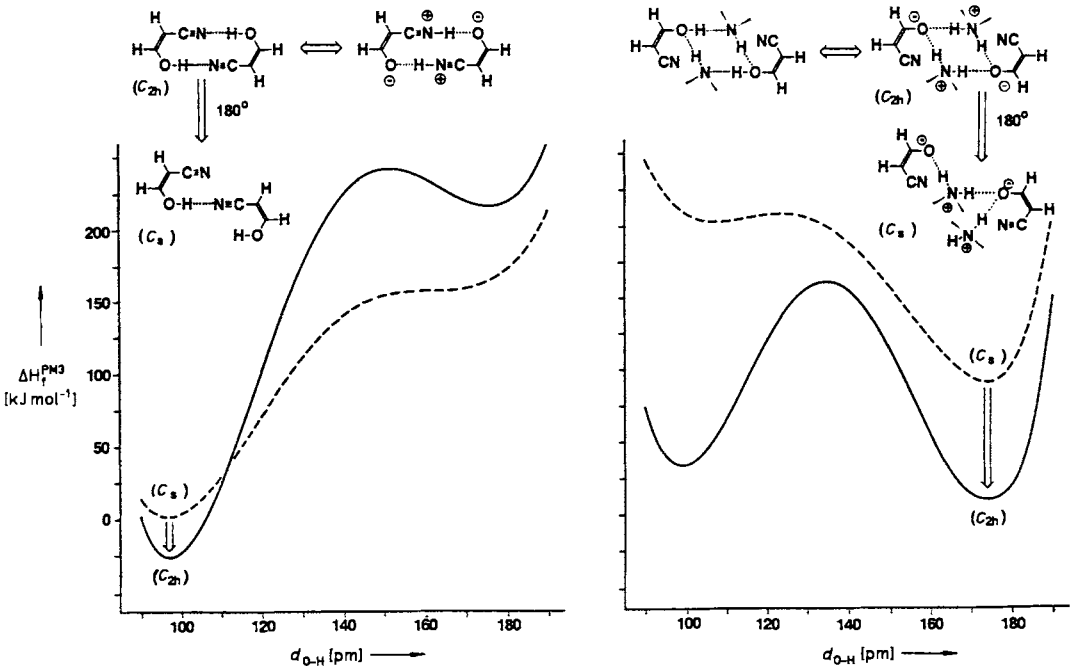
For rationalization of these unexpected structural findings, extensive and mostly geometry-optimized PM3 calculations[11] provide the following clues:

1) Monomeric tetracyanohydroquinone should exhibit a gas-phase structure[11a], which except for the angles COH (calcd 109°) and the O–H bond lengths (calcd 95 pm) satisfactorily agrees with the crystal structure data (Fig. 1) and, therefore, does not change significantly in the H-bonded aggregate. The PM3 enthalpy of formation calculated from the crystal structure data for the dimer and trimer, is lower than that for the monomer by $\Delta\Delta H_f^{PM3} = -27$ and -53 kJ mol^{-1},[11a] and yields for each O–H ··· NC hydrogen bond an average value of -13 kJ mol^{-1}.

2) The question pertinent to self-organization phenomena whether the structurally proven paired formation of $(O\text{–}H \cdots NC)_2$ bridges (Fig. 1a, b) is favored by a cooperative effect[2] can be elaborated upon by calculations of potential surfaces for the considerably smaller model system of two molecules of (*Z*)-2-hydroxyethenecarbonitrile, which reflects all essential structural facets (Scheme 2, left). Its selection is supported by the PM3 geometry-optimized structures[11b]: Of the two dimers, interconvertible by a 180° rotation around one H bond and containing either a single O–H ··· NC hydrogen bond (symmetry C_s, Scheme 1a: ---) or a pair of them (symmetry C_{2h}; Scheme 1, left: ——), the structure calculated for the latter satisfactorily resembles that for tetracyanohydroquinone determined experimentally (Fig. 1, right). Moving each H center along the geometry-optimized O ··· N distance of about 280 pm generates asymmetric double minimum potentials (see [1]). The distinct well on the OH side of each double minimum potential occurs about 100 pm from O, while on the NH side the well is considerably shallower because of the necessary charge separation. For each hydrogen bond within the nonpolar subunits $(O\text{–}H \cdots NC)_{1,2}$, the differences in enthalpy of formation $\Delta\Delta H_f^{PM3}$ are calculated to be 17 kJ mol^{-1} for single hydrogen-bond links ($n = 1$, C_s) and 19 kJ mol^{-1} for the doubly H-bonded dimer ($n = 2$, C_{2h}): the cooperative effect should therefore amount to approximtely 10%.

3) The PM3 enthalpies of formation[11] for the model dimers composed of the subunits ($NCHC{=}CH\text{–}O^{\ominus} \cdots H\text{–}{}^{\oplus}N(CH_3)_2\text{–}H$; Scheme 1, right) exhibit a different dependence on the distance parameter $d_{O \cdots H}$ (Fig. 1c and d) because of the structurally proven charge separation. For a constant O ··· N distance of 280 pm, the polar structures $(O^{\ominus} \cdots H\text{–}{}^{\oplus}NH)_{1,2}$ are clearly more stable, although for $(O\text{–}H \cdots N)_{1,2}$ hydrogen bonds on the other side of the rather high barrier of about 130 kJ mol^{-1} (Scheme 1, right, C_{2h}), a distinct minimum at $d_{O\text{–}H} \approx 100$ pm results. The bond energies calculated for each hydrogen bond amount to 37 kJ mol^{-1} for the dimer with one H bond ($n = 1$, C_s) and 55 kJ mol^{-1} for the dimer with H-bond pairs ($n = 2$, C_{2h}): Accordingly, the cooperative effect of about 32% exceeds the one estimated for nonpolar O–H ··· N bonds (Scheme 1a) considerably.

The comparison of the structural data (Fig. 1) and the additional calculations (Scheme 1) thus confirms



Scheme 1. Results of PM3 potential calculations (ΔH_f^{PM3}) for the model dimers of two molecules (*Z*)-2-hydroxyethenecarbonitrile (left) as well as two molecules each of (*Z*)-2-hydroxyethenecarbonitrile and dimethylamine (right) and their dependence on the distance $d_{O\cdots H}$ (– – –: dimers with a single H-bond of C_s symmetry; ——: dimers with H-bond pairs of C_{2h} symmetry).

unanimously that both the strength of the H bonds and the cooperative effect increase as their polarity ($O-H\cdots N) \Rightarrow (O^{\ominus}\cdots H-^{\oplus}N$) increases. The dependence of the morphology of H-bonded molecular aggregates on the basicity of the proton acceptor center,[1–4] which has far-reaching biochemical consequences,[2] can be tested further for many hydrogen-bonded molecular aggregates by adding suitable stronger bases.[1,2]

"Supersilyl" Compounds $(R_3Si)_3SiSi(SiR_3)_3$ and $(R_3Si)_3SiC_6H_4Si(SiR_3)_3$: Structures and Properties**

By *Hans Bock,** *Jochen Meuret,* and *Klaus Ruppert*

Dedicated to Professor Richard Müller

Tris(trimethylsilyl)silyl ("supersilyl") and tris(trimethylsilyl)methyl groups, according to space-filling structure models, should shield the central molecular skeleton in **1** and **3** completely or almost completely by a "H_3C-skin". In addition, special substituent effects are expected from the subunits $SiSi_3$ containing a local threefold axis, because of the low effective nuclear charge of their four Si centers.

Since their first syntheses[1a,b] supersilyl compounds have revealed many remarkable facts: Thus tris(trimethylsilyl)acyl silane $(R_3Si)_3SiC(=O)R'$ has been rearranged photochemically to $(R_3Si)_2Si{=}CR'OSiR_3$ to yield the first silaethene kinetically stabilized by alkyl shielding. Both thermally stable iminoborane $(R_3Si)_3SiB{\equiv}NCR_3$[1d] or the first formylsilane $(R_3Si)_3SiC(=O)H$[1e] could be isolated (R always refers to CH_3). According to a gas-phase electron diffraction structure determination of the spherical molecule $Si(SiR_3)_4$, the R_3Si groups still can rotate.[1f] The now commercially available $(R_3Si)_3SiH$ is used in organic syntheses as a reducing agent.[1g] Numerous metallorganic derivatives[1h] such as $(R_3Si)_3Si{-}Zn{-}Si(SiR_3)_3$[1i] have been prepared and their structures determined.

In contrast to the structurally related compounds containing $(R_3C)_3Si$ or $(R_3Si)_3C$ groups, which in $(R_3C)_3SiSi(CR_3)_3$, for instance, stretch the Si–Si bond by 35 pm (!)[2a] (Scheme 1) or in the 1,4-benzene derivative $(R_3Si)_3CC_6H_4C(SiR_3)_3$ decrease its first vertical ionization energy to a value of only 7.45 eV[2b] (Scheme 3), corresponding measurements for the analogous supersilyl-substituted compounds are lacking. Therefore, we report and discuss the single crystal structure of $(R_3Si)_3SiSi(SiR_3)_3$[3,4] (Fig. 1), the ionization energies of both title molecules determined by photoelectron spectroscopy (Scheme 3), and the spin distribution, determined by ESR spectroscopy, in the radical anion of the 1,4-disubstituted benzene[5b] (Scheme 4), which has been synthesized for the first time.

In "hexakis(trimethylsilyl)disilane" (Fig. 1), the two half-shells of the space-filling substituents $Si[Si(CH_3)_3]_3$ are con-

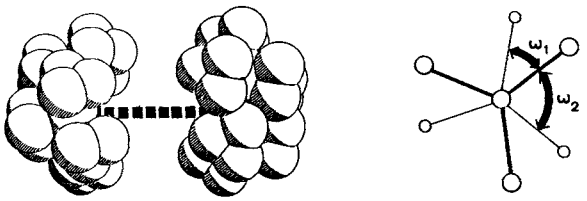
[**] Structures of Charge-Perturbed or Sterically Overcrowded Molecules, Part 22. This work was supported by the Deutsche Forschungsgemeinschaft, the State of Hesse, and the Fonds der Chemischen Industrie. Part 21.: H. Bock, C. Näther, K. Ruppert, B. Havlas, *J. Am. Chem. Soc.* **1992**, *114*, 6907.

nected by a Si–Si bond elongated to 240 pm. Some of the C···C distances between the two molecular halves amount to only 352 pm; that is, they are shortened by 12% relative to the sum of the van der Waals radii of two methyl groups (each 200 pm).[4] The molecular skeleton of $Si_3Si-SiSi_3$ exhibits D_3 symmetry and, unexpectedly, two different dihedral angles of 43 and 77° (Fig. 1 and Scheme 1). For a structural comparison based on a model in which the two substituent half-shells are separated along the central C_3 axis by spacers of different lengths (Scheme 1), the following molecules have been selected: hexakis(*tert*-butyl)disilane, which has a 270 pm (!) long Si–Si bond,[2a] linear (!) hexakis(*tert*-butyl)disiloxane,[5a] di[tris(trimethylsilyl)silyl]zinc[1i] and the acetylene and 1,4-benzene derivatives with tris(trimethylsilyl)methyl substituents on both sides.

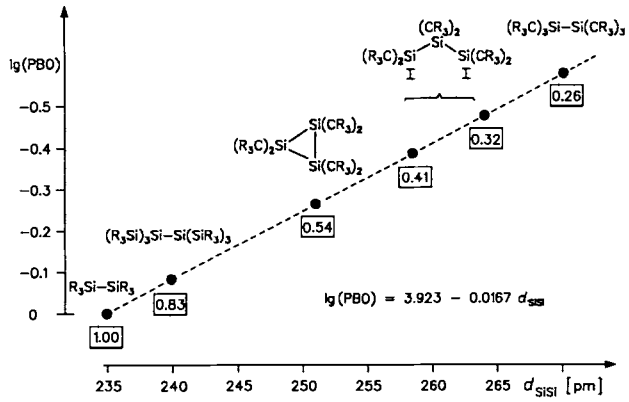


molecular framework	distance	$\omega(X_3Y\cdots YX_3)$
$Si_3Si-SiSi_3$	240 pm	43 + 77°
$C_3Si-SiC_3$	270 pm	45 + 75°
$C_3Si-O-SiC_3$	333 pm	45 + 75°
$Si_3C-C\equiv C-CSi_3$	414 pm	60°
$Si_3Si-Zn-SiSi_3$	468 pm	60°
$Si_3C-C_6H_4-CSi_3$	604 pm	60°

Scheme 1. Half-shell structural model for organosilicon compounds with spacers of different lengths, viewed along the substituent C_3 axis, and dihedral angles $\omega(X_3Y-YX_3)$ of the molecular skeletons.

As may be seen in Scheme 1, the dihedral angles ω_1 and ω_2 between the groups that are staggered when viewed down the spacer linking the half-shells are different if the substitution centers are less than 333 pm apart, but identical if more than 414 pm apart. The twisting $D_{3d} \rightarrow D_3$ of the molecular skeletons from the optimal conformation with $\omega(X_3Y-YX_3) = 60°$ is therefore an appropriate criterion for steric overcrowding, which leads to the extremely short C···C van der Waals distances between the methyl groups (Fig. 1, top), as a result of the additional cogwheel-meshing of these groups in the interior of the molecule.

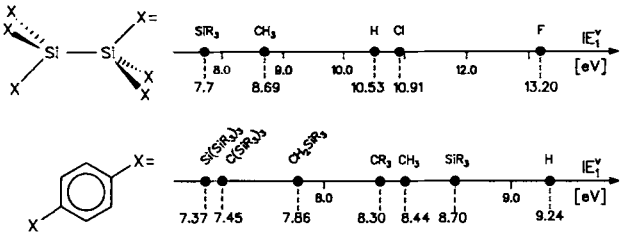
Spatial overcrowding especially due to tris(*tert*-butyl)silyl substituents with C–C distances, which are approximately 40 pm shorter than C–Si distances,[6] stretches the standard Si–Si bond length of 235 pm in hexamethyldisilane to 270 pm[6] and lowers the corresponding Pauling bond order from 1.0 to 0.26[2a, 7] (Scheme 2). It has been proposed,[7] therefore, that the weakened central Si–Si bonds (in some cases the weakening is extreme) are strengthened by additional attractive van der Waals interactions in the enveloping



Scheme 2. Si–Si bond lengths in di- and trisilane derivatives and the respective Pauling bond orders lg (PBO) = $[d(1)-d(X)]/60$ (PBO values are framed).

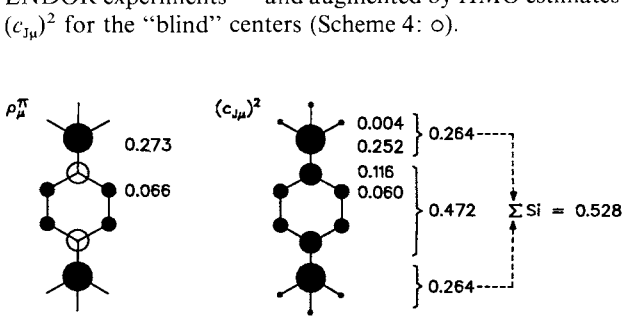
hydrocarbon "skin". This assumption would also be compatible with the structure of hexakis(trimethylsilyl)disilane, in which some of the intramolecular C···C distances only amount to 352 pm (Fig. 1, top).

The discussion on structure raises the question about how supersilyl substituents will modify especially the ground states of molecular ions. A comparison of the first vertical ionization energies of both title molecules[5b] (determined by PE spectroscopy) with those of other disilane or 1,4-benzene derivatives[8, 9] reveals the strongest lowering within each class of compounds for **1** and **2** (Scheme 3): apparently, in the ground states of the resulting radical cations the delocalization of the positive charge into the half-shells $Si(SiR_3)_3$ is energetically favorable. These half-shells are excellent donor substituents on account of the low effective nuclear charge of the Si centers.



Scheme 3. First vertical ionization energies of selected disilane and 1,4-benzene derivatives.

Supersilyl substituents are also well suited to stabilize negative charges considerably: in the radical anion of the 1,4-benzene derivative, more than half of the π-spin population ρ_μ^π is located in the $[(H_3C)_3Si]_3Si$ groups, according to ESR/ENDOR experiments[5b] and augmented by HMO estimates $(c_{J\mu})^2$ for the "blind" centers (Scheme 4: o).



Scheme 4. ESR/ENDOR π-spin populations ρ_μ^π in the radical anion of 1,4-di-[tris(trimethylsilyl)silyl]benzene and corresponding squared HMO coefficients $(c_{J\mu})^2$.

The steric and electronic effects of supersilyl substituents that are demonstrated here for the selected title molecules, stabilize radical cations as donors and radical anions as acceptors and are worth further investigation in other appropriately chosen organosilicon compounds.

Experimental Procedure

2: To a suspension of 0.25 g (10.2 mmoles) Mg turnings in 3 mL dry THF were added under Ar 0.5 mL of a solution of 1.2 g (5.1 mmoles) *p*-dibrombenzene in 4 mL dry THF until the exothermic reaction started. Subsequent addition of 3.07 g (10.8 mmoles) of tris(trimethylsilyl)chlorosilane and the remaining *p*-dibrombenzene yielded an opalescent solution, which was stirred 24 h at RT and then boiled for 50 h under reflux. The solution first turned green then red, and a white precipitate ($MgCl_2$) formed. After hydrolysis with 30 mL H_2O, triple extraction with 30 mL portions of diethyl ether, and drying with Na_2SO_4, filtration and removal of the solvent yielded an oily residue, which crystallized after addition of acetone. Chromatographic purification of a 4:1 solution of hexane and methyl acetate over silica gel (60 Å) enabled the isolation of white crystals (0.15 g, 5%), m.p. = 272 °C. ^{1}H NMR ($CDCl_3$/TMS): $\delta = 0.12$ (s, 54H), 7.21 (s, 4H); MS: *m/z* 571 ($M^{\oplus}$), 556 ($M^{\oplus} - CH_3$), 498 ($M^{\oplus} - Si(CH_3)_3$).

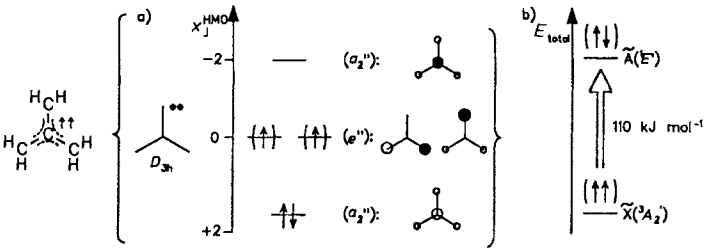
The Triplet Biradical Tris(3,5-di-*tert*-butyl-4-oxophenylene)methane: Crystal Structure, and Spin and Charge Distribution

By *Hans Bock,* Andreas John, Zdenek Havlas,* and *Jan W. Bats*

Dedicated to Professor Rudolf Zahradnik

Trimethylenemethane can be generated in a methylenecyclopropane single crystal at 77 K by γ irradiation and according to the ESR spectrum is a triplet biradical with axial symmetry.[1a] As a simplification, this observation can be rationalized by its alternating π system of D_{3h} symmetry with twofold degenerate e'' molecular orbitals,[1b] which according to the Pauli principle are each occupied by one electron of parallel spin (Scheme 1a). The energy difference between the triplet ground state $\tilde{X}(^3A_2')$ and the first excited singlet state $\tilde{A}(^1E')$ according to ab initio GVB/CI calculations is 110 kJ mol^{-1}[1c] (Scheme 1b).



Scheme 1. a) Topological (HMO) coefficients of π eigenvalues x_j^{HMO} as well the corresponding orbital diagrams of trimethylenemethane. b) Total energy difference (ab initio GVB/CI) between the triplet ground state $\tilde{X}(^3A_2')$ and the first excited singlet state $\tilde{A}(^1E')$.

Many paramagnetic compounds of the same structural type have been characterized by ESR/ENDOR spectroscopy,[2a] inter alia the dark violet title compound **1**, often referred to as Yang's biradical.[2b, c] It can be synthesized in three steps from 2,6-di-*tert*-butyl-4-lithiophenoxy(trimethyl)silane and diethyl carbonate[2d, 5a] [Eq. (a)].

[**] Structures of Charge-Perturbed and Sterically Overcrowded Molecules, Part 25. The research project is supported by the Deutsche Forschungsgemeinschaft, the State of Hesse, and the Fonds der Chemischen Industrie. Part 24. H. Bock, J. Meuret, K. Ruppert, *J. Organomet. Chem.*, in press.

triplet biradicals, which are of actual interest because of their potential ferromagnetism.[3] We report here the first[4] single crystal structure analysis of such a compound[5b] (Fig. 1) and the calculations based on it of its spin and charge distributions[7] (Scheme 2).

According to the structure determination (Fig. 1) and in contrast to the misleading valence line formula in Eq. (a), the triplet biradical exhibits approximately D_3 symmetry: steric interactions of the *ortho* hydrogen substituents (shortest distance H···H 235 pm) twist the six-membered rings in the same direction out of the central trimethylenemethane C_4 plane by 31, 31, and 34°. Within this plane the angles around

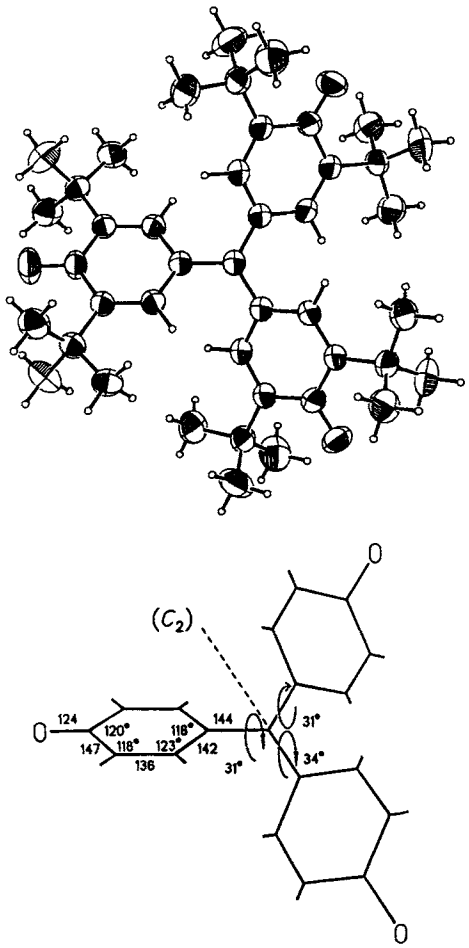

Fig. 1. Single crystal structure of tris(3,5-di-*tert*-butyl-4-oxopheylene)methane. Top: view in the *x* direction (50% thermal ellipsoids); bottom: molecular skeleton (without *tert*-butyl substituents) showing the twofold axis (C_2) and essential average bond lengths and angles (standard deviations: ±1 pm, ±0.5°).

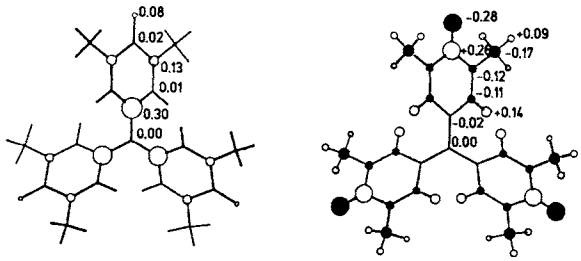
its C center are 120° and the C–C lengths 144 pm each. The six-membered rings are considerably quinoidally perturbed as inferred from the alternating CC bond lengths of 142, 136, and 147 pm, as well as from the inner angles of 118, 123, 118, and 120°. The average CO distances of 124 pm exceed those of electron-rich quinones[6] and approach those observed for the dimer of fluorenone radical anion (128 pm[6]), thereby indicating a substantial negative charge at the oxygen centers. The structure of the biradical **1** in its triplet ground state (Fig. 1), which except for the smaller phenyl twisting angles of only 12° resembles that of the diphenylene monoradical galvinoxyl $[HC(C_6H_2(CR_3)_2O)_2]^{\bullet}$,[8] illustrates the shielding and, therefore, kinetic stabilizing effect of the wrapping of the six *tert*-butyl substituents (Fig. 1).

In the crystal lattice the individual triplet biradicals occur as isolated species[5b] because of the inclusion of the solvent *n*-hexane into the interstices on crystallization.[5a] Therefore AM1/CI calculations[7] starting from the structural parameters (Fig. 1) could be performed, in part with additional geometry optimization. The (6 × 6)CI wave function composed of 225 configurations reproduces the propeller-like structure of **1** even in details such as the differing bond lengths or the inner angles of the six-membered rings.[7] The first excited singlet state $\tilde{A}(^1B)$, which exhibits only C_{2v} symmetry on account of the perpendicular conformation of one ring, should be 36 kJ mol^{-1} = 0.37 eV above the triplet ground state $\tilde{X}(^3B)$ of the C_3 symmetric triplet biradical according to the AM1/CI enthalpies of formation. This result is supported by the ESR/ENDOR measurements[2a–c] and suggests that it would be interesting to calculate in addition both the spin population and the charge distribution, which by definition,[9] represent different properties of the overall electron cloud and, therefore, are neither identical nor directly proportional to one another.[10]

The differences in the approximate spin densities and charge distributions calculated for the neutral biradical (Scheme 2) are amazing: Almost half the spin of the two unpaired electrons is expected at the outer centers of the trimethylenemethane group (see Scheme 1), whereas their charge orders are rather negligible. The connecting carbon center is no longer situated in a (zero) spin nodal plane because of the symmetry lowering $D_{3h} \rightarrow D_3$ (see Scheme 1) and according to the ESR/ENDOR data,[2a–c] exhibits a ^{13}C coupling of 0.86 mT. On insertion of the AM1/CI spin densities calculated for the adjacent centers and normalized with respect to the number of unpaired electrons[7] (Scheme 2 left: $\rho_{c'} = 0.30$) into the Karplus/Fraenkel equation,[2a] the values calculated ($a_{^{13}C} = |Q|\rho_c + \sum|Q_{cc'}|\rho_{c'} = [0 + 3 \times (-0.14) \times 0.3]/2 = -0.63$ mT) are in satisfactory agreement with the spectroscopic data.



Scheme 2. Spin densities $\rho_{\mu,\pi}^{AM1/CI}$ (left) and charge orders $q_{\mu}^{AM1/CI}$ (right) of **1**.

The charge orders (Scheme 2 right) confirm carbonyl groups polarized according to the effective nuclear charges that is, containing partial negative charge on the oxygen and partial positive charge on the carbon centers, as well as negatively charged *ortho* and *meta* ring centers, which partly reflect the electron-donor effects of the *tert*-butyl substituents.

Structural analyses of biradicals, often unjustifyingly classified as "exotic", thus provide interesting information on the paramagnetic individual molecule, especially if the lattice packing does not enforce intermolecular contacts.[5b] They supplement the ESR/ENDOR measurements in solution or in low-temperature glasses and the structural data are preferable as a basis for quantum chemical calculations. For all of these reasons, further crystal structure determination of known biradicals would be desirable, for example for the sterically less shielded 6-chloro-bis(*N*,*N*-diphenylhydrazyl)-

1,3,5-benzene tricarbonitrile, from which dark green single crystals with a metallic luster can be grown.[11]

[4] A CAS-on-line search with the key-words "bi/diradical" and "crystal structure" produced 32 citations, but none for a biradical in its triplet ground state. Examples of more recent crystal structures of diradicals with $S = 0$ (and a potentially temperature-dependent admixture of $S = 1$) are eightfold *tert*-butyl-substituted 2,5-dihydro-2,5-di(4-oxocyclohexadienylidene)-3,6-di(4-hydroxyphenyl)-thieno[3,2-*b*]thiophene (T. Sugimoto, M. Sakaguchi, H. Ando, T. Tanaka, Z. Yoshida, J. Yamauchi, Y. Kai, N. Kanehisa, N. Kasai, *J. Am. Chem. Soc.* **1992**, *114*, 1893), bis(1,3,2,4,6-thiaphosphatriazinyl)-1,4-phenylene (K. Bestari, G. Fergison, J. F. Gallagher, R. T. Oakley, *Inorg. Chem.* **1992**, *31*, 442; cf. also *J. Am. Chem. Soc.* **1992**, *114*, 1729). For Chichibabin and Thiele's biradicals a singlet ground state has also been proven (L. K. Montgomery, J. C. Huffmann, E. A. Jurczak, M. P. Grendze, *J. Am. Chem. Soc.* **1986**, *108*, 6004). For the complex $[Fe^{2\oplus}(mesitylene)_2][C_3(C(CN)_2)_3^{\ominus}]_2$ containing two hexacyanotriradialene anions, a triplet ground state has been detected by solid-state ESR spectra [3b].

[5] a) Preparation of **1** (according to [2d]) proceeded by reaction of the trimethylsilyl-blocked 2,6-di-*tert*-butyl-4-bromophenol with *n*-butyllithium and diethyl carbonate in *n*-hexane with addition of tetramethylethylenediamine TMEDA, followed by hydrolysis with aqueous HCl in methanol, and oxidation of the isolated bis(3,5-di-*tert*-butyl-4-hydroxyphenyl)-3,5-di-*tert*-butyl)-4-oxophenylenemethane with $K_3[Fe(CN)_6]$ in a degassed water/benzene mixture. The organic phase yields a violet powder on removal of benzene. Crystal growth is achieved by slow evaporation of the green *n*-hexane solution and yields dark violet rhombusses after 2 days. At room temperature, the ESR data for the compound dissolved in toluene $g = 2.0046$ and $a_H = 0.087$ mT for the septet of the six *ortho*-ring-hydrogens; the signal intensities provide no evidence for an additional quintet expected when a monoradical impurity is present. b) Crystal structure analysis $(C_{43}H_{60}O_3 \cdot C_6H_{14})$, $M_r = 711.13\ g\,mol^{-1}$, $a = 1150.4(5)$, $b = 1770.0(9)$, $c = 2253.0(2)$ pm, $\beta = 100.62(2)^\circ$, $V = 4509(5) \times 10^6\ pm^3$ (298 K), $Z = 4$, $\rho_{calcd} = 1.047\ g\,cm^{-3}$, $\mu(Cu_{K\alpha}) = 9.4\ cm^{-1}$, monoclinic, space group $C2/c$ (no. 15 Int. Tab.). Enraf-Nonius CAD4 diffractometer, 7055 reflections within $2^\circ < 2\theta < 120^\circ$, of which 3266 are independent with $I > 0$. Structure solution with direct methods (SHELXS), $N = 3266$, $N_P = 243$, $R = 0.059$, $R_w = 0.056$, $w = 1$. The crystal proved to be partially twinned; only reflections of the main domain, which amounts to 88% of the crystal volume, have been recorded. C,O positions anisotropically refined, H positions of the biradical are detected by difference Fourier analysis and are kept on calculated positions; residual electron density $< 0.26\ e_0 Å^{-3}$. The crystal packing does not show any short intermolecular contact distances; in the biradical crystal interstices *n*-hexane molecules are found disordered along a twofold axis. Further details of the crystal structure analysis can be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2, on quoting the deposition number CSD-56 969, the authors, and the full journal citation.

[7] a) The calculations have been performed with the program SCAMP 4.1 (T. Clark, University Erlangen) on an IBM RISC 6000 workstation. For the triplet biradical a CI wave function (6 × 6, 225 configurations) has been applied. The matrix elements $P_{\mu\mu} = \sum_K a_K^2 P_{\mu\mu}^K$ of the configurations K yield for the individual centers X, according to $P_{XX}^{spin} = \sum_\mu P_{\mu\mu}^{spin}$, the spin populations, and according to $P_{XX} = \sum_\mu^X P_{\mu\mu} - Z_X$, the charge orders. In addition, all structures have been geometry-optimized. b) Triplet ground state (D_3): $\Delta H_f^{AM1/CI} = 42\ kJ\,mol^{-1}$, $d_{C\cdots C} = 143$ pm, $\omega = 29^\circ$, rings: $d_{CC} = 145, 137, 150$ pm, $\sphericalangle CCC = 117, 124, 120, 118^\circ$, eigenvalue $\varepsilon_j(e'') = -5.56$ eV. First excited singlet state (C_2!): $\Delta H_f^{AM1/CI} = 78\ kJ\,mol^{-1}$, $d_{C\cdots C} = 147, 147, 136$ pm, $\omega = 30, 30, 90^\circ$, eigenvalues $\varepsilon_j = -5.40, -5.68$ eV. c) Closed shell singlet state (C_2): $\Delta H_f^{AM1} = 144\ kJ\,mol^{-1}$, $d_{C\cdots C} = 146, 146, 134$ pm, $\omega = 30, 30, 90^\circ$, eigenvalues -2.94 eV (unoccupied), -7.89 eV (doubly occupied).

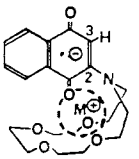
[10] The dependency between spin and charge distribution, which is often complex, can be illustrated by selection the contact ion pairs of the [15]crown-5-2-aminonaphthosemiquinone radical anion (**2**), which also contains a quinoid six-membered ring as in the title compound (Fig. 1). Alkali



2

metal counter cations $M^\oplus$ polarize the crown-side carbonyl group $>C^{\delta\oplus}O^{\delta\ominus}\cdots M^\oplus$ differently on account of their different effective ionic charges. Therefore, at the carbonyl oxygen negative partial charges result, which increase when the cation changes from $Cs^\oplus$ to $Li^\oplus$. The ring proton couplings $a_{H,3}$ determined by ENDOR-spectroscopy confirm that the spin density in the quinone six-membered ring increases with the negative partial charge at the oxygen centre (Scheme 2) and that its spin component therefore decreases (H. Bock, B. Hierholzer, F. Vögtle, G. Hollmann, *Angew. Chem.* **1984**, *96*, 74; *Angew. Chem. Int. Ed. Engl.* **1984**, *23*, 57).

Enantioselective Synthesis of α-Amino Acetals and α-Amino Acids by Nucleophilic 1,2-Addition to Diethoxyacetaldehyde SAMP Hydrazone**

By *Dieter Enders,* Rudolf Funk, Martin Klatt, Gerhard Raabe*, and *Eric R. Hovestreydt*

Dedicated to Professor Joachim Goerdeler on the occasion of his 80th birthday

Protected, enantiomerically pure α-aminoaldehydes are of great interest as chiral synthetic building blocks because they are bifunctional, and this results in a wide range of application.[1] Although the synthesis and applications of N-protected α-aminoaldehydes are well known, the analogous carbonyl-protected compounds have attracted little attention.[2–6] The standard syntheses of carbonyl- and N-protected α-aminoaldehydes generally start from the naturally occurring α-amino acids. Asymmetric synthesis of carbonyl-protected α-aminoaldehydes has only recently become known.[7–9] One of the methods most frequently employed in this respect for the generation of the amino group is the addition of organometallic compounds to the CN double bond[10] of imines,[11] acylimines,[12] nitrones,[13] sulfen-

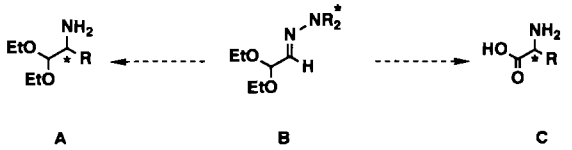
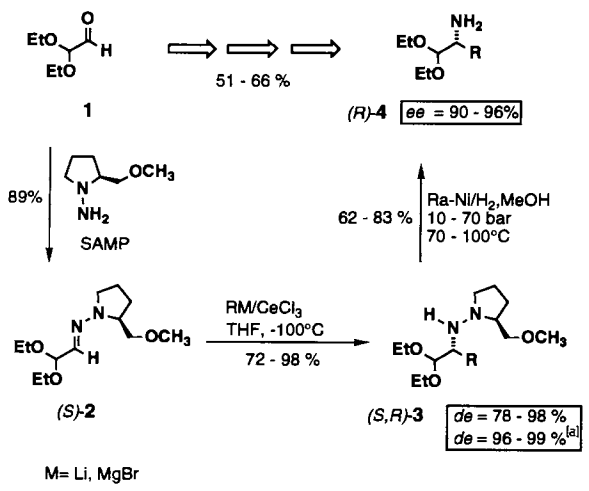
[**] This work was supported by the Fonds der Chemischen Industrie and contains important parts of the dissertation of R.F., Technische Hochschule Aachen, **1990**. We are grateful to Degussa AG, BASF AG, Bayer AG, and Hoechst AG for gifts of chemicals. – SAMP = (*S*)-1-Amino-2-methoxymethylpyrrolidine.

imines,[14] sulfonylimines,[15] sulfoxyimines,[16] oxime ethers,[17] and hydrazones.[8, 9, 18–21] Organolanthanoid compounds are used with increasing frequency for this purpose.[22]

We report here an enantioselective synthesis of α-amino acetals **A** starting from α-SAMP or -RAMP hydrazone acetals **B**. The key step is the diastereoselective nucleophilic 1,2-addition of organocerium and organolithium compounds to the hydrazone double bond. Oxidative transformation of the acetal into an acid group thereby provides a new, highly enantioselective entry to α-amino acids **C**.



The reaction of diethoxyacetaldehyde **1**[23] with SAMP[24] gave the SAMP hydrazone (*S*)-**2** in very good yield. The latter was treated at −100 °C with organocerium or lithium compounds in THF. The organocerium compounds were obtained according to a procedure of Imamoto et al.,[25] in which anhydrous $CeCl_3$ is treated in THF with the appropriate organolithium or Grignard reagent. The 1,2-additions, which occurred in very good yields (72–98%) and with very high diastereomeric excess (78–98%), provided the sensitive hydrazines (*S*,*R*)-**3** after aqueous workup. After chromatographic separation of the minor diastereomers, the almost diastereomerically pure hydrazines (*S*,*R*)-**3** were converted to the α-amino acetals (*R*)-**4** by reductive cleavage with Raney nickel/hydrogen in methanol. The chiral amine (*S*)-**2**-methoxymethylpyrrolidine (SMP, recovery of the auxiliary) was separated by chromatography, and after subsequent distillation (kugelrohr) the pure, colorless α-amino acetals (*R*)-**4** were obtained (Scheme 1, Table 1).



Scheme 1. Enantioselective synthesis of α-amino acetals **4**. $RM/CeCl_3$ was employed in excess (5 equiv). [a] After chromatography.

Table 1. SAMP α-amino acetals **3** (prepared by nucleophilic 1,2-addition to diethoxyacetaldehyde SAMP hydrazone) and their cleavage to **4**.

The absolute configurations are in parentheses. [d] The solvent used was 0.1 N HCl. [e] RAMP was employed as chiral auxiliary. [f] Yields of both diastereomers. [g] Without addition of $CeCl_3$. [h] R = *cyclo*-C_6H_{11}.

contrast to many of the corresponding N-protected compounds, are completely configurationally stable. Even after several weeks at room temperature no loss in optical activity could be observed. The enantiomeric excess for the amino acetals (*R*)-**4** was determined in all cases by comparison with the racemates via the 3,3,3-trifluoro-2-methoxy-2-phenylpropionic acid (MTPA) amides[26] by gas chromatography or NMR spectroscopy. The racemates were synthesized in similar fashion via the corresponding dimethylhydrazones. The absolute configuration of the α-amino acetals (*R*)-**4** could be determined by two independent methods: The optical rotation was compared with that of the known compound (*S*)-**4a**,[3] and an X-ray crystal structure analysis of the (*S*)-MTPA derivative of the compound (*R*)-**4g** gave the (*R*) configuration for the newly generated stereogenic center (Fig. 1).[27, 28] The enantiomers (*S*)-**4** are accessible by simply changing the auxiliary (RAMP instead of SAMP) (see (*S*)-**4a**, Table 1).

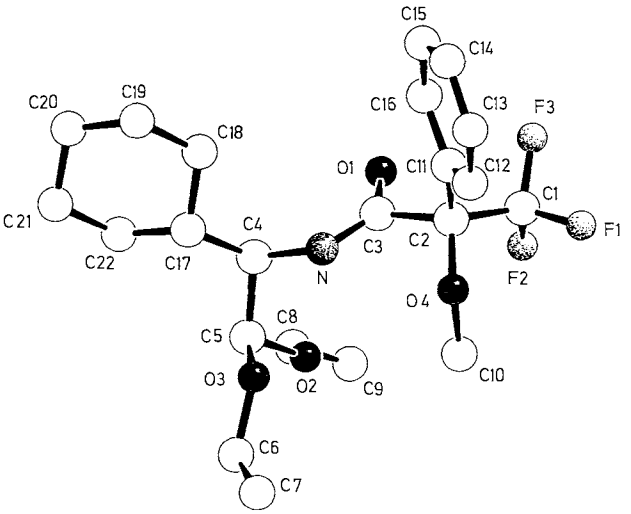

Fig. 1. Crystal structure of the MTPA amide of **4g**[7,28].

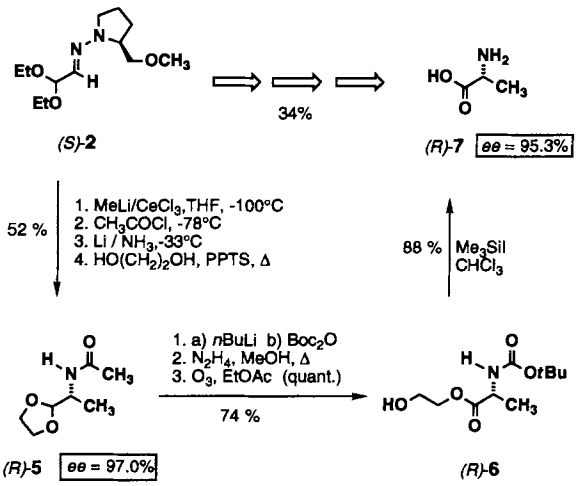
Cleavage of the N–N bond in hydrazines (*S*,*R*)-**3** by hydrogenolysis occurred with little racemization, so that the enantiomeric excess lies slightly below that of the diastereomeric excess. During hydrogenolysis of (*R*)-**3g** the phenyl ring was also hydrogenated. The α-amino acetals, in

As demonstrated in Scheme 2 for the example of the enantioselective synthesis of (*R*)-alanine (*R*)-**7**, diethoxyacetaldehyde SAMP hydrazone (*S*)-**2** can also function as an equivalent for the glycine cation, thereby permitting a new entry to α-amino acids. The key to success lies in the use of ozono-

lysis for the cleavage of the cyclic acetal with the 1,3-dioxolane structure to the hydroxyethylester, according to the method of Deslongchamps et al.[29] After addition of the organocerium compound from MeLi/$CeCl_3$ to (*S*)-**2** and trapping with acetylchloride, the N–N bond was cleaved reductively without racemization by reaction with Li/NH_3.[30] Finally, the *N*-acetyl-protected α-amino acetal was converted into the cyclic acetal (*R*)-**5** (*ee* = 97.0%) with ethylene glycol in a yield of 83%. After introduction of the *tert*-butoxycarbonyl (Boc) protecting group with $(Boc)_2O$ and hydrazinolysis, the carbamate-protected α-amino acetal was obtained. Ozonolysis, requiring only a few minutes at −78°C, gave the α-amino acid ester (*R*)-**6** quantitatively. The protecting group was removed by treatment with three equivalents of trimethylsilyliodide and the ester group hydrolyzed simultaneously. The amino acid, after purification by ion-exchange chromatography (Lewatit SP 112), was obtained in an overall yield of 34% and an enantiomeric excess of 95.3%.[31]



Scheme 2. Enantioselective synthesis of (*R*)-alanine. PPTS = pyridinium *para*-toluenesulfonate. Me_3SiI was used in excess (3 equiv).

The methods described here provide a new, highly enantioselective entry to both enantiomers of α-amino acetals and α-amino acids. Initial results show that the process is also applicable for homologous β-SAMP hydrazone acetals, thereby leading to the corresponding β-amino acetals and β-amino acids.[32]

Experimental Procedure

α-Amino acetals **4**: 5 Equiv $CeCl_3 \cdot 7H_2O$ was dried in a Schlenk flask with stirring for 2 h at 140 °C/0.1 Torr. After cooling, the anhydrous $CeCl_3$ was stirred at room temperature under argon with dry THF (3 mL mmol^{-1} $CeCl_3$) for 2 h and then for 1 h in an ultrasound bath. The colorless suspension was cooled to −78 °C and treated dropwise with 5 equiv RLi or RMgX. Upon addition of RLi a bright yellow suspension was obtained, whereas addition of RMgX caused the color to change to light gray. After the resulting suspension was stirred for 2 h at −78 °C, the reaction mixture was cooled to −100 °C (ethanol/liquid nitrogen). The SAMP hydrazone (*S*)-**2**, dissolved in THF (3 mL mmol^{-1}), was added to the suspension very slowly (10 mL h^{-1}; syringe pump). The reaction mixture was first held at −100 °C for 2 h and then allowed to warm to room temperature over ca. 15 h. The mixture was hydrolyzed with ca. 40 mL saturated $NaHCO_3$ solution, the organic phase separated, and the residue extracted several times with ether. The combined organic phases were concentrated, dissolved in 50 mL ether, washed with water, and finally dried over Na_2SO_4. After concentration, the sensitive hydrazines (*R*)-**3** were purified by flash chromatography (silica gel, ether:petroleum ether 2:1 to 1:3). A solution of the hydrazine in methanol (5–10 mL mmol^{-1}) was treated with freshly prepared Raney nickel[33] (0.5–1.0 g Ni-Al alloy per mmol of hydrazine) and hydrogenated in an autoclave with stirring at 70–100 °C and a hydrogen pressure of 70 bar for 20–60 h (monitored by thin-layer chromatography). After completion of the reaction, the catalyst was removed by filtration through celite, the solvent removed from the filtrate, the residue dissolved in ether, and the resulting ethereal solution dried over Na_2SO_4 and concentrated to dryness. The α-amino acetals were purified by flash chromatography (silica gel, anhydrous methanol) followed by removal of the methanol and distillation (kugelrohr).

α-Amino acids **7**: The product resulting from nucleophilic 1,2-addition to the SAMP hydrazone (*S*)-**2** (see above) was trapped at −78 °C with 5.5 equiv acetyl chloride and then stirred for 1 h at 0 °C. The product was worked up with 40 mL saturated Na_2CO_3 solution and ether. The hydrazines were purified by flash chromatography (silica gel, ether:petroleum ether 2:1). A solution of the *N*-acylated hydrazine in anhydrous THF (1 mL mmol^{-1}) was mixed with ammonia (15 mL mmol^{-1}) at −78 °C, and the mixture treated with clean Li wire (4 mmol mmol^{-1}). The resulting solution rapidly turned blue. The cooling bath was removed, the solution allowed to stir for 1 h at −33 °C, the reaction stopped by addition of NH_4Cl (12 mmol mmol^{-1}), and the ammonia allowed to evaporate. The residue was dissolved in 40 mL water and extracted several times with ether. After the combined organic phases were dried and concentrated, the *N*-acetylated α-amino acetals were obtained. These were dissolved in glycol (3 mL mmol^{-1}), treated with 0.1 g pyridinium *p*-toluenesulfonate (PPTS), and stirred for 3 h at 80 °C. After distillation of the volatile components, the whole was taken up in 40 mL water and extracted with CH_2Cl_2. The combined organic phases were dried over Na_2SO_4 and concentrated, and the α-amino acetals (*R*)-**5** were purified by flash chromatography (silica gel, ethyl acetate). A solution of (*R*)-**5** in anhydrous THF (5 mL mmol^{-1}) was treated with 1.1 equiv *n*BuLi at −78 °C, stirred for 4 h at this temperature, and then trapped with $(Boc)_2O$ (5 mmol mmol^{-1}). The crude solution was concentrated and the residue taken up in methanol (5 mL mmol^{-1}), treated with anhydrous hydrazine (3 mL mmol^{-1}), and stirred for 4 h at reflux. After aqueous workup and extraction with ether the α-amino acetals, protected as carbamates, were obtained. Purification was by flash chromatography (silica gel, ether:petroleum ether 2:1). The acetals were dissolved in ethyl acetate (15 mL mmol^{-1}) and treated with ozone at −78 °C (reaction followed by thin-layer chromatography). The solvent was removed to provide the pure ester (*R*)-**6**, which was allowed to react with 3 equiv Me_3SiI in $CHCl_3$ (5 mL mmol^{-1}) under argon (3–5 min). Workup was with 1 N HCl, and the amino acids were purified by ion-exchange chromatography (Lewatit SP 112, 2 N aqueous NH_3 solution).

Enantioselective Aldol Reactions with a Phosphoenolpyruvate Equivalent: Asymmetric Synthesis of 4-Hydroxy-2-oxocarboxylic Acid Esters**

By *Dieter Enders*,* *Hubert Dyker*, and *Gerhard Raabe*

Dedicated to Professor Rudolf Hoppe on the occasion of his 70th birthday

The aldol reaction is the preferred method for the stereoselective synthesis of 1,3-dioxygenated building blocks.[1] Enantiofacial differentiation in the enolates can be diastereoselectively controlled by covalently bound auxiliaries, which permit formation of one or two stereogenic centers with high selectivity and predictable configuration.

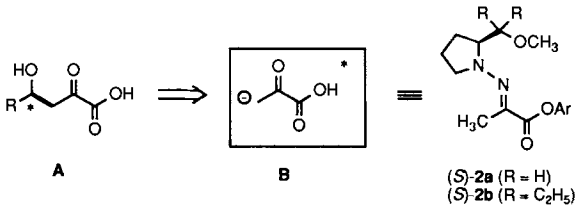
Enzyme-catalyzed aldol reactions are used in nature, for example, in the stereoselective formation of monosaccharides. The transfer of the pyruvate unit as phosphoenolpyruvate (PEP) to aldoses with the generation of 4-hydroxy-2-oxocarboxylic acids **A** in the biosynthesis of ulosonic acids[2] and sialic acids[3] is one of the most important synthetic routes of this type. Aldolases, which catalyze this reaction, have recently been used in the biocatalytic synthesis of natural and unnatural higher monosaccharides from PEP or pyruvate and aldehydes.[4-8]

Several achiral metalated pyruvic derivatives (d^2 synthons **B**) have been used as chemical equivalents for PEP in imitation of the synthetic principle used in nature.[9] Stereoselective reactions of these reagents are nevertheless limited to diastereoselective aldol reactions with enantiomerically pure aldehydes.[9g-9i]



A **B** (*S*)-**2a** (R = H) (*S*)-**2b** (R = C_2H_5)

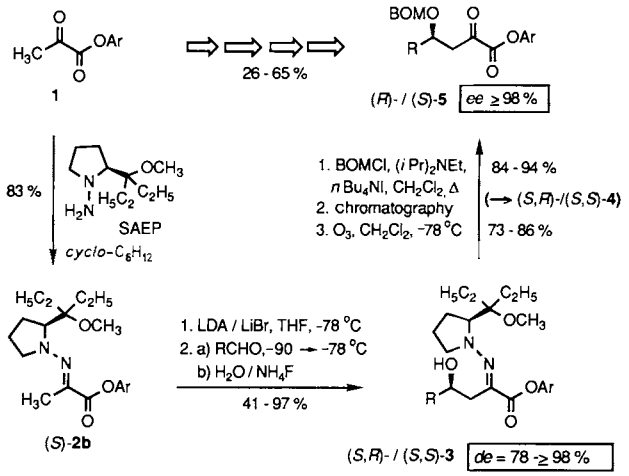
Ar = 2,6-di-*tert*-butyl-4-methoxyphenyl

We recently reported on the development of an enantiomerically pure, homologous PEP equivalent[10] in which our SAMP/RAMP hydrazone method[11,12] was employed and on its use in the enantioselective synthesis of 3-substituted 2-oxacarboxylic acid esters. We now introduce an enantiomerically pure, chemical PEP equivalent, which permits the biomimetic enantioselective synthesis of 4-hydroxy-2-oxocarboxylic acid esters **A**. The key step is the diastereoselective aldol reaction of (*S*)-**2** with achiral and chiral aldehydes.

In initial investigations of the metalation and alkylation conditions, simple alkylation of SAMP hydrazone (*S*)-**2a** was examined. The uniformly (*E*) hydrazone was obtained in 96% yield as light yellow solid (m.p. 84 °C) by reaction of the appropriate pyruvic acid ester **1**[10] with (*S*)-1-amino-2-methoxymethylpyrrolidine (SAMP).[12,13] Employing the 2,6-di-*tert*-butyl-4-methoxyphenyl ester[14] to avoid the self-condensation of the corresponding azaenolate is decisive.[10]

Surprisingly, the alkylation of hydrazone (*S*)-**2a** with benzylbromide by metalation with 1.1 equivalents of lithium diisopropylamide (LDA) was incomplete. The alkylated product was isolated in 71% yield, together with 21% unreacted starting material. The use of 2.2 equivalents of LDA gave both the monoalkylated and the bisalkylated products in variable yield. Complete conversion in the alkylation (98% yield) was achieved only when 1.1 equivalents of base were employed in the presence of 2 equivalents of lithium bromide at $-78\,^{\circ}C$ in THF. Similar effects have been described for related systems.[9j,15] The aldol reaction of the SAMP hydrazone (*S*)-**2a** metalated in this manner with 3-methylbutanal at $-90\,^{\circ}C$ gave the aldol product (*S,R*)-**3a** in similar good yield, albeit with only moderate stereoselectivity (84 °% yield, *de* = 36 °%). The stereoselectivity of the aldol reaction could be increased considerably when SAMP was exchanged for the sterically more demanding auxiliary (*S*)-1-amino-2-(1-ethyl-1-methoxypropyl)pyrrolidine (SAEP)[16] (Scheme 1, Table 1).

The condensation of pyruvic acid ester **1** with the hydrazine SAEP gave the (*E*)-configurated hydrazone (*S*)-**2b**



Scheme 1. Four-step enantioselective synthesis of BOM-protected 4-hydroxy-2-oxocarboxylic acid ester **5** (BOM = $PhCH_2OCH_2$).

in 83% yield as a viscous yellow oil. Metalation of the hydrazone with LDA in the presence of lithium bromide under the conditions given above, and reaction of the resulting reactive azaenolates with aldehydes at temperatures between −90 and −78 °C gave hydrazones (*S*,*R*)-/(*S*,*S*)-**3** in very good yield (86–97%) and with high diastereomeric excess (*de* = 78– ≥ 98%) as highly viscous yellow substances that could be purified by chromatography and characterized. Only the reaction with the isopropylidene-protected (*R*)-glyceraldehyde gave a low yield (41%, *de* ≥ 98%, (*S*,*S*,*R*)-**3h**).

Table 1. Enantiomerically pure BOM-protected 4-hydroxy-2-oxocarboxylic acid esters **5** synthesized by the enantioselective aldol reaction of the SAEP hydrazone (*S*)-**2b** prepared from pyruvic acid ester **1**.

[a] Diasteromeric excess determined by ^{13}C NMR. [b] Yield of the major diastereomer **5** after flash chromatography. [c] $c = 1$, $CHCl_3$. [d] Determined as *de* at the stage of hydrazone **4** by ^{13}C NMR spectroscopy. The absolute configuration is given in parentheses. [e] SAMP was employed as chiral auxiliary. The diastereomers were not separated at the hydrazone stage. [f] M.p. 57–59 °C.

As 4-hydroxy-2-oxocarboxylic acid esters **5**, the final products of the reaction sequence described here, are inclined toward elimination and side reactions during the chromatographic purification,[9k,l] introduction of a protecting group was necessary. Use of *O*-silyl and *O*-acetyl protecting groups was unsuccessful. Isolation of the final products **5** without decomposition was achieved, however, by the introduction of the *O*-benzyloxymethyl (BOM) protecting group. The BOM group was introduced with very good yield (generally over 90%) by reaction of the aldol products **3** with excess benzyloxymethylchloride in the presence of Hünig base. Separation of the diastereomers was possible by simple flash chromatography, so that after chromatographic purification products **4** were obtained diastereomerically pure (*de* ≥ 98%) and in yields of 84–94% as light yellow, highly viscous oils. A further isomer could not be detected by ^{13}C NMR spectroscopy.

The protected aldol products **4** could be converted without racemization and in good yield by oxidative cleavage with ozone to give the enantiomerically pure final products (*R*)- and (*S*)-**5**, which were purified by rapid flash chromatography (73–86% yield).

The diastereomeric excesses of the hydrazones **3** and the BOM-protected aldol products **4** were determined by ^{13}C NMR spectroscopy. The values given for the enantiomeric excesses of the final products **5** refer to the diastereomeric excesses of the BOM-protected aldol products **4** determined by ^{13}C NMR spectroscopy. Isolation of (*S*,*R*)-**5h** in diastereo- and enantiomerically pure form verified that the introduction of the protecting group and cleavage of the hydrazone proceed without racemization.

The absolute configurations given for the hydrazones and, thereby, the final products **5** are based on a crystal structure analysis of a single crystal of hydrazone (*S*,*R*)-**4a** (Fig. 1),[17] the only product obtained as a solid (m.p. 57–59 °C), and the assumption of a uniform reaction mechanism. The (*R*) configuration determined for the newly generated stereogenic center ((*S*) configuration for R = Ar and in case **h**) is in agreement with the stereochemical process previously observed in aldol reactions with SAMP/RAMP hydrazones.[18–20]

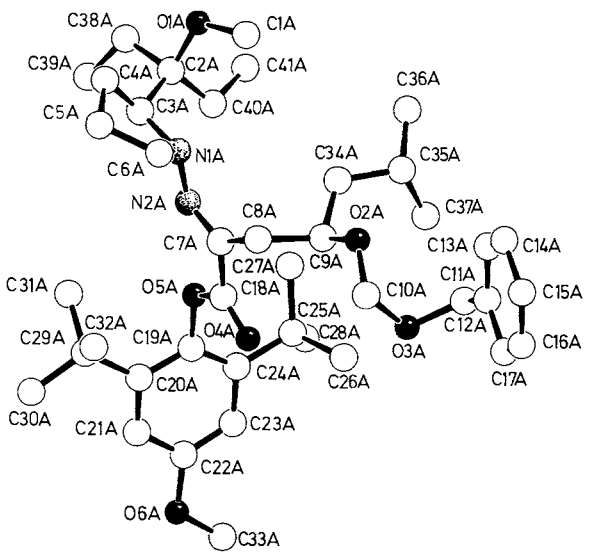

Fig. 1. Crystal structure of one of the two independent molecules of (*S*,*R*)-**4a** (Schakal plot[21]).

The methods described here permit the efficient, highly enantioselective transfer of the pyruvate unit to achiral and chiral aldehydes.[22] The synthesis of natural products, demonstrated with the example of the protected 2-keto-3-deoxygluconate (KDG) **5h**,[4] and their analogues is the subject of current investigations, which include the extension of this new synthetic process to homologous phosphoenolpyruvate equivalents.

Experimental Procedure

To 2.2 mmol of an LDA/LiBr solution (prepared by addition of 1.47 mL of a 1.5 M solution of *n*-butyllithium in *n*-hexane to a solution of 0.22 g (2.2 mmol)

diisopropylamine and 0.35 g (4 mmol) LiBr in 15 mL anhydrous THF at 0 °C under argon) cooled to −78 °C was slowly added dropwise a solution of 0.95 g (2 mmol) hydrazone (*S*)-**2b** dissolved in 3–4 mL THF, and the reaction mixture was stirred at this temperature for 1–2 h. The resulting solution was cooled to −90 °C and 2.2 mmol of the aldehyde dissolved in 2 mL THF added slowly. The reaction mixture was held at −90 °C for 1–2 h, allowed to warm to −78 °C, stirred at this temperature for 1 h, and then hydrolyzed with 2 mL saturated NH_4Cl solution. The mixture was warmed to room temperature and diluted with 150 mL ether. The organic phase was washed with 10 mL water, buffer solution (pH 7), and saturated NaCl solution, and dried over $MgSO_4$. After removal of the solvent in vacuo the product was purified by flash chromatography (silica gel, petroleum ether/ethyl acetate 4:1). For the introduction of the benzyloxymethyl (BOM) protecting group, 1 mmol of the aldol product was dissolved together with 14 mg (0.1 mmol) nBu_4NI in 10 mL anhydrous CH_2Cl_2, and 0.52 g (4 mmol) *N*-ethyldiisopropylamine and 0.47 g (3 mmol) benzylchloromethylether were slowly added in that sequence. The resulting solution was heated at reflux for 12–15 h. After the reaction was complete the solution was treated with 2 mL methanol to quench the excess chloride, stirred for 2 h at room temperature, and concentrated. The residue was dissolved in 150 mL ether, the solution then washed with 10 mL of saturated NH_4Cl solution and 10 mL saturated NaCl solution, dried over $MgSO_4$, and concentrated. The product was purified by flash chromatography (silica gel, petroleum ether/ethyl acetate 95:5). For cleavage of the auxiliary, 1 mmol of the hydrazone was dissolved in ca. 50 mL CH_2Cl_2 and cooled to −78 °C under argon. Ozone was passed through the solution at this temperature until the reaction was complete. After removal of the excess ozone by purging with a stream of argon, the reaction mixture was warmed to room temperature, and concentrated. The product was purified by flash chromatography (silica gel, petroleum ether/ethyl acetate/2-propanol 90:10:1).

[17] Suitable crystals for the X-ray structure analysis were obtained by crystallization from methanol at 2 °C. Monoclinic, space group $P2_1(4)$, $a = 10.940(1)$, $b = 15.822(2)$, $c = 23.817(4)$ Å, $\beta = 92.42(1)°$. From the cell volume of 4118.9 Å^3, two independent molecules in the asymmetric unit, and $M_r = 680.98$ a density of $\varrho_{calc} = 1.098$ g cm^{-3} can be calculated. Total electron count per unit cell $F(000) = 1488$. Enraf-Nonius CAD4 four-circle diffractometer, graphite monochromator, $\Omega/2\theta$ scans, −50 °C, $Cu_{K\alpha}$ irradiation ($\lambda = 1.54179$ Å), $\mu = 5.42$ cm^{-1}. A total of 7218 independent reflections ($\pm h + k + l$), of which 6518 were observed ($I > 2\sigma(I)$), $R_m = 0.008$, $\sin\theta/\lambda_{max} = 0.620$. The structure solution was obtained with direct methods (SHELXS-86 [23]) and the refinement by application of the routines of the SDP program package [24]. The two independent molecules differ considerably in the conformation of the substituents at C3A,B of the five-membered ring. For the phenyl groups C12A,B-C17A,B the ideal positions were calculated because of disorder in the atoms C14A,B-C16A,B and the substituents refined isotropically as rigid groups. Hydrogen atom positions were calculated. For the refinement 783 parameters were used, $R = 0.089$ ($R_w = 0.120$). Isotropic extinction coefficient $a = 2.2 \times 10^{-6}$. Residual electron density is largely localized in the region of the phenyl groups C12A,B-C17A,B, maximum value 0.45 e Å^{-3}. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information GmbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-56869, the names of the authors, and the journal citation.

Diastereo- and Enantioselective Synthesis of C_2-Symmetrical HIV-1 Protease Inhibitors**

By *Dieter Enders*,* *Udo Jegelka*, and *Barbara Dücker*

Since the Center for Disease Control in Atlanta (USA) defined[1] the diagnostic term AIDS (Acquired Immunodeficiency Syndrome) in 1982 only three medications have been authorized for treatment of AIDS: 3′-azido-3′-deoxythymidine (AZT, Wellcome, 1987), 2′,3′-dideoxyinosine (DDI, Bristol Myers Squibb, 1992), and 2′,3′-dideoxycytosine (DDC, Hoffmann LaRoche, 1992), which was recently introduced for limited use. These drugs inhibit the enzyme reverse transcriptase of the human immunodeficiency virus (HIV). Nevertheless, they are only able to prolong somewhat the survival of patients with advanced cases of AIDS. They also lead to considerable side effects (bone marrow damage, neuropathy) and to the generation of more resistant strains of the virus.[2]

Since the solution of its structure in 1989[3] HIV-1 protease has become a new, highly favored target for chemotherapy.[4] This protease belongs to the class of acidic aspartate proteases and has an unusual homodimeric C_2-

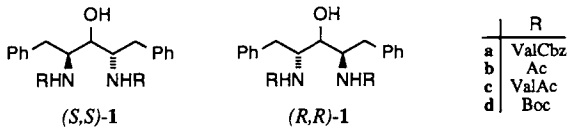
symmetrical structure. Starting from the Phe-Pro cleavage point most frequently preferred by the enzyme, Erickson and Kempf et al.[5] developed the C_2-symmetrical, highly selective HIV-1 protease inhibitor A-74704 (*S,S*)-**1a**. They demonstrated that the marked inhibiting effect of the inhibitor relies on its optimal fit in the active center of the C_2-symmetrical protease. Derivatives with other substituents at the amino group, for example (*S,S*)-**1b** and -**1c**,[6] are also active compounds.



A-74704 (R=ValCbz)

We report here on a new, highly diastereo- and enantioselective entry to C_2-symmetrical HIV-1 protease inhibitors of type **1**. To demonstrate the process both enantiomers of the *tert*-butyloxycarbonyl (Boc)-protected diaminoalcohol **1d** and the racemate *rac*-**1d** (dimethylhydrazone method[11]) were synthesized from the dibenzylated ketones (*R,R*)- and (*S,S*)-**3** (*de*, *ee* = 98%). The compounds (*R,R*)- and (*S,S*)-**3** were prepared from the dihydroxyacetone derivative **2**[7-9] according to the SAMP/RAMP-hydrazone method[10] in four steps and in over 60% yield.

As shown in Scheme 1 (Route A), ketone (*R,R*)-**3** was reduced with lithium aluminum hydride to provide the alcohol, which was then protected as the benzylether, and hydrolyzed under acidic conditions to release diol (*R,R*)-**4** (*de*, *ee* = 98%, overall yield 92%). Attempts to obtain bisazide (*S,S*)-**5** via a bismesylate, itself available quantitatively, with sodium azide in dimethylformamide (20 h, 90 °C), gave **5** and the corresponding HN_3-elimination product in the unfavorable ratio of 1:1. We produced (*S,S*)-**5** with double inversion in 85% yield (*de*, *ee* = 98%) by converting **4** into the bistriflate with trifluoromethanesulfonic acid anhydride (Tf_2O) and substituting with tetramethylguanidinium azide[12] in dichloromethane. In both cases the elimination product could be separated easily by chromatography. The bisazide was ultimately converted to the Boc_2-protected diamine by hydrogenation in the presence of a catalytic amount of Pd/C and 2.4 equivalents of Boc_2O. When ethyl acetate was employed as solvent, then the completely *N*-Boc- and *O*-Bn-protected diaminoalcohols were obtained in 75% yield. Subsequent hydrogenation in methanol led quantitatively to (*S,S*)-**1d** in almost diastereo- and enantiomerically pure form; (*R,R*)-**1d** was prepared by use of the corresponding auxiliary SAMP (Route B). The overall yield of **1d**, best characterized as the 3,3,3-trifluoro-2-methoxy-2-phenylpropionic acid (MTPA) ester,[13] is 58–59% starting from **3** and 36% based on **2** (Scheme 1).

When the hydrogenation of (*S,S*)-**5** was conducted in methanol, a 75% yield of the unprotected diaminoalcohol (*S,S*)-**1** (R = H) was obtained, which can be converted into the C_2-symmetrical HIV-1 protease inhibitor A-74704 (*S,S*)-**1a** according to Kempf et al.[6] and Dreyer et al.[14] Since in the previously described syntheses either L-phenylalanine[6] or D-arabitol[14] were incorporated into the final product, Route A described here provides an entry to the first asymmetric synthesis of A-74704, and at the same time Route B allows a flexible and efficient access to its enantiomer.

For synthesis of the racemate of **1d** the *meso* compound **7** was first prepared in four steps from **2** by the dimethylhydrazone method[11] with an overall yield of 44%. In contrast to the *trans* double alkylation of simple cyclic ketones via the *N,N*-dimethylhydrazone (DMH) derivatives, the α,α-dibenzylation of **2** via *rac*-**6** provided the *cis* product and thereby *meso*-**7** (*de* = 98%) diastereoselectively. After conversion to the mono-protected triol *meso*-**8** (*de* = 98%) analogous to that shown in Scheme 1, bisazide *rac*-**5** was obtained in 71% yield by a Mitsunobu reaction in the presence of zinc azide and diisopropylazidocarboxylate.[15] In this Mitsunobu reaction only one stereogenic center is generated by inversion and the other with retention. This can be explained by invoking an S_Ni reaction: initially, the 1,3-diol is converted into an oxetane ring, which is opened by azide with assistance by Zn^{2+} (retention). The azidoalcohol formed then undergoes substitution with inversion to give the bisazide.[16] After subsequent hydrogenation in the presence of Boc_2O in analogy to that in Scheme 1, *rac*-**1d** was obtained (*de* = 98%) (Scheme 2).

The asymmetric syntheses described here provide an efficient and stereochemically flexible entry to C_2-asymmetric HIV-1 protease inhibitors. The inhibiting effect and the pharmacological properties of these new agents may possibly be improved further for the treatment of AIDS, as certain properties can be varied almost at will:[17] the stereogenic center, which can be selected by the choice of the

auxiliary (SAMP/RAMP); the side chain (here $PhCH_2$), by the choice of electrophile;[7-9] and the substituents on the amino group.[3, 6]

Experimental Procedure

(*S,S*)- and (*R,R*)-**1d**: Compound **3** [9] (1.50 g, 4.8 mmol) was dissolved in 3 mL Et_2O and added dropwise to a suspension of 0.5 equiv (0.09 g) lithium aluminum hydride in 25 mL Et_2O at room temperature (RT). After 3 h the reaction mixture was hydrolyzed with 100 mL water, stirred for 15 min, and extracted with ether (3 × 200 mL). The organic phase was washed with saturated solutions of $NaHCO_3$ and NaCl, then dried over $MgSO_4$. After removal of the solvent and chromatography (silica gel, ether/petroleum ether 1:2), 1.50 g (99%) of the alcohol was obtained. This compound was dissolved in 60 mL THF, and treated with 2 equiv NaH and 0.02 equiv Bu_4NI at 0°C. After the reaction mixture was allowed to warm to RT, 4.9 mmol benzylbromide was added dropwise. After 15 h, 9.6 mL of a 20% KOH solution and a spatula tip of SiO_2 were added. The gelatinous precipitate was removed by filtration, the aqueous phase extracted with ether, and the combined organic phases dried over $MgSO_4$. After concentration and chromatography (silica gel, ether:petroleum ether 1:20), 1.93 g (100%) of the benzylether was obtained. This was dissolved in 10 mL methanol, stirred for 0.5 h with 10 mL of 3N HCl, and then neutralized with solid $NaHCO_3$. After the crude mixture was extracted with ether, the organic phase was dried over $MgSO_4$ and concentrated. Chromatographic purification (silica gel, ether/petroleum ether 2:1) gave 1.61 g (93%) **4**. After dissolution in 22 mL CH_2Cl_2, **4** was treated with 2.0 mL trifluoromethanesulfonic acid anhydride (Tf_2O) at −78°, then 5 min later with 1.5 mL 2,6-lutidine. The reaction mixture was stirred for 30 min, before a further 0.2 mL Tf_2O and 0.15 mL 2,6-lutidine were added. After a further 30 min a solution of tetramethylguanidinium azide (4.1 g dissolved in 22 mL CH_2Cl_2) was added dropwise. The reaction mixture was left to stand for 15 min, allowed to warm to 0°C, and stirred at this temperature for a further 2 h. The crude mixture was filtered through silica gel and evaporated to dryness. Chromatography (silica gel, ether/petroleum ether 1:10) gave 1.54 g (85%) **5** as a colorless oil. To a mixture of 0.05 g Pd/C (10%) in 1 mL ethyl acetate at RT under hydrogen was added dropwise a solution of 0.24 mmol **5** and 2.4 equiv Boc_2O in 4 mL ethyl acetate. After stirring for 12 h, filtration through Celite, and chromatography (silica gel, ether/petroleum ether 1:4), 0.1 g (75%) of the triply protected diaminoalcohol was obtained as colorless crystals, m.p. 125°C (petroleum ether); $[\alpha]_D^{23}$ + 23.5 (*c* = 1.0, $CHCl_3$) for the compound with (*R,R*) configuration. Subsequent debenzylation by hydrogenation [0.05 g Pd/C (10%), H_2, 5 mL MeOH, 3 h] gave 0.08 g **1d** (quantitative); MTPA derivative [18]: colorless oil, $[\alpha]_D^{23}$ + 19.39 (*c* = 0.98, $CHCl_3$) (*R,R*).

rac-**1d**: Compound **2** (26.0 g, 0.2 mol) was heated with 3 equiv *N,N*-dimethylhydrazine under reflux at 65°C for 20 h. The reaction mixture was concentrated and dissolved in 400 mL ether and washed with water. The organic phase was dried over $MgSO_4$, the solvent removed, and the residue purified by distillation to give 29.9 g (87%) of the DMH derivative of **2** (pale yellow oil, b.p. 57°C/2.25 Torr). This compound (20 mmol) was treated with *t*BuLi and BnBr (under the conditions given ref. [9] for the SAMP hydrazones) and the crude α,α-bisalkylated product oxidatively cleaved with ozone in CH_2Cl_2 at −78°C. After chromatography (silica gel, ether/petroleum ether 1:30), 2.94 g (44% based on **2**) of *meso*-**7** (*de* = 98%) was obtained as a colorless oil. Conversion into *meso*-diol **8** was achieved in similar manner to that described for **4**. For the substitution with zinc azide according to Mitsunobu [16] 0.63 g (1.71 mmol) *meso*-**8** was used. Chromatographic purification gave 0.42 g (71%) of *rac*-**5** (*de* = 98%) as colorless crystals, m.p. 91°C (petroleum ether). Conversion to *rac*-**1d** followed in similar fashion to that used for (*R,R*)-**1d**; 0.33 g (58%).

Silylamines with Pyramidal Coordination at Nitrogen**

By *Karin Ruhlandt-Senge, Ruth A. Bartlett, Marilyn M. Olmstead*, and *Philip P. Power**

The nature of the Si–N bond in silylamines has been a subject of considerable interest[1] since the planar structure of $N(SiH_3)_3$ was originally established in 1951.[2] For several

[**] This work was supported by the National Science Foundation and the Petroleum Research Fund.

years, it was argued that characteristics such as short Si–N bonds, planar nitrogen coordination, and poor amine basicity could be plausibly accounted for in terms of an N–Si p–d π-bonding model. The importance of this bonding has been questioned, particularly from a theoretical standpoint, for a number of years.[3–5] It is now thought that multiple N–Si interactions, if they occur in silylamines, involve a p–σ^* rather than a p–d interaction.[4, 6]

With regard to the planarity of EX_3 species (E = main group 5 element, X = substituent), it has been shown experimentally[7b, c] and theoretically[7d] that an increase in the electropositive character (e.g. replacing C by Si) of the substituents X reduces the inversion barrier at E, thereby making planar coordination at E more probable. This may be illustrated by noting that the inversion barrier in NH_3 is 5.8 kcal mol^{-1} whereas in H_3SiNH_2 it is calculated to be almost 1 kcal mol^{-1}.[8] If it is accepted that the introduction of a single silyl group in ammonia reduces the inversion barrier to about 1 kcal mol^{-1}, the observation of a pyramidal geometry at nitrogen in such a compound would tend to imply that Si–N π bonding (which tends to favor planar geometry in order to maximize overlap) should be quite weak. In this paper the synthesis and structural characterization of the silylamines **1**–**3** are described.

H_2NSiPh_3 **1** $(H_2N)_2SiMes_2$ **2** $(H_2N)_3SiTriph$ **3**

Mes = 2,4,6-$Me_3C_6H_2$, Triph = 2,4,6-$Ph_3C_6H_2$

These compounds were chosen for study because steric effects at the nitrogen are minimized through the use of two hydrogen substituents. In addition, electronic effects are minimized through the use of only one electropositive ligand. Such considerations maximize the chances of observing a nonplanar geometry and the effects of this strategy are seen in the structures of **1**–**3** which display varying degrees of pyramidicity at nitrogen.

H_2NSiPh_3 (**1**) was synthesized by using a literature procedure.[9] The new species **2** and **3** were synthesized as described in the Experimental Procedure. The X-ray crystal structures[10] of **1**–**3** are illustrated in Figures 1–3. Important bond lengths and angles for **1**–**3** are given in Table 1. Clearly, the nitrogen centers in **1**–**3** are pyramidal to varying degrees and have substantial out of plane angles ϕ. There is

Table 1. Important Structural Parameters **1**–**3**.

Parameter	1	2	3
Si-N [Å]	1.711(2)	1.713(2), N(1) 1.717(2), N(2)	1.710(6), N(1) 1.710(7), N(2) 1.708(7), N(3)
$\Sigma \sphericalangle$ N[°][a]	351.9	350.2, N(1) 344.8, N(2)	344.1, N(1) 349.2, N(2) 358.1, N(3)
ϕ [b]	25.5	30.5, N(1) 33.9, N(2)	37.0, N(1) 29.9, N(2) 14.6, N(3)

[a] Sum of angles at N; [b] ϕ is the out of plane angle at N, see **A**.

neither a dramatic variation in the observed Si–N distances in the three compounds, nor are the Si–N distances outside the normal range.[11] Other structural parameters such as Si–C and C–C distances are also unremarkable. There are also no unusual angles or evidence of severe steric crowding or interactions with the N–H groups that would readily account for the pyramidicities at the nitrogen atoms.

The structures of **1**–**3** represent the first X-ray crystal structures of acyclic[12] silylamines which show a substantial pyramidal character at nitrogen. Compound **3** is also unique in the sense that it is the first stable compound that has three NH_2 groups bound to one silicon atom. Pyramidal coordination at nitrogen in silylamines has been previously intimated in H_3SiNMe_2 and related species by an electron diffraction study.[13] The structure of H_3SiNMe_2 was later questioned and the data were said not to rule out planar geometry at nitrogen.[14] Further work indicated planar geometry in the gas phase for H_3SiNMe_2 and slightly pyramidal geometry at nitrogen (sum of the angles at N ca. 358°) in the crystal.[15] An important feature of the data in Table 1 is the consistency of the Si–N distance in all three compounds. Taken together, the pyramidicity at nitrogen and lack of variation in Si–N distances indicate that the π component (whether it is of a p–σ* or p–d type) in the Si–N bonds of silylamines must have an extremely small, even negligible, effect on the structural parameters. In arguments regarding π bonding in Si–N systems considerable significance has often been attached to the planarity at nitrogen and shortness of the N–Si bonds. However, as noted previously, the inversion in silylamines is quite low (ca. 1 kcal mol^{-1}).[8] Yet, in neither **1**, **2**, nor **3** are all the nitrogen centers capable of attaining planar geometry in order to maximize π overlap. The confinement of the N–Si distances to the narrow range 1.708(7)–1.717(2) Å also suggests that N → Si electron pair π donation is not very significant.[11] A greater variation might have been expected since the amount of lone-pair electron donation (and π bonding) by each individual nitrogen atom is expected to decrease as the number of nitrogen atoms increases, owing to negative charge buildup at silicon.

The N–Si distances in **1**–**3** are somewhat shorter than the value predicted (1.75 Å) when the ionic contribution is taken into account.[11] However, they are closer to the Si–N bond length (1.735(1) Å) observed in the sterically relaxed species $N(SiH_2Ph)_3$.[16]

It is unlikely that pyramidicity at the nitrogen atom in **1**–**3** is induced exclusively by extrinsic forces such as packing effects, since pyramidicity at nitrogen is observed in the three different molecules. A more likely explanation is that pyramidal coordination can be observed even in the presence of a very low inversion barrier because of the lowered steric congestion[16] (hydrogen substituents) and because inductive effects are minimized (only one silyl substituent).

Experimental Procedure

2: Under anaerobic and anhydrous conditions Mes_2SiCl_2 [17] (3.37 g, 10 mmol) was dissolved in liquid ammonia (100 mL) and refluxed for 4 h (dry ice condenser). The ammonia was evaporated and the white residue taken up in warm diethyl ether (100 mL). Filtration followed by reduction of the solution volume to 20 mL and storage at −40 °C gave colorless crystals of **2** in quantitative yield. M.p. 125–126 °C (NH_3 evolved > 200 °C); IR: νN–H = 3495, 3455, 3449, 3430, 3370, 3350 cm^{-1}. ^{1}H NMR (300 MHz, C_6D_6) δ = 0.831 (s, 4H, NH), 2.137 (s, 6H, *p*-CH_3), 2.392 (s, 12H, *o*-CH_3), 6.738 (s, 4H, *m*-H).

3: $Li(OEt_2)_2$Triph (5.71 g, 10 mmol) [18] was dissolved in a mixture of *n*-hexane (100 mL) and diethyl ether (100 mL) and cooled with an ice bath. Freshly distilled $SiCl_4$ (1.7 g, 10 mmol) in diethyl ether (20 mL) was added dropwise. A white precipitate was formed immediately and the mixture was refluxed for 18 h. Filtration followed by removal of solvents afforded crude $TriphSiCl_3$ as a white solid. This was cooled in a dry ice/acetone bath and ammonia (150 mL) was added. The reaction commenced immediately as indicated by the formation of a copious white precipitate. The mixture was refluxed for 4 h (dry ice condenser). The ammonia was evaporated and the residue was extracted into 100 mL of warm diethyl ether and filtered. The volume was reduced to 30 mL and cooled to −20 °C. This afforded **3** as colorless crystals. Yield 2.72 g, 71%. M.p. 118–120 °C (NH_3 evolution). IR: νN–H = 3465, 3460, 3440, 3378, 3345, 3335 cm^{-1}. ^{1}H NMR (300 MHz, C_6D_6): δ = 0.284 (s, 6H, NH), 6.9 (m, 17H, Triph).

[11] a) E. Lukevics, O. Pudova, R. Sturkovich, *Molecular Structure of Organosilicon Compounds*, Ellis-Horwood, Chichester, **1989**; b) W. S. Sheldrick, *The Chemistry of Organosilicon Compounds, Vol. 1* (Eds.: S. Patai, Z. Rappoport), Wiley, New York, **1989**, Chapter 3. Most neutral silylamines have Si–N distances in the range 1.70–1.76 Å. This is considerably shorter than the sum of the radii of silicon (1.17 Å) and sp^2 hybridized nitrogen (0.7 Å) that is, 1.87 Å. When this value is corrected for ionic contributions by using Allred–Rochow electronegativities and the Schomaker–Stevenson equation ($r_{AB} = r_A + r_B - 0.09|EN_A - EN_B|$) and Si–N distance of 1.75 Å is calculated. If the modified equation ($r_{AB} = r_A + r_B - 0.085|EN_A - EN_B|^{1.4}$) of Haaland and Blom (R. Blom, A. Haaland, *J. Mol. Struct.* **1985**, *129*, 21) is used the Si–N distance is also calculated to be 1.75 Å.

[12] A pyramidal coordination for a silylamine nitrogen (sum of angles at N = 346.8°) has been observed in the bicyclic compound NSi*t*Bu$_2$Si*t*Bu$_2$CHCMe$_2$SCH*i*Pr)). The constraints on the nitrogen geometry may significantly increase the inversion barrier in this case [7]: M. Weidenbruch, B. Flintzer, S. Pohl, D. Haase, J. Martens, *J. Organomet. Chem.* **1988**, *338*, C1.

Nucleophilic Substitution of Bis(cyclopentadienyl)-tin(II); Synthesis, Structure, and Solution Dynamics of *trans*-$[(\eta^3\text{-Cp})Sn\{\mu_2\text{-}N{=}C(NMe_2)_2\}]_2$

By *Dietmar Stalke, Michael A. Paver,* and *Dominic S. Wright**

Recently we have been interested in the occurrence and nature of bonds between later main group metals (Groups 3–5) and early main group metals (Groups 1 and 2). These studies have led to the synthesis and characterization of $Ph_3ELi \cdot$ pmdeta complexes (E = Sn,[1] Pb;[2] pmdeta = $MeN(CH_2CH_2NMe_2)_2$), the first compounds in which such bonding has been identified. With a view to finding other related complexes, we have more recently been investigating the reactions of cyclopentadienyl complexes of heavy p block metals (as convenient and stabilized precursors) with nucleophiles. Nucleophilic *addition* of CpNa to bis(cyclopentadienyl)tin(II)[3] in the presence of pmdeta (mol ratio 1:1:1) resulted in the formation of the unusual trigonal-planar "paddle wheel" triorganostannate complex $[(\eta^5\text{-Cp})_2\text{-}Sn(\mu\text{-}\eta^5\text{-Cp})Na \cdot \text{pmdeta}]$.[4]

We report here the outcome of the reaction of $[LiN{=}C(NMe_2)_2]_6$,[5] which contains a more potent nucleophile, with $[Cp_2Sn]$ (mol ratio 1:1). The result is the nucleophilic *substitution* of just one of the Cp ligands and the formation of the dimeric mixed-ligand organotin(II) complex *trans*-$[(\eta^3\text{-Cp})Sn\{\mu_2\text{-}N{=}C(NMe_2)_2\}]_2$ (**1**). This is the first iminotin(II) complex and the first structurally characterized oligomeric cyclopentadienyl organotin(II) complex. Nucleophilic substitution of cyclopentadienyl complexes of heavy p block metals provides a clean and potentially general route to such mixed-ligand metal complexes.

Addition of a solution of $[Cp_2Sn]$[3] in THF to a solution of $[LiN{=}C(NMe_2)_2]_6$[5] in THF (mol ratio 1:1) [Eq. (a)] produces a bright yellow solution which affords colorless crystals of **1** (see Experimental Procedure).

$$[Cp_2Sn] + [LiN{=}C(NMe_2)_2] \xrightarrow{THF} \underset{\mathbf{1}}{[CpSnN{=}C(NMe_2)_2]} + CpLi \quad (a)$$

An X-ray crystallographic study of complex **1**[6] (the crystal was mounted wet from solution) shows it to be a centrosymmetric dimer $[(\eta^3\text{-Cp})Sn\{\mu_2\text{-}N{=}C(NMe_2)_2\}]_2$ with a Sn_2N_2 ring (Fig. 1). One THF molecule per dimer unit is found in the crystal lattice; it is readily removed when the crystals are placed under vacuum for a short period of time (10^{-1} bar, 15 min), although the crystals are then destroyed. In the planar ring of each dimer, the imino groups bridge the two Sn centers almost symmetrically (Sn(1)–N(1) 2.196(3) Å, Sn(1)–N(1a) 2.185(3) Å, cf. typical Sn–N lengths in amidotin complexes, e.g., 2.202(1) Å in $[Sn(NtBu)]_4$[7]). There is extreme rhombic distortion within this ring (N-Sn-N, 75.36(12)°, Sn-N-Sn, 104.64(12)°). To our knowledge, more acute angles at Sn have been observed only in the heptaatomic species $[Sn_3(NtBu)_2(OtBu)_2]$ (N-Sn-N, 68.0(2)°).[8] The terminal η^3-Cp ligands have a *trans* orientation with respect to this ring (the shortest Sn–C contact is Sn(1)–C(4), 2.432(5) Å). The essentially flat imino anions are eclipsed in order to avoid the *trans* Cp ligands. They fit into the "slot" left to them by the Cp ligands, and are inclined to the Sn_2N_2 ring plane by approximately 37°.

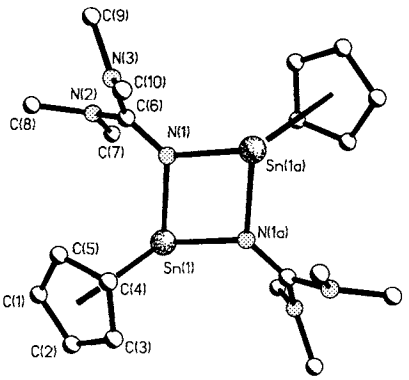

Fig. 1. Crystal structure of **1**; selected bond lengths [Å] and angles [°]: Sn(1)-N(1) 2.196(3), Sn(1)-N(1a) 2.185(3), Sn(1)-C(4) 2.432(4), Sn(1)-Cp(center) 2.432(4), N(1)-C(6) 1.294(5), C(6)-N(2) 1.371(5), C(6)-N(3) 1.370(5), average N-Me 1.445(7); N(1)-Sn(1)-N(1a) 75.4(1), Sn(1)-N(1)-Sn(1a) 104.6(1), N(1)-Sn(1)-C(4) 91.6(2), N(1a)-Sn(1)-C(4) 93.8(2).

The structure of **1** is unprecedented among the structures of cyclopentadienyltin(II) complexes. Most other structurally characterized compounds are mononuclear, for example, neutral $[Cp_2Sn]$ and compounds related to the cationic $[CpSn]^+$ system.[9] In polymeric $[(\eta^5\text{-Cp})SnCl]_\infty$, prepared from $[Cp_2Sn]$ and $SnCl_2$ (mol ratio 1:1), alternating monomer units are associated by bridging Sn···Cl contacts.[10] The structure of **1** can be compared to those of iminoaluminum complexes in which μ_2-bridging imino groups connect the metal centers.[11, 12] In the latter, the Al_2N_2 rings show a similar rhombic distortion to that seen in **1**, although with less sharp angles at their metal centers (N-Al-N, ca. 83°).

Studies of the temperature- and concentration-dependence of the ^1H NMR spectra of **1** in THF (400.13 MHz) indicate that an equilibrium exists between the *cis*- and *trans*-Cp isomers. At +25 °C both isomers coexist in an approximately 1:1 ratio. In the *trans* form, the same structure as that in the solid state, the steric demands lead to restricted rotation of the Me_2N groups of the imino ligands; the Me groups are consequently nonequivalent (δ = 2.73, 2.68 (1:1)). In the *cis* form, presumably because of their less sterically crowded environment, these Me groups are free to rotate and are equivalent (δ = 3.11). Two separate Cp signals for the *cis* and *trans* isomers (δ = 5.98 and 5.91) are also observed. Reducing the temperature leads to a broadening of the Me resonances of the *cis* isomer and, at approximately −95 °C, this signal begins to split. At −125 °C, these Me groups are fully resolved into two (1:1) signals. This is consistent with the less restricted rotation of the imino groups of the *cis* isomer compared to those in the *trans*, and consequently the lower activation energy for rotation in the former. The fact that the same ratio of intensities for the signals of both species in solution is observed regardless of concentration supports an intramolecular *cis–trans* equilibrium. An alternative interpretation of an intermolecular dimer–monomer equilibrium can be ruled out, as the ratio of the solution species would then be expected to vary with concentration.

[**] This work was supported by the SERC (M. A. P., D. S. W.), the Associated Octel Co. Ltd., U.K. (M. A. P., D. S. W.), the Royal Society (D. S. W.), the Nuffield Foundation (D. S. W.), the Deutsche Forschungsgemeinschaft (D. S.), and the Fonds der Chemischen Industrie (D. S.).

Variable-temperature ^{119}Sn NMR spectra of **1** in THF (148.89 MHz) showed only one resonance at all the temperatures investigated.[13] Although this observation does not allow firm conclusions, two very distinct signals would be expected in an alternative equilibrium involving dimers and solvated monomers of **1**. ^1H NMR spectroscopy and molecular mass measurements in aromatic solvents suggest that only the *cis* isomer is present. Only one Cp ($\delta = 5.28$) and one Me resonance ($\delta = 2.62$) are seen at $+25\,^{\circ}C$ in the ^1H NMR spectra of **1** in toluene. The Me signal begins to broaden at approximately $-80\,^{\circ}C$, and this resonance resolves into two signals (1:1 ratio) at $-95\,^{\circ}C$ as rotation of the Me_2N group is frozen out. Cryoscopic measurement of a saturated solution of **1** in benzene confirms that **1** is dimeric ($n = 2.05 \pm 0.07$ (0.026 M)). The behavior of **1** is similar to that of $[Sn(\mu\text{-}Cl)NCMe_2(CH_2)_3CMe_2]_2$ for which *cis* and *trans* isomers were identified in toluene at low temperature, while in THF only one (unidentified) isomer was found.[14]

The synthesis of **1** by a nucleophilic substitution reaction of $[Cp_2Sn]$ with $[LiN{=}C(NMe_2)_2]_6$ is worthy of note. Previous studies have centered on the reactions of electrophiles with $[Cp_2Sn]$.[9] Although nucleophilic disubstitution of $[Cp^*_2Sn]$ ($Cp^* = C_5Me_5$) with organolithium compounds has been reported, monosubstitution does not appear to be possible; the reaction of $[Cp^*_2Sn]$ and $(Me_3Si)_2CHLi$ gives a mixture of Cp*Li, $[(Me_3Si)_2CH]_2Sn$, and unreacted Cp^*_2Sn.[15] We are currently examining reactions of $[Cp_2E]$ (E = Sn,[3] Pb[16]) with a variety of nucleophiles (containing C, O, S, N, and P centers), and combined addition[4] and substitution reactions with $[Cp_2Sn]$ for the syntheses of new triorganostannate reagents containing three different organic groups.

Experimental Procedure

A solution of $[Cp_2Sn]$ [3] in THF (0.500 g, 2.0 mmol in 1.5 mL) was added to a solution of $[LiN{=}C(NMe_2)_2]_6$ (2.0 mmol in 5 mL THF) under nitrogen atmosphere. A bright yellow solution was formed, and after removal of ca. 1 mL of solvent under vacuum, the solution was cooled to 5 °C for 24 h. Crystalline, colorless, air-sensitive rods, identified as **1**, were isolated. These contain one molecule of THF per unit of **1**. Placing these crystals under vacuum (10^{-1} bar, 15 min) gave a dry powder in which THF lattice solvation is completely removed. The following analytical and spectroscopic data were obtained on this dry, unsolvated material. First batch yield (0.25 g (42%); m.p. 179–181 °C (decomp to brown liquid). Satisfactory C,H,N-analysis. IR (solid): $\tilde{\nu}[cm^{-1}] = 3066$, 1512 (cf. 1600 cm^{-1} in $(Me_2N)_2C{=}NH$). ^1H NMR (25 °C, 400.13 MHz, [D$_8$]THF): $\delta = 5.98$, 5.91 (5H each; Cp in *cis* and *trans* isomers of **1**), 3.11 (s, 12H; Me_2N groups in *cis* isomer), 2.73, 2.68 (12H each; separate Me groups of *trans* isomer). ^1H NMR (25 °C, 400.13 MHz, [D$_8$]toluene): $\delta = 5.28$ (s, 5H; Cp of *cis* isomer), 2.62 (s, 12H; Me_2N in *cis* isomer).

Facile Formation of Hexahydroporphyrin Complexes by Reduction of Octaethylisobacteriochlorinnickel(II)**

By *Goutam K. Lahiri* and *Alan M. Stolzenberg**

Dedicated to Professor Richard H. Holm on the occasion of his 60th birthday.

The isobacteriochlorin macrocycle is remarkable for its ability to form isolable complexes of Ni(I) and Cu(I), oxidation states which are not commonly attained in a tetrapyrrole environment.[1, 2] The accessibility of these complexes reflects, in part, their resistance to further reduction. The nickel(I) and copper(I) octaethylisobacteriochlorin-(OEiBC) anions exhibit no cathodic processes in cyclic voltammograms in acetonitrile or dimethylformamide (DMF) and resist reduction by sodium amalgam. During recent studies, we had occasion to conduct amalgam reductions of [Ni(OEiBC)] (**1**) in the presence of proton donors and in a wider range of solvents than previously examined.[3] Unexpectedly, we observed the facile formation and interconversion of the two isomeric hexahydroporphyrin complexes **2** and **3**. Compounds **3** and **4**, the free base of **2**, were first prepared during Eschenmoser's investigations of chemistry relevant to the prebiotic origin and biosynthesis of Vitamin B_{12}.[4] Precorrins 2 (15,23-dihydrosirohydrochlorin) and 3, which are intermediates in the biosynthesis of Vitamin B_{12} and of Factor F430, have chromophores identical to **2**.[5]

A red-brown colored solution of **2**, whose UV/VIS spectrum is shown in Figure 1, is obtained by reduction of **1** with

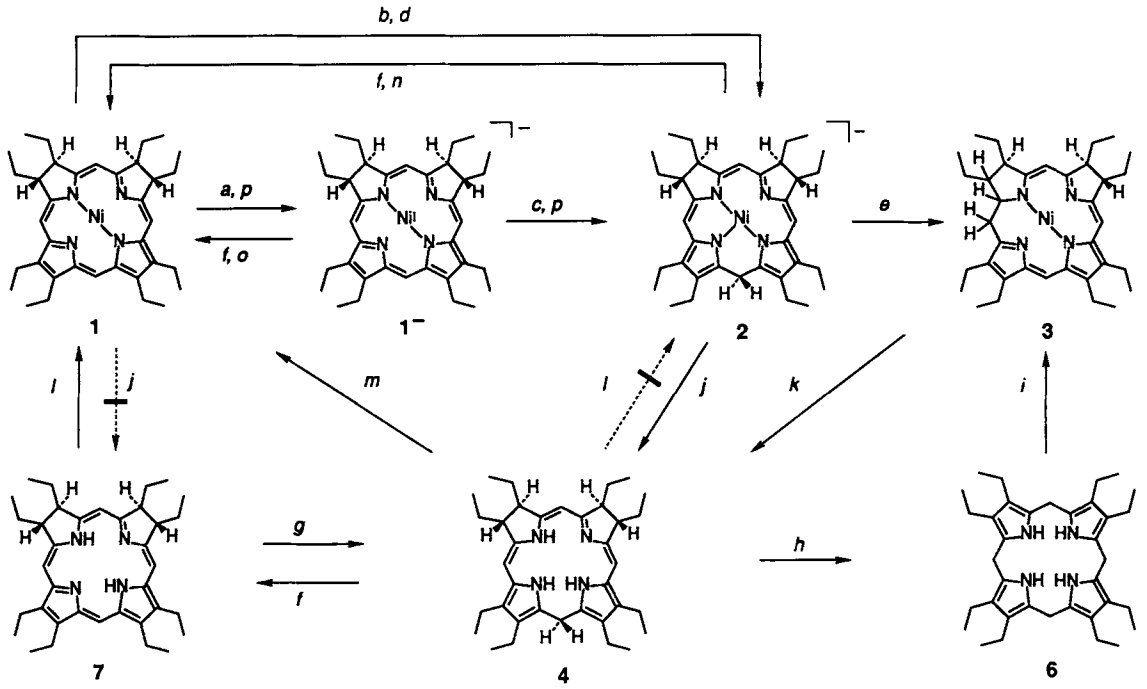
[**] The Reductive Chemistry of Nickel Hydroporphyrins, Part 3. This work was supported by the National Institutes of Health (grant GM 33882). Part 2.: [1].



Scheme 1. All reactions were conducted at room temperature unless noted. *a*: Solution of **1** in various solvents (excluding those listed in *b*) + excess sodium amalgam (1% sodium). *b*: 2,5-Dimethyl-THF, TMEDA, or *N*-methylformamide solution of **1** + excess sodium amalgam (1% sodium) about 30 min–2 h. *c*: Acetonitrile, tetrahydropyran, THF, or 2-methyl-THF solution + excess sodium amalgam (1% sodium), about 2–48 h. *d*: Excess sodium amalgam (1% sodium) and $[(n\mathrm{Bu})_3\mathrm{NH}][\mathrm{ClO}_4]$, about 10 min. *e*: $[(n\mathrm{Bu})_3\mathrm{NH}][\mathrm{ClO}_4]$, about 2 min. *f*: O_2 or other oxidants. *g*: H_2, Pt on carbon (5%), in ethyl acetate solution [10]. *h*: In pyridine/acetic acid (1:1), 60 °C, evacuated tube, 40 h [10]. *i*: 7.3 equiv $[\mathrm{Ni(OAc)_2}]\cdot 4\mathrm{H_2O}$ in *p*-xylene + 2 vol.% $\mathrm{AcOH/Et_3N}$ (4:1), 140 °C, evacuated tube, 15–21 h [7]. *j*: AcOH, CF_3CO_2H, or HBF_4. *k*: Excess HBF_4 and $[(n\mathrm{Bu})_3\mathrm{NH}][\mathrm{ClO}_4]$. *l*: 3 equiv $[\mathrm{Ni(acac)_2}]$ in benzene or THF under reflux; see [13]. *m*: 3 equiv $[\mathrm{Ni(acac)_2}]$ + more than 3 equiv Et_3N in benzene or THF. *n*: $[\mathrm{Ni(acac)_2}]$ or $NiClO_4$. *o*: Excess H_2O, AcOH, CH_3OH, or C_6H_5SH; see [3]. *p*: Sodium naphthalide.

an excess of 1% sodium amalgam in specific solvents (Scheme 1).[6] In some solvents, the formation of $[\mathrm{Ni^I(OEiBC)}]^-$ ($\mathbf{1}^-$) is not observed during the reduction. However, in others the reduction initially affords $\mathbf{1}^-$, which later converts to **2**. Conversion of $\mathbf{1}^-$ to **2** requires 12–48 h in THF and acetonitrile, the solvents used in our original studies.[1] Ion $\mathbf{1}^-$ is stable to further reduction in dimethoxyethane, *N*-methylpyrrolidinone, dimethylformamide (DMF), and hexamethylphosphoric triamide (HMPA) even in the presence of a large excess of amalgam. The complex **2** could not be obtained by electrolysis in bulk solution or in an optically transparent thin-layer electrode electrochemical cell.

Reduction of **1** in the presence of the proton donor salt $[(n\mathrm{Bu})_3\mathrm{NH}][\mathrm{ClO}_4]$ requires significantly less time. If amalgam is present in large molar excess relative to salt, the final product is **2**. When salt is in excess, reduction affords a green solution of the known nickel(II) complex of octaethyl-1,2,3,7,8,20-hexahydroporphyrin (**3**).[7] Complex **3** also can be obtained within minutes at room temperature by addition of the perchlorate salt to a solution of **2** in the absence of amalgam.

Solutions of **2** are extraordinarily air-sensitive and are more difficult to handle than $[\mathrm{Ni^I(OEiBC)}]^-$. Partial oxidation of **2** to **1** invariably occurs upon transfer, dilution, or standing in the absence of amalgam. Analysis or purification of **2** by chromatography or isolation as a pure solid is not possible. In contrast, solutions of **3** are relatively stable. They can be purified by chromatography and can withstand brief exposure to air without sigificant reoxidation to **1**.

As initially obtained, **2** appears to be a single compound. NMR data and the similarity of the UV/VIS absorption bands of **2** prepared in widely varying solvents speak against a mixture of compounds with different saturation levels and sites. The ^{1}H NMR spectrum of **2** in $[D_8]$THF shows *meso* proton signals, which give a 1:2 ratio on integration, at $\delta = 5.55$ (C5) and 6.05 (C10 and C20). Each signal is partially resolved into two singlets of unequal height, which suggests that **2** is a mixture of diastereomers, like **1**.[7, 8] No signals are observed at lower field, with the exception of the *meso* protons of the [Ni(OEiBC)] impurity.[9] The twofold symmetry of **2** that is required by the *meso* proton signals, the rearrangement of **2** to the hexahydroporphyrin **3** in the absence of a reducing agent, and the facile and apparently quantitative oxidation of **2** to **1** establish that **2** is an anionic complex formed by saturation of C15 of **1**.

Complex **2** is the first metal complex of a 2,3,7,8,15,23-hexahydroporphyrin. Known free bases of compounds with this type of chromophore include precorrins 2 and 3,[5] **4**,[10] and 5-cyano-3,3,7,7,15,23-hexahydro-2,2,8,8,12,13,17,18-octamethylporphyrin (**5**).[11] The chemical shifts of the C5, 10, and 20 *meso* protons of these free bases fall exclusively in the range $5.0 \leq \delta \leq 6.1$, which distinguishes 2,3,7,8,15,23-hexahydroporphyrins from all other hexahydroporphyrin tautomers as well as from all tetrahydro- and dihydroporphyrin tautomers. The close correspondence of the ^{1}H NMR spectra of **2** and **4** and the absence in the spectrum of **2** of an NH proton peak near $\delta = 7.9$ are consistent with **2** being the nickel complex of **4**.

Eschenmoser et al. demonstrated that hexahydroporphyrins of type **4**, saturated at C15, are not favored in equilibria with other hexahydroporphyrins. Compound **4** tautomerizes to octaethylporphyrinogen (**6**).[10] Hexahydroporphyrin **5** can be transformed to a free base or nickel hexahydroporphyrin of the same chromophoric type as **3**.[11] Similar conditions can affect conversion of **6** to **3**.[7] All of

these conversions require extreme conditions: several days at temperatures of 60–140 °C. Thus, the facile conversion of **2** to **3** at room temperature is extraordinary.

The UV/VIS spectrum of **4** prepared by the literature method[10] is shown in Figure 1. Reaction of **2** with a small excess of acid results in immediate formation of a yellow compound whose UV/VIS spectrum is identical to that of **4**. In contrast to the rapid demetalation of **2**, solutions of purified **3** are unaffected by acid. However, in the presence of a large excess of both HBF_4 and $[(n\text{Bu})_3\text{NH}][ClO_4]$, **3** is rapidly demetalated to afford **4**. Thus, hexahydroporphyrins saturated at C15 are not always disfavored in equilibria with other hexahydroporphyrin tautomers.

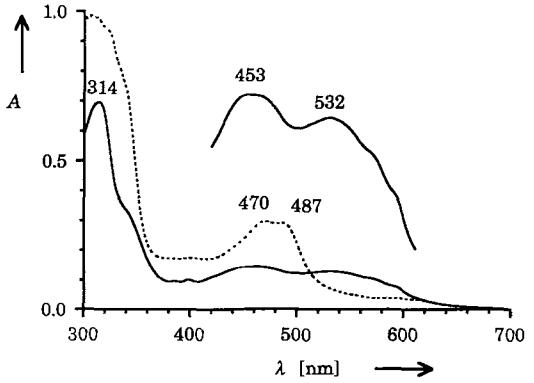


Fig. 1. UV/VIS spectra of nickel complex **2** (——) and free base **4** (– – – –) in THF. A = absorbance. Scales of the y axis for the two spectra are not the same. Inset: expansion of the spectrum of **2**.

Attempts to prepare **2** by metalation of **4** or catalytic hydrogenation of **1** were unsuccessful. Smith et al. used hydrogenation catalyzed by Raney nickel to prepare nickel hexahydroporphyrin complexes of the same type as **3** from Ni(II) anhydromesorhodochlorin and pyropheophorbide complexes.[12] Because solutions of **4** are easily reoxidized (but less readily than solutions of **2**) to octaethylisobacteriochlorin (**7**), a gentle method of inserting metals with $[M(acac)_2]$ complexes was investigated.[13] No reaction occurs when M = Ni, Cu, or Zn, even after hours at reflux in THF or benzene. Addition of base to assist in deprotonation of **4** results in immediate formation of the [M(OEiBC)] complex. Separate experiments showed that **2** is oxidized to **1** by either $[Ni(acac)_2]$ or $NiClO_4$ and is, therefore, unstable to the metalation conditions. Complex **1** suffers partial dehydrogenation to nickel octaethylchlorin, [Ni(OEC)], during catalytic hydrogenation in the presence of Pt/C catalyst. Raney Ni (Aldrich, pH > 9, slurry) completely bleaches solutions of **1** or of [Ni(OEC)]. Neither **6** nor any other identifiable compound can be isolated from the reaction.

It is curious that proton donors and potentially acidic solvents favor the reduction of **1** to **2** because proton donors oxidize $\mathbf{1}^-$, [Eq. (a)].[3] Indeed, more than 7 mol of H_2 are produced per mol of **2**, when **2** is prepared in *N*-methylformamide (NMF). This might implicate a hydrido-[Ni(OEiBC)] intermediate as the reagent that reduces **1** to **2**. However, the failure of $LiAlH_4$ to react with **1** and the lengthy reaction time (3 days) required for reduction of **1** to **2** by $Li(Et_3BH)$ suggest otherwise.

$$\underset{\mathbf{1}^-}{[Ni^I(OEiBC)]^-} + HA \longrightarrow \underset{\mathbf{1}}{[Ni(OEiBC)]} + 0.5\,H_2 + A^- \qquad (a)$$

In an effort to understand the reaction sequence that leads to **2**, we examined the cyclic voltammetry of **1** in THF, a solvent that has a potential limit of nearly −3 V vs. a saturated Calomel electrode (SCE) with $[(n\text{Bu})_4\text{N}][ClO_4]$ as electrolyte. The totally irreversible second reduction process observed at −2.56 V (cathodic peak) would appear to be beyond the range of sodium amalgam, whose potential is approximately −2.05 V vs. SCE in acetonitrile and THF.[14] However, this is a standard reduction potential, not the potential in the absence of electrolyte (i.e. $[Na^+] = 0$). We determined that the potential of 1% sodium amalgam in organic solvents (solutions 0.1 M in $[(n\text{Bu})_4\text{N}][ClO_4]$, but 0 M in added Na^+) is typically −2.25 V vs. SCE. Furthermore, the position of the cathodic peak includes a contribution from an overpotential. The peak underwent a 200 mV anodic shift when a hanging Hg drop electrode was used in place of a Pt electrode. Finally, ion pairing with the small Na^+ cation, the only counterion present during amalgam reduction, could cause significant anodic shifts in reduction potential as has been observed for aromatic dianions.[15] Thus, the thermodynamic potential of the second reduction of **1** and the potential of sodium amalgam under actual experimental conditions may be close enough to permit partial formation of $[Ni^I(OEiBC^{\bullet})]^{2-}$ [Eq. (b)]. Isobacteriochlorin anion radicals have unprecedentedly large spin density at C15.[16] Protonation of the strongly basic radical dianion at C15 accompanied by internal electron transfer from Ni^I to the π system [Eq. (c)] should be irreversible and drive formation of **2**. Consistent with this sequence, titration of **1** by sodium naphthalide sequentially produces $\mathbf{1}^-$ and **2**.

$$\underset{\mathbf{1}^-}{[Ni^I(OEiBC)]^-} + e^- \longrightarrow [Ni^I(OEiBC^{\bullet})]^{2-} \qquad (b)$$

$$[Ni^I(OEiBC^{\bullet})]^{2-} + H^+ \longrightarrow \mathbf{2} \qquad (c)$$

Reductions of zinc, copper, and palladium octaethylisobacteriochlorin (**8**–**10**) were reexamined in light of our results for **1**. The zinc complex **8** has a reversible second reduction at −2.13 V. Complexes **9** and **10** have irreversible second reductions with cathodic peaks at −2.57 and −2.68 V, respectively. All three are reduced by sodium amalgam to species with UV/VIS spectra similar to that of **2** in solvents that favor formation of **2**. These species reoxidize more readily than **2**. Proton donors appear to assist the formation of these species. Reduction of **8** or **9** does not proceed beyond $[Zn(OEiBC^{\bullet})]^-$ or $[Cu^I(OEiBC)]^-$, respectively, in 'dry' DMF. In 'wet' DMF,[17] **9** is reduced partially and **8** completely to species analogous to **2**.

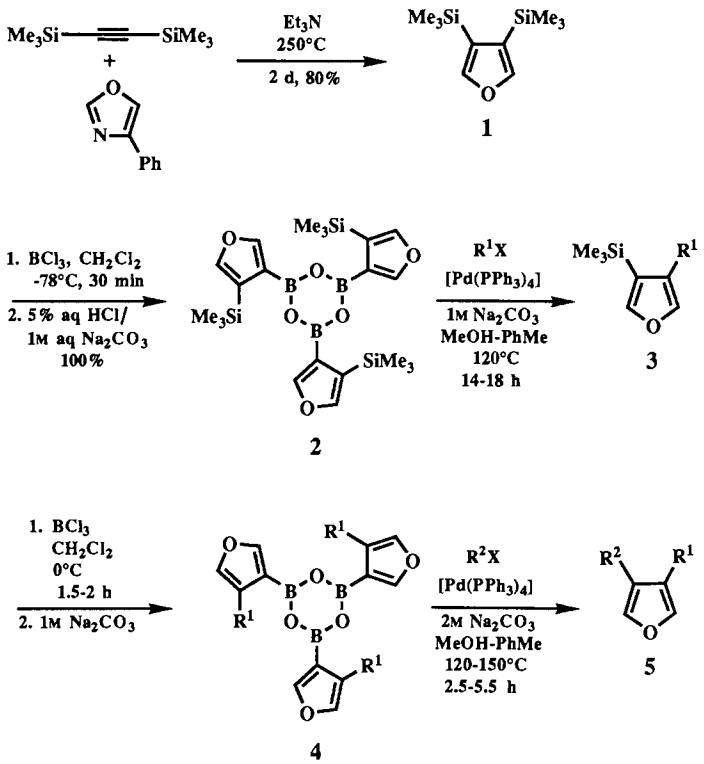
Regiospecific Conversion of 3,4-Bis(trimethylsilyl)furan to 3,4-Disubstituted Furans: A Novel Suzuki-Type Cross-Coupling of Boroxines**

By *Zhi Zhong Song, Zhong Yuan Zhou, Thomas C. W. Mak,* and *Henry N. C. Wong**

Polysubstituted furans are important building blocks for natural and nonnatural product synthesis.[1] However, the tendency of furans to undergo both lithiation and electrophilic substitution at C2 or C5[2] makes the synthesis of 3,4-disubstituted furans an exceedingly difficult task. To circumvent this, several special methods have been developed.[3] Recently we reported the preparation of 3,4-bis(trimethylsilyl)furan (**1**) and some of its conversions.[4] In this communication, we disclose that **1** can be converted regiospecifically into various boroxines,[5] which in turn undergo the well-established Suzuki-type cross-coupling reactions[6] to give 3,4-disubstituted furans.

The yield of **1** was optimized to 80% by heating equimolar quantities of bis(trimethylsilyl)acetylene and 4-phenyloxazole[7] in 5 mol% of triethylamine at 250 °C in a sealed tube for 2 days (Scheme 1). The presence of triethylamine is essential for retarding the rearrangement of **1**.[8, 9] In a separate experiment, trifluoroacetic anhydride containing a catalytic amount of trifluoroacetic acid was found to promote the rearrangement of **1** efficiently,[8, 9] which furnished 2,4-bis(trimethylsilyl)furan as the only isolable product in 85% yield.[10]

Attempts to displace the trimethylsilyl groups of **1** directly with aryl or alkenyl groups by palladium-catalyzed coupling have so far been unfruitful, although similar reactions on fluorinated silanes are well-documented.[11] Furthermore,



Scheme 1. The reaction of bis(trimethylsilyl)acetylene and 4-phenyloxazole was performed in a sealed tube.

Friedel–Crafts acylation of **1** with various acid chlorides only led to mixtures of compounds with substitution at both C2 and C3.[10] After several manipulations, we eventually discovered that **1** underwent regiospecific *ipso*-substitution[12] with one to two equivalents of boron trichloride at 0 °C to room temperature.[13] Subsequent workup[14] of the resulting dichloroborane by addition of either 5% HCl or 1 M Na_2CO_3 afforded unexpectedly the air-stable tris[(4-trimethylsilyl)furan-3-yl]boroxine **2** in quantitative yield (Scheme 1). The structure of **2** has been substantiated by NMR spectrometry and shown to exhibit approximate C_{3h} symmetry by an X-ray crystallographic study (Fig. 1).[15]

Although the trimeric anhydrides of boronic acids, the boroxines, have been known for more that fifty years,[5] their synthetic applications[16] have been restricted mainly to characterization and purification of the corresponding

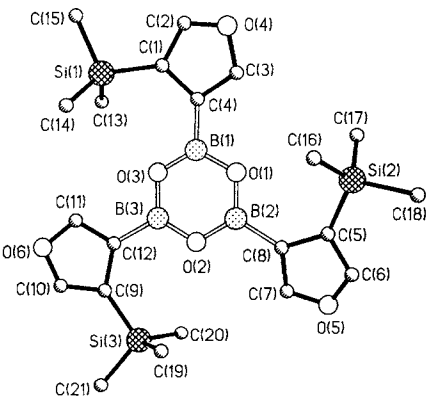


Fig. 1. Perspective view of the molecular structure of **2** with atom numbering. In the boroxine ring the average B–O bond lengths are 1.372(6) Å and O-B-O angles are 119.3(5)°.

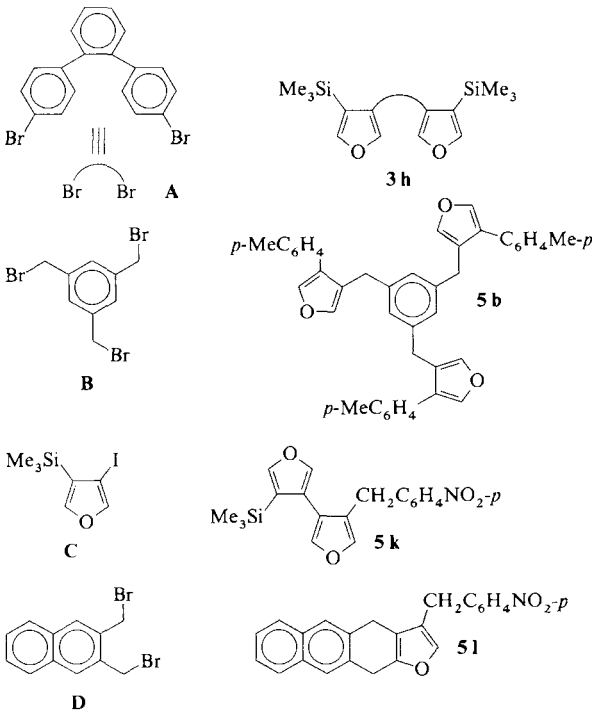
[a] For structural formulas, see Scheme 2.

boronic acids.[17] However, we found that boroxine **2** smoothly underwent regiospecific Suzuki-type cross-coupling reaction[6] catalyzed by 10 mol% of $[Pd(PPh_3)_4]$ to afford furans **3** (Table 1, Scheme 2). With only one notable exception (**3i**), which might perhaps be attributed to steric hindrance, the yields of **3** are generally higher than 90%.



Scheme 2. Structures of the halides **A**–**D** and the furans **3h**, **5b**, **5k**, and **5l**.

To achieve our ultimate goal of preparing 3,4-disubstituted furans, the remaining trimethylsilyl groups of **3** were replaced by the dichloroboranyl group with boron trichloride, and the reaction mixtures were subsequently worked up by addition of 1 M Na_2CO_3. As expected, boroxines **4** were obtained, albeit in somewhat inferior yields (Table 1). Apparently the displacement of the second trimethylsilyl group in **3** by boron trichloride is less facile. Again, boroxines **4** readily underwent Suzuki-type cross-coupling reactions catalyzed by 10 mol% of $[Pd(PPh_3)_4]$ to furnish 3,4-disubstituted furans **5** in good yields (Table 1). As can be seen, the intriguing generation of **5b** aptly demonstrates the versatility of boroxine in the cross-coupling reaction. The formation of **5l**, on the other hand, shows that palladium(0) is able to trigger an unexpected intramolecular Heck-type coupling at C2 of the furan nucleus.

In conclusion, we have shown that the cross-coupling reaction for boroxines is quite efficient in terms of the ease of product workup and yields. However, in practice, it should be noted that R^1 must be insensitive to Lewis acid. The choice of R^2 is less demanding, depending solely on the limitation of the Suzuki reaction. A number of 3,4-disubstituted furans, which are otherwise difficult to realize, have been prepared. This palladium-catalyzed silicon–boron strategy for synthesis of 3,4-disubstituted furans is expected to have interesting uses in organic synthesis.

Experimental Procedure

1: A mixture of 4-phenyloxazole (0.1 mol), bis(trimethylsilyl)acetylene (0.12 mol), and triethylamine (5 mmol) was heated in a sealed tube at 300 °C for 7 days. Vacuum distillation gave a colorless liquid. Purification by column chromatography (SiO_2, 350 g, hexanes) yielded **1** (17 g, 80%) as colorless oil, b.p. = 30–32 °C (0.6 mmHg). ^1H NMR (250.132 MHz, $CDCl_3$, 25 °C): δ = 0.25 (s, 9H, $Si(CH_3)_3$), 7.41 (s, 1H, H2); ^{13}C NMR (62.896 MHz, $CDCl_3$): δ = 0.42 (q, $Si(CH_3)_3$), 121.90 (s, C3), 149.61 (d, C2); EI-MS (70 eV): *m/z* 212 (M^+, 60%), 73 ($Si(CH_3)_3$, 100).

2: *To a solution of* **1** *(0.05 mol) in* CH_2Cl_2 *(100 mL)* was added slowly a 1.0 M solution of BCl_3 in CH_2Cl_2 (50 mL) under a nitrogen atmosphere at room temperature. The reaction was quenched with 2 M Na_2CO_3 solution, and the mixture extracted with ether (3 × 20 mL). The organic layer was dried ($MgSO_4$), and the solvent evaporated. The crude product was chromatographed (SiO_2, 250 g, hexanes/ether, 2:1). Colorless crystals of **2** were obtained (8.1 g, 98%), m.p. = 167–168 °C. ^1H NMR (250.132, $CDCl_3$, 25 °C): δ = 0.38 (s, 9H, $Si(CH_3)_3$), 7.43 (d, 1H, J = 1 Hz, H5), 8.17 (d, 1H J = 1 Hz, H2); ^{13}C NMR (62.896 MHz, $CDCl_3$): δ = – 0.42 (q, $Si(CH_3)_3$), 117.05 (br. s, C3), 122.21 (s, C4), 149.10 (d, C5), 156.55 (d, C2); EI-MS (70 eV): *m/z* 498 (M^+, 13%), 483 (M^+ – Me, 90), 275 (48), 73 ($Si(CH_3)_3$, 100).

3j: A mixture of **2** (10 mmol), *p*-nitrobenzyl bromide (30 mmol) and $[Pd(PPh_3)_4]$ (0.5 mmol) in methanol/toluene (70 mL, 1:1) was stirred. After 5 min, a 2 M Na_2CO_3 solution (4 mL) was added. The reaction mixture was then stirred while heating at reflux for 5 h at 140 °C. After addition of water (100 mL) and cooling to room temperture, the mixture was extracted with ether (3 × 25 mL). The combined organic solution was washed with water, dried ($MgSO_4$) and concentrated. Purification by column chromatography (SiO_2, 200 g, hexanes/ether, 10:1) yielded **3j** (7.8 g, 95%) as a colorless oil. ^1H NMR (250.132 Hz, $CDCl_3$, 25 °C): δ = 0.11 (s, 9H, $Si(CH_3)_3$), 3.93 (s, 2H, CH_2), 7.19 (d, 1H, J = 1.2 Hz, H5), 7.31 (d, 1H, J = 1.2 Hz, H2), 7.34 (d, 2H, J = 8.7 Hz, *m*-H(NO_2)), 8.11 (d, 2H, J = 8.7 Hz, *o*-H(NO_2)); ^{13}C NMR (62.896 Hz, $CDCl_3$): δ = – 0.81 (q, $Si(CH_3)_3$), 31.52 (t, CH_2), 118.90 (s, C4), 123.22, 123.35

(each d, each 1C, *o*-C(NO_2)), 126.02 (s, C3), 129.29, 129.58 (each d, each 1C, *m*-C(NO_2)), 141.34 (d, C2), 146.58 (s, *p*-C(NO_2)), 148.05 (s, CNO_2), 148.88 (d, C5); EI-MS (70 eV): *m/z* 275 (M^+, 29%), 260 (M^+ − Me, 100), 199(30), 180(33), 137(18), 73 ($Si(CH_3)_3$, 27).

4j: To a solution of **3j** (7 mmol) in CH_2Cl_2 (200 mL) was added slowly a 1.0 M solution of BCl_3 in CH_2Cl_2 (14 mL) under a nitrogen atmosphere at room temperature. The reaction was quenched with 2 M Na_2CO_3 solution, and the mixture extracted with ether (3 × 20 mL). The organic layer was dried ($MgSO_4$), and the solvent evaporated off. The crude product was chromatographed (SiO_2, 250 g, hexanes/ether, 1:1) to give **4j** (0.98 g, 61%) as a semisolid. ^1H NMR (250.132 Hz, $CDCl_3$, 25 °C): δ = 4.11 (s, 2H, CH_2), 7.16 (s, 1H, H5), 7.34 (d, 2H, J = 8.6 Hz, *m*-H(NO_2)), 7.83 (s, 1H, H2), 8.08 (d, 2H, J = 8.6 Hz, *o*-H(NO_2)); ^{13}C NMR (62.896 Hz, $CDCl_3$): δ = 30.80 (CH_2), 113.85 (br. s, C3), 123.45, 123.61 (each d, each 1C, *o*-C(NO_2)), 126.11 (s, C4), 129.11, 129.33 (each d, each 1C, *m*-C(NO_2)), 141.98 (d, C5), 146.80 (s, *p*-C(NO_2)), 148.17 (s, CNO_2), 155.19 (d, C2); EI-MS (70 eV): *m/z* 687 (M^+, 19%), 203(75), 128(100).

5j: A mixture of **4j** (0.32 mmol), 9-bromophenanthrene (0.96 mmol), and [Pd(P-$Ph_3)_4$] (0.1 mmol) in methanol/toluene (30 mL, 1:1) was stirred for 5 min, where upon 2 M Na_2CO_3 solution (3 mL) was added. The reaction mixture was again stirred while heating at reflux for 5 h at 140 °C. After addition of water (50 mL) and cooling to room temperature, the mixture was extracted with ether (3 × 20 mL). The combined organic solution was washed with water, dried ($MgSO_4$), and concentrated. Purification by column chromatography (SiO_2; 20 g, hexanes/ether, 7:1) yielded **5j** (317 mg, 87%) as semisolid. ^1H NMR (250.132 Hz, $CDCl_3$ 25 °C): δ = 3.51 (s, 2H, CH_2), 6.80 (d, 2H, J = 8.5 Hz, *m*-H(NO_2)), 7.24–7.68 (m, 10H), 8.53 (t, 2H, J = 8.0 Hz, *o*-H(NO_2)); ^{13}C NMR (62.896 Hz, $CDCl_3$): δ = 30.23 (CH_2), 122.52, 122.85, 123.13, 126.41, 126.57, 126.90, 128.40, 128.89, 129.25 (each d, each 1C), 124.21, 124.89, 127.98, 130.15, 130.42, 131.25, 131.54, (each s, each 1C), 140.43 (d, C2), 141.52 (d, C5), 146.31 (s, *p*-C(NO_2)), 147.37 (s, CNO_2); EI-MS (70 eV): *m/z* 379 (M^+, 100%), 255(26), 184(33), 119(42), 118(42).

A Short Synthetic Route towards a Biologically Active Heparin-like Pentasaccharide with a Pseudo-Alternating Sequence**

By *Hans Lucas, Jan E. M. Basten, Peter Konradsson* and *Constant A. A. van Boeckel**

It is now well established that only a small heterogeneous pentasaccharide domain[1, 2] of the anti-thrombotic drug heparin (a glycosaminoglycan) is responsible for the inactivation of blood coagulation factor Xa (αXa-activity) mediated by antithrombin III (AT III). The synthetic pentasaccharide **15a**, which has an extra sulfate group at the 3 position in unit H[3] (Fig. 1), was found to be one of the most active counterparts of the unique heparin domain, eliciting an αXa-activity of 1250 U mg^{-1}.

Recently, it was discovered that the replacement of all "N-sulfate" groups in **15a** by "O-sulfate" functions and methylation of all free hydroxyl groups[4] to give the highly modified "nonglycosamino" glycan analogue **15b** actually increased the biological activity (compound **15b** displayed an αXa-activity of 1323 U mg^{-1}). In comparison with the syntheses of pentasaccharides corresponding to the unique heparin domain, the preparation of the nonglycosamino glycan analogue is much easier: a) The free hydroxyl groups are permanently blocked as methyl ethers meaning that the protecting group strategy required for the preparation of heparin fragments can be abandoned; it is not necessary to discriminate between sulfated (acyl esters) and nonsulfated (benzyl ethers) hydroxyl groups. b) No α-coupled glucosamines are present which require elaborate synthetic routes towards azide-containing building blocks. c) Selective N-sulfation need not be performed at the end of the synthesis.

Having the simplified derivative **15b** at our disposal, we wondered whether even shorter synthetic routes could be devised towards this compound or closely related analogues. With this in mind we designed analogue **15c** (Fig. 1), which has a pseudo-alternating sequence, that is, because of the

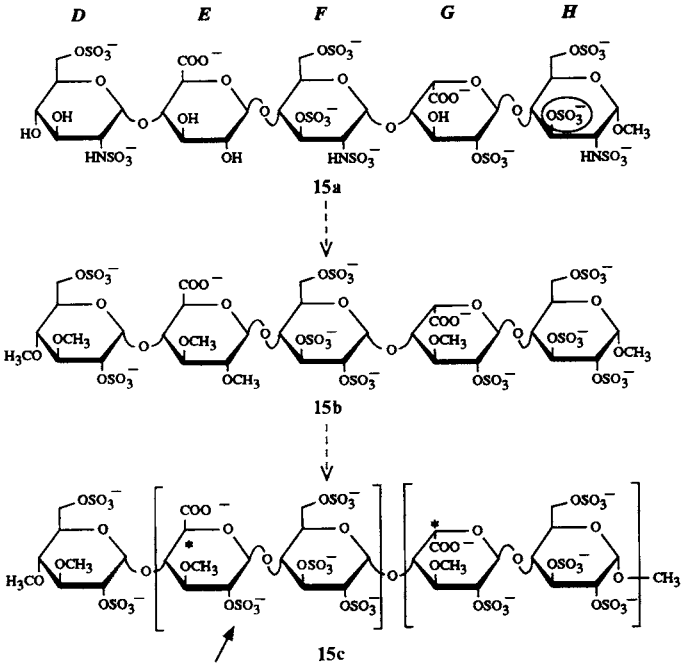

Fig. 1. Replacement of all *N*-sulfate groups in **15a** with *O*-sulfate groups and methylation of all free OH functions gives the active nonglycosaminoglycan analogue **15b**. In analogue **15c** an extra sulfate group in the 2-position of unit E (see arrow) has been introduced to create a pseudo-alternating sequence. The disaccharide fragments between brackets only differ in their configuration at C5 of the uronic acid moieties (*).

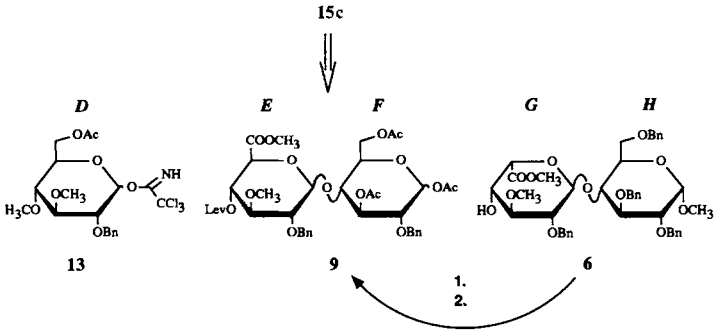
2-sulfate group at unit E, the disaccharide fragments EF and GH have the same substitution pattern.

The only remaining difference between the disaccharide fragments EF and GH of compound **15c** is the opposite configuration at C5 of the uronic acid moieties. Hence, a shorter synthetic route[5] to **15c** could be developed in which the disaccharide fragment EF is obtained from its counterpart GH by epimerization.[6] In the transformation of the epimerized GH building block into an appropriate EF glycosyl donor the acetolysis of the locked anomeric center also plays a pivotal role (Scheme 1).



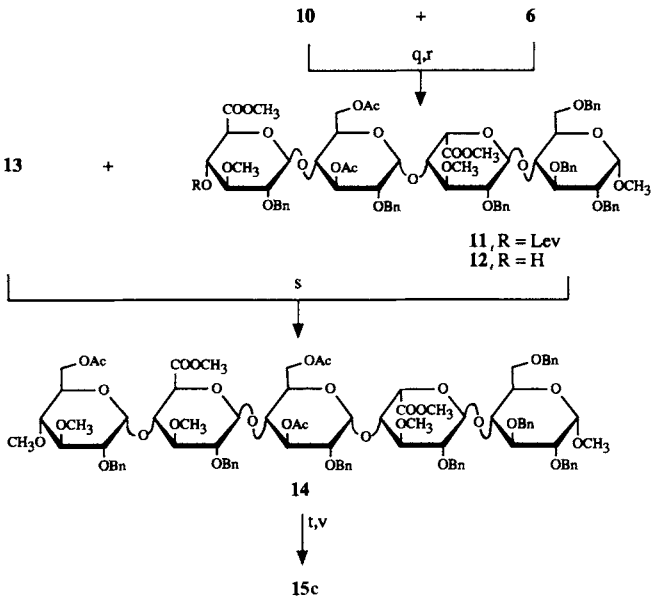
Scheme 1. The retrosynthetic analysis for pentasaccharide **15c** shown here is based on the epimerization (1.) and acetolysis (2.) of an iduronic acid GH disaccharide acceptor **6** to give an EF donor.

The key intermediate in the synthesis of pentasaccharide **15c** is the suitably protected iduronic acid building block **6**. Since the required epimerization is carried out under strongly basic conditions we had to protect the GH building block **6** exclusively with benzyl groups. Fortunately, this does not present a problem in this new series of pentasaccharides (in contrast to the synthesis of the natural fragments), as we can select ether or ester protecting groups for all hydroxyl groups to be sulfated. Glycosylation of the glycosyl acceptor **2**[7] with the known 3-*O*-methyl idopyranosyl fluoride **1**[4a] in the presence of $BF_3 \cdot OEt_2$ and 4 Å molecular sieves in dichloromethane at 0 °C gave the disaccharide fragment **3** in 90% yield (Scheme 2). Saponification of the ester functions of compound **3** and subsequent introduction of the 4′,6′-benzylidene acetal afforded intermediate **4** in an overall yield of 64%. Next, the free hydroxyl group of compound **4** was quantitatively benzylated to afford crystalline **5**. According to well-established reaction sequences[4a, 8] compound **5** could be converted into the key intermediate **6** in 41% overall yield. Compound **6** was then treated with sodium methoxide in methanol under reflux (16 h) to accomplish the C5′ epimerization. Despite the strictly anhydrous conditions, hydrolysis of the methyl ester could not be avoided during the epimerization reaction. Hence, after neutralization of the reaction mixture with DOWEX H^+, the free carboxylate group was methylated with CH_3I in *N*,*N*-dimethylformamide (DMF) and in the presence of $KHCO_3$ to give a mixture of **7** and **6** (ratio 10:1). After purification over silica gel the glucuronic acid fragment **7** was isolated in about 73% yield together with recovered **6** (7%). Protection of the free

(50%, steps f–j); k) NaOMe, MeOH, reflux, 16 h; l) $KHCO_3$, CH_3I, DMF, MS 4 Å, RT, 3 h (73%, steps k–l); m) levulinic acid, DCC, dioxane, DMAP, RT, 2 h (97%); n) HOAc/Ac_2O/TFA 1/25/3.5, RT, 2 d; o) piperidine, THF, RT, 16 h; p) Cs_2CO_3, $NCCCl_3$, CH_2Cl_2, RT, 0.5 h (75%, steps n–p). Lev = $OC(O)CH_2CH_2C(O)CH_3$.

4′-hydroxyl group in **7** as a levulinoyl ester afforded compound **8**, which was acetolyzed in a mixture of trifluoroacetic acid/acetic anhydride/acetic acid (3.5/25/1, v/v/v). Under the aforementioned conditions we observed the acetolysis of the anomeric center as well as of the 3- and 6-benzyl ethers.[9, 10] Fortunately, the 2-benzyl ether essential for the subsequent introduction of an α-glycosidic linkage remained unaffected.

After two days at room temperature disaccharide **9** was formed in nearly quantitative yield. The anomeric acetate of compound **9** was selectively removed by treatment with piperidine in THF. The trichloroacetimidate function was then introduced in a mixture of dichloromethane and trichloroacetonitrile and in the presence of cesium carbonate[11] to give the desired EF glycosyl donor **10** in 75% overall yield. Coupling of disaccharide donor EF (compound **10**, 1.2 equiv) and acceptor GH (compound **6**) in dichloromethane with trimethylsilyltriflate as promoter in the presence of 4 Å molecular sieves at −15 °C afforded tetramer **11** in a yield of 75% (Scheme 3). Selective removal



Scheme 3. q) $Me_3SiO_3SCF_3$(TMSOTf), CH_2Cl_2, MS 4 Å, −15 °C, 1 h (75%); r) $H_2NNH_2 \cdot H_2O$, HOAc, pyridine, RT, 6 min. of the levulinoyl function of **11** afforded acceptor **12**, which was then glycosylated with the known glycosyl donor **13**[4c] at low temperature under the same conditions as described for the preparation of **11**. The fully protected pentasaccharide **14** was obtained in a yield of 65% after chromatography. Successive saponification, hydrogenolysis, and sulfation of compound **14** according to described procedures[12, 13] afforded the *O*-methylated/sulfated analogue **15c** in about 76% overall yield. Pentasaccharide **15c**[14] displayed a high αXa-activity of 1025 U mg^{-1} in an amidolytic assay.

In comparison with the synthesis of the analogues of the natural product (e.g. compound **15a**), which requires about 60 steps, this preparation of a biologically active pentasaccharide is much more efficient and opens new perspectives for the development of biologically active heparin-like drugs.

[5] A similar synthetic route can be used for a methylated/sulfated analogue which contains 2,3-di-*O*-methyl-substituted uronic acid moieties. The preparation of this compound and others in the series of methylated/sulfated analogues will be published elsewhere.
[6] Apparently the configuration of the glucuronic acid moiety is lower in energy than the corresponding iduronic acid. Epimerization attempts on glucuronic acid model compounds led to little if any of the iduronic acid entities.

A Simple One-Step Synthesis of Symmetrical Thiocrown Ethers and the Molecular Structure of an Unusual Sandwich-like Tetrametallic Silver Thiocrown Ether Complex**

By *Jilles J. H. Edema,* H. Thijs Stock, Jan Buter, Richard M. Kellogg,* Wilberth J. J. Smeets, Anthony L. Spek*, and *Fre van Bolhuis*

Many heavy metal ions are known to complex easily with thiocrown ethers.[1–7] This phenomenon has stimulated wide interest in the design of ion-selective receptors for heavy metals like Ag, Cd, Cu, and Hg,[1–4] which has led to significant improvements in the syntheses of macrocyclic thioethers during the past two decades. In particular, Mo-,[5] Ru-,[6] and Cs-based[7, 8] syntheses along the lines of the 1 + 1 approach depicted in Scheme 1 have allowed the isolation of preparative quantities of the desired macrocycles. The key point in these cyclizations is the experimentally enforced preference for cyclization over polymerization.[7] We now report a new simple method for the one-pot preparation of cyclic oligothioethers, which, in many cases, are formed

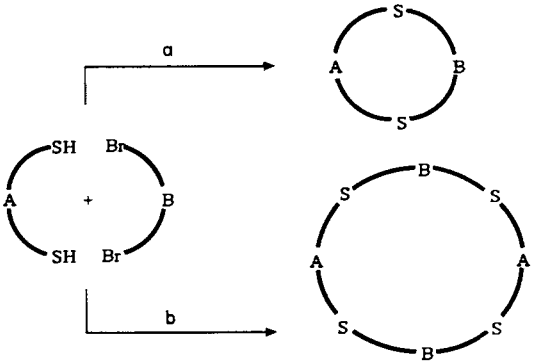
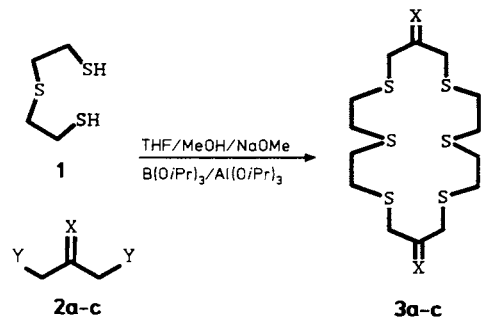
[**] The crystallographic facilities in Utrecht are supported by the Netherlands Foundation for Chemical Research (S. O. N.).

by a 2+2 coupling (Scheme 1, method b). An advantage of this new method, in addition to the good yields, is its applicability in the presence of functional groups such as ketones and alkenes.



Scheme 1. Syntheses of thiocrown ethers. a) 1+1 approach, for example, with Cs_2CO_3 in dimethylformamide (DMF); b) 2+2 approach with $B(OiPr)_3$/$Al(OiPr_3)$.

Reaction of **1** with 1,3-dibromopropane (**2a**) in THF/alcohol mixtures in the presence of a 5:1 B/Al-alkoxide couple afforded 1,4,7,11,14,17-hexathiaicosane (**3a**) in 52% yield. In contrast the corresponding 10-membered ring system (the 1+1 product) is formed exclusively by the reaction of the Cs salt of **1** with **2a** in DMF;[7d] **3a** was contaminated with only traces of the 1+1 product.



a, X = H_2, Y = Br, **b**, X = O, Y = Cl, **c**, X = CH_2, Y = Cl

Somewhat in contrast to the above results, the analogous reaction of **1** with 1,4-dibromobutane gave rise to the formation of a 1:4 mixture of 11- and 22-membered (1+1 and 2+2 products, respectively) rings.[10] The ratios of the products were determined by ^1H NMR and ^{13}C NMR spectroscopy. The 1+1 products (S_3-cyclophanes) are formed exclusively in yields of 85% or higher from the reaction of **1** with *ortho, metha*, and *para*-α,α'-xylylene dibromides.[11]

The molecular structure of **3a** is illustrated in Figure 1. The molecule is centrosymmetric; the sulfur atoms adopt an overall *anti* arrangement with respect to each other and point away from the molecular cavity. This arrangement is found in most large macrocyclic thioethers containing S-C-C-S linkages.[1, 7-9]

The reactions of **1** with 1,3-dichloroacetone (**2b**) or 3-chloro-2-(chloromethyl)propene (**2c**) proceed essentially as with (**2a**), leading to the formation of 9,19-dioxo-1,4,7,11,14,17-hexathiaicosane (**3b**) and 9,19-dimethylene-1,4,7,11,14,17-hexathiaicosane (**3c**) in 42 and 67% yields

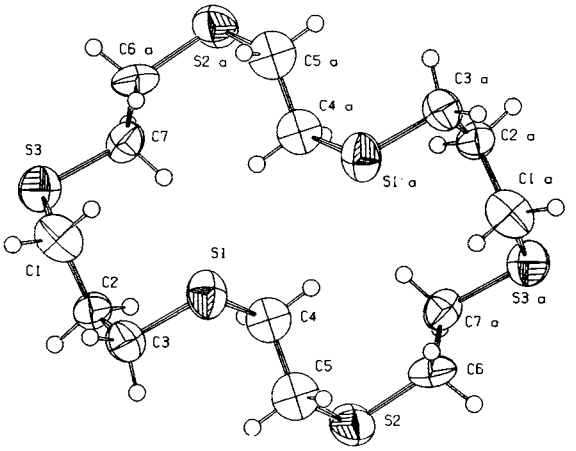


Fig. 1. Molecular structure of **3a** (thermal ellipsoids for 50% probability). Selected dihedral angles [°]: S1-C4-C5-S2 176.2(11), S2-C6-C7a-S3a −175.2(6), S3-C1-C2-C3 164.0(10) [15].

(non-optimized), respectively. Only minor quantities (<5%) of 1+1 products could be detected.

The molecular structure of **3b**, as determined by us, is shown in Figure 2. The highly symmetrical molecule possesses an inversion center. As in **3a**, the sulfur atoms point away from the molecular cavity, but the two carbonyl groups point inward into the cavity. As found for **3a** and other large cyclic oligothioethers, the S-C-C-S linkages are nearly perfectly *anti*:[1-4, 8, 9, 12] The dihedral S-C-C-S angles have values ranging from 175 to 177° and these compare well with those found in **3a**. During the course of the investigations reported here, we became aware of an alternative synthesis and solid-state structure of **3b** (in 6% yield) reported by Setzer et al.[13]

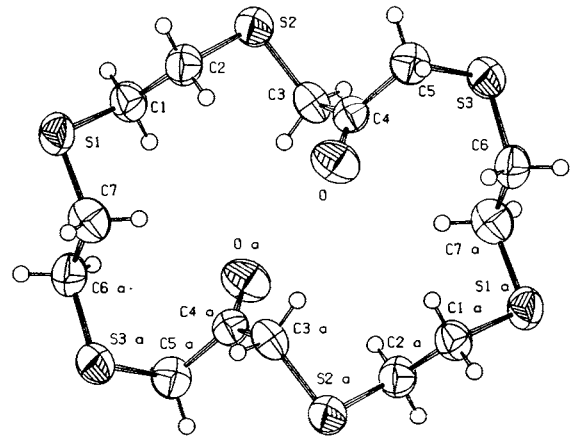

Fig. 2. Molecular structure of **3b** (thermal ellipsoids for 50% probability). Selected dihedral angles [°]: S1-C1-C2-S2 −176.3(2), S3-C6-C7a-S1a 175.7(2), O-C4-C5-S3 108.3(4), S2-C3-C4-O 104.4(4) [16].

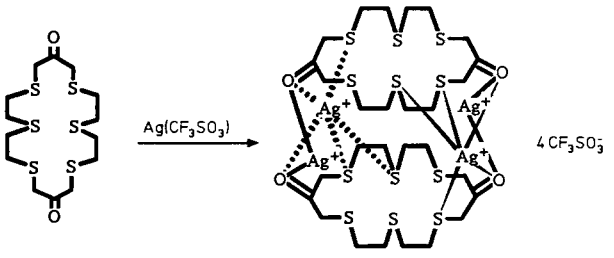
Suitable crystals of the free ligand **3c** have not yet been obtained. Comparison of the spectroscopic data of **3c** with those of a sample prepared by an unambiguous multistep synthesis employing Cs thiolates, established the 2+2 composition of **3c**; this was further confirmed by mass spectrometry.

The mechanism of cyclization is unclear. Aggregates involving B and Al dithiolates are thought to form under the conditions used. Understanding of the nature of this aggre-

gate structure is necessary before the factors that determine 1+1 or 2+2 cyclization can be defined. Experiments with 1+1 products in the presence of the B/Al alkoxido couple indicated no trace of interconversion into 2+2 products.

It has recently been reported that in the presence of the Lewis acid $BF_3 \cdot Et_2O$, 1,4-dihydro-2,3-benzodithiin reacts with alkenes to form mixtures of 2+2 and 1+1 products.[14]

Complexation of **3b** with $Ag(CF_3SO_3)$ in THF/MeCN proceeds smoothly and forms irreversibly the tetracation $[(\mathbf{3b})_2Ag_4]^{4+}$ as the $CF_3SO_3^-$ salt, in the form of colorless crystals. From conductometric titration experiments[19] in MeCN, the direct formation of 2:4 adducts was established without detectable formation of 1:1 adducts. Furthermore, conductometric experiments with preformed salt established that the $[(\mathbf{3b})_2Ag_4]^{4+}$ fragment is stable in solution. The sandwich-like structure probably prevents nucleophilic attack of solvent molecules at the metal centers.



3b $[(\mathbf{3b})_2Ag_4](CF_3SO_3)_4$

The molecular structure of $[(\mathbf{3b})_2Ag_4](CF_3SO_3)_4$ has been established by X-ray diffraction methods (Fig. 3). The cation is centrosymmetric and consists of four Ag^+ ions that are arranged in a quadrangular fashion. The two thiocrown ethers are positioned above and below the Ag_4 plane. The four $CF_3SO_3^-$ ions are placed rather loosely around the molecular core of the cation without any significantly short Ag–O contacts in accord with the results of the conductometric experiments.

The thioether ligand is slightly folded as a result of coordination to the silver ions. In contrast with free **3b** the sulfur atoms are arranged *gauche* to each other (S-C-C-S angles ranging from 60–120°). Thus a major conformational rearrangement occurs on complexation.

The Ag–S bond lengths are reasonably similar and range from 2.52 to 2.61 Å, and thus compare well with those found in other Ag^+–thiocrown ether complexes and related compounds.[1, 2, 5, 6, 7d, 12]

The simultaneous bridging coordination of the carbonyl groups to the two Ag^+ ions is unexpected. The Ag–O bond lengths range from 2.56 to 2.76 Å and are comparable with those in the closely related Ag^+ complexes of 3-oxo-1,4,8,11-tetrathiacyclotetradecane[6] and 3-oxo-1,5-dithiacycloheptane.[12]

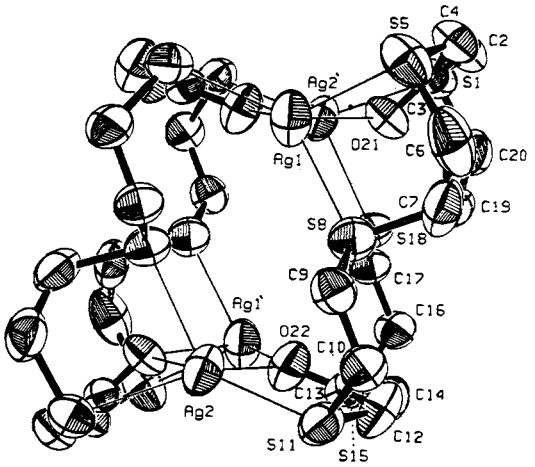


Fig. 3. Molecular structure of the cation in $[(\mathbf{3b})_2Ag_4](CF_3SO_3)_4$ (thermal ellipsoids for 50% probability). Selected bond lengths [Å] and angles [°]: Ag2'-O21 2.817(3), Ag2-O22 2.669(3), Ag1-O21 2.175(3), Ag1'-O22 2.527(3); S1-C2-C3-C4 −171.90(30), S1-C2-C3-O21 8.6(6), S5-C6-C7-S8 −60.07(47), S8-C9-C10-S11 −66.18(36), S15-C16-C17-S18 67.83(37), S18-C19-C20-S1 59.43(45), S11-C12-C13-O22 18.45(5), S11-C12-C13-C14 −161.73(32), O21-C3-C4-S5 −6.35(57) [17].

Experimental Procedure

$Ag(CF_3SO_3)$, **1**, **2a**, **2b**, **2c**, and MeCN (HPLC grade) were purchased from Aldrich and used without further purification. ^1H NMR and ^{13}C NMR spectra were recorded on a Varian 200 MHz spectrometer. IR spectra were obtained from a Perkin Elmer 768 spectrophotometer.

Synthesis of **3a** as a typical example: To a solution of $B(OiPr)_3$ (5 mmol) in THF (250 mL) was added $Al(OiPr)_3$ (1 mmol) and MeOH (40 mL). The mixture was refluxed for 30 min, after which Na (20 mmol) was added. The mixture was then refluxed until the sodium had dissolved. After the mixture had been cooled to 20 °C, **1** (10 mmol) was introduced over 15 min. The solution was subsequently refluxed again for 60 min. The mixture was kept at reflux and a solution of **2a** (10 mmol) in THF (75 mL) was added dropwise over a period of 8–10 h. After the addition was complete, the stirring was continued for 4 h. The mixture was evaporated to dryness and the residue was redissolved in CH_2Cl_2. The organic layer was washed with brine to remove the borate and aluminum salts. The solvent was removed in vacuo and the residual solid was chromatographed over silica gel with CH_2Cl_2/hexane 2/1 as eluent. The organic layer was evaporated to provide the product, yield 52%. ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 1.83 (quint.), 2.66(t), 2.76(m); ^{13}C NMR (50.3 MHz, $CDCl_3$, 25 °C): δ = 29.52(t), 30.62(t), 32.17(t), 32.34(t); IR(KBr): ν[cm^{-1}] = 2950m, 1400s, 1280s, 1210m, 1080s, 920w; MS (70 eV): *m/z* 388.031 (theor. 388.032).

3b: Yield 42%. ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 2.72(s), 3.54(m); ^{13}C NMR (50.3 MHz, $CDCl_3$, 25 °C): δ = 31.17(t), 31.85(t), 37.51(t), 204.01(s); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2995m, 1734m, 1689s, 1646m, 1558w, 1425s, 1400s, 1393s, 1297s, 1278s, 1255s, 1222m, 1204s, 1195s, 1147s, 1076s, 945s, 890w, 880m; MS (70 eV): *m/z* 416.010 (theor. 416.010).

3c: Yield 53%. ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 2.75(m), 3.33(s), 5.11(s, br); ^{13}C NMR (200 MHz, $CDCl_3$, 25 °C): δ = 31.18(t), 31.83(t), 35.51(t), 115.99(t), 140.87(s); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2930s, 1719m, 1636m, 1524w, 1425s, 1380w, 1268m, 1230m, 1198s, 1120s, 1020w, 917s, 784m; MS (70 eV): *m/z* 412.051 (theor. 412.051).

$[(\mathbf{3b})_2Ag_4](CF_3SO_3)_4$: To a solution of **3b** (5 mmol) in THF/MeCN (50 mL) was added $Ag(CF_3SO_3)$ (2 mmol) in MeOH (40 mL). The mixture was refluxed for 50 min. The mixture was evaporated to dryness and the residue was redissolved in MeCN. The solution was layered with diethyl ether after which white crystals separated; yield 67%. ^1H NMR (200 MHz, CD_3CN, 25 °C): δ = 2.99 (s, 16H), 3.57(s, 8H); ^{13}C NMR (50.3 MHz, CD_3CN, 25 °C): δ = 33.21(t), 33.62(t), 41.49(t), 214.01(s); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2995m, 1734m, 1689s, 1646m, 1558w, 1425s, 1400s, 1393s, 1297s, 1278s, 1255s, 1222m, 1204s, 1195s, 1147s, 1076s, 945s, 890w, 880m.

[15] Crystal data for **3a**: $C_{14}H_{28}S_6$, $M = 388.77$, monoclinic space group $C2/c$, $a = 22.485(4)$, $b = 5.4334(10)$, $c = 17.894(3)$ Å, $\beta = 117.63(2)^\circ$, $V = 1936.9(7)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.333$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 6.7$ cm^{-1}. Data were collected on a CAD 4 ($Mo_{K\alpha}$, Zr-filtered, $\theta_{max} = 27.5^\circ$) for a colorless transparent crystal. The structure was solved with the TREF option of the SHELXS-86 program. An empirical absorption correction was carried out with DIFABS. The structure was refined by full-matrix least-squares on F with SHELX-76. A disorder model was used to describe a 53:47 conformational disorder in part of the ring. Convergence was reached at $R = 0.078$ ($R_w = 0.053$, $w^{-1} = \sigma^2(F) + 0.000043F^2$) for 592 reflections with $I > 2.5\sigma(I)$ [18].

[16] Crystal data for **3b**: $C_{14}H_{24}S_6O_2$, $M = 416.74$, monoclinic space group $P2_1/c$, $a = 10.3406(5)$, $b = 9.3270(4)$, $c = 11.1102(5)$ Å, $\beta = 108.363(3)^\circ$, $V = 1016.98(8)$ Å^3, $Z = 2$, $\rho = 1.361$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 6.5$ cm^{-1}. Data were collected on a CAD 4T with a rotating anode ($Mo_{K\alpha}$, 9 kW, $\theta_{max} = 27.5^\circ$) for a colorless crystal. The structure was solved with DIRDIF92 and refined by full-matrix least-squares on F with SHELX-76 to $R = 0.047$ ($R_w = 0.038$, $w^{-1} = \sigma^2(F)$) for 1395 reflections with $I > 2.5\sigma(I)$ [18].

[17] Crystal data for $[(\mathbf{3b})_2Ag_4](CF_3SO_3)_4$, $M = 930.61$, monoclinic space group $P2_1/n$ (approximate dimensions $0.45 \times 0.20 \times 0.15$ mm), $a = 14.920(1)$, $b = 12.237(2)$, $c = 16.426(1)$ Å, $\beta = 92.12(1)^\circ$, $V = 2996.9(9)$ Å^3, $Z = 4$, $\rho_{calcd} = 2.062$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 19.06$ cm^{-1}. Data were collected on a CAD 4 ($Mo_{K\alpha}$, Zr-filtered, $\theta_{max} = 27.5^\circ$) for a colorless transparent crystal. The structure was solved by direct methods and refined with full-matrix least-squares techniques to $R = 0.043$ and $R_w = 0.042$; $w^{-1} = \sigma^2(F)$ for 4430 reflections $I > 3.0\sigma(I)$ [18] including 361 parameters.

[18] Further details of the crystal structure determinations are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

Structure of Diamagnetic $[W(O\text{-}4\text{-}Me\text{-}C_6H_4)_2Cl_2(PMePh_2)_2]$ and Comparison with Related Paramagnetic 2,6-Diphenylphenoxido Complexes: A Steric Effect on π-Bonding and Electronic Structure**

By *Lauren M. Atagi* and *James M. Mayer**

Sterically demanding ligands have become increasingly important in modern inorganic and organometallic chemistry. Bulky ligands including phosphanes[1] and alkyl, aryl,[2] cyclopentadienyl,[3] alkoxide,[4] aryloxide,[5] amide,[6] and imido groups,[7] to mention just a few, have been utilized in advances ranging from carbon monoxide and arene hydrogenation[3-5] to well-defined olefin metathesis catalysts[7] to the study of multiple bonds between the heavier main group elements.[2] Bulky groups are typically selected for their steric properties, but can have a substantial electronic influence as well. For instance, the five methyl groups in η^5-C_5Me_5 (Cp*) make it a much more electron-donating ligand than η^5-C_5H_5 (Cp).[8] We describe here a new kind of electronic difference between bulky and unencumbered ligands, revealed by a comparison of tungsten(IV) aryloxido complexes $[W(OAr)_2Cl_2(PR_3)_2]$. In the complex with the small *para*-cresolato ligand, a short W–OAr bond is formed, whereas such a close approach is more difficult for the large 2,6-diphenylphenoxido ligand and results in weaker W–O π-bonding. As a result, the complexes have substantially different bond lengths and, most interestingly, different electronic ground states.

The phenoxido and cresolato complexes **1a** and **1b** were prepared by reaction of $[WCl_2(PMePh_2)_4]$ with phenol and

$[W(OPh)_2Cl_2(PMePh_2)_2]$ **1a**

$[W(O\text{-}4\text{-}Me\text{-}C_6H_4)_2Cl_2(PMePh_2)_2]$ **1b**

cresol, respectively.[9] Spectral and analytical data clearly indicate the compositions of the materials and that they are diamagnetic. The ^{1}H, ^{31}P, and ^{13}C NMR spectra are consistent with either all-*trans* (D_{2h}) or *trans-cis-cis* (C_{2v}) structures. We originally favored the latter because similar complexes **2** containing 2,6-diphenylphenoxido ligands were

$[W(O\text{-}2,6\text{-}Ph_2\text{-}C_6H_3)_2Cl_2(PMe_2Ph)_2]$ **2a**

$[W(O\text{-}2,6\text{-}Ph_2\text{-}C_6H_3)_2Cl_2(PMePh_2)_2]$ **2b**

reported by Rothwell and co-workers[5a] to have the all-*trans* configuration and to be paramagnetic (contact shifts in the ^{1}H NMR spectra).

We were therefore surprised when an X-ray crystal structure of **1b**[10] showed it to have the all-*trans* geometry (Fig. 1). Crystals of both **1b** and **2a** contain isolated mole-

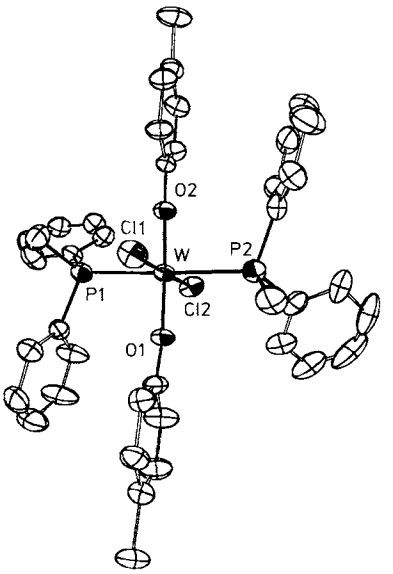

Fig. 1. Crystal structure of **1b** (ORTEP).

cules with close to regular octahedral geometries. The *trans* angles in **1b** are 177.5(3) (O-W-O), 177.5(1) (Cl-W-Cl), and 174.7(1)° (P-W-P), in **2a** they are crystallographically imposed 180° angles; the *cis* angles in both compounds range from 87 to 95°. The bond lengths, however, are quite different (see Table 1 which also contains data for the related tungsten(v) aryloxido complex **3**[5a]). The W–O distances in

$[W(O\text{-}2,6\text{-}Ph_2\text{-}C_6H_3)_2Cl_3(PMe_2Ph)]$ **3**

the cresolato complex **1b** are 0.12 Å shorter than those in the 2,6-diphenylphenoxido complex **2a**, while the W–Cl distances are ≈0.1 Å longer. The W–O bond lengths in **1b** are more comparable to those in the d^1 complex **3** (Table 1). The

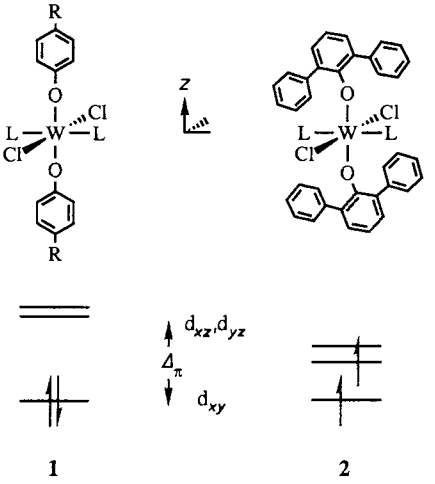
Table 1. Bond lengths [Å] and angles [°] of complexes **1b**, **2a**, and **3**.

	1b [a]	**2a** [b]	**3** [b]
W-O	1.848(5), 1.840(5)	1.966(4)	1.853(4), 1.877(4)
W-Cl	2.471(2), 2.440(2)	2.354(2)	2.351(2), 2.356(2), 2.392(2)
W-P	2.526(3), 2.534(3)	2.551(2)	2.579(2)
W-O-C	166.3(6), 171.7(5)	140.0(4)	[c]

[a] This work. [b] Ref. [5a]. [c] Not reported.

W-O-C bond angles are larger in the less crowded *para*-cresolato complex (average 169° in **1b**, 140° in **2a**); Rothwell et al. have shown that this parameter does not correlate with metal–oxygen distance or bond order but is rather primarily the result of steric or packing interactions.[11] The conformation in **1b** may be influenced by π-stacking interactions between the cresolato ligands and phenyl groups of the phosphane ligands, since the phenyl planes are close (3.47(2) and 3.77(2) Å apart, vs. 3.35 Å in graphite) and almost parallel (dihedral angles of 13(2) and 15(2)°).

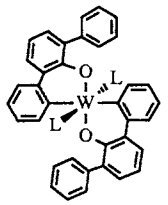
What is the origin of these structural differences and why are compounds **1** diamagnetic and **2** paramagnetic? These are very similar compounds: **1** and **2b** differ only in their aryloxido ligands, small OPh and O-*para*-tolyl versus 2,6-diphenylphenoxide (**2a** has a slightly different phosphane ligand, PMe_2Ph instead of $PMePh_2$). The fact that the W–O bonds in **1b** are 0.1 Å shorter than those in **2a** suggests a stronger bond in **1b**, most likely due to increased O → W π-bonding.[11] This π-bonding splits the three tungsten d_π orbitals—the octahedral "t_{2g}" set of orbitals that are roughly degenerate in the absence of π interactions. If the O-W-O axis is assigned as the *z* axis, π-donation from the aryloxido ligands raises the level of the d_{xz} and d_{yz} orbitals (Scheme 1). In compounds **1**, this splitting (Δ_π) is enough to cause the electrons to pair in the one nonbonding orbital, d_{xy}. But in **2**, the steric bulk of the aryloxido ligands makes it energetically costly for them to approach the metal closely enough to make strong π bonds, so the splitting Δ_π is smaller and the electrons unpair to give a paramagnetic ground state. This situation is analogous to the classical high-spin/low-spin dichotomy in octahedral d^4–d^7 complexes, except that here π-bonding alone accounts for the splitting within the octahedral t_{2g} manifold. As a result of the large bending of the aryloxido ligands in **2a** (W-O-C 140°) the d_{xz} and d_{yz} orbitals are also split; the O → W π-bonding is concentrated in the one unoccupied orbital and the π-antibonding interaction between the oxygen lone pairs and the unpaired electron in d_{xz} or d_{yz} is minimized. This antibonding interaction may contribute to the long W–O distances in **2a**.[12] In the d^1



Scheme 1. Qualitative energy level diagram illustrating the splittings of the d_π orbitals in **1** and **2**.

complex **3**, the electron occupies the nonbonding d_{xy} orbital and short W–O bonds are observed.

The key difference between **1** and **2** is *not* that the *para*-cresolato ligand is more electron rich than the 2,6-diphenylphenoxido ligand. Such substituent effects are typically invoked to explain differences between more and less bulky ligands, as in comparisons between Cp and Cp*. But complexes analogous to **1** with 4-phenylphenoxido and 4-bromophenoxido ligands are, like **1**, diamagnetic, even though 4-bromophenoxide is less electron-rich than 2,6-diphenylphenoxide. Similarly, a related tungsten complex with cyclometalated phenylphenoxido ligands (**4**, L = $PMePh_2$) is diamagnetic and has short W–O bonds comparable to those of **1b** because there is little steric penalty for a close approach of the aryloxido oxygen atom to the tungsten center.[13] The essential difference between **1** and



4

2 is that the 2,6-diphenylphenoxido ligand is so bulky that it cannot come close enough to the tungsten center to form strong π bonds. This may be the first clear example of a steric influence on metal–ligand π-bonding.

Experimental Procedure

$[WCl_2(PMePh_2)_4]$ (0.40 g, 0.38 mmol), toluene (17 mL), and *p*-cresol (0.44 g, 4.07 mmol, 11 equivalents) were stirred in a sealed tube at 25 °C for two weeks. The volatiles were removed and the residue washed with pentane and ether to give 0.20 g (61%) **1b**. For ^1H and ^{31}P NMR spectra see ref. [9]. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 162.2 (s, C-O), 140.0 (t, 20 Hz, *ipso* C-P), 133.5, 131.6, 129.7, 129.2, 116.9 (s, Ph), 20.6 (s, aryl-Me), 15.8 (t, 13 Hz, PMe). Satisfactory C,H,O-analysis.

The 4-phenylphenoxido and 4-bromophenoxido complexes were prepared by addition of $4\text{-}PhC_6H_4OH$ and $4\text{-}BrC_6H_4OH$ to $[WCl_2(PMePh_2)_4]$ in benzene. For $[W(O\text{-}4\text{-}Ph\text{-}C_6H_4)_2Cl_2(PMePh_2)_2]$ ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.5–6.8 (m, 38H), 1.83 (t, 3 Hz, 6H; PMe); ^{31}P NMR: δ = −87.0 (s, $J_{(W,P)}$ = 310 Hz); MS (FAB): *m/z* 995, 993 ($M + H^+$, 70%), 794, 792 ($M^+ - PMePh_2$, 100%). For $[W(O\text{-}4\text{-}Br\text{-}C_6H_4)_2Cl_2(PMePh_2)_2]$ ^1H NMR: δ = 7.60 (m, 8H; PPh_2), 7.06 (d, 9 Hz, 4H; OC_6H_4Br), 6.87 (m, 12H; PPh_2),

6.40 (d, $J = 9$ Hz, 4H; OC_6H_4Br), 1.56 (t, $J = 3$ Hz, 6H; PMe); ^{31}P NMR: $\delta = -104.6$ (s, $J_{(W,P)} = 306$ Hz); MS: m/z 1000, 998 (M^+, 80%), 800, 798 ($M^+ - PMePh_2$, 100%).

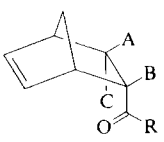
A New Photoreaction of γ,δ-Unsaturated Ketones: The Oxadi-π-ethane(ODPE) Rearrangement

By *Johannes Leitich* and *Kurt Schaffner* *

The readily accessible *endo*-Diels–Alder adducts **1** from 1,3-cyclopentadiene and *cis*- or *trans*-1-cyclohexenyl methyl (or phenyl) ketone or methyl vinyl ketone were prepared by us during an investigation of the photochemistry of these ketones.[1] Unexpectedly, we found a novel photoisomerization of **1**, which leads to the strained tricyclo[3.2.0.0][3,6]-heptane framework and, in some cases, occurs in high chemical yields.



1	A	B	C	R
a	$(CH_2)_4$		H	Ph
b	$(CH_2)_4$		H	Me
c	H	H	H	Me
d	H	$(CH_2)_4$		Me
e	H	$(CH_2)_4$		Ph

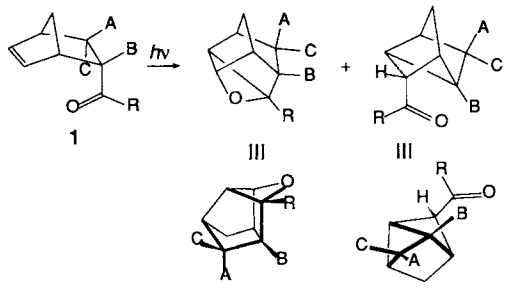
Stiftstrasse 34–36, D-W-4330 Mülheim an der Ruhr (FRG)

The intramolecular photoreactions of γ,δ-unsaturated ketones known so far include, depending on structural type, oxetane formation,[4, 5] oxa-ene addition,[4] cyclopentane ring closure,[4] β cleavage with the formation of allyl and oxaallyl radicals,[6] and *Z*/*E* isomerization of the C=C bond.[7] Sauers et al. observed the smooth formation of the oxetanes **2** on irradiation of numerous *endo*-bicyclo-[2.2.1]hept-2-en-5-yl-ketones of the type **1** (e.g. of **1c**[8]), and investigated these reactions in detail.[5] Correspondingly, we also found that **2a** and **2b**[9] form in a uniform way from **1a** and **1b**, respectively, on direct irradiation (conditions see Table 1); for **1a** also on triplet sensitization (Scheme 1).



Scheme 1.

However, on triplet sensitization of **1b**, surprisingly, the isomeric ketone **3b** was formed in approximately 60% yield and the expected product **2b** only in about 20% yield. The E_T value (triplet energy in kcal mol^{-1}) of the sensitizer benzonitrile (76.5[10]) indicates an excitation of the C=C bond (norbornene: $72.3 \leq E_T \leq 76$[11]), and not of the C=O bond (E_T value for acetone: 79–82).[12] In contrast to **1b**, under the same sensitization conditions **1c** only slowly formed the oxetane **2c** as the main product in addition to a mixture of undefined by-products. For **1d** and **1e** the formation of products of type **3** predominates: triplet-sensitized **1d** affords exclusively **3d**; on direct irradiation **1d** affords **2d** and **3d** in about equal yields. Finally, **1e**, in sharp contrast to **1a**, exclusively forms **3e** under both sets of conditions. These results are summarized in Table 1.

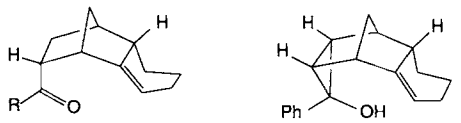
On direct irradiation **3e** undergoes an efficient secondary photoreaction to give **4** (R = Ph) and **5**; these products are formed in a ratio of 1:1.2. Correspondingly, **3d** is transformed into **4** (R = Me).[13] These secondary photoreactions are prevented completely by addition of the triplet quencher 1,3-pentadiene (1 M); in contrast, the formation of **3** (and **2**) is not influenced by this addition.

The decision whether **1** reacts to give **2** or **3** is influenced by at least three factors: first, by the electronic excitation

Table 1. Products (fractions were determined by ^{1}H NMR spectroscopy; 1.0 = 100% of the treated starting material) after direct irradiation and after triplet sensitization of compounds of the type **1**.

Compound	Direct irradiation [a]		Triplet-sensitized		
1	**2**	**3**	**2**	**3**	Conditions
a	1.0	0.0	1.0	0.0	[b]
b	1.0	0.0	0.2 [c]	0.6	[d]
c	1.0	0.0	0.8 [c]	0.0	[d]
d	0.5	0.5	0.0	1.0	[d, e, f]
e	0.0	1.0	0.0	1.0	[b, f]

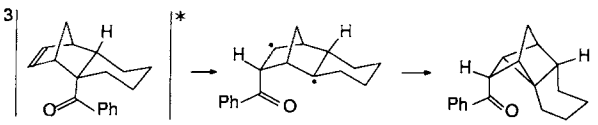
[a] $\lambda > 300$ nm; Hg high-pressure lamp, hexane or acetonitrile. [b] Acetophenone as solvent $\lambda > 300$ nm. [c] At present it cannot be excluded that the formation of **2** in these cases is a result of singlet sensitization by benzonitrile and/or the direct absorption of light occurring to < 1%. [d] Benzonitrile in *tert*-butyl alcohol, $\lambda = 254$ nm. [e] Acetone as solvent or acetophenone in benzene, $\lambda > 300$ nm. [f] Benzophenone in benzene, $\lambda > 300$ nm.



4 **5**

used, as shown by the examples **1b,d**; second, by the degree of alkylation at the C atom from which the acyl group shifts to form ultimately **3**, as shown by the comparison of **1b**/**1c**; third, the proximity of carbonyl C atom to the C=C bond (particularly in **1d,e**) favors the formation of **3**. This particular proximity of carbonyl C atom to the C=C bond in **1d,e** gives rise to a bathochromic shift of the longest wave ($n\pi^*$) UV absorptions by 450–500 cm^{-1} with respect to those of the corresponding hydrogenated ketones (for **1a,b** and **1c** a much smaller shift is observed). It also appears to lead to a large decrease in the energy of the lowest triplet state, as shown by the efficient sensitization of the formation of **3d,e** by benzophenone (E_T = 68.6); by contrast, for the formation of **3b**, benzonitrile (E_T = 76.5) is required.

The designation (in the title) "oxadi-π-ethane" rearrangement for the formation of **3** is derived from the analogy to the "di-π-ethane"[14] and the "oxadi-π-methane" (ODPM) rearrangements. The latter rearrangement, which has been known for a long time,[15] formally differs from the one described herein only by the presence of a second saturated C atom between the C=C and the C=O unit; as a result a 1,3 shift instead of a 1,2 shift of the acyl moiety occurs and a cyclobutane ring closure instead of a cyclopropane ring closure takes place. To our knowledge, a non-allylic 1,3 shift of the acyl moiety has not been observed so far. In addition to the described similarity there is a clear analogy to the ODPM rearrangement with regard to the dependence of the reactivity on the electronically excited state,[15] suggesting that the two rearrangements have similar mechanisms. Thus, the two-step mechanism formulated in Scheme 2, which uses **1e** as an example, is assumed.



^{3}[**1e**]* **3e**

Scheme 2.

[9] The molecular structures and the stereochemistry of all compounds were derived from their 400 MHz ^{1}H and 100 MHz ^{13}C NMR spectra (broad band decoupling, DEPT sequence) including ^{13}C/^{1}H COSY, ^{1}H/^{1}H spin-spin decouplings and NOE spectra. In these spectra all the resonance signals (except the badly resolved ones of the central sections of the tetramethylene bridges) could be assigned unequivocally. In addition, the molecular structure of **3e** was confirmed by a single-crystal X-ray structure analysis (I. Ortmann, C. Krüger, unpublished).
[10] Unless otherwise stated all E_T values are from: S.L. Murov, *Handbook of Photochemistry*, Dekker, New York, **1973**.

[12] Acetophenone (E_T = 73.7) had no effect as sensitizer; acetone (as solvent, E_T = 79–82) led to a complex mixture, containing no **2b** and only a little **3b**; instead it contained mainly products which seem to have resulted from a hydrogen transfer from acetone to the excited C=C bond.
[13] These reactions are apparently induced by a δ-H abstraction by the oxygen atom of the excited carbonyl group. The resulting 1,5 diradical stabilizes by fragmentation of a strained C–C bond to give a 1,3 diradical, which reacts to give **4** and **5**.

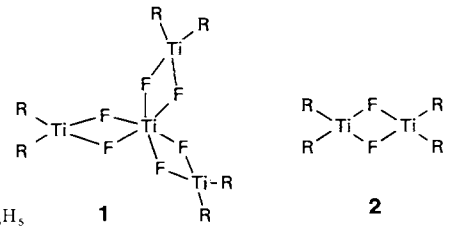
Organometallic Titanium Complexes with Unpaired Electrons: Syntheses and Structures of $[\{(\eta^5\text{-Cp})_2TiF_2\}_3Ti]$ and $[\{(\eta^5\text{-Cp}')_2TiF_2\}_3Al]$**

By *Feng-quan Liu, Heinz Gornitzka, Dietmar Stalke,* and *Herbert W. Roesky**

Dedicated to Professor Jean'ne M. Shreeve on the occasion of her 60th birthday

The polynuclear titanium complexes previously reported[1] all contain titanium in its highest oxidation state. Well-known paramagnetic d^1 electron systems such as $[\{Cp(C_5H_4)TiOH\}_2]$[2] (Cp = η^5-C_5H_5), $[\{Cp_2Ti(\mu\text{-}H)_2\}_2AlCl]$,[3] $[\{Cp_2TiX\}_2ZnX_2]$[4] (X = Cl, Br), or $[\{Cp_2TiCl\}_2MnCl_2]\cdot 2OC_4H_8$[5] are formed with a maximum of two titanium atoms. All these complexes have oxo, hydrido, chloro, or bromo bridging ligands. Since fluorine atoms have a marked tendency to form bridges, the syntheses of the corresponding fluorotitanium complexes should be possible.[6]

The reaction of $[Cp_2Ti(CO)_2]$[7] with $[Cp_2TiF_2]$[8] in a 1:1 ratio leads to the formation of the complexes **1** and **2**[9] (Scheme 1), as well as brown insoluble precipitate. Com-



Scheme 1. R = η^5-C_5H_5 **1** **2**

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Volkswagenstiftung, and the Fonds der Chemischen Industrie. We would like to thank D. F. Koch (Riedel-de-Haen, Seelze, FRG) for supplying the perfluorinated polyethers for the crystal application.

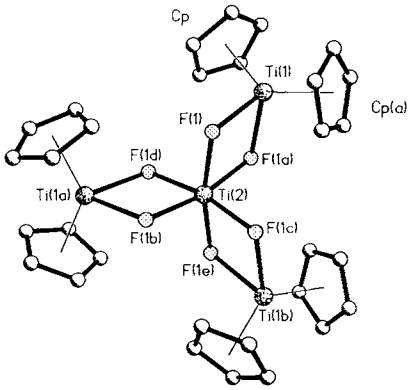

Fig. 1. Molecular structure of **1**. Selected distances [pm] and angles [°]: Ti2-T1 197.5(1), Ti1-F1 209.4(1), Ti1-Cp 204.4(1); F1-Ti2-F1a 76.18(6), Ti2-F1-Ti1 106.34(5), F1-Ti1-F1a 71.15(6), Cp-Ti1-Cp(a) 135.8; the planes of the three four-membered Ti_2F_2 propeller blades intersect with an angle of 86.5°.

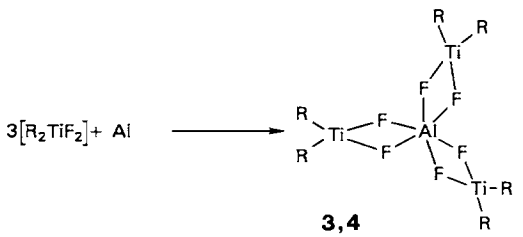
pound **1** crystallizes as blue crystals, whereas those of the known complex **2** are green. The X-ray structure analysis[10] reveals the characteristic structural feature of complex **1**; a distorted octahedral TiF_6 moiety at the central Ti2 atom (Fig. 1).

We replaced the central Ti atom with aluminum because for the latter the formation of an octahedral AlF_6 group is particularly favored. Indeed, $[Cp_2TiF_2]$ or $[Cp'_2TiF_2]$ ($Cp' = \eta^5$-C_5H_4Me) reacts with activated aluminum to give the compounds **3** and **4**, respectively (Scheme 2). The blue



Scheme 2. **3**: R = η^5-C_5H_5; **4** = η^5-C_5H_4Me.

complex **3** is slightly soluble in THF and toluene, and as expected **4** is more soluble in these solvents.

The structure of **4** was determined by X-ray structure analysis (Fig. 2) and found to be isostructural with that of **1**. The

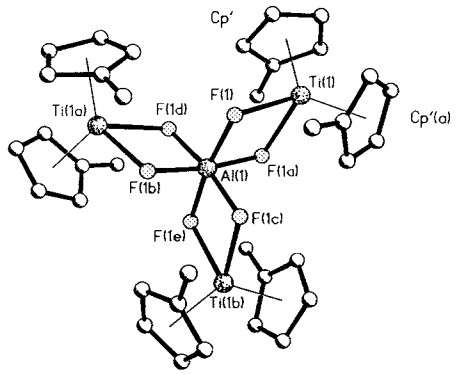


Fig. 2. Molecular structure of **4**. Selected distances [pm] and angles [°]: Al1-F1 181.2(2), Fi1-F1 209.5(2), Ti1-Cp 204.2(1), F1-Al1-F1a 80.91(10), Al1-F1-Ti1 105.40(8), F1-Ti1-F1a 68.29(9), Cp-Ti1-Cp(a) 134.3; the planes of the three four-membered $AlTiF_2$ propeller blades intersect with an angle of 86.9°.

four-membered Ti_2F_2 (**1**) and $AlTiF_2$ (**4**) rings in the two structures are unsymmetrical [**1**: Ti2–F1 197.5(1), Ti–F1 209.4(1) and **4**: Al1–F1 181.2(2), Ti1–F1 209.5(2) pm]; the octahedral coordination of the central atoms Ti2 and Al1, respectively is significantly distorted, and they are surrounded by the four-membered rings (Ti_2F_2 and $AlTiF_2$) in a propeller-like manner. The "propeller blade angle" between the planes of the four-membered rings is 86.5° in **1** and 86.9° in **4**. Because of the distortion of these rings [**1**: F1-Ti2-F1a 76.18(6)° and Ti2-F1-Ti1 106.34(5)°; **4** F1-Al1-F1a 80.91(10)° and Al1-F1-Ti1 105.40(8)°] a metal–metal bonding interaction can be excluded (**1**; Ti1 ··· Ti2 325.77(10); **4**: Al1 ··· Ti1 311.3(2) pm). A comparable nonbonding Ti ··· Ti distance of 319.5(4) pm was found in $[\{Cp(C_5H_4)TiOH\}_2]$.[2, 10] A similar coordination to the aluminum atom in **4** was found in $[\{(Me_3Si)_2N\}_2Al(NH_2)_2\}_3Al]$.[11]

The ESR spectra of the complexes **1** and **4** confirm the paramagnetic behavior. In toluene a very broad resonance signal is observed for each compound;[12] similar observations were made for $[\{Cp_2TiCl_2\}_2Zn]$.[4] Although, organometallic titanium and zirconium compounds, in combination with aluminum compounds, are mainly used as catalysts in the polymerization of olefins, very little is known to date about their interactions.[13, 14] Compounds **1**, **3**, and **4** are interesting examples of the symbiosis of classical Werner coordination and organometallic chemistry.

Experimental Procedure

1: A mixture of $[Cp_2Ti(CO)_2]$ (0.35 g, 1.5 mmol) and $[Cp_2TiF_2]$ (0.33 g, 1.5 mmol) in THF (50 mL) was stirred for 24 h at room temperature and 6 h at 70 °C. The solution turned green. After removal of the solvent and the volatile reaction products under vacuum the residue was crystallized from a hexane/THF (1:1) mixture. A brown amorphous solid remained. Blue crystals of **1** (0.11 g, 0.14 mmol) formed from the solution and subsequently green crystals of **2** [9] (0.23 g, 0.58 mmol). **1**: M.p. > 310 °C (decomp), MS(EI) *m/z* 197 (Cp_2TiF) biggest fragment; IR (Nujol) $\tilde{\nu}[cm^{-1}]$ = 3108, 1024m, 1012m, 804s, 498s, 405s; correct elemental analysis of $C_{30}H_{30}F_6Ti_4 \cdot C_4H_8O$ (768.2).

2: M.p. > 228 °C (decomp) MS(EI) *m/z* 216 (Cp_2TiF_2), 197 (Cp_2TiF). IR (Nujol): $\tilde{\nu}[cm^{-1}]$ = 3091m, 1093m, 793st, 471s; weak bands are not reported.

3: A solution of $[Cp_2TiF_2]$ (0.43 g, 2 mmol) in THF (50 mL) was added to Al (0.2 g) and stirred for 40 h at room temperature. A green solution and a blue solid were formed. The solution was filtered and the solid was extracted with toluene (50 mL). Yield of **3** 0.25 g (55%). M.p. > 320 °C (decomp) IR (Nujol) $\tilde{\nu}[cm^{-1}]$ = 3100m, 1017m, 800s, 617m, 552m, 397m; correct elemental analysis for $C_{30}H_{30}AlF_6Ti_3$ (675.2).

4: $[Cp'_2TiF_2]$ (0.5 g, 2 mmol) was dissolved in THF (50 mL) and treated with aluminum (0.1 g). The mixture was stirred for 2 d at room temperature, during which time the solution turned dark green. After the solution had been filtered the solvent was removed under vacuum. The residue was crystallized from hexane/THF (1:1); yield of **4** 0.35 g (70%). M.p. > 172 °C (decomp), IR (Nujol): $\tilde{\nu}[cm^{-1}]$ = 3119m, 1498m, 1353m, 1027m, 899m, 861m, 814m, 789m, 582s, 541m, 446s, 405m; correct elemental analysis for $C_{36}H_{42}AlF_6Ti_3$ (759.3).

BOOKS

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Book Reviews

Following the Trail of Light: A Scientific Odyssey. (Series: Profiles, Pathways, and Dreams. Series editor: *J. I. Seeman.*) By *M. Calvin.* American Chemical Society, Washington, DC, 1992. XXIII, 175 pp., hardcover $ 24.95.—ISBN 0-8412-1828-5

As a young assistant professor enamoured of coordination chemistry, I had occasion to refer frequently to Professor Calvin's 1952 monograph *Chemistry of the Metal Chelate Compounds* (coauthored with Arthur E. Martell). Therefore I regarded Calvin as an inorganic chemist. When he was awarded the 1961 Nobel Prize in chemistry "for his research on the carbon dioxide assimilation in plants", I began to think of him as an organic chemist. After reading his latest book, I have come to realize that this multidisciplinary scientist defies categorization. In explaining the book's title, "Following the Light", he states "The word 'light' was not meant in its literal sense, but in the sense of following an intellectual concept or idea to where it might lead" (p. 134). In promoting this goal, he assembled in his laboratory "scientists whose disciplines ranged from psychology to botany, from organic photochemistry to chemical evolution" (p. xxii).

Born on April 8, 1911 in St. Paul, Minnesota of emigrant parents (father from Lithuania; mother from Russian Georgia) of limited financial means, Calvin showed an early interest in science, dismantling his toys and reassembling them after understanding how they worked. The family moved to Detroit, Michigan, where he attended high school. With the aid of a scholarship he attended the Michigan College of Mining and Technology (now Michigan Technological University) but interrupted his studies there for a year to earn money as an analyst in a brass factory to continue his education. After receiving his B. S. degree in chemistry (1931) he worked on the electron affinity of halogen atoms under George C. Glockler at the University of Minnesota, from which he received his Ph.D. degree (1935). He spent the academic years 1935–1937 at the University of Manchester in England, where he worked on coordination catalysis, activation of molecular hydrogen, and metalloporphyrins with chemist, political scientist, economist, and philosopher Michael Polanyi, who introduced him to the advantages of the interdisciplinary approach to science that was to characterize Calvin's scientific career. In 1937, at the invitation of Gilbert Newton Lewis, whose intuitive approach to science also exerted a great influence on him, Calvin became an Instructor at the University of California, Berkeley, the first chemist not a UC graduate to be hired since 1912. He has remained at Berkeley ever since and is now University Professor of Chemistry.

Calvin's collaboration with G. E. K. ("Gerry") Branch resulted in the publication of *The Theory of Organic Chemistry* (1941), the first book on the subject written in the United States to employ quantum mechanics. Its publication marked the advent of theoretical organic chemistry in the United States and made Berkeley one of its foremost centers. The World War II years saw his work on the use of cobalt complexes that reversibly bond with molecular oxygen applied to an oxygen-generating machine for destroyers or submarines. He also became involved in the Manhattan Project, applying his expertise in chelation and solvent extraction to the problems of decontaminating (purifying) the irradiated uranium in fission products and isolating and purifying plu-

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1993 0570-0833/93/0303-0444 $ 10.00+.25/0

tonium. In 1942 he married Genevieve Jemtegaard, with whom he had two daughters and a son. Following the death of their first child because of R_h incompatibility, he collaborated with his wife to determine the chemical factors causing this problem. After the 1973 oil embargo the two worked together to seek plants, such as those of the genus *Euphorbia*, that would convert solar energy to hydrocarbons to be used as fuels, an area of research in which Calvin is still active.

When the radioisotope carbon-14 became available, Calvin, in 1946, begin his Nobel-winning work on tracing the path of carbon in photosynthesis. Simultaneously he investigated the electronic, photoelectronic, and photochemical behavior of porphyrins; molecular genetics; chemical evolution and organic geochemistry, including examination of organic constituents of lunar rocks; free radicals in reactions; the effect of deuterium in biological reactions; chemical and viral carcinogenesis; and artificial photosynthesis ("synthetic chloroplasts"). Calvin discusses all these topics as well as those previously mentioned. The history of the Bio-Organic Chemistry Group is related, from its inception in 1945 through its move to the new Laboratory of Chemical Biodynamics (1964) and, following Calvin's retirement as director in 1980, its present activity as the Melvin Calvin Laboratory, one of the world's first and foremost interdisciplinary laboratories. Calvin's numerous awards, honors, services, memberships, consultantships, books, and family relationships are discussed. The Nobel Prize ceremonies are described in detail by his wife, who died of cancer in 1987.

The book abounds with many of the maxims for which Calvin is justly famous, e.g., "It is better to act in relative ignorance than not to act at all" and "We are here to learn, and as chemists we can learn better than most". In addition to structural formulas, equations, reaction schemes, and figures, it contains 52 illustrations—not only formal photographs and informal snapshots but also congratulatory telegrams from the Nobel Foundation Secretary and U.S. President John F. Kennedy, as well as building plans (the circular Laboratory of Chemical Biodynamics, colloquially referred to as the "Round House" or "Calvin Carousel", with open laboratories, many windows, and few walls was specifically designed to promote Calvin's research philosophy of interaction, discussion, and cooperation). The volume is a gold mine of scientific and autobiographical data lacking in most scientific articles; Calvin even recollects the exact moment when his sudden insight into the cyclic character of the path of carbon in photosynthesis occurred (he was sitting at the wheel of his car waiting for his wife) (p. 68). Although scrupulously documented (101 numbered references, many of which are multiple ones), the book is eminently readable. A 12-page (2 columns per page) index facilitates access to specific information. I heartily recommend these engrossing memoirs of a fascinating, multifaceted scientific pioneer to scientists, historians of science, and all persons interested in research and its practice.

Semiclassical Mechanics with Molecular Applications. (International Series of Monographs on Chemistry, Vol. 25.) By *M. S. Child.* Oxford University Press, Oxford, 1991. X, 417 pp., hardcover £ 50.00.—ISBN 0-19-855654-3

To come straight to the point, this (long overdue!) monograph by Child meets the needs of theoretical chemists and molecular physicists who want a thorough, modern treatment of this important borderline area between classical mechanics and quantum mechanics, and may also wish to apply the knowledge. Although Child's treatment includes the traditional territory of semiclassical mechanics, such as the Bohr model of the atom, the Landau–Zener model for nonadiabatic transitions, the relationship between quantum-mechanical wave functions and classical trajectories based on the work of Jeffreys, Wentzel, Kramers, and Brillouin (JWKB theory), the quantization of nonseparable systems according to Einstein, Brillouin, and Keller (EBK theory), and the procedure for determining molecular potential curves from spectroscopic data based on the work of Rydberg, Klein, and Rees (RKR method), he goes far beyond this. Of even greater significance are the descriptions of important new developments and applications of semiclassical mechanics, few of which can yet be found in applications-orientated textbooks. Examples are the problems of the quantization of classical chaotic behavior, the classification of semiclassical approximation methods using catastrophe theory, modern semiclassical theories of reaction dynamics as developed by Marcus, Miller, and others, and Heller's revolutionary time-dependent approach to dynamics and spectroscopy based on Gaussian wavepackets. In brief, the book covers just about everything that one could wish for in semiclassical matters, clearly set out, and supported by about 500 carefully chosen references and useful author and keyword indexes.

However, some criticisms must also be mentioned. First, the level of treatment is not sufficiently uniform; depending on the topic under discussion it varies from elementary introductions for students to the sort of erudite information that passes from one expert to another. Just one example of this: Chapter 11 on "Wavepackets" begins with a very detailed explanation of Heller's concept of wavepackets described by properties and variables that are partly classical (trajectories) and partly quantum-mechanical (dispersion, coherence, interference). A well motivated student working through the first ten pages or so of this should be able to master the basic principles as applied to important areas of current research, and is also provided with a guide to the relevant original literature. But then things change—there follows in Section 11.4 ("Franck–Condon Transitions, Raman Spectroscopy, and Photodissociation") a four-page description of applications in spectroscopy and molecular reaction dynamics. Not a single example of photodissociation is given (there are so many interesting ones that could have been described!), and in all of this the relevant equations are presented to the unprepared reader without explaining the background.

A second weakness of the book is that some sections mention examples from the original literature without placing them within an appropriate larger context, as one should in a monograph. For example, in Section 7.3 ("Uniform Quantization at a Resonance") a system of coupled Morse oscillators is treated semiclassically using action angle variables, but the connection with the important Thiele and Wilson model for molecular vibrations is not explained. It would have been useful even to relate it to the nowadays common representation in terms of local, normal, and hyperspherical modes of vibration.

The third criticism is that Child's treatment is occasionally just a little slipshod. Apart from the incorrect spellings of some authors' names (Beidenharn, Engleke, Romelt, etc.), a more serious fault is that diagrams or even model systems are often reproduced from the original papers without taking the necessary care with detailed figure legends, labeling and scaling of graph axes, specifying the model Hamiltonian operator on which the analysis is based, etc.

The last criticism concerns a rather fundamental point. None of the examples of applications involves systems of more than one or two dimensions, except for a few rare literature references to systems of higher dimensionality. It might be argued that this is justified from a didactic standpoint, insofar as one starts with the simpler cases. On the other hand, students faced with the arduous task of ploughing through some of the more demanding parts of semiclassical theory may well ask themselves whether it is worth the effort, since the model systems treated in the book can nowadays be handled numerically by quantum-mechanical methods right from the start, with good accuracy and in a clearly understandable way. Child has undoubtedly succeeded here in clearly showing how semiclassical theory can explain many molecular phenomena. On the other hand, he has occasionally succumbed to the temptation to let formulas run riot, with results that can only be appreciated by readers who are already thoroughly familiar with the subject.

What is missing, in my view, is a clear and well-founded statement of the future outlook for semiclassical theory; one might claim, for example, that it offers the prospect of providing a satisfactory description of the dynamics and spectroscopy of complex multidimensional molecular systems that seem likely to remain untreatable by pure quantum-mechanical methods. But is this in fact true?

To summarize, this monograph is a must for departmental libraries concerned with theoretical chemistry and molecular physics. There is no other remotely comparable treatment of this topical field. However, the book should be read with a critical attitude.

Photochemistry in Organized and Constrained Media. Edited by *V. Ramamurthy*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1991. XVI, 875 pp., hardcover DM 236.00.—ISBN 0-89573-775-2/3-527-27936-9

How are photochemical and photophysical processes affected when one arranges for them to take place not in one of the usual solvents, but in a medium that restricts the mobility of the reactive molecules? For example, how is the selectivity of the [2+2]-photocycloaddition of cinnamic acid altered if, instead of irradiating the molecules in solution, one irradiates them in the ordered crystalline form, or how are the proportions of the different products altered when photolytic α-cleavage occurs within a zeolite? Can one control the selectivity of a photoreaction by first aligning the reacting molecules in an ordered environment? What types of media are suitable as matrices for ordering the molecules in this way? Such questions are not only of interest for potential applications in synthesis; their answers also yield new information about the mechanisms of photoreactions and the structures of the media. One of the scientists who has made important contributions to the progress of research in this area is V. Ramamurthy. His experience and knowledge of this subject was summarized several years ago in a comprehensive review article (*Tetrahedron* **1986**, *42*, 5753–5839). An updated and greatly augmented treatment has now been published in book form. Ramamurthy has brought together as authors 29 well-known specialists from the disciplines of organic chemistry, physical chemistry, and biochemistry. The resulting work can be read either in its entirety, as a definitive account of organic chemistry in "non-classical" reaction media, or selectively to learn about one or more of the specific topics covered in the 19 chapters. Although it is intended mainly for photochemists, it can also be recommended to other chemists who are interested in finding new ways of obtaining enhanced selectivity.

In Chapter 1, M. Garcia-Garibay and N. J. Turro explain their ideas for describing organized, supramolecular systems in terms of topological geometry. Taking as an example the α-cleavage of dibenzylketones, they show how different reaction media can be classified and compared from a topological standpoint. The reader thus obtains an insight into the concepts that underlie the studies described in the later chapters, and also an aid to interpreting the data that are presented.

Chapters 2, 3, 12, and 13 describe modern spectroscopic methods for studying ordered systems. K. Kalyanasunderam describes all the most important molecules that can be incorporated into micelles, vesicles, or biological membranes, or into cyclodextrins or zeolites, to act as fluorescence probes. He explains how such probes can be incorporated, and classifies them according to their interactions with the surrounding medium. C. Bohne, R. W. Redmond, and J. C. Scaiano describe experimental arrangements for laser spectroscopic studies, and show how these methods can be used to determine the physical properties of microheterogeneous systems; the main emphasis is on determining physical and kinetic parameters for micelles. D. Avnir and M. Ottolenghi discuss photophysical processes involving molecules adsorbed on the surfaces of heterogeneous catalysts. They start from the assumption that these surfaces are fractal in nature, and show that the effects of the surface properties on the reactivity of adsorbed substances can be calculated using exponential relationships of the kind that occur in fractal geometry. To conclude this group, W. R. Ware shows the kinds of information that time-resolved spectroscopy can yield regarding the kinetics of fluorescence quenching in microheterogeneous systems. Here again the main emphasis is on micelles, but work on cyclodextrins, silica gel, and biological systems is also featured.

The treatment of true photo*chemistry* starts with Chapter 4. Chapters 4–6, consisting altogether of about 170 pages, deal with photoreactions in crystals, subdivided into biomolecular photoreactions (Ch. 4, K. Venkatesan, V. Ramamurthy), monomolecular photoreactions (Ch. 5, J. R. Scheffer, P. R. Pokkuluri), and the preparation of chiral products in crystals (Ch. 6, M. Vaida, R. Popovitz-Biro, L. Leiserovitz, M. Lahav). The last-mentioned chapter contains a particularly interesting account of experiments aimed at using crystal symmetry to produce chiral products from achiral educts. Unfortunately, however, the quality of reproduction of some of the figures is poor.

Chapter 7 (V. Ramamurthy) is concerned with photoprocesses involving host–guest complexes in the solid phase. The center-point of this chapter is Ramamurthy's own work on Norrish reactions and photochemically-induced Fries rearrangements in cyclodextrins, but all the other important systems are also given an appropriate amount of space. It is regrettable that some of the guest systems described as being suitable for photoreactions are not accompanied by examples of reactions for which they have been used, and also that some of the figures are of poor quality: even readers already familiar with the subject will be unable to recognize in Figure 18 the effect referred to in the text.

Chapters 8–11 could be summarized under the general heading "Photoprocesses of Molecules Adsorbed on the Surface and in the Interior of Metal Oxides". In Chapter 8, L. J. Johnston has collected together the reactions of molecules adsorbed on silica gel and alumina, and arranged them according to reaction types. W. Jones then describes in Chap-

ter 9 photophysical processes involving molecules intercalated between the layers of clays, micas, and other metal oxide phases with layer structures. Chapter 10 (V. Ramamurthy) contains a review of photochemical reactions within zeolites, which is especially worth reading. Like Chapter 8, Chapter 11, by H. Al-Ekabi, dealing with photoelectron transfer induced reactions on the surface of semiconductor catalysts, is again classified according to reaction types.

Photophysical and photochemical processes in liquid crystals form the subject of Chapter 14 (R. G. Weiss). The author begins by considering photophysical processes in mesophases, and shows how the analysis of spectroscopic data yields information on the structures of excimers and exciplexes in these phases. This is followed by detailed descriptions of various chemical reactions, in particular of Norrish Type II reactions and [2+2]-cycloadditions.

Chapter 15, in which S. P. Spooner and D. G. Whitten deal with photoreactions in Langmuir–Blodgett films, is again logically divided into a physical part and a chemical part. The authors explain how the structure of the film determines which types of energy and electron transfer mechanisms are effective, and they describe some of the most important types of photochemical reactions for chromophores that are incorporated as subunits into the amphiphiles used to form the films. Examples of such reactions are the *cis–trans* isomerization of azobenzene, (reversible) [2+2]-cycloadditions, and reactions of merocyanine dyes. However, the authors do not give details of possible applications of Langmuir–Blodgett films, such as in information storage or in biochemical analysis.

In Chapter 16, A. Ueno and T. Osa describe two particularly interesting types of host–guest complexes, namely cyclodextrin complexes and systems containing crown ether structures. The section on the photochemistry of cyclodextrin complexes in solution is complementary to the discussion in Chapter 7, where the corresponding solid-phase reactions were described. That on crown ether systems contains a review of metal complexes that are of potential interest in relation to the development of an ion-specific photometric analysis method and the photoinduced transport of ions through membranes.

Chapters 17 and 18 discuss examples of photochemical processes in biological systems. C. V. Kumar reports some findings on details of the photochemistry of photosynthesis, and describes the use of DNA as an organized medium for influencing the selectivity of photochemical processes. R. S. H. Liu and Y. Shichida show how the *cis–trans* isomerization of retinal in rhodopsin is influenced by the protein environment. The collection ends with an article by D. F. Eaton (Chapter 19), giving some interesting examples of potential technological applications of photochemistry in organized media.

It is unfortunate that this otherwise very comprehensive and detailed collection of articles on photochemistry in organized systems includes nothing on the particularly important topic of micelles. The explanation given in the preface is that to include this would have exceeded the planned size of the book, and also some up-to-date reviews are already available. This is not very convincing, since every chapter in the book begins by referring to other relevant review articles, some of which are very recent. Indeed, the particular advantage of this book is that it gathers together information from a wide range of specialist areas and journals, so that one can recognize parallels leading to ideas for new experiments.

However, despite this gap in coverage, the principle of having an expert to report on each specialist topic means that the reader gets a wealth of up-to-date information at first hand. Ramamurthy has succeeded remarkably well in matching together the individual contributions and avoiding repetition. Frequent cross-references to related areas of work in other chapters are included. The incidence of printing errors is remarkably small, and there are no really serious errors that could lead to misunderstandings. This demonstrates the wisdom of Ramamurthy's practice of having each article cross-checked by three expert referees, and the work as a whole checked again by P. de Mayo and N. J. Turro. Finally, Ramamurthy has collected all the manuscripts together and used the computer to put them into a uniform format. Only someone who has previously undertaken such a task will appreciate how much time and patience it requires. The version finally seen by the reader is a photographically reduced and bound copy of the computer printout. Nevertheless, it must be said that, although the printout appears superficially very neat with a close resemblance to a normal printed text, it is appreciably less agreeable to read than, for example, a typewritten transcript of a lecture. The characters produced by the laser or ink-jet printer are simply too thick and lacking in sharpness when reproduced in the size that is appropriate for a book page. It would have been better, and perhaps more economical, if the text could have been typeset directly from the computer.

der Universität Münster (FRG)

State Selected and State-to-State Ion–Molecule Reaction Dynamics. Part 1: Experiment, Part 2: Theory. (Series: Advances in Chemical Physics, Vol. 82.) Edited by *C.-Y. Ng* and *M. Baer*. Wiley, Chichester, 1992. Pt. 1: XIII, 686 pp., hardcover £ 109.00, $ 164.00.—ISBN 0-471-53258-4; Pt. 2: XIII, 561 pp., hardcover £ 109.00, $ 164.00.—ISBN 0-471-53263-0

The time is ripe for the publication of a textbook on the subject described by the above title, and in these two volumes the editors have achieved an important step in that direction. It is a collection of soundly prepared review articles, eight in each volume, on experimental investigations into ion–molecule reactions (Pt. 1) and their theoretical treatment (Pt. 2), which presents the current state of research in this field, and also discusses promising new methods of investigation. Research into the reaction dynamics of ions is important not only in relation to processes occurring in interstellar space, the atmosphere, and plasmas, but also for contributing to a better fundamental understanding of reactions between neutral species.

The dynamics of ion–molecule reactions is, of course, predominantly influenced by long-range ion–multipole interactions, and probably the most important difference compared with reactions between neutral reactants is in the mechanisms of charge transfer. Nevertheless, many of the experimental and theoretical methods used are similar in the two cases. For example, resonance enhanced multiphoton ionization (REMPI) provides a bridge between studies of neutral–neutral and of ion–molecule reactions, serving in the former case as a state-selective detection method, and in the latter as a means of state selection for the ionic reactants.

The absolute reaction cross-section for an ion–molecule reaction can be determined relatively easily up to very high collision energies. However, it is more difficult to investigate collisions with low energies in the meV range. The problems can be partly overcome by using well-defined ion beams in conjunction with inhomogeneous radiofrequency (RF) fields

and ultrasonic excitation, a technique described by D. Gerlich in the first chapter of Part 1. This review of the theory and applications of inhomogeneous RF field studies of low energy ion–molecule reactions contains much useful technical information and practical advice. The discussion of the integration of RF ion optics into such experiments, and of other variants such as single and multiple photon ionization, photodissociation, chemiluminescence, chemical ionization, and coincidence techniques, gives an insight into applications in other areas besides the specific dynamics of particular collision processes.

In Chapter 2 S. Anderson describes multiphoton ionization (MPI) methods for preparing reactant ions in selected states. As well as explaining the principles of the MPI method, he describes its successful application to a number of individual ionic species. However, it would have been useful from the experimentalist's point of view if information on the laser power needed in each case had been included. In Chapter 3 J. Weishaar describes further applications of the MPI method, with particular emphasis on cations of transition metals. Studies of these reactants should help to elucidate the influence of electronic states on the chemical reactivity of systems with partially filled d-shells. Such investigations should also yield information about the chemistry of metal clusters, whose much more complex electronic structures are still largely unknown.

In Chapter 4 I. Koyano and K. Tanaka report on an extension of the now well-established photoelectron–photoion coincidence (PEPICO) technique for the state- or energy-resolved analysis of dissociation processes. In this method, threshold photoelectron secondary ion coincidence (TESICO), the reactant ions are formed by photoionization at a fixed wavelength, and one detects the ionic products that appear in coincidence with the photoelectrons emitted at the energy threshold. The data thus obtained give direct information about the reaction of ions in a particular electronic state, which is selected by the choice of wavelength.

In Chapter 5 J.-Cl. Brenot and M. Durup-Ferguson discuss aspects of multiple coincidence methods. Present limitations of electronics and data processing techniques mean that the use of such methods to determine absolute state-to-state cross-sections is still in the future, but hopefully is not too far away.

The article by C.-Y. Ng (Chapter 6) definitely belongs in the present, being mainly concerned with the determination of state selected and state-to-state cross-sections for simple ion–molecule reactions and comparison of the results with the theory. This makes possible, for the first time, a critical test of theoretical calculations. The experiments reported by Ng on state-to-state cross-sections are probably the most significant carried out so far.

Chapter 7 is a review by J. Futrell of the most recent experiments on charge transfer processes of monatomic and diatomic ions in crossed molecular beams. In the final chapter of this part G. Niedner-Schatteburg and P. Toennies review 15 years of high resolution studies of the scattering of protons by atoms and molecules, yielding important information about interaction potentials and dynamic vibrational coupling mechanisms. Using a time-of-flight method one can achieve an energy resolution of 10 meV, which gives an impressive indication of the capabilities of this state-of-the-art technique.

In Part 2, dealing with theory, the first three chapters discuss various methods for calculating potential energy hypersurfaces. Charge transfers are nonadiabatic processes, since the reactant and product systems carry different charges and are therefore also in different electronic states. In the transition between these states the system must pass through a small region where there are strong electronic interactions which are nonadiabatic. For large regions, however, an adiabatic treatment involving different hypersurfaces may be permissible. B. Lengsfield III and D. Yarkony provide an answer to the important question of which variables need to be determined in order to describe an electronic nonadiabatic process. They also discuss effective methods for locating crossovers and avoided crossovers. V. Sidis then deals with diabatic descriptions of the potential energy hypersurface. This chapter includes a detailed account of a method for calculating the potential energy hypersurface and coupling terms from first principles, so that the corresponding nonadiabatic coupling terms are kept relatively small. F. A. Gianturco and F. Schneider calculate model potentials by means of the diatomics-in-molecules (DIM) method, in which information from various asymptotic electronic states of atoms and diatomic fragments is used to construct a basis set, from which wave functions, energies, and couplings of electronic states can then be obtained using the variational principle.

The last five chapters deal with the dynamics of the species of interest on the potential hypersurface, beginning with an account by M. Baer of quantum-mechanical calculations. The calculated total and differential state-to-state cross-sections are compared with experimental results. H. Nakamura then describes a semiclassical approach to the problem of the charge transfer process.

E. A. Gilason, G. Parlant and M. Sizun describe classical calculations of pathways for charge transfer processes in ion–molecule collisions. The computational techniques are discussed in detail, giving an insight into the most suitable numerical methods for such calculations. S. Chapman describes special types of classical trajectory calculations; in regions where the Born–Oppenheimer approximation is valid the normal methods are used for calculating the trajectories, whereas in the limited regions of strong nonadiabatic couplings the trajectories are allowed to jump between the coupled energy hypersurfaces.

For all the dynamic calculations described an important prerequisite is a precise knowledge of the potential hypersurfaces, which unfortunately is only available for very few reactions. For this reason statistical theories, which are reviewed in detail by J. Troe in the last chapter, may be extremely useful. The author gives derivations of rate constants and cross-sections for uni- and bimolecular reactions, and nonadiabatic corrections are also included.

In summary, the appearance of this two-volume work was already overdue. Both books can be recommended for everyone working in this or related fields. However, there is as yet no introductory text giving an overview of ion–molecule reaction dynamics for nonspecialists or advanced students wishing to learn something about this subject.

Institut für Physikalische und Theoretische Chemie
der Universität Frankfurt am Main (FRG)

Biosynthesis of Tetrapyrroles. (Series: New Comprehensive Biochemistry, Vol. 19. Series editors: *A. Neuberger, L. L. M. van Deenen.*) Edited by *P. M. Jordan.* Elsevier, Amsterdam, 1991. XII, 309 pp., hardcover HFl 225.00.—ISBN 0-444-89285-0

Tetrapyrroles such as chlorophyll, heme, the cytochromes, and vitamin B_{12} fulfill key roles in the world of living organisms, and can be appropriately described as the "pigments of

life". Consequently their structures, functions, synthesis, and biosynthesis attract much attention as research topics. The aim of this book is to outline the progress achieved during the last twenty years in understanding the biosynthesis of tetrapyrroles. The editor, P. M. Jordan, has enlisted the help of a number of expert authors who, like himself, are active in this field of research.

In the first chapter (66 pp.) P. M. Jordan deals with the early stages in the biosynthesis of tetrapyrroles that are common to the different cases, by describing the biosynthesis of 5-aminolevulinic acid and its conversion to uroporphyrinogen III. The depth of treatment of the different biosynthetic steps varies considerably; thus, whereas the tetramerization of porphobilinogen to hydroxymethylbilane is described in detail, other conversions such as the cyclization of hydroxymethylbilane to uroporphyrinogen III are given relatively scant attention. Again, in the discussion of possible mechanisms of action of uroporphyrinogen-III-synthase the reader is only referred to a review article, which is quite inadequate. The impression of a lack of balance is intensified by the fact that the published work treated in most detail is Jordan's own. In Chapter 2 (33 pp.) M. Akhtar is concerned with the conversion of uroporphyrinogen III to the red blood pigment heme. The mechanistic and stereochemical studies that have been carried out are thoroughly described, and the author also draws attention to aspects that still need to be investigated. The problem of understanding the biosynthesis of vitamin B_{12} is certainly one of the most difficult that nature has posed for biosynthetic research. In Chapter 3, which is regrettably rather short (38 pp.), A. I. Scott and P. J. Santander clearly show that the important advances outlined here would have been inconceivable without the use of modern NMR spectroscopic methods. However, this is not a review article in the conventional sense, since here again rather large sections are devoted to the authors' own work. Thus, whereas the authors describe their "pulse labeling" experiments to elucidate the methylation sequence between uroporphyrinogen III and cobyrinic acid, they unfortunately neglect to mention the pioneering work of Battersby's group (H. C. Uzar, A. R. Battersby, *J. Chem. Soc. Chem. Commun.* **1982**, 1204). Chapter 4, by H. C. Friedmann, A. Klein, and R. K. Thauer, (16 pp.) is devoted to the biochemistry of the porphinoid nickel complex coenzyme F 430, which is found in methanogenic archebacteria. F 430 is the prosthetic group of the enzyme, which catalyzes the final step of methane formation in these bacteria. It is pleasing to note that the authors have included the determination of the configurations at C-17, C-18, and C-19, which was reported as recently as 1991, but unfortunately not all the formula diagrams have been altered to take account of this. In Chapter 5 (81 pp.) S. I. Beale and J. D. Weinstein give a very detailed account of the magnesium-containing chlorophylls and the bilins, which are the photosynthetic pigments present in plants and algae. As well as describing the individual biosynthetic steps they also explain the mechanism whereby the formation of the pigments is regulated. Chapter 6 (19 pp.) is devoted to the bacteriochlorophylls. Here K. M. Smith briefly discusses their occurrence and structures, and the rather scanty knowledge that exists about their biosynthesis. In the last chapter (38 pp.) the editor again makes an appearance. Here he and B. I. A. Mgbeje give a lucid and masterly summary of present knowledge regarding the genes involved in the biosynthesis of tetrapyrroles. The discussion underlines the importance of the contributions that molecular biology is now making to studies of biosynthetic pathways.

In this book it is impressively shown that progress in biosynthetic studies is only possible by ingeniously combining physical methods such as NMR spectroscopy with enzymology and the methods of molecular biology and organic synthesis. However, as in many multiauthor books there is a lack of consistency in style and in the use of abbreviations and naming conventions. Some of the articles are quite short, whereas others are rather long, and there is inevitably some overlapping of subject matter. The numbers of illustrations and their quality also vary considerably from one chapter to another; unfortunately not all the contributions are as well illustrated as that by Scott and Santander. Also the formulas in some of the chapters are not numbered in sequence, which is inconvenient for the reader. However, the book succeeds on the whole in presenting a good account of recent and very recent results on the biosynthesis of tetrapyrroles. About 1300 references to original papers and reviews are included, covering the literature up to late 1990 and early 1991. Unfortunately the index is incomplete, and the question arises as to whether it is appropriate to publish books on areas of research that are in a state of very rapid development, as this book demonstrates.

However, despite the above criticisms, this very well produced (though by no means cheap) book can be recommended to all readers with an interest in the biosynthesis of tetrapyrroles.

Physical Chemistry. By *R. A. Alberty* and *R. J. Silbey*. Wiley, Chichester, 1992. XIII, 898 pp., paperback £ 35.95.—ISBN 0-471-55220-8

This well known textbook of physical chemistry traces its origins back 79 years to a book entitled "Outlines of Theoretical Chemistry" written by F. Getman in 1913. The title of the book was changed to "Physical Chemistry" in 1955 when R. Alberty became coauthor of the book together with F. Daniels. For the new edition the responsibility is shared between R. J. Silbey and the senior author R. A. Alberty.

Like earlier editions the book is still divided into four parts. The chapter on thermodynamics begins by describing the interconversion of various kinds of energy and the changes in physical properties that are involved (first law of thermodynamics). Based on the second law of thermodynamics and the definition of entropy the natural direction of physical and chemical processes is investigated in more detail, and the question of whether a process may occur or not is answered. This leads to the definition of the equilibrium constant of a chemical reaction and its dependence on temperature, pressure, and concentration. The concept of chemical equilibrium is then applied to the equilibrium between different phases, electrochemical cells, and biochemical reactions.

The second chapter introduces the basic concepts of quantum mechanics and applies them to atoms and molecules to deduce their spectroscopic properties and to get an understanding of the nature of the chemical bond. Methods for calculating energy levels and the molecular geometry are discussed in detail for atoms and small molecules. Symmetry is introduced as a concept to simplify these calculations for larger and more complicated systems. Various spectroscopic techniques, ranging from NMR to UV spectroscopy, are described in detail. These techniques are used to identify individual atoms and molecules and to collect information about their physical and chemical properties. The importance of the development of the laser for atomic and molec-

ular spectroscopy is discussed, and the increasing importance of NMR spectroscopy is recognized by dedicating a separate section to this powerful technique.

In the chapter on statistical mechanics and kinetics the information provided by quantum mechanical calculations and spectroscopic measurements is used to calculate thermodynamic properties for simple systems. Intermolecular interactions are then taken into account to extend these ideas to dense gases, liquids, and solids. The kinetic theory provides insight into transport properties of gases and the control of chemical reaction rates in the gas phase. After the discussion of complex mechanisms in chemical reactions, the potential energy surface and the concept of the transition state is introduced. Photochemical methods to create and study highly reactive species are described in detail. Finally the basic concepts of chemical kinetics are extended to the liquid phase, where viscosity, diffusion, and electrical transport of ions must be taken into account.

The last chapter, on macroscopic and microscopic structures, deals with macromolecules having a molar mass from 10^4 to 10^6 $g\,mol^{-1}$. Different methods for gaining more insight into these systems are discussed. X-ray diffraction is described as a method to study the structure of solids. Electrical conductivity and its dependence on crystallographic properties is used to introduce the concept of semiconductors. A separate section is dedicated to the study of processes occurring at the interface between the solid and gas phases to get a better understanding of catalytic reactions.

The book is completed by a number of useful appendixes containing information about physical quantities and units, values of physical constants, thermodynamic tables, mathematical relationships, and symbols for physical quantities and their SI units. The whole book places emphasis on the meaning and the importance of using appropriate units for the measurement and interpretation of physical quantities.

Compared to previous editions some improvements and changes have been made. The section on the second law of thermodynamics has been changed completely. A thermodynamic temperature scale is introduced at an early stage, and the second law is deduced from the Clausius theorem. In general more emphasis has been put on the understanding of entropy and the solution of problems concerning chemical equilibrium. The difference between intensive and extensive properties has been clarified by using a new notation for molecular quantities. In the chapter on quantum mechanics and spectroscopy linear operators are introduced earlier than before and are used exclusively. Quantum mechanical ideas are applied throughout the chapter to deduce molecular properties and spectroscopic parameters. In the chapter on statistical mechanics the Maxwell–Boltzmann distribution is introduced right at the beginning. Thermodynamic properties of the ideal gas are then derived in a straightforward way. The basic idea of theoretical kinetics has been combined with the section on photochemistry to form a unified treatment. The photochemical destruction of the stratospheric ozone layer and the importance of femtosecond pulsed laser studies to improve the understanding of the transition state region are described in detail in a separate section. In the last chapter two complete new sections on macromolecules and surface dynamics have been added, to take account of the importance and rapid growth in these fields. The number of examples within the text has been increased by 30% as an aid to understanding the theoretical principles, and a number of problems have been updated.

Even though there are special sections about important and fast growing fields such as biochemical reactions, nuclear magnetic resonance, macromolecules, and surface dynamics one might get the impression that there is not much emphasis on the description of developments of new theoretical concepts and of new experimental techniques and possibilities. But it is clearly beyond the scope of this textbook to give a survey of all the new activities going on in physical chemistry. The real merit of this textbook consists more in a well presented descripton and deduction of basic ideas and fundamental concepts, and therefore it is strongly recommended for students seeking a well founded understanding of physical chemistry.

Molecular Design: Chemical Structure Generation from the Properties of Pure Organic Compounds. (Studies in Physical and Theoretical Chemistry Series, No. 75). By *A. L. Horvath*. Elsevier, Amsterdam, 1992. XII, 1489 pp., hardcover $ 295.00/HFl 575.00—ISBN 0-444-89217-6.

It was in the early part of the nineteenth century that chemists first began to understand that molecules are tiny architectural edifices that can be broken down, reconstructed and modified in a variety of different ways. Almost as soon as this discovery had been made, physicists such as André Ampère, and physical chemists such as Hermann Kopp, started to develop methods that could be used to predict the properties of chemical substances from their molecular structure. Initially the focus was on physical properties, but over the intervening years methods have been evolved for the prediction of an enormous range of properties. In fact, it may now be said after over one and a half centuries of unrelenting endeavor that we have reached the point where it is possible to predict virtually any property with reasonable accuracy, provided that the substance has a well-defined molecular structure. Included among the methods that have been devised are a great variety of so-called additivity methods that exploit either atom, bond, or cluster additivities within a molecule, quantum-theoretical methods that make use of models of differing levels of sophistication, and methods that rely on mathematical descriptors of molecules such as topological indices or geometrical parameters.

The work under review here purports to provide a comprehensive survey of such methods, and is even ambitious enough to state that its prime aim is "to summarize the present state-of-the-art information on the generation and discovery of new and useful chemicals." Clearly a tall order, for such a mammoth undertaking would tax even the most inspired of authors to accomplish within the confines of a single monograph. It comes therefore as no surprise that the author fails in his mission. This work is not only tiresome and tedious but its contents are anything but state-of-the-art. No enlightening discussion on nonlinear structure–activity relationships, no introduction to the plethora of exciting new software now coming on to the market, no elucidation of the intricacies of hierarchical clustering, and no mention of the rapidly growing use of neural networks is to be found herein. Instead, what we are offered is a dreary and long-winded recital of additivity methods that would not be out of place in a text dating from the last century. If the reader's interest extends no further than this, he or she would do much better to consult Lyman's 1982 *Handbook of Chemical Property Estimation Methods*, which is at least entertainingly written. Given the author's eccentric notion of what constitutes state-

of-the-art, is there any merit in a detailed treatment of methods that are now largely of historical interest?

The first thing that strikes one about this book is its enormous size. The book is over 2½ inches (6.4 cm) thick, weighs over 5½ pounds (2.6 kilos), and contains 1500 pages. The text has been reproduced from camera-ready copy that is not justified on the right. Many pages are only partially filled and diagrams typically take up a whole page. It is my impression that this book represents a monumental waste of paper, for the entire contents could have been contained in a work of less than half the present length if the book had been typeset in the conventional way. The text may be roughly divided up into three sections each of some 500 pages in length. The first third concerns itself with a description of methods used for predicting the properties of pure organic compounds, the middle third discusses the characterization of molecular structure by means of various molecular descriptors, and the final third lists all of the literature references cited in the book and also includes ten appendixes. Roughly speaking, the first 500 pages are devoted to discussion of now dated methods (such as additivity methods), the next 500 pages make brief mention of more modern methods (such as the use of topological indices, pattern recognition, and molecular orbital theory), and the remaining 500 pages contain an assortment of references, many of which are irrelevant to modern molecular design. Lacking completely is any treatment of really modern methods or of exciting new approaches such as the use of neurocomputing.

The style in which this book is written is at least as eccentric as the choice of material it contains. Among other things, we are introduced to radically new ways of spelling English words, e.g. isomerizm (isomerism), algoritm (algorithm), approximative (approximate), occurence (occurrence), and valance (valence). Leading workers in the field also have their names misspelt, e.g. Bollzmann (Boltzmann) and Boncher (Bonchev), and names always appear without accents, e.g. Randić and Trinajstić never have their accents. British and American spellings are completely mixed up, e.g. odor on page 748 becomes odour on page 1486 and vapor on page 585 becomes vapour on page 620. Moreover, symbols are used inconsistently, e.g. the Wiener index is represented by w on page 63, but becomes W on page 181 and ΔW on page 278. In addition this work contains much redundant or useless information, e.g. we are told on page 283 that "the boiling point temperature is known for a large number of substances" and on page 747 that "more and more sophisticated methods are needed for the reduction and effective analysis of data." Worse still, the information that this work proffers is often so vague as to be misleading, e.g. on page 55 we learn that "in chemistry, the symmetry plays a great role for the estimation of structural regularities which are the foundations of many thermodynamic systems at various conditions" and on page 861 that "structure generation is the inverse problem of the estimation methods for physical properties of substances with well defined structure." On occasion, the text degenerates into pure gibberish, examples of which are to be found on page 606 in the sentence: "The molecular structures may be examined at a three-dimensional level, and studying the overlapping each other and to compare the molecular shapes quantitatively", and on page 799 in the sentence: "The objective with all collected data is to use them for establishing or proving some phenomenon which is expected or demonstrating that the data do not characterize the inter-relationships for the parameters under study."

In short, it may be said that Horvath's book is a misbegotten attempt to treat the highly complex and tremendously fascinating subject of molecular design. The failure is to be laid at the door of both the author and the publisher. The author has quite clearly sought to write a work that is beyond him. The publisher should have noticed that the manuscript was written in atrocious English and unfit for publication. The end result is a massive book that contains practically nothing of interest to the modern designer of molecular species. This work deserves to be forgotten and to sink without a trace—a prospect that is happily quite likely in view of the great weight of this volume.

Pulsed Magnetic Resonance: NMR, ESR, and Optics. A Recognition of E. L. Hahn. Edited by *D. M. S. Bagguley*. Clarendon Press, Oxford, 1992. XV, 550 pp., hardcover £ 65.00—ISBN 0-19-853962-2

Pulsed excitation is nowadays standard for acquisition of NMR spectra. In fact the availability of pulsed excitation has made possible the development of most modern NMR methods and extended the range of applications from conventional one-dimensional spectra to multidimensional NMR spectra for structure determination of biological macromolecules in solution, solid state NMR, and NMR imaging. Pulsed excitation is now conquering ESR spectroscopy, following a similar route as in NMR. It is even used in optical spectroscopy, where many phenomena analogous to magnetic resonance can be observed as well as additional, new effects.

Why is pulsed excitation special? Old-fashioned continuous excitation with a narrow-band irradiation source requires simultaneous detection of the response. Each frequency interval has to be measured in successive steps. By pulsed excitation all frequency components of the spectrum are measured simultaneously, resulting in far shorter acquisition times or better signal-to-noise ratios. Furthermore, excitation and detection are separated into different periods on the time axis. Thus sophisticated pulse sequences can be developed, which are tailored to the properties to be interrogated in the experiment. The Nobel Prize in Chemistry was awarded to Professor Richard Ernst in 1991 for the development of pulsed NMR into a routine method and for an abundance of pioneering new NMR methods.

But pulsed magnetic resonance was born as early as 1949 in the discovery of the spin echo by Professor Erwin Hahn, just four years after the first successful NMR experiments. It turned out that the echo provided confirmation of the famous "Umkehreinwand" of Lohschmidt against Boltzmann's irreversible increase of entropy. After the decay of the initial pulse response, the signal could be made to reappear following a second pulse some time later. The reappearing signal is the echo, which Erwin Hahn discovered accidentally during his PhD work and subsequently explained and exploited for use in NMR, ESR, and optics. The echo can be explained by a time reversal. The decay of the echo amplitude as a function of the echo time measures the homogeneous linewidth or the phase relaxation time T_2. This quantity is of great interest for molecular dynamics, as it characterizes translation and reorientation processes.

A second important contribution of Erwin Hahn to magnetic resonance spectroscopy is the development of cross-polarization, the transfer of magnetization from one nuclear species to another by matching the precession frequencies of the two species in the applied radiofrequency fields. Here the

Hartmann–Hahn condition must be satisfied, a rule well known to every solid state NMR spectroscopist. These and many other contributions to pulse spectroscopy have led to the conclusion of Richard Ernst quoted on page 117 of this book: "The influence of Erwin Hahn on the development of time domain magnetic resonance during the past forty years has been very significant. Even some of the roots of two-dimensional spectroscopy may be found in his early work together with Maxwell".

Erwin Hahn reached his 70th birthday in 1991. An international symposium was held in his honor. The editor of this book, Dr. Bagguley, spent considerable time and effort to have many speakers of this symposium contribute scientific articles on current developments in physics and chemistry which have, in one way or another, been inspired by earlier work of Erwin Hahn and his colleagues. This book is an excellent birthday present, not only to Erwin Hahn, but to the entire magnetic and optical resonance community. It contains 22 contributions from well-known scientists, mainly dealing with the fundamentals and the use of echoes and polarization transfer in NMR, ESR, optical spectroscopy, and magnetic resonance imaging. Many of them are written in a personal fashion, from a friend to a friend, spiced with some reminiscences of the past. Some of the highlights are "The Echo Phenomenon" by D. M. S. Bagguley, "Pulsed NMR in Solids—Then and Now" by C. P. Slichter et al., "New Angles in Motional Averaging" by A. Pines et al., "The Multidimensional Importance of Time Domain Magnetic Resonance" by R. R. Ernst, "Spin Echoes and Thermodynamics" by J. S. Waugh, "Thermodynamics of Hartmann–Hahn Cross-Polarization" by M. H. Levitt, "Spin Choreography" by R. Freeman, "Imaging by Nuclear Magnetic Resonance" by P. Mansfield, "Pulsed Electron–Nuclear Spectroscopy and the Study of Metalloprotein Active Sites" by H. Thomann and W. B. Mims, "Coherent Raman Beats in Electron Paramagnetic Resonance Spectroscopy" by M. K. Bowman et al., and "Optical Excitation and Detection of Spin Precession" by M. Mehring et al. The editor has succeeded in bringing together a coherent and stimulating account of research that has grown out of the original papers by Erwin Hahn. The book will be of benefit not just for the specialist, but for a wide range of students and research workers. The practical use of the book is enhanced by a list of Hahn's published papers, a glossary of abbreviations, an author index, and a subject index. It is highly recommended for acquisition by libraries, and by individuals who enjoy accounts of modern pulse spectroscopy with a historical perspective.

Bernhard Blümich
Max-Planck-Institut für Polymerforschung
Mainz (FRG)

Chemical Information Management. By *W. A. Warr* and *C. Suhr*. VCH Verlagsgesellschaft, Weinheim, 1992. XIII, 261 pp., hardcover DM 128.00.—ISBN 3-527-28366-8

In the preface to this book two things already become apparent. Firstly, advantage has been taken (unusually) of the facility for listing additional recent publications that appeared too late to be mentioned in the text. Secondly, it is explained that the book consists mainly of a reprint of a chapter on the same subject in *Ullmann's Encyclopedia of Industrial Chemistry* (Vol. B1, Ch. 12). Therefore the question at once arises as to whether double publication of this kind is helpful from the standpoint of the reader and/or purchaser. In this case it is, since (to anticipate the favorable verdict of this reviewer) the high quality and information content of this text by two authors who are well known in the field merits ensuring that it reaches as wide a readership as possible. In my experience most chemists are (unfortunately!) not likely to seek information of this kind in "Ullmann", and therefore this book offers the only realistic possibility of having it constantly to hand in the laboratory or in private collections. The book's high price, combined with its compactness and the demanding standard of the contents, means that chemistry students are unlikely to buy it, but for the same reasons no chemistry departmental library should be without it. In contrast to the well-known guides to the chemical literature by Wolman, Mücke, Skolnik, Maizell, and others, which concentrate on practical aspects (e.g., where and how to seek information on a specific topic), this book presents a survey of the whole field of chemical information and of the basic principles that is concise, informative, and up-to-date, but by no means limited to digital data processing. In the absence of any other suitable up-to-date and comprehensive treatment, it could even be used as a more advanced, though very compact, textbook on chemical information and literature sources, to follow an initial introduction using a book such as *Communication, Storage and Retrieval of Chemical Information*, by Ash et al. In addition to giving a practically orientated guide to the literature, the book provides the background information that is essential to understanding the subject, and predictions about likely future developments. The teaching institutions are notorious for their neglect of this area of chemistry, and it is remarkable that it has been left to these two authors from industry to fill a gap that existed.

Right at the beginning of the book one finds a very useful and comprehensive list of common acronyms, the numbers of which continue to grow on an epidemic scale in this as in other fields. The comprehensive bibliography of more advanced literature is given in complete form for each chapter—this means that a particular reference can appear several times if cited in different chapters. Unfortunately, however, instead of giving these lists of references at the ends of the relevant chapters, which would have made the book easier to use and would have justfied the redundancy just mentioned, they are collected together at the end of the book.

The first three chapters present a concise and readable survey of the primary, secondary, and tertiary literature. The following two chapters are fairly detailed, and deal with matters that often cause problems and are unfamiliar to many chemists, namely the "gray literature" and commercial information. Chapters 6 ("Computer Hardware") and 7 ("Software") are rather brief and superficial, but Chapter 8 ("Information Retrieval") and those that follow contain more detailed treatments appropriate to their subjects. The chapter on data banks is a highlight of the book; all the latest developments receive at least a brief mention, including the SPECINFO system and the Gmelin data bank. Chapter 10, on the handling of chemical structures, is typical, consisting of an introduction to the basic principles with references to more advanced reading (6 pp.), followed by a review of current developments (6 pp.) then, as the main material, a 16-page description of operational systems, including relevant PC software (although naturally the latter compilation already needs to be extended). The following chapter on "Artificial Intelligence" presents a survey encompassing neuronal networks as well as hypermedia. This is immediately followed by a topic that might be regarded as the opposite extreme: Chapter 12 and the subsequent ones deal with patents and make up nearly a third of the book. The detailed treatment of this subject is certainly appropriate to its impor-

tance in industry, and its length has been approximately doubled compared with its predecessor in "Ullmann". Guides to the literature often devote very little space to patents (perhaps as a consequence of the bias that exists against patent information in the teaching institutions where there is no relevant expertise), and therefore this part of the book is nearly enough in itself to justify buying it. The discussion of legal aspects is confined to matters that are essential for an understanding. From Chapter 14 onwards the emphasis is on patents as an information source. Chapter 15 briefly discusses some of the less obvious differences between patents and other publications. Chapters 16–22 then deal with the layout of patent specifications, storage of patent information (including new storage media such as CD-ROM), patent searches, patent information services, and data banks.

The book concludes in Chapter 23 ("The Future of Patent Information Management") by inviting its readers ".... to soon render it obsolete by making their own creative contributions to the fascinating world of information management". Some of the fascination that the subject holds for the authors is conveyed as one reads this book. It is to be hoped that the word "Management" in the title will not deter chemists in teaching and technology from reading this book, which will be of great value to them in view of the growing importance of information in their day-to-day work.

Engelbert Zass
Laboratorium für Organische Chemie
der Eidgenössischen Technischen Hochschule
Zürich (Switzerland)

Graphics and Animation in Surface Science. Edited by *D. D. Vvedensky* and *S. Holloway*. Adam Hilger, Bristol (UK), 1992. VIII, 117 pp., hardcover £ 27.50.—ISBN 0-7503-0188-X

For many years now the computer has been an indispensable tool of experimental science, not only for the recording and interpretation of data, but also for preparing manuscripts and disseminating results. Recently, however, another way of using computers has become increasingly important. This is computer graphics, which not only enables one to present experimental results in clever and visually appealing forms, but also often reveals new scientific relationships not previously apparent. For example, very rapid processes can be studied in a slowed-down presentation, allowing intermediate states to be observed for the first time. Conversely, very slow processes can be presented as a rapid sequence of images, so that the effects of interest can be much more easily recognized.

The advantages that can result from using such computer graphics can be particularly well illustrated by examples from the physics and chemistry of surfaces. That is the purpose of the book reviewed here, in which the editors have collected together seven individual contributions on computer techniques applied mainly to various research topics in surface physics. The results, some of which are quite spectacular, would hardly have been possible without effective graphics and animation techniques.

The book begins with a general introduction by the editors in which they mention, among other aspects, the application of graphics methods to ab initio calculations of total energy, to describing dynamic molecular processes, for Monte-Carlo simulations, and for studying surface reactions.

In Chapter 2 N. M. Harrison gives a concise account of the use of advanced graphics computers in surface research, with particular attention to technical aspects of the choice of computer systems (hardware and software), the problems of generating hard copies suitable for reproduction, and some possible applications of individual graphics user packages in surface physics.

Chapter 3 by O. H. Nielsen has the title "Animation in Surface Science". In this context animation implies that experimental or theoretical results that do not convey a clear picture in the form of tabulated data or a two-dimensional diagram, or are even quite incomprehensible in these forms, are reprocessed to yield a suitable multidimensional representation and/or a sequence of colored images (a movie) that makes them understandable. As an example to illustrate the use of computer animation in surface physics the author chooses the perspective representation of a solid surface. The rest of the chapter is mainly concerned with the computational and technical problems of animation.

In Chapter 4 M. W. Rickets deals with a more specialized topic, describing the well known WINSOM software package and its application to some selected problems in molecular modeling, liquid crystals, potential fields, and complex biological structures.

Chapter 5 by P. Stolze is likely to be of special interest to surface physicists; this emphasizes the immense value of graphics and animation techniques for simulating dynamic molecular processes. One aspect of this is the presentation in graphic form of the results of numerical calculations. A very good example is the visual representation of the trajectories of interacting atoms or molecules over long periods (e.g., in a liquid or a crystal undergoing melting). Such graphics methods have contributed especially to the understanding of crystal growth, premelting phenomena, and roughening transitions.

In Chapter 6, "Animation of Large-Scale Simulations", M. R. Wilby and S. Clarke are mainly concerned with the graphical representation of Monte-Carlo simulations of the molecular beam epitaxy (MBE) process, which is of great technological importance. As in the previous chapter, the aim here is to compute and display the trajectories of the atoms taking part in the growth over a period of time for different values of the variables, in this case the (anisotropic) interaction energies with the substrate, so as to give a better understanding of the macroscopic growth processes.

The book ends with a chapter on "Animation of Quantum Scattering Events using Hypercard", by D. M. Halstead and S. Holloway. The authors discuss the theoretical problem of quantum scattering at potential barriers, which is important for calculating the trajectories of molecules undergoing adsorption, for example, and they explain how the theoretical results are presented graphically.

First, a few critical comments. The title of the book is rather general, and appears at first to promise the reader a snapshot of the whole topic of computer animation in surface research. However, it quickly becomes obvious that such a slim volume can only cover a small selection of topics or applications. Thus, some extremely useful graphics and animation programs known to this reviewer, such as those for displaying structures of surfaces and adsorbates, or for visualizing lattice vibrations (phonons in the bulk and at the surface), are not included. Again, there is no mention of programs for the processing and display of scanning tunneling microscopy images, probably now the most topical and fruitful of the techniques used in surface physics. However, the editors have taken on the risky task of opening to a wider readership a field that is undergoing very rapid development, and the fact that they have not only attempted this but have produced a worthwhile result is greatly to be welcomed. Every

physicist and chemist who wishes to learn about computer animation in surface research should buy this little book, despite the risk that parts of it may be overtaken by computer developments within a few years. Moreover, the affordable price for this well produced book (containing many colored figures) should have an *animating* effect on readers.

Klaus Christmann
Institut für Physikalische und Theoretische Chemie
der Freien Universität Berlin (FRG)

The Meaning of Quantum Theory. By *J. Baggott*. Oxford University Press, Oxford, 1992. XIV, 230 pp., hardcover £ 11.95. ISBN 0-19-855575-X

In recent years there has been a growing trend towards the publication of books on technical aspects of quantum mechanics and quantum chemistry for chemists with theoretical interests. Although these differ greatly in emphasis and degree of difficulty, most of them follow a common pattern. Their central theme is to provide the reader with quantum theoretical methods—thus they present quantum theory in the form of a technological toolkit. Any reader who approaches J. Baggott's book expecting something of this kind will certainly be disappointed. The author's purpose here is to examine the meaning of quantum theory as a conceptual structure from a scientific and philosophical standpoint. The most important message can be summarized in one succinct statement: the central elements of quantum theory are open to more than one possible interpretation. Baggott illustrates this by the example of the old controversy between, on the one hand, the positivist school of Bohr and the young Heisenberg, and on the other hand the realistic interpretation based on wave mechanics, as put forward by Einstein and Schrödinger. The positivist approach to quantum theory is a conceptual structure of a puristic kind. Baggott describes positivism as a view based on the premise that any observation on a quantum-mechanical system involves a disturbance of the system, and therefore the description requires a Hamiltonian operator that includes both the quantum-mechanical system itself and the spectrometer or observer.

Baggott characterizes the realistic viewpoint by the concept of "local realities". In this framework an experimental system can also be described by restricting the treatment to localized subfragments. Baggott explains the scientific controversy in terms of certain imaginary experiments of historical importance, such as the Einstein–Podolsky–Rosen theorem, the Bell inequality, and the intellectual construction known as Schrödinger's cat.

The book is divided into five chapters. In Chapter 1 the author summarizes the historical facts that led to the development of quantum mechanics, and discusses in detail the wave–particle duality hypothesis of de Broglie. This chapter provides an easily readable introduction to the theoretical ideas, and also introduces a number of novel relationships. Chapter 2 begins with an explanation of the operator concept of quantum mechanics. Here Baggott also describes lucidly the considerations that led to the formulation of the Schrödinger equation. In this chapter, which is orientated mainly towards mathematical techniques and formalisms, the author explains in an easily understandable way the elements of quantum mechanics, such as state vectors in Hilbert space and the Pauli exclusion principle. Chapter 3 moves on from the technical background to an examination of the meaning of the quantum theory. The reader learns that the controversies between the positivists and the realists were often emotional and heated. Chapter 4 takes up the subject of the conceptual "experiments" mentioned above, that were put forward in support of either the positivist or the realist interpretations.

Unfortunately, after about the first 100 pages, the book loses some of its initial excitement and conciseness. In the opinion of this reviewer, the last part could have been tightened up and condensed to about half its length. In Chapter 5 Baggott moves away from the themes of the previous chapters and focuses attention on the relationships between quantum theory and philosophy. He also discusses, among other topics, the ideas of Karl Popper and of René Descartes. The chapter concludes with some metaphysical considerations. The question of the existence of a deity, which is introduced carefully and dicreetly at this point, rests on the same philosophical basis of the debate between determinism and indeterminism as do the fundamentals of quantum theory—hence the excursions into matters of religion. The merit accorded to this part of the book will no doubt vary from reader to reader.

Some of the comments that Baggott includes are trenchant and worthy of attention. One of the best passages is that on page 79: "It would, perhaps, be very difficult for high-energy physicists to justify the financial investments ... if they were not convinced of the reality of the objects on which they wish to make measurements".

In this book Baggott presents a skillful analysis of those concepts of quantum mechanics with which we have, in the course of time, learned to be "comfortable". He succeeds in opening the reader's mind to new questions about quantum mechanics and thereby taking a fresh look at hitherto accepted conceptual models. The book can be recommended for readers interested in the philosophical aspects of quantum theory. Large parts of it are stimulating to work through. However, this requires a good deal of concentration, apart from the "technical information" parts. Unfortunately Baggott's treatment is not at a consistent level throughout, but against this it must be said that the aim was very ambitious. The minor criticisms above should not deter anyone from buying this interesting and stimulating book. It is desirable that as many chemists and physicists as possible should concern themselves with aspects of quantum theory other than technological applications, and this book offers a good introduction to the subject.

Transuranium Elements: A Half Century. Edited by *L. R. Morss* and *J. Fuger*. American Chemical Society, Washington, DC, 1992. XXIV, 562 pp., hardcover, $ 99.95.—ISBN 0-8412-2219-3

When news of Otto Hahn and Fritz Strassmann's discovery of nuclear fission in 1939 reached the University of California, scientists at Berkeley began experiments to reproduce the unexpected results. By May, 1940 Edwin M. McMillan, an assistant professor of physics, and Philip H. Abelson, a recent Berkeley physics alumnus, succeeded in producing the first transuranium element (at. no. 93) by bombarding uranium (at. no. 92) with neutrons from Ernest O. Lawrence's cyclotron. They named it neptunium after Neptune, the next planet after uranium. A mere seven months later, on December 14, 1940, Berkeley chemistry instructors Glenn T. Seaborg and Joseph W. Kennedy and graduate student Arthur C. Wahl synthesized the second transuranium element (at. no. 94) by bombarding uranium with deuterons from the

same cyclotron. They named it plutonium after Pluto, the planet beyond Neptune. Seaborg and McMillan shared the 1951 Nobel Prize in Chemistry for their accomplishments.

As is well known, the discovery of plutonium led to the second nuclear bomb ("Fat Man"), while the discovery of these first two transuranium elements added a new dimension to the Periodic Table and changed forever the world in which we live. A half century later the discovery was celebrated by articles, books, conferences, and meetings. One of the most prominent of the meetings, a Symposium to Commemorate the 50th Anniversary of the Discovery of Transuranium Elements, was sponsored by the Divisions of Nuclear Chemistry and Technology, the History of Chemistry, and Inorganic Chemistry of the American Chemical Society and was held at the 200th National ACS Meeting, Washington, DC, August 26–31, 1990. The volume reviewed here, dedicated to Glenn T. Seaborg "in recognition of his inspiring leadership in the discovery of the transuranium elements and in the elucidation of their chemical properties", contains 51 of the 67 papers presented at the symposium by 109 internationally renowned authorities from the United States (many from nuclear research centers such as the Los Alamos, Argonne, Brookhaven, and Oak Ridge National Laboratories, the Lawrence Berkeley Laboratory, and the University of California, Berkeley) as well as from Australia, Belgium, China, Finland, France, Germany, India, Japan, Portugal, Russia, and Switzerland. Many of the chemists, physicists, materials scientists, and engineers who pioneered the historic research on transuranium elements during the 1940s are among the contributors.

The book is divided into eight sections—(1) Introduction: Transuranium Elements: Their Impact on Science and Technology, by the editors; (2) Historical Viewpoints (12 papers by Seaborg, Abelson, Connick, Katz, and other early pioneers); (3) Spectroscopy, Photophysics, and Photochemistry (7 papers); (4) Chemistry (7 papers); (5) Separations and Thermodynamics (6 papers); (6) Materials Physics (4 papers); (7) Materials Chemistry (10 papers); and (8) Analytical Chemistry (4 papers). Each paper is prefaced by an abstract, and the volume is replete with 310 tables, figures, reaction schemes, and photographs of great historical significance, such as portraits of the discoverers and crucial pages from laboratory notebooks.

The papers reflect the unique and challenging nuclear, spectroscopic, physical, chemical, and solid-state behavior of the transuranium elements and present predictions and perspectives for the conduct of future research, including that on the "superheavy" elements (atomic numbers above 111). They discuss the impact of fundamental and applied physical research on the characterization and properties of elements caused by the filling of the 5f electron subshell. Seaborg's celebrated actinide concept, postulating that transuranium elements constitute a second rare earth series, which accounted for their position in an expanded Periodic Table and predicted conditions for their synthesis and isolation, is featured prominently in many of the contributions, but important differences between the actinides and lanthanides are not neglected.

A judicious balance is struck between papers presenting first-hand historical accounts and anecdotes, review papers, and reports describing the most recent contemporary research (synthesis of new derivatives, corrosion studies, thermodynamic interpretations, and methods for detecting and disposing of radioactive fuel waste, both on a laboratory scale and plant scale). Despite the multiplicity of authors from various laboratories, which often results in the inconsistent format, uneven appearance, and large number of mis spellings usually associated with symposium proceedings, the book is most attractive and virtually error-free, thanks to the efforts of the editors and the staff of the ACS Books Department, which maintains exacting editorial and production standards. A detailed name and subject index (27 pp., 2 columns per page) makes the contents readily accessible.

In reflecting the dynamics and trends of research on the actinides, this excellent collection of papers of historical and contemporary value is a major contribution to the scientific community. I recommend it highly to historians of science and technology, practicing chemists, physicists, and engineers, as well as to anyone interested in this family of fascinating elements whose unusual and complex chemical, physical, and nuclear properties pose a multitude of challenging problems for scientists and whose control has created thorny issues for the world's politicians and statesmen.

Optical Spectroscopy of Single Impurity Molecules in Solids

By W. E. Moerner* and Thomas Basché*

Optical spectroscopy of a single impurity molecule provides the first truly local probe of host–guest interactions in doped solids. In conventional optical high-resolution experiments with many molecules only ensemble averages of the microscopic parameters can be obtained. In the single-molecule regime, the exquisite sensitivity of an individual dopant molecule to both the local environment and to external perturbations has been exploited in recent experiments to reveal a wealth of fascinating novel phenomena such as spectral diffusion in crystals and polymers, optical modification of a single impurity molecule (spectral hole-burning), local field measurements at the site of a single impurity molecule, and quantum optics in a solid.

1. Introduction[**]

Significant progress in the optical spectroscopy of single quantum systems confined in traps or on surfaces has occurred in the last decade. For example, imaging and spectroscopy of single ions confined in electromagnetic traps has led to novel measurements that test the foundations of quantum physics. In particular, various workers have reported direct measurement of quantum jumps, Doppler sidebands, photon antibunching, extremely narrow optical linewidths, and other fundamental phenomena such as ion crystallization and chaos.[1–3] The original work on trapped single electrons and on the Paul trap led to the Nobel Prize in physics for Dehmelt, Paul, and Ramsey in 1989.[4]

At the other extreme, recent advances in various near-field spectroscopies such as scanning tunneling microscopy (STM)[5, 7b] have provided detailed images of single atoms, of single molecules of benzene and CO on Rh surfaces,[6] and of liquid crystal molecules on graphite[7] to name only a few examples. The invention of STM earned Binnig and Rohrer[5] the Nobel Prize in physics in 1986, and many workers around the world are applying this technique to a large variety of systems. Moreover, the STM work has inspired a broad array of sensitive surface measurements based on the atomic force microscope.[7b, 8] A requirement of STM is the need for a strong bond between the molecule of interest and the underlying surface so that the molecule can remain in a fixed configuration long enough for the tunneling spectrum to be obtained.

By contrast, the relatively new field of single-center optical spectroscopy in condensed matter is only now beginning to provide novel chemical and physical insights. For single molecules in liquids, the emphasis has been on the detection of single molecules labeled with fluorophores for analytical applications without recording detailed spectra. In the early work, use of laser-induced fluorescence and a hydrodynamically focused flow to reduce the scattering volume allowed the detection of single molecules of the protein B-phycoerythrin, whose fluorophore is equivalent to 25 rhodamine 6G molecules.[9, 10] Recent enhancements of the method have

allowed the detection of single molecules of rhodamine 6G in a flowing liquid.[11, 12] One distinct advantage here is that the experiments are usually conducted at room temperature; however, the fluorescent molecule and the solution must be chosen carefully to maximize photostability. In the first work to go beyond digital (present/not present) detection of a molecule, two fluorescent species were distinguished by the difference in fluorescence lifetime.[13]

This review concerns single-center spectroscopy when the center of interest is a molecular or ionic dopant (defect) hidden deep inside a solid. The detection and spectroscopy of a single absorber in a solid (in the case of a molecular impurity called single-molecule detection, SMD) provides a natural complement to the earlier hole-burning and coherent transient spectroscopy of impurities in solids.[14–17] Single-center spectroscopy in solids provides a useful tool for the study of local host–guest interactions where the absorbing center is essentially at rest, confined by the host lattice, and where the normal averaging over many "equivalent" centers is removed. Although this paper focuses on molecular impurity centers, the physical concepts apply equally well to ions, color centers, and other defect absorptions in solids.

As an important first step toward single-molecule detection (SMD), it was necessary to make a very detailed examination of the inhomogeneously broadened optical absorption line of a defect in a solid with large numbers of absorbers (the usual regime). In this limit, a fundamental effect called statistical fine structure (SFS) was observed for the first time.[18, 19] SFS results from (static) fluctuations in the spectral density of absorbers with optical wavelength, and therefore scales as the square root of the number of absorbers in resonance. The observations of SFS and other steps toward SMD will be described in Section 2. Crucial to these measurements was the use of a powerful zero-background laser technique called frequency modulation (FM) spectroscopy, first described by Bjorklund[20] in 1980.

With a firm understanding of SFS in inhomogeneous lines, it became possible to approach the ultimate limit of single-molecule detection (SMD) and spectroscopy. One motivation for the development of SMD comes from the fact that for an inhomogeneously broadened line, the centers located within a homogeneous width of a given laser frequency are located at that particular spectral position for a variety of possible reasons. This intrinsic multidimensional inhomogeneity cannot be removed with spectral hole-burning or coherent transient techniques. However, with SMD the absorption spectrum of a unique individual absorber in its particular environment can become directly accessible, as long as no other centers absorb at the same frequency. This is the primary reason for pursuing the spectroscopy of individual centers in condensed matter. The use of powerful spectroscopic methods (FM spectroscopy) and the properties of the inhomogeneous line itself make SMD feasible; the first successful SMD experiments[21–24] will be described in Section 3.

The advent of a superior technique, fluorescence excitation with extremely high collection efficiency,[25] allowed greatly increased signal-to-noise ratio (SNR) for single-molecule spectra. Examples of precise measurements of the optical linewidth[26] and other phenomena which then became observable will be presented in Section 4. In studies of pentacene molecular defects in crystalline *para*-terphenyl, a novel physical effect called spectral diffusion was observed,[27, 28] which will be summarized in Section 5. Section 6 describes how extensions of SMD to polymeric hosts[29, 30] allow direct observations of hole-burning and stochastic kinetics for an individual center. Section 7 presents results of very recent single-molecule spectroscopy in which spectral shifts due to external electric fields (the Stark effect) have been measured in both crystalline and amorphous materials.[31, 32] Finally, Section 8 reviews a novel new experiment on quantum optics in solids, where the fundamental photon antibunching expected for the fluorescence emission from a single molecule in a solid has been observed.[33] With these results, a new regime of optical spectroscopy may be envisioned in which some of the scientific

W. E. Moerner was born in 1953 in Pleasanton, California. After receiving three Bachelor's degrees in 1975 from Washington University, St. Louis, he obtained M. S. (1978) and Ph.D. (1981) degrees in physics from Cornell University, where he worked with A. J. Sievers. He joined the IBM Research Division, Almaden Research Center in 1981, and worked extensively in the area of spectral hole-burning. He received the Roger I. Wilkinson Outstanding Young Electrical Engineer Award from the Eta Kappa Nu Honorary Electrical Engineering Society of the U.S. in 1984 and an Outstanding Technical Achievement Award from IBM in 1988 and in 1992. He is a Fellow of the Optical Society of America and the American Physical Society, a Senior Member of the Institute of Electrical and Electronics Engineers, and a member of the American Chemical Society. His current interests include single-molecule spectroscopy in solids, optical storage, and polymeric photorefractive materials.

Thomas Basché, born 1959 in Bingen, Germany, did his undergraduate studies in chemistry at the University of Munich where he received his Ph.D. in 1990 for his work with C. Bräuchle. In 1991 and 1992 he was a postdoctoral fellow with W. E. Moerner at the IBM Almaden Research Center in San Jose. His current research interests include optical line-narrowing experiments with adsorbed molecules and single-molecule spectroscopy in condensed phases.

advances and observations of physical effects made possible by the ion trap and STM techniques may be applied to condensed matter.

2. First Steps toward Single-Molecule Spectroscopy

2.1. Background on Inhomogeneously Broadened Optical Lines

It is well known that absorbing guest centers in solids with zero-phonon transitions give rise to inhomogeneously broadened lines[34, 35] where the overall line profile is caused by an approximately Gaussian distribution of center frequencies for the individual absorbers that is broader than the (usually Lorentzian[36]) homogeneous lineshape of the individual absorbers. This situation is shown schematically in Figure 1 and by simulation in Figure 2, which will be described in Section 2.2. The distribution of center frequencies is caused by dislocations, point defects, or random internal electric and strain fields and field gradients in the host material. Inhomogeneous broadening is not only a universal feature of high-resolution laser spectroscopy of defects in solids,[15, 37] but it also appears in a fundamental way in other spectroscopies of impurity centers such as NMR, ESR, and Mössbauer spectroscopy. Inhomogeneous broadening also occurs in amorphous hosts, where the (generally broad) center frequency distribution is caused by the large multiplicity of local environments. Although the work reviewed here is focused mainly on the lowest electronic transition of the absorbing molecule, all of the concepts apply equally well to inhomogeneously broadened vibronic lines as well as to inhomogeneously broadened purely vibrational zero-phonon lines.

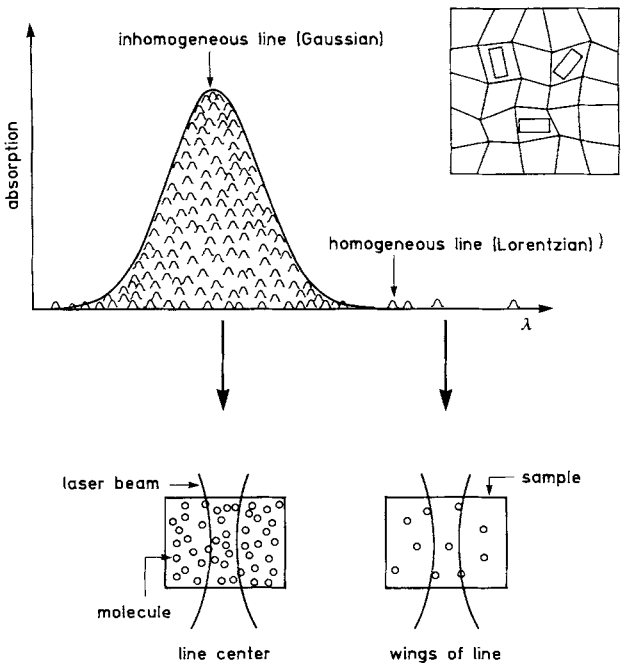

Fig. 1. Top: Schematic representation of an inhomogeneous absorption band at low temperatures and the principle of single-molecule detection in solids. The entire band is formed as a superposition of Lorentzian profiles of the individual absorbers; a distribution of center resonance frequencies is caused by random strains and imperfections. The lower part of the figure shows how the number of impurity molecules in resonance in the probed volume can be varied by changing the laser wavelength. The laser linewidth ($\simeq 3$ MHz) is negligible (after ref. [23]).

Inhomogeneous broadening generally dominates at low temperatures, because the homogeneous zero-phonon lines become much narrower than the inhomogeneous distribution of center frequencies only when the host phonons are quenched. For example, for pentacene in *p*-terphenyl, the homogeneous width of the lowest electronic transition at 593 nm is 7.8 MHz at 1.5 K,[38] while the overall inhomogeneous line is 42 GHz in width in crystals grown by the Bridgman method.[39] In the single-molecule spectroscopy to be described in Section 3, inhomogeneous broadening will be used to select one single absorber for study by proceeding out into the wings of the inhomogeneous line as shown on the right side of Figure 1.[40] Since the center frequencies for these absorbers are displaced very far from the most common center frequencies near the center of the inhomogeneous line, such absorbers have highly unique and strained sites. For this reason, various recent SMD experiments have also considered the situation where the concentration of impurity centers is lowered and single molecules are measured much closer to the center of the inhomogeneous line.

2.2. Statistical Fine Structure

Before the single-molecule limit can be approached, however, it is necessary to review the statistical properties of inhomogeneous lines. To quantify the number of impurity centers absorbing at a particular frequency or wavelength, it is useful to define the quantity $\bar{N}_H$, which is the average number of centers in the probed volume whose center frequencies are within one homogeneous width of the laser wavelength. Due to the unavoidable randomness associated with the imperfections in solid hosts even for a single molecular orientation or "site", inhomogeneous absorption lines (at least where $\bar{N}_H \gg 1$) are often approximated by smooth, Gaussian profiles.[34, 39] However, since the inhomogeneous line on a microscopic scale is simply a superposition of discrete homogeneous lines with widths as much as 1000 times narrower than the overall inhomogeneous profile, the true shape of the inhomogeneous line cannot be a smooth function. In fact, unavoidable fluctuations in the number of absorbers per unit wavelength interval should give rise to a "spectral noise" on the overall Gaussian background that scales as the square root of the mean number of centers in resonance. In other words, there should be a statistical fine structure (SFS) present on the absorption profile scaling in absolute magnitude as $\sqrt{\bar{N}_H}$ (in the limit of $\bar{N}_H \gg 1$). Since SFS arises from the absorption of many overlapping impurity absorptions, the absolute magnitude of the SFS is clearly larger than a single-molecule absorption signal (where $\bar{N}_H \simeq 1$). Therefore, observations of SFS would be expected to precede true single-molecule or single-center detection. This is more than just a pedagogical point: in fact, in any experiment with sensitivity capable of reaching the single-molecule limit, SFS should be observed first and used as a "test signal" to optimize the detection conditions.

Figure 2 shows a computer simulation of an inhomogeneous lineshape for various total numbers of centers N and

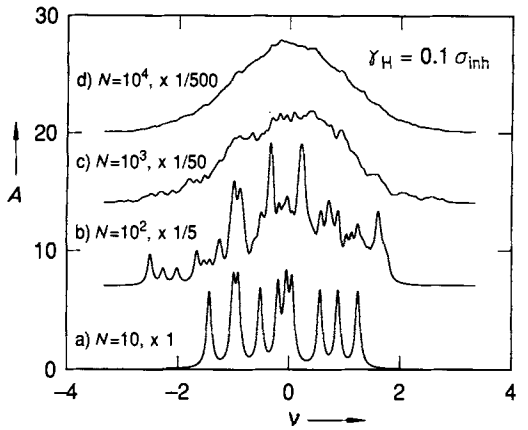

Fig. 2. Simulated absorption spectra with different total numbers of absorbers N. A Gaussian random variable was used to select center frequencies. The homogeneous linewidth is one-tenth of the standard deviation of the inhomogeneous distribution. A = absorption in arbitrary units, ν = frequency in units of σ_{inh} (see text).

hence different values of $\bar{N}_H$. Here γ_H is the (assumed Lorentzian) homogeneous width (full width at half-maximum absorption, FWHM), and σ_{inh} is the standard deviation of the normally distributed distribution of center frequencies. For clarity, a small value of the ratio $\sigma_{inh}/\gamma_H = 10$ was chosen for the simulation; in real solids, this ratio usually ranges from 10^2–10^5. The main point here is that even though the center frequencies were chosen by sampling from a (smooth) normally distributed random variable, the actual center frequencies never form a smooth uniform covering of the allowed frequency space. This is merely a statement that the usual number fluctuations encountered in many areas of physics and chemistry must occur here as well. As Figure 2 shows, the average absorption $\bar{\alpha}$ grows linearly with $\bar{N}_H$, while the relative fluctuations in absorption $\Delta\alpha/\bar{\alpha}$ decrease with $(\bar{N}_H)^{-1/2}$. Therefore, in terms of relative changes in absorption it appears that low-concentration samples ($\bar{N}_H < 10$, for example) might be expected to be optimal for the observation of SFS. While this is true for most techniques, SFS was in fact first observed in a different regime.

2.3. Detection of Statistical Fine Structure with Laser Frequency Modulation Spectroscopy

The limit $\bar{N}_H \to 1$ is in fact the single-molecule regime itself. In the early work, it was realized that statistical fine structure could be measured without completely solving the problem of single-molecule detection. The zero-background technique of laser frequency modulation (FM) spectroscopy[20] provides a solution, because the variable measured is $\Delta\alpha$ itself, which increases with $(\bar{N}_H)^{1/2}$. In other words, statistical fine structure is easier to detect at large $\bar{N}_H$ if FM spectroscopy is used. A glance at Figure 2d verifies that the size of the absorption variations due to SFS in terms of departures from the average absorption is indeed far larger than the size of the absorption signal from a single molecule. Rather than describe the details[41] of FM spectroscopy here, it is more useful to describe the characteristics of the method: 1) The laser is phase-modulated at the radio frequency ν_m, and the transmitted beam is detected with a radio frequency lock-in amplifier at ν_m. 2) The background is zero in the absence of residual amplitude modulation (RAM). 3) The noise on the signal is derived from the laser noise at ν_m, which may be at the quantum limit if no excess noise is introduced by the detector. 4) The signal is largest when the width of the spectral feature is comparable to or less than ν_m; broad spectral features produce no signal. More precisely, in FM spectroscopy the detected signal (in the cosine phase) is proportional to $[\alpha(\nu + \nu_m) - \alpha(\nu - \nu_m)]L$, where ν is the laser frequency and L is the sample thickness. Thus the FM signal measures the difference in αL at the two sideband frequencies. It can easily be shown[19] that as long as the optical density is not too large the FM signal resulting from statistical fine structure is described by Equation (a), where σ is the

$$(\Delta\alpha)L = \sigma(\bar{N}_H)^{1/2}/A = \sigma(\rho_H L/A)^{1/2} \quad \text{(a)}$$

peak absorption cross section, A is the beam area, and the volume density per homogeneous linewidth is given by $\rho_H = \bar{N}_H/AL$. Therefore, the FM signal increases if the concentration of absorbers or the sample length increases, and increases for smaller laser spots. Further, centers with higher cross section lead to larger FM signals.

For the well-studied model system[15,42] pentacene in p-terphenyl crystals statistical fine structure can be easily detected by FM spectroscopy at 1.5 K.[18,19] A schematic illustration of the location of the pentacene molecules in the p-terphenyl host crystal is shown in Figure 3. Pentacene can

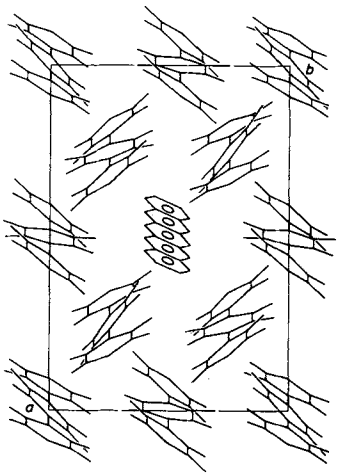

Fig. 3. Schematic representation of the crystal struture of p-terphenyl showing one possible location for a pentacene dopant molecule. This depiction of the pseudomonoclinic crystal structure (projected onto the ab plane) was adapted from ref. [43].

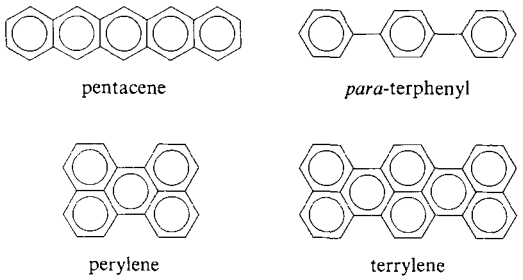
substitute for any one of the four p-terphenyl molecules in the low-temperature unit cell[39,43] giving rise to four $S_1 \leftarrow S_0$ optical absorption origins near 593 nm, called O_1, O_2, O_3, and O_4. It is convenient to focus on the inhomogeneously broadened origins O_1 and O_2, because the homogeneous linewidths are smaller here than for the other origins.

An example of the static nature (and repeatability) of the SFS spectra measured with FM spectroscopy is shown in Figure 4, where the bottom panel shows a 5-GHz-wide scan near the peak of the O_1 line. The spectra were acquired by



repeatedly scanning the desired frequency range with a Rhodamine 6G single-frequency dye laser (2.8 MHz linewidth). Contrary to what the reader might think, this is not a recording of some noisy signal. The many peaks and valleys are actual, repeatable fine structure as is demonstrated by the two expanded traces in the top panel of Figure 4, the lower

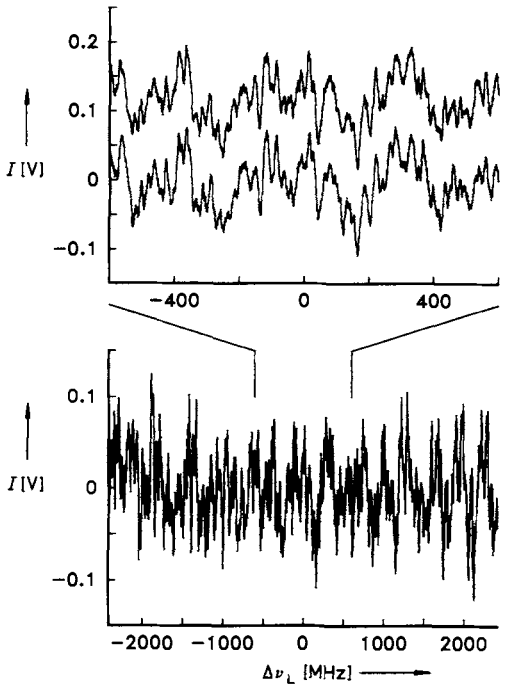


Fig. 4. Frequency modulation spectrum over a wide scan range showing statistical fine structure. The lower panel shows the result of 64 averages of a 5 GHz region of the inhomogeneous line of pentacene in *p*-terphenyl ($T = 1.4$ K). The upper panel shows a portion of the same spectrum on an expanded frequency-scale together with another acquisition of the spectrum taken 20 min later, offset for clarity. Laser power 3 μW, focal spot diameter 20 μm (after ref. [19]). *I* is the intensity of the SFS signal in Volts.

of which is an expansion of the trace in the bottom panel and the upper of which is a subsequent acquisition of the same spectral region more than 20 min later. The agreement is quite good, indicating that at 1.4 K there is little or no rearrangement or annealing of the strains and other imperfections in the *p*-terphenyl crystal which defined the inhomogeneous distribution when the crystal was cooled. Most, if not all, of the slight differences between the spectra are due to the quantum and avalanche noise of the detection system. As expected from Equation (a), the root mean square amplitude of the SFS spectra should grow as $(\bar{N}_H)^{1/2}$, and indeed a measured dependence of $(\bar{N}_H)^{0.54\pm0.05}$ has been observed experimentally.[18]

More insight into the source of SFS can be derived from spectra from different sample volumes. The formation of a specific set of center frequencies for a given sample volume is a random process which reflects the underlying probability distribution for center frequencies; thus SFS should be different for different sample volumes. A "SFS landscape" of the sample can be generated by acquiring multiple SFS spectra as a function of the position of the laser spot, as shown in Figure 5. This display allows one to search for "mi-

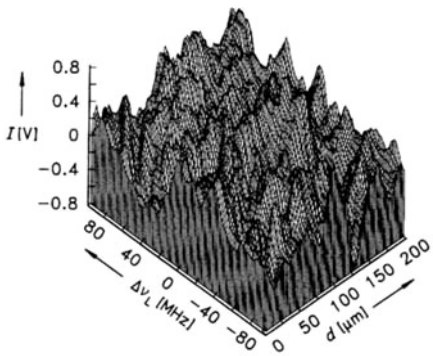

Fig. 5. Statistical fine structure (SFS) versus laser spot position *d* and laser frequency ν_L (0 MHz = 592.32 nm) near the inhomogeneous line center for pentacene in *p*-terphenyl. A sequence of 100 spectra were obtained; the 20 μm laser spot was moved by 2 μm after each spectrum, and the results plotted as a three-dimensional plot of the SFS signal to show the SFS "landscape" (after ref. [19]).

crosites", special (more probable) frequencies that would appear as ridges in this three-dimensional plot. No evidence for microsites or departures from the statistical source for SFS have been observed in this system. As a final point, the value of the underlying homogeneous linewidth can be determined directly by an autocorrelation analysis of the SFS spectra.[19] In systems with weak spectral hole-burning and weak spectral diffusion, this method of obtaining the homogeneous width should work as well as the older, more established techniques of coherent transients or hole-burning, as long as the signal-to-noise ratio of the SFS spectrum is reasonable.

2.4. Further Steps Toward the Single-Center Limit

Subsequent to the first observations of statistical fine structure, other researchers utilized both FM spectroscopy and fluorescence excitation to observe SFS in other classes of materials at smaller and smaller values of $\bar{N}_H$. Lange et al.[44] relied upon fluorescence excitation of Sm^{2+} ions in CaF_2 at 77 K with a fixed-frequency laser in tightly focused spots. They saw Poisson fluctuations in the detected fluorescence as a function of the position of the focal spot, and concluded that they had reached the level $\bar{N}_H = 5$. In a particularly novel approach, developed by the Yen group at the University of Georgia,[45,46] laser fluorescence excitation was used in a glass fiber doped with Nd^{3+} ions. Here the fiber geometry effectively maintained a small focus and a small sample volume, and background signals from the host were reduced. The measured SFS led these researchers to conclude that they had reached $\bar{N}_H$ values on the order of a few tens of ions,

although the spectral features were somewhat broad. In both of these cases, special detection geometries were required to reduce interfering background fluorescence from Rayleigh and Raman scattering.

Equation (a) shows that SFS becomes harder and harder to detect when σ decreases. The drop in signal can be partially offset by increasing the concentration of centers, but for constant optical density the signal still suffers as the square root of the cross section. Nevertheless, FM techniques with the addition of secondary Stark modulation to remove residual amplitude modulation (RAM) allowed the observation of SFS for Cr^{3+} ions in alexandrite.[47] Another approach when σ is low is maintaining a focused spot over a long distance in an optical fiber. In this case the SFS signal increases as the square root of the fiber length, as long as the optical density is less than unity. Using this approach and FM spectroscopy techniques, Brocklesby et al.[48] observed SFS for Nd^{3+} ions in a silica fiber. These experiments demonstrated that SFS can indeed be detected for absorbers in amorphous hosts and for relatively weakly absorbing centers.

3. Detection of Single Molecules in Solids with Absorption Techniques

3.1. Detection with FM Double-Modulation Techniques

Compared to the previous single-absorber experiments on ions in traps, molecules on surfaces, and molecules in hydrodynamic flows, single-molecule detection in solids provides a different set of experimental challenges. The problem can be likened to finding a needle in a haystack, because unlike the ion-trap experiments, for example, the molecule of interest is hidden within a solid containing a large number ($\approx 10^{12} - 10^{18}$) of nonabsorbing, potentially interfering host molecules within the laser focal volume. If laser-induced fluorescence excitation were used for SMD and the host molecules had appreciable Raman (or Rayleigh) scattering cross sections, the signal from the one absorbing molecule could be swamped by the scattering signal from the host.

The first successful SMD experiment,[21] also performed on the pentacene/*p*-terphenyl system, avoided the problem of fluorescence background from the host "haystack" by using the powerful zero-background properties of FM spectroscopy.[20] This method also has the advantage that it is sensitive only to spectral features with widths on the order of the modulation frequency ν_m. Therefore, any impurity molecules in the host matrix with wide absorption lines as a result of stronger electron–phonon coupling or much shorter excited state lifetimes than that of pentacene do not contribute to the observed signal. In this method narrow spectral features in the sample are used to convert the frequency- (phase-) modulated light beam into an amplitude-modulated beam. Since the method directly measures the conversion of frequency into amplitude modulation, any residual amplitude modulation (RAM) from imperfections in the modulator can give rise to a spurious background signal. To overcome this, a secondary modulation of the spectral feature itself was implemented by using oscillating Stark (or separately, ultrasonic) fields.

In the case of pentacene, the applied secondary Stark modulation with oscillating electric fields at frequency f (in the kHz range) shifts the absorption profile twice each cycle by the quadratic Stark effect.[49, 50] The secondary modulation with demodulation at $2f$ generates the first derivative of the FM signal. Because the physical effects giving rise to the RAM are insensitive to the Stark modulating field, this detection system yields a signal that is free from RAM background. It is clear that other local perturbations of the impurity molecule might also be used for double-modulation detection. Other RAM suppression methods that do not require secondary modulation could also be utilized.[51, 52]

The size of the expected absorption signal from a single molecule in an FM spectrum is straightforward to estimate.[21] The change in absorbance, $(\Delta\alpha)L$, is given by the probability of absorption of a photon in the incident beam by the molecule, σ/A, where σ is the peak absorption cross section and A is the area of the laser beam. Clearly, then, one would prefer tightly focused laser spots and molecules with strong absorptions. In the first experiments, the focal spot was $\simeq 3$ μm in diameter, and the peak (low-temperature) absorption cross section for pentacene is 9.3×10^{-12} cm^2, yielding an absorbance change of $\simeq 10^{-4}$. This is not an extremely small signal, but detection must be performed with a light intensity that does not produce extreme power broadening. To meet this constraint in a tightly focused spot, the measurements were performed with only 0.1 μW of light at the detector, which is an extremely small laser power for FM spectroscopy. Such a low light level required an avalanche photodiode to avoid detector Johnson (thermal) noise and resulted in detection approximately 3 dB above the quantum limit.

In spite of these limitations, the FM/Stark and FM/ultrasound methods can be used to detect the optical absorption of a single molecule of pentacene in a solid crystal of *p*-terphenyl.[21, 23] Figure 6 shows examples of the spectra for the FM/Stark case. The first three traces are simulations to illustrate the expected single-molecule lineshape for either Stark or ultrasonic double-modulation. Trace a shows a Lorentzian absorption profile of width γ, trace b the expected simple FM signal:[41] two copies of the absorption line with opposite sign, spaced by $2\nu_m = 150$ MHz (in the limit $\gamma \ll \nu_m$, where ν_m is the rf modulating frequency). With secondary modulation that causes frequency shifts less than the linewidth, the resulting double-modulation lineshape is the derivative of the simple FM lineshape (trace c). Thus the signature of a single molecule is a W-shaped feature with a large negative slope and a large positive slope separated by $2\nu_m$.

In a typical experiment, the laser frequency was set near the center of the inhomogeneous line, and the resulting strong SFS signal was used to optimize the optical and electronic configuration. Then as the laser wavelength was moved out into the wings of the line, the SFS amplitude dropped uniformly. Eventually spectra that appear to be superpositions of two to five single-molecule spectra were observed. Finally, sufficiently far out into the wings of the line, true single-molecule spectra could be recorded. Trace d in Figure 6 shows a set of eight FM/Stark double–modulation spectra of a strong in-focus molecule far out in the long-wavelength edge of O_1, along with several unavoidable,

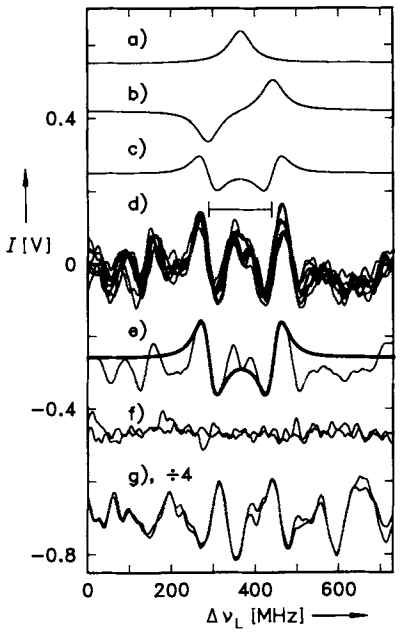

Fig. 6. Single-molecule spectra obtained with the FM/Stark technique (quadratic Stark effect) for pentacene in *p*-terphenyl. a) Simulation of the absorption line. b) Simulation of the FM spectrum with $\nu_m = 75$ MHz. c) Simulation of FM/Stark double-modulation lineshape. d) SMD spectra at $\lambda = 592.423$ nm, 512 averags, 8 traces overlaid; the bar corresponds to $2\nu_m = 150$ MHz. (O_1 line center is at 592.326 nm.) e) Average of traces in (d) and the fit to the in-focus molecule (smooth curve). f) Signal at $\lambda = 597.514$ nm very far from the line center; same conditions. g) Traces of SFS at the O_2 line center, $\lambda = 592.186$ nm, 128 averages each. The vertical scale is correct for trace d; the other traces have the same scale but are offset vertically for clarity (after ref. [21]). I = intensity of the double-modulation signal.

weak, repeatable features from out-of-focus molecules at the left and right edges of the laser scan range. These out-of-focus features were caused by molecules not located at the peak of the laser intensity profile. The fiducial bar in Figure 6 marks a spectral range equal to $2\nu_m$. Trace e shows the average of the eight scans in trace d, along with a fit to the central feature generated by a simple model for the double-modulation process.[23] The fit to the essential features of the SMD lineshape is reasonable, and the homogeneous width required by the fitting process is somewhat larger than the low-power homogeneous width, as expected.

Trace f in Figure 6 shows the detected signal from a laser wavelength so far away from the pentacene site origins that no absorptions are expected to lie in the laser scan range; this is the background shot and avalanche noise. In samples of undoped pure *p*-terphenyl, only a baseline noise level similar to the off-line data in trace f was observed, even near the center of the inhomogeneous line. Trace g shows spectra of the strong SFS observed near the center of the inhomogeneous line for which a smaller number of averages were used. This spectrum is composed of a superposition of many W profiles similar to trace d in Figure 6 with many different center frequencies, illustrating the qualitative difference between spectra of large numbers of molecules (trace g) and spectra of one molecule (trace d). By using the related FM/ultrasound technique and both longitudinal and transverse (shear) ultrasonic waves,[21, 23] single-molecule detection was confirmed.

In summary, the shape of the observed features, the position relative to the pentacene in *p*-terphenyl origins, the lack of such signals in undoped samples, and the appearance of single-molecule spectra with both the FM/Stark and FM/ultrasound techniques, led to the conclusion that the recorded spectra were indeed due to single molecules of pentacene. However, in both cases, the signal-to-noise ratio (SNR) was only approximately 3–5, and further improvements in this SNR proved difficult since the measurements were already performed near the quantum limit and power broadening was already present. Indeed, one cannot underestimate the difficulty in acquiring spectra like those in Figure 6, especially since later work to be described in Section 4 showed that many molecules spectrally diffuse within seconds. The single molecules observed by FM spectroscopy must have been class I (see Section 4) stable pentacene molecules with no spectral diffusion.

3.2. Signal-to-Noise Limits in FM Detection

The characteristics of the signal-to-noise ratio (SNR) for nonsaturating absorbers in FM spectroscopy have been described in ref. [41]. We will outline here the additional complications of avalanche photodiode detection and saturation of the optical transition as they affect single-molecule detection.[*] The analysis in this section is the result of unpublished work by W. P. Ambrose and one of the authors (W. E. M.). For simplicity, the signal-to-noise ratio for simple frequency modulation will be presented, with the assumption that the principal effect of the double-modulation is to remove residual amplitude modulation (RAM) and that the secondary modulation is strong enough to provide maximal signal.

The signal-to-noise ratio (SNR) of simple frequency modulation (FM) can be expressed in terms of a voltage or current ratio [Eq. (b)], where the (homogeneous) saturation of the absorption is described by Equation (c). P_0 is the laser

$$\mathrm{SNR} = \left[C \frac{P_0^2 (\Delta\alpha L)^2}{P_0 + J} \right]^{1/2} \tag{b}$$

$$(\Delta\alpha L) = \sigma/A = \frac{\sigma_0/A}{1 + I_+/I_s} \tag{c}$$

power at the detector, σ_0 is the unsaturated peak cross section, I_s is the saturation intensity, and $I_+ = \beta^2 P_0/4AT_w$ is the laser intensity in the first-order sideband at the sample, β is the modulation index, and T_w is the total transmittance of all optical components between the sample and the detector.

The SNR limits of FM spectroscopy derive from the two noise terms in the denominator of Equation (b), which represent the contributions of the shot noise of the laser beam (carrier) and the Johnson (thermal) noise of the detector, respectively. The constant J is given by $4kT/2eR_L RG_a^2 F_e$ with k Boltzmann's constant, T the absolute temperature, e the electron charge, R_L the load resistance, R the detector responsivity in AW^{-1}, G_a the avalanche gain, and F_e the avalanche excess noise factor. As one can see, the effect of the Johnson noise in reducing SNR is suppressed due to the

[*] Readers not interested in this particular problem may move on to the next section.

gain of the avalanche photodiode. Similarly, the constant C is given by $R\beta^2/16eBF_e$, with B the detection bandwidth. While FM spectroscopy has been shown to be capable of detecting absorption changes as small as 10^{-7} in a 1 Hz bandwidth if several mW of power is available at the detector, the severe limitations on the laser power in single-molecule detection greatly reduce the sensitivity of the technique. When the best possible gains for Si avalanche detectors of approximately 100 and F_e factors near 2.2 are used, the peak FM SNR is on the order of 1 for a saturation intensity of 70 mWcm^{-2}, which is the value for pentacene in *p*-terphenyl including triplet saturation. This SNR is consistent with the observed SNR in the FM experiments, and can be improved only by the use of laser beams with reduced quantum noise. As will be shown below, many pentacene centers have smaller values of saturation intensity and thus were probably not observable in the FM experiments.

4. Improvements in Signal-to-Noise Ratio by Fluorescence Excitation

4.1. Signal-to-Noise Limits in Fluorescence Excitation

The relatively low signal-to-noise ratio (SNR) available from FM absorption spectroscopy and the high powers required to attain this SNR placed severe limits on the physical and chemical information that could be obtained. The demonstration by Orrit et al. (see Section 4.2) that fluorescence excitation with high collection efficiency can be accomplished with acceptable background scattering levels provided greatly increased SNR at lower probing intensity, thus opening the door for additional detailed spectroscopic studies. In the fluorescence excitation method the frequency of a single-mode laser is tuned across the molecular absorption line, and the Stokes-shifted fluorescence intensity is monitored as a function of the excitation wavelength. The fluorescence excitation spectrum then represents an image of the absorption spectrum. An example of the experimental arrangement used by the IBM group is shown in Figure 7. (In the original setup by Orrit et al. a focusing lens was not used and the sample was placed at the end of a single-mode optical fiber.) For optimal collection of the emitted photons, the sample is placed at the joint focus of a lens focusing the laser beam and a paraboloid with numerical aperture near 1.0. The sample is mounted on a transparent substrate made of an alkali metal halide to reduce the possibility of first-order Raman scattering from the substrate. The emitted radiation passes through a long-pass color filter before detection with photon-counting apparatus.

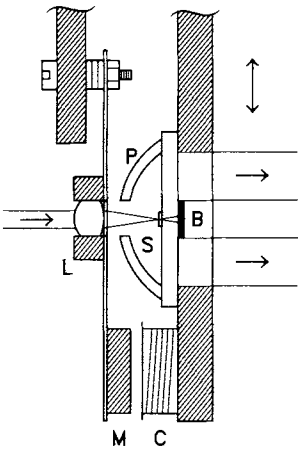

Fig. 7. Experimental set-up for single-molecule fluorescence excitation spectroscopy in a solid at liquid helium temperatures. The excitation laser beam enters from the left and is focused by a lens (L) with a 10 mm focal length into the sample (S), which is mounted on an alkali metal halide plate. The excitation beam is terminated with a piece of black tape (B). The fluorescence from the sample is collected by a parabolic mirror (P), which collimates the emission into a beam propagating to the right in the figure. Fine positioning of the lens (L) relative to the sample is accomplished with an electromagnetic actuator consisting of a coil (C) and magnet (M). Vertical displacement of the sample relative to the laser focal spot (resolution: 10 μm) is performed with a translation stage and micrometer screw (not shown) (after ref. [28]).

The attainable signal-to-noise ratio (SNR) for single-molecule detection in a solid by fluorescence excitation can be approximated by Equation (d), where S_1 is the peak fluorescence signal from one molecule, Φ_f is the fluorescence quantum yield, σ ist the peak absorption cross section on resonance, P_0 is the laser power, τ is the integration time (counting interval), $h\nu$ is the photon energy, N_d is the dark count rate, and C_b is the background count rate per Watt of excitation power. The factor $D = \eta_Q F_p F_f F_i$ describes the overall efficiency for the detection of emitted photons, where η_Q is the photomultiplier tube quantum efficiency, F_p is the fraction of the total emission solid angle collected by the paraboloid, F_f is the fraction of emitted fluorescence which passes through the long-pass filter, and F_i is the total transmission of the windows and collection optics along the way to the photomultiplier. The three terms in the denominator of Equation (d) represent shot noise contributions from the emitted fluorescence, background, and dark signals, respectively.

$$\frac{S_1}{(\text{noise})_{\text{rms}}} = \frac{D\Phi_f\sigma P_0\tau/Ah\nu}{\left[\frac{D\Phi_f\sigma P_0\tau}{Ah\nu} + C_b P_0\tau + N_d\tau\right]^{1/2}} \quad \text{(d)}$$

According to Equation (d) there are several important criteria that have to be fulfilled for optimum SNR, once the collection efficiency D is maximized. First, the peak absorption cross section σ and the fluorescence quantum yield Φ_f of the impurity in the matrix should be as high as possible. Further, the area of the laser spot at the sample plane should be as small as possible, which requires tight focusing of the probing laser beam. The power P_o cannot be increased arbitrarily because saturation causes the peak absorption cross section to drop,[53] $\sigma \rightarrow \sigma(I) = \sigma_o/(1 + I/I_S)$, where I is the laser intensity. For maximum I_S for organic molecules, it is favorable to have the triplet quantum yield low and the triplet lifetime short (expressions for I_S are given in ref. [54]).

To give a concrete example of the application of Equation (d) to a specific material we now consider the parameters appropriate for the model system pentacene in *p*-terphenyl at 1.5 K. Prior work has established that $\Phi_F = 0.78$[57] and that $\sigma_o = 9 \times 10^{-12}$ cm^2.[23] For I_S we use the measured[55] value of 2.5 mW cm^{-2}, which is lower than the value one would calculate using published photophysical parameters.[28, 57] The collection optics and GaAs photomultiplier tube yielded a collection efficiency of $D = 0.01$, and background and dark count parameters of $C_b = 7 \times 10^{10}$

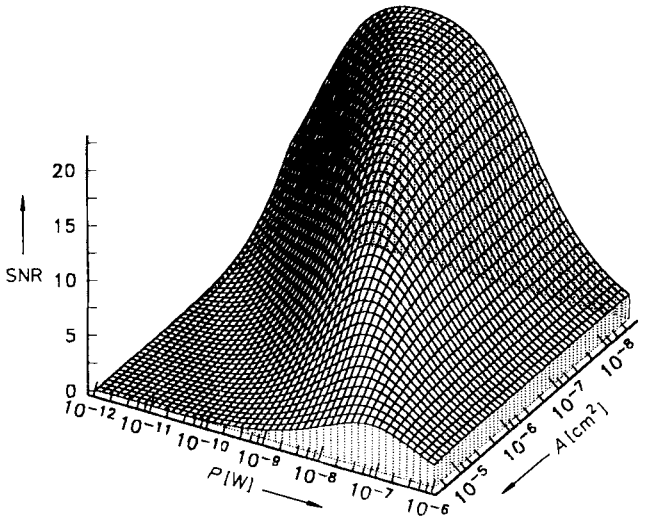

Fig. 8. Signal-to-noise ratio (SNR) for fluorescence excitation of pentacene in *p*-terphenyl versus laser power P and laser beam cross-sectional area A.

counts $W^{-1}\,s^{-1}$ and $N_d = 30$ cps, respectively. With these values, a three-dimensional plot of SNR for an integration time of 1 s versus laser power and beam area can be produced (Fig. 8). It is clear that for a fixed laser spot area, an optimal power exists which maximizes the tradeoff between the saturating fluorescence signal and the linearly increasing (with P) background signal. The lens focusing arrangement shown in Figure 7 produced a spot size of $\approx (5\,\mu m)^2$ located at the midpoint of the area axis. The SNR values predicted by Equation (d) are in reasonable agreement with the experimentally obtained values. One final fact to recognize from Figure 8 is that the best-case SNR at smaller and smaller beam areas levels off. This is due to the effect of saturation and shot noise; at smaller and smaller areas the power must be reduced eventually to the point where the SNR is controlled by the shot noise of the detected signal [first term in the denominator of Eq. (d)].

Of course, in single-molecule studies in solids, a crucial physical effect not included in Equation (d) must be taken into account. Persistent spectral hole-burning (PSHB), which can be observed for certain impurities in crystals and which is a more or less general phenomenon in amorphous hosts,[114] can cause the single impurity to change its absorption frequency before it emits enough photons to be detected above the noise level. The amount of hole-burning that can be tolerated depends upon the total number of molecular excitations required to achieve adequate SNR. A general rule of thumb for practical situations with collection efficiency D near 1% is that approximately 10^5 excitations are required to achieve a SNR on the order of 10 with 1 s integration time. This means that the hole-burning quantum efficiency should be $\leq 10^{-6}$. This indeed may be the most important factor limiting the number of materials systems suitable for single-molecule studies.

4.2. Fluorescence Excitation Measurements for Pentacene in *p*-Terphenyl

Recognizing from the SMD experiments using FM detection that pentacene in *p*-terphenyl is nearly ideal for such studies, Orrit et al. were the first to apply fluorescence excitation with high-efficiency collection to this system.[25] Figure 9 shows the first spectra generated with apparatus similar to that in Figure 7 except that an optical fiber rather than a lens was used. The sample itself was a thin sublimed platelet which helped to reduce the volume available for scattering. In the upper traces, the single-molecule signals appear as isolated dots; expansion of the scan range in the lower trace shows a clear, well-defined single-molecule profile with much improved SNR. These results led most investigators to subsequently use the fluorescence excitation method.

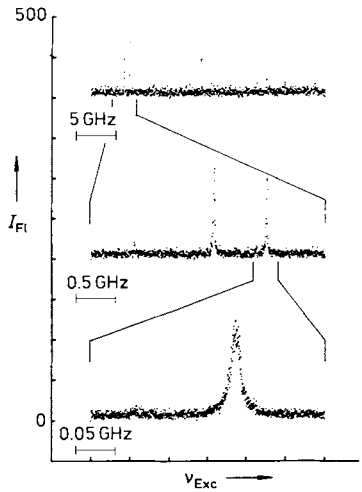

Fig. 9. Fluorescence excitation spectra of single molecules of pentacene in *p*-terphenyl ($T = 1.8$ K) (after ref. [25]). ν_{Exc} = excitation frequency, I_{Fl} = fluorescence intensity in arbitrary units.

The entire inhomogeneous line may now be measured over a wide wavelength range in order to provide specific data that can be contrasted with the schematic picture in Figure 1. Figure 10 shows data for a ≈ 10-μm-thick, low-concentration, sublimed sample of pentacene in *p*-terphenyl at 1.5 K,[28] which was carefully mounted to avoid strain. This 18 GHz spectrum, obtained by scanning a 3 MHz linewidth dye laser, contains 20000 points; showing all the fine structure usually requires several meters of linear space. Figure 10 top shows the frequency region covering the central part of the inhomogeneous line for the O_1 site at 592.321 nm. The structures appearing to be noise are not; they are direct measurements of the statistical fine structure (SFS) as described in Section 2. This structure is static and repeatable and arises directly from statistical variations in the spectral density of absorbers with laser frequency. It is immediately obvious that the inhomogeneous line is far from Gaussian in shape and that there are tails extending out many standard deviations from the center both to the red and to the blue.

More interesting are the spectral features in the wings of the inhomogeneous line (Fig. 10 bottom). At a detuning of -2.7 GHz and elsewhere, clearly resolved, individual single-molecule peaks can be observed. Similar single-molecule peaks are present on the blue edge of the inhomogeneous line. There is a slight variation in the height of the single-molecule peaks since some molecules are not exactly in the center of the Gaussian intensity profile of the laser beam.

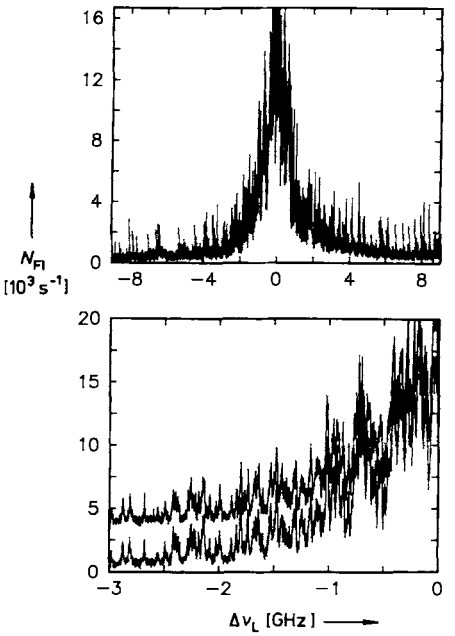

Fig. 10. Fluorescence excitation spectrum of pentacene in *p*-terphenyl (T = 1.5 K). The value of 0 on the frequency axis corresponds to a wavelength of 592.321 nm, which is near the center of the O_1 site inhomogeneous distribution. N_{FI} = Fluorescence count rate, $\Delta\nu_L$ = laser detuning. The unit $10^3\ s^{-1}$ means 10^3 counts per second. Top: An excitation spectrum obtained over 10 min with 2 nW of laser power. Bottom: Two spectra on an expanded scale (the upper trace is displaced from the lower) in the wing of the O_1 site inhomogeneous distribution. The isolated peaks out in the wing are excitation peaks for single pentacene defects (after ref. [28]).

The total pentacene concentration for the sample can be estimated directly by counting the number of molecules in the spectrum; a value of $1.7\times10^{13}\,cm^{-3}$ or 8×10^{-9} mol mol^{-1} is obtained. At different concentrations and in samples with differing levels of strain from mounting, the inhomogeneous linewidth can be varied over a wide range. It has been observed (as in Fig. 9 and confirmed by the IBM group) that in some samples epoxied to the end of an optical fiber the strain can become so great as to spread out the inhomogeneous line over several hundred GHz in frequency space.

Upon close examination of an individual single-molecule peak, the lifetime-limited linewidth of 7.8 ± 0.2 MHz can be observed[26] (Fig. 11). This value is in excellent agreement with previous photon echo measurements on large ensembles of pentacene molecules.[38, 58] The single-molecule excitation profile is well described by a Lorentzian function, as would be expected, since all inhomogeneous broadening has been removed. The laser intensity required for this measurement was 0.5 mW cm^{-2} (laser power 89 pW), and special care was required to remove the interfering effect of laser frequency drift during the measurements.

In general the homogeneous linewidth (full width at half-maximum, FWHM) of an optical transition in a solid is given by Equation (e), where T_1 is the excited state lifetime

$$\Delta\nu_H = \frac{1}{2\pi T_1} + \frac{1}{\pi T_2^*} \qquad \text{(e)}$$

and T_2^* is the (pure) relaxation time (dephasing time). Pure dephasing effects alter the phase of the excited transition without causing excited state decay, as for example when a lattice phonon scatters off the impurity molecule. In the pentacene/*p*-terphenyl system T_2^* goes to infinity for low temperatures ($T < 4$ K), because the host phonons and local modes are essentially quenched. Therefore, the homogeneous width as shown in Figure 11 is given solely by the

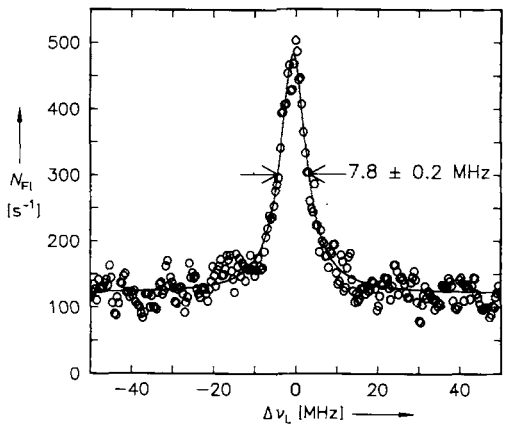

Fig. 11. Low-power fluorescence excitation spectrum for a single pentacene molecule in a sublimed crystal of *p*-terphenyl (T = 1.5 K). 0 MHz ≡ 592.407 nm, which is in the wing of the O_1 site inhomogeneous line. The solid line is a Lorentzian fit to the data (after ref. [26]).

lifetime contribution T_1. It is important to recall that in hole-burning experiments[16] the width of a spetral hole is given in principle by twice the homogeneous width, because a spectral hole is a convolution of the population hole (with width $\Delta\nu_H$, produced during the burning step) and the homogeneous lineshape (produced during the readout step). In many real (especially amorphous) systems, the hole width, however, can be much larger than $2\Delta\nu_H$ due to spectral diffusion occurring on a broad range of timescales.[59] The effect of spectral diffusion on the single-molecule lineshape in a polymeric host is described in Section 6. The point here is that the lineshape in Figure 11 shows neither spectral diffusion nor pure dephasing effects; the width has reached the smallest value allowed by Equation (e) and thus is the true homogeneous linewidth.

By slowly translating the laser focal spot across the face of the crystal and obtaining spectra at each position, one may observe single-molecule peaks localized in both frequency and position. It is thus possible to acquire a "spectral landscape" from the fluorescence excitation spectrum of the sample similar to that obtained for the statistical fine structure at high concentration near the inhomogeneous line center (see Fig. 5). Figure 12 shows a three-dimensional color plot of spectra taken at a series of overlapping laser spots 0.568 μm apart, in which the displacement was accomplished by translating the incident laser beam across the sample.[28] Within the 300 MHz tuning range shown, isolated single-molecule excitation peaks occur at laser detunings of +20, +130, and −120 MHz (relative to the center of the scan) at different positions in the crystal of 30, 35, and 40 μm. The shape of an excitation peak along the position axis is a direct measure of the (Gaussian) intensity profile of the laser beam in the crystal, as probed with the fluorescence emitted by a single molecule. In Figure 12, the spatial width (FWHM) of

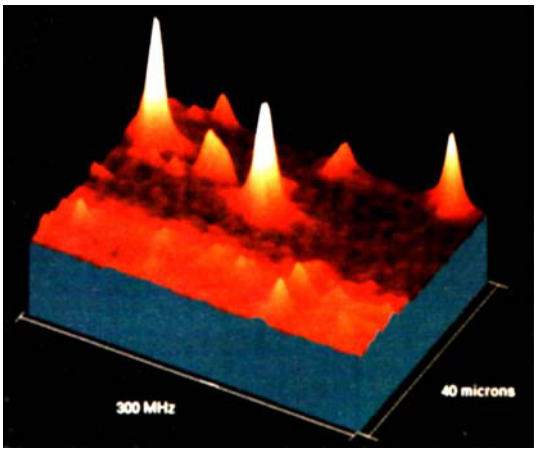

Fig. 12. "Spectral landscape" of the fluorescence excitation of a single pentacene molecule in a crystal of *p*-terphenyl ($T = 1.5$ K). The horizontal axis covers 300 MHz; the center of the axis corresponds to 592.544 nm. The axis extending into the page was generated by measuring successive, excitation spectra (scan time 2 min). The laser focal spot was displaced laterally by 0.57 μm between each measurement to cover a total distance of 40 μm. The intensity of the fluorescence is plotted on the vertical axis.

a single-molecule peak, and hence that of the laser focal spot is $\approx 5 \pm 0.5$ μm. The fluorescence peaks have different sizes because the molecules do not pass directly through the center of the laser focus and "experience" different peak laser intensities. The frequency widths of the peaks in Figure 12 are slightly larger than the lifetime-limited width (Fig. 11) due to the higher probing intensity used. The other oddly shaped peaks in the figure result from molecules that are spectrally diffusing. This effect will be discussed in more detail in the next section.

Spectra like those shown in Figure 11 are ideal for detailed measurements. For example, the intensity saturation behavior of both the linewidth and the emission rate for several single molecules in the wings of the inhomogeneous line was measured,[28] yielding a (free-space) value for the saturation intensity of $I_s = 2.5\ \mathrm{mWcm^{-2}}$. Usually, absolute intensity measurements are difficult because of the Gaussian shape of the laser spot and the difficulty in determining the size of the laser spot in the sample. Here, however, the laser spot diameter may be easily determined simply by using the single molecule as a probe. In the high-intensity limit, the peak fluorescence emission rate saturates at $(7.2 \pm 0.7) \times 10^5$ photons per second. As the peak emission rate saturates, the emission rate in the wings of the line continues to increase with intensity, and the homogeneous linewidth broadens according to the expected form [Eq. (f)].[60] It is remarkable that the value

$$\Delta\nu_{\mathrm{FWHM}}(I) = \Delta\nu_{\mathrm{FWHM}}(0)[1 + I/I_S]^{1/2} \qquad \text{(f)}$$

of I_s expected based on previously determined photophysical parameters for pentacene in *p*-terphenyl is larger than the measured value by more than a factor of 20. The exact reason for this discrepancy is unknown, although it is reasonable that some of the photophysical parameters are modified for the single molecules located in the wings of the inhomogeneous line. It is likely that the intersystem-crossing rate and/or triplet lifetime are affected rather than the fluorescence lifetime, since the intersystem-crossing process is more likely to be affected by strain.[56]

It is also possible to measure the linewidths (FWHM) of the signals of single pentacene molecules as a function of temperature. Such data have been acquired at temperatures up to 10 K where the linewidth increases by almost a factor of 100 compared to the value at low temperatures.[28] The data are in excellent agreement with previous photon echo experiments[15, 61, 62] in which the temperature dependence of the echo decay time was found to follow a form described by dephasing via a single pentacene librational mode[61] with librational energy $\Delta E/k = 38 \pm 1\ \mathrm{K} = 27 \pm 0.7\ \mathrm{cm^{-1}}$. To date, this same temperature dependence was found for all single molecules studied, indicating that the local mode is intrinsic to the defect center and is not influenced by the specifics of the local environment. This is to be contrasted with the local electric fields which do show a distribution (Section 7).

5. Detection of Spectral Diffusion of a Single Molecule in a Solid

In the course of the fluorescence excitation studies by Ambrose et al. on pentacene in *p*-terphenyl, an unexpected physical effect was observed: spectral diffusion of individual pentacene impurity molecules in a crystal at 1.5 K.[27] Here, spectral diffusion means changes in the resonance frequency of a defect at low concentration due to changes in the nearby host, rather than the energy transfer effects that can occur for impurity centers at high concentration.[37] Two distinct classes of impurity molecules were identified: class I, which have center frequencies that are stable in time, and class II, which show spontaneous, discontinuous jumps in resonance frequency of 20–60 MHz on a timescale of 1–420 s. Class II molecules were responsible for the distorted single-molecule peaks in Figure 12 which appeared to change shape between the individual laser scans. Figure 13 shows the behavior of a particular class II defect more clearly; the laser scan speed was increased to 1 scan every 2.7 s so that the spectral position of the molecule could be recorded with improved time resolution. The upper part of the figure shows how the resonance frequency of a spectrally "jumping" class II defect evolved with time, where each trace was digitally smoothed. A digital waveform recorder located the peak in each scan and recorded this resonance frequency as a function of time in the lower part the figure. For this defect, the optical transition energy appears to have a preferred set of values, and the defect performs spectral jumps between these values that are discontinuous on the one-second timescale of the measurement. This type of jumping behavior occurred for some tens of class II defects. In one case, one single molecule was observed that discontinuously jumped between only two allowed frequencies, but spectral jumps between a larger number of allowed frequencies was much more common (see below).

Before summarizing other types of behavior, we should present two crucial observations: First, the occurrence of class II defects was quite common in the wings of the inhomogeneous line (increasing to 40% of the studied molecules at a distance of +0.23 nm from line center), but only class I

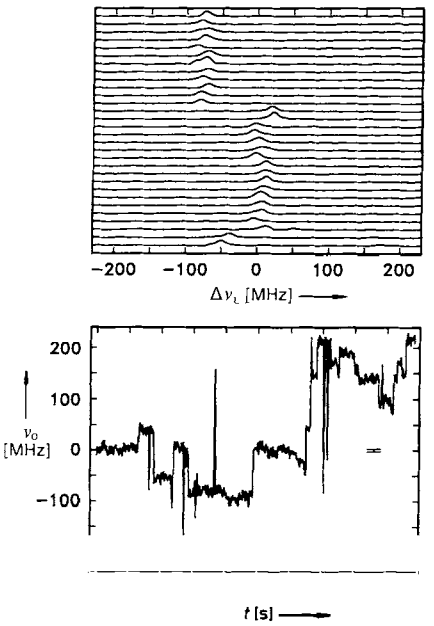

Fig. 13. Spectral jumps in the resonance frequency ν_0 of a class II single pentacene defect in p-terphenyl ($T = 1.5$ K). In the upper half of the figure are individual excitation spectra measured successively (scan time 2.7 s). The peak in each spectrum is represented as a function of time t in the lower half of the figure (after ref. [28]). $\Delta\nu_L$ is the laser detuning.

defects were observed in a spectral region from 0.003 to 0.01 nm from line center. The fraction of pentacene molecules showing class II behavior increased for wavelengths further and further from line center, suggesting that disorder in the crystal is partially responsible for the spectral migration. Second, the jumping rate did not depend upon the laser power used to measure the fluorescence excitation spectrum. This is the main reason that the observed changes in resonance frequency were attributed to a spontaneous process rather than a light-induced spectral hole-burning ef-

The behavior shown in Figure 13 shows relatively discontinuous resonant frequency changes, but in fact a wide array of characteristics was observed. Figure 14 provides an example that also illustrates the general effect of increasing temperature. These measurements of the time dependence of the resonance frequency of a single molecule were taken on a sample mounted on the end of a single-mode optical fiber placed at the focus of the collection paraboloid. This "wandering" defect spectrally diffused rapidly, and was found at a new frequency in every laser scan. During the 1600-second measurement at 1.5 K (Fig. 14 top), the spectral wandering for this defect was confined to a 500 MHz region. At 4.0 K (Fig. 14 bottom), the wandering range expanded to 700 MHz, and the spectral diffusion rate also appears to be higher. This could have been due to a larger number of small jumps between the laser scans, or the spectral jump sizes may have increased with temperature.

Of course, a detailed study of the temperature dependence of an appropriately defined average jumping rate would help to identify the source of the spectral diffusion effect. Such data have not been obtained to date for technical reasons relating to the difficulty of following the same single molecule over the entire temperature range. In samples attached to the end of the optical fiber molecules with wandering behavior like that in Figure 14 were found almost exclusively, which reflects the increased disorder in these samples. In future work, it should be possible to obtain useful temperature-dependence data even with the lens arrangement (Fig. 7) by cooling below 1.5 K with ^{3}He or a dilution refrigerator.

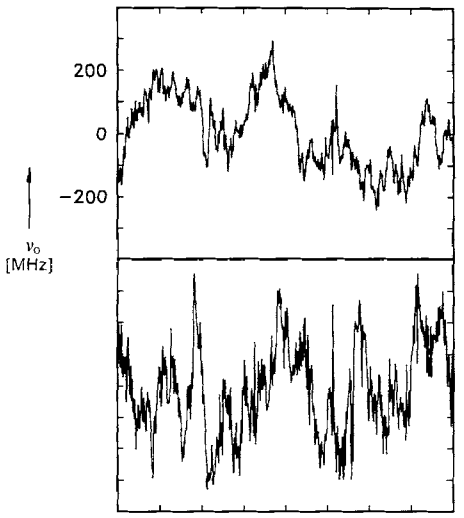

Fig. 14. Qualitative increase in spectral diffusion rate with temperature. In both traces the resonance frequencies ν_0 for a spectrally jumping molecule near the 592.582 nm excitation wavelength are shown. This molecule jumps often, appearing at a new frequency in each spectrum (scan time 2.7 s). Raising the temperature from 1.5 K (top trace) to 4.0 K (bottom trace) appears to increase the spectral diffusion rate and jumping range (after ref. [28]).

As a final illustration of the fascinating spectral diffusion phenomenon, Figure 15 shows the peak frequency trend of another pentacene defect over 1.6 h at 1.5 K. For this defect, which is on the low-frequency side of the inhomogeneous distribution, the overall trend can be described as "creeping" by successive jumps towards higher optical frequencies. As

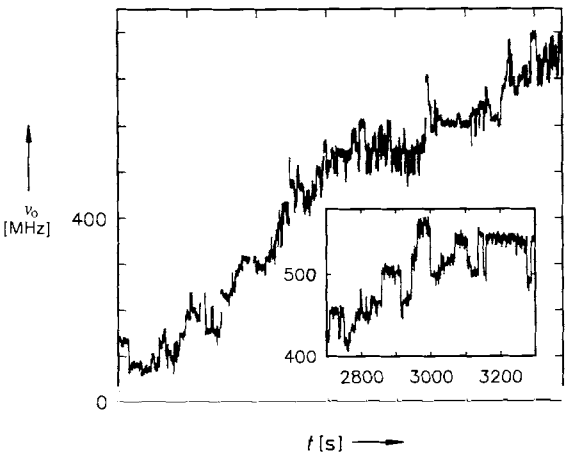

Fig. 15. Frequency "creep" of a spectrally jumping pentacene defect over an extended time. The peak frequency ν_0 of a class II defect near 592.544 nm (on the long-wavelength side of the O_1 inhomogeneous distribution) spectrally jumps no more than 100 MHz on short timescales, but tends towards higher frequencies over 1.6 h. The inset, an expansion of the trace recorded over 600 s, shows the individual jumps < 80 MHz. (after ref. [28]).

shown in the inset, there are residence times on the order of 30 s, and the molecule appears at new, higher frequencies at later times. This "creeping" pentacene defect may be in an environment that is structurally relaxing at 1.5 K into an environment more typical of those found at the center of the inhomogeneous line.

The resonance frequency of an impurity molecule in an inhomogeneously broadened line is extremely sensitive to the strain at the position of the molecule. Thus the spectral jumps appear to occur because the class II pentacene molecules are coupled to an (unidentified at present) ensemble of two-level systems (TLS) in the host crystal undergoing phonon-assisted tunneling or thermally activated barrier crossing. One possible source for the tunneling transitions could be discrete librations of the central ring of the nearby *p*-terphenyl molecules about the molecular axis. As Figure 3 shows, the *p*-terphenyl molecules have a particular dihedral angle between the central and outer phenyl rings, depending upon the specific position in the crystal.[43] When the monoclinic, room-temperature crystal strucure becomes triclinic below 170 K, it is not unreasonable to postulate that the sample may contain several single-crystal domains even though the phase transition is not destructive to the sample.[63] The *p*-terphenyl molecules in a domain wall may have lowered barriers to such central-ring tunneling motions, and the pentacene molecules near the domain walls would "sense" such local motions and show class II behavior. Further experiments are necessary to conclusively identify the molecular motions responsible for the effect. Of course, the spectral diffusion surprisingly observed here in a crystalline system is analogous to spectral diffusion processes that play a crucial role in the physics of glasses and other amorphous materials.[64] Most importantly, with the single-molecule detection technique the spectral changes can be followed in real time for each individual impurity molecule; no ensemble averages over "equivalent" centers need be made.

6. Single-Molecule Spectroscopy in Polymeric Hosts

6.1. Physical Properties of Glasses and Polymers at Low Temperatures

The experiments described so far were performed with single impurity molecules doped into a crystalline matrix. Amorphous systems such as glasses and polymers have a number of interesting physical properties at low temperatures that are quite different from those for crystalline materials.[65] A wealth of information on the low-temperature dynamics of amorphous systems was obtained by doping these materials with optical impurities and probing them with optical line-narrowing techniques such as fluorescence line-narrowing,[37] persistent spectral hole-burning,[14] and photon echoes.[59]

To understand the optical properties of these systems, a brief description of the amorphous state is in order. A glassy or amorphous material is characterized by a complex, multidimensional potential energy surface. According to the two-level system (TLS) model, the potential energy surface can be approximated by a distribution of asymmetric double-well potentials or so-called two-level systems. The TLS model assumes that at low temperatures only the two lowest energy levels of each double-well are important. Transitions from one side of the double-well to the other occur by phonon-assisted tunneling and represent changes in the local structure of the glass. As a result of the broad distribution of barrier heights and well-asymmetries, structural relaxation processes can occur on a wide distribution of timescales. When an impurity molecule is doped in an amorphous solid, its optical transition can couple to the TLSs (e.g. by dipole–dipole coupling), and the lineshape of the optical transition reflects the dynamical processes of the host.[66]

One important physical effect that occurs often in amorphous hosts is persistent spectral hole-burning (PSHB). In PSHB experiments, narrow bandwidth laser irradiation is used to select a reasonantly absorbing subensemble of molecules out of the inhomogeneously broadened absorption band. The optical excitation induces either photochemical changes in the excited centers or photophysical (nonphotochemical) alterations in the nearby host, and a narrow spectral hole can develop in the absorption because the altered centers no longer absorb at the laser wavelength. While photochemical hole-burning can occur in amorphous or crystalline systems, the nonphotochemical process is an almost general phenomenon in amorphous systems and is most likely caused by TLS transitions induced by the laser excitation.[67] By measuring the hole-shape as a function of temperature and/or thermal cycling,[16] information on the host dynamics can be obtained.

6.2. Detection of Single Perylene Molecules in Polyethylene

Aromatic hydrocarbons in non-hydrogen-bonding matrices are systems that show nonphotochemical hole-burning and have low PSHB quantum efficiencies. Taking this important prerequisite into account, perylene in a polyethylene matrix was found to be a suitable candidate for single-molecule detection.[29] Furthermore, the photophysical parameters for this system are favorable: the homogeneous linewidth of the optical transition is narrow, the absorption cross section ($\sigma_0 = 3.5 \times 10^{-11}$ cm^2) and the fluorescence quantum yield $\Phi_F = 0.98$ are high, and the triplet yield and lifetime are low.

The maximum of the inhomogeneous line for the lowest electronic transition of perylene in polyethylene lies at approximately 440 nm. The width of the inhomogeneous distribution is much larger than in a crystalline system, and single molecules were detected in the red wing of this distribution between 445 and 450 nm. In Figure 16 a fluorescence excitation "spectral landscape" of a perylene-doped thin film of polyethylene is shown at 1.5 K. This picture was taken with the same procedure as Figure 12. The signal sizes of the six strong single-molecule fluorescence peaks are again different, partly because the molecules "experience" different peak laser intensities. In an amorphous matrix, however, the orientations of the impurity transition dipoles are statistically distributed, and with a fixed polarization of the incoming laser the single molecule fluorescence intensities vary as

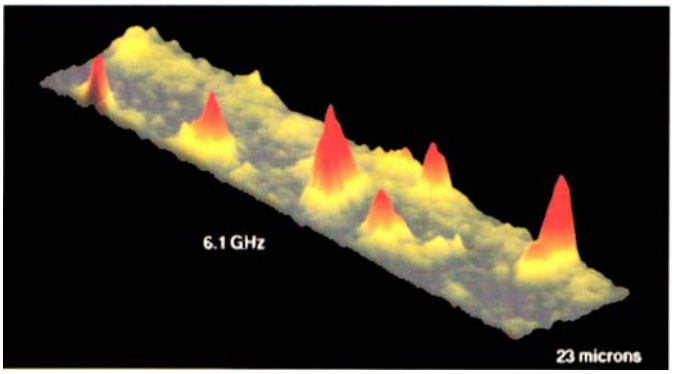

Fig. 16. "Spectral landscape" of the fluorescence excitation of single perylene defects in a polyethylene film. Each "mountain" represents the fluorescence from an individual molecule as the probing laser scans the frequency (6.1 GHz, horizontal axis) and is translated spatially across the face of the sample (23 μm, axis extending up and right).

$\cos^2\theta$, where θ is the angle between the laser polarization and the transition dipole axis. Hence, in this case there are two mechanisms that can lead to varying signal intensities. A close examination of the signal shapes along the frequency axis reveals that these shapes are slightly distorted. This distortion is due to a real physical effect, namely spectral diffusion, the various manifestations of which will be described in the next section.

6.3. Spectral Diffusion in a Polymeric Host

In the pentacene/*p*-terphenyl system the observation of spectral diffusion of single molecules was quite surprising, as the phenomenon occurred in an ordered crystalline material. By contrast, in disordered, amorphous matrices spectral diffusion is a well-known phenomenon.[59, 68] In the TLS picture spectral diffusion occurs due to spontaneous (phonon-driven) transitions in the double-well potentials of the host when the impurity molecules are in their electronic ground states. In hole-burning experiments spectral diffusion is observable by the time-evolution of the hole shapes (broadening) after the burning process.[69] How does spectral diffusion manifest itself in single-molecule experiments in a polymer?

In the perylene/polyethylene system spectral diffusion appeared in two ways in single-molecule spectra.[70] First, discontinuous jumps in frequency space on the scale of several hundred MHz between or during consecutive laser scans (scan time 2.86 s) were observed which were similar to the effects observed with pentacene/*p*-terphenyl (Section 5). Second, a broadening of the single-molecule lineshape was observed which varied from molecule to molecule. The observed linewidths ranged from 52 MHz to 142 MHz, and all these values were larger than the lifetime-limited width of 22.7 MHz. It should be mentioned that part of the observed line-broadening could be due to pure homogeneous dephasing by fast, global (non-local) TLS transitions. According to standard theories, this contribution to the width, however, is generally assumed to be the same for all molecules.

These results give direct evidence that spectral diffusion may occur over a range of frequencies and timescales. When the TLS model is employed, the experimental findings can be qualitatively explained by a hierarchy of TLSs surrounding the impurity. Distant TLSs produce fast shifts that are small in magnitude; in this case spectral diffusion appears as a broadening of the linewidth on the one-second timescale of the measurement. The closer TLSs produce larger shifts that are more infrequent; in this case spectral diffusion appears as frequency jumps which can be resolved on the experimental timescale.

6.4. Spectral Hole-Burning of a Single Molecule

A spectral hole usually refers to a dip in the inhomogeneously broadened absorption spectrum of many molecules when light irradiation alters the absorption frequencies of a portion of the resonant absorbers. In the single-molecule regime, however, only the isolated absorption profile of a single center is present. When photochemical or photophysical changes occur as a result of optical excitation, the absorption line simply appears to vanish as the resonance frequency of the single center shifts away from the laser frequency. As the underlying mechanisms are the same in both cases, we will continue to use the term persistant spectral hole-burning (PSHB) even for the single-molecule case.

An example of spectral hole-burning of a single perylene molecule in a polyethylene host is presented in Figure 17.

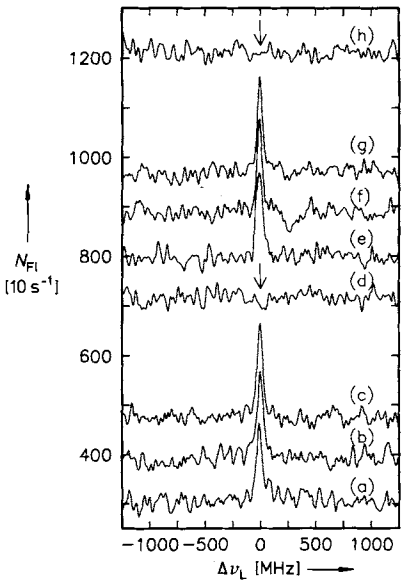

Fig. 17. Persistent spectral hole-burning (PSHB) of a single perylene molecule in a polyethylene film at 1.5 K (see text). 0 MHz ≡ 488.021 nm. The laser power for burning and scanning is 9 nW, and the scan time is 25 s (after ref. [29]). The vertical scale is correct for trace a, the other traces have the same scale but are offset vertically for clarity.

Before the traces shown in the figure were recorded, the molecule was scanned five times, and no significant changes were observed. Traces a, b, and c show three additional scans of the molecule. After trace c the laser was tuned into resonance with the molecule until the fluorescence decreased suddenly. Trace d was then acquired, which showed that the resonance frequency had shifted by more than ±1.25 GHz

as a result of the light-induced change; in other words, PSHB had occurred. A further scan some minutes later (trace e) showed that the molecule surprisingly returned to the burning frequency. After trace g the molecule was "burnt" again, and the whole sequence could be repeated several times.

The exact location of the new resonance frequency, however, could not be determined in these experiments. By analogy with previous nonphotochemical hole-burning studies of large ensembles of molecules,[17] the shift may be expected to be as much as 100 cm^{-1}. Besides the reversible single-molecule hole-burning illustrated in Figure 17, it was possible to observe other single molecules where the light-induced change was irreversible on the timescale of the experiment. The irreversible process was more common at high light power levels.

The possibility of burning one and the same molecule several times was used to determine the power dependence of single-molecule PSHB and to measure the kinetics of this process. Figure 18 shows that with increasing power, the burning time, although stochastically distributed, decreases. The power dependence of the hole-burning process was confirmed in this way for many single molecules. The experiments unambiguously showed that the single-molecule hole-burning is truly a light-driven process in contrast to excitation-power-independent spectral diffusion.

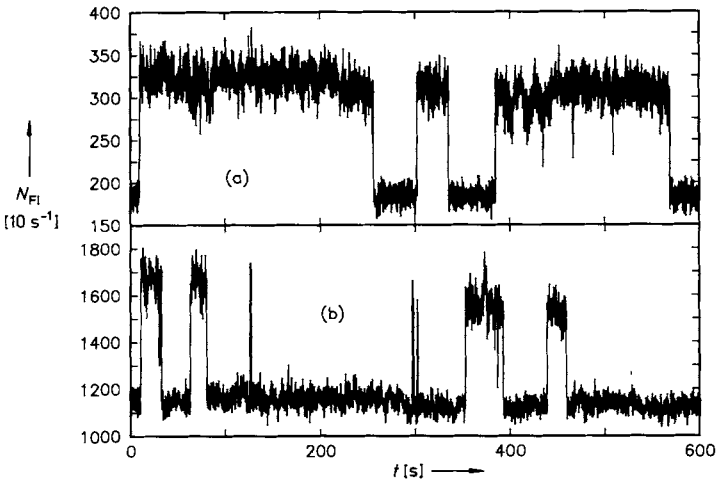

Fig. 18. Illustration of the power dependence of the hole-burning process for a single perylene molecule in a polyethylene film. a) The laser is tuned to resonance (λ = 448.159 nm) with the single molecule in the first 10 s at a power level of 4.5 nW. The abrupt drop of the fluorescence signal at 260 s is the hole-burning event; the return of the fluorescence signal indicates that the molecule has returned to its original frequency, only to be burnt again, and so on. b) The laser power level was increased to 27 nW; now the time in resonance, although stochastic, is clearly shorter (after ref. [29]).

In Section 6.3 two types of TLSs interacting with the impurity were discussed, those producing broadened single-molecule lineshapes, and those producing resonance frequency jumps. There are, however, also the so-called external TLSs which are created by doping the host with the impurity molecules.[71] These TLSs are thought to be in the close vicinity of the impurity and effectively locked because the barrier to configurational changes is too high. A common model for nonphotochemical hole-burning[17] assumes that by optical excitation of the impurity this barrier is lowered and a transition of the TLS can take place. The spontaneous return of perylene molecules after a burning event to exactly the same wavelength was somewhat surprising, though not absolutely unexpected. It suggests that coupling to exactly one dominant nearby TLS, rather than a succession of TLS configurations, is involved in the hole-burning process. In this picture optical excitation induces a (phonon-assisted) transition in the double-well potential in one direction which is reverted by a spontaneous (phonon-assisted) transition at some time later when the molecule is in its electronic ground state.

6.5. Measurement of the Stochastic Phototransformation Kinetics of a Single Molecule

The single-molecule hole-burning experiments are measurements with a single quantum system, although the molecule and its surrounding matrix cage have to be regarded as a kind of "supermolecule". Therefore, it is not surprising that the burning time for one molecule at a fixed power level is a stochastic quantity. By measuring a large number of burning events for one and the same perylene molecule in a polyethylene host it was shown that the burning times are exponentially distributed (Fig. 19).[70] This may be understood by the following simple argument.

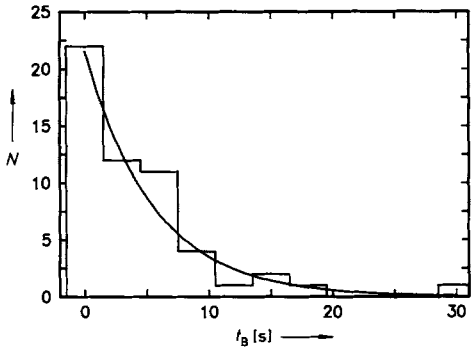

Fig. 19. Histogram of a random sample of 54 burning events measured for a single perylene molecule in a polyethylene matrix by using a power level of 4.5 nW (T = 1.5 K, λ = 448.156 nm). The plotted curve is the result of an exponential fit to the data (after ref. [70]). N is the number of events per time interval.

Single-molecule hole-burning is an example of a Poisson random process. The probability distribution for r successes (hole formation) in a finite time interval τ is therefore given by $P(r,\tau) = \exp(-\lambda\tau)/(\lambda\tau)^r r!$. In the hole-burning experiment, however, the waiting time before the first burning event (i.e. $r = 0$) was measured, and this waiting time therefore has the probability distribution $P(0,\tau) = \exp(-\lambda\tau)$. This corresponds to the familiar result that the distribution of waiting times between Poisson random events is exponential. The smooth curve in Figure 19 is a result of a fit of a simple exponential to the data. The histogram of the random sample of burning times is reasonably well approximated by an exponential distribution function with rate parameter $\lambda = 0.18\ s^{-1}$. This also means that the single perylene molecule investigated has an average hole-burning quantum efficieny of 2.9×10^{-7} per photon absorbed.

It is interesting to point out a formal analogy between these experiments and "quantum-jump" measurements with single trapped ions in a vacuum. In the latter investigations the bright fluorescence from a strong (allowed) transition ceases when the single atom "jumps" into a dark state which is weakly coupled to the ground state by a forbidden transition. In this case the number of quantum jumps per unit time is given by a Poisson distribution and the waiting times between quantum jumps by an exponential distribution as well.[72, 73]

7. Stark Effect Studies with Single Molecules

The fact that spectra of a single molecule in a solid can be obtained with high signal-to-noise ratios naturally leads to measurements of such spectra under the influence of external fields. One can imagine that Zeeman effects, Stark effects, and stress-induced splittings and shifts can be observed. In recent work, two groups have completed Stark effect studies on single molecules, in one case in a crystalline host and in the other case, a polymeric host.

7.1. Pentacene in *p*-Terphenyl Crystals

The first single-molecule Stark effect studies of the pentacene/*p*-terphenyl system were performed by Wild et al. using a longitudinal geometry in which the sample was held between a thin metal plate with a 5 μm pinhole and a SnO_2-coated glass plate.[31] (In fact, both the linear and quadratic Stark effects for this single-molecule system were utilized in the double-modulation scheme reported in Section 3 for the initial detection of single molecules with FM absorption.) In the recent work, fluorescence excitation spectra of single molecules were recorded with various DC external electric fields applied in order to determine specific values for the polarizability change and the internal field. In all cases, only shifts and no splittings of the single molecule spectra were observed.

Figure 20 shows the energy shifts recorded for four single molecules, along with best-fits to the data using second-order polynomials.[31] In general, a quadratic shift was observed with an offset from zero which was different for different molecules. The high symmetry of the pentacene molecule is consistent with a quadratic shift, and the linear term was attributed to different internal crystal fields at the positions of the various single molecules. The data were used to determine that the internal fields ranged from -1.6×10^3 kVcm^{-1} to $+0.8\times10^3$ kVcm^{-1}, and that the polarizability change $\Delta\alpha$ ranged from 1.1×10^{-39} Fm^2 to 2.5×10^{-39} Fm^2. The unambiguous observation of a quadratic shift, which was relatively constant from molecule to molecule, and a first-order shift, which varied considerably from molecule to molecule, gives direct evidence for one underlying source of inhomogeneous broadening that has been long postulated—randomness in the local crystal field.

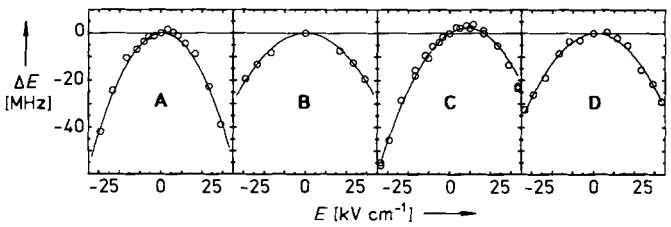

Fig. 20. Stark shift of four molecules of pentacene **A–D** in *p*-terphenyl as a function of electric field. The plotted curves are the result of second-order polynomial fits to the data (after ref. [31]).

7.2. Terrylene in Polyethylene

Numerous Stark effect studies of impurity molecules in amorphous materials have been performed over the last decade by using hole-burning techniques.[74, 75] Even with centrosymmetric molecules, only linear Stark effects were observed, due to the reduction of symmetry caused by local fields. To address the important question as to whether or not linear Stark effects persist down to the single-molecule level, Orrit et al. have recently studied a new system composed of terrylene molecules in low-density polyethylene.[32] The terrylene molecule is similar to perylene, except that three rather than two naphthalene molecules are condensed at the peri positions. This modification conveniently shifts the first electronic transition to longer wavelengths. The thin films were sandwiched between two transparent conducting plates for the optical measurements. As with pentacene in *p*-terphenyl, only shifts of the single-molecule lines were observed.

Figure 21 shows the observed frequency shifts for a selection of six single molecules. Only linear Stark shifts were detected, suggesting that the local fields were quite effective

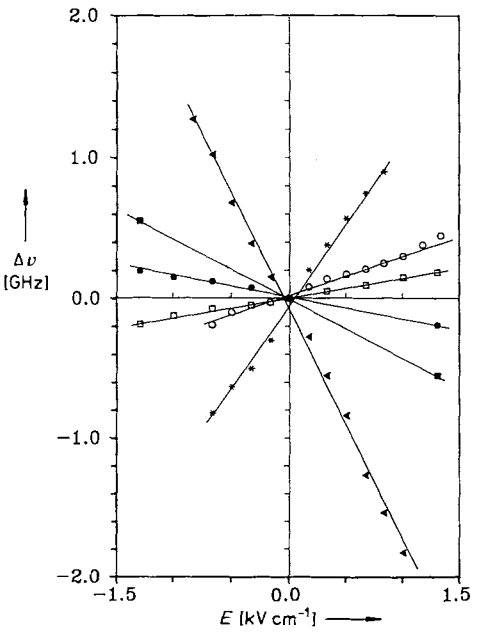

Fig. 21. Stark shift of single terrylene molecules in polyethylene as a function of electric field. The plots are linear to within experimental error; the magnitudes and signs of the slopes depend upon the orientation of the field relative to the molecule and the matrix cage. The largest slope corresponds to a change in dipole moment of several Debye (after ref. [32]).

in lowering the molecular symmetry. By studying a large number of single molecules, the distribution of Stark coefficients could be sampled, and positive coefficients were found to be more common than negative coefficients. It is certainly clear that these results provide individual measurements of the local fields, and that such perturbations are averaged in the conventional measurements at large values of $\bar{N}_H$. If it will be possible to measure the splitting coefficients for a single molecule with several directions of applied field, more specific information about the local symmetries may be obtained.

8. Measurements of Quantum Effects with Single Molecules in Solids

In all the experiments described in the preceding sections the single molecule served as an ultrasensitive probe for measuring truly local host–guest interactions. A single molecule can also be used to study the fundamental interaction of light and matter in experiments in which the fully quantum-mechanical nature of this interaction is revealed. So far investigations of this type with single particles were limited to single atoms stored in radio-frequency traps by photon-recoil cooling. A variety of fascinating experiments such as quantum jumps, quantum collapse and revival, photon antibunching, and many others were realized with laser-cooled ions.[1, 2] However, for all molecules, even diatomic species, the internal degrees of freedom prevent laser-cooling, and therefore trapping of a single molecule in a vacuum has not been achieved to date. As illustrated in the earlier part of this paper, however, single molecules can be easily "trapped" and observed optically in a solid. When the molecules are impurities in a solid and the samples are cooled to liquid-helium temperatures, the solid acts as a "trap" for the single impurity molecules. They are effectively held at rest, and in many cases, rotation of the impurity molecule is quenched and recoil effects are usually small (less than the optical linewidth).[35, 76]

One interesting aspect of the interaction of light and matter concerns the correlation between photons radiated by a single atom or molecule. As was shown for Na atoms in a weak atomic beam[77] or a single trapped Mg^+ ion,[78] the correlation between successive photons emitted by a single atom (ion) decreases near $t = 0$ (photon antibunching). This is in marked contrast to the case for coherent light, where the correlation is independent of the time separation between photons, and for thermal light, which shows an increase in correlation (photon bunching) near $t = 0$.

Photon antibunching in the resonance fluorescence of a single atom was predicted by Carmichael and Walls.[79] This phenomenon is a true signature of a quantum-mechanical radiation field which can be nicely rationalized with the following simple picture. In the correlation measurement the joint probability for the arrival of a photon at time $t = 0$ and the arrival of a photon at $t > 0$ is recorded. After emission of a photon at $t = 0$ the quantum system is in its ground state since it just emitted the photon. The probability of emitting a second photon at $t = 0$ is zero because the molecule cannot emit from the ground state. On the average, a time of half a Rabi period must elapse for the molecule to have a finite probability of being in the excited state and hence emitting a second photon.

Photon antibunching must be observed on a short timescale comparable to the excited singlet-state lifetime. Correlation measurements on the nanosecond timescale, or to be more specific, measurements of the second-order or intensity correlation function $g^{(2)}(\tau)$ were performed with single pentacene molecules in a *p*-terphenyl host.[33] The exciting laser pumped the lowest zero-phonon purely electronic transition $S_1 \leftarrow S_0$, and the photon correlation properties of the vibronically shifted fluorescence from the excited singlet state S_1 were analyzed. As in the single-atom experiments, the delay time distribution of consecutive pairs, $N(\tau)$, which is proportional to $g^{(2)}(\tau)$, was measured in a Start–Stop experiment, that is, by using a beamsplitter and two photomultipliers (PMTs) to record the emitted fluorescence. Detection of a photon from the first PMT starts a delay time counter, and the detection of a photon by a second PMT stops the counter. The distribution of such delay times is recorded for many Start–Stop pairs.

Plots of $N(\tau)$ are shown in Figure 22 for different levels of Rabi frequency (which is proportional to the square root of the intensity). The antibunching in the correlation function is clearly evident at short times $t \rightarrow 0$. With increasing power the background due to accidental pair correlations increases, leading to an increasing deviation of $N(\tau)$ from zero at the origin. The solid lines in Figure 22 show the results of numerical fits to the data using the solutions of the optical Bloch equations for a three-level system. At the highest power level (Fig. 22c) the correlation function shows, besides the antibunching, the expected Rabi oscillations which are damped out during the excited state lifetime.

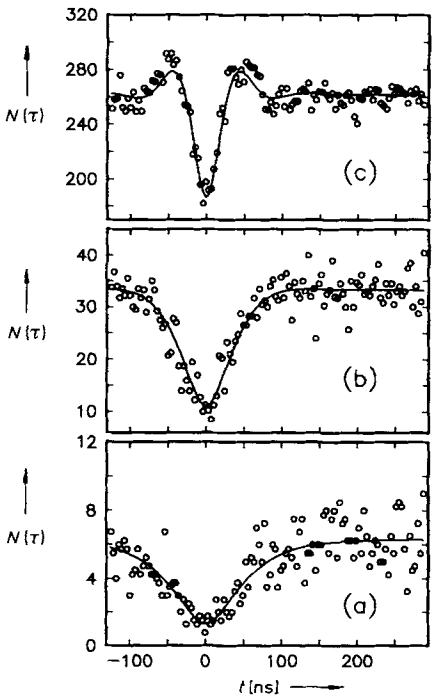

Fig. 22. Measured intensity correlation $N(\tau)$ [in counts per 0.9 ns] for a single pentacene molecule ($\lambda \approx 593.4$ nm). The antibunching is clearly seen for $t \rightarrow 0$. Rabi frequencies Ω: a) 11.2 MHz; b) 26.2 MHz; c) 68.9 MHz. The solid lines are fits to the data with $\Omega = 1-10$ MHz (a), 25.5 MHz (b), and 71.3 MHz (c) (after ref. [33]).

Since pentacene in *p*-terphenyl is effectively a three-level system when lowest triplet state is included, photon bunching should be observed for much longer times, comparable to the 40 μs triplet lifetime. This is a consequence of the fact that on average, the pentacene molecule emits roughly 200 photons due to singlet–singlet excitation before intersystem crossing into the "dark" triplet state occurs (the triplet yield is 0.0047[57]). This purely classical effect was observed clearly by Orrit et al.[25] and used to prove that the spectra in the early experiments arose from single molecules.

These first results on quantum optics in a solid demonstrate that single-molecule spectroscopy in solids can be used to investigate truly quantum-mechanical effects for multiatom molecules with zero-phonon optical transitions. Here the experimental data were not affected by transit time or secular motion effects as are the beam or ion-trapping methods. However, background signals and intersystem crossing into the triplet state did limit the single-molecule antibunching signal and must be controlled in each specific case. As long as the lowest electronic transition of the molecule is pumped, the presence of vibrational levels in the ground state and the detection of nonresonant fluorescence does not prevent the observation of photon antibunching.

9. Summary and Outlook

By utilizing the near-quantum-limited performance and low background of laser frequency modulated (FM) spectroscopy, the intrinsic fine structure on inhomogeneous lines in solids, statistical fine structure (SFS), was detected for the first time. With a detailed understanding of SFS and improvements to FM spectroscopy to remove residual amplitude modulation (RAM), it thus became possible to measure the optical absorption spectrum of a single molecule of pentacene in *p*-terphenyl. Dramatic improvements in the signal-to-noise ratio resulting from the use of fluorescence excitation with high-efficiency collection led to the observation of lifetime-limited widths, to saturation and dephasing studies, and to the surprising observation of spectral diffusion for a single impurity molecule in a crystal. Extensions of these investigations to systems with polymeric hosts allowed study of the spectral diffusion process widely postulated in amorphous materials, as well as to the observation of spectral hole-burning and stochastic kinetics for a single molecule. Stark effect studies in both crystals and polymers have yielded important new information about local symmetries and local fields. Fially, single-molecule techniques in recent work have led to the first quantum optics in a solid—the detection of photon antibunching for a single molecule.

The success of single-molecule detection and spectroscopy in solids opens up a new frontier of single-absorber experiments in which the measured properties of the absorbing center are not averaged over many "equivalent" absorbers. Here the absorbing entity is exquisitely sensitive to the symmetry and perturbations introduced by the local environment such as the local vibrational modes and the true local fields. While as a general technique the method presented here is not applicable to all molecular impurities, it can be applied to the large number of absorbing ions and molecules in solids that have zero-phonon transitions, reasonable absorption strength, and efficient fluorescence. The detectability of the resulting single-center signal, which ultimately depends upon the specific sample and weak or absent spectral hole-burning, must be evaluated in each case.

A number of fascinating future experiments based on the single-molecule detection techniques presented here may be contemplated. The temperature dependence of the spectral diffusion process in crystals may help to identify the source of the effect. It would be particularly interesting to measure the temperature dependence of the linewidth in a polymeric host to attempt to resolve the current controversy about dephasing processes in these systems. Nonlinear spectroscopy to measure the dynamic Stark effect for a single isolated molecule may also be performed. With the proper choice of lifetimes, one would expect quantum jumps and other processes observed for single ions in vacuum electromagnetic traps to become directly observable. The door is also open to true photochemical experiments on single absorbers, measurements of the dispersed fluorescence from a single molecule, and the possibility of optical storage with single molecules.[29]

In one novel experiment now possible the emission from a single molecule could be used as a light source of subnanometer-dimensions for near-field optical microscopy. Another possibility would be to perform cavity quantum electrodynamics studies with a single molecule in a solid. It is to be expected that single-molecule spectra will be obtained at higher and higher temperatures to extend the applicability of these studies to a wider range of materials. In all cases, improvements in the signal-to-noise ratio would be expected to open up a new class of applications. Because this field is only in its infancy, the possibilities are only limited at present by the imagination and the persistence of the experimenter and the continuing interest of the theoretician in the properties of single-quantum systems in solids.

10. Glossary

Coherent transient spectroscopy and photon echoes: In the present context we will limit our short explanation to the case of optical coherent spectroscopy where only two levels, the ground and excited electronic state of an atom or molecule, are involved. Coherent excitation of such a system with sufficiently high intensity lasers creates a coherent superposition of the ground and excited state wave functions. The coherent superposition, which is characterized by a well-defined phase relation between the two levels, leads to interference effects whose time evolution can be monitored with special spectroscopic techniques. The coherent state is described by the off-diagonal elements of the two-level density matrix in the optical Bloch equation formalism. The coherence is a transient phenomenon which is destroyed rapidly by population and phase relaxation processes. One example of coherent transient spectroscopy is the photon echo where the decaying coherence initially created by a first intense light pulse can be reestablished by a properly timed second light pulse. The photon echo can be formally described by the time evolution of a pseudo-spin vector in a fashion equivalent to the spin echo in magnetic resonance spectroscopy.

The time decay of the photon echo amplitude also gives information about the underlying homogeneous width when inhomogeneous broadening is present. See for example, L. Allen, J. H. Eberly, *Optical Resonance and Two-Level Atoms*, Dover, New York, **1987**.

Electron–phonon coupling and zero-phonon transition: When an impurity molecule in a solid matrix is electronically excited, the host vibrations (phonons) can couple to the electronic excitation (electron–phonon coupling) in the same way as is well known for the intramolecular vibrations of the impurity. Linear electron–phonon coupling, where the coupling strength is given by the displacement of the excited state potential surface with respect to the ground state potential surface, gives rise to phonon sidebands of the purely electronic transition line in absorption and emission. The purely electronic transition with no net creation or destruction of phonons is called the zero-phonon transition and can be viewed as the optical analogue of the recoil-free Mössbauer line. Quadratic electron–phonon coupling leads to a broadening of the zero-phonon line by phonon scattering. See for example, A. M. Stoneham, *Rev. Mod. Phys.* **1969**, *41*, 82; R. H. Silsbee, in *Optical Properties of Solids*, (Eds.: S. Nudelman, S. S. Mitra), Plenum, New York, **1969**, p. 607; K. K. Rebane, *Impurity Spectra of Solids*, Plenum, New York, **1970**, p. 99.

Frequency modulation (FM) spectroscopy: In FM spectroscopy the laser is frequency-modulated at a high frequency, narrow spectral features in the sample convert the frequency modulation into amplitude modulation, and the amplitude modulation of the light beam is detected with a high-speed detector and a lock-in amplifier. See G. C. Bjorklund, M. D. Levenson, W. Lenth, C. Ortiz, *Appl. Phys. B* **1983**, *32*, 145.

FWHM: Full width at half-maximum; a convention for measuring the width of spectral lines or of laser beam profiles.

Photon antibunching: A purely quantum-mechanical correlation property of a light beam which states that the probability of detecting two photons separated by a small time interval Δt approaches zero as $\Delta t \rightarrow 0$. See for example, R. Loudon, *The Quantum Theory of Light*, Clarendon, Oxford, **1983**, pp. 226–229.

Rabi period: In the time evolution of a two-level atomic system pumped by light, the Rabi period is the time required for the superposition of the two states to go from pure ground state, through the excited state, and back to the pure ground state again. See L. Allen, J. H. Eberly, *Optical Resonance and Two-Level Atoms*, Dover, New York, **1987**.

Residual amplitude modulation (RAM): Unwanted amplitude modulation of the laser beam in FM spectroscopy which represents a spurious background signal that can limit sensitivity. See for example, E. A. Whittaker, M. Gehrtz, G. C. Bjorklund, *J. Opt. Soc. Am. B* **1985**, *2*, 1320.

Statistical fine structure (SFS): This effect refers to the intrinsic variations in absorption coefficient versus wavelength which occur for inhomogeneously broadened transitions due to number fluctuations in the spectral density of absorbers. See T. P. Carter, M. Manavi, W. E. Moerner, *J. Chem. Phys.* **1988**, *89*, 1768.

SMD: Single-molecule detection.

SNR: Signal-to-noise ratio.

Spectral hole-burning: In spectral hole-burning experiments, narrow-bandwidth laser irradiation is used to select the resonantly absorbing subensemble of molecules out of an inhomogeneously broadened absorption profile. The optical excitation induces either photochemical changes in the excited centers or photophysical (nonphotochemical) alterations in the nearby host, and a narrow dip (spectral hole) can develop in the absorption spectrum because the altered centers no longer absorb at the laser wavelength. The width of the spectral hole can provide information about the underlying homogeneous linewidth when spectral diffusion effects are absent. Peristent spectral hole-burning (PSHB) refers to the situation in which the spectral hole lasts longer than any excited state lifetime. See for example, J. Friedrich, D. Haarer, *Angew. Chem.* **1984**, *96*, 96; *Angew. Chem. Int. Ed. Engl.* **1984**, *23*, 113; R. Jankowiak, G. J. Small, *Science* **1987**, *237*, 618–625; *Persistent Spectral Hole-Burning: Science and Applications* (*Top. Curr. Phys.* **44**), (Ed.: W. E. Moerner), Springer, Berlin, **1988**.

We are grateful to the Research Division of International Business Machines Corporation and to the U. S. Office of Naval Research for support of this research. We also acknowledge our colleagues, Drs. W. P. Ambrose, T. P. Carter, and L. Kador for their work which laid the foundations for single-molecule spectroscopy in solids.

[40] It would also be possible to drastically lower the impurity concentration and work near the center of the inhomogeneous line, and this has also been done. The present approach is somewhat more useful experimentally, since by tuning to the center of the inhomogeneous line where N is large, a convenient alignment signal results that can be used to optimize the detection system. Then, by tuning out into the wings, single-molecule absorptions can be observed.

Poly(hydroxyalkanoates): A Fifth Class of Physiologically Important Organic Biopolymers?**

By Hans-Martin Müller and Dieter Seebach *

Along with polyisoprenoids, polypeptides, polysaccharides, and polynucleotides, Nature contains a further group of biopolymers, the poly(hydroxyalkanoates). The commonest member of this group, poly[(*R*)-3-hydroxybutyrate] P(3-HB), had been identified by Lemoigne as early as the 1920s, as a storage substance in the microorganism *Bacillus megaterium* made up of more than 12000 (3-HB) units. However, the widespread distribution and significance of these biopolymers has only become clear recently. The work of Reusch, in particular, has shown that low molecular weight P(3-HB) (100–200 3-HB units) occurs in the cell membranes of prokaryotic and eukaryotic organisms. The function of P(3-HB) in the latter sources is largely unknown; it has been proposed that a complex of P(3-HB) and calcium polyphosphate acts as an ion channel through the membrane. Indeed, it has even been speculated that P(3-HB) plays a role in transport of DNA through the cell wall. In the present article, the following subjects will be discussed: metabolism of P(3-HB) and analogous polyesters in the synthesis and degradation of storage materials; P(3-HB) as a starting material for chiral synthetic building blocks; synthesis of cyclic oligomers (oligolides) of up to ten 3-HB units, and their crystal structure; high molecular weight bio-copolymers of hydroxybutyrate and hydroxyvalerate (BIOPOL) as biologically degradable plastics; nonbiological production of polyhydroxyalkanoates from 3-hydroxy carboxylic acids and the corresponding β-lactones; specific synthesis of linear oligomers with a narrow molecular weight distribution, consisting of about 100 (*R*)-3-hydroxybutyrate units, by using an exponential coupling procedure; structure of the polyesters, and a comparison with other polymers; the experimental results which led to the postulation of a P(3-HB) ion channel through the cell wall; modeling of P(3-HB) helices of various diameters, by using the parameters obtained from the crystal structures of oligolides; formation of a crown ester complex and ion transport experiments with the triolide of 3-HB. The article describes one example of the contributions that synthetic organic chemists can make to important biological problems in an interdisciplinary framework.

1. Introduction: Occurrence and Significance of Polyhydroxyalkanoates in Nature

Polyhydroxy acids (PHAs[1]) are synthesized by microorganisms under conditions of nutrient limitation in the presence of an excess carbon and energy source. Due to their low solubility and their high molecular weight PHAs do not cause an increase in osmotic pressure, and they are therefore ideal storage compounds.[2] In this role they are much more common in microorganisms than are glycogen, polyphosphates, or fats, for example.[3,4] The most prominent PHA is poly[(*R*)-3-hydroxybutyrate] [P(3-HB)], a linear, unbranched homopolymer built up of (*R*)-3-hydroxybutyric acid units. The molecular weight values given in the literature vary considerably, and are dependent on microorganism, cultivation conditions, and the method of isolation. Typically, the values lie between 1×10^5–7.5×10^5 g mol^{-1} ($n = 2500$–9000, polydispersity (M_w/M_n) = 1.7–2.9[5]), but they can be greater than one million g mol^{-1}. The copolymer from (*R*)-3-hydroxybutyrate and (*R*)-3-hydroxyvalerate P(3-HB/3-HV) has achieved a certain economic importance because of its polypropylene-like material properties, and is marketed by ICI under the tradename "BIOPOL". P(3-HB) and P(3-HB/3-HV) are both biodegradable, and their synthesis is based on renewable materials.[6] Great things are expected of them because of these qualities; this is apparent by their regular appearance in the press,[7] review articles which are published ever more frequently,[1b,4,5,8–13] and the increasing number of patents.[14]

P(3-HB) was first described by Lemoigne in 1925,[15] who later isolated and identified the material from *Bacillus megaterium*.[16] Since then, P(3-HB) has been discovered in a large number of different microorganisms,[11] for example in Archaebacteria, in both gram-negative and gram-positive bacteria, and in Cyanobacteria. Apart from a few phototrophic microorganisms, *Clostridium* and *Syntrophomonas* are the only strict anaerobes in which P(3-HB) has been found. Interestingly, enterobacteria (gut bacteria) such as *Escherichia coli* do not normally synthesize P(3-HB) as a storage compound.[11,17,18]

Apart from its occurrence as a storage compound, P(3-HB) is also found—in a low molecular weight form—in bacterial membranes and in the tissues of plants and animals, where it presumably forms part of an ion channel (see Section 7).[19–23] Recently it has also been detected in relatively large amounts in human blood plasma (between 0.6 and 18.2 mg per liter blood), where it is bound mainly to the so-called "low density lipoproteins" (20–30%), and to albumin (70–80%).[24]

[**] This review article contains part of the dissertation of H.-M. Müller (dissertation no. 9685, ETH Zürich, 1992).

Schulz and Toft have shown that in certain species of spiders from the Linyphia family, (*R*,*R*)-hydroxybutyrate dimers act as pheromones. They lead the male to roll up the web of unfertilized females, possibly in order to demonstrate that the female is now occupied. This behavior is not observed with the webs of already fertilized females.[25] P(3-HB) has also been discussed as a possible energy source for nitrogen fixation in *rhizobia*.[12, 17a, 26]

2. Polyhydroxy Acids as Cellular Storage Materials

Quantitatively, the most important role of poly(3-hydroxyalkanoates) is to store carbon-containing material and reductase equivalents in the cells of prokaryotic microorganisms (up to 90% of cell dry weight!). The biochemistry of the synthesis and degradation of high molecular weight P(3-HB) has therefore been subject to intensive studies. These have demonstrated which other hydroxy acids can be incorporated into the polymer, in natural or synthetic growth media. The enzymes involved in the biosynthesis have been identified, transferred to other microorganisms, and expressed by gene technological methods.

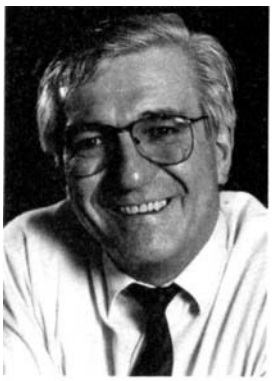
2.1. Intracellular Distribution of Polyhydroxy Acid Esters

PHAs occur in the cytoplasm of the cell in the form of inclusion bodies, so-called granules. Typically, these have a diameter of 100–800 nm, and have been shown to be surrounded by a kind of micelle ("monolayer"), but not by a double layered structure (typical membrane, lipoprotein bilayer).[27] Depending on the bacterium, the PHA-synthase and depolymerase system may also be bound to this envelope. Purified granules from *B. megaterium* consist of 97.7% P(3-HB), 1.8% protein, and 0.5% lipid.[5, 28]

The structure of P(3-HB) within the granules has been subject to debate until recently. All that was previously known was that treatment with solvents, bases or acids, as well as cooling or heating inhibited their enzymatic digestion.[29] More recently Doi et al.[30] by X-ray diffraction and Sanders et al. ([31a], but also[31b]) by high-resolution ^{13}C NMR spectroscopy have shown that the P(3-HB) within the native granules is present in an amorphous form. This is surprising, since isolated P(3-HB) normally reveals between 60 and 70% crystallinity.[32] The reasons for this are not yet clear; Sanders et al. postulate water as a plasticizer, whereas Doi et al. attribute an inhibitory effect on crystallization to an as yet unknown lipid component. Because of its thermodynamically less favorable state, amorphous P(3-HB) is probably more amenable to enzymatic degradation than P(3-HB) with a high content of crystalline domains.

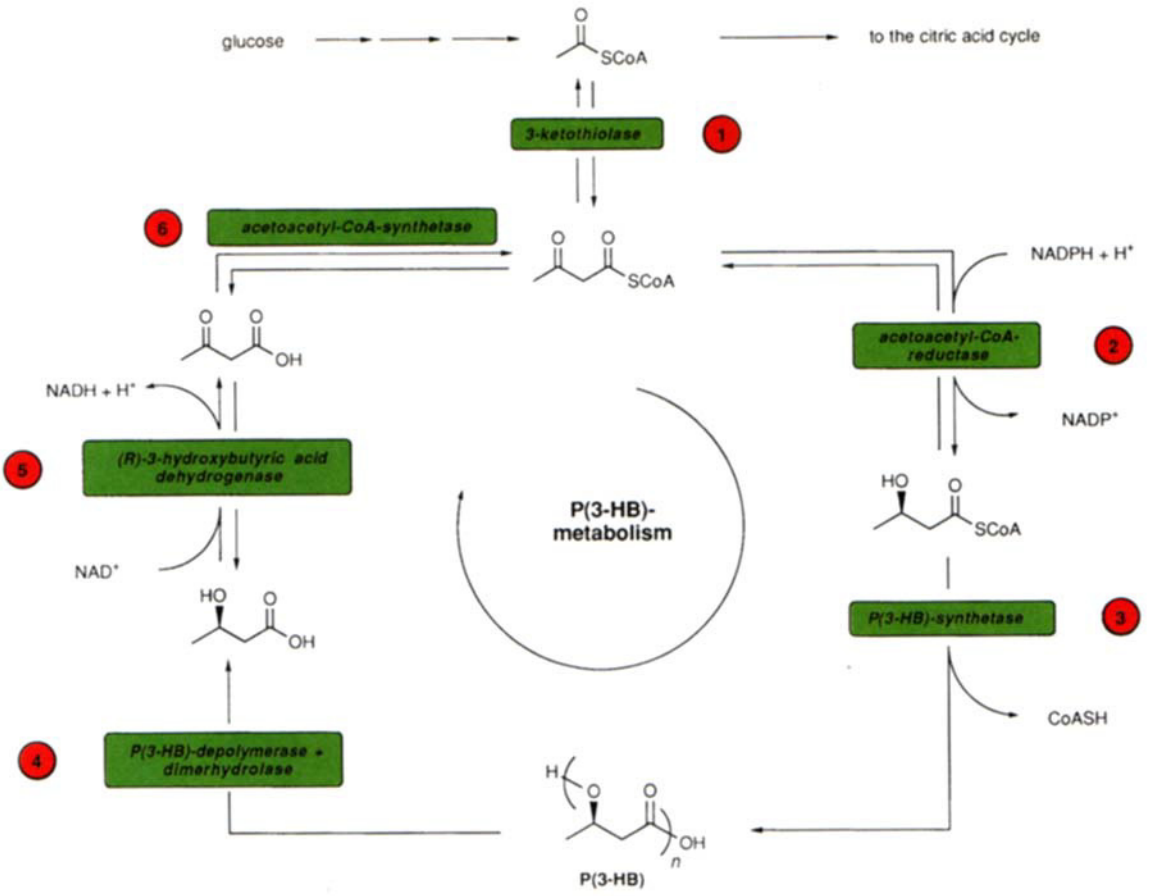
2.2. Poly[(*R*)-3-hydroxybutyrate] Metabolism

Intracellular P(3-HB) metabolism is a cyclic process, involving seven enzymes, as shown in Scheme 1. It has been investigated primarily by Schlegel et al. and Dawes et al. in *Alcaligenes eutrophus*,[33–40] by Dawes et al. in *Azotobacter beijerinckii*,[41–43] by Fukui et al. and Tomita et al. in *Zoologea ramigera*,[44–49] and in somewhat less detail by Merrick et al. and Doudoroff et al. in *Rhodospirillum rubrum* and *Bacillus megaterium*.[29, 50–56] It has also been studied in other microorganisms.[1b, 12]



Dieter Seebach was born in Karlsruhe in 1937, he studied chemistry at the University of Karlsruhe. He received his Ph.D in 1964 with a thesis on small-ring compounds and peroxides (supervisor R. Criegee). After a stay of almost two years at Harvard University as a postdoctoral fellow with E. J. Corey and lecturer of chemistry, he returned to Karlsruhe and his research led to a habilitation on S- and Se-stabilized carbanion and carbene derivatives in 1969. In 1971 he became a full professor at the University of Giessen and since 1977 he has been a full professor at the Eidgenössische Technische Hochschule in Zürich. He has had visiting professorships at the Universities of Madison (Wisconsin), Strasbourg, München (TU), Kaiserslautern, as well as Caltech (Pasadena) and the Max-Planck-Institut in Mülheim. His main areas of research are the development of new synthetic methods, mechanistic studies, structure determinations, and natural product syntheses. Recently his research has been concerned more and more with the topic discussed in this review.

Hans-Martin Müller was born in Herisau/Appenzell Ausserrhoden, Switzerland in 1962. After training as a chemistry laboratory assistant he studied chemistry at the Ingenieurschule in Basel (Diplom 1985). He subsequently studied chemistry at the ETH Zürich (Diplom 1988). He received his doctorate with D. Seebach with a thesis on polyhydroxybutyric acid in 1992 and in the same year joined the company Sandoz.



Scheme 1. The best known and probably most widely distributed P(3-HB) metabolic pathway, which also occurs in *A. eutrophus*, *Z. ramigera*, and *A. beijerinckii*.

A metabolic pathway slightly different from that in Scheme 1 has been proposed for *A. eutrophus* by Doi et al,[57] which uses butyric acid (and probably also the higher carboxylic acids) as substrate. Here, butyric acid is first esterified with coenzyme A (CoA) and then converted stepwise into acetoacetyl-CoA via crotonyl-CoA and (*S*)-3-hydroxybutyryl-CoA. The remainder of the pathway is identical to that shown in Scheme 1. In other bacteria, further metabolic variants have been found (see [58] and Section 2.3.1).

2.2.1. Biosynthesis

The following section will discuss primarily the P(3-HB) biosynthetic pathway observed in *A. eutrophus*, since this microorganism, as the basis of the production of BIPOL by the ICI process, has the greatest commercial importance.[59] The *A. eutrophus* strains NCIB11599[5] and N9A[60] produce more than 90% of their dry weight as P(3-HB), when the C source provided is glucose or fructose, respectively. In contrast to *Pseudomonas oleovorans* and other bacteria, only polyesters with C_3–C_5 monomer units are synthesized, from a variety of substrates.[61]

A. eutrophus possesses two 3-ketothiolases,[36] which catalyze the Claisen reaction of two carboxylic thioesters to the corresponding 3-ketocarboxylate. The mechanism of this reversible reaction has been studied in detail by Masamune et al.[62] Enzyme A acts predominantly on acetoacetyl-CoA, and is somewhat less active with 3-ketopentanoyl-CoA; it is therefore responsible for P(3-HB) metabolism. Enzyme B prefers higher 3-ketoacetyl-CoA substrates (C_4 to C_{10}), and is presumably more concerned with fatty acid metabolism. It is the only enzyme in Scheme 1 which is involved in both the biosynthesis and the biodegradation of polyesters.

For the second step, the reduction of acetoacetyl-CoA, two enzymes are again present in *A. eutrophus*,[37] an NADH- and an NADPH-dependent reductase. The NADH-dependent enzyme can oxidize both (*R*)- and (*S*)-3-hydroxybutyryl-CoA, whereas reduction affords only (*S*)-3-hydroxybutyryl-CoA. The NADPH-reductase is stereoselective in both the oxidation and reduction reactions, and is active only with (*R*)-3-hydroxybutyrate, which is also the exclusive product in the reduction. It is therefore only this reductase that is involved directly in P(3-HB) metabolism.

P(3-HB)-synthase, the last enzyme associated with the biosynthesis, is found in a soluble form and a "granule-associated" form.[39] Under normal growth conditions one finds only the soluble synthase, which is transformed to the granule-associated form under conditions of nitrogen limitation. This enzyme can only polymerize certain hydroxy acids, and therefore governs the composition of the polymer.[40]

2.2.2. Cloning and Expression of the Poly[(R)-3-hydroxybutyrate] Biosynthetic Pathway of Alcaligenes eutrophus

The transfer of an entire biosynthetic pathway into a foreign organism is always advantageous when an industrially

more robust strain is required, when different (cheaper) raw materials are sought, or in order to investigate mechanistic questions.[63] Often the genes coding for the biosynthesis lie close to each other, making transfer to another organism somewhat simpler. When one considers the great expectations placed on PHAs, it is hardly surprising that no fewer than three research groups have cloned and expressed the *A. eutrophus* P(3-HB) biosynthetic genes (steps 1–3, Scheme 1) in *E. coli*.[17b, 64–66] *E. coli* does not normally synthesize PHAs, but in this case can produce about 50% of its dry weight as P(3-HB) (with some strains up to 80%). Here, too, it appears in the form of intracellular granules. The three enzymes responsible for the synthesis are organized in a P(3-HB)-synthesis-operon, which is controlled from one promoter.[66] If the P(3-HB)-synthase gene is transferred alone into *E. coli*, no polyester can be produced. Clearly, *E. coli* is itself not capable of synthesizing (*R*)-3-hydroxybutyryl-CoA.[17b]

In addition to the P(3-HB)-operon, Lubbitz et al.[67] also built in a lysis gene, which is expressed at higher temperatures in the presence of divalent cations. The P(3-HB) granules are thus released into the surrounding medium through openings in the cell wall, and can be separated from the cell debris. This elegant method of isolation is also applicable to *Alcaligenes* species, and has recently been patented.[68]

Other projects are at present probably more visions of the future than reality. Somerville et al.,[69a] for example, plan to insert the P(3-HB)-synthesis genes of *A. eutrophus* into potatoes or other plants, in order to harvest a type of "plastic potato" after expression of the genes. A first realization of this idea has just been reported, but the transgenic plants were only able to produce tiny quantities of P(3-HB). The 3-ketothiolase is present in higher plants, but genes for both the reductase and P(3-HB)-synthase genes must also be introduced here for P(3-HB) production.

Apart from the PHA-structural genes from *A. eutrophus*, those of several other microorganisms, such as *Z. ramigera*[70] and *P. oleovorans*,[71] have also been identified and their nucleotide sequence determined.

2.2.3. Depolymerization

Depolymerization (step 4 in Scheme 1) of the granular, amorphous P(3-HB) to (*R*)-3-hydroxybutyric acid is catalyzed by a depolymerase which degrades P(3-HB) predominantly to dimers. Only in *A. eutrophus* is the direct product (*R*)-3-hydroxybutyric acid.[72] In other microorganisms, the dimers are subsequently cleaved by a dimer hydrolase to the monomers. The depolymerase has been isolated from *A. eutrophus*,[33] *B. megaterium*,[53] and *R. rubrum*.[29] However, its mode of action is still only poorly understood. In contrast to the depolymerase, the mechanism of the dimer hydrolase reaction is quite well known. This enzyme has been isolated from *Z. ramigera*[47] and *R. rubrum*,[52] and hydrolyzes not only the (*R*,*R*) dimers,[73] but, depending on the bacterium, also the (*R*,*S*) dimers (*R. rubrum*, *Z. ramigera*) and the (*S*,*R*) dimers (*Z. ramigera*). The latter are cleaved more slowly, however. The other enantiomers are not saponified by the respective organism. Higher oligomers (pentamers, for example) can also be attacked. As Tomita et al. have shown, these are degraded in *Z. ramigera* in an exo-fashion[74] from the alcohol end; the longer the chain, the greater the reaction rate. Even the corresponding methyl esters are hydrolyzed (except for those of the dimeric or monomeric compound).[47]

The oxidation of (*R*)-3-hydroxybutyric acid to acetylacetate (step 5 in Scheme 1) is catalyzed by a dehydrogenase. The enzymes have been isolated from *A. eutrophus*,[33] *A. beijerinckii*,[43] and *Z. ramigera*,[48] and are very similar with respect to optimum pH values, inhibitors, and the K_m value with (*R*)-3-hydroxybutyric acid. NAD^+ functions as cofactor in all cases.

Two different mechanisms have been found for the esterification of acetoacetate with coenzyme A (step 6 in Scheme 1). In *A. eutrophus* and *A. beijerinckii* the enzyme responsible is a 3-ketoacid-CoA transferase, and the CoA unit is supplied by succinyl-CoA.[43] In *Z. ramigera*, the same step is catalyzed by an acetoacetyl-CoA synthase, and involves ATP.[49]

2.2.4. Regulation of the Poly[(R)-3-hydroxybutyrate] Cycle

The control of PHA metabolism shown in Scheme 1 has been studied most extensively by Dawes et al. in *A. beijerinckii*. It proceeds analogously in *A. eutrophus* and *B. megaterium*, but cannot be extended generally to all bacteria.[12]

3-Ketothiolase is the only enzyme which participates in both the synthesis (Claisen reaction of two acetyl-CoA units) and degradation (retro-Claisen reaction of acetoacetyl-CoA) of P(3-HB), and it plays a central role in the control of the cycle. The Claisen reaction is inhibited by high concentrations of CoASH, while the retro-Claisen reaction is inhibited by acetoacetyl-CoA. The latter inhibition can be overcome by addition of high CoASH concentrations.

Normally, acetyl-CoA is used predominantly in the citric acid cycle, releasing CoASH; that is, the concentration of acetyl-CoA is low, that of CoASH is high, and the 3-ketothiolase is therefore inactive.

Limitation of a nutrient (either nitrogen, oxygen, or phosphorus, depending on bacterium[111]) has the effect of increasing NADH concentration, leading to less efficient degradation of acetyl-CoA by the citric acid cycle. The acetyl-CoA concentration therefore rises, and that of CoASH begins to fall. The inhibition of 3-ketothiolase is thereby overcome, and acetoacetyl-CoA can react with excess NADH according to Scheme 1, to yield P(3-HB). Synthesis of P(3-HB) acts to a certain extent as a sink for acetyl and reduction equivalents.

Degradation is initiated if too little C source is present; the high CoASH levels associated with this situation can override the inhibition of the 3-ketothiolase by acetoacetyl-CoA, and acetyl-CoA units can be released from P(3-HB). The details of regulation of the degradative pathway are still largely unclear, since not enough is known about the P(3-HB)-depolymerase.[75]

For *A. eutrophus*, Doi et al. have shown that under nitrogen limitation P(3-HB) biosynthesis and degradation can take place simultaneously. To what extent the released

monomer units are reused for polymer synthesis has not yet been clarified.[76]

2.3. Microbiologically Accessible Polyesters

A large number of studies have been made with various carbon sources in the growth medium, using different microorganisms capable of producing polyester storage materials. These have been carried out primarily with the aim of synthesizing enantiomerically pure starting materials required for organic synthesis, as discussed below, and in the search for biodegradable materials with a variety of structure-dependent characteristics.

2.3.1. Synthesis of Polyesters Containing no Further Functional Groups with Alcaligenes eutrophus and Pseudomonas oleovorans

A. eutrophus synthesizes only unsubstituted polymers, even when chlorinated or unsaturated acids, for example, 2-chloropropionic acid,[5] 5-chlorovaleric acid,[77] or 4-pentenoic acid[78] are used as substrate. Polyesters with C_4/C_5 hydroxy acid units are produced from almost all C sources, and C_3 structural units have till now been discovered in only a few cases (Table 1, no. 4); C_6 units have never been found.

Table 1. Preparation of polyesters with structural units 3-HP (3-hydroxypropionate), 3-HB (3-hydroxybutyrate), 4-HB (4-hydroxybutyrate), 3-HV (3-hydroxyvalerate), and 5-HV (5-hydroxyvalerate) from various carbon sources by *Alcaligenes eutrophus*.

No.	Substrate	3-HP	3-HB	4-HB	3-HV	5-HV
1	glucose	–	+	–	–	–
2	glucose + propionate	–	+	–	+	–
3	γ-butyrolactone [5, 79, 80] [a]	–	+	+	–	–
4	3-hydroxypropionate or 1,5-pentanediol [5]	+	+	–	–	–
5	5-chlorovalerate [77]	–	+	–	+	+

[a] In addition 4-hydroxybutyrate, 1,4-butanediol, 1,6-hexanediol, or 4-chlorobutyrate can also be used.

Glucose and propionic acid are the substrates which ICI employ for the production of P(3-HB) and P(3-HB/3-HV), and the limiting nutrient is phosphate in each case.[81] By changing the glucose/propionate ratio, the proportion of 3-HV can be varied between 0–20%. These polymers are available commercially under the tradename "BIOPOL".[82] The P(3-HV) homopolymers appear not to be microbiologically accessible; the highest 3-HV content found was about 90%, using valeric acid as C source.[57]

By using [D_3]acetate as substrate in H_2O or D_2O, P(3-HB) with varying degrees of deuteration can be synthesized.[83] Higher levels of deuteration can be achieved in *Rhodobacter sphaeroides*, which affords a maximum of 16% [D_6]3-HB with acetate in D_2O/H_2O (92:8).[84] Under the same conditions, [D_3]acetate leads to synthesis of 6% [D_6]3-HB, 73% [D_5]3-HB, and 16% [D_4]3-HB units.[85]

By use of suitably labeled C sources, ^{13}C- and ^{14}C-P(3-HB) can also be synthesized,[1b, 8] from which either crotonic acid or hydroxybutyrate derivatives of (*R*) configuration can be obtained.

Doi, Kunioka et al.[79, 80] discovered in 1988 that with certain substrates a copolymer of 3-HB and 4-hydroxybutyrate (4-HB) is synthesized (Table 1, no. 3). Depending on the composition of the C source, a 4-HB content between 9% and 40% can be achieved,[86] with the polymer constituting up to 30% of the dry cell mass. Both biodegradability[86] and material properties[87] are different from those of P(3-HB) or P(3-HB/3-HV).

The last two polymers in Table 1 have been relatively little studied, but help to demonstrate the variety of microbiologically accessible PHAs.

Witholt et al.[88] discovered in 1983 that *Pseudomonas oleovorans* also produces intracellular PHA granules, by using *n*-octane as substrate. However, they did not find P(3-HB), but exclusively poly-(*R*)-3-hydroxyoctanoic acid. Several groups subsequently investigated the potential of *P. oleovorans* and other pseudomonads to synthesize unusual PHAs.[40, 89, 90] *P. oleovorans* can metabolize straight-chain aliphatic hydrocarbons, their alcohols and carboxylic acids as substrates,[91] but cannot utilize glucose. In general, statistical copolymers of C_6 to C_{12} (*R*)-3-hydroxy acid units are formed. Units with a chain length smaller than C_6 or longer than C_{12} are only found in small quantities (Table 2).

Table 2. Composition of the PHAs from *Pseudomonas oleovorans* with carboxylic acids as carbon sources (from [89b]). The homologous series starting from 3-*hydroxy*caproate to 3-*hydroxydod*ecanoate is denoted by 3-HC–3-HDD.

Substrate	PHA [a] [%]	Repeating unit in the polyester [%] 3-HC	3-HH	3-HO	3-HN	3-HD	3-HUD	3-HDD
(*R*)-3-hydroxybutyrate	1.2	–	–	22	–	57	–	21
caproate	3.3	95	–	5	–	–	–	–
heptanoate	2.3	–	100	–	–	–	–	–
octanoate	8.7	8	–	91	–	1	–	–
nonanoate	9.1	–	35	–	65	–	–	–
decanoate	12.5	8	–	75	–	17	–	–
undecanoate	9.8	–	28	–	59	–	13	–
dodecanoate	6.6	6	–	57	–	32	–	5
pentadecanoate	5.3	–	32	–	47	8	13	–
heptadecanoate	–	–	–	–	–	–	–	–

[a] Given as percentage of the cell dry weight. The isolated PHA quantities are also only given in ref. [90b]. Evidently, the highest PHA quantites (0.7 $g L^{-1}$) are obtained with nonanoate as substrate.

With C_{2n+1} acids, polyesters with C_7, C_9, and C_{11} hydroxy acid units are produced, though the C_9 units predominate. C_{2n} acids result in analogous polymers built up of the even-numbered C_6, C_8, C_{10}, and C_{12} hydroxy acid units; the C_8 acid playing the major part. Polymers with relatively uniform side chain lengths are also formed from the hydrocarbons hexane, heptane, and octane.[40, 89a]

The longer the side chains of the hydroxy acids, the more elastic and the less crystalline are the polymers produced.[92a] On the other hand, the higher PHAs are no longer biodegradable, as has been shown for poly-(*R*)-3-hydroxyoctanoate or poly-(*R*)-3-hydroxynonanoate![1b, 5, 11]

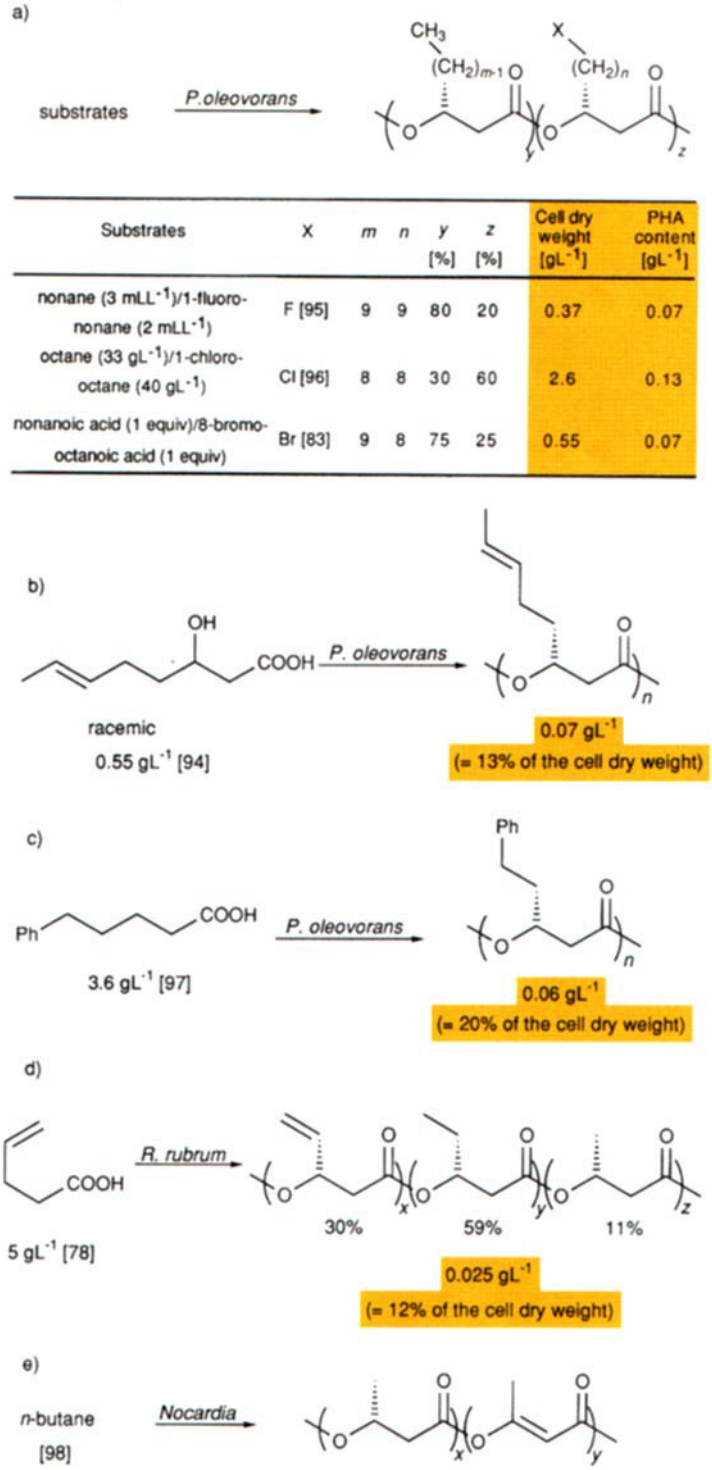
Presumably, PHA biosynthesis developed from P(3-HB) metabolism in pseudomonads when various strains developed the ability to utilize substrates with more than four C atoms. The direct polymerization of such substrates is en-

ergetically more sensible than first degrading them to the C_4 acids.[89a] Alkanes, however, can only be utilized by microorganisms possessing the so-called OCT-plasmid. This plasmid encodes the genetic information for those enzymes responsible for transforming alkanes to the corresponding alcohols.[93]

2.3.2. *Production of Polyesters with Further Functional Groups by Microorganisms*

With all the polyhydroxy acids described so far, subsequent modifications in the structure of the polymer are not possible; however, functionalized polymers are accessible by so-called polymer-analogous reactions. Certain bacteria can synthesize polyesters from functionalized substrates without loss of the functionality during construction, as does *A. eutrophus*. Here, too, the synthesis of homopolymers is the exception rather than the rule, since the biosynthesis of polyesters allows the incorporation of 3-hydroxy acid units with side chains shortened by C_2 or C_4 units. If, for instance, 3-hydroxy-7-octenoate is treated under analogous conditions to those given in Scheme 2b, a polymer is obtained which contains 23% 3-hydroxyhexanoic acid units.[94]

The first polyester with an additional functional group was isolated from *Nocardia* in 1964, though the enol ester structure of this polymer was only determined by IR spectroscopic studies.[98] In general, the functional groups may not lie too close to the main chain. Thus, for instance, no cell growth is observed with the substrates 6-bromohexanoic acid,[83] 3-phenylpropionic acid,[97] and 3-hydroxy-3-phenylpropionic acid.[97] The only substrate which can be converted to a homopolymer is 5-phenylvaleric acid (when 6-octenoic acid is used, the polymer shown in Scheme 2b contains only 80% of the given structural unit, whereas the remainder is composed of a mixture of other units.[94]). Surprisingly, a mixture of nonanoic and phenylvaleric acid yields the two corresponding homopolymers, and no copolymer![99] The yields are unsatisfactory in all cases.



Substrates	X	m	n	y [%]	z [%]	Cell dry weight [gL^{-1}]	PHA content [gL^{-1}]
nonane (3 mLL^{-1})/1-fluoro-nonane (2 mLL^{-1})	F [95]	9	9	80	20	0.37	0.07
octane (33 gL^{-1})/1-chloro-octane (40 gL^{-1})	Cl [96]	8	8	30	60	2.6	0.13
nonanoic acid (1 equiv)/8-bromo-octanoic acid (1 equiv)	Br [83]	9	8	75	25	0.55	0.07

Scheme 2. Microbially accessible polyesters with functional groups in the side chain.

3. Polyhydroxy Acids as Starting Materials for Chiral Compounds of Low Molecular Weight

Ten years ago, this subject brought our research group into contact with P(3-HB) for the first time, since we saw P(3-HB) as a welcome source of C_4 synthetic units with (*R*) configuration. We began to search for suitable procedures for the preparative degradation of P(3-HB) to the monomers, and were soon interested in the directed synthesis of oligomers from the monomers thus isolated.

3.1. Degradation of Poly[(R)-3-hydroxybutyrate] and the Chemistry of the Monomer

Because of their stereoregularity, microbially synthesized polyesters are extremely attractive sources of chiral building blocks. The investigations carried out for this reason were all limited to the polymers P(3-HB) or P(3-HB/3-HV), since these two were the only two polyhydroxy esters available in large quantities at the time. Depending on the aims of the study, either the oligomer mixtures or the monomers could be of interest. Various mixtures of oligomers can be formed by partial hydrolysis or alcoholysis, for example, or by ester pyrolysis at temperatures >175 °C, where the average molecular weight is determined by the length of the heating period.[100–103] At the alcohol end, the pyrolysis products all carry a crotonyl group, as is to be expected for mechanistic reasons. Product mixtures of the same type have also been obtained by Brändli et al.[104] by treating P(3-HB) or P(3-

HB/3-HV) in the presence of an excess of lithium diisopropylamide/LiCl at low temperatures. Even after repeated treatment of the same sample under the same conditions, one sees only a slight shift in the distribution maxima (assumed to be bimodal) to lower molecular weights (Fig. 1 b). Similarly, the yields of isolated oligomers change very little (ca. 75% for each degradation step). The mechanism of the degradation is not yet satisfactorily understood, but probably does not go through the poly-enolates originally postulated,[104] since no alkylation products could be identified with a variety of electrophiles (Fig. 1 a).

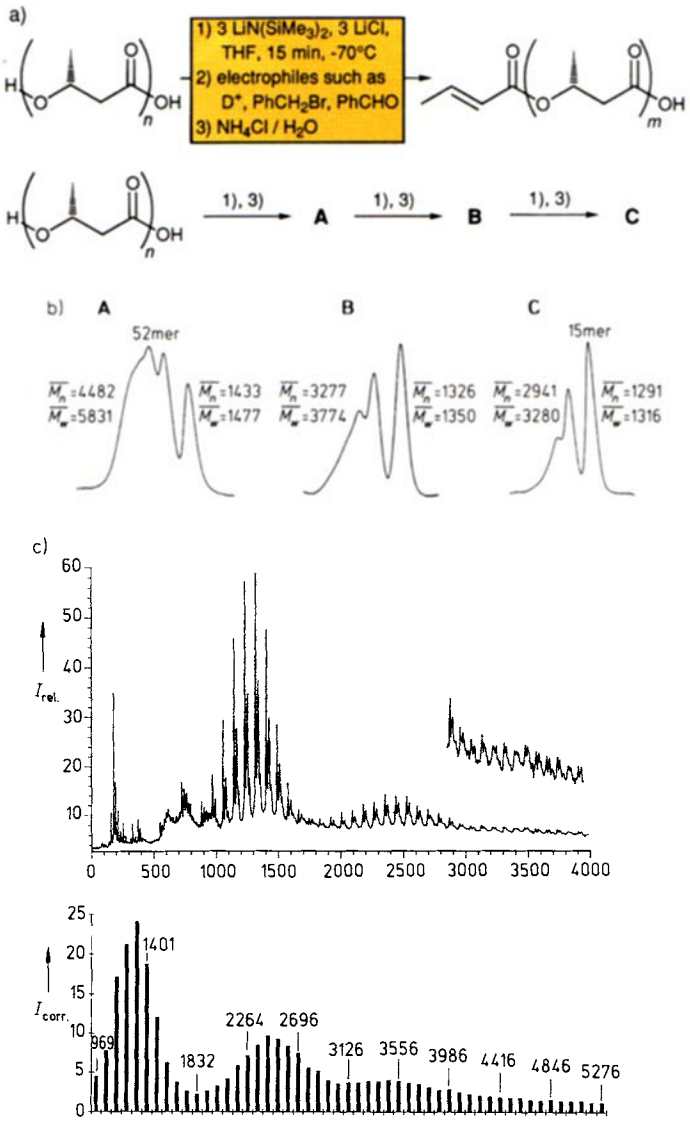


Fig. 1. Degradation of P(3-HB) ($M_n = 7.5 \times 10^5$) with $LiN(SiMe_3)_2$ in tetrahydrofuran at low temperature. Since the products arising from base treatment cannot be alkylated with electrophiles, polyenolates cannot be present as intermediates [104]. b) Gel permeation chromatograms of oligomer mixtures obtained by one (**A**), two (**B**), or three (**C**) repetitions of the reaction sequence shown in a). The two maxima are displaced only slightly towards lower molecular masses. The signal at high molecular weight corresponds to a 52mer for **A**, and to a 36mer for **C**, while the low molecular weight peak is a 17mer for **A** and a 15mer for **C**. The chromatograms shown were obtained by fractionation of a mixture on Shodex columns K-802, K-802.5, and K-803, by using chloroform as eluent. c) Top: matrix-supported laser desorption ionization spectrum (LDI) of the triple degradation product **C**. The insert is increased fivefold: the corresponding bar spectrum obtained when the [M + H] and [M + Na] peaks are counted together, and the area rather than the relative peak height is measured. Each m/z is given on the x axis. We thank Dr. K. Börnsen and Dr. M. Schär (Ciba-Geigy, Basel) for recording the LDI-spectra for us [105,106].

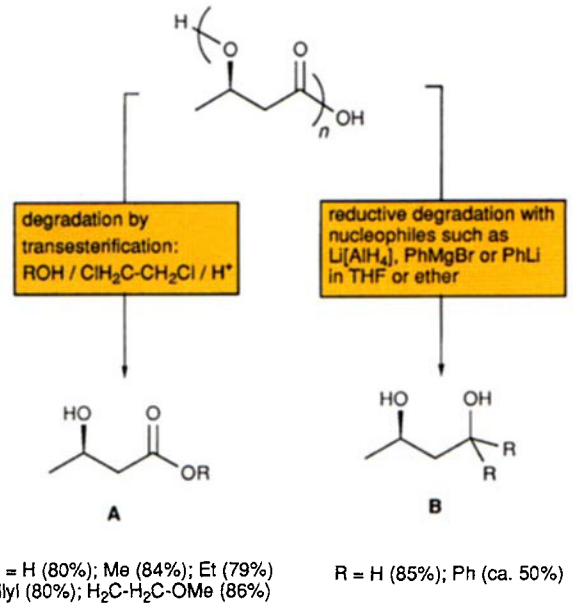
The work of Züger et al.[107] and Vanlautem et al.[108] has also made available the monomeric (*R*)-3-hydroxybutyric acid and its corresponding ester (**A** in Scheme 3), by acid-catalyzed saponification or transesterification of P(3-HB).[109] The reaction conditions were later optimized by Breitschuh et al.,[110] so that the monomers can now be obtained by a simple procedure in about 80% yield. Similarly, reduction of P(3-HB) with lithium aluminum hydride or its treatment with organometallic reagents leads directly to the 1,3-butanediols with (*R*) configuration of type **B** (Scheme 3).

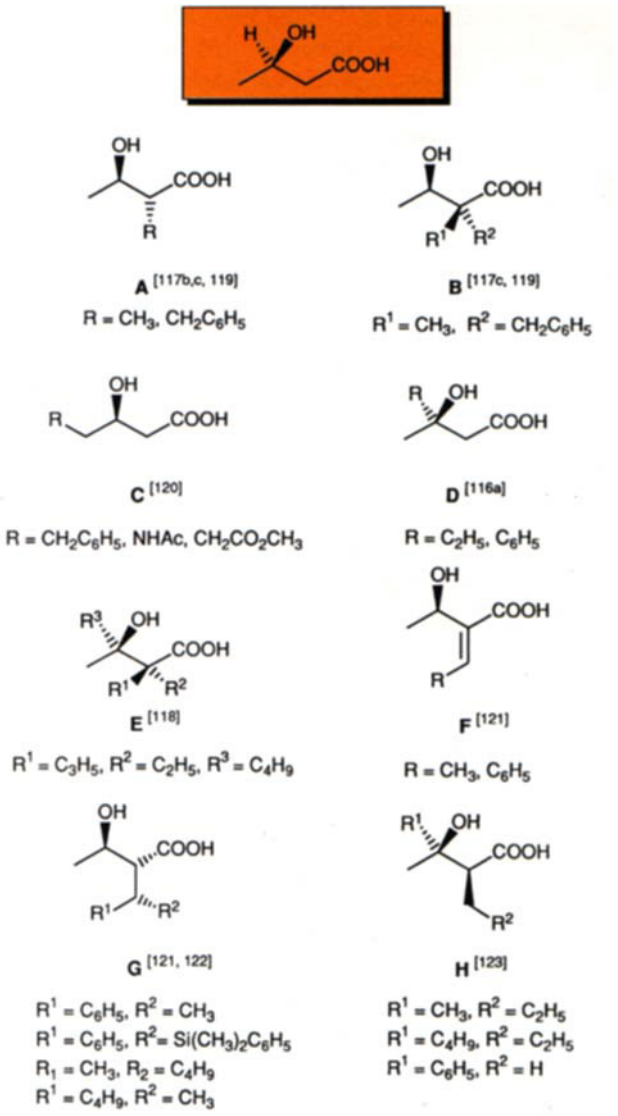


Scheme 3. Depolymerization of P(3-HB) by transesterification or by reduction of the ester carbonyl groups.

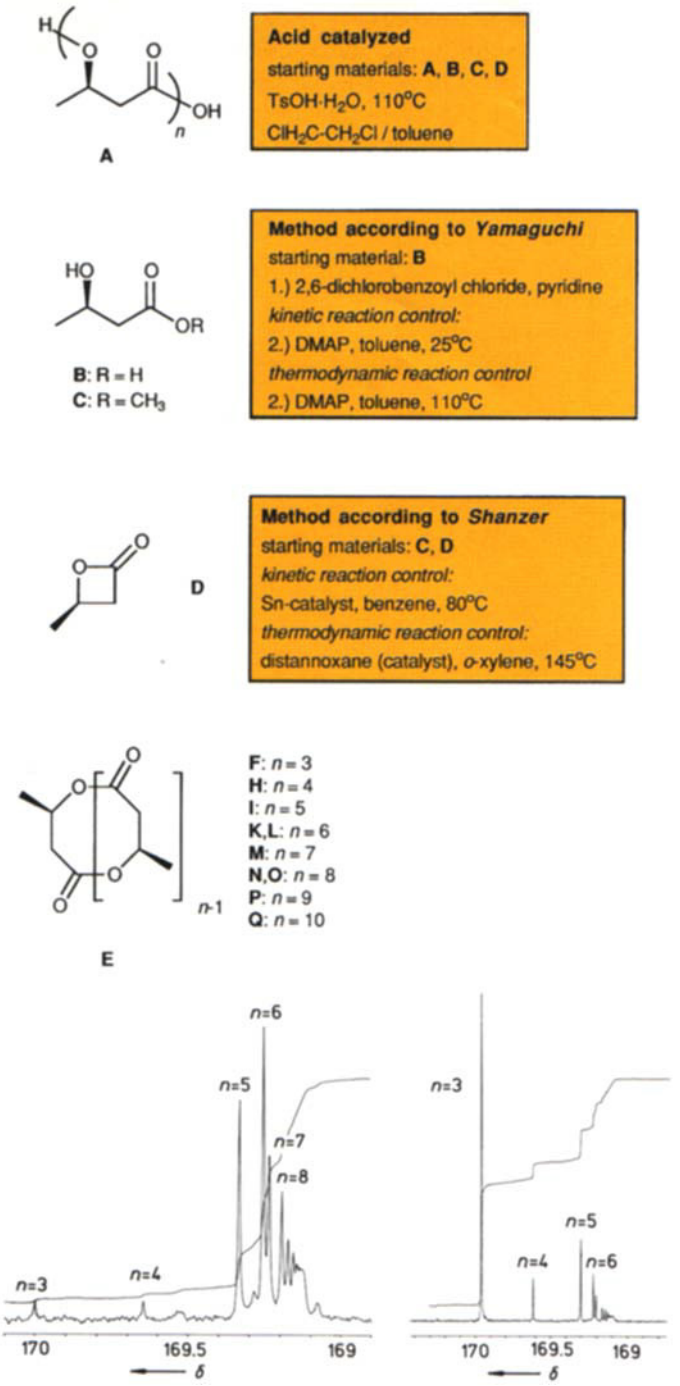
Derivatives as accessible as this can certainly be interpreted as an extension of the "pool of chiral building blocks".[111a] Natural product syntheses beginning from (*R*)-hydroxybutyric acid are being published continually,[111b] as shown by recent syntheses of gloeosporon,[112] grahamimycin A_1,[113] and (*R*)-lasiodiplodin.[114]

By now, any of the hydrogen atoms in (*R*)-3-hydroxybutyric acid can be replaced by other groups (product types **A**–**H** in Scheme 4).[115] The most notable developments in this area are the chiral acetoacetic ester derivative (*R*)-*tert*-butyl-6-methyl-2*H*,4*H*-1,3-dioxin-4-one[116] (this cycle yields compounds of type **D** and in principle also of type **C**, with regeneration of the stereogenic center[117]), and the diastereoselective synthesis of 2,5,5,6,6-pentaalkyl-substituted dioxanones[118] (see **E**; this corresponds formally to the product of an enantioselective aldol reaction of a α-branched carboxylic acid with a ketone).

The alcohol function of 3-hydroxybutyric acid can be substituted nucleophilically by other groups with inversion of configuration, either via the corresponding tosylate or via the β-butyrolactone[124, 125] (the former compound requires weakly basic nucleophiles such as $LiAlD_4$,[126] $Bu_4N^+NO_3^-$,[127] or NaN_3;[128a] the lactone can be opened with S-nucleophiles such as HS^- or $tBuS^-$,[129] for example, or with N-nucleophiles like benzylamine or NaN_3[129a]). Diastereoselective opening of dioxanones from HB by S_N2



Scheme 4. Products of the transformation of (*R*)-3-hydroxybutyric acid while retaining the acid and alcohol functions.



Scheme 5. Top: Synthesis of macrocycles of type E according to the methods of Yamaguchi, (via the mixed anhydride with 2,6-dichlorobenzoyl chloride) Shanzer, (by using the tin catalyst 1,1,6,6-tetrabutyl-1,6-distanna-2,5,7,10-tetraoxacyclodecane [136] (= template)), or by acid catalysis with toluenesulfonic acid monohydrate ($TsOH \cdot H_2O$). DMAP: *N*,*N*-dimethylaminopyridine. Bottom: ^{13}C NMR spectra of the carbonyl region of oligolide mixtures obtained under the conditions specified in a) by Yamaguchi lactonization (left) of (*R*)-3-hydroxybutyric acid (kinetic control) and acid catalyzed (right) by degradation of P(3-HB) (thermodynamic control). For completeness, it should be mentioned that the β-butyrolactone **D** of (*R*) configuration was never used as starting material, but rather its enantiomer, which is also formed by known methods from (*R*)-3-hydroxybutyric acid [124]. The (*R*) form was preferred here only for graphic reasons. Measurement conditions for the ^{13}C NMR spectra (100 MHz): Inverse-gated experiment with a relaxation delay of 3 s, an acquisition time of 3.2 s, and a pulse angle of 45°.

reaction at the acetal C atom is a greatly improved variant of the Johnson method with regard to selectivity and ease of execution in greater quantities as well as in the presence of groups sensitive to oxidation, in which hydroxybutyric acid is converted into crotonic acid, and thus sacrificed (*immolative* enantioselective reaction sequence).[117b,c,128]

3.2. Synthesis of Oligolides from 3-Hydroxybutyric Acid, and Structural Studies

Chiral macrolides of type **E** (Scheme 5) can be obtained directly from P(3-HB) **A** either by acid-catalyzed transesterification or from the monomeric building blocks **B**–**D**, by the methods of Yamaguchi,[130–133] Shanzer.[132–134] or again by acid catalysis.[135] Depending on the reaction conditions, the oligolides are obtained in various proportions, and can be separated from each other by careful chromatography.[133] Under thermodynamic control, triolide **F** (in Scheme 5) predominates; thus, acid-catalyzed transesterification of P(3-HB) affords this really quite complex compound in about 50% yield by simple distillation of the product mixture.[135]

Single crystals of the oligolides **F**–**O** in Scheme 5 were grown, and their structures were determined. For both the

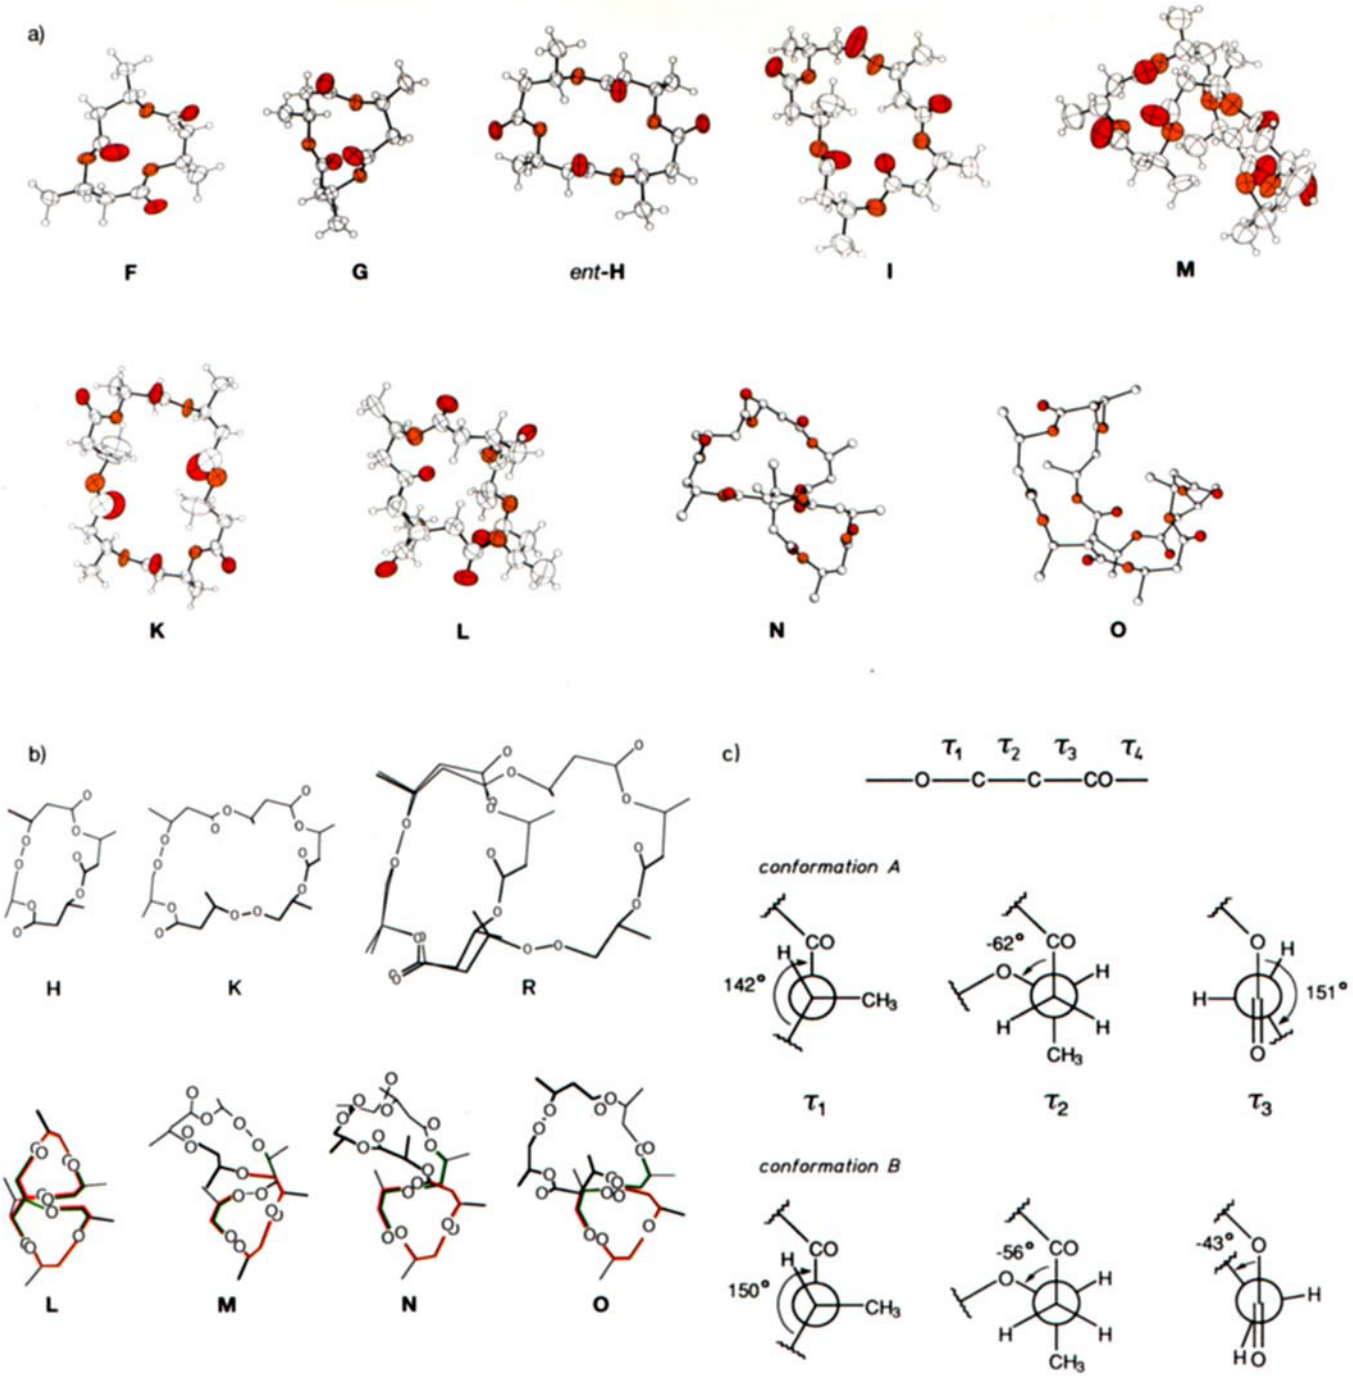


Fig. 2. a) Structures of the oligolides **F–O**, all in the all-*R*-form with the exception of *ent*-**H**, which is depicted in the all-*S*-configuration (**F**–**M** as ORTEP diagrams, and **N**,**O** as PLUTO plots). The *rac-epi* triolide **G** (shown here in the (*R*,*R*,*S*) form) is obtained, for example, by acid-catalyzed lactonization of *rac*-β-butyrolactone in boiling toluene/1,2-dichloroethane together with the racemic triolide *rac*-**F** in a 3:1 ratio. Red spheres are oxygen atoms of the CO functional groups, orange are OR oxygens on the ester groups. For synthesis and characterization of the oligolides see [131–135]. b) Structural similarities between the macrolides. MacMoMo views of the all-(*R*)-tetrolide **H** and of the C_2 symmetrical hexolide **K** and its superposition **R**. The higher macrolides **L–O** all contain as common structural fragments a Δ-shaped portion (red) and an S-shaped moiety (green). In the hexolide L they even appear twice [133]. c) Mean torsion angles τ_1–τ_3 and Newman projections of the bonds of the (*R*)-3-hydroxybutyric acid units in conformations **A** (the Δ-shaped building block) and conformation **B** (the S-shaped fragment) of the higher macrolides **L–O** [133,135b]. The torsion angles are given according to the IUPAC-IUB definition [138]; a zero-value represents a synperiplanar arrangement for the main chain.

hexolide ($n = 6$)[132] and the octolide ($n = 8$), two conformers were found (**K**, **L**, and **N**, **O**, respectively, see Fig. 2a). The structures show remarkable similarities (Fig. 2b). Comparison of the two C_2 symmetric conformations of the tetrolide **H** and the hexolide **K** show that the latter can be constructed from **H** by halving and introducing two hydroxybutyric acid units. The larger macrolide structures **L–O** are all constructed of folded rings and contain an S-shaped (Fig. 2b, green), and a Δ-shaped region (Fig. 2b, red) as common structural elements. A study of the interdependence of the torsion angles τ_1, τ_2, and τ_3 reveals two preferred configurations of the (*R*)-hydroxybutyric acid units in these cycles (Fig. 2c). Conformation **A** (which forms the Δ-shaped structural element) occurs about three times more frequently than **B** (which forms part of the S-shaped fragment).[137]

The potential of polyesters as precursors of chiral building blocks has certainly not yet been exhausted, as can be seen from the continuing publication of syntheses of further compounds from them.[139]

4. Polyhydroxy Acids as Biologically Degradable Plastics

Plastics make up about seven percent by weight and over thirty percent by volume of the total garbage produced today in the USA and Japan.[140] This can be explained in part by the fact that plastics are more and more replacing glass, paper, or metal as packaging materials. In principle, there are three possibilities for the disposal of plastics: incineration, recycling, and degradation in the environment. Each of these will presumably find future applications.

Several countries, such as Italy for example, have introduced legislation which requires all plastic packaging materials to be degradable by 1991.[141] The growth rate in the market for degradable polymers is expected to increase by 75% per year, representing a turnover in 1992 of about 400000 tons of polymer and approximately US$ 340 million. By then, some 15% of plastic refuse will be biodegradable, compared with 1% in 1987.[141, 142]

In principle, a macromolecule can be degraded by chemical, biological, or physical methods.[143] Cleavage by light is the most important degradative pathway for C–C main chain polymers, and is accelerated by the introduction of carbonyl groups[144] (which can be brought about by copolymerization of an olefin with carbon monoxide, for example[145]), or by photoactive additives such as benzophenone[146] (degradation by Norrish type I and II cleavage). Oxidative chain fission can be achieved by addition of hydrogen peroxide or suitable transition metals, and is important particularly with unsaturated polymers.[147]

The production of polymer mixtures (blends) of largely undegradable and biologically degradable materials (usually starch) is also widespread. In this way, the advantages of petrochemically derived plastics can be combined with those of biopolymers. During degradation, the biologically utilizable part of the mixture is dissolved, and the remainder must then be dealt with by nonbiological systems.

4.1. Requirements for Biodegradable Polymers

In contrast to chemical processes, microbial degradation processes are to a certain extent autocatalytic, since the substrate being degraded leads to an increase in the organism population. The bacteria concerned profit from the degradation; that is, the fragments produced must also be able to be utilized. Many monomers of synthetic polyesters and polyamides are in principle microbially degradable, but since the corresponding microorganisms do not have suitable depolymerases available, degradation is impossible. The same is true if the polymerase is present, but the resulting fragments cannot be broken down or metabolized. The most important type of cleavage is the hydrolysis of ester, amide, and glycosidic bonds. The corresponding hydrolases require only water as a reaction partner, and are therefore more common in the extracellular environment, since no complex cosubstrates are needed. Polyesters with easily degradable monomers such as glycolate, lactate, malate, caprolactone, and 3-hydroxy acid derivatives therefore have a good chance of being biodegraded.[149] Pure C-chain polymers are less suitable, though their degradation has been demonstrated.[150]

4.2. Extracellular Polyhydroxy Acid Degradation

A remarkable property of many microbially synthesized PHAs is their biodegradability in the environment, which proceeds more rapidly under anaerobic conditions than aerobically. For *A. eutrophus*, Doi et al.[5, 76] found that under anaerobic conditions the main intracellular metabolites are acetate and (*R*)-3-hydroxybutyrate. The conversion of acetyl-CoA to acetate is presumably coupled to the phosphorylation of ADP to ATP in this case. Under aerobic conditions, acetyl-CoA is broken down to CO_2 and H_2O by the citric acid cycle, releasing 12 ATP equivalents and allowing a far more economic use of the polyester.

Many bacteria and fungi possess extracellular depolymerases,[151] with which they can degrade PHAs and if necessary utilize them as a sole C source. Enzymes of this nature have been found in *Alcaligenes faecalis*,[152–155] *Pseudomonas lemoignei*,[156–160] *Pseudomonas delafieldii*,[161] *Penicillium simplicissimum*,[162] and *Eupenicillium sp.*,[162] though the enzymes of the first two species have been by far the best studied.

A. faecalis has two extracellular esterases, a P(3-HB) depolymerase and an oligomer hydrolase. The depolymerase degrades both P(3-HB) and water soluble oligomers. However, it displays significantly higher activity towards the longer oligomers, and attacks in an endo fashion at the second ester bond from the hydroxy terminus.[152] An octolide (i.e. a ring constructed of eight (*R*)-3-hydroxybutyrate units) is attacked in a similar fashion, but the open-chain trimer protected on the alcohol function with *tert*-butyldimethylsilyl groups is not degraded.[154]

The oligomer hydrolase attacks only water-soluble oligomers, but with approximately ten times higher activity than the depolymerase. Longer polymer chains are more rapidly degraded than the dimers. Of the four possible stereoisomers of 3-hydroxybutyrate dimers, the (*R*,*R*) form and the (*R*,*S*) form are hydrolyzed, the latter rather more slowly.[73] The monomeric methyl ester is also attacked, while the corresponding ethyl and benzyl esters are practically inert. Degradation occurs in an exo manner from the acid end.[153]

The gram-negative organism *P. lemoignei* also possesses two enzymes which are involved in extracellular degradation, but differs from *A. faecalis* in that only the depolymerase is exported from the cell. P(3-HB) is broken down outside the cell to a trimer/dimer/monomer mixture which is then transported through the cell wall and is only fully saponified to the monomer by a dimer hydrolase within the cell. Here too, the depolymerase attacks in an endo fashion at the second or third ester bond from the hydroxy terminus, though in this case both oligomers and P(3-HB) can be hydrolyzed.[160] In contrast to *A. faecalis*, the dimer hydrolase degrades the (*S*,*R*) dimer as well as the (*R*,*R*) form, while

their enantiomers are not saponified. (*R*)-3-(butanoyloxy)butyric acid is also attacked.[157]

Despite numerous investigations, many questions remain unanswered. It is not clear, for instance, how the depolymerase can attack both the water soluble oligomers and the hydrophobic P(3-HB), which in contrast to the intracellular case (see Section 2.2.3) is present here in a crystalline form! From a chemical point of view, it would also be interesting to investigate the influence of various end groups on the degradability; synthetically produced (all-*S*)-P(3-HB) is no longer biodegradable, and neither is a stereoblock-P(3-HB) built up of (*R*) and (*S*) residues.[111]

5. Synthesis of Poly[(*R*)-3-hydroxybutyrate] and Derivatives

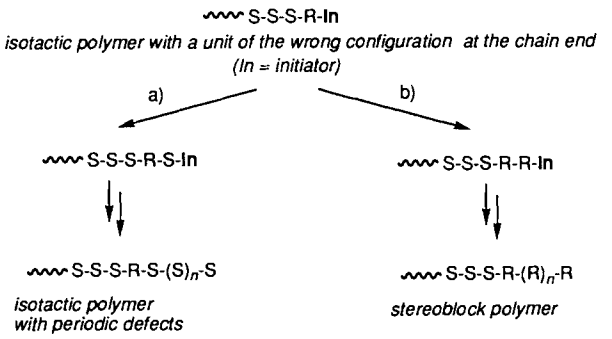
P(3-HB) was produced by synthetic means far earlier than by biotechnological methods. Processes of this sort are becoming ever more attractive, due to the facile methods now available for the synthesis of (*R*)- and (*S*)-hydroxy acids. In principle, two types of monomers are available for the polymerization, the 3-hydroxy acids and the corresponding β-butyrolactones. Because of their tendency to crotonize, the acids have never been used, however, since polyesters of high average molecular weight can only be obtained by polycondensation of very pure starting materials.[163] All the studies published to date have therefore started from β-butyrolactones, and have polymerized these with simultaneous ring-opening. β-Propiolactone can be polymerized easily with either anionic or cationic initiators, and the α-monosubstituted and α,α-disubstituted β-lactones react cleanly. Substituents in the β-position reduce the reactivity dramatically, so that conversion is often incomplete even after extended reaction periods.[164]

In all the studies published up till now, P(3-HB) was synthesized by one of the following procedures: a) from racemic β-butyrolactone and an achiral initiator, b) from racemic β-butyrolactone and a chiral initiator, or c) from enantiomerically pure β-butyrolactone and an achiral initiator.

5.1. Polymerization of Racemic β-Butyrolactone with an Achiral Initiator

Biologically degradable (all-*R*)-polymers cannot, of course, be obtained in this manner. However, suitable reaction conditions were thus developed with the readily available racemic β-butyrolactone,[165] and some of these could also be used for polymerization of enantiomerically pure lactone.

The step determining stereoselectivity in the ring-opening polymerization is the insertion of a monomer into the end position of the polymer-initiator complex.[166] In principle, this can lead to isotactic (*-RRR-/-SSS-*), syndiotactic (*-SRSRSR-*), or atactic (*-SSRSRRS-*) polyesters. β-Butyrolactone, however, yielded only isotactic and atactic P(3-HB). The result can be either a stereoblock polymer or an isotactic chain with periodic defects, depending on whether the polymer chain end or the initiator determines selectivity; atactic polymers are obtained when neither is dominant (Scheme 6).



Scheme 6. Stereoselectivity of monomer insertion into the terminal initiator-polymer bond. *R,S*: (*R*) configuration or (*S*) configuration unit in the polymer. In case a) the initiator is responsible for the selectivity, in b) the terminal monomer unit.

The tacticity was determined in earlier times by fiber X-ray diffraction,[167, 168] but today is much simpler to measure from the ^{13}C and ^{1}H NMR spectra. Isotactic and stereoblock-P(3-HB) cannot yet be distinguished either by X-ray diffraction analysis or by high-field NMR spectroscopy.[169] For this reason, whenever isotactic polyesters are mentioned in the following sections, stereoblock polymers may also be present.

Atactic and isotactic fractions may be separated by fractional crystallization from acetone or methanol, where the atactic polymer remains in solution. Initiators which have been applied with more or less success are summarized in Table 3. Classical Brønsted or Lewis acids such as CF_3SO_3H,[170] $BF_3 \cdot OEt_2$,[171, 172] $Et_3O^+BF_4^-$,[164] Et_2AlCl,[171] or nucleophiles like *n*BuLi,[171] pyridine,[173] NEt_3,[171, 173] PPh_3,[173] NaOMe,[170] and tetraethylammonium benzoate[170] afford oily mixtures of oligomers, at best.

In 1971, Agostini et al.[174] described in detail for the first time a synthesis of P(3-HB) from β-butyrolactone and $AlEt_3 \cdot H_2O$; Inoue et al. had briefly mentioned such a reaction in 1961, as part of a communication on polymerization of β-butyrolactone with $ZnEt_2/O_2$.[172] Tani et al.[170, 171] later improved the reaction conditions for the Al-initiated ring-opening polymerization, which was subsequently adopted by several other research groups. The long reaction times and the generally unsatisfactory conversions (Table 3) are conspicuous; the yield of isotactic P(3-HB) reaches 50% at best. The molecular weights achieved are comparable with those for microbiologically produced P(3-HB), depending on the catalyst used, but the molecular weight distribution is much broader. Exceptions are the two last systems (Table 3, nos. 8 and 9), in which relatively narrow molecular weight distributions are obtained. In no. 9, the actual initiator is potassium crotonate which, like potassium acetate or potassium benzoate, can be applied in the presence of [18]crown-6[177] or dibenzo[18]crown-6[173] instead of potassium naphthalide as a starter.

5.2. Polymerization of Racemic β-Butyrolactone with a Chiral Initiator

Polymerization of a racemic monomer with a suitable chiral initiator ought in the ideal case to yield only one enantiomer of the product, while the other enantiomer remains in

Table 3. Polymerization of *rac*-β-butyrolactone with achiral iniators.

No.	Initiator	Reaction conditions T [°C]	t [d]	solvent	Yield polymer [%]	of the isotactic fraction [%]	$M_n \times 10^{-3}$ (of the isotactic fraction)	M_w/M_n [d]	Ref.

[a] The initiator is synthesized from $AlEt_3$ and H_2O before the addition of the monomer in toluene. [b] The *ethyl*a*l*uminum *o*xide (EAO) initiator was synthesized as in [a], then the solvent was removed, and the residue dried at 180 °C/10^{-3} Torr, and this was then redissolved in toluene. [c] Initiator from 5,10,15,20-tetraphenylporphin and Et_2AlCl. [d] Determined with gel permeation chromatography by comparison with a polystyrene standard. [e] Estimated from the ^1H NMR spectrum. [f] Determined with vapor pressure osmometry. The monomer/initiator ratio for no. 8 is 100 and for no. 9 150.

the reaction mixture (the yield of polymer can therefore only be 50%, at most). LeBorgne and Spassky et al. have polymerized oxiranes and thiiranes with considerable success, by using as initiator a complex of (*R*)-3,3-dimethyl-1,2-butanediol and $ZnEt_2$.[178] However, with β-butyrolactone the reaction is far less selective (Table 4).

Table 4. Polymerization of *rac*-β-butyrolactone with the chiral initiator *A* (complex from (*R*)-3,3-dimethyl-1,2-butanediol and $ZnEt_2$) and *B* (*N*,*N*′-disalicylidene-(1*R*,2*R*)-1,2-cyclohexanediaminatocobalt(II)-$AlEt_3$ complex).

Catalyst	Reaction conditions T [°C]	t [d]	solvent	Conversion [%]	Isotactic fraction [%]	$[\alpha]_D$ of the polymer [a]	$M_n \times 10^{-3}$	M_w/M_n
A [179]	25	0.25	toluene	84	27	−0.6 ($CHCl_3$) [b]	ca. 20	–
B [180]	30	14	benzene	41	–	−46.1 (benzene) [c]	–	9.4

[a] Optical rotation of microbial all-(*R*)-P(3-HB): $[\alpha]_D = -1.8$ ($CHCl_3$). [b] $[\alpha]_D$ of the unreacted monomer: −12.8 ($CHCl_3$); (*S*)-β-butyrolactone: $[\alpha]_D = -34.8$ ($CHCl_3$). [c] $[\alpha]_D$ of the unconverted monomer: −1.65 (benzene); (*S*)-β-butyrolactone: $[\alpha]_D = -50.8$ (benzene).

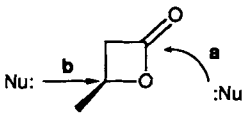
The selectivities achieved by this strategy are definitely not yet satisfactory. In the second case, the compound obtained is presumably a strongly atactic polyester or an isotactic P(3-HB) of low molecular mass, since (all-*R*)-P(3-HB) oligomers of size >1000 g mol^{-1} are almost insoluble in benzene.

5.3. Polymerization of Enantiomerically Pure β-Butyrolactone with an Achiral Initiator

Enantiomerically pure β-butyrolactone can be synthesized either by cyclization of 3-bromobutyric acid[124d] or 3-mesyloxybutyric acid,[124e] or by pyrolysis of the cyclic orthoester of 3-hydroxybutyric acid and triethyl orthoacetate,[124a,b] though with a maximal yield of 35%. Four-membered ring lactones can be opened by nucleophiles either with retention (path **a** in Table 5) or with inversion (path **b** in Table 5)[181] of configuration, and hence P(3-HB) constructed by this procedure does not necessarily consist entirely of units with identical configuration (i.e. 100% isotactic) (Table 5).

Once again, it was Agostini et al.[124d] who were the first to polymerize (*R*)-β-butyrolactone with $AlEt_3 \cdot H_2O$ to give P(3-HB) of preferentially (*R*) configuration, opening the lactone with retention of configuration. Lenz et al.[182] later found inversion, exactly the opposite reaction mechanism, in the same system (no. 2 in Table 5). They explained the change in mechanism with a different method of producing the aluminum complex.[183] In all cases, no stereoregular P(3-HB) was obtained, probably because of the polymeric nature of the initiators used, which can contain various active centers (see [183], but also [178a]). On the basis of the optical rotation

Table 5. Polymerization of chiral β-butyrolactone with achiral initiators.



No.	Initiator	Lactone configuration	Polymer	$[\alpha]\lambda_i$ in $CHCl_3$ [a]	$M_n \times 10^{-3}$	M_w/M_n	Ref.
1	$AlEt_3 \cdot H_2O$ (1:1)	(*R*)	(*R*)-P(3-HB)	+4.0 [b]	–	–	[124d]
2	$AlEt_3 \cdot H_2O$ (1:1)	(*S*)	(*R*)-P(3-HB)	+6.9	30	8.0	[182]
3	$ZnEt_2 \cdot H_2O$	(*S*)	(*S*)-P(3-HB)	−7.0	14	1.5	[182]
4	EAO [c]	(*S*)	(*S*)-P(3-HB)	−5.8	24	7.8	[182]

[a] For λ_i all-(*R*)-P(3-HB) has an optical rotation of +7.4 (the wavelength (λ = 589 nm) given in ref.[182] (no. 2–4) is probably incorrect). [b] $[\alpha]_{365}$ of all-(*R*)-P(3-HB): +10.2 ($CHCl_3$). (*R*)-β-butyrolactone with an optical purity of 73% was used as monomer. [c] EAO see footnote [b] in Table 3.

of the polymers obtained and the reproducibility of the experiments, the Zn system seems to be the best one. Recently Doi et al. used this system to show that in the polymerization of enantiomeric β-butyrolactone mixtures, the (*R*) and (*S*) units are statistically distributed in the polyester.[184]

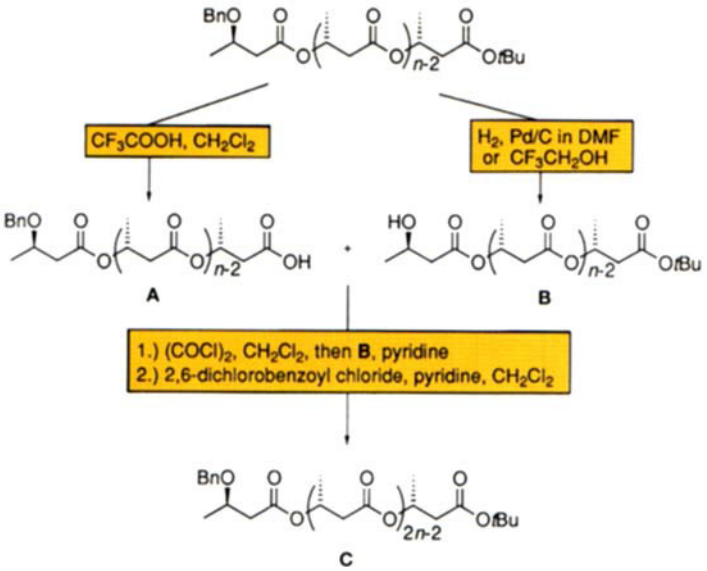
With the ethylaluminum oxide (EAO) initiator, the attainable molecular weights decrease as the size of the residue on the β-butyrolactone increases. In this way, Tani et al. were able to polymerize γ-mono, di-, and trichloro-substituted β-lactones in 1977,[170] which by now are also accessible in the enantiomerically pure form by the Wynberg method.[185] A further functionalized polymer was synthesized by Lenz et al. from racemic or from (*R*)-β-alkoxycarbonyl-β-propiolactone. The resulting malic acid polyesters are biodegradable.[186]

5.4. Synthesis of Defined Oligomers and Polymers from (*R*)-3-Hydroxybutyric Acid

Oligomers of uniform molecular mass have also been produced by directed synthesis. Such compounds were of interest in the past for a variety of reasons; they were used to obtain more detailed information about the intra- and extracellular degradation mechanism for P(3-HB),[152, 154, 187] or for synthesis of the corresponding straight-chain oligolide precursors.[131] In all previous syntheses, chain extension proceeded by stepwise addition of monomer units. Our aim was to study the structure and function of the presumed P(3-HB)-containing ion channel, already mentioned above, which required polymers with a length of 100–150 monomer units. For the synthesis of such large molecules, a stepwise technique is, of course, no longer practical. Polymerization of enantiomerically pure β-butyrolactone would probably lead to P(3-HB) samples with a relatively narrow size distribution (Table 3, nos 8 and 9), but from the results described above, these would not be likely to possess uniform configuration. A possible alternative was the segment condensation strategy, in which the two protecting groups on an unasymmetrically protected oligomer are selectively removed. The deprotected portions are then coupled to afford a molecule of "twice the size". The tetramers used as starting material in Scheme 7 were synthesized by one of the procedures described earlier,[131] though with some modifications. However, the coupling step via the acid chloride, and the benzyl ether and *tert*-butylester protecting groups were retained.

Characterization of the purified products becomes more and more difficult with increasing chain length, since because of their structural similarity, they display more or less identical analytical properties. Luckily, great progress has been made recently in the area of mass spectrometry, with the so-called soft ionisation methods.[189] In the case of P(3-HB), however, not all of these methods were equally useful, and larger molecules could finally only be characterized by means of matrix-supported laser desorption ionization (LDI) mass spectrometry (Fig. 3a,b).

For the fully protected 32mer **M**, the mass spectra each show three signals (as isotope distributions) with approximately the same *m/z* values and relative intensities (Fig. 3a). Such peaks were not observed with the smaller oligomers. They do not come about by fragmentation, but represent the



n	*n*mer acid **A**/ *n*mer alcohol **B**	2*n*	2*n*mer **C**	Yield [%] after the acid chloride coupling
4	**D/E**	8	**F**	>95
8	**G/H**	16	**I**	90
16	**K/L**	32	**M**	60
32	**N/O**	64	**P**	45
64/32	**Q/R**	96	**S** (96mer)	45

Scheme 7. Segment condensation algorithm for the synthesis of defined oligomers of (*R*)-3-hydroxybutyric acid. An *n*mer acid **A** is coupled to an *n*mer alcohol **B**, giving rise to a 2*n*mer product **C** of "twice the size". The yield after the acid chloride coupling step decreases with increasing size of the compounds. To improve the total yield for the larger molecules (**M**, **P**, and **S**), we "recoupled" with 2,6-dichlorobenzoyl chloride. This method allows activation of an acid in the presence of an alcohol [188].

molecular composition of the sample. A more detailed study of the reaction sequence showed that under the deprotection conditions specified in Scheme 7, terminal subunits may be cleaved off. For this reason, the average degree of polymerization (X_n) of the polymer mixture obtained was only 93, though this was distributed over a narrower range than would have been the case under ideal polymerization conditions[190] (Fig. 3b, see also reference to our own work in [106] and ref.[135b]).

These synthetic P(3-HB) oligomers represent a series of compounds, which can be used as standards to determine the molecular masses of polymers with similar constitution and configuration, by using gel permeation chromatography. For us, this was of special interest with respect to the ion channel already mentioned. Comparing molecular weights with those obtained after standardization with polystyrene or polyisoprene showed that the molecular weight values derived by using the latter standards can be appreciably higher (Fig. 3c).

5.5. Possible Future Applications of Polyhydroxyalkanoates

Up till now, the polyesters P(3-HB) and P(3-HB/3-HV) are the only PHAs that have been produced on a large scale

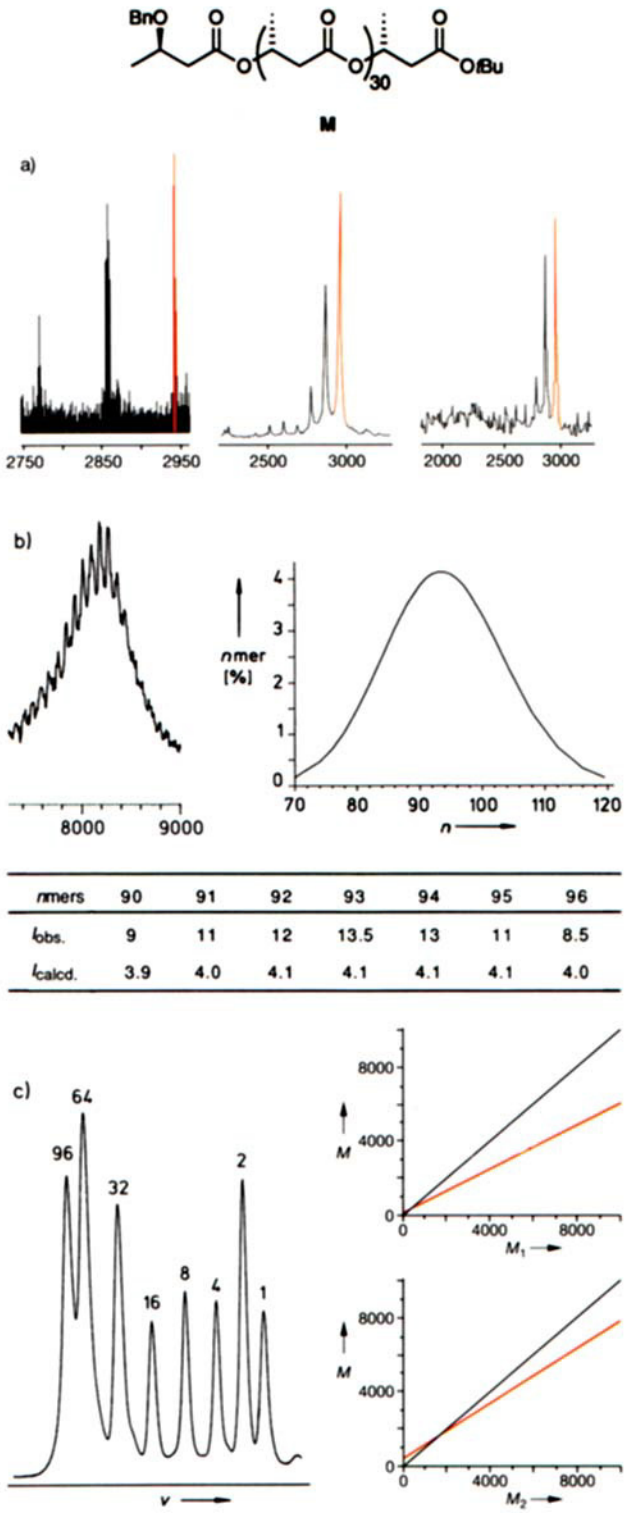


Fig. 3. a) Secondary ionization MS (in a 3-nitrobenzyl alcohol matrix, left), Plasma desorption ionization (PDI)-MS (center), and laser desorption ionization (LDI)-MS (in a 2,6-dihydroxy benzoic acid matrix, right) of the fully-protected 32mer (**M** in Scheme 7). We thank Prof. Dr. M. Przbylski and K. Schneider, University of Constance, for recording the PDI spectrum, and Dr K. Börnsen and Dr. M. Schär (Ciba-Geigy, Basel) for the LDI-spectra. b) Left: LDI mass spectrum of the fully-protected "96mer" (**S** in Scheme 7). The commonest compound in the distribution (right) is no longer the 96mer but the 93mer. In the distribution diagram the x axis is the degree of polymerization n; and the y axis is the share of $n$mer in %. Table: Comparison of the measured distribution of the "96mer" with that calculated for ideal polymerization conditions with a polymer length of 93 ($M_w/M_n = 1.01$) [163]. c) Gel permeation chromatogram of the fully protected P(3-HB) compounds (left). v = current. Comparison with the molecular masses determined after standardization using polystyrene or polyisoprene (right). M = real molecular mass; M_1 = apparent molecular mass with polystyrene; M_2 = apparent molecular mass with polyisoprene.

by using biotechnology. From 2.5 kg glucose, about 1 kg P(3-HB) can be synthesized in this way.[191a] In the middle of the nineties, the annual production of BIOPOL will be increased from about 300 tons to 5000–10000 tons.[191b] The production costs at present constitute about 50 DM per kilogram; the future aim is a kilo-price of 5–10 DM.[141]

By employing phototrophic microorganisms, it is even possible to utilize sunlight as energy source. Thus, *Rhodobacter sphaeroides* synthesizes up to 70% of its dry weight as P(3-HB).[192] Microbiological production of PHAs with a great variety of compositions and material properties is therefore possible, even if at present the yields are unsatisfactory, and the starting materials are oil-derived. How far these disadvantages can be countered by the use of genetechnologically modified organisms remains to be determined.

Synthetic methods are at present not well enough developed to compete with biotechnological production, at least of BIOPOL. On the other hand, a broad range of (*R*)- and (*S*)-hydroxy acids is now readily available, by enantioselective hydrogenation of the corresponding 3-keto esters.[193] We can therefore expect that in future synthetic processes will be developed which will be a match for microbial methods. With such a procedure, a variety of polymers would probably be accessible without great changes of the reaction conditions. In addition, workup of these reactions would be likely to prove far more simple than for biotechnological production methods, since it would be possible to work at high concentrations and in organic solvents.

With respect to molecular weight, melting region, crystallinity, flexibility, and tensile strength, BIOPOL and polypropylene are quite similar, though the former has disadvantages in its low tensile strength, poor solvent resistance,[194] limited resistance to acids, bases, and heat, and last but not least, its high price. It can be moulded thermoplastically, and processed to sheets and fibers,[195] but till now has been used primarily for the production of shampoo bottles (Fig. 4). Other applications for such polyesters can be found in agriculture (e.g. as cold frame sheeting, seed capsules, or formulations for the controlled release of pesticides or herbicides[1b]), or in human and veterinary medicine, because of their biocompatibility. Thus, numerous patents

Fig. 4. Shampoo bottles made of BIOPOL, after 0, 3, and 9 months in compost. The slower degradation of the printed areas is clearly visible. Doi et al. [92b] have shown that degradation occurs from the surface, and proceeds more quickly the larger the surface area. Nonenzymatic hydrolysis is several orders of magnitude slower than enzymatic depolymerization.

have already been registered, in which such materials are used for surgical implants to support organ and tissue healing processes,[196] as supports for "slow-release" systems,[10, 197] for the production of powders,[198] or as a component of membranes.[199] A process for elimination of nitrate from drinking water using P(3-HB) has also been developed.[200]

Recently attempts have been made to extend the field of application of P(3-HB) and P(3-HB/3-HV) by preparing degradable block copolymers with polystyrene and polyethers,[201] or "blends" with polyethylene, polystyrene, polyvinyl chloride, or polyethylene oxide.[202] Films of P(3-HB) act as a gas barrier in a similar way to polyvinyl chloride or polyethylene terephthalate.[202a] Because of these properties, P(3-HB) could well play an important role as a packaging material.

Judging by the increasing number of publications, the area is in the midst of great developments. How well PHAs can assert themselves against other biopolymers remains to be seen.

6. What is Known About the Structure of Polyesters?

The structures of many polyesters have been determined from fiber X-ray diffraction experiments.[203] In contrast to polyamides, polyesters cannot form hydrogen bonds, and so the force field is composed only of torsion, nonbonding, and electrostatic energy terms.[204] Figure 5 presents the structures that are known for aliphatic polyesters of hydroxy acids and their amino acid analogues, as far as the latter are known. Depending on the method of workup, solids with differing conformations are often isolated; for poly-β-propionolactone and polyglycine not all of these structures have been determined.

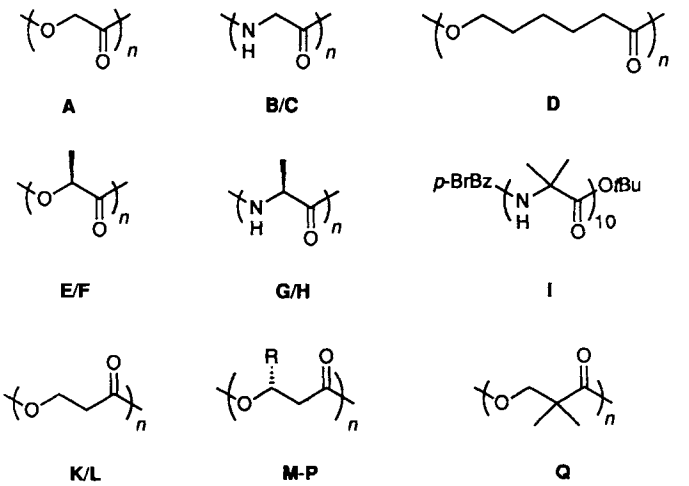
Prediction of the secondary structure of peptides and proteins is well established.[221] It has turned out that certain rules can also be derived for polyesters:

- polymers of the type -[O-(CH_2)n-CO-]- assume a staggered conformation (zigzag chain), at least for $n = 1$, 2, and 5 (**A**, **D**, and **L**, respectively in Fig. 5).[203]
- substituted poly-β-propiolactones always form a 2_1-helix (**M**–**Q** in Fig. 5). The pitch (axial spacing) of the helix decreases with increasing substituent size in the β-substituted poly-β-propionolactone series (**N**, **O**, and **P** in Fig. 5). According to Marchessault et al. a lower limit of 4.5 Å exists, below which changes in the helix geometry must occur.[217]

In the following sections, a few selected structures will be presented in more detail:

6.1. Structural Comparison of Homopolymers of α-Hydroxy Acids and α-Amino Acids

For polylactides, two conformations were found, a 10_3- and a 3_1-helix. These have practically the same energy content, and the latter is strongly reminiscent of the 3_1-helix of polyglycine (Table in Fig. 6), which forms no hydrogen bonds in this modification.[207] The α-helix of polyalanine



Name		Conformation [a]	Identity period [Å]	Ref.
A	polyglycolide	staggered	7.02	[205]
B	polyglycine I	?	–	[206]
C	polyglycine II	3_1-helix	9.3	[207]
D	polycaprolactone	staggered	17.05	[208]
E	β-poly-(*S*)-lactide	3_1-helix	9.00	[209b]
F	α-poly-(*S*)-lactide	10_3-helix	28.8	[209]
G	α-poly-(*S*)-alanine	β-staggered sheet	6.9	[210]
H	β-poly-(*S*)-alanine	4^7_{13}-helix [b]	70.3	[211]
I	deca-α-aminoisobutyrate	16_5-helix [c]	31.5	[212]
K	poly-β-propiolactone I	?	–	[213]

N	p(3-HB) (R: -CH_3)	2_1-helix	5.96	[167, 204,216]
O	p(3-HV) (R: -C_2H_5)	2_1-helix	5.56	[168]
P	p(3-HO) (R: -C_5H_{11})	2_1-helix	4.55	[217]
Q	poly-α,α-dimethylpropiolactone	2_1-helix	6.03	[218]

[a] On the basis of the crystallographic designation of screw axes the helix symmetry is expressed in the form n_r, which means that within an identity period n structural units form r rotations [219, 220]. This classification differs from the usual nomenclature for proteins; there in a n_r helix n denotes the number of amino acids per rotation and r the atom number of the ring formed from a hydrogen bond and its associated main chain segment [138]. [b] Corresponds to an α-helix. [c] Corresponds to a 3_{10}-helix.

Fig. 5. The known solid structures of polyesters of bifunctional monomers known to date, and those of the corresponding poly-(α-amino acid)amides, as far as these have been studied.

(**H** in Figs. 5 and 6), whose structure is stabilized by intramolecular hydrogen bonds, is not found with polyesters.

α-Aminoisobutyric acid (Aib) is a non-proteinogenic amino acid which is nonetheless found in many natural peptides (e.g. in peptaibols).[222] Single crystals have been grown from the fully protected oligomers containing up to ten Aib units.[212, 223] Because of the substitution pattern of Aib, the preferred secondary structure of such oligomers is not an α-helix but a 3_{10}-helix with a somewhat smaller internal diameter, which with the decamer **I** (Figs. 5 and 6) is almost ideal in form. The structure is also stabilized by intramolecular hydrogen bonds, and therefore has no analogue in the polyester series. Surprisingly, oligomers of α,α-diethylglycine (Deg) and α,α-dipropylglycine (Dpg) have staggered conformations, stabilized by intramolecular hydrogen bonds between the amide H atoms and the adjacent carbonyl groups, which are obviously energetically more favorable than a 3_{10}-helix.[223]

Fig. 7. MacMoMo views, and a comparison of the 2_1-helix torsion angles of polydiketene **M**, poly-(*R*)-3-hydroxybutyrate **N**, and poly-α,α-dimethyl-β-propiolactone **Q**. In each case, five structural units are shown. The torsion angles are defined as for Figure 2c; the letters **M**, **N**, and **Q** refer to the compounds in Figure 5. The values for P(3-HB) are taken from ref.[170].

6.2. Structural Comparison of Homopolymers of 3-Hydroxy Acids: Modeling Studies with the Structural Parameters from Oligolides of (*R*)-3-Hydroxybutyric Acid

The same left-handed 2_1-helix with an identity period of 5.9 Å has been derived independently by three different groups[167, 204, 216] from the diffraction pattern of P(3-HB) fibers, by using different algorithms.[224a] Depending on the method, slight variations in the torsion angles were found, but they still lie quite close to each other ($\tau_1 = +142°$ to $+152°$, $\tau_2 = -52°$ to $-59°$, $\tau_3 = -31°$ to $-42°$, $\tau_4 = -173°$ to $-180°$; Fig. 7).

So far, it has not been possible to grow suitable crystals of P(3-HB) or of linear (3-HB) oligomers,[224b] and so the P(3-HB)-helix has never been directly "seen". The only exact structural parameters available at present are those of (3-HB) oligolides (see above, Fig. 2). Thus, from the S-shaped partial structure (Fig. 2b, green) a left-handed helix with approximately two units per turn (2_1-helix) may be constructed, while the Δ-shaped structural element (Fig. 2a, red) can be used to make a right-handed helix with about three units per turn (3_1-helix) and a correspondingly larger internal diameter (Fig. 8).[133, 135b]

In the 2_1-helix the ester carbonyl plane is almost perpendicular to the helix axis. For the 3_1-helix, in contrast, it lies almost parallel to the axis. The latter structural type has not yet been found in solid P(3-HB), though this does not preclude its presence in solution. The structure in solution was and is the subject of numerous studies, with somewhat controversial results.[225]

Under tension, the identity periods of the polyesters change, presumably because either the helix or the amorphous regions of the polymer assume a staggered conformation (zigzag chain).[167, 204b] Recently Marchessault et al. have calculated the conformation of such a zigzag structure for P(3-HB), by energy minimization with an MM2 force field.[226] The chain is not ideally staggered, and the torsion angles are $\tau_1 = +113°$, $\tau_2 = -169°$, $\tau_3 = -113°$, and

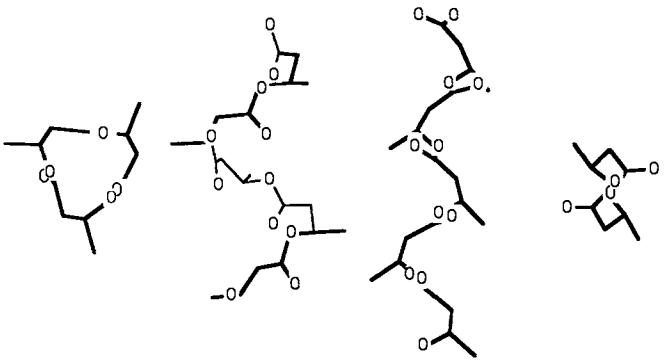

Fig. 8. MacMoMo views of the 2_1-helix (right) constructed from the S-shaped structural moiety (Fig. 2b, green), and the 3_1-helix (left) derived from the Δ-shaped spiral (Figure. 2b, red). In the middle, the two projections along the helical axes are shown (in each case only one turn of the helix is depicted).

$\tau_4 = +172°$ (identity period: 4.60 Å, for ideal staggering it would be 4.74 Å).

By using X-ray diffraction and ^{13}C NMR spectroscopy, it has been shown that the copolymer P(3-HB/3-HV) crystallizes in a P(3-HB)-helix up to 40% HV content, and in a P(3-HV)-helix above 55% HV (isodimorphism).[5, 227] Poly-β-isopropyl-β-propiolactone probably also crystallizes in a 2_1-helix, though all that is known about it is the identity period of 6.49 Å.[228] Unfortunately, at present it is not possible to compare the structure of the PHAs with the corresponding β-amino acid homopolymers, since there appear to be no structures known for the latter.[229]

7. Poly-(*R*)-3-hydroxybutyric Acid–Calcium Polyphosphate [P(3-HB)Ca-polyP$_i$] Complex: A Natural, Non-Proteinogenic Ion Channel?

Every cell has its own "microclimate". In order to preserve the special conditions required inside each cell, it surrounds itself with membranes. Biological membranes are essentially lipid bilayers containing interspersed proteins, usually about 75 Å thick. The hydrophobic interior is usually about 25 Å in size, but depending on the number of double bonds in the lipid chains can be up to 35 Å in breadth.[230] Because of their structure, lipid bilayers are practically impermeable for ions and most polar molecules. Nonetheless, these must somehow be able to pass through the membrane, since they play an important part in many physiological processes. Two transfer modes exist, carriers and channel mechanisms, whereby the latter is the more efficient and widespread of the two. Ion channels are mostly composed of proteins, with the channels themselves formed by ringlike conformations of several amphiphilic helices. The channel may consist of a single protein or of an aggregate of similar or identical subunits.[231] In addition, channel-forming peptides are also known, such as gramicidin,[232] for example, or alamethicin.[233]

Because of their great physiological importance, ion channels are at present the subject of intensive research; their importance was demonstrated in 1991 by the presentation of the Nobel Prize for medicine to Neher and Sakmann.

7.1. Findings which Led to the Postulation of an PHB-Containing Ion Channel

In 1983, Reusch et al. observed abrupt changes between 50 and 60 °C in the fluorescence intensity of *N*-phenyl-1-naphthylamine in the membranes of a variety of quite unrelated, genetically competent[234] gram-negative and gram-positive bacteria (*Azotobacter vinelandii*, *Bacillus subtilis*, and *Haemophilus influenzae*).[235] In each case, P(3-HB) was detected in the cell membranes, in significantly higher concentrations than were found in the noncompetent state. On the basis of these observations, the authors concluded that the characteristic changes in the fluorescence intensity must be somehow connected with P(3-HB).[19] Further experiments with *E. coli* showed that in the competent state, considerable quantities of P(3-HB) can be isolated (see Table 6).[235] The jump in fluorescence intensity at 50–60 °C was more intense if the competence protocol, which had been arrived at by "trial and error", was adhered to rigorously. A transition of this sort was not observed when biosynthesis of P(3-HB) was blocked with acetaldehyde, or if P(3-HB) was incorporated into liposomes. Clearly, the genetic transformability is connected with P(3-HB), but the P(3-HB) is not present by itself, but in the form of a quite unstable complex.[20] The authors later showed by freeze-fracture electron microscopy that in the plasma membranes of competent *A. vinelandii* and *E. coli* bacteria, islands with a visibly different structure are present.[21] Reusch and Sadoff were later able to isolate a labile complex from genetically competent *E. coli* bacteria, whose constituents were identified as P(3-HB), polyphosphate,[236] and calcium ions, and postulated a complex structure (see Figs. 9 and 10).[22, 23] In addition, they were able to show that the complex can be incorporated in vitro into liposomes, again using fluorescence spectroscopy.[22] Recently Reusch has also detected the complex more or less convincingly in plant and animal tissues (above all in the mitochondria and microsomes, to a lesser extent in the plasma membranes), though at significantly lower levels than in competent bacteria (see Table 6).[23]

Table 6. Occurrence of the complexes identified as [P(3-HB)Ca-polyP$_i$] in selected prokaryotes and eukaryotes [22,23].

Source	P(3-HB)$_{total}$ [μg g^{-1}]	Complex components [a] P(3-HB) [ng g^{-1}]	PolyP$_i$ [ng g^{-1}]	Ca^{2+} [ng g^{-1}]
E. coli log. phase	0.26	–	–	–

cow heart	9.2	662	353	178
cow liver	0.86	163	88	47

[a] The given numbers are based on the wet weight.

7.2. Composition and Possible Structure of the PHB-Containing Complex

According to Reusch, in the complex isolated from *E. coli*, 3-HB, phosphate, and Ca^{2+} occur in a ratio of 1:1:0.5. In contrast, the eukaryotic complex contains a longer polyP$_i$ chain (see Table 7). On the basis of molecular modeling and

Table 7. Chain lengths of the P(3-HB) and polyphosphate chains in organisms. (Determined from the gel permeation chromatogram by comparison of the retention times with standards) [22,23].

Complex	Chain length in monomer units	
	P(3-HB)	PolyP$_i$ [a]
prokaryotic complex	120–200 [b]	130–170
eukaryotic complex	120–200 [c]	170–220

[a] Gel: Showdex B804; standard: polyethylene glycol. [b] Gel: Altex m-Spherogel; standard: polyisoprene. [c] Gel: Altex m-Spherogel; standard: *erroneously given as polystyrene* [23]! According to a personal communication from Reusch, however, they too used polyisoprene.

energy minimization considerations (with the force field program Charmm), Reusch et al. postulate the exolipophilic-endopolarophilic structure shown in Figure 9.

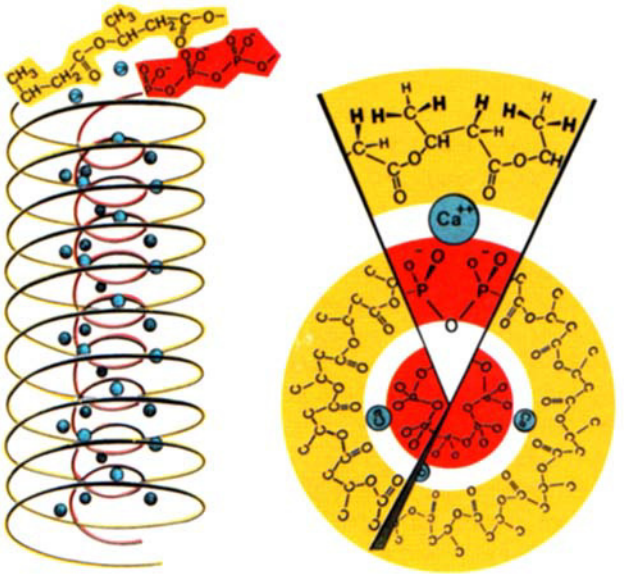

Fig. 9. Structure of a [P(3-HB)Ca-PolyP$_i$] complex suggested by Reusch [23].

The Ca^{2+} coordination geometry was decisive for the postulated spatial configuration. The external, right-handed P(3-HB)-helix must contain 14 units per turn, and the internal, also right-handed polyP$_i$-helix 7 units per turn, in order to bring the carbonyl and phosphate oxygen atoms into a suitable geometry for complexation with the Ca^{2+} ions (Fig. 10).[237] The Ca^{2+} ions lie vertically one above the other within the P(3-HB) cylinder. On the outside face, the methyl and methylene groups of the hydroxybutyric acid units also lie one above the other.

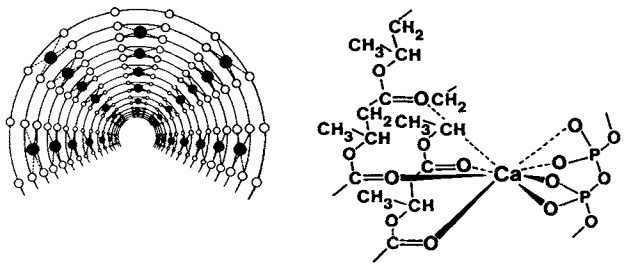

Fig. 10. Coordination geometry of the calcium in the postulated [P(3-HB)Ca-PolyP$_i$] complex [22].

A diameter of 24 Å,[238] and a length of 45 Å have been calculated, with an identity period of 4 Å, representing about 150 3-HB units and 80 P$_i$ units. To traverse the hydrophobic part of a membrane, 45 Å ought to be more than sufficient. However, in the projection shown in Figure 9, the ester bonds of the P(3-HB)-helix appear to assume at best the less favorable *E* conformation, which is about 3 kcal mol^{-1} less stable than the *Z* form.[239]

According to Reusch, the complex is quite labile in vitro, and extremely water-sensitive, probably due to the absence of stabilization of the postulated exolipophilic-endopolarophilic structure by the hydrophobic lipid bilayer.[240]

7.3. Possible Functions of the Ion Channel: DNA Transport?

The presumed exolipophilic–endopolarophilic structure is the ideal arrangement for an ion channel. Reusch assumes that such a channel would, above all, transport Ca^{2+} ions and polyphosphates across the plasma membrane. The inner, Ca-polyP$_i$-helix twists like a screw through the outer P(3-HB)-helix, and the Ca^{2+} ions are progressively transferred from one carbonyl group to the next. The transport of the neutral Ca-polyP$_i$ salt requires less energy than that of Ca^{2+} and polyP$_i$ ions separately. The interdependence of genetic transformability and complex concentration led Reusch to postulate DNA transport as well. However, for this to take place, the polyP$_i$ would first need to be removed from the P(3-HB)-helix. The outer P(3-HB)-helix remains intact as long as sufficient glucose is available as an energy source. According to Reusch and Sadoff, the internal diameter is sufficient to permit transport of single-stranded DNA. The structural requirements used to calculate this remain open—must the DNA be transported as a linear strand, or are secondary structures allowed? The secondary structures of single-stranded polynucleotides can display a considerable diameter. Thus, for example, the helix of polyadenosine has a diameter of 19 Å, only slightly less than that of double-stranded DNA (A-form: ca. 21 Å , B-form: ca. 22 Å, and Z-form: ca. 19 Å).[220] In addition, in transformation experiments, plasmids (cyclic, double-stranded DNA) are usually used, which in their supercoiled form have a far larger diameter! The role of calcium in genetic transformation, which is emphasized repeatedly by the authors, must also be somewhat modified, since transformation was obviously carried out according to the Hanahan protocol, where calcium plays only a subsidiary role![241] It is also unclear how such a channel could be opened and closed.

Nonetheless, this possible DNA-transport system through cell membranes is very intriguing, also with a view to future development of antisense medicaments.[242] The transport of charged oligonucleotides through cell membranes is still largely not understood.[242a, 243]

8. Complexation and Transport Experiments with Metal Ions and Polyesters

In the [P(3-HB)Ca-polyP$_i$] structure postulated by Reusch et al. the calcium ions are coordinated both to four

polyphosphate oxygen atoms and to four ester carbonyl oxygen atoms (Fig. 10). Complexes in which several ester carbonyl groups of the same acyclic molecule are coordinated to one cation are not known, to our knowledge. On the other hand, relatively many complexes exist between various cations and cyclic ligands, in which the ester carbonyl oxygen atoms cooperate with other functional groups. In nonactin, these are the ether oxygen atoms of the tetrahydrofuran rings.[244] Interestingly, these alkali metal complexes are very similar to the folded structure of the octolide of (*R*)-3-hydroxybutyric acid **O** (in Fig. 2), which in contrast to nonactin is not, however, active as an antibiotic (Fig. 11).[245] In the case of the depsipeptides, such as valinomycin, it is only the ester carbonyl groups which take part in complexation, but the structure is additionally stabilized by hydrogen bonds between the amide groups.[244]

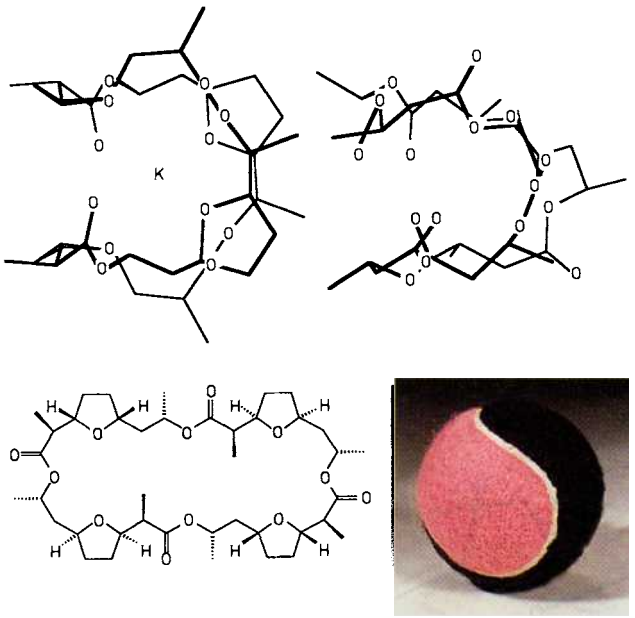

Fig. 11. MacMoMo views of the potassium complex of nonactin (top left) and the octolide structure **O** (top right) from Figure 2, and of the formula for nonactin (bottom left). Both 32-membered rings resemble the seam of a tennis ball in their structure (bottom right). The K^+ ion in the nonactin complex is surrounded by the four O atoms of the tetrahydrofuran rings and the four ester carbonyl O atoms in approximately cubic geometry. In the uncomplexed form nonactin has a different conformation to that in the potassium complex, and no longer resembles the octolide [244].

With the synthesized linear and cyclic P(3-HB) compounds in hand, we were in a position to investigate the complexing ability of polyesters of (*R*)-3-hydroxybutyric acid in more detail. All attempts at crystallization of such complexes with the open-chain molecules and larger cycles were unsuccessful, but promising results were obtained with the triolide **F** (in Fig. 2). Its structure is almost ideal for complexation, since the carbonyl groups are all practically parallel to each other, in the same hemisphere. Solutions of the triolide with sodium or potassium rhodanide in acetonitrile led to precipitation of solids whose structures could be determined.[135] For KSCN, crystals were only formed after the solution had been left open to air moisture for a little time: this proved that a little water was required for crystal formation. Both complexes are polymeric, and only in exceptional cases, for the sodium complex, were three ester carbonyl groups of one triolide molecule chelated to the same cation. Both the sodium and the potassium ions showed no particular preference for one coordination geometry with the ester carbonyl oxygen atoms (Fig. 12). Schreiber et al. made the same observation for alkali metal complexes with other carbonyl ligands.[246]

On the basis of ^{1}H NMR studies, and measurements of the dipole moment, the triolide appears to have a similar structure in solution to that in the crystal. In methanol, an interaction was observed with the alkali metal ions, which disappeared progressively, however, with gradual dilution. P(3-HB) also seems to undergo a certain degree of complexation with lanthanides in solution. Delsarte and Weill have suggested a structure for P(3-HB) in solution,[225c] by using the geometric data which they obtained from the McConnell–Robertson relationship of the pseudocontact complex of P(3-HB) with $Eu(fod)_3$ (fod = 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octadienato).

Okada et al.[247] and Burke et al.[248] have studied the transport of alkali metal picrates through an organic medium, by using cyclic polyesters which also contained additional acetal or ether oxygen atoms. Analogous experiments with triolide **F** showed increasing transport efficiency as the radius of the alkali metal ion increased (Fig. 13).[104b] These results can be explained readily by the increasing lipophilicity of the ions. The lack of ion selectivity could be connected to the rigidity of the triolide skeleton, whose structure remains almost unchanged even in the complexes with NaSCN and KSCN (Fig. 13). Similarly, high molecular weight P(3-HB) and linear oligomers of about 35 (3-HB) units also transported Cs^+ ions through a CH_2Cl_2 phase.[104b]

9. Conclusions and Outlook

After the discovery of P(3-HB) by Lemoigne about seventy years ago, interest in this biopolymer was at first very limited. The existence of this compound was known only to a few specialists. Because of the accessibility of polymers of this type from regenerable carbon sources, by using fermentation, an explosive development took place in this field at the time of the oil crisis about twenty years ago. Recently this has been strengthened by the fact that the poly(hydroxyalkanoates) are biodegradable and biocompatible polymers. Review articles and books have been written, and conferences held, whose participants from industry, academia, and state institutions were a more colorful interdisciplinary mixture than even the more experienced of us had ever seen. In a very recent international symposium on bacterial polyhydroxyalkanoates (ISBP '92, 1–5. June 1992) in Göttingen, the speakers and audience comprised biologists, microbiologists, geneticists, botanists, chemists, physicists, polymer scientists and polymer engineers, biotechnologists, pharmaceutical and medical scientists, many of whom came from institutes for raw materials and agrotechnology, food sciences,[249] groups concerned with waste disposal, housing and water management,[250] catalyst and surface research, even construction and building![251] Interest was concentrated almost exclusively (35 of 37 lectures) on high molecular

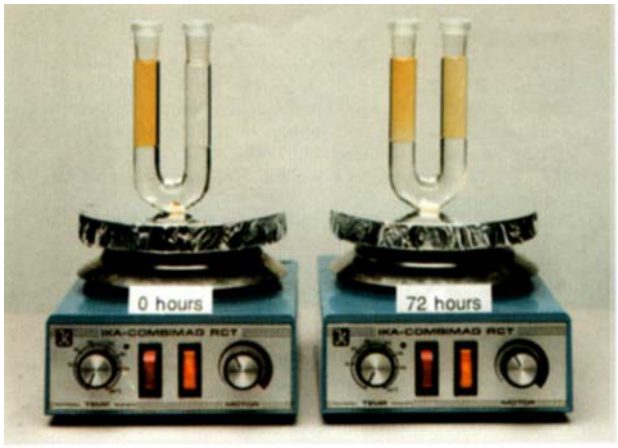
O_4	22°	143°
O_5	17°	160°

Fig. 12. a) PLUTO diagram of sections of the crystal structures of the triolide complex with KSCN (left) and with NaSCN (right). All potassium and sodium ions are hexacoordinated with the ester carbonyl O atoms of the triolides and the N atoms of the rhodanide ions as ligands. In the potassium complex, an additional water molecule is complexed to K_1. Red spheres are oxygen atoms of the CO functional groups, orange are OR oxygen atoms of the ester groups, white are carbon atoms, yellow are sulfur atoms, and green are nitrogen atoms. b) Coordination geometries of the potassium and sodium ions in the two complexes with selected ester carbonyl groups. For comparison: In the C_2 symmetrical nonactin–potassium complex, the angles are about α 61° and 67°, β 154° and 150°. c) Superposition of the free triolide (black) on the threefold coordinated triolide (red) in the Na complex (right), and on the twofold coordinated triolide (red) in the K complex (left).

weight polyhydroxyalkanoates, the bacterial storage materials made up of over 10000 (3-HB) units (referred to in the following as s-PHA or s-P(3-HB)[252]): their genesis, production, structure, material properties, applications, and biological degradation.[253]

Besides high molecular weight P(3-HB) in granules in microorganisms, the work of Reusch et al. has shown that short-chain P(3-HB), consisting of 100–200 (3-HB) units is also present in prokaryotic and eukaryotic organisms (referred to in the following as c-P(3-HB)[254]). It is always found in a complexed form, for example, in the cell membranes with Ca ions and probably a polyphosphate [19–23] and in human blood plasma with albumin and the so-called "low-density lipoproteins" (LDL).[24] In *E. coli*, which normally does not produce s-P(3-HB) (see also ref.[18]), the c-P(3-HB)-containing complex is only found in the inner cell membrane in the genetically competent state of the microbe, while in eukaryotes the complex is concentrated primarily in the mitochondria (the "microorganisms of the eukaryotic cell") and the microsomes; these facts suggest that c-P(3-HB) has important effects and functions. The results of our studies on the structure and properties of linear and cyclic (3-HB) oligomers do not contradict the hypothesis that c-P(3-HB) could be a component of an ion channel through cell membranes. It is notable that it should occur specifically as part of a complex with Ca polyphosphate, especially in view of a proposal made by Lipmann in 1965; he suggested that the first organisms on our planet may have used not ATP as their energy carrier, but inorganic polyphosphate or pyrophosphate (Polyphosphate – "a metabolic fossil"!).[255]

If one disregards inorganic polyphosphate [251, 257] and the aromatic amino acid-derived plant polymer lignin, which is non-uniform and difficult to classify,[258, 259] there are four classes of physiologically important biopolymers ("biomacromolecules"): polyisoprenoids, polynucleotides,



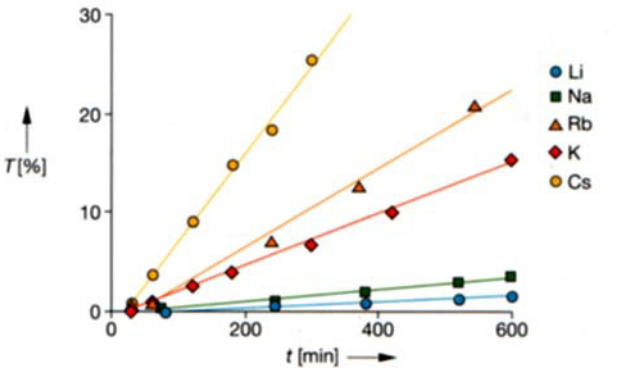


Fig. 13. Top: Apparatus for performing transport experiments through a "fluid membrane". The ions are transported out of a Tris-buffered (0.1 M) solution initially containing 1 mM alkali metal picrate/0.1 M alkali metal chloride, in the left side of the U-tube, through a 0.1 M triolide/CH_2Cl_2 solution into the other arm of the U-tube, whose water phase becomes progressively more yellow as the experiment proceeds. The picrate concentration is determined spectroscopically at λ_{max} = 356 nm. Bottom: Relative transport velocity T of the various alkali metal ions. These represent a so-called lipophilic series (without selectivity for a certain ionic radius!) [104b].

polypeptides, and polysaccharides. All four are distinguished by the facts that a) their monomeric building blocks are fundamental metabolic intermediates of the organisms, b) the respective oligomers display important effects, for example, as cofactors, hormones, or vitamins, in signal transduction or information transfer, or in recognition mechanisms, and c) the high molecular weight forms possess important functions, for example, as catalysts and receptors, as information carriers, as transport vehicles, storage materials, or structural elements. According to these criteria, poly(hydroxyalkanoates) must now also be regarded as a fifth important class of biopolymers. a) Their building blocks, the hydroxycarboxylic acids, in the simplest case hydroxybutyric acid, are a part of fatty acid metabolism; like the isoprenoids and polyketides[260] they are eventually derived from acetic acid. b) The oligomers, called c-P(3-HB) above, occur as components of complexes with other molecules, with effects as yet unknown; c-P(3-HB) is involved in the modification of cell membrane properties (phase transition, fluidity, permeability). c) The high molecular weight s-P(3-HB) is a microbial storage material (carbon reservoir, NADH-equivalents). In Table 8, examples are given of the five classes of biopolymers, and the polymers are contrasted with their low molecular weight equivalents.

Last of all, we come to the question of why low molecular weight c-PHA was discovered so late, and why its importance is only now slowly being recognized. Clearly, it was overlooked in the lipid fractions of cell extracts because of its chemical (heat, acid, base) and biochemical (ester-cleaving enzymes) instability. c-P(3-HB) occurs in *E. coli*, for example, only in very small amounts; it is synthesized to achieve a specific effect (membrane modification) and is then degraded again. It is probably subject to rapid anabolism/catabolism in the organism. The situation is therefore similar to that for hormones, whose stable representatives have been known and identified for a long time, while such important molecules as those of the arachidonic acid cascade (also lipids!), namely the leukotrienes, prostaglandins, thromboxanes etc. have only been isolated, characterized, synthesized, and their full importance recognized in the last few years (several have half-lives in serum or in tissues of less than a minute!).

Table 8. Comparison of monomers, oligomers, and polymers in chemistry and biochemistry of natural products.

Monomer *metabolic intermediates* biosynthesis and degradation from and to other low molecular weight building blocks	**Oligomers** *action* e.g. as hormone, cofactor, vitamin, information carrier, signal, recognition	**Polymers** *function* catalyst, receptor energy, storage material, transport vehicle, structural elements
amino acids	oligopeptides e.g. endorphines,bradykinin	polypeptides, e.g. fatty acid synthase hemoglobin, immunoglobulins skin, nails, hair, silk
monosaccharides, sugars	oligosaccharides e.g. blood group determinants heparin, sugar part of the glycoprotein dextrin	polysaccharides e.g. cellulose, starch chitin, glucan, glycogen murein
acetic acid, mevalonic acid isopentenyl pyrophosphate	isoprenoids carotinoids, rhodopsin, vitamin A, E, squalene, steroids, steroid hormones	polyisoprenoids, rubber, gutta-percha
purine and pyrimidine bases nucleosides, nucleotides, phosphate	oligonucleotides NADH, NADPH, tRNA	polynucleotides *m* and *r*RNA, DNA
hydroxycarboxylic acids	low molecular weight P(3-HB) (c-PHB, complexation)	high molecular weight P(3-HB) (s-PHB, storage)

We thank Silvia Sigrist for her tireless efforts in producing the manuscript. Without the help of Hans-Michael Bürger, Andreas Brunner, and Urs Lengweiler in preparing the final versions of Figures, Schemes, and Tables, the work would not have succeeded!

[1] a) The expression poly(hydroxy acid) (PHA) was coined in 1983 by Findlay and White (R. H. Findlay, D. C. White, *Appl. Environ. Microbiol.* **1983**, *45*, 71) when it was realized that homopolymeric poly-(*R*)-3-hydroxybutyric acid occurred as the exception rather than the rule. Polymers with various hydroxy acid units are far more common. b) Recently the German term Polyhydroxyfettsäuren (PHF) has been proposed by Steinbüchel (A. Steinbüchel, *Nachr. Chem. Tech. Lab.* **1991**, *39*, 1112-1124)

[4] In this context it was demonstrated that microorganisms with PHA storage materials could survive "starvation periods" much better than those without them. The ability to survive is often directly proportional to the initial PHA content (E. A. Dawes, *Microbial Energetics*, Blakie, London, **1986**).

[18] The *E. coli* strain K-12 can produce up to 1.2% of its dry weight as P(3-HB), under suitable nutritional conditions. If it also harbors the R-plasmid RP1, and growth is under C-limiting conditions, this value can reach 5.8% (P. Gilbert, M. R. W. Brown, *J. Bacteriol.* **1978**, *133*, 1062). However, the authors do not comment on whether it is present as a storage material or as a membrane component (see Section 7).

[58] A third variant [Eq. (a)] was found by Merrick et al in *R. rubrum* [54]. The (*S*)-hydroxybutyric acid derivative is first formed from acetoacetyl-CoA, and this is then epimerized to the (*R*) configuration by an enoyl-CoA hydratase. The subsequent reaction sequence proceeds as shown in Scheme 1. Evidently, *R. rubrum* cannot synthesize (*R*)-hydroxybutyryl-CoA directly by reduction of acetoacetyl-CoA.

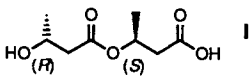
[72] The authors could only isolate an enriched depolymerase from *A. eutrophus*. They maintain that the lack of evidence for a dimer can possibly be ascribed to the action of an esterase, which copurifies with the depolymerase [33].

[73] (*R,S*) dimer, or (3*R*)-3-[(3′*S*)-3′-hydroxybutyryloxy]butyric acid **I**:



I

The (*R,S*) dimer is identical with the compound described as 3-L-[3-D-hydroxybutyryloxy]butyric acid (= LD dimer) in earlier publications [47, 52].

[74] Exoenzymes attack the polymer chains from the ends, in contrast to endoenzymes, which can also cleave within the polymer chain (*Lexikon der Biochemie*, (Eds. : H. D. Jakubke, H. Jeschkeit), VCH, Weinheim, **1974**).

[75] Merrick et al. have shown that the depolymerase is normally deactivated by an inhibitor whose action can be neutralized by an activator protein. The inhibitor can also be destroyed or removed by treating the P(3-HB) granules with trypsin, or extracting with alkali [55, 56]. The activities of the other enzymes are also affected by certain metabolic products. Thus, for example, NADH, pyruvate, and in some organisms oxaloacetate [35] or 2-oxo-glutarate inhibit 3-hydroxybutyrate dehydrogenase [43].

[106] Mass spectrometric methods are becoming more and more established as new methods for determination of molecular weight distribution see, for example, J. V. Bletsos, D. M. Hercules, D. vanLeyen, B. Hagenhoff, E. Niehuis, A. Benninghoven, *Anal. Chem.* **1991**, *63*, 1953, and references therein. As yet, there are relatively few publications concerned with the mass spectrometric determination of P(3-HB): A. Ballistreri, D. Garozzo, M. Giuffrida, G. Impallomeni, G. Montaudo, *Macromolecules*, **1989**, *22*, 2107; A. Balliestreri, D. Garozzo, M. Giuffrida, G. Montaudo in ref.[13], p. 49–64; A. Ballistreri, G. Montaudo, D. Garozzo, M. Giuffrida, M. S. Montaudo, *Macromolecules*, **1991**, *24*, 1231; ref. 104; H. M. Bürger, H.-M. Müller, D. Seebach, K. O. Börnsen, M. Schär, *Macromolecules* submitted: here P(3-HB)-oligomer distributions determined by GPC analysis are compared with those obtained by matrix-supported LDI mass spectrometry.

[107] D. Seebach, M. Züger, *Helv. Chim. Acta* **1982**, *65*, 495; P. Schnurrenberger, M. F. Züger, D. Seebach *ibid.* **1982**, *65*, 1197; D. Seebach, M. F. Züger, *Tetrahedron Lett.* **1984**, *26*, 2747 (preparation of (*R*)-3-hydroxyvalerate from P(3-HB/3HV) copolymer).

[108] N. Vanlautem, G. Jacques, *Eur. Pat. Appl.* **1982**, EP 43 620 A1 (*Chem. Abstr.* **1982**, *96*, 163397f).

[109] Naturally, mixtures of oligomers (without crotonyl endgroups) are also accessible in this way; their mean molecular weight can be determined from the ratio P(3-HB)/alcohol: S. Akita, Y. Einaga, Y. Miyaki, H. Fujita, *Macromolecules* **1976**, *9*, 774; see also ref. [101], articles by Montaudo et al. in [106] and [108].

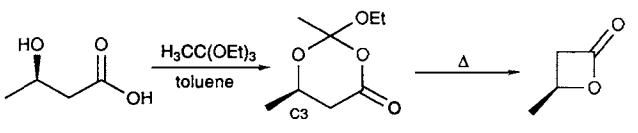
[124] The best method for synthesizing enantiomerically pure β-butyrolactone at present goes through the orthoester **II**, from which the β-butyrolactone can be liberated by pyrolysis, with exclusive inversion of the configuration at C-3, in 30-35% yield. The S_N2 attack on the lactone therefore corresponds formally to retention with respect to the (*R*)-hydroxybutyric



II

acid used as starting material. The original synthetic method, and an improved version: a) A. Griesbeck, D. Seebach, *Helv. Chim. Acta* **1987**, *70* 1320; b) R. Breitschuh, D. Seebach, *Chimia* **1990**, *44*, 216; other synthetic methods: c) A.R. Olson, R.J. Miller, *J. Am. Chem. Soc.* **1938**, *60*, 2687; d) J.R. Shelton, D.E. Agostini, J.B. Lando, *J. Polym. Sci. [139] For example, recently the following compounds **IV**–**VII** have been produced or generated from 3-hydroxy acids. Compound **IV**: D. Seebach, U. Misslitz, P. Uhlmann, *Angew. Chem.* **1989**, *101*, 484; *Angew. Chem. Int.*

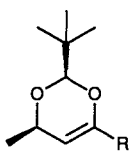
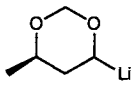
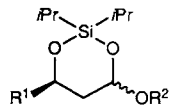
IV



V



VI



VII

Ed. Engl. **1989**, *28*, 472; D. Seebach, U. Misslitz, P. Uhlmann, *Chem. Ber.* **1991**, *124*, 1845. Compound **V**: U. Gysel, dissertation (Chromatographische Enantiomerentrennung von 1,3-Dioxinonen und Synthese von enantiomerenreinen 1,3-Dioxinen aus 3-Hydroxybuttersäure, dissertation no. 9473), ETH Zürich, **1991**. Configurationally stable 4-lithium-1,3-dioxanones with structure **VI** have been synthesized in several steps from P(3-HB). In THF, the (4*R*, 6*R*) derivative is stable at −78 °C, and the(4*R*, 6*S*) epimer is stable at 0 °C (R. J. Linderman, B. D. Griedel, *J. Org. Chem.* **1991**, *56*, 5491). Lactols of type **VII** have recently been synthesized by hydrosilylation of the corresponding 3-hydroxy acids. They can be diastereoselectively alkylated with allylsilane and suitable Lewis acids (A. P. Davis, S. C. Hegarty, *J. Am. Chem. Soc.* **1992**, *114*, 2745). Numerous pheromones have been synthesized by Mori et al. from 3-hydroxybutyrate and 3-hydroxyvalerate (K. Mori, *Tetrahedron* **1989**, *45*, 3233-3298).

[142] In contrast to this, it is emphasized repeatedly at conferences and seminars on the subject that greater application of biodegradable polymers is not to be desired. On the one hand, they can be disposed of without commercial use, and on the other, their degradation products may pollute waterways (e.g. by eutrophication).

[189] *Methods Enzymol. (Mass Spectrometry)* **1991**, 193.
[190] The rate of the reaction of the monomer with the initiator must be greater than the rate of the polymerization reaction, and no chain transfer or chain termination reactions may occur. It can then be shown that in such cases the molecular weight follows a Poisson distribution, and the proportion of *n*mers in the mixture can be calculated, as can the polydispersity (M_w/M_n) [163]. In this way, "living polymers" with a relatively narrow distribution can be produced. More recent developments in this area include group transfer polymerization (GTP): D. Y. Sogah, W. R. Hertler, O. W. Webster, G. M. Cohen, *Macromolecules*, **1987**, *20*, 1473; M. T. Reetz, *Angew. Chem.* **1988**, *100*, 1026; *Angew. Chem. Int. Ed. Engl.* **1988**, *27*, 994, ring-opening metathesis polymerization (ROMP): R. Grubbs, *J. Am. Chem. Soc.* **1986**, *108*, 733; R. R. Schrock, *Acc. Chem. Res.* **1990**, *23*, 158, and cationic polymerization: T. Higashimura, S. Aoshima, M. Sawamoto, *Makromol. Chem., Macromol. Symp.* **1988**, *13/14*, 457; *ibid.* **1988**, *13/14*, 513; M. Zsuga, R. Faust, J.P. Kennedy, *Polym. Bull.* (Berlin) **1989**, *21*, 273.
[191] a) From a seminar held by Dr. F. Wynne, ICI (FRG), at a workshop on biodegradable plastics at Zürich University on November 27, 1991; b) *Chimia* **1990**, *44*, 222.
[192] Independent of the C source, this organism also makes primarily P(3-HB) (H. Brandl, R. A. Gross, R. W. Lenz, R. Lloyd, R. C. Fuller, *Arch. Microbiol.* **1991**, *155*, 337)
[193] a) R. Noyori, M. Kitamura, *Mod. Synth. Methods* **1989**, *Vol. 5*, 115-198; R. Noyori, H. Takaya, *Acc. Chem. Res.* **1990**, *23*, 345–350; b) A. Tai, T. Kikukawa, T. Sugimira, Y. Inoue, T. Osawa, S. Fujii, *J. Chem. Soc. Chem. Commun.* **1991**, 795.
[194] P(3-HB) is readily soluble in halogenated solvents, for example dichloromethane, chloroform, 1,2-ethylene dichloride, or trifluoroethanol. On heating, it also dissolves in dimethylformamide, dimethylsulfoxide, xylene, pyridine, dichloroacetic acid, trifluoroacetic acid, and acetic acid, though in the last four of these depolymerization must be reckoned with, especially at higher temperatures. Further discussion of solubility can be found in ref. [1b] and [10].

[234] "Genetic transformation" indicates the ability of a cell to take up DNA from the external medium, leading to both a new genotype and—because of expression of the introduced DNA—a new phenotype (W. Wenzel, M. J. Amann, *Lexikon der Gentechnologie*, Springer, Heidelberg, **1985**; H. Smith, D. Danner, R. Deich, *Ann. Rev. Biochem.* **1981**, *50*, 41).
[235] It remains to be investigated how P(3-HB) can be produced by *E. coli* under the conditions described. Sinskey et al. [17b] have shown that only genetically modified *E. coli* containing the ketothiolase, reductase, and synthetase genes is capable of biosynthesis of P(3-HB) according to Scheme 1. The same appears to be true in plants [69b].
[236] As mentioned at the start, polyphosphates occur in many bacteria [4]. Their function is still not clear; they may act as reservoirs of energy or phosphate, or replace ATP in kinase reactions (K. A. Ahn, A. Kornberg, *J. Biol. Chem.* **1990**, *265*, 11734; I. S. Kulaev, *The Biochemistry of Inorganic Polyphosphates*, Wiley, New York, 1979 and ref.[13]). Their common appearance with P(3-HB) is not so surprising, since Doi et al. have

shown that in *A. eutrophus* polyphosphate synthesis and P(3-HB) synthesis are connected [76].

[237] In this approach, the structure of calcium metaphosphate $[Ca(PO_3)_2]_n$ is clearly not critical (four different modifications are known, the α, β, γ, and δ forms) (A. O. McIntosh, W. L. Jablonski, *Anal. Chem.* **1956**, *28*, 1424). The structure of the β form is known; it is zigzag-shaped and not a helix (M. Schneider, K. H. Jost, P. Leibnitz, *Z. anorg. allg. Chem.* **1985**, *527*, 99). However, the rotation barrier of the P-O-P bond is relatively low, so that depending on the cation various conformations have been found, including helical arrangements with $[AgPO_3]_n$ or $[NaPO_3]_n$, in the Kuroll A and B modifications (D. E. C. Corbridge, *The Structural Chemistry of Phosphorus*, Elsevier, Amsterdam, **1974**).

[238] This presumably refers to the external diameter, which was not defined in the article quoted [22].

Neural Networks in Chemistry

By Johann Gasteiger* and Jure Zupan*

The capabilities of the human brain have always fascinated scientists and led them to investigate its inner workings. Over the past 50 years a number of models have been developed which have attempted to replicate the brain's various functions. At the same time the development of computers was taking a totally different direction. As a result, today's computer architectures, operating systems, and programming have very little in common with information processing as performed by the brain. Currently we are experiencing a reevaluation of the brain's abilities, and models of information processing in the brain have been translated into algorithms and made widely available. The basic building-block of these brain models (neural networks) is an information processing unit that is a model of a neuron. An artificial neuron of this kind performs only rather simple mathematical operations; its effectiveness is derived solely from the way in which large numbers of neurons may be connected to form a network. Just as the various neural models replicate different abilities of the brain, they can be used to solve different types of problem: the classification of objects, the modeling of functional relationships, the storage and retrieval of information, and the representation of large amounts of data. This potential suggests many possibilities for the processing of chemical data, and already applications cover a wide area: spectroscopic analysis, prediction of reactions, chemical process control, and the analysis of electrostatic potentials. All these are just a small sample of the great many possibilities.

1. Introduction

In many areas where complex information needs to be processed--from the stock-market to medical diagnosis and chemistry—people are suddenly talking about "neural networks". Neural networks appear to be a new secret weapon to combat a multitude of problems. In order to illustrate this, Figure 1 shows the dramatic rise in the number of publications on the use of neural networks in chemistry. What makes neural networks so attractive? Are they really a panacea for information processing ?

Neural networks were originally developed as models of information processing within the brain. This explains some of their fascination: The human brain has phenomenal processing power, far beyond that even of supercomputers today. Obviously the human brain processes information in a completely different way from that of today's conventional computers, which are constructed along the lines of the "von Neumann" architecture. A von Neumann computer works through a program (an algorithm) step by step, that is, sequentially.

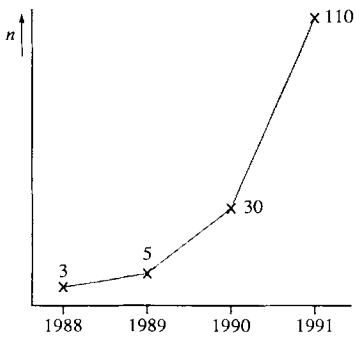

Fig. 1. Increase in the number of publications on the use of neural networks in chemistry over the period 1988-1991.

In contrast the human brain operates largely in parallel: incoming information is channeled through many processing units simultaneously. This can be demonstrated by the "100 Step Paradox": We know from neurophysiology that a nerve cell or neuron recovers approximately one millisecond after firing. On the other hand we also know that the human brain is able to perform intelligent processes, such as recognizing a friend's face or reacting to some danger, in approximately one tenth of a second. Therefore the brain is able to perform difficult tasks in less than 100 sequential steps. This small number of steps is of course insufficient to solve such complex problems, so we conclude that many tasks must be performed simultaneously and in parallel.

Artificial neural networks are nowadays usually implemented as software packages which run on conventional von Neumann computers and merely simulate parallel processing. True parallel processing is only possible on appropriate hardware (Transputers) and is still rare today. The software approach permits the use of the same program for quite different knowledge domains. The same algorithm can be used to study the relationships between chemical structure and the infrared spectrum, to simulate a tennis match, or to predict stock-market trends.

In conventional programming one tries to solve problems by finding a *problem-specific algorithm* where every instruction is tailored to exactly the task at hand. Alternatively one may solve the problem by using an expert system, which distinguishes strictly between the knowledge specific to the task and the mechanism to draw conclusions and make decisions. Neural network algorithms, however, do not belong to

Prof. Dr. J. Zupan
National Institute of Chemistry
Hajdrihova 19, SLO-61115 Ljubljana (Slovenia)

any particular knowledge domain, but may be used generally to solve certain *classes of problems* from a wide variety of fields.

No longer is it the sequence of instructions that is specific to a task. It is the type of information that is fed into the neural network and the way it is represented there that tailor a study involving a neural network to the task at hand.

Neural networks may be used to solve the following problem types:

- Classification: An object, characterized by various properties, is assigned to a particular category.
- Modeling: Neural networks can output both binary and real values. Through this feature, by combining certain experimental results for an object we can arrive at other properties for it. Statistical methods produce such relationships by using an explicit mathematical equation. Neural networks however are able to express such relationships implicitly; this is especially useful in cases where an explicit equation can not be set up.
- Association: Neural networks can be used for the task of comparing information because they are able to store information of similar kinds. Thus they are able to recognize that two pictures of a face depict the same person, even when one of the pictures is distorted (autoassociation). Furthermore, they can be used for associative tasks where one object has a particular relation to another object (heteroassociation).
- Mapping: Complex information can be transformed into a simpler representation (e.g., projection onto a plane) while preserving all essential information.

In this introductory article we shall first introduce the basic features of the various types of neural networks before giving an overview and selected examples of the application of neural nets in the field of chemistry.[1, 2]

2. Neurons and Networks

In this review the term neural networks always refers to "artificial neural networks", because these were developed in order to emulate the biological neural networks of the human brain. However for simplicity the epithet "artificial" is omitted here.

2.1. A Model of a Neuron

Neural networks consist of subelements, the neurons, which are connected together to form a network. The artificial neuron is supposed to model the functions of the biological nerve cell. Although there are at least five physiologically distinct types of nerve cell, we need only present one type here (Fig. 2), since we discuss only the basic structure of a neuron; the physiological processes—and the chemical processes[3] that cause them—cannot be examined in more detail.

The nerve's cell body possesses a large number of branches, known as dendrites, which receive the signals and pass them on to the cell body. Here the signals are accumulated, and when a particular threshold limit has been exceeded, the neuron "fires". An electrical excitation is transmitted across the axon. At its end each axon has contact with the dendrites of the neighboring neurons; this contact point is called the

Johann Gasteiger was born in Dachau in 1941. He studied chemistry at Munich and Zurich universities with a doctoral thesis (1971) on "Mechanistic Investigations into Reactions in the Cyclooctatetraene System" under R. Huisgen. In his post-doctorate studies (1971–1972) he carried out ab initio calculations on carbanions under A. Streitwieser, Jr. at the University of California in Berkeley. In 1972 he transferred to the Technical University of Munich where he developed, along with a group led by I. Ugi, a prototype for a synthesis-planning program. He received his "habilitation" in chemistry in 1978 with a study on models and algorithms for investigating chemical reactions and reactivity. Since 1989 he has been professor at the Technical University of Munich. His main area of research is the development of methods and computer programs for predicting reactions and planning syntheses, for evaluating and simulating mass spectra, and for the three-dimensional modeling of molecules. From 1987–1991 he was the project manager for the Fachinformationszentrum Chemie in the implementation of a reaction database based on ChemInform, and in 1991 was awarded the Gmelin–Beilstein memorial medal from the German Chemical Society for his achievements in the field of computer chemistry.

Jure Zupan was born in Ljubljana, Slovenia in 1943. He studied physics at the University of Ljubljana, where he received his doctorate in 1972 under D. Hadzi with a thesis on the energy bands in boronitrides. Until 1973 he worked at the Josef Stefan Institute in the field of quantum chemistry and the magnetic properties of ceramic materials. Since 1974 he has led a group at the Institute for Chemistry in Ljubljana. His areas of work include chemometrics, artificial intelligence, and the development of expert systems and algorithms for chemical applications. In 1982 he was visiting professor at Arizona State University/USA, in 1988 at the Vrije Universiteit in Brussels, and 1990–1992 at the TU München in Garching. For his research work (approximately 150 original publications, 2 monographs, and 3 books) he received the highest Slovenian award for research in 1991. He obtained his habilitation in 1975 and has been Professor of Chemometry at the University of Ljubljana since 1988.

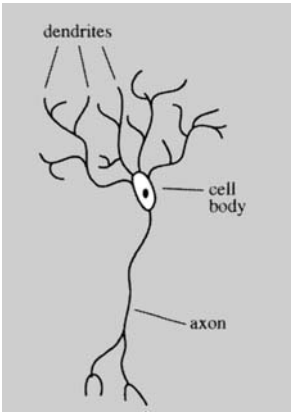

Fig. 2. Much simplified scheme of a nerve cell. The number of dendrites and the number of branches in the dendrites are much higher in reality.

synapse. Neurons are linked with each other across these synapses.

The synapses, however, also present a barrier that alters the intensity of the signal during transmission. The degree of alteration is determined by the synaptic strength. An input signal of intensity x_i has an intensity of s_i after crossing synapse i of strength w_i [Eq. (a), Fig. 3]. The synaptic strength may change, even between one impulse and the next.

$$s_i = w_i x_i \tag{a}$$

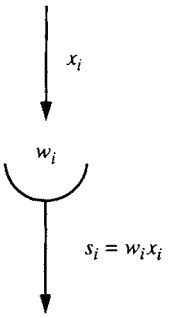

Fig. 3. Transformation of an input signal x_i on passage through a synapse of strength w_i.

Each neuron has a large number of dendrites, and thus receives many signals simultaneously. These m signals combine into one collective signal. It is not yet known exactly how this net signal, termed *Net*, is derived from the individual signals.

For the development of artificial neurons the following assumptions are made:

1. The *Net* is a function of all those signals that arrive at the neuron within a certain time interval, and of all the synaptic strengths.
2. The function is usually defined as the sum of the signals s_i, which in turn is given by the product of the input signals x_i ($i = 1, \ldots m$) and the synaptic strengths w_i ($i = 1, \ldots m$), now referred to as weights [Eq. (b)]. Figure 4 shows the model of a neuron as developed up to this point.

$$Net = s_1 + s_2 + \ldots s_i + \ldots s_m = w_1 x_1 + w_2 x_2 + \ldots w_i x_i + \ldots w_m x_m \tag{b}$$

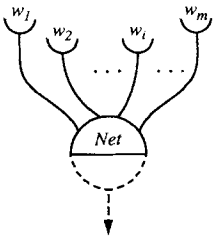

Fig. 4. First stage of a model of a neuron.

The net signal *Net* is, however, not yet the signal that is transmitted, because this collective value *Net* can be very large, and in particular, it can also be negative. It is especially the latter property that cannot be a good reflection of reality. A neuron may fire or not, but what is the meaning of a negative value? In order to attain a more realistic model, the value of *Net* is modified by a transfer function. In most cases a sigmoid function, also known as a logistic or Fermi function, is used. With this transfer function the range of values for the ouput signal *out* [Eq. (c)] is restricted to between zero and one, regardless of whether *Net* is large or small or negative.

$$out = \frac{1}{1 + e^{-(\alpha Net + \vartheta)}} \tag{c}$$

Most important, we now have a nonlinear relationship between input and output signals, and can therefore represent nonlinear relationships between properties, a task which can often only be carried out with difficulty by statistical means. Moreover, in α and ϑ we now have two parameters with which to influence the function of the neuron (Fig. 5).

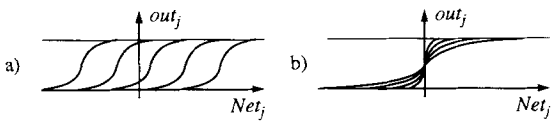

Fig. 5. Influence of α (a) or ϑ on the output signal out_j, defined as in Equation (c).

The transfer function completes the model of the neuron. In Figure 6a the synaptic strengths, or weights w are still depicted as in Figure 4; in the following figures they will no longer be shown, as in Figure 6b, but must of course still be used.

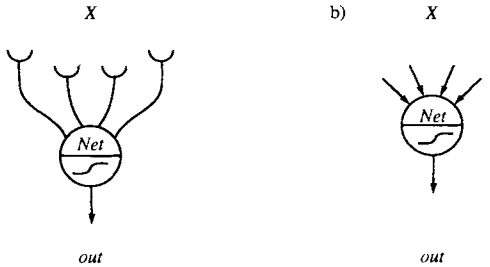

Fig. 6. Complete model of a neuron a) with and b) without explicitly defined synapse strengths w.

Symbols and Conventions

The literature on neural networks uses a confusing array of terminologies and symbols. In order that the reader may better compare the individual networks, a standard nomenclature will be followed throughout this article:

- Magnitudes that consist of a single value (scalar magnitudes) will be represented by lower-case letters in italics x_i. (The only exception is *Net* which is capitalized in order to distinguish it from the English word net. Moreover, though *Net* and *out* are symbols for single pieces of data, they are written with three letters so as to be more easily readable.)
- Data types which consist of several related values (vectors or matrices) are symbolized by a capital letter in bold italics: $\boldsymbol{X}$.
- An input object that is described by several single data (e.g., measured values from sensors) will thus be represented by $\boldsymbol{X}$, whereas the individual values are given by $x_1, x_2, \ldots x_m$. A single input value from this series is specified with the index i, thus x_i. A single neuron from one group (layer) of n neurons will be labeled with the index j; the whole of the output signals from these n neurons will be denoted $\boldsymbol{Out}$ $(out_1, out_2, \ldots out_n)$: The output signal from any one individual thus has the value out_j.
- In a layer of n neurons receiving m input data there are $n \times m$ weights that are organized into a matrix $\boldsymbol{W}(w_{11}, w_{12} \ldots w_{nm})$. A single weight from this matrix will be labeled w_{ji}.
- If there are more than one input objects, they will be distinguished by the index s: thus $\boldsymbol{X}_s$; the individual data will then be x_{si}.
- In a multilayered network the various layers will be labeled with the superscript l, e.g., out_j^l.
- Iterations in a neural network are characterized by the superscripts t, which are written in parentheses, e.g., $\boldsymbol{W}^{(t)}$.

2.2. Creating Networks of Neurons

The 100-step paradox teaches us that the advantage of the human brain stems from the parallel processing of information. The model of a neuron that we have just presented is very simple, but even much more complicated models do not provide any great degree of increased performance. The essential abilities and the flexibility of neural networks are brought about only by the interconnection of these individual arithmetic units, the artificial neurons, to form networks.

Many kinds of networking strategies have been investigated; we shall present various network models and architectures in the following sections. Since the most commonly applied is a layered model, this network architecture will be used to explain the function of a neural net.

In a layered model the neurons are divided into groups or layers. The neurons of the same layer are not interconnected, but are only linked to the neurons in the layers above and below. In a single-layered network all the neurons belong to one layer (Fig. 7). Each neuron j has access to all input data $\boldsymbol{X}$ $(x_1, x_2, \ldots x_i, \ldots x_m)$ and generates from these an output value which is specific to this neuron, out_j.

In Figure 7 the input units are shown at the top. They do not count as a layer of neurons because they do not carry out any of the arithmetic operations typical of a neuron, namely

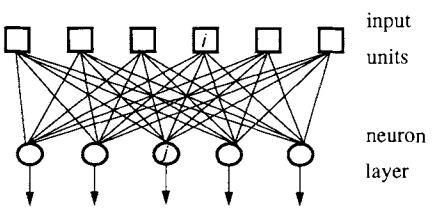

Fig. 7. Neural network with input units (squares) and one layer of active neurons (circles).

the generation of a net signal *Net*, and its transformation by a transfer function into an output signal *out*. In order to distinguish them from neurons, which are represented as circles in the following diagrams, input units will be shown as squares.

The main function of the input units is to distribute input values over all the neurons in the layer below. The values that arrive at the neurons are different, because each connection from an input unit i to a neuron j has a different weight w_{ji}, representing a specific synaptic strength. The magnitudes of the weights have to be determined by a learning process, the topic of Section 4.

The output value out_j of a neuron is determined by Equations (d) and (e), which are generalizations of Equations (b)

$$Net_j = \sum_{i=1}^{m} w_{ji}\, x_i \tag{d}$$

$$out_j = \frac{1}{1 + e^{-(\alpha\, Net_j + \vartheta)}} \tag{e}$$

and (c). The index j covers all n neurons and the index i all m input values.

In a single-layered network the output signals out_j of the individual neurons are already the output values of the neural network.

Equations (d) and (e) suggest a more formal representation for the neuron and the neural network. The input values can be interpreted as a vector $\boldsymbol{X}$ $(x_1, x_2, \ldots x_i, \ldots x_m)$ that is transformed by the matrix of weights $\boldsymbol{W}$ with elements w_{ji} and the transfer function into the vector of output values $\boldsymbol{Out}$ $(out_1, out_2, \ldots out_j, \ldots out_n)$ (Fig. 8).

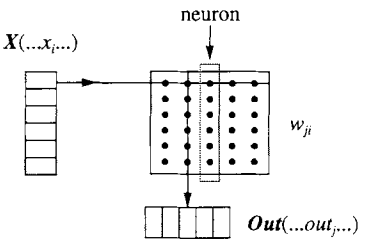

Fig. 8. Matrix representation of a one-layered network, which transforms the input data $\boldsymbol{X}$ into the output data $\boldsymbol{Out}$ by using the weights w_{ji}.

Each neuron represents a column in the matrix in Figure 8. In this matrix representation it is emphasized that every input value is fed into every neuron. The implementation of the layered model as algorithms is also realized in the matrix representation.

A single layer of neurons is known as a perceptron model and offers only limited flexibility as yet for the transformation of input values into output values. These limitations can be overcome by using several single layers in succession.

In a multilayered model the architecture chosen usually connects all the neurons of one layer to all the neurons in the layer above and all the neurons in the layer below. Figure 9 shows a two-layered neural network. (As we mentioned previously, the input units do not count here, because they are not neurons but serve only to distribute the input values across the neuron layer below.) The network user cannot

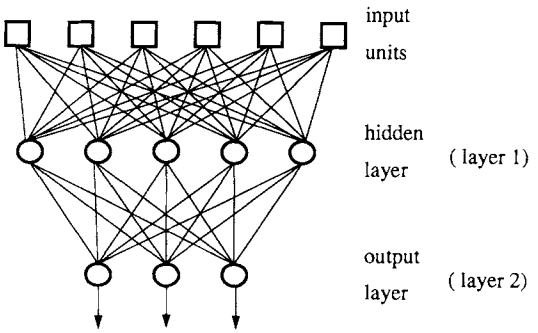

Fig. 9. Neural network with input units and two layers of active neurons.

access the first layer of neurons, which is therefore known as a hidden layer; the neurons in it are called inner neurons. The output values $\boldsymbol{Out}^1$ of the first layer of neurons are the input values $\boldsymbol{X}^2$ of the second layer of neurons. Thus each neuron in the upper layer passes its output value on to every neuron in the layer below. Because of the different weights w_{ji} in the individual connections (synapses) the same output value $\boldsymbol{Out}^1 = \boldsymbol{X}^2$ has a different effect on each individual neuron [Eq. (d)]. The result of the neural network as a whole is only given by the last layer in the network (here $\boldsymbol{Out}^2$). Figure 10 shows a two-layer network in matrix notation.

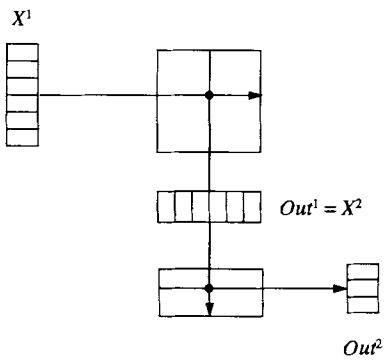

Fig. 10. Matrix representation of a two-layered network.

3. Historical Perspective

The dramatic increase in interest in neural networks does much to disguise the fact that people have been developing them for nearly 50 years.[4] As early as the forties McCulloch and Pitts[5, 6] developed a model of a neuron as a logical threshold element with two possible states. They were forced to leave open the question of how neurons learn, to which Hebb (1949) suggested an answer.[7] This Hebb learning rule states that the synaptic strength of a neuron varies proportionally with the activity in front of and behind the synapse.

Rosenblatt[8] organized a number of neurons in such a way that they corresponded essentially to a one-layered network (Fig. 7), and named this formation a perceptron.

The original enthusiasm for the development of models of biological nervous systems began to wane in the sixties for various reasons. The results with the networks of that time were hardly relevant to solving real-world problems and thus not very encouraging. With the advent of the computer, interest shifted more and more to problem-solving by directly programmed methods. The buzz-word invented for this, "artificial intelligence", shows only too clearly what was expected of this technology, although it was clear from the outset that the method chosen had very little to do with the processing of information as performed by the human brain.

Not surprising therefore that research into neural networks suffered a heavy blow from none other than Marvin Minsky, one of the main proponents of artificial intelligence. In 1969 together with Papert[9] Minsky published a very severe but probably justified criticism of the network models of the time. They showed in their theoretical study that perceptrons—at least as they were being developed at that time—offer only limited possibilities. Moreover they speculated that extending the architecture of perceptrons to more layers would not bring about any significant improvement in results. As a consequence of this criticism from so influential a personage as M. Minsky, research funding for the modeling of biological nervous systems became virtually unavailable.

In the years that followed very little work was done on neural network models; however, even at this time some important advances were made. The work of Albus,[10] Amari,[11] Grossberg,[12] Kohonen,[13] von der Malsburg,[14] and Widrow and Hoff[15] all deserves mention.

A decisive new impetus was given in 1982 by a physicist, Hopfield,[16] who was able to show that network models of binary neurons correspond formally to spin systems, and can be manipulated by the methods already developed for them.

The greatest boost for the application of neural networks then came through the publication of the "back-propagation" algorithm for learning in multilayered models, introduced by Rumelhart, Hinton, and Williams.[17, 18] Even though the back-propagation algorithm had been suggested earlier,[19] credit must go to the research group on "Parallel Distributed Systems"[20] for bringing it to the attention of the public.

Despite all the successes in the development of models for neural information processing, we must clearly acknowledge the fact that we are still very far from an understanding of the way the human brain works. The capacities of artificial neural networks must still be reckoned very rudimentary in comparison with the biological networks they are supposed to emulate. Nevertheless even these elementary models of neural networks have shown new ways of processing information. It is precisely to the possibilities they are opening up, especially in the area of chemistry, that we wish to devote ourselves in this article.

4. Architectures and Learning Processes

Over the years a whole series of research groups have developed their own characteristic artificial neural networks. Some of these models are closer to their biological counterparts than others; some seem to emulate certain processes in the human brain very well, whereas others bear only a slight similarity to their biological forbears.

Our primary concern here however is not the faithfulness to reality of each neural network model. We wish rather to

show which kinds of problems can be processed with the various models, and what capacities these neural networks offer to information processing. An artificial neural network can still have great significance for information processing, even if it bears but little relationship to biological systems.

As we mentioned in the introduction, neural networks can be applied to a whole series of problems: classification, modeling, association, and mapping. Each neural network is more or less suitable for handling these problem types; each has its own characteristic strengths and weaknesses. We wish expound upon this here and to develop some feeling for which network model is best applied to a particular task.

Three elements essentially characterize every neural network model:

1. the arithmetic operation in a neuron
2. the architecture of the net, that is, the way the individual neurons are connected
3. the learning process that adapts the weights so that the correct result is obtained.

The model of a neuron mentioned in Section 2 is only one of many, albeit a very common one. Even the organization of neurons into layers need not necessarily be that described in Section 2. The learning process, though, is very tightly coupled to the architecture of the neural network. There are essentially two types of learning processes: learning with or learning without instruction ("supervised" and "unsupervised" learning).

In supervised learning the neural net is presented with a series of objects. The input data $\boldsymbol{X}$ from these objects is given to the net, along with the expected output values $\boldsymbol{Y}$. The weights in the neural net are then adapted so that for any set p of known objects the output values $\boldsymbol{Y}$ conform as closely as possible to the expected values $\boldsymbol{Y}$ (Fig. 11).

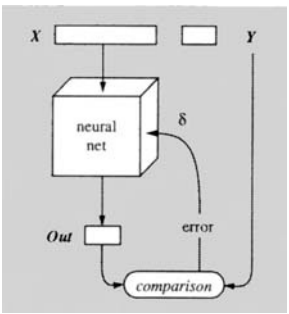

Fig. 11. Supervised learning. A comparison with expected values yields an error δ, which determines whether further adjustment cycles are necessary.

In unsupervised learning the input data are passed repeatedly through the network until it has stabilized, and until the input values map an object into certain areas of the network (Fig. 12).

4.1. The Hopfield Model

The American physicist Hopfield brought new life into neural net research in 1982 with his model.[16] He pointed out analogies between neural networks and spin systems and

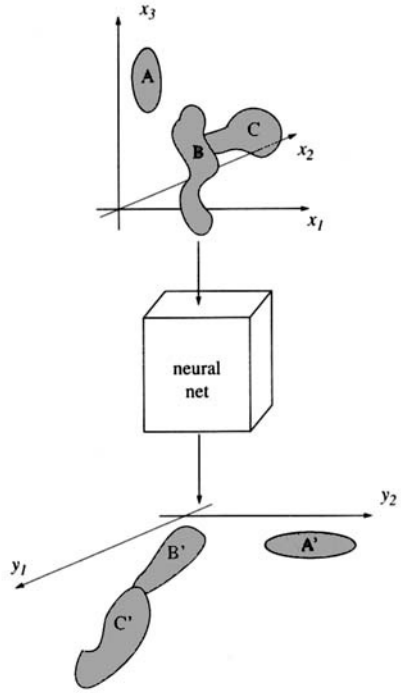

Fig. 12. Unsupervised learning.

was thereby able to apply a whole series of mathematical methods from theoretical physics to research into neural networks. In addition to this he is also responsible for the introduction of nonlinear transfer functions.

The Hopfield net performs one of the most interesting functions of the human brain: it can *associate*. This means that stored pictures (or any other kind of complex information that can be represented as a multidimensional vector or matrix) can be recognized even from partial information or distorted versions of the original picture. For example, one could recognize one particular face from a collection of faces, even if only the eyes and nose are shown.

The Hopfield net is a one-layered model that has exactly the same number of neurons as input nodes. Because every input node is connected to every neuron (Fig. 7), $m \times m$ weights must be determined for m input nodes. The original Hopfield model works with bipolar input data ($+1$ or -1) (f). The net result in neuron j is attained by the multiplication

$$x_i \begin{cases} +1 \\ -1 \end{cases} \tag{f}$$

of all input signals x_i by the weights w_{ji} for that neuron, as in Equation (d). The transfer function here is a simple step function (Fig. 13) as may be produced by the sign of the value.

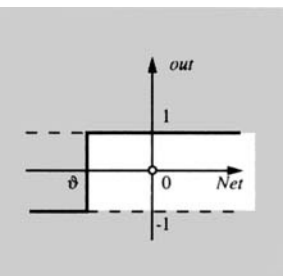

Fig. 13. A step function as a transfer function.

The output signal of a neuron, out_j, in a Hopfield net is given in Equation (g), where as already mentioned, x_i can only assume the values $+1$ and -1.

$$out_j = \text{sign}(Net_j) = \text{sign} \sum_{i=1}^{m} w_{ji}\, x_i \qquad \text{(g)}$$

In order to understand the learning process in Hopfield networks we introduce an example at this point: We require a Hopfield net to learn the four pictures in Figure 14. Each

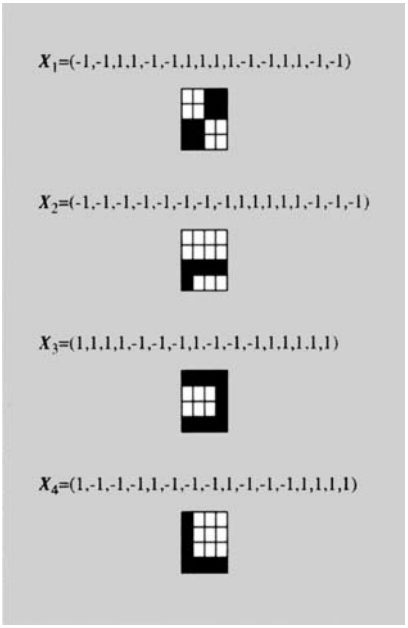

Fig. 14. Four pictures X_1, X_2, X_3, and X_4 used to train a Hopfield network.

picture consists of 4×4 fields (pixels) that are either black ($+1$) or white (-1), so that each picture may be represented as a $4 \times 4 = 16$ dimensional vector. Figure 15 shows the architecture of the corresponding Hopfield net and the input of the first picture with values represented by -1 (for a white pixel) and $+1$ (for a black one). In the picture used for training, the output values are exactly equal to the input values.

The weights w in a Hopfield net do not have to be derived from a costly, iterative learning process, but can be calculated directly from the pictures: If p pictures are presented to the Hopfield net, then the weights w_{ji} for the neuron j may be derived from the input values of the individual pictures s and thus X_s according to (h) and (i). This means that the weight

$$w_{ji} = \sum_{s=1}^{p} x_{sj}\, x_{si} \quad \text{for} \quad j \neq i \qquad \text{(h)}$$

$$w_{ji} = 0 \quad \text{for} \quad j = i \qquad \text{(i)}$$

w_{ji} increases by 1 if, in a particular picture, the pixels j and i are either both black or both white, and decreases by 1 if, in that picture, the ith and jth pixels are of different colors. The more pictures there are in which pixels j and i match, the greater is the weight w_{ji}. The 4×4 pictures from Figure 14 are stored accordingly in a Hopfield net consisting of 16 neurons with 16 weights in a weight-matrix of dimensions 16×16.

We should first test whether a Hopfield net has stabilized. For this purpose an input vector (e.g., one of the four pictures from Fig. 14) is fed into the Hopfield net, and the output values derived from Equation (g). These output values are compared to the input values. If they are equal then the process can terminate, otherwise the output values are fed into the net again as new input values and the process is repeated (Fig. 16). If after a few cycles one receives as output the same values as the original input, then one can say that the net has stabilized. Of course a Hopfield net is not intended simply to reproduce its own input values as output; this is just a stability test.

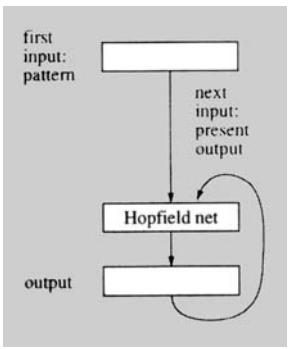

Fig. 16. Testing a Hopfield net for stability.

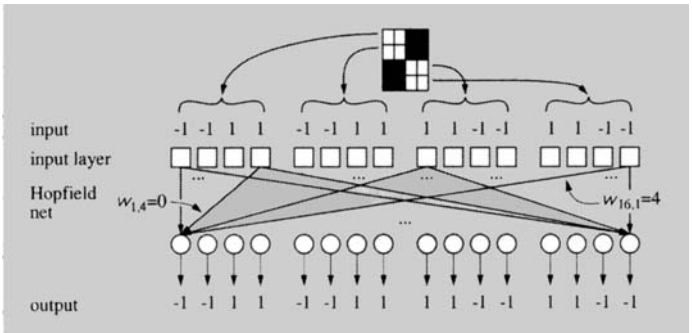

Fig. 15. Architecture of the Hopfield net complete with input and output of the first picture of Figure 14. The given w_{ji} values are determined from Equation (h) for the four pictures of Figure 4.

The true value of a Hopfield net becomes evident in the retrieval of the original stored data from incomplete or distorted data; we can for instance retrieve an original picture in the Hopfield net from a blurred or spoiled picture.

We shall investigate this phenomenon with the four pictures from Figure 14 and a Hopfield net in which they are stored in the form of 16×16 weights. We produce distorted pictures by altering a certain number of pixels in the original pictures, that is, by changing fields from black to white and vice versa. In Figure 17 we have shown the results obtained when each picture is altered by two, five, or indeed even thirteen pixels.

One can see that with a distortion of two pixels the original pictures are retrieved correctly after only 1–2 iterations. When five fields are altered (a noise level of 31%!), the

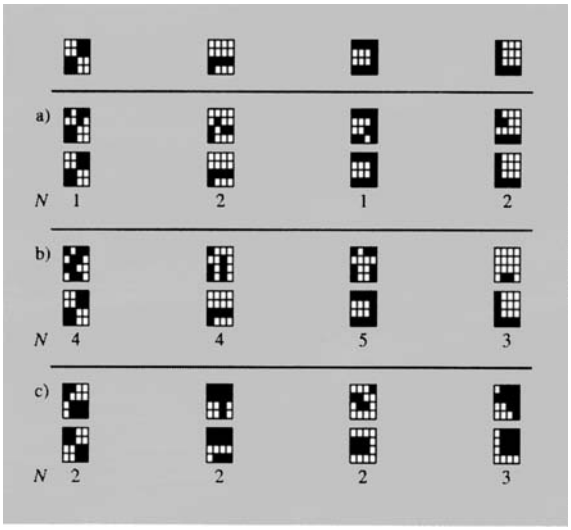

Fig. 17. Search for original pictures (showed at the top) stored in a Hopfield network after input of pictures with a) two, b) five, and c) thirteen altered fields. N is the number of iterations required to arrive at the result (bottom line in a–c) when presented with the erroneous input (top line in a–c).

original pictures are still found successfully, but only after 3–5 iterations. This is not always so; we have observed cases with a five-pixel distortion where the wrong picture is output, or the right picture in negative form (black and white pixels swapped), or an oscillation occurs between two patterns that represent none of the stored pictures, so that the operation has to be aborted.

If thirteen pixels in the pictures are altered (81% distortion) the original pictures are retrieved after 2–3 iterations as negatives. How does this come about? After all, significantly more than half the fields have been altered in color. It is remarkable that the negative of the original picture is returned, and not the negative of some other picture.

Thus we have seen that as simple a model as a Hopfield net can still reproduce one of the human brain's more interesting faculties, namely the power of association. The Hopfield net does however have one significant drawback: The number of patterns (pictures, vectors) that can be stored is severely limited. In order to store more pictures an increased number of neurons is required; thus the size of the weight matrix grows very rapidly.

4.2. An Adaptive Bidirectional Associative Memory

With the Hopfield net we have shown that a neural network has the power to associate. An adaptive bidirectional associative memory (or ABAM)[21] can do this as well. We shall now show, however, that an ABAM is able, in addition, to combine patterns. An ABAM is, like a Hopfield net, a one-layered network. The number of output neurons n is however usually much lower than the number of input units m.

In order to simplify the notation, and because in the case of ABAMs the meanings of input and output are apt to blur, in the following sections we refer to an input vector as $\boldsymbol{X}$ and the output values as $\boldsymbol{Y}$. Thus we always observe pairs of input ($\boldsymbol{X}_s$) and output ($\boldsymbol{Y}_s$) values (the index s characterizes the individual input values and their corresponding outputs):

$$\boldsymbol{X}_s = (x_{s1}, x_{s2}, \ldots x_{sj}, \ldots x_{sm})$$
$$\boldsymbol{Y}_s = (y_{s1}, y_{s2}, \ldots y_{si}, \ldots y_{sn})$$

Given a series of such pairs $\{\boldsymbol{X}_s, \boldsymbol{Y}_s\}$ where it is known which $\boldsymbol{Y}_s$ value is to be expected from a particular $\boldsymbol{X}_s$ value, the weights are determined in a supervised learning process.

First starting values are calculated for the weights according to Equation (j). The weight matrix is now no longer square, as in the Hopfield net, but rather rectangular. It has dimensions $m \times n$.

$$w_{ji} = \sum_{s=1}^{p} x_{sj}\, y_{si} \qquad \text{(j)}$$

The basic idea of learning with an ABAM net is that one can multiply an $m \times n$ matrix in two different ways: the standard way by multiplying by an m-dimensional vector, which results in an n-dimensional vector, or in the alternative transposed form, by multiplying by an n-dimensional vector to give an m-dimensional vector (Fig. 18).

$$\{\boldsymbol{X}^{(0)}, \boldsymbol{Y}^{(0)}\} \longrightarrow \boldsymbol{W}^{(0)}$$
$$\boldsymbol{X}^{(0)}\boldsymbol{W}^{(0)} \longrightarrow \boldsymbol{Y}^{(1)}$$
$$\boldsymbol{Y}^{(1)}\boldsymbol{W}^{(0)\mathrm{T}} \longrightarrow \boldsymbol{X}^{(1)}$$
$$\{\boldsymbol{X}^{(1)}, \boldsymbol{Y}^{(1)}\} \longrightarrow \boldsymbol{W}^{(1)}$$
$$\vdots \longrightarrow$$
$$\boldsymbol{X}^{(t)} = \boldsymbol{X}^{(0)}$$
$$\boldsymbol{Y}^{(t)} = \boldsymbol{Y}^{(0)}$$

Fig. 18. The learning process in an adaptive bidirectional associative memory (ABAM).

The learning process is as follows: An initial weight matrix $\boldsymbol{W}^{(0)}$ is calculated from the predefined pairs $\{\boldsymbol{X}^{(0)}, \boldsymbol{Y}^{(0)}\}$. From $\boldsymbol{X}^{(0)}$ and $\boldsymbol{W}^{(0)}$ the output values $\boldsymbol{Y}^{(1)}$ are produced, which do not as yet correspond to the goal values. Therefore these $\boldsymbol{Y}^{(1)}$ values are multiplied by the transposed matrix $\boldsymbol{W}^{(0)\mathrm{T}}$ to give a set of $\boldsymbol{X}^{(1)}$ values. Applying Equation (j) to the pairs $\{\boldsymbol{X}^{(1)}, \boldsymbol{Y}^{(1)}\}$ we calculate a new weight matrix $\boldsymbol{W}^{(1)}$. This process is repeated until the pair $\{\boldsymbol{X}^{(t)}, \boldsymbol{Y}^{(t)}\}$ corresponds to the predefined values $\{\boldsymbol{X}^{(0)}, \boldsymbol{Y}^{(0)}\}$.

In the procedure the $\boldsymbol{Y}$ values are calculated in the usual way. Here, too, the individual x and y values are bipolar $(+1, -1)$ [Eq. (k) and (l)].

$$Net_j = \sum_{i=1}^{m} w_{ji}\, x_i \qquad \text{(k)}$$

$$y_i = \mathrm{sign}(Net_j) \qquad \text{(l)}$$

As with the Hopfield net we also use simple pictures here as an illustration of how an ABAM may be applied. Pictures made of 5×5 fields, where each field may each be black $(+1)$ or white (-1), will serve as input information. These can

thus be represented by a 25-dimensional vector, so that 25 input units will be required. We use only five such pictures and identify them on the output side by a 5-dimensional vector. Each of the five patterns (pictures) is assigned one of the five positions in the vector, thus in the case of the first picture the first position is 1 and all the others are zero (10000), the second picture is represented by (01000) etc. (We are actually dealing with bipolar values +1 and −1 here, but for clarity's sake we use binary notation (1,0) in the following sections). Figure 19 shows the five patterns and their identifications. The ABAM has a 25×5 architecture, and thus 25×5 weights.

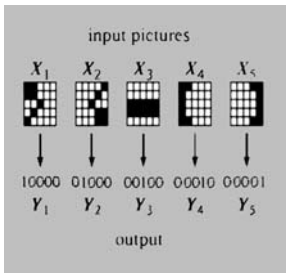

Fig. 19. Five pictures used to train the ABAM, their symbols, and vector representations.

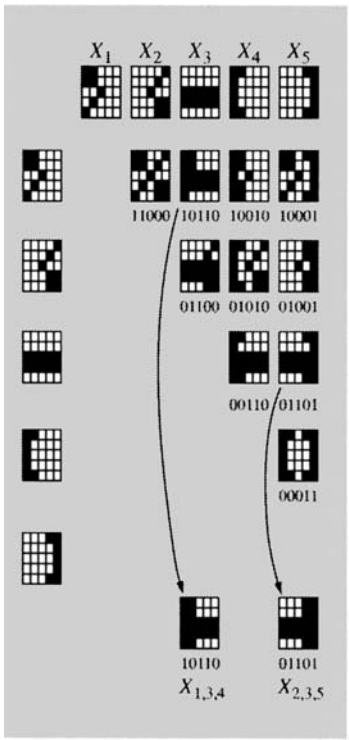

Fig. 20. All combinations of two pictures from Figure 19. The two cases where three bits were activated erroneously are compared with the combination of three pictures drawn in the bottom row (see text for details).

An ABAM was trained with these five pictures and the five-dimensional vector (consisting of four zeros and one 1 in each case). Then the ABAM's ability to associate distorted pictures with stored undistorted ones was put to the test. All possible 1-pixel errors were generated; in the case of five pictures each of 5×5 pixels this makes a total of 125 different distorted pictures. The ABAM identified the correct undistorted output picture in all cases.

Next the ability of the ABAM to combine individual pieces of information was tested: that is, can it recognize, when presented with pictures made of two patterns, which combination of two pictures it is, despite previously having been presented with the patterns only singly? Figure 20 shows all ten permutations of pairs for the five patterns, with the answer from the ABAM written underneath as a five-bit vector. In eight cases the ABAM returns a 1 in exactly the right two positions. Thus, for example, for the first combined pattern, which consists of the patterns 1 and 2, it returns the answer (11000), meaning that first and second patterns are contained in it. In the cases of the other two pattern combinations (1 + 3 and 3 + 5) the ABAM also recognizes which individual patterns are present in the combination, but makes the mistake of identifying a third pattern. If we generate these three-pattern combinations, as demonstrated in the bottom row of Figure 20, they differ very little from the two-pattern combinations (1 pixel difference). The ABAM's answers in these two cases are therefore not very far from the truth.

The ABAM's ability to combine two patterns has been discussed here in more detail for two reasons: Firstly, the ability to recognize that a piece of information is a combination of other pieces of information is, of course, an important capability of the human brain. Therefore if the ABAM can do this too, we have reproduced an important aspect of biological, neural information processing. Secondly, the ability to combine single pieces of information is required in many problem tasks in chemistry, especially in the study of relationships between structure and spectral data: If a neural network learns this relationship from pairs of spectra and structures, it should be able to derive all the component substructures from a new spectrum, even if it has never "seen" this particular combination of substructures previously.

4.3. The Kohonen Network

4.3.1. Principles

T. Kohonen[22, 23] developed a neural network which of all models has the greatest similarity to its biological counterpart.[24] This is especially true of the way in which the brain processes sensory signals.

There is a broad strip of tissue in the cerebral cortex which specializes in the perception of touch and is known as the somatosensory cortex. Particular areas in this tissue are responsible for particular parts of the body; parts of the body that carry the most sensory receptors are assigned correspondingly large, contiguous areas, whereas areas of skin which are supplied with relatively few sensory nerves are assigned only small areas, even if the part of the body in question is actually very large by comparison. In addition, neighboring parts of the body are assigned neighboring regions in the somatosensory cortex, so that for the sense of touch there is a contorted mapping of the body surface onto the brain (Fig. 21).

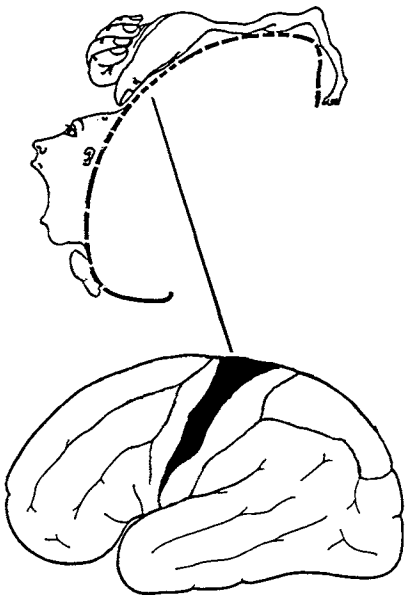

Fig. 21. Map of the human body (top) in the somatosensory cortex of the brain (bottom).

Kohonen introduced the concept of a "self-organized topological feature map" that is able to generate such mappings. Briefly, these are two-dimensional arrays of neurons that reflect as well as possible the topology of information, that is, the relationships between individual pieces of data and not their magnitude. Using the Kohonen model we are able to create a *mapping* of multidimensional information onto a layer of neurons, that preserves the essential content of the information (relationships). The whole process therefore represents a kind of abstraction. Figure 22 shows the two-dimensional organization of the neurons in a Kohonen net.

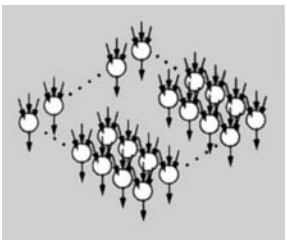

Fig. 22. Two-dimensional assignment of the neurons in a Kohonen network.

In this context mapping of information means that the similarity of a pair of signals is expressed in the proximity or "neighborhood relation" of the neurons activated by them: the more alike two signals are, the closer together the neurons they activate should lie. However, as we are talking here about topological and not Euclidean distance, a neuron in a square array (Fig. 23a) has eight neighbors in the first "sphere", since the neuron has eight direct neighbors. In a Kohonen network where the neurons are arrayed in a square the spheres of neighborhood grow through the network as shown in Figure 23b.

We must take the discussion on the topology of the Kohonen net a little further before we can proceed to the learning algorithm because the topology is the decisive factor in a Kohonen net. If every neuron is to have the same number of neighbors, a square, planar array is poorly suited to the task because the neurons at the edges have fewer neighbors than those in the center of the net (Fig. 23c).

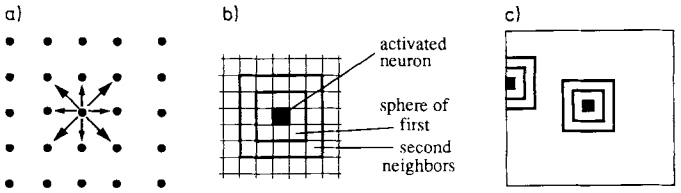

Fig. 23. Proximity relations of the neurons in a Kohonen network. a) First sphere of neighbors; b) growth of the spheres; c) neurons at the edge of the network.

From a square or rectangular array of elements we can nevertheless easily construct a topology in which each element has exactly the same number of neighbors. In order to do this we must wrap the surface around on itself and connect ("glue together") its opposite edges. Thus from the surface we produce first a cylinder and then a torus, as shown in Figure 24.

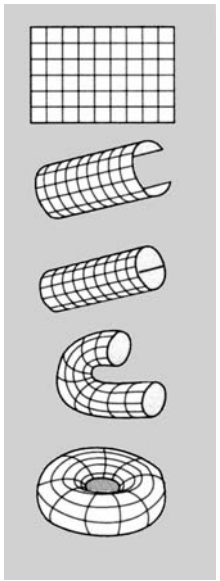

Fig. 24. The transformation of a rectangular array of neurons into a torus in which each neuron has the same number of neighbors.

In a torus each element has the same number of neighbors: eight in the first circle, 16 in the second etc. Of course it is not easy to display in its entirety a mapping onto a torus. We shall therefore continue to represent Kohonen networks as

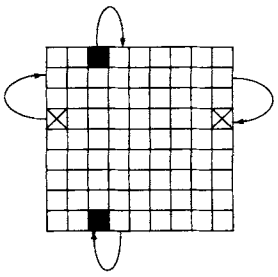

Fig. 25. Representation of the surface of a torus on a plane. The topmost edge wraps onto the bottom, and the left edge wraps onto the right.

flat surfaces in the knowledge that if one arrives at one of the edges the surface carries on over to the opposite edge (Fig. 25). Both the filled-in squares are therefore immediate neighbors. The same is true in the horizontal axis for those fields marked by crosses.

The topology of the Kohonen net has been discussed a little more fully here in order to understand the examples better (see Sections 10.1 and 10.2).

4.3.2. The Learning Process

Learning in a Kohonen net is a competitive process: all the neurons compete to be stimulated by the input signal. The input signal is an object that is described by m single values and can therefore be interpreted as a point in an m-dimensional space, projected onto a plane. Only one single neuron is finally chosen as the "best" ("winner takes all"). Different criteria are applied to find the "best" neuron—the central neuron c. Very often the neuron whose weights are most similar to the input signal $\boldsymbol{X}_k$ is chosen [Eq. (m)].

$$out_c \leftarrow \min \left\{ \sum_{i=1}^{m} (x_{ki} - w_{ji})^2 \right\} \qquad \text{(m)}$$

For this central neuron c, the weights w_{jc} are corrected so that the output value becomes even more similar to the input signal. The weights on the other neurons are also corrected, albeit proportionally less the further they are from the strongly stimulated (central) neuron. Here it is the topological distance which counts, that is, which sphere of neighborhood (as reckoned outwards from the central neuron) includes the neuron under consideration (compare Fig. 23).

Then the process is repeated with the next input data. Every object (that is, every point in the m-dimensional space) stimulates a very specific neuron, so that every object is assigned a definite point in the Kohonen net.

A simple example, the mapping of the surface of a sphere onto a Kohonen net, will explain the workings and the results of the Kohonen net in more detail (Fig. 26). The spherical surface was divided into eight sectors, as shown in Figure 26b; a point on this surface is defined by its three coordinates (x, y, z values). An array of $15 \times 15 = 225$ neurons was used to make a Kohonen net, which therefore had three input units distributing their data over 225 neurons. Thus a total of $3 \times 225 = 675$ weights had to be determined.

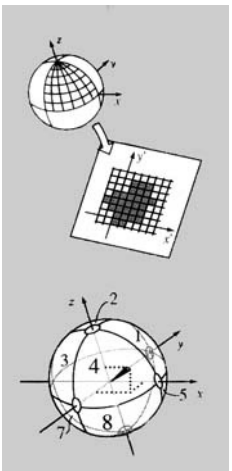

Fig. 26. The representation of the surface of a sphere in a Kohonen network. The sphere's surface is divided into eight sectors. Each point on the surface of the sphere is characterized by its assignment to one of these sectors. The point marked in the sphere at the bottom belongs to sector number 4.

Two thousand points were chosen at random from the spherical surface, and their sets of x, y, and z coordinates used severally to train the Kohonen net. For the graphical representation of the net that had developed after the learning of these 2000 points, each point was identified by the number of the spherical sector from whence it came. (This information was not used in the learning process, however, but only at the end for identifying the points.) Because 2000 points have to be mapped onto 225 fields there are several points mapped onto each field. As it turns out, however, at the end of the learning process only points from the same sector of the sphere arrive at the same field, and points from neighboring regions of the spherical surface are projected onto neighboring fields. Figure 27 shows the resulting Kohonen net.

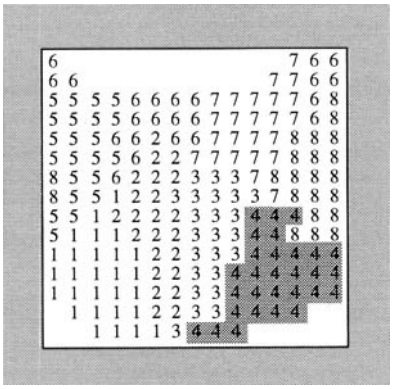

Fig. 27. Result of the projection of a spherical surface onto a Kohonen network.

Fields with the same number, that is, points from the same sector of the sphere, form contiguous areas in the Kohonen net. It must be remembered that the surface shown here actually forms a torus (Fig. 24); therefore points on the left-hand edge are continued over onto the right hand edge (Fig. 25). Thus the two fields on the left-hand edge marked with the number 8 do indeed have a direct connection to the remaining fields with the number 8. Some fields (neurons) in the Kohonen net were not assigned any points from the spherical surface. That the spherical surface was mapped onto the Kohonen net while preserving the neighborhood relations between the points on the sphere may also be seen from the details of the Kohonen net as shown in Figure 28. Sectors on the sphere which meet at lines of longitude or at the equator are also neighbors in their projection on the Kohonen net, and hold whole borders in common. In several regions four fields meet together; these regions or points correspond to the points where the coordinate axes break through the spherical surface. For example at the circle in Figure 28 (bottom row, center) the sectors 1,2,3 and 4 converge. This corresponds to the "North pole" of the sphere.

The mapping of a sphere onto a Kohonen net has been explained in this detail to show how a simple three-dimensional body can be mapped onto a plane. This illustrates well the way a Kohonen net functions as a topology-preserving

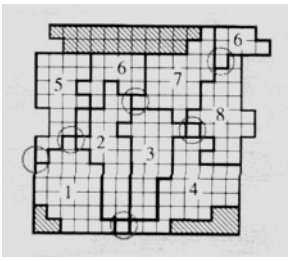

Fig. 28. Areas on the Kohonen map of Figure 27 where four sectors meet, highlighted by circles.

map and lays the foundation for a good understanding of the application of Kohonen networks to examples from the field of chemistry.

4.4. Back-Propagation

The majority of neural net applications uses the "back-propagation" algorithm. This algorithm does not represent any particular kind of network architecture (a multilayered net is generally used) but rather a special learning process. Although this method was not introduced until 1986 by Rumelhart, Hinton, and Williams[17] it quickly gained widespread popularity and contributed decisively in the eventual triumph of neural networks. A few years ago a study carried out on publications about neural networks in chemistry showed that in 90% the back-propagation algorithm was used.[2]

The attraction of learning through back-propagation stems from the fact that adjustments to the neural net's weights can be calculated on the basis of well-defined equations. Nevertheless this procedure for correcting errors has very little in common with those processes responsible for the adjustment of synaptic weights in biological systems.

The back-propagation algorithm may be used for one- or multilayered networks and is a supervised learning process. The input data are passed through the layers; the output data of a layer l, $\boldsymbol{Out}^l$ form the input data $\boldsymbol{X}^{l+1}$ of the layer $l+1$. The results for the input data should eventually be delivered by the final layer. This will, however, not be the case at first. The output data, $\boldsymbol{Out}^{last}$, of the final layer are therefore compared with the expected values $\boldsymbol{Y}$ and the error determined. This error is now used to correct the weights in the output layer. Next the weights in the penultimate layer are corrected with regard to the error from the final layer. Thus the error is fed back layer by layer, from bottom to top, and used to correct the weights at each level (Fig. 29). The error therefore flows counter to the direction of the input data; hence the name back-propagation, or loosely formulated, "error-correction in reverse".[25] In the following sections we demonstrate the basic features of the back-propagation algorithm. For a detailed explanation we refer the reader to the literature.[1, 17, 18, 25]

The back-propagation algorithm is intended to change the weights until the error in the output values $\boldsymbol{Out}$ is minimized; that is, they must correspond as closely as possible to the provided values $\boldsymbol{Y}$.

In the case of the last layer the error can be determined directly because the value $\boldsymbol{Y}$, which is the expected output value, is known. The weight adjustments for the final layer,

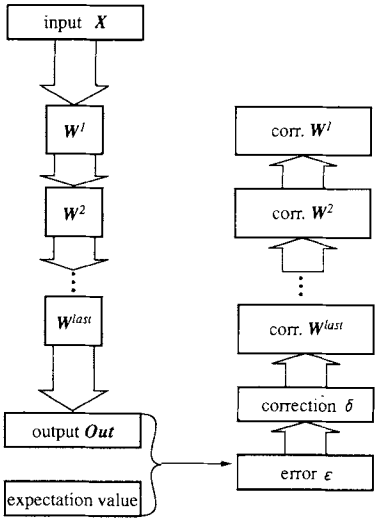

Fig. 29. The learning process of the back-propagation algorithm. The weights are corrected by feeding the errors back into the network.

Δw_{ji}^{last}, are determined by deriving the error ε [Eq. (n)] according to the individual weights. The chain rule leads to Equations (o) and (p).

$$\varepsilon = \sum_{j=1}^{m} (y_j - out_j^{last})^2 \tag{n}$$

$$\delta_j^{last} = -\partial\varepsilon/\partial Net_j^{last} \tag{o}$$

$$\Delta w_{ji}^{last} = \eta\, \delta_j^{last} out_j^{last-1} \tag{p}$$

In the hidden layers the error is not directly known because it is not known what output values, $\boldsymbol{Out}^l$, should be produced by those layers. At this point we make the assumption that the error from the layer below was distributed evenly over all the weights in the layer above. This assumption enables the error in one layer to be calculated from the error in the layer below (which has just been calculated). This is the basis of the back-propagation algorithm: The error is carried back through the individual layers (hence "back-propagation of errors") thus enabling us to correct the weights in each layer.

All in all we derive the closed form (q) for correcting the weights of a single layer. Here η is a parameter, the learning

$$\Delta w_{ji}^{l} = \eta \sum_{k=1}^{r} \delta^{l+1} w_{jk}^{l+1} f'(Net_j^l) out_i^{l+1} \tag{q}$$

rate, that determines how rapidly a neural net learns. Usually a value between 0.1 and 0.9 is chosen for it. Frequently when correcting the weights, the changes in weights from the cycle before (previous) are also taken into account. This is accomplished by extending the Equation (q) by the contribution $\mu \Delta w_{ji}^{l(previous)}$. The parameter μ is the momentum term. It determines the extent to which the previous weight changes are taken into account; it gives the learning process a certain capacity for inertia. The smaller μ is, the quicker previous changes in weights are forgotten. It can be shown that the sum of η and μ should be about 1.[26]

5. Other Neural Network Models

Apart from those mentioned in Section 4, a number of different processes for analyzing data with neural networks are still available. We wish briefly to mention only two more.

The counterpropagation network consists of a Kohonen layer combined with a look-up table in order to give answers.[27]

The *a*ssociative *m*emory *s*ystem (AMS) was developed as a model of information processing in the cerebellum, which is primarily responsible for processing motoric stimuli.[10] The AMS model has been used to predict chemical reactivity data, in particular the polar reactivity of bonds.[28]

6. Overview of Applications in Chemistry

A great many approaches to problems from diverse branches of chemistry have already been investigated by applying neural networks—from very general tasks such as structure-spectrum relationships, chemical reactivity, secondary and tertiary structures of proteins and process monitoring, to such specific questions as the classification of energy levels in the curium atom and the recognition and classification of aerosol particle distributions, as well as the relationship between the physical structure and the mechanical properties of polyethylene–terephthalate fibers.

This diversity underlines the fact that neural networks represent quite general, broadly applicable problem-solving methods. The final, concrete application is determined only by the nature of the data fed into the neural network.

This article is intended to convey some feeling for the kinds of problems best approached with neural networks, so that the reader will be able to decide whether these methods can be used for his particular problem. The goal is therefore to demonstrate the capabilities of the methods and to give incentive to further applications, rather than to give a comprehensive overview of all the work that has gone before. For this reason only a selection of typical neural network applications in chemistry will be given in the following sections; these will not be organized by application area but rather by problem type, that is, according to whether the task in question is one of classification, modeling, association, or mapping.

There is, of course, a whole series of methods that can be used as alternatives to neural networks—and which have been used successfully for many years. Many tasks for which neural networks are used today could be solved equally well by using statistical and pattern-recognition methods such as regression analysis, clustering methods, and principal component analysis. In many cases these methods should be able to deliver results that are every bit as good. What is unfortunately lacking in most papers is a comparison between the capabilities of neural networks and those of more established methods. Comparisons such as these might bring out the advantages of neural networks more. These advantages include the following:

- the mathematical form of the relationship between the input and output data does not need to be provided
- neural networks are also able to represent nonlinear relationships.

On the other hand, the application of neural networks requires exactly the same care in the formulation of the problem, the representation of information, the selection of data, and the division of data into training and test sets as is necessary for pattern-recognition and statistical methods. It must be stated clearly that the quality of the results obtained from neural networks depends crucially on the work and trouble invested in these subtasks.

Essential aspects must be considered before deploying any kind of neural network.

- What is the nature of the task under consideration? Classification, modeling, association, or mapping?
- Which kind of learning process should be chosen? Supervised or unsupervised learning? Is there a set of expected results available for the objects, or must the structure of the information first be found?

In Table 1 the various methods are correlated with problem types and learning processes to make it easier to decide which neural network method should be used for a specific task.

Table 1. Possibilities for applying neural networks.

	Hopfield network	ABAM	Kohonen network	Back-propagation
classification		x	x	x
modeling				x
association	x	x		x
mapping			x	
learning process [a]	unsup.	unsup. + sup.	unsup.	sup.

[a] unsup. = unsupervised learning, sup. = supervised learning (see Section 4).

In chemistry most problems are of the classification or modeling types. This is one of the reasons why multilayered networks trained by the back-propagation algorithm predominate. The results of a survey of those neural network applications in chemistry that appeared before the end of 1990 show that over 90% of studies used the back-propagation algorithm.[2] Hopfield networks were used twice, an adaptive bidirectional associative memory only once, and a Kohonen net coupled with the counterpropagation algorithm likewise only once. This distribution need not hold true in future, however, since ABAM and Kohonen networks as well as the counterpropagation algorithm all offer possibilities that have by no means been exhausted.

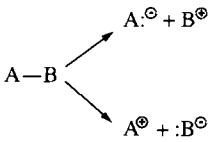
If we consider only the multilayered model with the back-propagation algorithm, we still have a broad spectrum for the complexities of the networks used: from networks with only 20 weights up to some with 40000, in one case even 500000 weights! The number of data used for training a net should, in the case of the back-propagation algorithm, be at least as large as the number of weights. This rule was by no means always followed. The number of times the training data-set was passed through the net (number of epochs) also varied considerably: from 20 up to 100000 iterations. As may be imagined, the training times increased greatly in proportion with the number of weights and the number of iterations, from a few minutes on a personal computer up to hours on a Cray supercomputer.

7. Classification

Classification problems are one of the most common areas of application for neural networks. An object is first characterized by various measurements and on that basis assigned to a specific category. Alternatively it may be found not to have a particular characteristic or not to belong to the class in question. Thus the output data are binary in nature: a feature is either present or it is not; the object either belongs to a certain class or it does not. The input data that characterize the object can be binary in nature but can also be real values (measured data). Classification is a traditional domain for the use of statistical and pattern-recognition methods. Neural networks have the advantage that they can still be applied in cases where the relationships between the object data and the classes to which they are to be assigned are highly complex. Neural networks are suitable even for relationships that cannot or can only barely be expressed in terms of explicit equations. In the following sections we show examples from several branches of chemistry where either a single condition is to be diagnosed (Section 7.1) or a single category is to be chosen from a series of others (Section 7.5), or alternatively where an object is to be assigned to several classes simultaneously (Sections 7.2–7.4).

7.1. Chemical Reactivity

The chemist derives his knowledge about the reactivity of bonds and functional groups from a great many observations of individual reactions. How can this process be transferred to a neural network? Let us look at the problem of polar bond breaking (Scheme 1), the first step in many organic reactions.[29]



Scheme 1. Polar bond cleavage.

The reactivity is characterized very roughly in this case: namely whether a bond is easy or hard to break heterolytically. For this a single output neuron that is set to one if the bond may be easily broken and to zero if the bond is difficult to break will suffice. We still have to characterize the polar bond breaking by parameters that serve to influence the process. For this purpose a number of energetic and electronic effects were used: bond dissociation energy (BDE), difference in total charge Δq_{tot}, difference in π-charge Δq_π, difference in σ-electronegativity $\Delta\chi_\sigma$, σ-polarity Q_σ, polarizability of bonds α_b, and the degree of resonance stabilization $R^\pm$ of the charges that arise from polar bond breaking. Values for these quantities were calculated by empirical methods.[30–34] For these seven parameters, seven units are required into which are fed the (real) values of the individual quantities. A hidden layer of three neurons completes the architecture for this study (Fig. 30).

A data set that consisted of 29 aliphatic compounds containing 385 bonds was created. As each bond may be broken

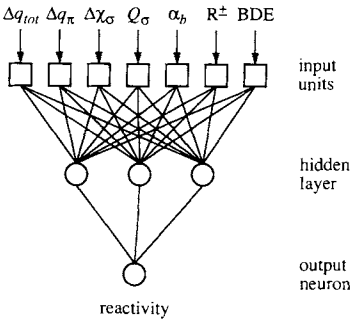


Fig. 30. Architecture and input parameters for a neural network to predict the breaking of bonds. For details see text.

heterolytically in two directions (see Scheme 1), there was a total of 770 possible bond breaks. From these, 149 heterolyses of simple bonds were chosen and 64 of them used to train the net by the back-propagation algorithm; the remaining 85 bond-breaks were used to test the net (the division into training and test data sets will be explained in Section 10.1). Figure 31 shows a selection of molecules from the data set, in which those bonds classified as breakable or unbreakable have been marked.

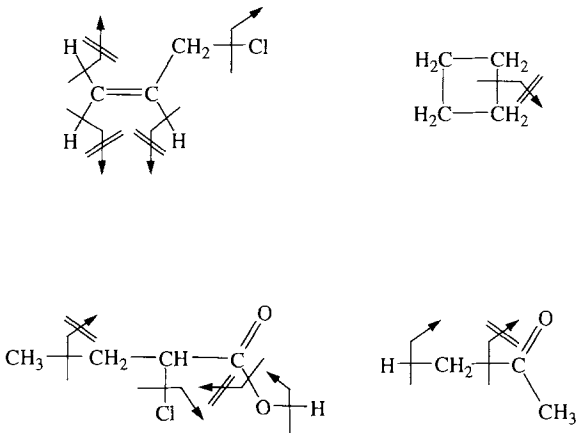

Fig. 31. Selection of structures from the training set indicating which bonds are easy (arrow) or difficult (arrow crossed through) to break heterolytically. The direction of the arrows indicate to which atom the electron pair will be shifted in bond cleavage (that is, which atom will receive the negative charge).

After 1300 cycles (epochs) the net had correctly learned all 64 bond breaks from the training data set. Then the bond breaks from the test data set were passed through the already trained neural net. These 85 bond breaks, about which the net had hitherto received no information, were also classified correctly. The division of the bonds into those easily and those not easily broken was predicted by the net exactly the same way as the chemist had determined them. The net had therefore learned the relationship between electronic and energetic parameters and polar bond-breaking.

The net was then ready to be applied to compounds that were contained neither in the training nor the test data sets. It even made correct predictions about bond types which contained atoms that were not used at all in training. In Figure 32 the predicted reactive bonds of a structure which was not used to train the net are shown. The dissociation of

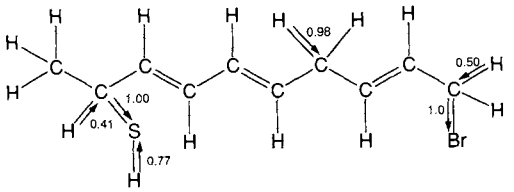

Fig. 32. Bond cleavages predicted by the neural network for a structure which was not used in training. The direction of the arrows indicate the shifts of electron pairs, the values the predicted probability for heterolysis.

a bromide ion and a thiol group, both in allyl position, were found to be especially reactive, as were the removal of a proton from the central allylic position and from the thiol group. The allylic positions at the ends of the system were estimated to be less acidic, whereas the position at which the bromine atom can still function in an inductively stabilizing way receives a higher acidity. Thus all results correspond closely to chemical experience.

It is remarkable that the reactivity of the SH group was correctly judged, even though the training data set did not contain a single structure with a sulfur atom. This is made possible by the use of those electronic and energetic parameters that contain the influence of the atom in general form in the techniques used for calculation of the inputs. Thus even a type of atom which does not occur in the current training set can be taken into consideration, provided that it is contained in the calculation process.

This neural network is able to predict which bonds can easily be broken in a polar manner for a wide range of aliphatic structures.

7.2. Process Control

For many chemical processes the relationship between process data and control parameters can be represented, if at all, only by nonlinear equations. It is therefore very hard to model these processes and to predict their behavior. It therefore comes as no surprise that neural networks are being used intensively for tasks in process control.[35-41] This includes not only the classification of certain events (yes/no decisions), but also the modeling of control parameters (prediction of a real value).

An example in which the task is to choose between membership of different classes will serve to illustrate the possible applications.[36] The goal was to derive individual failure modes from six different sensor values for a continually stirred reaction vessel in which an exothermic reaction was in progress.

The following measurements were taken (cf. Fig. 33): 1) The outlet concentration of the educt C_e, 2) the reactor temperature T_r, 3) the volume of the contents of the reactor V_r, 4) the outlet flowrate FR_p, 5) the temperature of the cooling water T_c, and 6) the flowrate of the cooling water, FR_c. These six parameters were to be used as "symptoms" to diagnose several failure modes of the reactor. Malfunction can be caused by incorrect inlet concentration of the educt C_{eo}, inlet temperature T_e, and inlet flow-rate FR_e. If any of these measurements deviates by more than 5 percent from the normal value, a failure has occurred in the reactor.

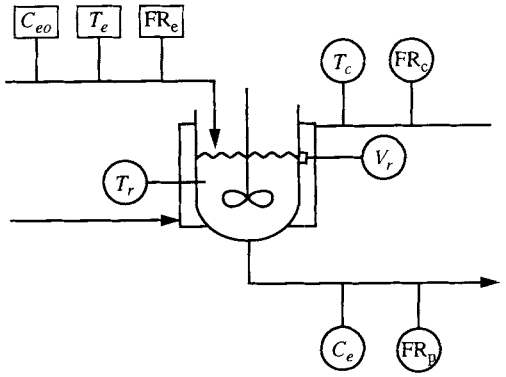

Fig. 33. Diagram of a reactor tank showing the six measured values (C_e, T_r, V_r, FR_p, T_c, FR_c) and the state variables that give rise to a failure mode (C_{eo}, T_e, FR_e).

Each one of the failure modes affects almost all the symptoms, that is, all six measured values, so that a specific failure mode can not be diagnosed directly from a single measurement. Moreover, it is possible for the failure modes to occur not just singly but simultaneously, and for the effects of simultaneous failure modes to compensate in the sensor values, or contrarily to amplify each other synergetically.

Which network architecture was chosen in this case? Because six real measured values are to be input, six input units are required. Likewise the number of output neurons chosen was six; for each of the three crucial inlet parameters (C_{eo}, T_e, and FR_e) one neuron for a deviation over the normal value and one for a deviation below it. Thus if any of the six failure modes occurs the corresponding output neuron should also be activated. Five neurons in a hidden layer complete this multilayered net (Fig. 34).

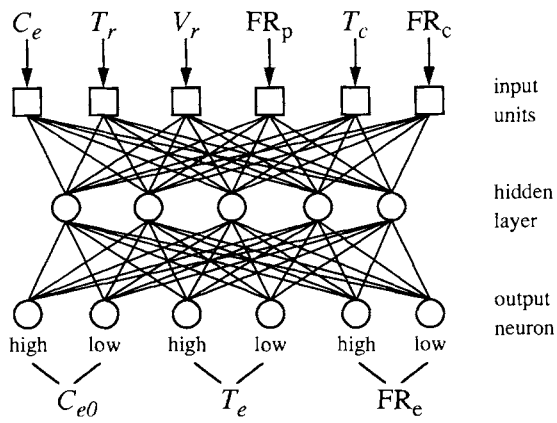

Fig. 34. Neural network for diagnosing failure modes of the chemical reactor depicted in Figure 33.

Accordingly for this neural network $6 \times 5 + 5 \times 6 = 60$ weights were to be determined. Twelve individual failure modes were deliberately produced, and the network trained by using the sensor data measured from them on application of the back-propagation algorithm. The network so trained was able to identify sensor data from the reactor running normally (data which were not used in the training process) as undisturbed behavior. Furthermore, when four multiple

failure modes were produced the neural net was likewise able to derive these correctly from the sensor data taken at the time.

Neural networks will certainly become very important in the area of process control. It should also be possible to take a neural network that has been trained on a specific process, hard-code this onto a chip, and build this chip into the control process.

7.3. The Relationship between Structure and Infrared Spectra

In the examples from Sections 7.1 and 7.2, rather simple neural networks with relatively few weights were used. For the following application a considerably larger network with almost 10000 weights was developed.

Modern structure elucidation is based on spectroscopic methods. However, as the relationships between the structure of an organic compound and its spectroscopic data are too complex to be captured by simple equations, there are a multitude of empirical rules. The enormous amount of spectroscopic data thus available fulfills an important precondition for the training of neural networks. The first steps to store the relationships between structure and spectroscopic data in neural networks have already been taken. Nevertheless, as we shall see, there is still much development to be done in this area.

Munk et al.[42] investigated to what extent conclusions could be drawn by a neural network about the substructures contained in a particular compound from an infrared spectrum. The range of an infrared spectrum between 400 and 3960 cm^{-1} was divided into 256 intervals, and each of these intervals assigned to an input element. If an absorption band was found in such an interval, its intensity was fed into the input element. The neural network had 36 output neurons, each of which was responsible for one of 36 different functional units (primary alcohol, phenol, tertiary amine, ester etc.). If a functional unit was present in the compound under investigation, then the corresponding neuron received the value one, otherwise the value zero. Further, an intermediate layer containing 34 hidden neurons was used, which required $265 \times 34 + 34 \times 36 = 9928$ weights to be determined for this multilayered network. The basic procedure and the architecture of the neural network are sketched in Figure 35.

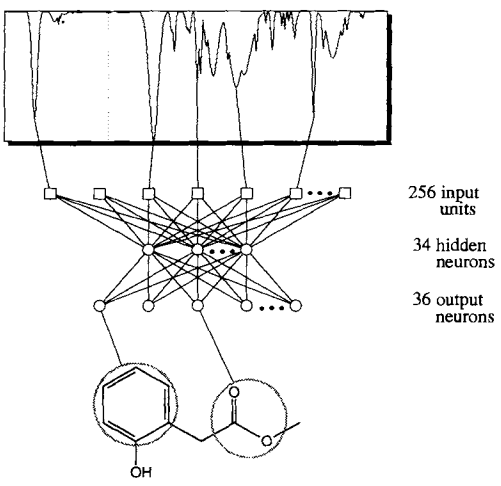

Fig. 35. Neural network to learn the relationships between the infrared spectrum of a compound and the substructures present in it.

To determine the weights of the neural network, 2499 infrared spectra together with their structures, which were broken down into their functional units, were learned through the back-propagation algorithm. Then 416 spectra were used to test the predictive ability of the net. A single cycle through all spectra required 10 min CPU time on a VAX 3500; for a training session with many cycles (called epochs—typically 100 epochs were necessary) a Cray supercomputer was used.

For each functional group the quality of the results was measured by a number, named the A50 value. This value represents the precision at 50% information return, that is, the precision with which a functional group can be ascertained when the threshold value is set to the mean of the distribution curve.

Figure 36 shows a typical result, in this case for primary alcohols. The threshold value here lay at an output value of

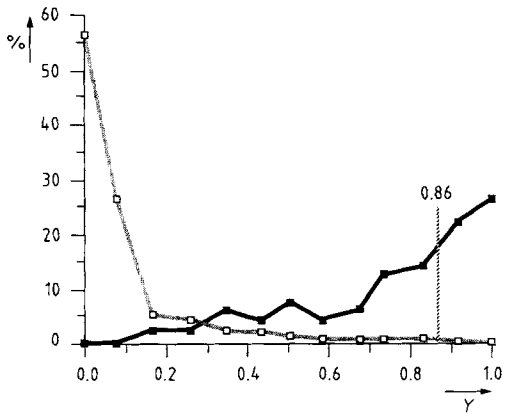

Fig. 36. Percent distribution of the output values Y of the neural network for primary alcohols. The solid line represents compounds which are primary alcohols, the shaded line all other compounds. The mean of the output values for primary alcohols is 0.86.

0.86. At this value 132 of the 265 primary alcohols contained in the training set are correctly identified, but 34 compounds are incorrectly classified as primary alcohols as well. The A50 value for this group is therefore $132/(132 + 34) = 79.5\%$. This value was still deemed to be good. Thirty of the 36 functional groups were able to be predicted with similar or better precision.

The results from this network, which contained a hidden layer, were compared with classification capabilities of a network without a hidden layer.[43] The hidden layer brought about a considerable improvement in results.

This experiment has, of course, not solved the problem of resolving the relationships between infrared spectrum and structure. For the most part, work concentrated on a few important functional groups, and the molecular skeleton was ignored. Even for those groups the predictions were only of moderate quality; to recognize 132 out of 265 primary alcohols in addition to 34 false assignments is disappointing. If one sets the threshold value even higher one can determine to a high degree of certainty whether a functional group is

present or absent, but a large range of compounds remains for which no reliable predictions can be made. In an automatic structure–elucidation system, however, these kinds of predictions allow a considerable reduction of the search space. Herein lies the value of these results.

This is not the last word on the relationship between structure and infrared data. Further experiments should attempt to classify vibrations of the skeleton. This would, however, necessitate a change in the way structures are coded.

7.4. The Relationship between Structure and Mass Spectra

The relationships between mass spectra and structure are even more complex than those between infrared spectra and structure. Nevertheless, this problem also has already been approached with neural networks.

In this case, too, a multilayered network containing a hidden layer was trained with the back-propagation algorithm.[44] The mass spectra were described by 493 features; these included the logarithms of the intensity of the peaks between m/z 40 and 219, the logarithms of the neutral losses between m/z 0 and 179, autocorrelation sums, modulo-14 values, etc. The values for these 493 spectral characteristics were fed into the same number of input units.

Here too the structure of an organic compound was characterized by 36 substructures which, however, differed partly from those used in the study on infrared spectra. Thirty-six output neurons were needed for this. As the number of neurons in the hidden layer was 80, $493 \times 80 + 80 \times 36 = 42320$ weights had to be determined.

Correspondingly larger data sets were investigated: with 31926 mass spectra for training and 12671 mass spectra for testing. With such large data sets and a network with so many weights, the learning process (the back-propagation algorithm was also used here) required a great deal of time. One epoch (that is the process of passing all 32000 spectra once through the net) needed 6 h on a HP 9000/370 or SUN-4 workstation. Typically 50 epochs were needed; thus training alone required two weeks computing time on a high-performance workstation.

The results of the classification from the fully trained neural network, MSnet, were compared with results from STIRS.[45] STIRS, from the group led by McLafferty, is a powerful expert system for determining the presence of functional groups from mass spectra.

The classification results from MSnet were somewhat better than those from STIRS. MSnet offers a few additional advantages however: 1) A probability value can be given for the assignment of a compound to a particular class. 2) Not only the presence but also the absence of a functional group can be diagnosed. 3) The computing time required for queries to MSnet is two orders of magnitude lower than for STIRS.

The following point must be emphasized: Even though the training of a neural network may require a great deal of CPU time, a fully trained neural network can make predictions in minimal time.

In order to satisfy as general a requirement as representing or learning the relationship between molecular structure and spectroscopic data for the entire domain of organic chemistry, we must confront a fundamental problem, the statistical distribution of data. For example, the data set of 32000 compounds contains 33 phthalic acid esters, which give a very characteristic peak at m/z 149. However, most of the spectra which have a peak at m/z 149 happen not to be phthalic acid esters because there are only very few of them in the total set. As a consequence phthalic acid esters are not recognized.

In this paper[44] an interesting attempt is made to overcome this general problem: a hierarchy of neural networks is proposed (Fig. 37). A preliminary network first undertakes

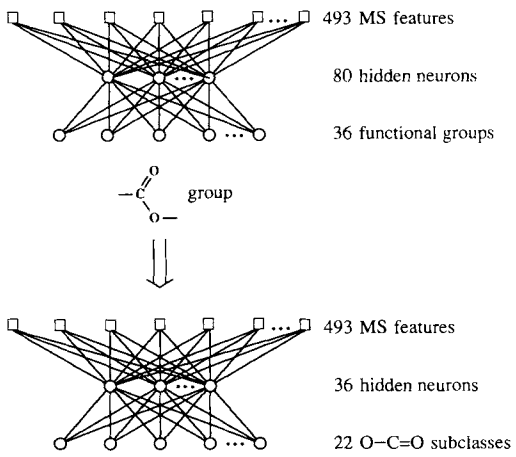

Fig. 37. Hierarchy of neural networks for deriving substructures from mass spectra.

the partitioning according to the most important functional groups, while specialized neural networks carry out further refinements of the compound classes. Thus a special network was developed which divided compounds containing the O–C=O group into 22 subclasses (saturated esters, aromatic esters, lactones, anhydrides etc.).

This idea of using a hierarchy of neural networks could prove very useful in other problem areas.

7.5. Secondary Structure of Proteins

In the example from the previous section we were still dealing with a rather simple network architecture. We now move on to describe cases with a rather extensive coding of the input data. The neural network involved is correspondingly complex, with a large number of weights.

To gain a deeper insight into the physiological characteristics of proteins one must know their secondary structure. For this reason there has been no scarcity of attempts to derive the secondary structure of proteins from their primary structures (that is, from the sequence of amino acids). Chou and Fasman[46] introduced a method which is much used today to decide from the sequence of amino acids what secondary structure the individual parts of a protein will assume. This procedure is able to predict with 50–53% accuracy for the individual amino acids in a protein whether they take part in an α-helix, β-sheet or an irregular coiled struc-

ture.[47] Over the past few years a series of papers have appeared in quick succession[48-56] on applications of neural networks to predict the secondary or even tertiary structure of particular sections of a protein from the sequence of amino acids. Our intention is to demonstrate the principal procedure based on the work of Qian and Sejnowski.[48] Most of the other investigations[49-56] have chosen a very similar strategy.

Both the Chou and Fasman method[46] and the application of neural networks are based on the assumption that the amino acid (AA) itself and its immediate surroundings (that is, the amino acids immediately before and after it in the sequence) decide which secondary structure it will adopt.

In order to take the dependence of the secondary structure on the sequence into account, the amino acid under examination will be fed into the net along with the six amino acids preceding and the six following it in the sequence. Thus from the amino acid sequence, a "window" of 13 amino acids is extracted every time. This window is pushed in steps of single AAs down the entire length of the amino acid sequence, so that each individual AA in turn may find itself in the center.

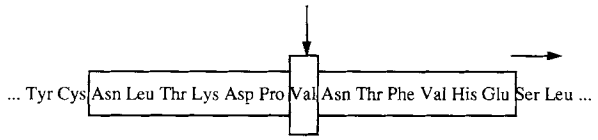

Fig. 38. Section ("window") of 13 amino acids from a protein sequence. The window helps to determine the secondary structure in which the amino acid in question (in this case valine) finds itself.

How are the individual amino acids coded? For each AA in the window of 13 AAs a bit vector of length 21 is used. For each of the 20 naturally occurring amino acids a particular position in the bit vector is reserved (e.g., the 14th bit is set to 1 when the AA proline is present). A last bit is required in order to mark that the window is at the beginning or end of the protein and thus that there are no more AAs at one of its ends. Thirteen input units are needed for the size of the window and 21 for the identity of the AA, thus $13 \times 21 = 273$ input units altogether; each feeds only one bit, a zero or a one, into the network.

The network had three output neurons: one for the presence of an α-helix, one for a β-sheet, and one for a coiled structure. After experimenting with between 0 and 80 hidden neurons, a hidden layer of 40 neurons was chosen as optimal for the net, which meant that $273 \times 40 + 40 \times 3 = 11\,040$ weights were to be determined. Again in this case the back-propagation learning algorithm was chosen. The overall architecture is pictured in Figure 39.

The network was trained with 106 proteins containing a total of 18 105 amino acids. The efficacy of the net was tested with 15 additional proteins, which comprised 3250 AAs in total. A prediction accuracy of 62.7% was achieved.

Thus one could say with 62.7% certainty whether an amino acid was part of an α-helix, a β-sheet or a coiled structure. This is a noticeable improvement over traditional methods for predicting secondary structures but still leaves something to be desired. It is therefore understandable that this area is being researched so actively.[48-56]

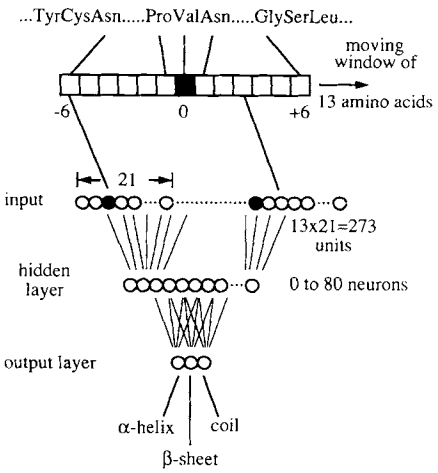

Fig. 39. Neural network for deriving the secondary structure of a protein from the sequence of amino acids.

7.6. Summary

These applications from very different branches of chemistry serve to underline the broad range of possibilities which neural networks offer for classification. In every one of the examples portrayed, a multilayered network was used that was trained by the back-propagation learning process.

The number of neurons in the hidden layer is usually determined by a systematic series of experiments. With too few neurons a problem can not be correctly learned; the larger the number of neurons the smaller the error in learning, but the longer the training times. Too many neurons and too long a training period can lead to another problem: overtraining. This means that a neural net has been trained for so long that, although it can reiterate the training set without error, it may give bad predictions when faced with new data. Multilayered networks usually have many weights, and therefore many degrees of freedom in adapting to a data set. This presents the danger that one might fall into an erroneous local minimum in training, thus reducing the ability to make predictions based on new data.

The complexity of the neural net (mainly the number of weights and the number of training data used) can bring with it a large increase in the training time. One should not be discouraged too much by long training times, however, because ideally a network needs to be trained only once. Once it has finished learning, predictions on new data can be made very rapidly, because these data only have to be passed through the fully trained net once.

In the case of classification problems it is desirable to obtain values of one or zero in the output neurons so that an object belongs unambiguously to a category or not. In reality values between one and zero are obtained, and decisions are made on the basis of threshold values (e.g., 0.8 or 0.2) whether an object belongs to that category. These numeric output values can also be interpreted as probabilities, and as such may be used in a decision support system.

The numerical output clearly points to the transition to modeling problems, which are the subject of the next section. In modeling tasks it is desirable to obtain function values, (i.e., real data). These can be produced by taking those val-

ues between zero and one and transforming them through mathematical functions.

In summary, the most important task when implementing a neural network is to find a suitable representation for the input and output data. The hierarchical ordering of multiple networks (Section 7.4) and the movable window from Section 7.5 demonstrates that the technology sets no limits to the imagination.

8. Modeling

We have already seen that even in the case of classification a neural network returns values between zero and one, that is, a continuum of values. It is also possible, however, to train a neural network with real expectation values and to use the output values in their real magnitudes, just as one might normally calculate the value of a function from a series of variables. This task of using data about an object (compound, reaction, spectrum) and deriving other characteristics of the object from them has commonly come to be called "modeling", and is what we shall use the term to mean in the following sections. The neural network therefore assumes the task of using input variables (data) from an object to find the value of some dependent characteristic (or even several of them). A neural network offers the advantage of not requiring an explicit formulation of the relationship as a mathematical equation. It expresses this relationship implicitly in the connections between the individual neurons.

8.1. HPLC Analysis

A simple example shall serve to represent the potential of this technique in analytical chemistry.

In the HPLC analysis of Spanish wines, the dependence of the separation of the components (expressed as the selectivity factor SF) on the ethanol content (10, 20, or 30%) and the pH value (5.0, 5.5, or 5.6) of the liquid phase was determined. These nine experimental points were fitted to a quadratic equation with standard modeling techniques.[57] The result is given in Equation (r), where x_1 = % ethanol and x_2 = pH value. This functional relationship is also represented in Figure 40 in the form of lines of the same selectivity factor.

$$SF = 0.018\,x_1^2 - 1.42\,x_2^2 + 0.015\,x_1\,x_2 - 0.995\,x_1 + 16.16\,x_2 - 31.86 \qquad (r)$$

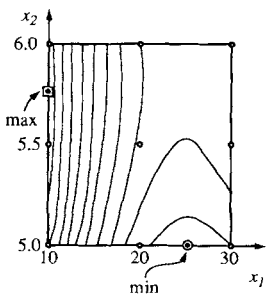

Fig. 40. HPLC analysis of Spanish wines: Shown is the dependence of the selectivity factor SF on the ethanol content x_1 and on the pH value x_2 of the liquid phase. The curved arrows highlight the maximum (left) and minimum SF (bottom).

The same nine experimental data were built into a neural network with two input units (one for the ethanol content and one for the pH value), one output neuron (for the selectivity factor), and six neurons in a hidden layer, which was trained with the back-propagation algorithm.[58]

Values for the ethanol content and the pH were fed into the network and the results entered into the diagram in Figure 41. Here too, just as in Figure 40, lines of the same selectivity factor were drawn in. A comparison between Figures 40 and 41 shows that both standard modeling and neural network techniques arrive at quite similar results. In particular, the positions for the minimum and the maximum values of the selectivity factor are very similar.

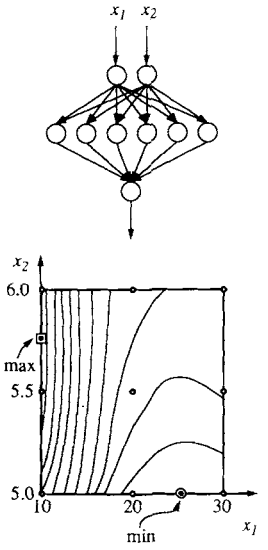

Fig. 41. The results obtained from a neural network (shown at the top) on the selectivity of the HPLC analysis of Spanish wines: dependence of SF on the ethanol content and on the pH value. See also Figure 40.

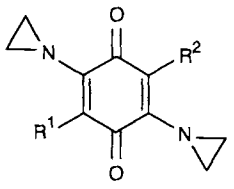
The advantage of the neural network is clear: in statistical modeling the mathematical form of the functional relationship (here a quadratic equation) had to be given explicitly. With the neural network this is not necessary; it finds the relationship by itself, implicitly, by assigning appropriate weights.

8.2. Quantitative Structure–Activity Relationships (QSAR)

The search for quantitative structure–activity relationships (QSARs) is one of the most important application areas for modeling techniques. A great deal of trouble and effort has been invested, especially in the prediction of pharmacological and biological data. It is therefore all the more surprising that as yet very few studies have been published which employ neural networks to provide quantitative relationships between structure and biological activity.[59, 60] A typical study shall briefly be described here.

For this study a data set that had already been investigated with statistical modeling techniques (a multilinear regression analysis) was deliberately chosen in order to compare the performance of a neural network against a standard method from the field of QSAR. The data set comprised 39 *para*-quinones, some of them anticarcinogenic (Scheme 2).



Scheme 2. *para*-Benzoquinones containing two aziridine substituents, a class of compounds which includes some anticarcinogenic members. R^1 and R^2 are, for instance, CH_3, C_6H_5, etc.

The influence of the substituents R^1 and R^2 was described by six physicochemical parameters: the contribution of R^1 or of both substituents to the molar refractivity index, MR_1 and $MR_{1,2}$, their contribution to the hydrophobicity, π_1 and $\pi_{1,2}$, the substituent constants of the field effect (F), and the resonance effect (R). Accordingly for a description of the influences of the substituents, six input units were required (Fig. 42).

The neural network was intended to yield the minimum effective dosage of the medication for a single injection. This minimum effective dosage is given by the amount of substance (as $\lg 1/c$) that leads to a 40% increase in length of life. A single neuron was present in order to output the value of $\lg 1/c$. A hidden layer of 12 neurons completed the network architecture (Fig. 42).

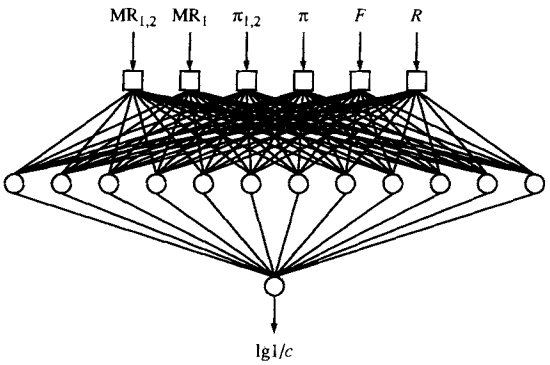


Fig. 42. Neural network for predicting the anticarcinogenic activity of *para*-benzoquinones.

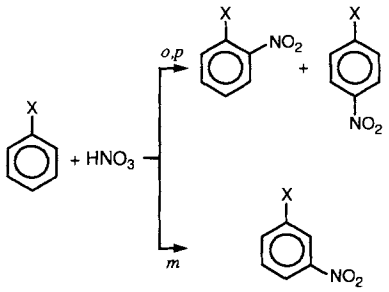
Thirty-five benzoquinones were used to train the multilayered network with the back-propagation algorithm. The values for $\lg 1/c$ obtained from the network were compared with the results calculated from an equation determined by multilinear regression analysis. In 17 cases the results from the neural network were better, for 6 more or less as good, and for 12 worse. In other words, the results from the neural network are significantly better. Nevertheless this problem can be solved quite well by a linear method that leaves little room for improvement by a neural network. In the case of QSAR problems containing nonlinear relationships more might be gained by using neural networks.

8.3. Chemical Reactivity

Whereas in Section 7.1 we were satisfied with a yes/no decision on chemical reactivity (does a bond break easily in a polar manner or not), here we wish to make a quantitative statement about the behavior of a chemical reaction.

The electrophilic aromatic substitution of monosubstituted benzene derivatives can lead in principle to three isomers: *ortho*, *meta*, and *para* products (Scheme 3). The dependence

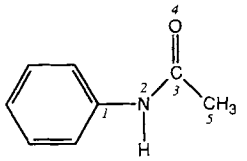


Scheme 3. Isomeric distribution in electrophilic aromatic substitution.

of the isomer distribution on the nature of the substituents X is a classical problem in organic chemistry. Basically the substituents may be divided into two classes: electron-donating substituents (inductive or mesomeric), which prefer to direct into *o*- and *p*-positions, and mesomeric electron acceptors which steer towards the *m*-position. The factors that determine the *o*/*p* ratio are both steric and electrostatic in nature.

In one study[61] into the product ratios for the nitration of monosubstituted benzene derivatives, the amounts of *ortho* and *para* products were combined. Accordingly, one output neuron was used for the $o + p$ content and a second for the percentage of *m*-isomer. As already mentioned, the distribution of product is determined by the nature of the substituent, especially by the electronic effects which it produces. In order to represent this, two codings of the input information were tested. In the first attempt the partial atomic charges on the six carbon atoms of the benzene ring as they are calculated in the semi-empirical quantum mechanical program suite MOPAC[62] according to Mulliken population analysis were used as the six inputs. In addition an intermediate layer with 10 hidden neurons brought the total number of weights to be determined to $6 \times 10 + 10 \times 2 = 80$.

As an alternative method the structure of the substituent was represented directly in the form of a connection table. This had dimensions of 5×5; each row contained first the atomic number of the atom in question then the index of the atom itself followed by the index of the adjacent atom further away from the ring, the order of this bond, and the formal charge on the atom. For each atom of the substituent except a hydrogen atom a new row was used. The first row reflects the situation at the atom which is directly bonded to the ring. With each successive row a further step is taken into the substituent (cf. Fig. 43). If the substituent had fewer than five non-hydrogen atoms then the rest of the 25 entries were filled with zeros. If it had more than five heavier atoms, those atoms which were further away from the point of attachment of the substituent on the ring (atom 1) were left out. Figure 43 explains this coding by connection table for the example of acetanilide. For this coding $5 \times 5 = 25$ input units were required, the intermediate layer had five neurons, and the network thus $25 \times 5 + 5 \times 2 = 135$ weights.



atomic number	relevant bond: reference atom	adjacent atom	bond order	charge
7	2	1	1	0
6	3	2	1	0
8	4	3	2	0
6	5	3	1	0
0	0	0	0	0

Fig. 43. Example illustrating the representation of monosubstituted benzene derivatives by a connection table of the substituent.

The network was trained with 32 monosubstituted benzene derivatives and the back-propagation algorithm; it was then tested with 13 further benzene derivatives. In this example the enormous number of 100000 epochs or training cycles was necessary before the error in the training data set had been reduced to a sufficient degree.

Of the two forms of coding with their networks, the second version—that is, the input of the substituent by means of a connection table—clearly produced the better results. Only the percentages of the *meta* products (Table 2) are necessary

Table 2. Results of attempts at predicting the amount of *meta*-product in the nitration of monosubstituted benzene derivatives. The size of the error in the prediction is quoted [%].

Method	Training data (32 compounds)	Test data (13 compounds)
network based on charge	5.2	19.8
network based on connection table	0.3	12.1
CAMEO	18.0	22.6
estimate by chemists	–	14.7

to judge the quality of the results. The training data set was able to be learned down to an average error of 0.3% for the *m*-isomer content. For the network obtained from the charge values the average error was 5.2%. With the test data of 13 compounds that the network had not seen before, the connection table coding gave an average error of 12.1% in predicting the percentage of *m*-product. For the atomic charge representation the error was noticeably higher at 19.8%

The results from these two neural networks were compared to values produced by CAMEO,[63] an expert system for predicting reactions. They were in every respect better than those produced by CAMEO. Finally the 13 monosubstituted benzene derivatives were given to three organic chemists to predict the expected percentage of *m*-product from the nitration. The values they gave were averaged; this gave an error of 14.7%. The chemists were thus better than the neural network with charge-coding and better than CAMEO, but were beaten by the neural network with the connection-table input!

Though the results for predicting the product ratios from the nitration of monosubstituted benzene derivatives with a neural network based on the coding of the substituents by a 5×5 connection table are very encouraging, they do deserve more detailed comment. First, it is not surprising that the coding by the partial charges on the six ring atoms was rather unconvincing. Apart from the known inadequacies of Mulliken population analysis, the ground-state charge distribution is only one of the factors (not even the most important electronic effect) that influences the product ratios in electrophilic aromatic substitution. For these reasons the charge values can not represent the benzene derivatives sufficiently well to explain the product ratios from nitration.

As satisfactory as its results may be, the coding of the benzene derivatives by a 5×5 connection table can not provide an explanation for the effects responsible for regioselectivity, nor for the influence of the reaction conditions. Nor can it explain the product ratios from di- and polysubstituted benzene derivatives. To do this one must choose a different representation for the benzene compounds, which is indeed feasible.[64] The substituent should not be described globally. Rather its influence on the individual positions on the aromatic ring should be represented directly: for each position on the ring a value for the resonance effect, the local electrostatic potential, and the steric effect should be given. Because this represents the influence of a substituent at every single position on the ring, we can extend inferences from monosubstituted benzene derivatives to di- and polysubstituted compounds. Then we can make predictions about isomer distributions in further substitution. In addition, it is also possible to take account of the influence of the medium by providing a further input unit for the concentration of sulfuric acid. The network is trained with this alongside the descriptors for the influences of the substituents.[64]

8.4. Summary

Modeling tasks are very common in many branches of chemistry. This opens up a wide area for the application of neural networks. At present this area is dominated almost exclusively by multilayered networks and the back-propagation algorithm. This need not be the case. Other neural network architectures, especially the counterpropagation algorithm,[27] can certainly be used just as well for creating models.

The deployment of neural networks for modeling (that is, for predicting some characteristic of an object from a series of other parameters or measurements from that object) should always be considered carefully in relation to the use of statistical methods. If one has a relatively clear idea which variables influence the feature sought, and if there is some largely linear relationship between them, then traditional methods, such as multilinear regression analysis clearly offer advantages: these methods are faster and require less computing time, they give measures for the quality of the discovered relationship, and, above all, the equation derived from the statistical modeling allows a clear interpretation of the individual effects of the feature sought.

Neural networks should be used, however, if it is presumed that nonlinear relationships exist between the dependent and the independent variables, and if it is not possible to specify exactly which parameters influence the characteristic under investigation.

Whether the choice falls on statistical methods or neural networks, the success of a study depends crucially on the selection of the data set, on the representation of the information, and on the methods employed to validate the results. Moreover, when implementing neural networks, the following points are of crucial importance:

- the selection of a homogenous data set for training (e.g., by using experimental design techniques or a Kohonen network – see Section 10.1)
- the partitioning of the data set into training and test data sets
- the selection of suitable parameters as input data to describe the objects.

9. Association

The capacity to associate is closely related to the recognition of similarities between different objects. Neural networks can also be conceived of as memories, because they store the information they have learned from the training data in the form of weights or "synaptic strengths". Should a new object be fed into the neural network whose input data resemble those of an object used in training, some network architectures are able to recognize this and yield the stored object from the training phase as output.

This ability of neural networks to associate, to recognize similarities in given data, has been exploited very little in chemistry up to now. Even the two studies presented here are essentially only feasibility studies. The basic solution to a problem is demonstrated here on small, simply structured data sets. For a real-world application however, larger sets of more complex data would have to be investigated.

9.1. Adjustment of Base Lines

Systematic deviations from the base line may be observed in many spectra and could be caused by impurities, the influence of solvents, or problems with technical equipment. Five different types of base line (normal, ascending, descending, concave, convex) were stored in a Hopfield network as simple black pixel-patterns in a matrix consisting of 6×20 points.[65] Then a simple, simulated spectrum which contained a convex base line was fed into the thus trained Hopfield network. After three iterations the pattern for this baseline was output by the network (Fig. 44).

Afterwards therefore, a background correction could be undertaken for this spectrum. We have already pointed out in this review that a real-world application would need a far higher resolution; thus the base lines would have to be represented by a larger pixel matrix (e.g., 20×250). However, because of the basic limitations on the storage capacity of Hopfield networks, and in order to make good predictions, 2×10^7 matrix elements would need to be checked. It only makes sense to carry out this task by hardware implementations of parallel neural networks.

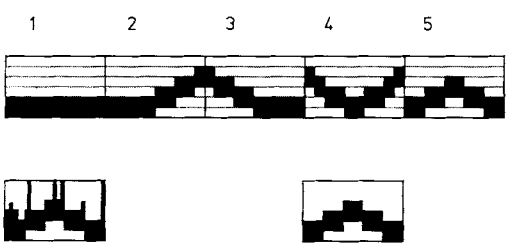


Fig. 44. Five types of base lines of a spectrum (top), a much simplified spectrum with a concave baseline (bottom left) and the concave base line recognized by the neural network after three iterations (bottom right).

Because of the storage and calculation problems presented by Hopfield networks, the same task was also investigated with a Hamming network.[65] A Hamming network,[66] which requires far less memory capacity, was in fact also able to be solve the problem. However, in this case too, only a 7×20 matrix was used to represent the five types of base line; an application which uses experimental data with a high resolution has yet to appear.

9.2. Identification of Spectra

Another feasibility study was made into how slightly altered UV spectra (e.g., through the influence of solvents) might be recognized.[67] Prototypes of UV spectra were represented by a sequence of points (pixels) in two 10×10 fields; the first field containing the band maxima was placed at the input of an adaptive bidirectional associative memory (ABAM), and the second field, comprising the tailing portions, was placed at the output (Fig. 45a). Because of the bidirectional nature of the ABAM the terms input and output are of course purely arbitrary.

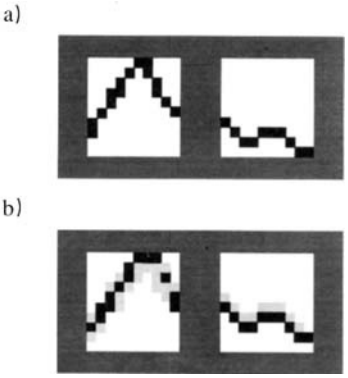

Fig. 45. Grid representation of an ultraviolet spectrum (a) and fuzzy coded forms of this spectrum (gray dotted fields) (b).

The ABAM was trained with five model UV spectra coded in this way. For testing fuzzy codings and slightly altered spectra were used (cf. Fig. 45 b). The recall capability of the ABAM was heavily dependent on the choice of various network parameters; however, in the end a set of parameters was found that was able to recall all five spectra learned from the input of its distorted counterpart.

10. Mapping

Many chemical phenomena are influenced simultaneously by a whole series of factors and depend on many parameters. These parameters can be seen as coordinates in a multidimensional space. Individual observations then represent

points in this multidimensional space. To visualize the structure of this multivariate information in order to make visible the essential relationships between the individual data points, the dimensionality of the space has to be reduced to such a degree that it can be represented graphically and thus analyzed by the human eye. Such a mapping, say onto a two-dimensional plane, should preserve the essential relationships between the individual data points as far as possible.

In Section 4.3 we saw how a three-dimensional space, the surface of a sphere, could be mapped by a Kohonen network onto the surface of a torus, and the neighborhood relationships between the points on the sphere were kept intact. In the following sections we present two examples for the mapping of multidimensional chemical information by a Kohonen network.

10.1. Chemical Reactivity

We wish once more to examine the data set introduced in Section 7.1, which classified a series of single bonds in aliphatic molecules according to whether they were easy or difficult to break heterolytically[29] (cf. Figure 31). Each of the bonds was characterized by seven electronic and energetic parameters, such as difference in charge and polarizability, and bond dissociation energy (cf. Figure 30). The rupture of a bond is thus represented by a point in a seven-dimensional space.

The question now is, are the points with reactive bonds in this seven-dimensional space separated from those of the nonreactive bonds? Moreover, if this is the case, can this separation be retained in a map onto a two-dimensional surface by means of a Kohonen network?

A Kohonen network consisting of 11×11 neurons was trained with the 149 bonds; the values of the seven electronic and energetic factors were used as input data (see Fig. 30).

The results are shown in Figure 46. Indeed the reactive bonds do find themselves predominantly in certain neurons, and the nonreactive bonds in different neurons. Additionally the neurons of the reactive bonds form a contiguous part of the Kohonen network.[29]

It may be concluded from this that the chosen parameters characterize the heterolysis of a bond well (because reactive and nonreactive bonds are separate) and that a Kohonen network is able to preserve this separation even when mapping it onto a surface. It should be emphasized once again that the Kohonen network learns without supervision, and therefore that the information on the reactivity of a bond was not used during the learning process.

Yet another conclusion may be drawn from Figure 46. Bond cleavages that activate the same neuron ought also to contain more or less the same reactivity information; the interaction of the seven parameters ought to produce a similar net effect in reactivity. Accordingly, if the relationships between reactivity and the electronic and energetic parameters are to be investigated further, it is sufficient to choose a single bond out of the many that activate the same neuron. At the same time, at least one bond should be chosen from each occupied neuron in order to cover as much as possible of the reactivity spectrum. In fact the data set that was learned by the back-propagation algorithm (see Section 7.1) was chosen with these considerations in mind. Thus two different neural network models were used: a Kohonen network for the selection of the data set and a multilayered neural network, trained by the back-propagation algorithm, for the task of classification.[29]

The Kohonen method can therefore be used to make balanced selections of data sets for investigations with statistical or pattern-recognition methods, or even used with other neural networks.

10.2. Electrostatic Potential

The electrostatic potential surrounding a molecule has a decisive influence on many physical, chemical, and biological properties. Electrostatic potentials are analyzed in detail, especially in investigations into the interactions between substrate and receptor, but also in studies into chemical reactivity.

If one moves a probe charge, for example a positive unit charge in the form of a point, around a molecule, for every point in space the electrostatic potential may be determined by quantum mechanical or classical electrostatic methods.

Scheme 4 shows a three-dimensional molecular model of 3-chloro-3-methylbutan-1-ol, and Figure 47 the electrostatic potential that a positive point charge experiences on the van der Waals surface of this molecule. The magnitude of the

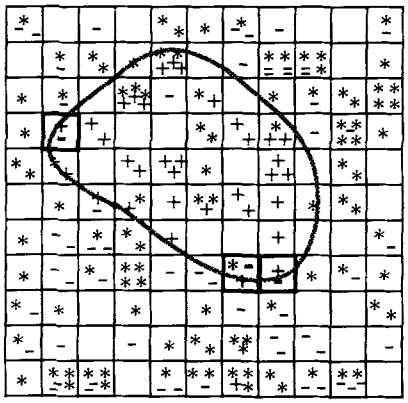

Fig. 46. A Kohonen network that maps polar bond rupture characterized by seven electronic and energetic parameters. + indicates a reactive bond, – a nonreactive bond, and * a bond whose reactivity was not decided.

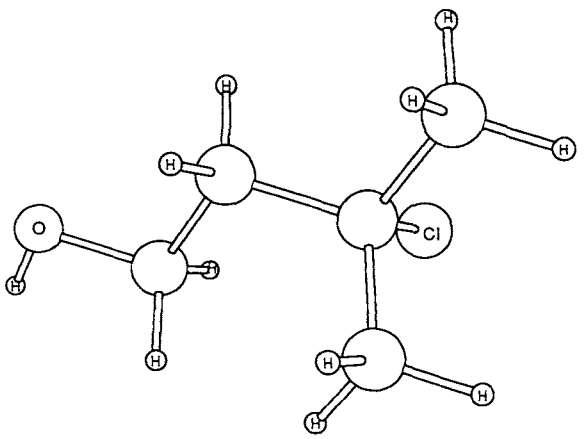

Scheme 4. Molecular model of 3-chloro-3-methylbutan-1-ol.

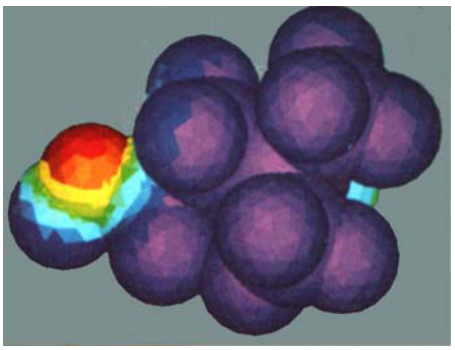

Fig. 47. Electrostatic potential on the van der Waals surface of 3-chloro-3-methylbutan-1-ol. Red regions possess a negative potential, and thus attract a positive charge; blue and violet regions repel this charge.

electrostatic potential is translated into a color code: Strongly negative values of the electrostatic potential (positions to which a positive charge is attracted—that is, nucleophilic positions) are represented by red. Strongly positive values (positions from which a positive charge is repelled—that is, electrophilic positions) are marked in blue or violet. The intermediate values are represented by continuous blends of color. The electrostatic potential was calculated in the classical way by summing the Coulomb interactions of the probe charge with the atomic charges as calculated by the PEOE procedure.[30, 31]

Figure 47 represents a parallel projection of the distribution of the electrostatic potential on the van der Waals surface of the molecule onto the plane of the graphics screen. Of course, only that part of the electrostatic potential that happens to be visible to the observer can be shown. Thus for example, the chlorine atom can barely be seen in Figure 47. A complete view of the distribution of the electrostatic potential can only be obtained by taking a series of such mappings from different observation points. The more complex the form of the van der Waals surface and the variation in electrostatic potential, the more mappings are required. For this reason it will be very difficult to obtain a complete impression of the distribution of the electrostatic potential and the relationships between all electrophilic and nucleophilic centers.

The inadequacies of a parallel projection onto a plane (monitor screen) led us to look for other projection methods that are capable of representing the essential aspects of the potentials on a molecular surface in a single mapping.[68] A Kohonen network is one such projection method.

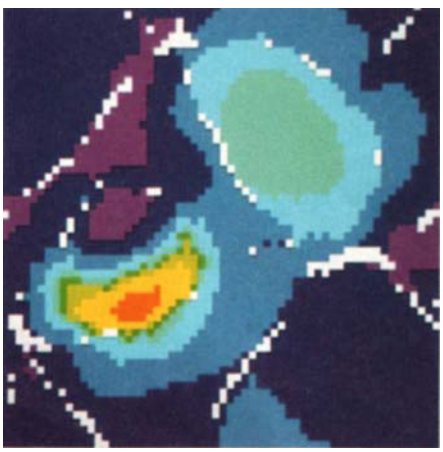

Fig. 48. Kohonen network of the electrostatic potential in Figure 47.

Figure 48 shows the projection of the electrostatic potential of 3-chloro-3-methylbutan-1-ol from Figure 47 onto a Kohonen network. To obtain this mapping, 20000 points were chosen at random from the molecular surface and a Kohonen network of 60×60 neurons was trained with the x, y, and z coordinates of each point. After each point had been passed through the network the neurons were examined to see which points were assigned to which neurons.

Points of the same or similar potential values were indeed found to be located in the same or neighboring neurons. The electrostatic potential on the van der Waals surface of a molecule had therefore been mapped onto the Kohonen map, and the neighborhood relationships on the van der Waals surface were largely preserved intact.

We remind the reader once more that in the case of a Kohonen network the mapping takes place onto a torus, that is onto a surface without beginning or end (cf. Figure 24). The map in Figure 47 can therefore be shifted up, down, to the left or to the right.

A comparison between Kohonen maps of electrostatic potentials of different molecules reflects the essential similarities of the electronic properties on the surface of the molecules, that is, at the places where molecules come into direct contact with their environment. The electrostatic potential on the surface of a molecule is a decisive factor in the interaction of a substrate with a biological receptor. Kohonen maps of electrostatic potentials of different molecules that are bound to the same receptor should therefore indicate certain similarities.

Indeed, it could be shown that Kohonen maps of the electrostatic potential of compounds that bind to the muscarinic receptor have common characteristics. Similarities are also perceived in the Kohonen maps of electrostatic potentials of molecules that bind to the nicotinic receptor, but these characteristics are different from those for molecules bound to the muscarinic receptor.[68]

Kohonen maps show in a single picture essential characteristics of electrostatic potentials. These characteristics are apparently responsible for the binding of a substrate to a biological receptor.

11. Summary and Outlook

Although the development of computational models of information processing in the human brain can look back on a history of almost 50 years, it is only in the last four to five years that neural networks have been applied widely to problem solving. New, efficient algorithms have paved the way for a multitude of applications, and the use of neural networks is still increasing—also in the field of chemistry—by leaps and bounds.

The models of neural networks and their potential applications of classification, modeling, association, and mapping are as diverse as the capabilities of the human brain are varied. The potential in neural networks for the processing of chemical information is very far from being exhausted.

In chemistry the task is often to assign objects to certain categories or to predict the characteristics of objects. This

accounts for the dominance of the back-propagation algorithm. A whole series of other neural network models exists, however, which could be applied successfully to the field of chemistry. This should be explored more widely in future.

Undoubtedly, many of the problems that have been approached with neural networks could also have been solved with statistical or pattern-recognition methods. Neural networks, however, offer capacities which exceed the possibilities of traditional methods of data analysis. Of special importance is the fact that the relationship between input and output data need not be specified in mathematical form, but is derived from the data themselves and represented implicitly. This enables the modeling even of nonlinear relationships.

The use of neural networks still requires much experimentation; guidelines to arrive as quickly as possible at a viable solution to a problem become apparent only gradually. Of crucial importance to the successful application of a neural network is the strategy for data representation; the better the chemical information to be examined is coded, the easier and better the problem may be solved.

The cooperation between our two working teams depended crucially on support from the Bundesministerium für Forschung und Technologie of the Federal Republic of Germany and from the Slovenian Research Ministry. Particularly the provision of a guest-professorship for Jure Zupan at the Technical University of Munich within the framework of BMFT project 08G 3226 has enabled us to develop a productive scientific exchange. We would like to thank especially our co-workers A. Fröhlich, P. Hofmann, X. Li, J. Sadowski, K.-P. Schulz, V. Simon, and M. Novic, who undertook with us the first steps into the Terra Nova of applying neural networks to chemical problems.

Defect Chemistry: Composition, Transport, and Reactions in the Solid State; Part II: Kinetics**

By Joachim Maier*

Dedicated to Professor Hermann Schmalzried on the occasion of his 60th birthday

Within the last few decades—though with its beginnings traceable to as early as 60 years ago—a direction of research has developed almost unnoticed by the classical chemical disciplines, such that one can now recognize a chemistry *within* the solid state that is analogous to the long-familiar chemistry in the liquid state. It arises from those departures from the ideal structure that are thermodynamically unavoidable, the point defects, and is referred to as defect chemistry. It includes the description of ionic and electronic effects, and it considers diffusion as a special step of the overall reaction. This area of chemistry enables one to describe and treat in a unified way many apparently widely different phenomena such as ionic conduction in crystals, doping effects and p–n junctions in semiconductors, color centers in alkali metal halides, image development in photography, passivation and corrosion of metals, the kinetics of the synthesis and sintering of solid materials, the problems of rock formation during the earth's evolution, the mechanisms of gas sensors and high temperature fuel cells, the performance of photosensitive electrodes, variations of the electron balance in high temperature superconductors, elementary processes of heterogeneous catalysis, nonequilibrium transitions and oscillations in semiconductors in electric fields, and many more. In such phenomena the equilibrium concentration of defects has an important double role: it not only determines the disorder and the departures from the stoichiometric composition in the equilibrium state, but also, together with the mobility as the kinetic parameter, is the key parameter concerning the rates of physical processes, which are the main subject of the present discussion. Following the account of the thermodynamic fundamentals in Part I, this second part of the review will be concerned with kinetic processes. These are essentially the equilibration processes (physical diffusion, electrical conduction, chemical diffusion, and reactions) that take place under the influence of chemical and electric driving forces. As in Part I, here again the general characteristics of defect chemistry will clearly emerge, including the coexistence of ionic and electronic charge carriers, and the importance of the spatial coordinates. The concluding section will discuss some special characteristics of nonlinear processes that are too often overlooked in solid-state studies.

1. Introduction

Part I of this review[1] consisted of a detailed presentation which showed that in thermodynamic equilibrium all solids contain point defects whose nature and concentration depends not only on the material but also on the temperature, the hydrostatic pressure, and the chemistry of the environment—for example, the oxygen partial pressure in the adjacent phase in the case of a binary oxide. Such defects may take the form of extra "particles" (ions, electrons, etc.), missing particles, or foreign particles. In the same way as the H^+ and OH^- ions or dissolved foreign species in water, these defects determine not only the exact composition of the phase but also its reactivity and in particular and the transport processes within it. Although Part I was essentially confined to equilibrium thermodynamics, we already saw there that the concentrations of defects can be determined by measuring the ionic or electronic conductivities, which result in the ionic case from excess ions, vacancies, or foreign ions, or in the electronic case from excess electrons or electron holes.[2] The conductivity is extremely sensitive to the defect concentration, since it is normally only the defects that contribute, not the regular structural units. Moreover, as will be shown later, the conductivity is the key quantity in understanding the dynamic processes in solids. In this article, therefore, we shall start by considering the kinetic component of conductivity, which is the mobility of the point defects, or in chemical terminology the rate constant for the "hopping reaction". Next we will deal with the self-diffusion of the particles, then with the kinetics of "true" chemical reactions—first, as a simple example, the homogeneous case of the "dissolution" of oxygen in oxides, then as a phase-forming process the corrosion of a metal, and lastly a solid–solid reaction. In cases where such processes are diffusion-controlled the relevant kinetic parameters are the diffusion coefficients, which are closely related to the ionic and electronic conductivities. The concentrations of point defects are also decisive for the rates of local chemical reactions, which occur especially at surfaces (interfacial reactions, heterogeneous catalysis). The article will conclude by discussing nonlinear phenomena that are observed under conditions far removed from equilibrium.

2. General Features of Solid-State Kinetics

In contrast to the situation in liquids the regular structural units in solids are immobile, except for vibrations and rotations about their equilibrium positions. Nevertheless, there is a degree of internal mobility due to point defects. Figure 1 illustrates this by taking vacant crystal sites as an example.

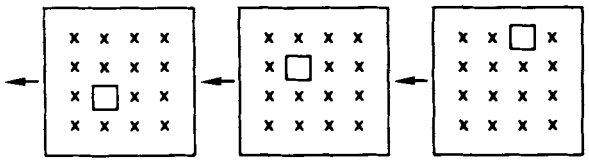

Fig. 1. Schematic representation of the migration of vacancies in a crystalline phase. The mass transport is in the opposite direction.

At sufficiently high temperatures a neighboring atom or ion can move into the vacant site, and the resulting newly formed vacancy then serves as a destination for a jump by another neighbor. From an energetic point of view the new situation does not differ from that existing previously. To be more exact, there is no overall change in the standard free enthalpy between initial and final state. However, it is necessary to supply an activation energy corresponding to the bottleneck (or, more correctly, the saddle point) for the jump process. (A more sophisticated model has been developed for the case of highly disordered materials.)[3] It is evident that the resulting mass transport can be described much more easily as the migration of a vacancy, rather than as a complex superposition of the motions of all the particles involved. In a similar way a particle occupying an interstitial lattice site also confers mobility, but here the direct hopping from one such interstitial site to the nearest equivalent site will nearly always be less energetically favorable than, for example, the jump of an interstitial particle towards an adjacent regular particle which itself is then forced into another vacant interstitial site.

It is a characteristic feature of the solid state that the positional coordinates must always be taken into account. Strictly speaking, all reactions in the solid state are heterogeneous, in other words they are associated with a transport component. So that we can approach the problem from a chemical standpoint, particle transport will be treated formally as a chemical reaction in the following discussion. If we represent such a general reaction by Equation (1), this can include not only

$$A(x) \rightleftharpoons B(x') \tag{1}$$

the case of a conventional homogeneous chemical reaction ($x \equiv x'$) but also that of a simple transport process (from x to x') when A is identical to B. Under equilibrium conditions there is no difference between the chemical potentials $\tilde{\mu}$ on the left- and right-hand sides of Equation (1). Consequently, for the case of particle transport, there must be no gradients in the electrochemical potential (The electrochemical potential is the sum of a chemical potential term and an electrical potential term, as explained in Part I). Conversely, the existence of gradients in the electrochemical potential means that there are driving forces causing a particle flow J, which, in the absence of external influences that may maintain the gradients, will lead to a restoration of the equilibrium. The behavior is depicted in Figure 2. If we express J as a power series in $(\partial/\partial x)\tilde{\mu}$ and neglect all higher terms beyond the linear term, we can describe the kinetic behavior in the neighborhood of equilibrium by Equation (2). Here the factors β_k

$$J_k = -\beta_k(\partial/\partial x)\tilde{\mu}_k \tag{2}$$

are the corresponding kinetic coefficients. This mathematical description[4] of linear irreversible thermodynamics[5, 6] is found in practice to be highly suitable in the case of the transport behavior, but for chemical reactions a linear equation of this kind can only be used in situations very close to equilibrium (Fig. 2). Before examining this in greater detail, let us consider the special cases of pure electrical conduction and pure diffusion (Fig. 2, right-, and left-hand branches, respectively, under "particle transport"). Pure diffusion occurs in the trivial case where the particles or defects concerned carry no charges. The only remaining driving force is then the gradient of the chemical potential μ; for sufficiently low concentrations this is given[7] by Equation (3), and thus

$$(\partial/\partial x)\mu = (RT/c)(\partial/\partial x)c \tag{3}$$

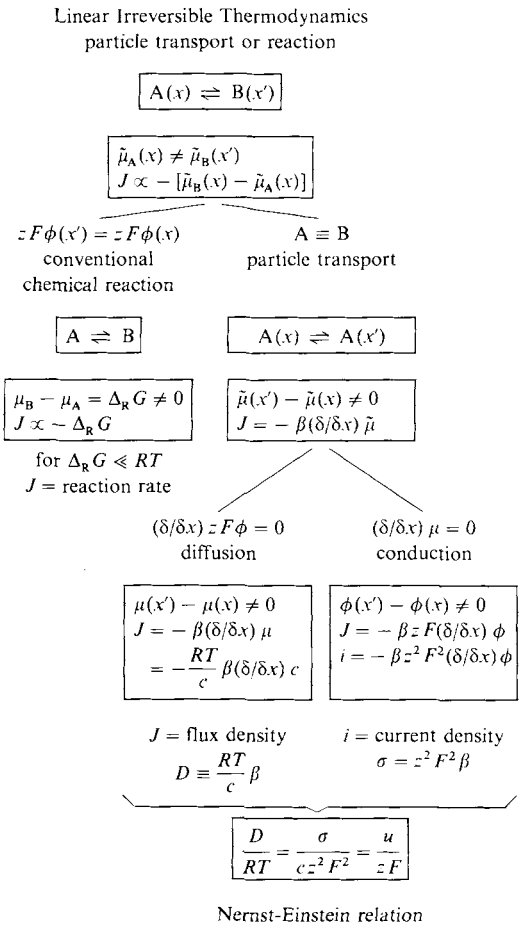

Fig. 2. Diagram summarizing nonequilibrium behavior in solids close to equilibrium. The generalized representation includes both conventional chemical reactions ($x \equiv x'$) and particle transport (A ≡ B) as special cases. Particle transport also includes the cases of pure diffusion ($z\Delta\phi = 0$) and pure electrical conduction ($\Delta\mu = 0$).

the concentration gradient can also be conceived as the driving force. Equations 2 and 3 then lead to Fick's law, in which the diffusion coefficient D is proportional to β/c. The other special case of pure conduction occurs for very high defect concentrations; the gradient of the chemical potential then disappears, resulting in a current that is proportional to the gradient of the electrical potential ϕ. This is obviously Ohm's law, with the conductivity σ proportional to β. It follows from this that the quantities D and σ are related through the coefficient β; for particles with charge number z the relationship is given by Equation (4), which is the Nernst–Einstein

$$\frac{\beta}{c} = \frac{D}{RT} = \frac{\sigma}{cz^2F^2} = \frac{u}{zF}. \tag{4}$$

relation (see bottom to Fig. 2), F is the Faraday constant). Here the quantity u is the mobility, which contains the same information, expressed in electrical units, as does the diffusion coefficient expressed in thermal units.

If we now take a more detailed look at the kinetics (Fig. 3), it becomes possible to specify the conditions under which the treatment given here is valid. It is not necessary to restrict the conditions to near-equilibrium. However, the simple rate equations that are familiar to the chemist, and are applied in the following discussion, are only valid if we assume low concentrations from the outset. We again treat reactions and transport in a unified way [Eq. (1)] with rates for both the forward and reverse processes, as is usual in chemical kinetics. In the general case the free energy profile for the process is assumed to be modified by an electrical potential (Fig. 3). If the variation in the electrical potential from the initial state to the final state is assumed to be linear, its effect is to alter the transition threshold roughly by the amount $\pm zF\Delta\phi/2$ and thus the usual chemical rate constants must be multiplied by $\exp(\pm zF\Delta\phi/2RT)$. In the case of a chemical reaction the linear relationship between "flow rate" (i.e. reaction rate) and driving force ($\Delta_R G$) only applies if $\Delta_R G/RT \ll 1$ (left-hand side of Fig. 3), a condition that is only satisfied very close to equilibrum. In the case of particle transport (right-hand side of Fig. 3) A and B are identical, and the energy profile is symmetrical (apart from the superimposed effect of an electric field, if present), so that $\Delta_R G^0 = 0$, since one is dealing with a shift of a defect from one lattice site to the nearest equivalent site. This involves passing through a saddle point whose energy is higher than that of the initial and final states. The difference between the initial (or final) state and the transition state is the free enthalpy of migration. The reaction coordinate in this case is the positional coordinate. In this sense, therefore, transport can perhaps be regarded as the simplest of chemical reactions, namely a positional rearrangement with a negligible standard affinity. The G^0 profile for this case is defined not by a snapshot, but by scanning the variation in free enthalpy as the defect successively occupies all the different positions. For the case of pure diffusion ($z\Delta\phi = 0$), this leads directly to Fick's first law, in which D corresponds to the chemical rate constant, that is it is proportional to $\exp(-\Delta G^{\neq}/RT)$. Thus the linear theory (as shown in Fig. 2) is found to be entirely valid in this case. For pure electrical conduction we must initially consider a nonlinear law (in fact a sinh $zF\Delta\phi/RT$ law, see Fig. 3).

However, the potential difference applied to the specimen is usually of the order of 1 V or less, and since the jump distance Δx is approximately 10^{-7} cm, compared with a specimen thickness of about 10^{-1} cm or greater, the relevant potential difference $\Delta\phi$ between adjacent sites is about 1 μV or less. In contrast, the quantity F/RT is of the order of 10 V^{-1} even at 1000 K, and thus $F\Delta\phi/RT \ll 1$. It is only necessary to use the high field law for very high voltages or very thin films, or for boundary layers at which there is a voltage drop of typically 0.5 V over the Debye length (typically 10^{-6} cm).[8]

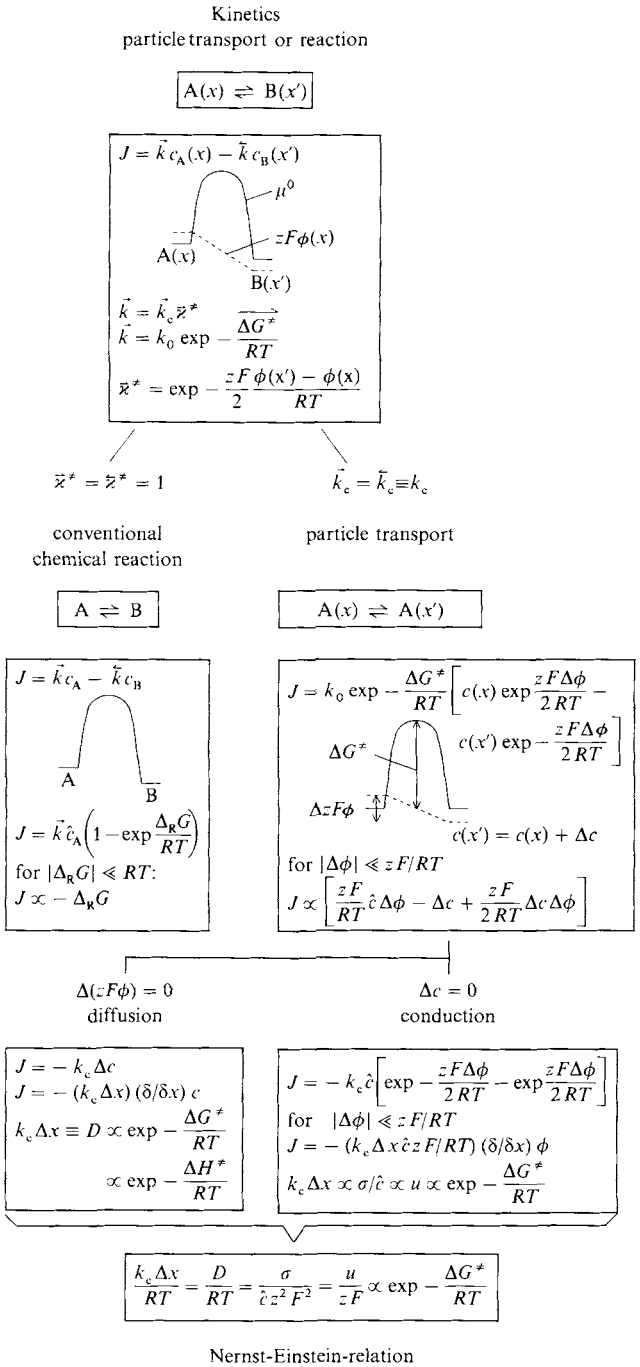

Fig. 3. Diagram summarizing the kinetic treatment of nonequilibrium behavior at low defect concentrations. Chemical reactions, diffusion, and electrical conduction appear as special cases ($\hat{c}$ = equilibrium concentration). In the case of transport, k_c is proportional to Δx.

In particular, in reactions carried out in electrochemical cells the relationship between current and voltage follows the Butler–Volmer equation[9] rather than Ohm's law (see Section 4.7). Ohm's law is obtained for near-equilibrium conditions by expanding the exponential function as a power series and truncating after the linear term. One can then treat c as approximately constant and replace it by the equilibrium concentration (Fig. 3). In addition to the Nernst–Einstein relationship [Eq. (4)], it is found that the mobility corresponds essentially to the rate constant for the hopping reaction (see Fig. 1), and a particular consequence of this is that the temperature dependence of the mobility is determined by the enthalpy of migration [Eq. (5)]. In the above approximation it is necessary to apply an external voltage (i.e. $\Delta\phi \neq 0$) to obtain any measurable effect at all, but $\Delta\phi$ has a negligible effect on the migration threshold.

$$\Delta H^{\neq}/RT = \Delta G^{\neq}/RT + \Delta S^{\neq}/R \qquad (5)$$

3. Chemical Diffusion

Although diffusion processes associated with compositional effects almost exclusively manifest themselves as changes in the positions of neutral components of a system, the defects that are involved carry electric charges, and consequently, such diffusion is always charge-coupled (ambipolar diffusion). For example, the diffusion of oxygen into an oxide (with a change in the "oxygen content") usually involves a coupled diffusion of O^{2-} ions and electrons, in which the electron flux must be twice as great as the ion flux and in the opposite direction.[10, 11] The process can thus be formally regarded as a diffusion of "O". It can be seen that there is a parallel between the treatment of chemical diffusion and that of a chemical equilibrium.[1] Corresponding to the chemical equilibrium conditions ($(\partial/\partial x)\tilde{\mu}_k = 0$), we have in this case the flow equations ($J_k \propto (\partial/\partial x)\tilde{\mu}_k$) and the electroneutrality condition corresponds to the coupling of the particle flows. Just as the potentials are linked to the control parameters in a chemical equilibrium, here the gradients must be so linked. The analysis shows that the oxygen flow J_O resulting from the coupling is given by Equation (6),

$$J_O = J_{O^{2-}} = -\frac{1}{2}J_{e^-} \propto -\frac{\sigma_{e^-}\,\sigma_{O^{2-}}}{\sigma_{e^-} + \sigma_{O^{2-}}}\frac{\partial \mu_O}{\partial x} = -\left(\frac{\sigma_{e^-}\,\sigma_{O^{2-}}}{\sigma_{e^-} + \sigma_{O^{2-}}}\frac{\partial \mu_O}{\partial c_O}\right)\frac{\partial c_O}{\partial x} \qquad (6)$$

and the proportionality constant relating it to the externally applied driving force is thus a mixed-transport coefficient (proportional to $\tilde{D}$).[10, 11] Such mixed-transport coefficients or chemical diffusion coefficients $\tilde{D}$ (essentially the expression in parentheses on the right-hand side of Eq. (6)) play a very important role in solid-state chemical kinetics and result in cases where no redox effects occur, mostly from the coupled, electrically neutral migration of different ionic species.[2, 12] If a current i is applied from an external source, the internal currents no longer cancel each other out. In this case it is also possible to have pure electrical conduction (as is usual in metals or solid electrolytes). In the general case the flow of one of the components k is the sum of a conduction term and a diffusion term (stoichiometry term). The conduction term is given by the external current multiplied by a weighting factor, the fractional contribution of the conductivity σ_k to the total conductivity σ, which results in the expression $(\sigma_k/\sigma)i$. The diffusion term is determined by the concentration gradient and the ambipolar diffusion coefficient.[10, 14]

The principles set out in this and the previous section will now be illustrated by some representative examples.

4. Examples

4.1. Example 1: The Mobility in Electrically Conducting Materials

Numerous examples of conductivity measurements in which the ultimate purpose was to determine the equilibrium concentration of defects have already been discussed in Part I of this review. In measuring the conductivity one automatically excludes diffusion terms, and pure conduction takes place. The electric fields used for such measurements are kept low enough to ensure that the normal Ohm's law behavior can be assumed in the calculations (see Fig. 3). Various elegant DC and AC methods have been developed[2, 11, 13, 14] for resolving the conductivity into its different components, such as electronic p-type or n-type conduction, or ionic conduction by vacancies or by interstitial ions. One such method, based on electrodes with a selective blocking function, has been mentioned in Part I,[1] and this will be referred to again briefly in Section 4.3. Another method, which does not involve measuring an external current, is the concentration cell experiment. This enables one to separate the ionic and electronic parts of the conductivity when these are of similar magnitudes.[15] In general, if a galvanic cell contains a solid electrolyte whose conduction is partly electronic, this acts as an internal short circuit, and consequently the measured e.m.f. is only a fraction of the Nernst value depending on the electronic contribution.[16]

The most important of the kinetic parameters which affect the conductivity is the mobility ($u \propto \sigma/c$), and the present discussion centers on this quantity. We note once again that, from the parallel with chemical kinetics, the mobility corresponds to the rate constant for the hopping reaction, apart from a proportionality factor that is unimportant in this context. The mobility term can be determined separately if the charge carrier concentration is known from measurements of the Hall effect or thermoelectric power, or is simply fixed by the level of doping. Figure 4 shows values for the mobilities of interstitial ions and vacancies in AgCl, determined from conductivity measurements on AgCl specimens with different levels of Cd doping. The Arrhenius plot is seen to be linear, as Figure 3 leads one to expect. The slope of each line yields the corresponding migration enthalpy; in agreement with computer simulations, this is found to be appreciably greater for transport by vacancies than for transport by interstitial ions.

In contrast, conduction by electronic charge carriers through a band mechanism is only slightly temperature dependent. In this case raising the temperature increases the scattering and thus slightly reduces the mobility. In the case

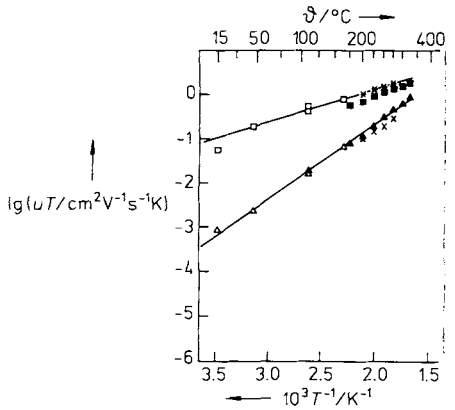

Fig. 4. Mobility of Frenkel defects in AgBr as a function of temperature [18]. (Interstitial mechanism: top line, vacancy mechanism: bottom line).

of acoustic phonon scattering the temperature dependence is typically of the form given in Equation (7). Figure 5 shows

$$u \propto T^{-3/2} \tag{7}$$

mobility data for SnO_2; at sufficiently high temperatures a power law similar to Equation (7) applies. At lower temperatures the mobility is probably limited by polaron transport, in which the polarization of the surrounding medium results in a thermally activated charge transport mechanism, involving a localized hopping process. In superconducting states, of course, u is infinite.

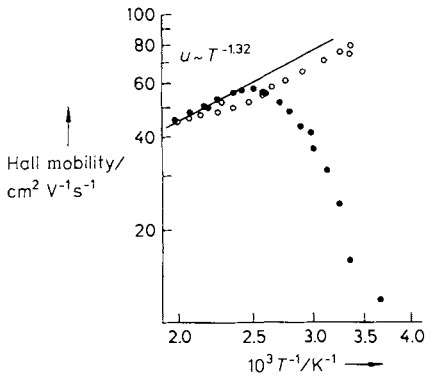

Fig. 5. Mobility of excess electrons as a function of temperature for two different SnO_2 samples, determined by Hall effect measurements [19].

4.2. Example 2: Tracer Diffusion in Oxides

As was shown previously, ionic conduction usually involves only one type of defect. The ionic conductivity is proportional to the concentration of this defect species and to its mobility u_k or diffusion coefficient D_k. Let us suppose that, in the absence of more detailed information about the defect chemistry, we group together all the relevant ions (oxygen ions in our example), regardless of whether they are fixed or mobile (that is, at regular or defect sites). We can then determine from σ_{ion} an average mobility, or more correctly a self-diffusion coefficient, which is, of course, much smaller than the mobility of the defect species.[12] Its value is given by Equation (8), and it therefore bears a simple relationship [Eq. (9)] to the diffusion coefficient D_k of the mobile defects.

$$D_{O^{2-}} = \frac{\sigma_{ion} RT}{c_{O^{2-}} 4F^2} \tag{8}$$

$$D_{O^{2-}} = \frac{c_k}{c_{O^{2-}}} D_k \tag{9}$$

Thus, whereas the diffusion coefficient of the defects, D_k, is proportional to their mobility u_k, $D_{O^{2-}}$ is directly proportional to the ionic conductivity, and thus to the product $u_k c_k$. $D_{O^{2-}}$ can also be determined by a tracer diffusion experiment, in which one observes the mixing of two isotopes, such as ^{16}O and ^{18}O, by the interdiffusion of the corresponding O^{2-} ions. In cases where the gas exchange is sufficiently rapid, the most convenient method is to enrich one portion of the natural O_2 gas with $^{18}O_2$, then to interrupt the experiment after a certain time and measure the change in mass of the gas phase. Alternatively, by using low temperatures one can freeze the concentration profile and analyze it by secondary ion mass spectrometry (SIMS) or by some other method. The ideal procedure would be to place the oxide specimen in contact with a second oxide specimen with a different isotope content, but this is not usually possible. The change of concentration with time in a defined volume is given by the difference between the inward and outward flow rates, and therefore by the flux divergence ($\partial c/\partial t = -\partial j/\partial x$), and since also for tracer diffusion Fick's first law is obeyed we obtain Equation (10). This equation (Fick's second law)

$$\partial c/\partial t = D^{Tr} \partial^2 c/\partial x^2 \tag{10}$$

can be solved to determine D^{Tr} for the appropriate boundary and initial conditions.[122] Except for some small corrections (correlation factors), D^{Tr} is identical to the self-diffusion coefficient mentioned previously, and from it one can calculate $D_{O^{2-}}$ and an ionic conductivity. Figure 6 shows some results from tracer–SIMS diffusion measurements on the $(La,Sr)_2CuO_4$ system. These can be understood on the basis of the defect chemistry described in Part I of this review (see Fig. 14 of Part I).[1] The relationship between D^{Tr} and σ_{ion} is much more complicated in the case of $YBa_2Cu_3O_{6+x}$, as different charge carriers are present (see Section 4.4). Figure 7 shows the results of tracer measurements on isotopically labeled iron in Fe_3O_4 as a function of the oxygen partial pressure.

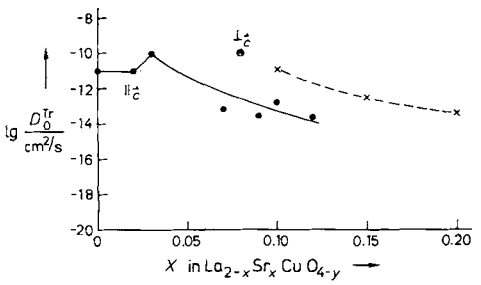

Fig. 6. Tracer diffusion results for monocrystalline (solid) [20] and polycrystalline (dashed line) [21] $(La,Sr)_2CuO_4$ materials at $T = 600\,^{\circ}C$; according to ref. [20].

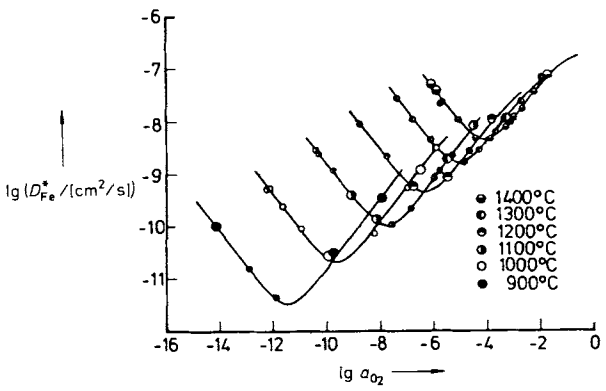

Fig. 7. Tracer diffusion results for ^{59}Fe in magnetite $Fe_{3-\delta}O_4$ [23]. D^* is the tracer diffusion coefficient.

The transition from an interstitial cation mechanism to a cation vacancy mechanism can be clearly seen.[23]

4.3. Example 3: Oxygen Uptake and Release in Oxides: Chemical Diffusion and Surface Reaction

In the previous example no chemical effects are involved; in other words there are no chemical gradients. The situation alters radically when we consider the uptake or release of oxygen in an oxide as a most simple example of a chemical reaction. Leaving aside surface reactions, we are again concerned here with a diffusion process, but one that is associated with a change of composition, namely of the local oxygen concentration. Our example is $SrTiO_3$, which was previously discussed in Part I of this review[1] in connection with the dependence of the electronic defect concentrations, and therefore of the conductivity, on the oxygen partial pressure. The data shown there (see Fig. 15, in ref. [1]) enable one to read off the initial and final concentrations, and hence the respective values of the conductivity, when the oxygen partial pressure is changed from P_1 to P_2. However, to determine the rate of approach to the final state it is necessary to consider the kinetics of the reaction [(Eq. (11)]. A knowledge of

$$SrTiO_{3-\delta} + \frac{\Delta\delta}{2} O_2 \rightarrow SrTiO_{3-\delta+\Delta\delta} \tag{11}$$

this rate is needed if, for example, the sensitive dependence of the electrical conductivity on the oxygen content is to be used as the basis of an oxygen sensor. Here, in contrast to Example 2, (Section 4.2) only the defects are involved in the diffusion. The relevant diffusion coefficient refers to the mobile particles, and is very much greater than $D_{O^{2-}}$. It can easily be seen that the diffusion of "O" into the material is an electrically neutral process involving the coupled migration of O^{2-} ions and electrons (at low oxygen partial pressures the mechanism involves oxygen vacancies, $V_O^{\cdot\cdot}$, and conduction electrons, e', at high partial pressure, $V_O^{\cdot\cdot}$ and holes, $h^{\cdot}$ (for the notation see also Part I,[1] Section 2)). This chemical diffusion coefficient is given by an expression [(Eq. (12)] which, as

$$\tilde{D} = \frac{RT}{4F^2} \frac{\sigma_{eon}\sigma_{ion}}{\sigma c_{O^{2-}}} \frac{\partial \ln a_O}{\partial \ln c_O} \tag{12}$$

expected from the equivalence of the ionic and electronic currents [see Eq. (6)], contains a mixture of ionic and electronic transport terms. It can be seen that for very good electronic conductors ($\sigma \simeq \sigma_{eon}$), the expressions for D^{Tr} [Eq. (8)] and $\tilde{D}$ are identical except for the thermodynamic factor $\partial \ln a_O / \partial \ln c_O$. However, owing to the high oxygen concentration (in contrast to the low defect concentration) and the strong ionic bonding, this factor differs greatly from 1 (a_O is the oxygen activity). Assuming that the defect chemistry is simple, the thermodynamic factor is approximately given by Equation (13), in which c_v and c_n are the concentrations of

$$\left(\frac{\partial \ln a_O}{\partial \ln c_O}\right) \simeq c_{O^{2-}} \left(\frac{1}{c_v} + \frac{4}{c_n}\right) \tag{13}$$

the oxygen vacancies and of the conduction electrons, respectively. For a purely ionic conductor, in which the ionic conductivity, and therefore also the concentration of ionic defects, are much greater than the corresponding electronic quantities, it follows from Equation (13) that $\tilde{D}$ is identical to the diffusion coefficient of the electronic defects (in this case D_n). This means that the rate of diffusion is limited by the electron flux. For an electronic conductor with an abundance of electrons, we have the opposite case in which $\tilde{D}$ is limited by the diffusion coefficient of the ionic defects D_v. However, there are many electronic conductors in which ionic defects predominate, resulting in the mixed case given by Equation (14). In the general case, assuming a simple defect chemistry, $\tilde{D}$ has a value intermediate between D_n and D_v [Eq. (15)].[24] In Equations (14) and (15) n and v are to be

$$\tilde{D} = \left(\frac{\sigma_v}{\sigma_n}\right) D_n = 4\frac{c_v}{c_n} D_v \tag{14}$$

$$\tilde{D} = \left(\frac{\sigma_n}{\sigma}\right) D_v + \left(\frac{\sigma_v}{\sigma}\right) D_n \tag{15}$$

understood as representing the dominant electronic and ionic defect species, respectively. Measuring the variation of the stoichiometry with time is a simple method of estimating the chemical diffusion coefficient, which thus describes the kinetics of the chemical reaction in the solid state (where this is diffusion-limited). Such measurements can be simply performed by using gravimetric or conductometric methods. Two alternative methods are described below.[11, 25]

The defect chemistry of nominally pure $SrTiO_3$ is very often dominated by the presence of iron impurities. A proportion of the iron ions (normally Fe^{3+}) are tetravalent, depending on the oxygen partial pressure, and in interaction with the normal defect chemistry. The associated transfer of an electron from the valence band to the iron level in the band gap can be described by Equation (16). The presence of

$$Fe'_{Ti} + h^{\cdot} \rightleftharpoons Fe^{x}_{Ti} \tag{16}$$

Fe^{4+} ions gives the oxide a reddish color, and their concentration can be measured in situ by optical absorption spectroscopy.[27] It can be shown that here too the chemical diffusion is, to a first approximation, governed by Fick's second law. The solution for small values of the time t, and the

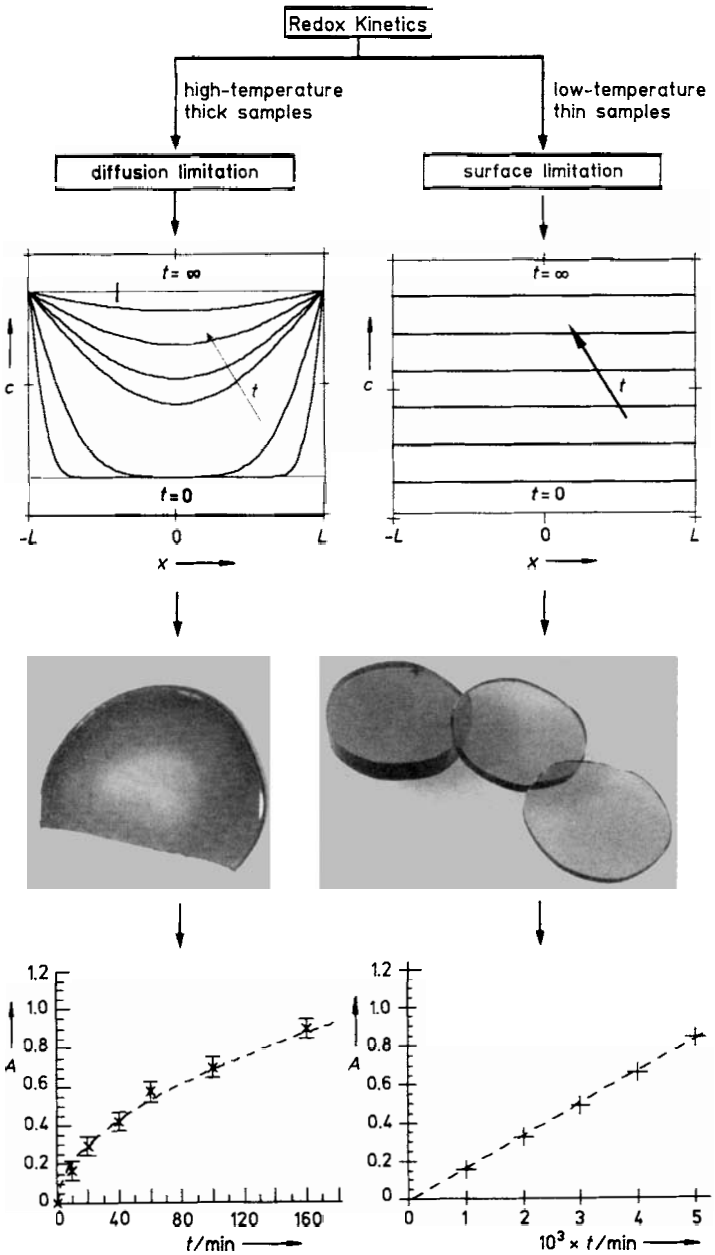

Fig. 8. Kinetics of the uptake and release of oxygen in $SrTiO_3$: theoretically predicted profiles, and experimental data from optical absorption measurements (see text) [25]. c = defect concentration, x = spatial coordinate, A = reduced absorption (arbitrary units).

appropriate boundary and initial conditions, gives a $\sqrt{t}$ law, from which $\tilde{D}$ can be calculated (Fig. 8 left-hand column) (As will be described in the next section, in this and many other cases, internal trapping effects must also be included in the analysis). In practice the overall process of oxygen uptake and release is much more complicated [Eq. (17)]. Following

$$\tfrac{1}{2}O_2(g) \rightleftharpoons \tfrac{1}{2}O_2\ (\text{surface}) \rightleftharpoons O_{ad} \rightleftharpoons O_{ad}^{2-} - 2e^- \rightleftharpoons O \qquad (17)$$

the arrival of the oxygen at the surface by gas diffusion, it must be adsorbed and must dissociate, then become ionized, pass through the phase boundary, and migrate through the space charge zones, before the chemical diffusion within the material can actually begin. The suggested sequence shown here does not show all the individual steps, nor does it take into account other possible reactions proceeding in parallel. The extent to which any one in this succession of migration and reaction processes may become a rate-limiting step depends on the region within which the state parameters fall. In fact it is found that at low temperatures the relative change of (reduced) optical absorption increases linearly with time for small values of t, indicating that under these conditions the rate-limiting step is not diffusion but the reaction at the interface (Fig. 8, right-hand column). For this case the photographic images show uniform coloration, in contrast to those for high temperatures in which color profiles corresponding to concentration profiles can be observed across the sample (diffusion-limited case). Results such as these allow quantitative determination of diffusion coefficients and rate constants.[25]

Another method, whose principle has been described by Yokota,[11] is based on earlier work by Wagner;[13] its application to yellow PbO is described here.[14] A sample of the oxide with a defined composition (corresponding to the value of the external oxygen partial pressure P_{O_2}) is compressed between two purely ionic conducting materials, sealed off from the laboratory atmosphere by a glass coating, and polarized by a constant current (or constant voltage). In contrast to the example described above, an electric current term is here superimposed on the chemical diffusion (as discussed earlier). The ionic and electronic currents cancel each other locally, except for the external current i. The variation with time of the concentration profile is determined, to a first approximation, by Fick's second law. As a consequence of the boundary conditions the development of the profile is symmetrical.[28] The driving force for the variation of the composition within the material arises from the fact that only the oxygen ions can cross the phase boundary between the oxide and the purely ionic conductor. Electrons cannot transfer through the phase boundaries either on one side (negative pole) or on the other (positive pole). The electron concentration profile that is thereby set up must, on electroneutrality grounds, be charge-compensated by an ionic profile. In the steady state only ionic currents exist, even

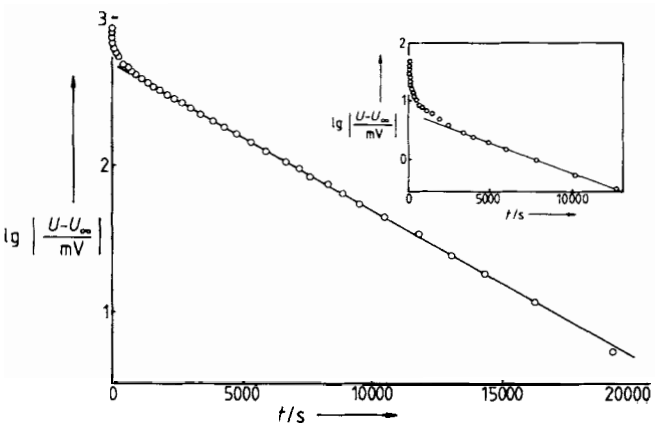

Fig. 9. The voltage of an electrochemical polarization cell consisting of PbO between ZrO_2 electrodes, during polarization with a constant current and during depolarization (i.e., after switching off the current, see insert). In the steady state the internal flow is purely ionic. In the transient state at sufficiently large values of t the voltage follows an exponential law, and from the time constants the chemical diffusion coefficient can be determined. $T = 503\,^{\circ}C$, $i = 21.83\,\mu A\,cm^{-2}$, $\tilde{D}$ (polarization) $= 2.3 \times 10^{-7}\,cm^2\,s^{-1}$, $\tilde{D}$ (depolarization) $= 2.2 \times 10^{-7}\,cm^2\,s^{-1}$.

locally; the ionic conductivity can therefore be separated from the total conductivity (which determines the voltage jump at the start of the experiment), and the chemical diffusion coefficient can be determined from the variation of the profile with time. It can be shown that for small values of t the change in the voltage is a linear function of $\sqrt{t/\tau}$, and for large values of t it is a linear function of $\exp(-t/\tau)$; here $\tilde{D}$ is inversely proportional to the time constant τ, which itself is proportional to the square of the sample thickness. The depolarization after switching off the current behaves similarly (Fig. 9).[10, 11, 14] The same method can also be used to determine ionic conductivities and chemical diffusion coefficients in efficient electronic conductors such as $YBa_2Cu_3O_{6+x}$ (Fig. 10).[26]

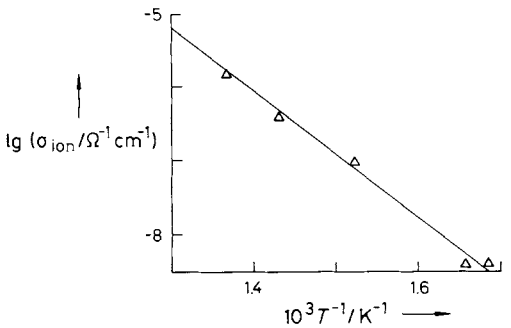

Fig. 10. The steady-state voltage as a function of temperature for an electrochemical polarization cell consisting of $YBa_2Cu_3O_{6+x}$ between ZrO_2 electrodes. The slope yields the ionic conductivity of $YBa_2Cu_3O_{6+x}$ [26].

4.4. Example 4: Modification of Chemical Diffusion by Trapping Effects

The normal relationships need to be radically modified when, in addition to the diffusion process itself, there are reaction processes, especially those associated with the trapping of electronic charge carriers by ionic centers.[29] Localized variations of concentration with time can then also arise from the source and sink terms associated with internal shifts in the equilibria of the trapping reactions, as indicated in Figure 11. These effects require modification not only of the

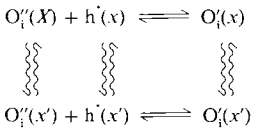

Fig. 11. Diffusion in a solid accompanied by changes in valency represented here as a combined reaction–diffusion process.

flow equations involving the diffusion coefficients, but usually also of the formulas for evaluating these by the electrochemical methods. The details will not be discussed here, but can be found in the literature.[14, 17]

The Fe-doped $SrTiO_3$ material discussed in the last section serves as a relatively simpe application. The usual expression for the chemical diffusion coefficient [Eq. (15)] gives good agreement with the observed temperature dependence at high temperatures, but at lower temperatures the predictions are in error by several orders of magnitude. The trapping reaction shown in Equation (16) is exactly the type of internal reaction that leads to a local particle production through the effects of diffusion, even when there is local equilibrium. It can be shown that Equation (15) must then be modified by including a trapping factor,[17] whose value can be calculated from a knowledge of the defect chemistry. The absolute calculation of $\tilde{D}$ then gives an excellent quantitative fit to the observed temperature dependence (Fig. 12). The underlying

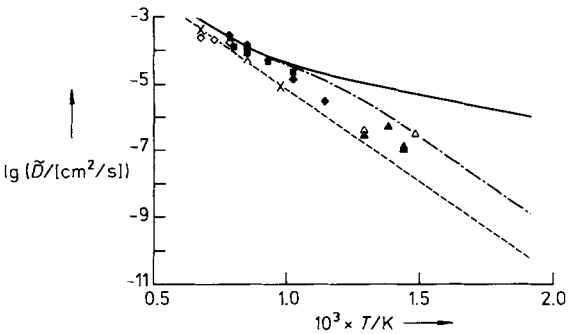

Fig. 12. Temperature dependence of the chemical diffusion coefficient for oxygen in $SrTiO_3$. When dynamic trapping effects are included the theory accounts satisfactorily for the data without recourse to a fitting parameter: —— $\tilde{D}$ without trapping, - - - $\tilde{D}$ with trapping, --- self diffusion coefficient of $V_O^{\cdot\cdot}$; this curve was calculated, symbols are measured values; according to ref. [25].

reason for this is that the process described by Equation (16) provides mobile electronic charge carriers by dissociation of the trapped states for example electron holes from Fe^{4+}, so that a different ($\sigma_{h^{\cdot}} \gg \sigma_{Fe^{4+}} \simeq 0$) effective concentration has to be considered.

For a solid such as YBa_2CuO_{6+x} in which, as explained in Section 3.1.3 of Part I of the review, the differently charged defects O_i'', O_i', and O_i^x must be taken into account, a more general treatment is needed. These defect species are again connected by redox reactions, but can also themselves contribute to the migration process.[14, 17] For this general case Equation (12) is replaced by Equation (18). Here σ_2 and σ_1

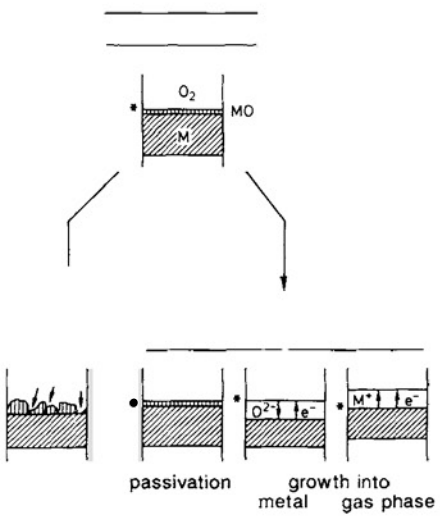
$$\tilde{D} = \frac{RT}{8F^2}\left[\frac{(\sigma_2 + 2\sigma_1)(\sigma_e - \sigma_1)}{\sigma} + 2\sigma_1 + 4s\right]\frac{d\mu_{O_2}}{dc_O} \qquad (18)$$

are the respective contributions of O_i'' and O_i' to the conductivity, and s is an analogous quantity that is proportional to the diffusion coefficient for O_i^x. Equation (18) can be put into a generalized form for all types of charge carriers.[14, 17]

For $YBa_2Cu_3O_{6+x}$ also, one can similarly determine the ionic conductivity and the chemical diffusion coefficient by a Wagner–Hebb polarization experiment,[26] and the self-diffusion coefficient of the oxygen ions by tracer experiments.[21] However, to understand the significance of the quantities measured and their interrelationships, a more detailed consideration is necessary, which takes into account

the redox interactions.[14, 17] In particular, the tracer diffusion coefficient is no longer proportional to the ionic conductivity, nor is the ionic conductivity in the polarized state necessarily the same as the normal ionic conductivity, owing to the dissociation processes. Furthermore, neutral defects play an important role in determining the behavior of the tracer and chemical diffusion coefficients. A simple statistical model based on the defect model in Part I (Section 3.1.3) predicts a thermodynamic factor for $YBa_2Cu_3O_{6+x}$ which is good agreement with the experimental results.[26]

For solid-state reactions that are diffusion-controlled, which is very often the case for specimens of macroscopic dimensions (thickness L), since $J \propto L^{-1}$ the most important kinetic parameter is nearly always the chemical diffusion coefficient. A simple example is the oxidation of a metal M, to its oxide, which was discussed many years ago by Carl Wagner.[31] The reaction begins at the gas–metal interface with the formation of a thin oxide layer. If the molar volume of the oxide in this layer differs significantly from that of the metal,[32] this usually results in the formation of islands or cracks allowing the reaction to progress further by gaseous diffusion (Fig. 13, left). If, on the other hand, a dense layer is formed (Fig. 13, right), further reaction is only possible if



there is a chemical diffusion of either the metal (involving migration of M^+ and e^- in the same direction) or the oxygen (migration of O^{2-} and $2e^-$ in opposite directions). In the former case the oxide grows outward into the gas phase, and in the latter case it grows inward into the metal. If either the ionic or the electronic conductivity is negligibly small at the relevant temperature, as is the case for Al_2O_3 at room temperature, the defect layer has a passivating function.[33] Thus, corrosion of the type described above is only possible if an oxide phase with a mixed conduction mechanism exists. For example, in the case of SnO_2, corrosion would take place through a migration of oxygen vacancies and conduction electrons in the same direction, whereas for ZnO the probable mechanism involves a migration of zinc ions (in the interstitial lattice) and electrons in the same direction (since this is an n-type semiconductor).[34] The effective flow rate of the metal M through the oxide, which determines the rate of reaction, can be determined from Equation (6). This leads to Equation (19). As the flow geometry is known, the rela-

$$J_M = J_{M^+} = J_{e^-} \propto \frac{\sigma_{M^+}\sigma_{e^-}}{\sigma}\frac{\partial \mu_M}{\partial x} \propto \left\langle \frac{\sigma_{M^+}\sigma_{e^-}}{\sigma} \right\rangle \frac{\Delta \mu_M}{L} \qquad (19)$$

tionship can also be expressed in integrated form [Eq. (19), second part]. Here the brackets indicate an average value, since there is usually an appreciable variation in composition, and therefore in conductivity, through the thickness L of the oxide layer. The chemical potential of the metal has its highest (and maximum possible) value on the metal side of the interface, and its lowest value on the gas side; that of the oxygen has its lowest (and minimum possible) value on the metal side, and its highest value on the gas side.

The four main factors influencing the flow rate can be identified (1, 2, 3, and 4 below) from Equation (19). For a high rate the driving force, which is the (average) gradient of the thermodynamic potential for this component ($\Delta\mu_M/L$), must be as large as possible (there is a linear relationship between the flow rate and the driving force). Since there is no gradient on the metal side, this requirement is fulfilled when 1) the oxygen partial pressure is as high as possible, and 2) the layer thickness is as small as possible. However, a high rate also requires that the specific kinetic coefficient (the expression in parentheses) should be sufficiently large; thus the electronic conductivity 3) and the ionic conductivity 4) must both be sufficiently large. (If neutral O atoms can migrate, as is possibly the case in $YBa_2Cu_3O_{6+x}$, then $D_{O_i''}$, represented by s in Eq. (18), also becomes important.) Since the flow rate J, and therefore ultimately the resulting rate of increase of the oxide layer thickness ($\dot{L}$), are both inversely proportional to the thickness ($i \propto L^{-1}$), this yields the well-known square root law [Eq. (20)].[31]

$$L \propto \sqrt{t} \qquad (20)$$

Figure 14 shows that these predictions are confirmed in the case of the oxidation of zinc. The slope is a measure of the

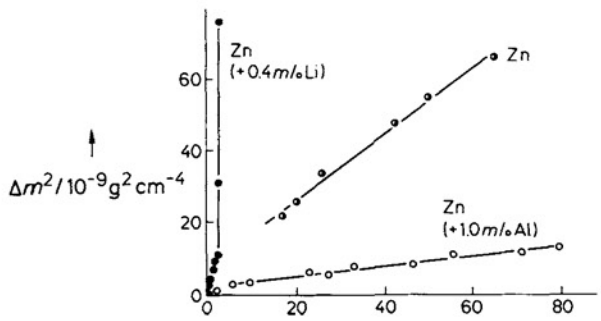


Fig. 14. Progress of corrosion in zinc ($Zn + 1/2\,O_2 \rightarrow ZnO$) with and without doping (Δm = increase in mass, which is proportional to the thickness of the oxide layer; one-dimensional geometry is assumed) [35]. $k_d \propto \langle \sigma_{Zn^{2+}} \rangle$, $\sigma_{Zn^{2+}} \propto [Zn_i^{\cdot\cdot}]$; $T = 390\,^{\circ}C$. (m/o Al: mol % Al).

effective rate constant, which is proportional to $\langle \sigma_{ion}\sigma_{e^-}/\sigma \rangle$. Since electronic conduction predominates in ZnO, this expression reduces simply to $\langle \sigma_{ion} \rangle$. The steep temperature dependence of the ionic conductivity readily explains why the rate of growth of the oxide layer thickness is extremely sensitive to the temperature. The effects of homogeneous doping are clearly evident in Figure 14. In ZnO the ionic conductivity is probably due mainly to zinc ions in the interstitial lattice, although oxygen vacancies are an alternative possibility; in any case, however, the charge carriers are positively charged ionic defects. In either case doping the metal (as in Part I[11]), and therefore also the oxide, with lithium (Li'_{Zn}) causes an increase in the ionic charge carrier concentration. This results, as expected, in much faster corrosion. The effect of the relatively small change in the activity of the metal is insignificant here. Doping with aluminum, which leads to the formation of $Al^{\cdot}_{Zn}$ (or $Al_i^{\cdot\cdot\cdot}$), has the opposite effect, giving a considerable degree of corrosion protection.

Solid–solid reactions can be approached in a similar way. An example is the reaction whereby a spinel is formed from the oxides of two elements[2a] (in this case the mechanism may also involve an ambipolar diffusion of the different cationic species). Figure 15 shows that at large layer thicknesses the growth follows a $\sqrt{t}$ law, whereas for small thicknesses the growth is linear. For small values of L the diffu-

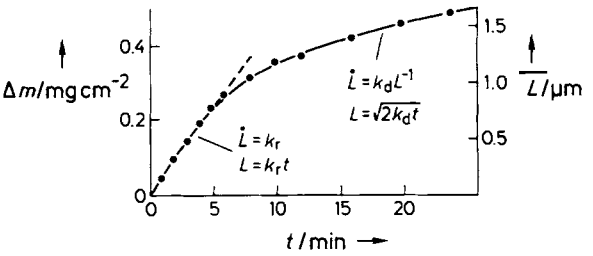

Fig. 15. Growth of the spinel layer ($ZnAl_2O_4$) in the reaction between the oxides ZnO and Al_2O_3 (one-dimensional geometry) [2b]. $T = 1350$ °C.

sion through the thickness is so rapid that the rate of growth $\dot{L}$ is determined by the surface reaction, and is independent of L, and thus $L(t)$ is a linear function. From the foregoing discussion it is clear that, even for the purely diffusion-controlled case, the predicted $\sqrt{t}$ law is based on a number of idealized assumptions (e.g., that space charge effects are negligible, that the interface is planar, and that one-dimensional geometry applies). It would be wrong to suppose that the above approach can lead to a complete and accurate treatment of a real reaction that takes place entirely in the solid state (with complications such as multiple phases, complex – possibly fractal – grain size distributions and geometries, the appearance of new phase boundaries, etc.), even though various attempts at such analyses have been reported. Nevertheless, useful information can be obtained, qualitatively at least, about important parameters, for example the requirements of intimate contact, small grain size, large driving force, or high temperature.

4.6. Example 6: Catalysis at the Surface and in the Interior of Solids

By its presence in a reacting system a catalyst alters the free activation energy but not the position of the equilibrium. This is expressed by Equation (21), where cat represents

$$d\Delta_R G^\circ/d[\text{cat}] = 0 \mp d\Delta G^*/d[\text{cat}] \quad (21)$$

the catalyst. The commonest examples of heterogeneously catalyzed reactions are those in which a solid influences a reaction in the gas state. The usual mechanism involves the adsorption of gas molecules at the surface followed by a reaction in the surface region. The effect of the catalyst in speeding up the reaction relies firstly on the increase in the effective particle concentration. However, in addition to the presence of adsorption centers, it is essential that rapid diffusion should be possible at the surface. Therefore it is not surprising that mixed conductors, a class that includes many transition metal oxides, often have very good catalytic properties.

A surface or interface can be treated as an extended defect, which is characterized by a surface tension; alternatively it can be regarded as an ensemble of interacting point defects, possessing a chemical standard potential different from that of the bulk.[36] In this way, based on the Langmuir theory, the adsorption of a gas molecule G onto the catalyst can be described by Equation (22), in which V_{ad} and G_{ad} are surface

$$G + V_{ad} \rightleftharpoons G_{ad} \quad (22)$$

defects. This might, for example, represent the adsorption of N_2 onto the iron catalyst in the Haber–Bosch ammonia synthesis. By applying the law of mass action to Equation (22) we obtain the familiar Langmuir equation [Eq. (23)], in

$$P_G(1 - \theta) = \theta/K_{ad} \quad (23)$$

which θ is the fraction of the surface sites that are occupied.[37] In many cases the catalyst increases the reaction rate to such an extent that the adsorption becomes the rate-determining step. Since we are dealing with a typical chemical reaction, similarly as in the case of dissociation, recombination, and desorption that might follow, the rate can be adequately described by usual kinetic relationships (for example, forward rate $\propto P_G\theta$) under nonequilibrium conditions. Only when the conditions are very close to equilibrium does this relationship reduce to one of proportionality to the free reaction enthalpy, as is required by linear irreversible thermodynamics (see Figs. 2, 3).

An elegant example of how the defect chemistry influences reaction rates is the HCl elimination reaction of *tert*-butyl chloride, which has been investigated by Simkovich and Wagner.[38] Acid- and base-catalyzed homogeneous elimination reactions are well known in organic chemistry. As described in Part I, doping AgCl with $CdCl_2$ increases the concentration of vacancies that act as bases. It is possible that here it facilitates the detachment of a proton (with subsequent or simultaneous elimination of the chlorine ion). The experiments show that the rate constant is, in fact, proportional to the cadmium concentration.

More recent experiments with AgCl heterogenously doped by contact with Al_2O_3 have yielded a deeper understanding.[39] As expected from the analogy between heterogeneous and homogeneous doping as explained in Part I, the rate of elimination of HCl from *tert*-butyl chloride is in-

creased considerably by the presence of $AgCl:Al_2O_3$ dispersions. Figure 16 shows the pressure increase measured during the reaction. Evidently the increased V'_{Ag} concentration

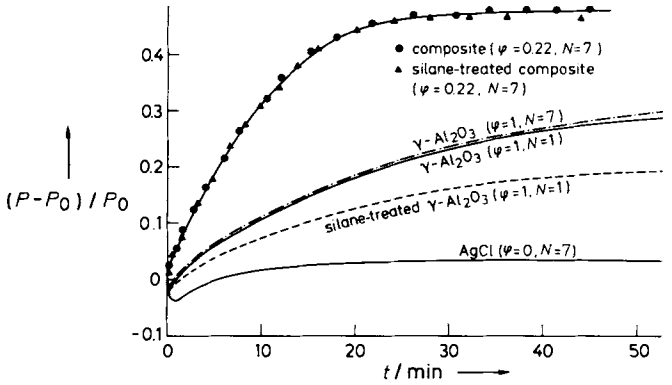

Fig. 16. Fractional pressure increase as a measure of the progress of the reaction during the elimination of HCl from *tert*-butyl chloride, showing the catalytic effect of silver chloride heterogeneously doped with Al_2O_3 (φ = volume fraction of Al_2O_3 in the catalyst, N = number of catalyst pellets). The effects of pure Al_2O_3 and pure AgCl are both very much smaller (despite the greatly increased specific surface area of the former) [39]. T = 423 K, particle size = 0.06 μm.

has the effect of a basic catalyst, facilitating the adsorption of *tert*-butyl chloride and the detachment of a proton. As in the discussion of the boundary effects on the conductivity (see Part I), data on the conductivities of such composite electrolytes[1] yield quantitative information about rate constants as functions of volume fraction, particle size, temperature, and interface chemistry, but restricted space does not allow a detailed description here.

Defect chemistry in the bulk is of special interest in relation to electrocatalysis. In a hydrogen–oxygen fuel cell a considerably higher efficiency is attained than by direct combustion to water, since the chemical energy is converted directly into electrical energy instead of through heat energy. In addition to the importance of the electrolyte (for example, homogeneously doped ZrO_2 as a solid electrolyte oxygen vacancies as charge carriers see Fig. 12 of Part I[1]), the electrodes too play a vital role. If conventional electrodes are used, then the required reaction can only take place at the three-phase junction between the electrode (electron source or sink), the electrolyte (an O^{2-} or H^+ conductor), and the gas phase (O_2–H_2 reservoir), as in the upper diagram of Figure 17. If instead a mixed conductor is used for the electrodes with, for example, O^{2-} and e^- as charge carriers, as is the case for $(La,Sr)CoO_3$, then oxygen can migrate through the solid by chemical diffusion, and oxygen (or hydrogen) can enter at any point on the electrode surface (Fig. 17, lower).

In conclusion it must be mentioned that homogeneous catalysis can also be observed within the solid itself. An example is the more rapid transfer of electrons from the valence band into the conduction band, resulting in the formation of an electron–hole pair (or the reverse process of recombination), that may take place when states within the band gap (recombination centers) are also involved. The process is given, in the structure elements notation, by Equations (24)–(26), where VB and CB represent the valence and conduction bands, respectively. Equation (24) describes the transfer of an electron from the valence band into the redox level, and Equation (25) that of an electron from the redox level into the conduction band. The sum of these two equations is the band-band transfer reaction [Eq. (26)]. In the building elements notation the sum is the pair formation reaction [Eq. (27)] that is already familiar from Part I.

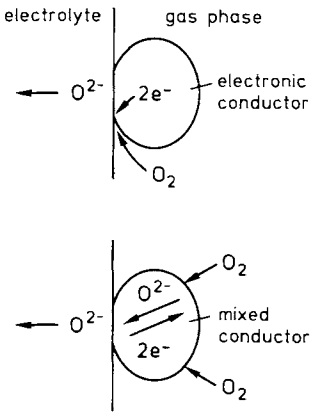

Fig. 17. With conventional metal electrodes, oxygen uptake can only take place at a three-phase junction. With an oxide mixed conductor as the electrode, oxygen can enter at any point on its surface.

$$e'_{VB} + M^{+\,+} \rightleftharpoons M^+ + V_{VB} \quad (24)$$

$$M^+ + V_{CB} \rightleftharpoons M^{+\,+} + e'_{CB} \quad (25)$$

$$e'_{VB} + V_{CB} \rightleftharpoons e'_{CB} + V_{VB} \quad (26)$$

$$\text{nil} \rightleftharpoons e' + h^{\cdot} \quad (27)$$

4.7. Example 7: The Electrochemical Transfer Reaction

The transfer of a charge carrier from the surface into the bulk is neither a conventional reaction ($A \neq B$, $x = x'$ nor a pure transport process ($A = B$, $x \neq x'$). Over the reaction distance there exists a strong electric field as well as a difference in the standard potential. Here, therefore, the analysis of an electrochemical reaction, as represented in Figure 3, must be applied in its most general form [Eq. (1)]. If the current is limited by this transfer step, as is very often the case when the diffusion in the bulk and the sorption at the surface are both rapid, the current–voltage curve takes the form described by the Butler–Volmer equation.[9] Figure 18 shows a current–voltage characteristic measured for CaO-doped CeO_2.[40] At high overvoltages the logarithm of the current, and not the current itself, is a linear function of the overvoltage (i.e. Tafel law instead of Ohm's law). A direct proportionality law only applies close to zero voltage ($U \rightarrow 0$). The resistance corresponding to the ohmic regime is proportional to the exchange current density, which is a measure of the reversibility of the electrode reaction, and can also be interpreted in terms of the defect chemistry.

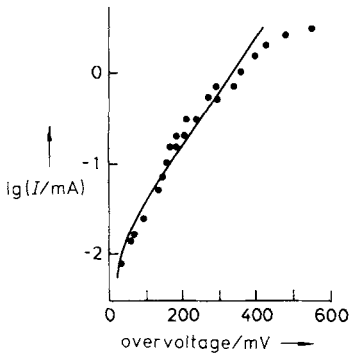

Fig. 18. The steady-state current-voltage characteristic for CaO-doped CeO_2. The kinetic behavior is entirely determined by the phase boundary transfer step, resulting in a markedly nonlinear characteristic [40].

4.8. Example 8: Nonlinear Effects

It has been amply demonstrated here that in transport processes there is normally a linear relationship between rate and driving force (see Fig. 2). Nevertheless, it has been mentioned at several points (e.g., in Section 4.7) that this no longer applies for large driving forces; such behavior is especially common for field effects, and even more so for chemical reactions. In this section, however, the emphasis will be on the type of nonlinear effects that are characteristic of complex systems under conditions far from equilibrum.[41] Even for some quite simple reaction schemes, including those encountered in defect chemistry, conditions leading to nonlinear behavior can arise very easily.

A necessary criterion for equilibrium in a system is that there is no entropy production within the system. In the nonequilibrium case the entropy production is always positive for any process, in accordance with the second law of thermodynamics. Consequently, any (slight) departure from equilibrium results in a retroactive force (negative feedback); this tends to restore the equilibrium state, which is thereby stabilized. Often, however, there are external conditions that hinder the system from attaining its equilibrium state; an example is the previously described case of a specimen through which a current is passed and in which the electron current is blocked by ionic conductor contacts. If a constant voltage is applied in this case, then a steady state becomes established, in which a (reduced) ion current flows through the circuit (cf. the measurement of the ionic part of the conductivity in $YBa_2Cu_3O_{6+x}$, as mentioned in Section 4.3). If the applied voltage is sufficiently small, so that the conditions are close to equilibrium, the entropy production is, of course not zero, but at a minimum according to the principle of Glansdorff and Prigogine.[41] It can also be shown that a steady state close to equilibrium is stable. However, under conditions far from equilibrium we have the interesting situation that a steady state is no longer necessarily stable, and such states can then undergo changes in a variety of ways. The most impressive examples of this are found in living organisms (usually involving chemical reactions).

A kinetic peculiarity that can very easily result in a system becoming nonlinear, and therefore interesting, is autocatalysis (see Fig. 19, top). The process shown here (top row) represents, quite generally, a growth reaction; for example, this might be the multiplication of bacteria, or the growth of a city, as well as impact ionization in a solid (in which an electron already present gives up some energy to form a new electron–hole pair).[41] In such a process the increase in concentration of the product causes an acceleration of the reaction, and the system explodes or produces an allergic response. Here there is a positive feedback mechanism, which drives the system further from equilibrium. It can very easily be shown that Equation (28) then holds. (If the back reaction becomes important, its rate is proportional to $[A]^2$, and in the neighborhood of equilibrium a negative feedback becomes dominant [Eq. (29)], as one expects.) Such a destabi-

$$\delta[A]^{\cdot}/\delta[A] > 0 \tag{28}$$

$$\delta[A]^{\cdot}/\delta[A] < 0 \tag{29}$$

lizing relationship between flow and driving force (e.g., between current and voltage) often occurs in solids when the current density in the system falls with increasing voltage (negative differential conductivity). For example, the impact ionization already mentioned acts in this way.[43] In the second row of Figure 19 the "growth reaction" is accompanied by a competing "decay reaction". Whether or not the species X "survives", to use the biological term, depends not only on the rate constants but also on the "food supply" [A]. If the stationary solution $[X]_{ss}$ (zero or finite) is plotted as a function of [A], it is found that there is a characteristic quantitative change corresponding to a nonequilibrium phase transition. Where there are several species X, the question of whether or not a given species survives is determined entirely by the rate constants and the food concentration, which is assumed to remain constant and is thus inexhaustible. On the other hand, if [A] is not inexhaustible there is a competition situation in which the survival criteria become ever more severe as the process continues, as analyzed by Eigen.[44] If the surviving species now undergo modification, for example through the effects of radiation (mutation in the biological case), these new variants may either replace the old ones or die out. It can be seen that under nonlinear conditions, even very simple reaction sequences can lead to effects analogous to the "biological" phenomena of growth, selection, and mutation. A slightly more complicated reaction scheme can lead to reactions that oscillate with time; examples include the Lotka–Volterra and Belousov–Zhabutinski reactions.[41] The analysis also explains certain spatial effects, especially spatially periodic patterns such as the dissipative structures in the Belousov reaction, or patterns observed in biologial systems.[42] Here the spatial coordinate enters into the analysis due to the fact that diffusion is now an important part of the overall process. Instabilities can destroy the spatial symmetry in such cases. An increasing divergence from equilibrium, passing successively through a number of bifurcation points, can eventually lead to a fractal pattern characterized by a deterministic chaos situation (in which the end result cannot be predicted).

The above discussion obviously has important implications for defect chemistry. Even a small degree of complexity in defect reactions is enough to lead to such effects. Moreover, the reactions are usually linked to diffusion processes. In semiconductor physics especially, effects of the kind de-

autocatalytic reaction	$A + X \longrightarrow 2X$		growth, positive feedback
autocatalytic + decay reaction	$A + X \underset{k_2}{\overset{k_1}{\rightleftharpoons}} 2X$ $X \xrightarrow{k_2} Z$		growth or death
no selection pressure	$[A] = \text{const}$ $W_c = k_1[A] - k_2$		nonequilibrium phase transformation bifurcation
autocatalytic + decay + selection pressure (+ perturbation)	$A + X \longrightarrow 2X$ $X \longrightarrow Z$ $[A] \neq \text{const}$ $W_c = f(t)$		competition selection mutation
Lotka–Volterra reaction scheme	$A + X \longrightarrow 2X$ $X + Y \longrightarrow 2Y$ $Y \longrightarrow Z$		structurally unstable oscillation
Brusselator reaction scheme	$A \longrightarrow X$ $2X + Y \longrightarrow 3X$ $B + X \longrightarrow Y + D$ $X \longrightarrow Y$		limit cycle oscillation
or catalytic CO oxidation	$(CO + O \rightleftharpoons CO;\ Pt_{hex} \rightleftharpoons Pt_{sq})$		symmetry breaking, deterministic chaos
above reaction scheme + diffusion	(e.g. $X(x) \rightleftharpoons X(x')$		compartmentation, dissipative structure in space

Fig. 19. Summary of chemical kinetics under conditions far from equilibrium, showing that even quite simple reaction sequences can result in typical nonlinear phenomena, such as kinetic phase transformations, dissipative structures, and deterministic chaos (see text). B = bifurcation parameter, x = site.

scribed have been observed.[43] A typical autocatalytic reaction is the impact ionization mentioned earlier. Here, for example, an electron whose energy lies in the conduction band causes the formation of a new electron–hole pair as in Equation (30) (the reverse process of Auger recombination),

$$e' \rightleftharpoons 2e' + h^{\bullet} \tag{30}$$

so that the overall effect is an electron-catalyzed growth in the electron concentration. The departure from equilibrium can also often be controlled by an external voltage (overvoltage). Figure 20 shows a nonequilibrium phase transition observed in gold-doped silicon when the applied voltage exceeds a critical value. This corresponds exactly to the third diagram in Figure 19. Here the relevant growth and decay

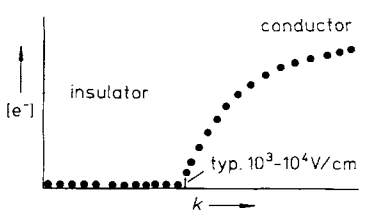

Fig. 20. Nonequilibrium phase transition (from insulator to conductor) in Au-doped silicon, controlled by varying the applied voltage in the nonlinear region [43]. $[e^-]$ = concentration of stationary electrons, k' = rate constant of the impact ionization.

mechanisms are impact ionization [Eq. (30)] and band–band

$$e' + h^{\bullet} \rightleftharpoons 0 \tag{31}$$

recombination [Eq. (31)]. Since the dependent variable in this case is the stationary electron concentration, the effect observed is a (voltage-induced) insulator–conductor transition. Figure 21 shows current oscillations observed with different values of the applied voltage for doped germanium at high electric field strengths, and simultaneous irradiation in the far IR region. As the field is increased the oscillation period is doubled, and eventually deterministic chaos is reached. This is apparent from the "phase portraits" (I vs. $\dot{I}$),

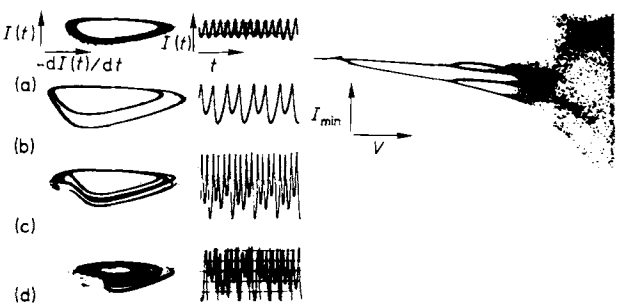

Fig. 21. Periodic structures and chaos phenomena in germanium, controlled by varying the applied voltage in the nonlinear region [45].

from the time evolved $I(t)$, and from the plot of the current minima as a function of the voltage.[45] Finally, Figure 22 shows images from a nonequilibrium structure in p-type germanium, recorded with a scanning electron microscope by using the EBIC (electron-beam-induced current) technique.[46] The bright lines (current filaments) represent zones in which the electron concentration has changed. These are only observed under nonequilibrium conditions, and accordingly disappear when the current is switched off. Spatial (and also temporal) periodic structures and deterministic chaos behavior can also be observed under suitable conditions during the catalytic oxidation of CO on platinum surfaces.[47] The study of nonlinear effects in solids, especially with regard to ionic conduction phenomena, and questions of the morphology can be expected to reveal many more surprises in the future.

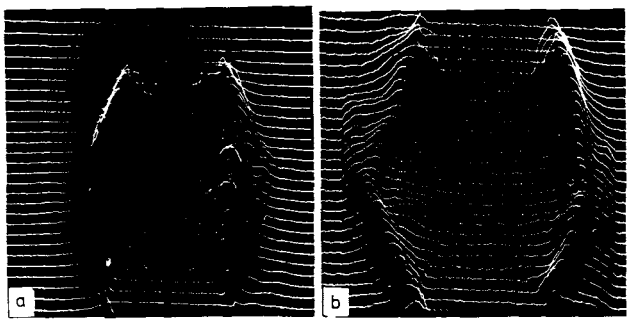

Fig. 22. Current filaments observed by the EBIC (electron-beam-induced current) technique in p-type germanium with two different voltages [46].

5. Summary

The most important points that have been discussed qualitatively in the two parts of this article, the thermodynamic and the kinetic, are the following:

1) All solids with ordered structures exhibit a finite concentration of point defects in thermodynamic equilibrium. Although these are of no consequence for some properties, they play a key role in a wide range of phenomena of importance in chemistry, especially transport and reactivity. With regard to properties such as these, the behavior of a solid cannot be predicted without a prior knowledge of its detailed composition and therefore of the state parameters that control it, for example the oxygen partial pressure in the case of an oxide.

2) Defect chemistry, which is the study and quantitative description of the nature and concentration of such defects and of their interactions, is a logical extension of the solution-state chemistry of the relevant species, of which the most familiar example is the chemistry of aqueous solutions. In an analogous way defect chemistry provides the basis for the thermodynamic and kinetic treatment of solid-state chemistry.

3) As well as leading to a universally valid treatment of the chemistry of ions in the condensed state, the approaches developed in defect chemistry also provide a unified description of ionic and electronic charge carriers, allow boundary layer effects to be incorporated into the overall theory, and enable diffusion to be treated as a special case of an elementary chemical reaction step. In particular, every solid-state chemical reaction must begin at a boundary and extend into the interior by chemical transport.

4) In view of the above, defect chemistry, which is the chemistry of the solid state, is an essential foundation stone of modern materials research. This review has aimed to present the case for defect chemistry, and the examples described are a testimony to its capabilities.

Peptoids—A New Approach to the Development of Pharmaceuticals

By *Horst Kessler**

Molecular recognition of a target is not only the basis of biological regulation and communication, but also the foundation for rational drug design. For an increasing number of diseases, target systems have been identified whose selective inhibition may prevent the progression of the disease or its symptoms, or even provide a complete cure.

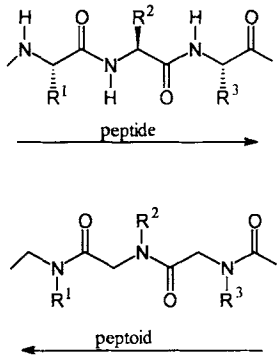
Since most often relatively little is known about the structure and dynamics of the target systems—often macromolecular receptors—the successful direct design of a drug recognized by the target molecule is rare even today. Thus, an efficient screening method is required for testing the effect of a variety of spatial arrangements of different functional groups on the binding and activity against the target molecule. In this respect peptides have been shown to be very suitable because of their modular construction, the large variability of their functional groups, and their rational and automated chemical or biological synthesis.[1, 2] Nowadays, almost every pharmaceutical company has a "peptide group" whose goal is to develop new lead structures for drugs.

The general procedure in the development of peptide mimetics begins with searching for a peptide that binds to the target molecule. Either naturally occurring, biologically active peptides/proteins are used as starting points, or structures are searched for by a systematic screening of peptide libraries.[3] Then the "active sequence" is located by the systematic replacement of each amino acid by Gly, Ala, and/or a D-amino acid.[4] In the next step, the conformational flexibility of this sequence is reduced in order to determine the optimal spatial orientation of the pharmocophors, the groups important for the binding to the receptor.[5] Finally, nonpeptides are sought that have the bioavailability, high selectivity (minimal side effects), high activity (low dosage), and sufficient metabolic stability required for orally administered drugs.

In a recently published report by 16 authors a new, promising concept in the search for active molecules and the localization of the active sequence was suggested:[6] the side chains on the α-carbon atom of the peptide chain are "shifted" by one position along the peptide backbone to the nitrogen atom to give an N-substituted oligoglycine (Scheme 1). The advantages of these new structures, called peptoids, are

- metabolic stability, since natural proteases cannot cleave the N-substituted peptide bond
- great variability in functional groups by simple chemical synthesis
- high flexibility and thus the possibility of probing a large conformational space
- the absence of additional spatial restrictions which are present in peptides due to the chirality of the α-C atom.

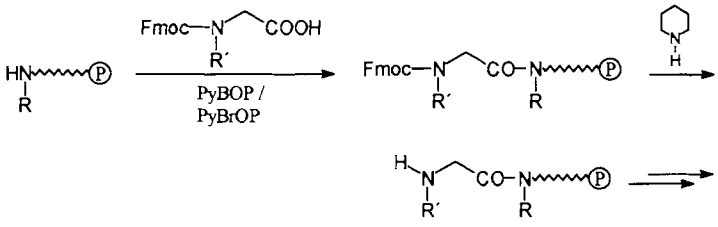
The new concept is in some ways reminiscent of the PNAs recently reviewed in this journal:[7] an achiral, flexible backbone is equipped with functional groups (for PNAs, the nucleobases; for peptoids, peptide side chains) spaced at intervals comparable to those in the naturally occurring polymer. This provides a structurally flexible molecule with the properties required for molecular recognition.



Scheme 1. Comparison of a portion of a peptide chain and a peptoid chain. Note that the direction of the peptide bonds are reversed in the peptoid ("retrosequence") to maintain the relative orientation of the carbonyl groups to the R groups. Peptoids are achiral.

It is evident from inspection of the structures in Scheme 1 that the order of the amino acids must be reversed in the peptoid ("retrosequence") if the carbonyl group contributes to the binding of the target molecule. In fact, the peptide retrosequences had the same behavior as the corresponding peptides in binding to three receptor systems: inhibition of α-amylase by peptides derived from tendamistat, inhibition of the hepatitis A virus 3C protease, and binding to the TAT RNA of the HIV virus.

Two approaches have been used in the chemical synthesis of peptoids. The first synthesis used the technique of Merrifield with Fmoc strategy[8] (Scheme 2). Recently Zuckermann et al. reported an interesting variation using "submonomer" solid-phase synthesis.[9] In both approaches the construction of the peptoid proceeds from the C-terminal to



Scheme 2. Synthesis of peptoids according to the Merrifield method. The protected monomer unit is coupled to the growing chain and then deprotected. The [4-{(2,4-dimethoxyphenyl)aminomethyl}phenoxy]methyl residue serves as a linker (Rink resin); the peptoid can be cleaved from this linker under mild acid conditions. PyBOP = benzotriazol-1-yloxy-tris(pyrrolidino)phosphonium hexafluorophosphate, PyBrOP = bromo-tris(pyrrolidino)phosphonium hexafluorophosphate.

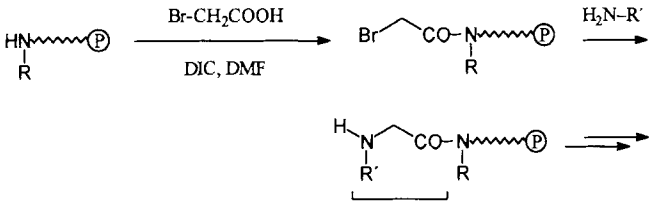
the N-terminal end. The new method (Scheme 3) does not employ the complete, N-substituted glycine unit; instead the amino group of the growing resin-bound peptide chain is converted into the α-haloamide by treatment with chloroacetic acid under standard conditions. The following side chain protected amino group is then introduced by nucleophilic substitution of the halogen (bromine and iodine give better yields than chlorine).



Scheme 3. Synthesis of peptoids by the submonomer solid-phase synthesis. The resin-bound monomer is synthesized stepwise from two building blocks. Since the two steps are different reactions, protecting group chemistry is not necessary and the monomer (designated by ⌴) does not need to be preconstructed. DMF = dimethylformamide, DIC = *N*,*N*'-diisopropylcarbodiimide.

The advantage of this procedure is its flexibility and that it avoids the tedious synthesis and deprotection of the N-terminal Fmoc-protected glycine building block. The efficiency of the method was demonstrated for nine pentapeptoids as well as a 25-mer, which was prepared in 86% yield and 65% purity (by HPLC). It remains to be shown if the problems of purification and the elimination of side products in the submonomer solid-phase synthesis can be solved.

The new class of compounds, the peptoids, opens a new dimension in peptide chemistry. The investigation of their chemical, biological, and structural potential is just beginning. The branch of medicinal chemistry involved with the search for new lead structures for the targeted intervention in pathological processes will certainly benefit from peptoids.

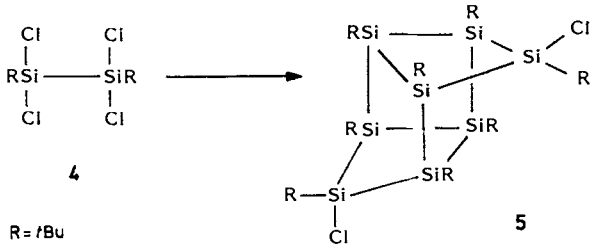
Compounds Containing Silicon, Germanium, and Tin Polyhedra: The First Octahedral Tin Cluster

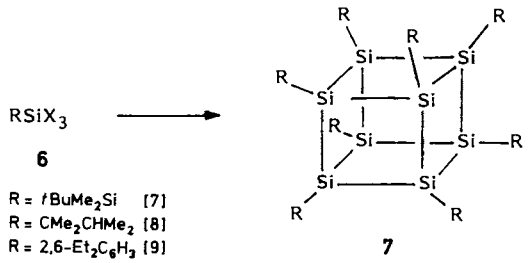
By *Manfred Weidenbruch**

Polyhedral compounds, and in particular the platonic bodies have always aroused a fascination that was founded on the harmony within these molecules. Accordingly, the resonance was large when the platonic hydrocarbons cubane (**1**),[1] tetrahedrane (**2**),[2] and dodecahedrane (**3**)[3] were isolated as derivatives or as the parent compounds.[4]

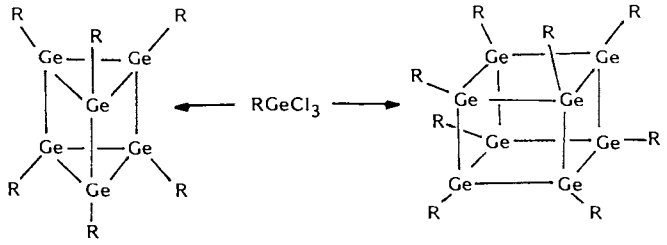
Polyhedral compounds of the heavy carbon homologues, on the other hand, have not been known for long, and only a few have been prepared. It is certainly not the thermodynamic instability of such compounds that complicates their synthesis, since calculations of the tetrahedrane (X_4H_4), prismane (X_6H_6), and cubane systems (X_8H_8) have shown that the strain energies of these molecules decrease to a different extent from X = carbon to the heavier homologues.[5] The problem is rather one of limited accessibility. Whereas for the formation of **1**–**3** the possibilities of organic synthesis were skillfully employed, mostly only one-pot reactions are available for analogous compounds of heavy homologues, in which many bonds are broken and remade.

So the reductive halogen elimination from **4** affords a series of mono- and oligocyclic compounds. Of these, octasilane **5** contains the most cycles.[6] While in **5** the unfavorable orientation of the two chlorine atoms hinders the formation of the cubane framework by another dehalogenation, the use of bulky R groups in silanes of type **4** or **6** indeed leads to octasilacubane **7**,[7] whose structure was proven by X-ray structure analyses on two derivatives.[8, 9]

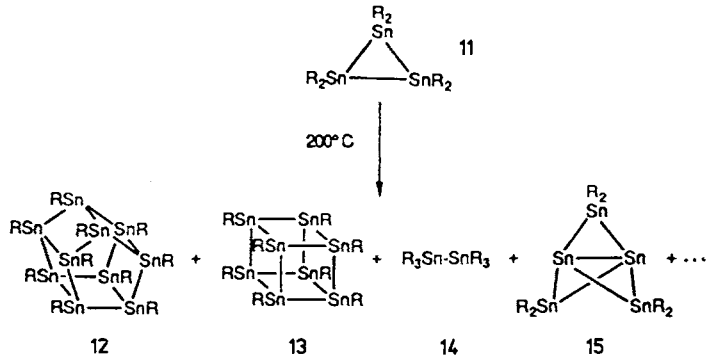




The polycyclic oligogermanes show a similar dependence on substituents. Reductive dehalogenation of *tert*-butyltrichlorogermane or tetrabromo-1,2-di-*tert*-butyldigermane affords the germanium compounds analogous to **5**.[10] The subtle differences in spatial requirements of the substituents R are documented by the reactions of **9** with reducing agents, which either furnish hexagermaprismane **8**[11] or the octagermacubanes **10**.[9]



However, the very low yields of these polycyclic compounds signal that care is necessary—besides the isolated materials, other molecules of this sort are also likely to be present. A good example is the thermolysis of cyclotristannane (**11**) in the presence of naphthalene or benzophenone, which leads to reaction mixtures from which a whole range of polycyclic oligostannanes can be isolated in laborious separations. Decastanna[5]prismane **12**,[12] octastannacubane **13**,[13] and pentastanna[1.1.1]propellane **15**[14] are successively isolated together with distannane **14** and other tin-containing products. It is clear from the spectrum of products that the stannylene R_2Sn: resulting from the decomposition of **11** affords compounds both of the type $(RSn)_{2n}$ and other compositions by disproportionation with aryl group migration.

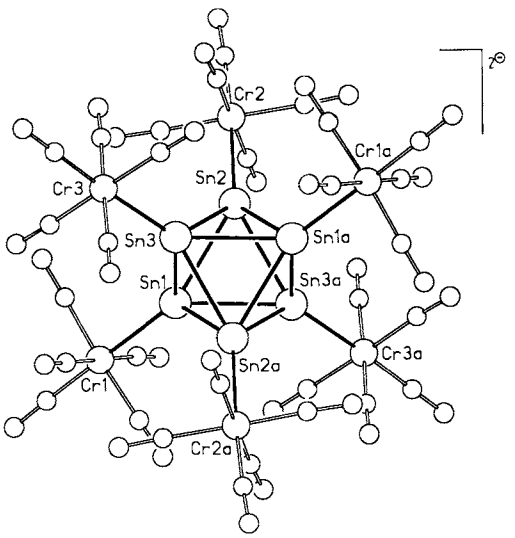


The striking feature of the compounds containing polyhedra of silicon, germanium, and tin is the dominance of the [*n*]prismanes. Results of theoretical studies also predict that these are the preferred products.[5, 15] For example, calculations on Si_6H_6 revealed that hexasilaprismane is more stable

[*] Prof. Dr. M. Weidenbruch
Fachbereich Chemie der Universität
Carl-von-Ossietzky-Strasse 9–11, D-W-2900 Oldenburg (FRG)

than hexasilabenzene, which is, in turn, distinctly lower in energy than hexasilaoctahedrane.[15] This result seems feasible, since in octahedral molecules X_6R_6 the skeletal atoms X would each be five-coordinate.

That with a suitable number of framework electrons and the correct choice of the protecting groups an octahedron can also be the coordination polyhedron has now been demonstrated by Schiemenz and Huttner in a noteworthy paper. Treatment of $SnCl_2$ with $K_2[Cr(CO)_5]$ in the presence of [2.2.2]cryptand yielded the cluster anion **16**, which has an almost perfect octahedral arrangement of the tin atoms.[16]



16

Formally **16** is composed of six stannylene-like building blocks, $[(OC)_5CrSn:]$. As a result, on inclusion of the two negative charges with the electron pairs of six skeletal atoms, a total (6 + 1) pairs of electrons are available for the bonds within the cluster. According to the Wade rules, **16** is analogous to $B_6H_6^{2-}$, a *closo* compound that with six skeletal atoms is expected to have the octahedral structure proven here.[17] Interestingly, the octahedral clusters of main group elements were only known in the case of boron. In the field of Zintl ions, which is certainly not lacking in homonuclear polycyclic compounds, the octahedral structure is found as construction principle only in the hexaborides of the CaB_6 type.[18, 19] Even though **16** was in fact formed rather incidentally, and as yet only in low yields, the concept shown here seems to be generalizable and might serve as basis for the synthesis of other polyhedral molecules or molecular ions.

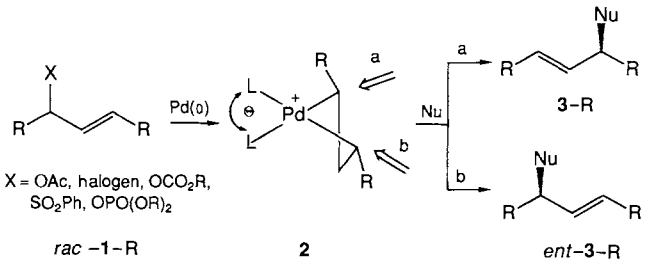
Palladium-Catalyzed, Enantioselective Allylic Substitutions

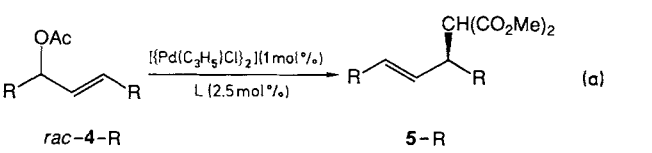
By *Oliver Reiser**

The development of enantioselective-catalyzed reactions has led to great success over the past few years. Numerous chiral metal catalysts have been tested, which have achieved a wide range of selectivities, never thought possible, for a great number of reactions by using tailored ligands.[1] A problem in the catalysis repertoire was palladium-catalyzed, enantioselective allylic substitution.[2] Elegant mechanistic investigations have contributed to the development of this reaction as a valued method of synthesis. The understanding of factors such as the initial conformation of the allylic component,[3] the nature of its leaving group,[4] the conformation of the intermediate allylic palladium complexes,[5] the hardness of the nucleophile,[6] and the electronic and steric properties of the ligands bound to the palladium center,[7] today allow such substitution reactions to be carried out with high regio- and diastereoselectivities.

Most of the asymmetric allylic substitution processes start from racemic allylic components *rac*-**1**-R (where for **1**-R, R designates the general group of the compound, e.g. **1**-Me is **1** with R = Me), which in the absence of chiral ligands form *meso* complexes of the type **2** with palladium(0). Since a nucleophile can attack at either of the two ends of the allylic component, the enantiomers **3**-R and *ent*-**3**-R are formed. The degree of the enantioselectivity of a reaction depends on how well a chiral ligand in **2** can direct the attack of the nucleophile (Nu) to *one* of the two allylic termini.



The problem with allylic substitutions, such as reaction (a), is that a soft nucleophile attacks the complexes **2** from the side opposite to the ligands L; as a result the distance between the reaction centers and the chiral inductor is large.

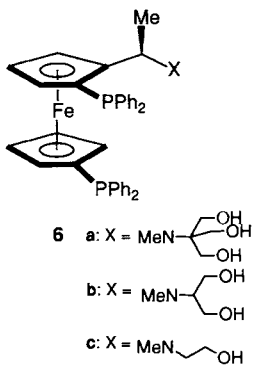


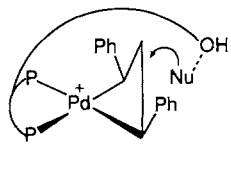
Thus, it is not surprising that ligands which are normally highly selective, such as (+)-DIOP,[8] achieved an enantiomeric excess of only 22% *ee* (Table 1) for the preparation of **5**-Me.[9] Even ligands such as BINAP[8], or Chiraphos[8] have so far only shown a high selectivity for few substrates.[10] As a result, ligands were developed which can "reach over" to the *exo* side of the allylic complexes **2**, for example the ferrocene **6** designed by Hayashi.[11] In the allylic complex **7** a flexible hydroxyl group of the phosphane ligand directs the nucleophile. With this ligand **5**-Ph was synthesized in up to 96% *ee*.

Table 1. Enantioselective allylic alkylation of *rac*-**4**-R according to Equation (a).

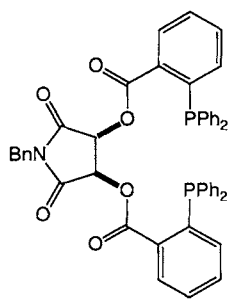
4-R	5-R	L	Yield [%]	% *ee*	Ref.
4-Me	5-Me	(+)-DIOP [c]	66–88 [a]	22	[9]
4-Me	5-Me	**17**-*t*Bu	96 [b]	71	[18]
4-*n*Pr	5	**17**-*t*Bu	96 [b]	69	[18]
4-*i*Pr	5	**17**-*t*bu	88 [a]	96	[18]
4-Ph	5-Ph	**6a** [d]	85 [a]	96	[11]
4-Ph	5-Ph	**6b** [d]	97 [a]	90	[11]
4-Ph	5-Ph	**6c** [d]	80 [a]	86	[11]
4-Ph	*ent*-5-Ph	**13**	99 [b]	95	[14b]
4-Ph	5-Ph	**14**	97 [b]	97	[14b]
4-Ph	5-Ph	**16** [e]	63 [a]	68	[17]
4-Ph	5-Ph	**16** [f]	89 [a]	81	[17]
4-Ph	5-Ph	**17**-Ph	99 [b]	99	[18]

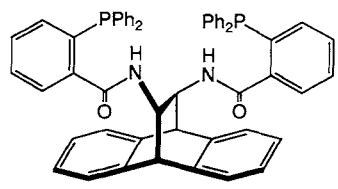
[a] $NaCH(CO_2Me)_2$. [b] $CH_2(CO_2Me)_2$, BSA, KOAc. [c] 100 mol% $PdCl_2$, 200 mol% ligand. [d] 0.5 mol% $[\{Pd(C_3H_5)Cl\}_2]$, 1 mol% ligand. [e] 2.5 mol% $[\{Pd(C_3H_5)Cl\}_2]$, 10 mol% ligand. [f] 2.5 mol% $[\{Pd(C_3H_5)Cl\}_2]$, 50 mol% ligand.





A different concept is pursued with the synthesis of ligands which are derived from 2-diphenylphosphinobenzoic acid.[12] By the coordination of **8** or **9** to palladium a 13-

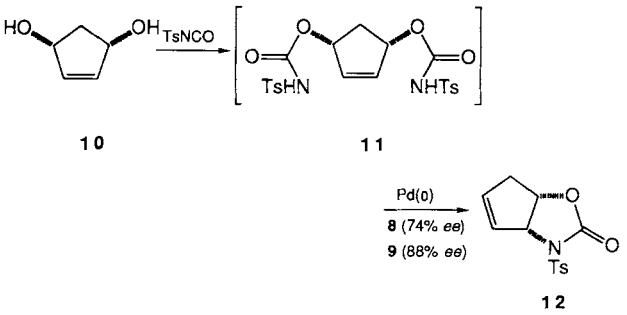




[*] Dr. O. Reiser
Institut für Organische Chemie der Universität
Tammannstrasse 2 D-W-3400 Göttingen (FRG)

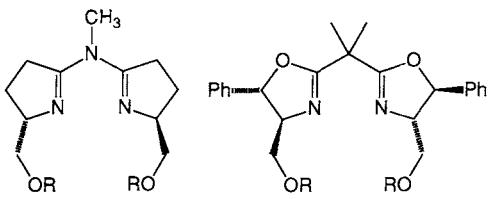
membered ring is formed each time. This chelate ring extension causes an increase of the bite angle θ in **2**, whereby the chiral centers of the ligands are positioned closer to the allylic component.

The *meso*-ditosylcarbamate **11**, which is generated in situ from the diol **10**, cyclizes to give the oxazolidinone **12** with up to 88% *ee*; the highest enantioselectivity for this system obtained so far. Unfortunately, there are no selectivity values of **8** or **9** (as yet?) for substitutions at **4**-R, so that a direct comparison of the different ligand concepts is not possible.



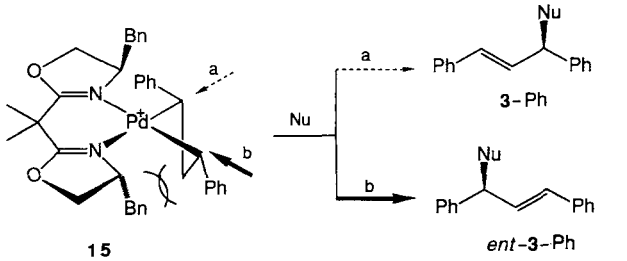
10 **11** **12**

C_2 symmetric, chiral semicorrines[13] and bis(dihydrooxazoles)[14] have given a great boost to catalysis research over recent years. They have also proved to be efficient ligands in the enantioselective synthesis of **5**-Ph and *ent*-**5**-Ph,[14b] although these ligands neither "attack" the *exo* side of the complex **2** nor can they increase the bite angle θ in the macrocyclic chelate. A selectivity of 95% *ee* is achieved for the substitution at **4**-Ph with ligand **13** and with **14** even one of 97% *ee* (see Table 1) in an almost quantitative reaction. For this substitution, instead of sodium dialkylmalonate as nucleophile, the use of a mixture from dimethyl malonate and *N*,*O*-(bistrimethylsilyl)acetamide (BSA) proved successful.[15]



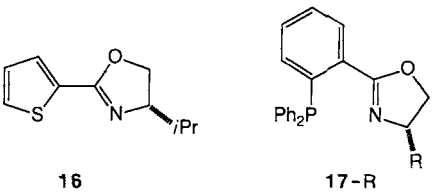
13 R = $SiMe_2tBu$ **14**

These excellent results, supported by an X-ray structure analysis of complex **15**, could be explained convincingly;[16] one benzyl group in the ligand and one phenyl substituent at the allylic terminus repel each other considerably. This steric hindrance is, for example, illustrated by a clear twisting of the dihydrooxazole ring in question and from the lengthening of the corresponding Pd–C bonds. The nucleophile attacks at the allylic terminus which is sterically strained, since in this way, in combination with the rupture of the Pd–C bond, the steric strain can be reduced.



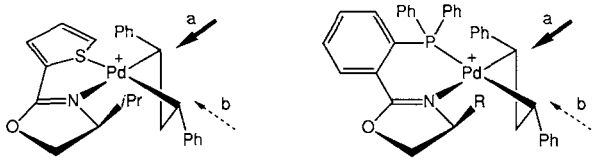
15

If people have so far been under the impression that the basic condition for an efficient ligand is C_2 symmetry, they might have to change their ideas as a result of two very recent publications. The ligand **16**, consisting of a chiral dihydrooxazole and an achiral thiophene unit, leads to only a moderate enantioselectivity of 68–81% *ee* for the reaction of **4**-Ph and sodium dimethylmalonate; however, a new principle is illustrated here, according to which the selectivity in metal-catalyzed reactions can be controlled by steric and stereoelectronic factors.[17]



16 **17**-R

The most favorable arrangement sterically between the allylic component and **16** should occur in complex **18**. The thiophene ligand as an electron-rich π system acts as donor and, as a result of the *trans* effect, should transfer electron density to the allylic carbon atom *trans* to the sulphur atom. This carbon atom should less willingly undergo nucleophilic attack because of the increased electron density. Thus, the favorable attack occurs by route a to give **5**-Ph.



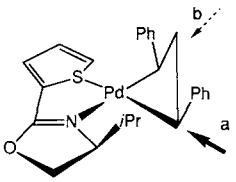
18 **19**

Ligand **17**-R has two different coordination sites, in this case, a triphenylphosphane and a dihydrooxazole unit. Ligand **17**-R shows record selectivities (Table 1) not only for the substitution of **4**-Ph, but for the first time also with alkyl-substituted propenylacetates.[18] If here, too, the most favorable conformation sterically **19** is taken as the starting point, the attack of the nucleophile occurs *trans* to the nitrogen atom. However, this is surprising in view of the model established for **18**, since the triphenylphosphane group should clearly be a better π-acceptor than the dihydrooxazole unit, and this should be transferred to a position at the allylic terminus *trans* to the acceptor.

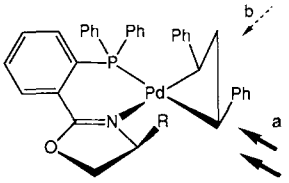
An interesting NMR study provided an explanation for these stereoelectronic facts.[19] According to this study, in an allylic palladium complex the carbon atoms of the allylic

termini are shifted with increasing acceptor strength of the ligands (e.g., change from nitrogen to phosphorus coordination) to higher field in the ^{13}C NMR spectrum. This effect is particularly marked for the carbon atom in the position *trans* to the ligand. With the necessary caution required when dealing with the correlation of ^{13}C NMR shifts with charge distributions, this is an indication that the electron density of an allylic carbon atom *trans* to the phosphane ligand, in comparison to the nitrogen ligand, should be reduced significantly.

It can be noted that **18** and **19** are attacked by the nucleophile mainly at the same allylic carbon atom, despite their different electronic properties. This might be an indication that neither structure **18** nor **19** is the reactive conformation. Finally, a speculative mechanism may be proposed: is it possible that through a π–σ–π mechanism an equilibrium **18** $\rightleftharpoons$ **20** and **19** $\rightleftharpoons$ **21** predominates, whereby **20** and **21** are significantly more reactive towards nucleophiles than **18** or **19** because of their greater instability? In addition to the



20



21

stereoelectronic factors, the aspect of reduction of the steric strain during the attack of the nucleophile would again become important. Whereas in **20** steric and stereoelectronic factors work against each other, these problems do not occur in **21**: the attack *trans* to the triphenylphosphane ligand simultaneously reduces the steric strain. This model could explain the superior selectivity of **17** over **16**, despite their very similar steric volume.

Further mechanistic investigations, developments, and applications of ligands such as **16** or **17**-R are eagerly anticipated. Although 1993 has only just begun, **17**-R might already be a promising candidate for the reagent of the year. Without doubt, palladium-catalyzed allylic substitution has been transformed from the cinderella to a princess of catalysis.

Concerning "An Opinion on the Heterogeneous Photoreduction of N_2 with H_2O"

First Letter

By *Vincenzo Augugliaro** and *Javier Soria*

In a recent commentary, Edwards et al.[1] reported on the inefficiency in their attempts to photoreduce molecular nitrogen on heterogeneous surfaces. They used coprecipitated or surface-loaded iron-doped titania and certain single or binary oxide xerogels for performing two types of irradiation experiments in the presence of $N_{2(g)}$ enriched to 99% with ^{15}N and water vapor or liquid water. Though we accept the main conclusion of their work, namely that the authors were unsuccessful in photosynthesizing ammonia, in our opinion, on the basis of the results of their own negative experiments, Edwards et al. should question the reasons for their unsuccessful runs, instead of questioning the reproducibility of this intriguing reaction, which was first described in 1977[2] and which has since been reproduced in different laboratories[3, 4] under similar experimental conditions and with different TiO_2-based photocatalysts.

We believe that readers of Angewandte Chemie should be made aware of the fact Edwards et al. performed most of their experiments under conditions substantially different from those described in the literature and with different and inadequately characterized photocatalysts. Thus, most of their photoreduction experiments were conducted with "single or binary oxide xerogels" whose photocatalytic activity has not been documented in the scientific literature[5] and which, on the basis of our experience, are not expected to be photoactive. Moreover, the great majority of irradiation experiments were conducted in aqueous suspensions in which photoreduction of nitrogen is not generally observed. Only a total of twelve irradiation experiments were apparently performed with iron-doped TiO_2 powders of not reported composition and characterization which were allegedly prepared according to published procedures.[2, 3] We stress the point that the specimen preparation is crucial for the success of the process; this is why all papers in the field of heterogeneous catalysis report details on the specimen preparation and characterization. All researchers working in heterogeneous catalysis are well aware that an undetected contamination can invalidate all the findings. For the preparation of photocatalytically active TiO_2 powders, the iron-doped anatase must be subjected to a heat-treatment to effect a rearrangement of anatase into rutile. This requires carefully controlled conditions, since it is accompanied by drastic changes in crystal sizes and surface areas (see e.g., refs. [3, 6]). It is difficult to assess whether Edwards et al. had catalytically active powders as they did not provide details such as the rutile/anatase ratio, particle size, or the surface areas. Neither were specifications given for the photoreactivity runs. The reaction conditions such as mass of catalyst, time of irradiation, irradiated surface area of catalyst, temperature inside the photoreactor, and method of avoiding warming of catalyst due to the IR radiation of the 450 W lamp used were absent. The authors worked in batch vessels of quartz, which thus were more UV-transparent than our Pyrex vessels or our Pyrex continuous photoreactor. This may have favored the photooxidation of ammonia which becomes a side reaction especially after longer irradiation periods.

The authors are certainly correct in warning against ammonia contamination problems. However, it must be stressed that although contamination could explain random results, it could not explain trends in photoreactivity or changes in activity in response to changes in operating conditions or photocatalyst composition.[3] We call to mind the experiments[4] in which cycles of activation–deactivation of photocatalyst were clearly observed and also explained on the basis of ESR spectra performed contemporaneously with the photoactivity experiments. Only an "intelligent" contamination could explain all the results obtained in the field of dinitrogen photoreduction.

In discussing the possibility of direct nitrogen photooxidation reactions, a previously published paper should have been quoted.[7] Last but not least, the remarks made by Edwards et al. on the photoreduction of nitrogen on desert sands are quite unfounded as Schrauzer et al.[8] clearly explained how they calculated the ammonia yields from their $^{15}N_2$ experiments. Moreover, they also reported the yields of nitrogen photooxidation products, and already pointed out that ammonia photooxidation occurs as a side reaction.

Second Letter

By *Leonardo Palmisano, Mario Schiavello,** and *Antonino Sclafani*

Edwards et al.[1] in their communication in essence convey the impression that the photoreduction of dinitrogen on heterogeneous photocatalysts is thermodynamically close to impossible and that the ammonia yields observed by previous workers[2, 3] may have been due to erroneous measurements of background contamination.

The authors furthermore claim to have conducted numerous experiments with promising photocatalysts under conditions identical to those used by the earlier investigators. This is actually not quite true. For example, Edwards et al. performed their experiments in quartz, rather than Pyrex vessels and employed, a medium-pressure Hg lamp; accordingly, the relative contribution of short UV light was higher than in the experiments conducted by us and most other workers in the field. Furthermore, and more seriously, the majority of the experiments seem to have been done with solids that would be expected to have little or no photocatalytic activity. Thus, Edwards et al. performed most of their experiments with "binary oxide xerogels" composed of TiO_2, Fe_2O_3, NiO, Al_2O_3, and SiO_2, which we would judge to have little chance of being photoactive in the first place. Only very few experiments were actually performed with iron-doped TiO_2 under conditions where nitrogen photoreduction could have taken place. In these experiments, the Fe–TiO_2 photocatalysts must first be heat-treated at defined temperatures and for known periods of time and subsequently stored in humid air. From the information given, it is our impression that the authors did not spend enough time and effort to optimize the photocatalyst pretreatment conditions. It should be recalled that only homogeneous samples having Fe^{3+} ions in the lattice of TiO_2 are photoactive. Heterogeneous samples, that is, those in which the surface is covered by iron oxides, or those with mixed iron–titanium oxides such as Fe_2TiO_5 on the surface, are photochemically completely inactive. The heat treatment temperature must be chosen so that the anatase–rutile conversion does not occur too rapidly. Prolonged heating at temperatures that are too high produces large crystals of low or zero photocatalytic activity. The optimal heating temperatures and times must be determined for each batch, as both vary from sample to sample, and numerous samples must be prepared and tested individually prior to the actual photoreduction experiments.

Based on the evidence provided, we can only conclude that Edwards et al. probably never had active photocatalysts at their disposal. Furthermore, we must point out that their discussion of the thermodynamics of dinitrogen photoreduction is also seriously flawed and misleading. They argue that the yields would have to be "absurdly low" (on the order of 10^{-50} M with respect to NH_3 or O_2) in view of the unfavorable thermodynamic equilibrium concentrations of the reactants. This reasoning is naive inasmuch as many thermodynamically "uphill" reactions involving TiO_2 are already well documented. Best known among these is the water splitting reaction (a).[4]

$$3H_2O + h\nu \rightarrow 3H_2 + 3/2\ O_2 \qquad (a)$$

This reaction is possible because the potential corresponding to the band gap in TiO_2 (E_{cb}) is negative vs. the normal hydrogen electrode (NHE) ($E_{cb} < E_{H^+/H_2}$), for any pH value. From the Pourbaix diagram,[5] the reduction potential E_{N_2/NH_3} is positive vs. NHE ($E_{N_2/NH_3} > E_{H^+/H_2}$). Since the formation of NH_3, according to Equation (b) is known, it follows that, irrespective of mechanism, the photoreduction of N_2, according to Equation (c) in feasible given TiO_2' band gap energies.

$$N_2 + 3H_2 \rightarrow 2NH_3 \qquad (b)$$

$$N_2 + 3H_2O + h\nu \rightarrow 2NH_3 + 3/2\ O_2 \qquad (c)$$

Last but not least, we must reject the suggestion that our NH_3 yields were due to background contamination. This source of error was always safely eliminated by conducting blank experiments either in the absence of photocatalyst or in the dark.

Reply: Standards of Demonstration for the Heterogeneous Photoreactions of N_2 with H_2O

By *Julian A. Davies* and *Jimmie G. Edwards**

The claim that ammonia can be synthesized catalytically from nitrogen and water in the presence of simple metal oxide powders by the action of light suggests a process of overwhelming importance to the future of the human race. For that reason, the possibility deserves our utmost attention. For the same reason, it can be very enticing to conduct large numbers of experiments with various potential catalysts that appear to produce tantalizingly small amounts of ammonia, as has been occurring now for fifteen years. If the small amounts are adventitious and not photosynthetic, all the effort has been wasted, and nothing positive has been added to the human condition. The concept of a major discovery that remains continually on the borderline of demonstration is internally inconsistent. It behooves us, then, to settle this issue now by setting guidelines to decide the validity of this putative process. If the claim is valid, we should proceed to fulfill its stupendous promise of a completely renewable, solar-driven source of ammonia. Our communication[1] gave such guidelines and expressed our skepticism about the validity of the claim.

In the correspondence,[3] the authors object to the procedures and conclusions given in our Communication. We are nonplussed by the statements, "Only an 'intelligent' contamination could explain all the results..." and "...irradiated surface area of catalyst..."[2a] and by the unusual coefficients in Equation (a).[2b] We did note that this choice of coefficients makes the reaction have about the same ΔG°(298 K) as that of their putative reaction (c). Both correspondents take us to task for not fully referencing prior published work or providing complete experimental details. We followed the "Instructions to Authors" where the page limit (inclusive of all literature citations) and the instruction to summarize experimental details in Communications for *Angewandte Chemie* are clearly stated. Full experimental details of our work are available elsewhere,[3] and more work is to be published in the near future. A complete review by us of the literature in this field has been accepted for publication.[4] Our Communication included only our statistically most significant results, exactly as stated therein.

The correspondents dismiss our results with the assertion that they are possessed of special arts in catalyst synthesis not known to us and that our reaction conditions were somehow unsuitable for the putative photoreaction: "it is difficult to assess whether Edwards et al. had catalytically active powders..."[2a] and "Edwards et al. probably never had active photocatalysts at their disposal".[2b] We confirm unequivocally that no powder that we examined ever showed any statistically significant catalytic activity for the putative photoreaction under discussion here. Despite the claims that only very special substances prepared under highly controlled conditions will catalyze the putative reaction, a vast array of different materials, prepared and characterized by diverse techniques, has been examined for potential photocatalysts of this reaction, and success with them has been reported by many workers.[4] Low levels of ammonia have been reported from reactions that employed vastly different putative catalysts, among them desert sands, and that were performed under very different experimental conditions. It is stated[2a] that "It should be recalled that only homogeneous samples having Fe^{3+} ions in the lattice of TiO_2 are photoactive." The origin of this statement is obscure to us, especially in the light of the work on desert sands (cited in[2a]) whose precise structure and homogeneity are unknown. In connection with this topic, we note that a review article by Augugliaro and Palmisano cites without critical comment a report that boiling chips catalyze the putative photosynthesis of ammonia.[5]

Statistically significant results that unequivocally confirm the photocatalytic synthesis of ammonia from nitrogen and water over oxide catalysts are not found in the literature.[4] If the correspondents are indeed possessed of special arts in catalyst synthesis, then it would be straightforward for them to prepare catalysts that can generate ammonia from $^{15}N_2$ at a level where unambiguous demonstration is routine[3] and where a statistically significant number of experiments can easily be performed. We note the operational technique[2b] ("....numerous samples must be prepared and tested individually prior to the actual photoreduction experiments") where it seems each batch of catalyst was tested and only those that produced the desired result were reported. The authors state that we "claim to have conducted numerous experiments with promising photocatalysts under conditions identical to those used by the earlier investigators." We made no such claim in our Communication. Here we ask both correspondents to publish the specific conditions necessary to prepare effective catalyst powders, and the specific parameters and their values that identify the powders as effective, so that their operational selection method can be avoided.

We believe that no more effort should be expended on production of tiny amounts of ammonia from natural nitrogen as described in most of the published work. We have demonstrated a variety of ways by which adventitious ammonia and various other contaminants can give false indications of ammonia synthesis at such levels.[3] In view of the enormous importance of the putative photoreaction, the cost of isotopically enriched nitrogen gas is small; furthermore, the use of isotope-ratio mass spectrometers in correctly designed, statistically significant experiments can settle the issue conclusively.

After we have been proven wrong in our skepticism, and this new, extraordinarily important way of catalyzing ammonia synthesis has been firmly established, scientists will then face the challenge of understanding the process. In particular, it will be a demanding task to learn how a material as simple as iron-doped titania (or even a boiling chip) can contain sites so special that they organize at least one molecule of nitrogen, three molecules of water, six electrons, six holes, and enough photons to generate the electrons and

holes in a way that can drive the reaction uphill by more than 600 kJ mol^{-1}. The energy problem might be worse in Pyrex vessels, to which both the correspondents refer, since in such cases only the lower energy photons can contribute to the energy balance. The thermodynamic and kinetic issues we raised in our Communication cannot be rationalized away, despite the argument that our "discussion of the thermodynamics of dinitrogen reduction is [also] seriously flawed and misleading".[2b] The analogy of water photolysis [$H_2O \rightarrow H_2 + 1/2\ O_2$] is used,[2b] a process that is best conducted photoelectrochemically, and that minimally requires only a single reactant molecule and which can be driven uphill by a single photon of UV radiation unless its equation is balanced in the misleading way of their Equation (a). The analogy fails.

Augugliaro and Soria[2a] raise the issue of photooxidation of ammonia, a process readily catalyzed by every powder we synthesized. This mechanistically fascinating but thermodynamically favorable process has been firmly established since the early work of Gopalarao et al.[6] We observed it whenever we irradiated aqueous ammonia in the presence of gaseous nitrogen and a titania-based powder. We have considered the possibility that titania-based catalysts 1) promote nitrogen reduction at one type of site and ammonia oxidation at a second type of site, or 2) promote nitrogen reduction at one wavelength of incident radiation and ammonia oxidation at a second wavelength; each of these processes would fix nitrogen. However, we found no statistically significant evidence of fixed nitrogen, as reported in our Communication.

In conclusion, we advise those who would continue with this line of research to attend to the standards of demonstration we set in our Communication, this letter, and elsewhere.[3, 4]

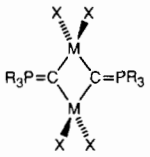
Ti^{IV} Complexes with Bridging Ylide Ligands: Double Oxophiles in Reactions with Aldehydes

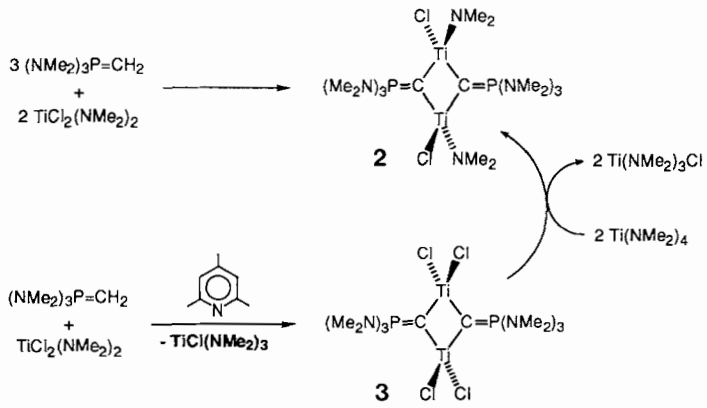
By *Karin A. Hughes, Pablo G. Dopico, Michal Sabat,* and *M. G. Finn**

The series of complexes of Group 4 metals with bridging ylide ligands and the general structure **1**, prepared by Schmidbaur and co-workers,[1] comprise an interesting combination of phosphorus and early transition metal oxophiles. We report here two new examples of this class of metallacycles and the selective production of allenes from their reactions with aromatic aldehydes.



1

When an excess of $(Me_2N)_3P{=}CH_2$ was treated with $TiCl_2(NMe_2)_2$ according to the general procedure of Schmidbaur[1c,d] (by employing the phosphorus methylide as base as well as nucleophile), complex **2** was obtained, the first such compound having different terminal ligands on titanium (Scheme 1). The X-ray crystal structure analysis of **2** revealed the centrosymmetric structure shown in Figure 1, with a *trans* orientation of Cl ligands.[2] While the bond lengths and angles of **2** are similar to those in the analogous complex $[\{(Et_2N)_3P{=}C{-}TiCl_2\}_2]$,[1c] π-donation from the amido ligands results in slightly longer Ti–Cl bonds and shorter Cl–P1 bonds in **2**.



Scheme 1. Synthesis of complexes **2** and **3**.

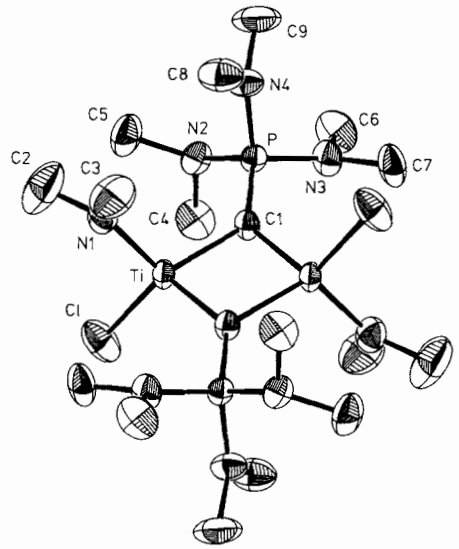


Fig. 1. Crystal structure of **2** (ORTEP). Selected bond lengths [Å] and angles [°]: Ti-Cl 2.303(2), Ti-N1 1.928(4), Ti-Cl 2.014(4), Ti-Cl* 1.936(4), Cl-P 1.693(4), P-N2 1.673(4), P-N3 1.660(4), P-N4 1.650(4); Cl-Ti-Cl 115.5(1), Cl-Ti-Cl* 114.8(1), N1-Ti-Cl 111.7(2), Cl-Ti-Cl* 87.6(2), Ti-Cl-Ti* 92.4(2), Ti-Cl-P 131.8(2), Ti*-Cl-P1 135.5(2).

The addition of 2,4,6-trimethylpyridine to an equimolar mixture of ylide and $TiCl_2(NMe_2)_2$ provided the new metallacycle $[\{(Me_2N)_3P{=}C{-}TiCl_2\}_2]$ (**3**) instead of **2**, in a yield of 17% (Scheme 1). The crude reaction mixture was found to contain a substantial amount of $TiCl(NMe_2)_3$ arising from disproportionation of $TiCl_2(NMe_2)_2$, which implies that the other disproportionation product, $TiCl_3(NMe_2)$, is the active reagent for the synthesis of **3**. However, use of $TiCl_3(NMe_2)$ in place of $TiCl_2(NMe_2)_2$ afforded **3** in the same isolated yield.[3] These observations and the apparent loss of a Ti-bound NMe_2 group in the isolation of **3** suggest that crystallization of the metallacycle is the critical step in the synthesis, proceeding in low yield and driving exchange of chloride for the amido ligand on titanium.

Complex **3** underwent ligand exchange reactions at titanium without disruption of the metallacycle core. Thus, the addition of 2.5 equivalents of $Ti(NMe_2)_4$ to **3** at ambient temperature afforded **2** in quantitative yield. Analysis of this reaction by NMR spectroscopy reveals the formation of an intermediate compound (presumably the ylide metallacycle with one amido group), which disappeared to give **2** over a period of approximately one hour (Scheme 1). This exchange rate is considerably slower than that of many titanium halides, amides, and alkoxides, indicative of steric hindrance at each metal center. This is further demonstrated by the slow decomposition (requiring several days) of **2** and **3** in the presence of a large excess of benzophenone, affording no characterizable organic products.

However, metallacycle **3** reacted immediately with an excess of 4-methylbenzaldehyde or 4-methoxybenzaldehyde in

reduced pressure], and its structure was determined by X-ray crystallography (Fig. 1).[15]

p-[$3^2.5^6$]Octahedrane **1** has the point symmetry D_{3d} rare among hydrocarbons; the point symmetry corresponds to the unusual space group $R\bar{3}c$ of the crystals. Its 500 MHz ^{1}H NMR spectrum (in $CDCl_3$) shows only two broad singlets at $\delta = 3.00$ (6H, 1(5,6,7,8,12)-H) and 1.60 (6H, 2(3,4,9,10,11)-H). The coupling between the cyclopropyl protons and those at the central ring, determined from the COSY long-range ^{1}H NMR spectrum, is apparently very small, which must be attributed to the relatively large H-C-C bond angle [H2-C2-C1: 123.5(15)°, H1-C1-C2: 115.3(13)°] at the five-membered rings, which are rigid and folded with an angle of 34.1°.[16] With respect to the ^{1}H NMR signal of dodecahedrane **3** ($\delta = 3.38$, in $CDCl_3$), the signal of the protons belonging to the five-membered rings on the central six-membered ring of **1** undergoes a high-field shift, apparently the effect of the diamagnetic anisotropy of the three-membered rings.[17] This is also manifest in the 125.7 MHz ^{13}C NMR spectrum (in $CDCl_3$) of **1**, which displays two doublets at $\delta = 62.3$ ($^1J_{C,H} = 140$ Hz, C1(5,6,7,8,12))[18] and 33.6 ($^1J_{C,H} = 170$ Hz, C2(3,4,9,10,11)). The relatively large ^{13}C–H coupling constant of 170 Hz at the cyclopropyl positions[19] reflects a different type of hybridization at the cyclopropyl carbon atoms than in simple cyclopropane derivatives, as a result of the bending of the three C–C bonds in each ring that point inward. The increased s character of 34% for the cyclopropylic C–H bonds in **1** that correlates[20] with the coupling constant of $^1J = 170$ Hz probably implies an increased C–H acidity. As a result an independent chemistry for suitable derivatives of the dicarboxylic acid **8** and perhaps also for the hydrocarbon **1** can be predicted.[21] The bond lengths of 1.507(4) Å in the three-membered ring of **1** are normal, and the stretching of the bonds of the three-membered rings proximal to the methoxy carbonyl groups and contraction of the distal bonds in diester **7** corresponds to the usual effect of an electron-withdrawing substituent.[22]

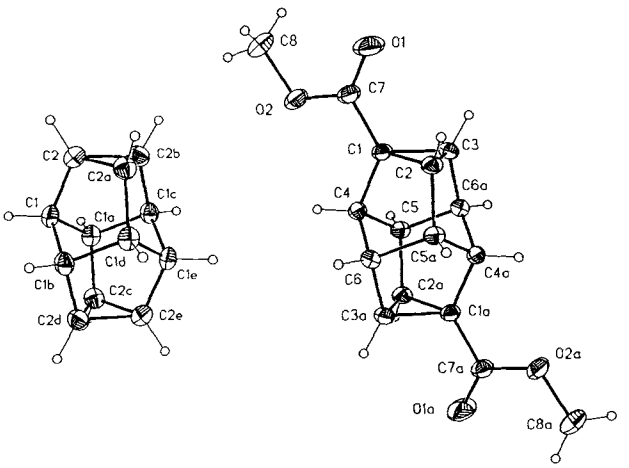

Fig. 1. Crystal structures of the dimethyl ester (**7**) of *p*-[$3^2.5^6$]octahedrane-2,10-dicarboxylic acid (right) and *p*-[$3^2.5^6$]octahedrane (**1**, left) [13]. Bond lengths [Å] and angles [°] (numbering does not conform to IUPAC rules): **7**: (averaged for C_{2h} symmetry): C1-C2 1.529(1), C1-C4 1.527(2), C1-C7 1.476(2), C2-C3 1.495(1), C4-C5 1.551(1), C5-C6a 1.554(1); C1-C3-C2 60.7(1), C2-C1-C4 106.9(1), C2-C1-C7 119.1(1), C4-C1-C7 126.6(1), C1-C4-C6 106.0(1), C2-C1-C3 58.6(1), C5-C4-C6 101.0(1). – **1**: C1-C2 1.520(3), C1-C1a 1.550(3), C2-C2a 1.507(4); C2-C1-C1a 106.4(1), C1a-C1-C1b 100.7(2), C1-C2-C2a 106.9(1), C2-C1-C1b 106.4(2), C2a-C2-C2b 60.0(1), C1-C2-C2b 106.8(1).

The Incorporation of C_{60} in Molecular Sieves

By *Andreas Gügel, Klaus Müllen, Horst Reichert, Wolfgang Schmidt, Günter Schön, Ferdi Schüth,* Jochen Spickermann, Jeremy Titman,* and *Klaus Unger*

Fullerenes have attracted wide interest in recent years because of their qualities. Their inclusion in molecular sieves could alter their optical and electronic properties and thus create new materials. In this communication the possibility of including large quantities of fullerenes in molecular sieves was investigated.[1] Zeolites and their analogues are particularly suitable as matrix materials: they have pores from 2.7 (in clathrasils) to 12.1 Å (in VPI-5).[2] We used the aluminophosphates VPI-5, $AlPO_4$-5, and $AlPO_4$-8, which contain one-dimensional pore systems and were prepared according to references [3] and [4]. The free channel diameters are given in Figure 1. High-vacuum activation at elevated temperature removes adsorbed water and leaves the pore system freely accessible.

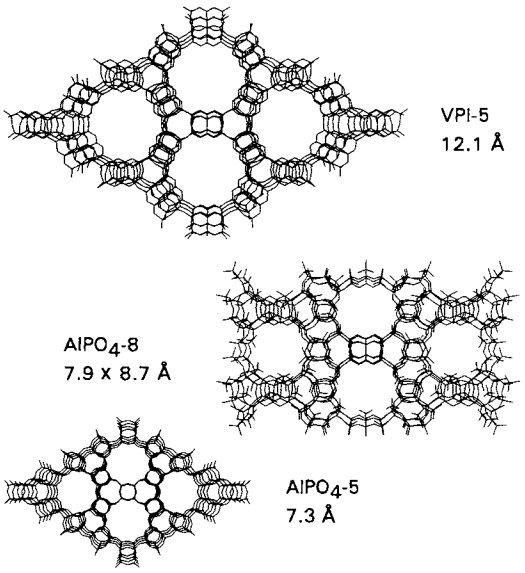

Fig. 1. The aluminophosphates VPI-5, $AlPO_4$-8, $AlPO_4$-5 are constructed from alternating AlO_4 and PO_4 tetrahedra, which are linked by oxygen bridges. The pore diameters are given below the aluminophosphate names.

The loading of the aluminophosphate with C_{60} was studied both by adsorption from the liquid phase and from the gas phase. In no sample treated directly with a concentrated solution of C_{60} in toluene could significant amounts of the fullerene be detected in the pores. However, it was possible to incorporate C_{60} into VPI-5 and $AlPO_4$-8 from the gas phase. The C_{60} used in all experiments still contained toluene that could not be removed by drying in an oil pump vacuum (about 28 wt.%).

The activated aluminophosphate was heated together with C_{60} in vacuum at 450 °C. C_{60} vaporizes and diffuses into the micropores of the aluminophosphate. The experiments were performed with various C_{60} loads (0.1–0.5 g C_{60} per 1 g $AlPO_4$). In this way VPI-5 and $AlPO_4$-8 were loaded with C_{60}, but the pore openings of $AlPO_4$-5 were apparently too small for adsorption of this fullerene. The success of the loading could even be observed optically by a yellow tint in the aluminophosphate crystals under a light microscope. Combined thermogravimetric/differential thermal analysis (TG/DGA) in a stream of air showed that the charged samples lost a considerable amount of their mass (up to 30 mass %) in an exothermic step in the temperature range of 400–900 °C. We attribute this to the burn off of C_{60} and perhaps of the toluene bound more firmly to C_{60}, since pure toluene was completely desorbed from the aluminophosphate channels at 200 °C. Figure 2 shows the IR spectra of C_{60}, C_{60} in $AlPO_4$-8, and unloaded $AlPO_4$-8, recorded on an IR microscope that enabled the study of individual crystals or crystal aggregates. The sharp absorption band of C_{60} at 1429 cm^{-1} broadened when the fullerene was adsorbed in the aluminophosphate and appears at 1432 cm^{-1} as a shoulder on the broader band of the aluminophosphate framework. At a higher C_{60} load both band types were observed. Other IR bands of the adsorbed fullerene could not be detected, because they were either hidden under the lattice vibrations of $AlPO_4$-8 or occurred at too low a frequency (cut-off of the detector, 700 cm^{-1}).

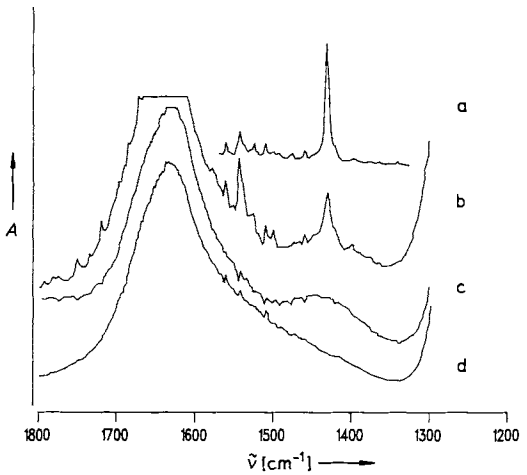

Fig. 2. IR spectra of a) unloaded $AlPO_4$-8, b) $AlPO_4$-8 loaded with C_{60} (0.144 g C_{60} per 1 g $AlPO_4$-8), c) $AlPO_4$-8 loaded with C_{60} (0.500 g C_{60} per 1 g $AlPO_4$-8), d) C_{60} (the signal was reduced by a factor 10) A = absorption units.

The sharp IR band that appeared in addition to the broadened band in more highly loaded samples indicated that here, to a certain extent, C_{60} was adsorbed on the surface of the aluminophosphate. The large amount of C_{60} detected by TG (up to 30 wt % of the samples) was, however, a further indication besides the broadened IR band that the major portion of C_{60} was in the interior of the molecular sieve crystals. Larger quantities of C_{60} outside the micropores could only be contained in mesopores between the individual aluminophosphate crystallites. Bulk C_{60} on the outer surface of the aluminophosphates can be easily detected by X-ray powder diffraction (XRD), since in this case the peaks typical for C_{60} appear beside the aluminophosphate peaks. These additional peaks were no longer present after ultrasonic treatment of the samples in toluene.

N_2 sorption measurements showed that the mesopores of a loaded VPI-5 molecular sieve (0.144 g C_{60} per 1.0 g VPI-5) were freely accessible to N_2. However, the free micropore

volume of the loaded VPI-5 was only about one third of that of an unloaded sample (unloaded: 0.184 cm^{-3}, loaded 0.065 cm^3).

Besides the proof of the inclusion of C_{60} in the micropores, this study also included preliminary investigations on the dynamics of the adsorbed C_{60}. For this purpose solid-state ^{13}C NMR spectra both with and without rotation about the magic angle (magic angle spinning, MAS) were recorded for aluminophosphate samples that have no detectable bulk C_{60} on the outer surface according to XRD. These spectra showed that the C_{60} molecules rotate freely within the channels of the aluminophosphates, because the line-broadening expected for restricted rotation[5] was not unambiguously observed. Nevertheless, the lines were broadened in those spectra recorded without MAS, from which a partial restriction of the free isotropic rotation can be deduced. A further, though only slight, broadening of the lines from 600 to 700 Hz was obtained by cooling the sample from 298 to 230 K. This might point to a transition from the "rotator" phase to the "rachet" phase (the low-temperature phase according to ref. [5]) in the aluminophosphate lattice at relatively high temperatures.[6] It should, however, be mentioned that coadsorbed water can influence the dynamics significantly.

At present we are studying in more detail the electronic and optical properties of the molcular sieves doped with C_{60}. In particular, we are attempting to separate C_{60}, C_{70}, and higher fullerenes in the gas phase by these methods. This would be an alternative to the usual separation by liquid chromatography[7, 8] and is also applicable on larger scales.

Experimental Procedure

Sample preparation: $AlPO_4$-5 and $AlPO_4$-8 were activated by simple heating to 200 °C in air to remove adsorbed water. Under analogous treatment VPI-5 was transformed irreversibly into $AlPO_4$-8 and had therefore to be dehydrated under high vacuum (10^{-5} Torr) [4].

The aluminophosphate samples were placed in one arm of an inverted glass U-tube, and the other was charged with C_{60}. The arm containing aluminophosphate was heated separately, and the sample chamber was evacuated prior to calcination through the opening in the center of the tube. At 10^{-5} Torr the aluminophosphates were first activated at 280 °C for 12 h and then at 480 °C for 1 h. Thereafter under maintenance of the vacuum the glass tube was fused, and the glass ampule containing the activated aluminophosphate and C_{60} was heated for 10 h at 450 °C. The tube was opened, and the sample washed in toluene, filtered off, and again washed for three periods of 15 min in toluene (200 mL portions per 1 g loaded aluminophosphate) in a ultrasonic bath. This procedure removed the last residues of C_{60} from the crystal surface (determined by XRD). The IR spectra were recorded on crushed crystal aggregates with an Analytical Plan IR microscope (SpectraTec) coupled to a Nicolet 5SXB FTIR spectrometer. The N_2 sorption measurements were performed at 77 K with a volumetric sorption apparatus (Omnisorp 100). To remove adsorbed water and toluene, the samples were first heated for 8 h at room temperature, followed by 10 h at 280 °C in vacuum. The NMR spectra were recorded on a Bruker 300 MSL NMR spectrometer (frequency 75.47 MHz, impulse duration 2 μs repeated every 10 s, 3600 scans; rotation frequency in the MAS experiment 2 kHz); the C_{60} signal appears at $\delta = 151$.

Selective Cleavage of a 35-mer Single-Stranded DNA Containing the Initiation Codon of the TAT Gene of HIV-1 by a Tailored Cationic Manganese Porphyrin**

By *Marguerite Pitié, Christiane Casas, C. Jeffrey Lacey, Geneviève Pratviel, Jean Bernadou*, and *Bernard Meunier**

Antisense oligonucleotides have been tested as potential antiviral agents over the last decade. Since the work of Zamecnik and Stephenson[1] on the inhibition of the replication of Rous sarcoma virus with a 13-mer oligonucleotide, it has been shown that HIV can be inhibited by various chemically modified oligonucleotides.[2–4b] Resistance to nucleases has been enhanced by using phosphorothioate oligonucleotides, and cellular uptake has been improved by attaching polylysine[5] or lipophilic groups.[6] However, many of these modified antisense oligonucleotides are active as antiviral agents in a non-sequence-dependent manner.[7] Moreover, the antiviral activity in cell cultures is often in the range of micromolar concentrations, at least two orders of magnitude above the concentration required for a fast development of new antiviral agents based on antisense oligonucleotides. Here we report that a 35-mer corresponding to (+)strand DNA sequence containing the first eight codons of HIV-1 TAT gene is efficiently cleaved in vitro by a cationic manganese porphyrin complex vectorized by a 19-mer complementary to the target, even in the presence of a large excess of random double-stranded DNA. Breaks are observed at low concentrations (10 nM) and with only 2.6 molecules of the metalloporphyrin conjugate per molecule of target.

Among all possible DNA cleavers[8, 9] to be attached to oligonucleotides to prepare active antisense oligonucleotides,[10] the motif tris(*N*-methylpyridinio)porphyrinatomanganese(III) (Mn-trisMPyp) has some significant advantages: 1) the parent molecule *meso*-tetrakis (4-*N*-methylpyridinio)porphyrinatomanganese(III) (Mn-TMPyP) is an efficient DNA cleaver able to hydroxylate C-H bonds at the 1′ and 5′ positions of deoxyribose units,[11, 12] 2) manganese ions are not removed from synthetic porphyrins in vivo,[13] and 3) these cationic manganese porphyrins exhibit a non-negligible anti-HIV activity.[14] Starting from a tris-(*N*-methylpyridinio)porphyrinatomanganese(III) precursor having an acid function at the *para* position of the *meso*-phenyl group (R′ = OH in Scheme 1), the covalent connection to the 19-mer bearing a 5′-amino link was achieved via an active ester prepared by carbonyldiimidazole followed by a transesterification with 1-hydroxybenzotriazole. The manganese porphyrin conjugate Mn-trisMPyP-5′-GGCTC-CATTTCTTGCTCTC (see Scheme 1 for structure) was purified on a short column of a polyacrylamide gel (Bio-Gel P-2(F) from Bio-Rad) and HPLC on Gen Pak-Fax column (Waters). No loss of product was detected on use of these purification methods, whereas sephadex columns led to extensive degradation of the hybrid molecule. The tether has 17 bonds, and its length is sufficient to allow the binding of the cationic manganese porphyrin within the minor groove formed by the 19-mer vector and its complementary sequence contained in the 35-mer target 5′-CAGAGGAGAG-

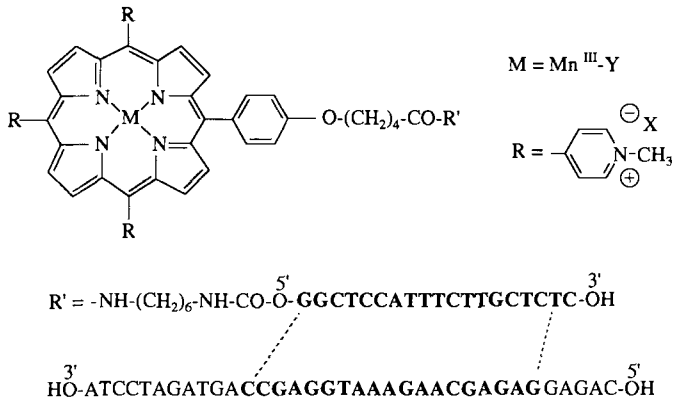
CAAGAAATGGAGCCAGTAGATCCTA. This DNA target corresponds to the region containing the initiation codon of TAT (35 mer = nucleotides 5360 to 5394 according to the numbering of ref. [15]). The expression of the HIV transacting factor TAT or other viral proteins like REV or ENV has been inhibited with antisense oligonucleotides.[16, 17]



Scheme 1. Structural formulas of the hybrid molecule and the initiation codon region of the HIV-1 TAT gene (R' in the hybrid molecule contains a 19-mer complementary to this initiation codon region with an amino link at the 5' position). The axial ligand Y is a water molecule at pH <7 and a hydroxo group at pH >7. The counter ion X^- of the tris(*N*-methylpyridinio)porphyrin used in the coupling reaction was I^-.

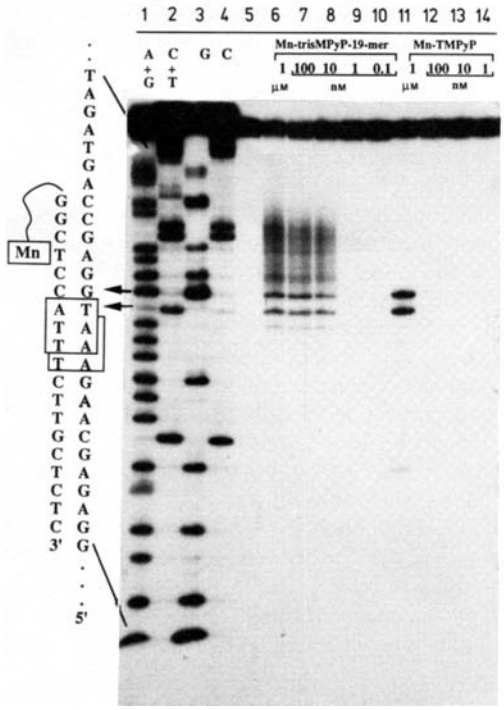


Fig. 1. Analysis by electrophoresis of the cleavage of a 5'-labeled 35-mer single-stranded DNA containing the initiation codon of the TAT gene of HIV-1 by a deliberately designed cationic manganese porphyrin conjugate Mn-trisMPyP 19-mer. Lane 1: Maxam-Gilbert A + G; lane 2: C + T; lane 3: G; lane 4: C; lane 5: 1 μM of the conjugate Mn-trisMPyP 19-mer without $KHSO_5$ (control); lanes 6 to 10: 1 μM, 100, 10, 1, and 0.1 nM of the conjugate Mn-trisMPyP 19-mer, respectively, with 1 mM $KHSO_5$; lanes 11 to 14: the Mn-porphyrin conjugate is replaced by 1 μM of free 19-mer and 1 μM, 100, 10, and 1 nM of Mn-TMPyP, respectively, with 1 mM $KHSO_5$.

In vitro assays of the anti-TAT nuclease activity of the vectorized manganese porphyrin were performed by using potassium monopersulfate, a water-soluble oxygen atom donor that we used to generate activated bleomycin[18] or oxomanganese–porphyrin complexes[11, 12, 19, 20] (such metal–oxo species can be generated in a cell by molecular oxygen and an electron source according to a mechanism similar to that of P-450 enzymes). Under the experimental conditions the manganese porphyrin conjugate Mn-trisMPyP 19-mer cleaves the HIV 35-mer at a very low concentration (10 nM) with only 2.6 equivalents of the vectorized DNA cleaver with respect to the target (lane 8 in Fig. 1). Such remarkable nuclease activity is obtained in the presence of a large excess of a random double-stranded DNA of salmon testes. The main cleavage sites (two discrete bands at T and G preceded by smears of high intensity) on the 35-mer are observed on the 3' side of a 5'-AAAT sequence. This sequence and the complementary strand make two A · T triplets (indicated by two overlapping squares in Fig. 1) which are the highest affinity sites of the parent metalloporphyrin Mn-TMPyP.[12] From previous studies, free Mn-TMPyP was expected to cleave the duplex formed by the 35-mer and the free 19-mer vector only at the vicinal nucleotides on the 3' side of each A · T triplet (T and G in the present case, see arrows in Fig. 1). This is effectively the case (lane 11) for the non-vectorized manganese porphyrin, but at higher concentration (1 μM). No cleavage was detected at nanomolar concentrations (lanes 12–14). The presence of two discrete bands and an intense smear in lanes 6 to 8 suggests that the mechanism of the DNA cleavage by the vectorized manganese porphyrin is not restricted to the specific 5' mechanism observed for the free metalloporphyrin Mn-TMPyP.[12]

Without question, the attachment of the cleaver motif tris(*N*-methylpyridinio)porphyrinatomanganese(III) to a 19-mer vector allowed selective recognition and cleavage of the complementary target, even in the presence of a large excess of random DNA. These data provide support for further investigations with nuclease-resistant manganese porphyrin conjugates on RNA-targets in vitro (an appropriate model for HIV would probably be a single-stranded RNA containing an AUG start codon as in viral RNA) and also at cellular level.

Experimental Procedure

Oligonucleotides were synthetized by standard solid-phase β-cyanoethylphosphoramidite chemistry on Cyclone Plus DNA equipment from Milligen/Biosearch. Both 35-mer and free 19-mer were purified to homogeneity on 20% polyacrylamide denaturating gels. Concentrations of single-stranded oligonucleotides were determined at 260 nm according to ref. [21]. The 35-mer was labeled at the 5' end by treatment with T4 polynucleotide kinase and [γ-^{32}P]ATP.

Synthesis of the manganese porphyrin conjugate Mn-trisMPyP 19-mer: The cationic, functionalized porphyrin (Scheme 1; R = methylpyridinio, R' = OH; for preparation see ref. [22]) was metalated by partially dissolving 5 mg (4.1 μmol) in 600 μL of a solution of $MnCl_2 \cdot 4H_2O$ (10.3 mg, 52 μmol) and heating in a sealed screw-cap Eppendorf tube for 4.5 h. The solution was evaporated to dryness (Speed-Vac), the residue dissolved in dry dimethylformamide (DMF), the solution filtered, and the product precipitated by addition of THF. The mixture was centrifuged (8000 rpm, 25 min), the supernatant drawn off, the pellet triturated with THF, and the mixture centrifuged a second time. The product was dried under vacuum. The metalated cationic porphyrin (2.87 mg, 2.3 μmol) was dissolved in 150 μL of dry DMF, and carbonyldiimidazole (CDI, 7.11 mg, 44 μmol) was added. Formation of the imidazolide was allowed to take place over 13 h. Then 1-hydroxybenzotriazole (12 mg, 88 μmol) was added, and after 4 h at room temperature the excess of CDI was hydrolyzed by addition of 20 μL of 0.2 M Hepes buffer, pH 8. After 30 min the solution was added to 2.1 optical density units (λ = 260 nm, 13.4 nmol) of NH_2-19-mer oligonucleotide in 20 μL of buffer (this oligonucleotide was prepared by the automated phosphoramidite method and functionalized at the 5' position by the method of Wachter et al. [23]). (Note: one optical density unit will yield an absorption of 1.0 in 10 mL of 0.1 M NaCl, pH 7.0 for a 1 cm light path, here at λ = 260 nm.) The solution was incubated at 37 °C for 20 h. The solvents were removed under vacuum (Speed-Vac), the residue taken up in 500 μL of water,

and the solution applied to a column (2.5 g, 10 mL) of Bio-Gel P-2(F) from Bio-Rad equilibrated with water. The crude product was purified by HPLC (Gen Pak-Fax column from Waters; A = 0.025 M Tris · HCl, pH 8.5; B = A + 1 M NaCl; linear gradient: 10 to 90% B over 45 min; flow rate = 0.7 mL min^{-1}; the chromatogram was monitored with a 2-channel diode array detector) and desalted on a bed of Bio-Gel P-2(F) (2 g, water). A comparison of the UV/VIS spectra before and after desalting revealed no loss of product. Spectrophotometric data were: oligonucleotide, $\varepsilon_{260} = 1.6 \times 10^5\ M^{-1}cm^{-1}$; Mn^{III} porphyrin: $\varepsilon_{466} = 0.98 \times 10^5\ M^{-1}cm^{-1}$; hybrid molecule: calculated $\varepsilon_{466}/\varepsilon_{260} = 0.62$, observed $A_{468}/A_{264} = 0.63$. Yield was 25% after final purification and desalting (measured by UV spectroscopy at 264 nm). The HPLC retention time of the conjugate was 20.1 min compared to 22.6 min for the starting oligonucleotide.

Each DNA cleavage reaction (see Fig. 1) was performed with 3.75 nM of the 5'-labeled 35-mer (21 300 cpm $nmol^{-1}$; 9.6 nCi $nmol^{-1}$), from 0.1 nM to 1 μM of Mn-trisMPyP 19-mer (DNA cleaver/target ratio between 0.026 and 260) and 400 μM in nucleotides of double-stranded salmon testes DNA (3000 equivalents with respect to the 35-mer) in a solution of 125 mM NaCl and 50 mM Tris · HCl buffer (pH 8). Annealing of the free Mn-trisMPyP 19-mer with the 35-mer was achieved by heating at 90 °C for 3 min and followed by a cooling to 37 °C within 4 h and overnight storage at 4 °C. All assays (total volume = 16 μL) were performed at 4 °C. For reactions without conjugate, the free 19-mer was hybridized with the 35-mer and then pre-incubated with 1 nM to 1 μM of the parent DNA cleaver without vector Mn-TMPyP (pentaacetate of *meso*-tetrakis(4-*N*-methylpyridinio)porphyrinatomanganese(III); see ref. [11] for preparation) for 15 min at 4 °C before addition of $KHSO_5$. DNA cleavage reactions were initiated by addition of 1 mM $KHSO_5$ and maintained at 4 °C for 1 h. Reactions were then quenched by 40 mM Hepes buffer (pH 8), and the mixtures heated at 90 °C for 30 min (all concentrations listed are final concentrations). After cooling to 4 °C, samples were diluted with 1 μL of yeast tRNA (10 mg mL^{-1}) and 100 μL of 0.3 M sodium acetate (pH 5.2), precipitated with 300 μL of ethanol, and finally rinsed with 75% ethanol and lyophylized. Fragments of DNA were analyzed by 20% polyacrylamide gel electrophoresis under denaturing conditions (7 M urea) as previously described[12].

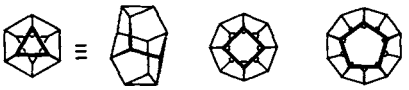
p-[$3^2.5^6$]Octahedrane, the $(CH)_{12}$ Hydrocarbon with D_{3d} Symmetry**

By *Chih-Hung Lee, Shelue Liang, Thomas Haumann, Roland Boese,* and *Armin de Meijere**

Dedicated to Professor Klaus Hafner on the occasion of his 65th birthday

As a rule, polycyclic cage hydrocarbons[1] have unusual properties, and research into them is as topical as ever.[1-3] Among the cage molecules with the formula $(CH)_{2n}$, those with the highest symmetry have always exercised the greatest attraction. Back in 1977 Garrat et al. pointed out the formal relationship between the polycycles **1**, **2**, and **3**.[4] All three contain a central *n*-membered ring whose carbon atoms are linked alternately to the corners of an *n*/2-membered ring lying above or below them. Whereas dodecahedrane **3** [$(CH)_{2n}$, where $n = 10$] has been prepared since then,[1,3] and its reactions are at present under intense investigation,[3e-h] no breakthrough could be achieved in the synthesis of *p*-[$4^2.5^8$]decahedrane **2**[5] and the unsubstituted *p*-[$3^2.5^6$]octahedrane **1**.[6,9] We now report a short synthesis of the dimethyl ester of *p*-[$3^2.5^6$]octahedrane-2,10-dicarboxylic acid (**7**) and the parent hydrocarbon **1**.



1 **2** **3**

The crucial precursor of the first synthesis of dodecahedrane,[3a] the dimethyl ester **4** of 2a,3,3a,5a,6a,6b,6c-octahydrodicyclopenta[*cd*,*gh*]pentalene-3,6-*endo*,*endo*-dicarboxylic acid,[11] served as starting material. The addition of bromine to **4** afforded a nonseparable mixture of the bromides **5** and **6** in 45% yield in a ratio of 2:1. Heating the mixture of **5** and **6** in methanol with five equivalents of sodium methyl alcoholate for 2 h furnished **7** in 55% yield (based on **6**). Its constitution with C_{2h} symmetry was consistent with the ^1H NMR spectrum (in $CDCl_3$, signals at $\delta = 3.60$ (s, 6 H), 3.56–3.50 (m, 2 H), 3.30–3.20 (m, 4 H), and 2.45–2.35 (br. s, 4 H)), and with the ^{13}C NMR spectrum (in $CDCl_3$, $\delta = 171.9$ (C=O), 61.2 (C1(6) or CH_3), 61.1 (CH_3 or C1(6)), 51.5 (C2(10)), 47.9 (C5(7,8,12)), and 45.8 (C3(4,9,11)). Colorless prisms that were suitable for X-ray structure analysis (Fig. 1)[12] crystallized from dichloromethane/cyclohexane (m.p. 213–214 °C).

The diester **7** was saponified with sodium hydroxide in methanol. Acidification with concentrated hydrochloric acid at 0 °C gave the dicarboxylic acid **8** in 80% yield which was transformed into the acid chloride with thionyl chloride. This was prepared for the decarboxylation according to Barton[14] with sodium pyridine-2-thione-*N*-oxide. Photolysis in benzene of the bis-*O*-acylthiohydroxamate obtained thus afforded the hydrocarbon **1** in 74% yield as a colorless solid [m.p. 134–135 °C (sealed capillary), after sublimation under

reduced pressure], and its structure was determined by X-ray crystallography (Fig. 1).[15]

p-[$3^2.5^6$]Octahedrane **1** has the point symmetry D_{3d} rare among hydrocarbons; the point symmetry corresponds to the unusual space group $R\bar{3}c$ of the crystals. Its 500 MHz ^{1}H NMR spectrum (in $CDCl_3$) shows only two broad singlets at $\delta = 3.00$ (6H, 1(5,6,7,8,12)-H) and 1.60 (6H, 2(3,4,9,10,11)-H). The coupling between the cyclopropyl protons and those at the central ring, determined from the COSY long-range ^{1}H NMR spectrum, is apparently very small, which must be attributed to the relatively large H-C-C bond angle [H2-C2-C1: 123.5(15)°, H1-C1-C2: 115.3(13)°] at the five-membered rings, which are rigid and folded with an angle of 34.1°.[16] With respect to the ^{1}H NMR signal of dodecahedrane **3** ($\delta = 3.38$, in $CDCl_3$), the signal of the protons belonging to the five-membered rings on the central six-membered ring of **1** undergoes a high-field shift, apparently the effect of the diamagnetic anisotropy of the three-membered rings.[17] This is also manifest in the 125.7 MHz ^{13}C NMR spectrum (in $CDCl_3$) of **1**, which displays two doublets at $\delta = 62.3$ ($^1J_{C,H} = 140$ Hz, C1(5,6,7,8,12))[18] and 33.6 ($^1J_{C,H} = 170$ Hz, C2(3,4,9,10,11)). The relatively large ^{13}C–H coupling constant of 170 Hz at the cyclopropyl positions[19] reflects a different type of hybridization at the cyclopropyl carbon atoms than in simple cyclopropane derivatives, as a result of the bending of the three C–C bonds in each ring that point inward. The increased s character of 34% for the cyclopropylic C–H bonds in **1** that correlates[20] with the coupling constant of $^1J = 170$ Hz probably implies an increased C–H acidity. As a result an independent chemistry for suitable derivatives of the dicarboxylic acid **8** and perhaps also for the hydrocarbon **1** can be predicted.[21] The bond lengths of 1.507(4) Å in the three-membered ring of **1** are normal, and the stretching of the bonds of the three-membered rings proximal to the methoxy carbonyl groups and contraction of the distal bonds in diester **7** corresponds to the usual effect of an electron-withdrawing substituent.[22]

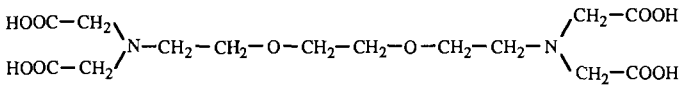
[MnM(egta)] · 8 H_2O (M = Mn, Cd): A Novel Type of Two-Dimensional Magnetic Lattice**

By *Juan J. Borrás-Almenar, Eugenio Coronado,* Carlos J. Gómez-García,* and *Lahcène Ouahab*

Research in the field of low-dimensional magnetism has been particularly active in the last decade, and major developments have occurred in both the theoretical and magnetochemical areas.[1] The most remarkable advance is perhaps the preparation and characterization of compounds containing ferrimagnetic chains, also called one-dimensional (1-D) ferrimagnets.[2] Typically, this kind of compound has two alternating metal sites in the structure and a characteristic magnetic behavior: a minimum in the plot of the product of the magnetic susceptibility and temperature versus temperature, arising from the noncompensation of the two alternating magnetic moments. Aside from the interest in 1-D magnetism, some of these compounds are of interest as molecular-based materials exhibiting cooperative magnetic effects (bulk ferro- and ferrimagnets) as a consequence of the interchain interactions.[3]

In this field, coordination chemistry has provided most of the known 1-D ferrimagnets. The next step is now the search for novel compounds of higher magnetic dimensionality. There are two reasons that justify this goal: From the physical point of view, 2-D systems are the most interesting in magnetism,[4] since they form the borderline between ordering and nonordering systems.[5] From the chemical point of view, it is essential to control the transition from 1-D to 2-D systems in order to shift the ordering temperature of a molecular ferromagnet toward higher temperatures. In this context, we previously demonstrated that removing some water from the ferrimagnetic chain compounds MM'[edta] · 6 H_2O (M, M' = Mn^{II}, Co^{II}, Ni^{II}, and Cu^{II}; edta = ethylenediaminetetraacetate) through a hydrothermal treatment results in an interconnection of the chains, and consequently, in an extension of the ferrimgnetic lattice.[6]

An alternative way to increase the dimensionality may consist of introducing more coordinating donor groups into the ligand. We report here such an example obtained by reaction of the ethylenedioxybis(ethylenenitrilo)tetraacetate (egta[7]) with Mn^{II} and Cd^{II} ions. This new series of isomorphous complexes can be formulated as [MnM(egta)] · 8 H_2O and shows an unprecedented puckered, layered structure, which may give rise to a novel type of two-dimensional magnetic lattice.



H_4egta

The X-ray crystal structure determination, carried out on Mn–Cd crystals,[8] shows the presence of two different metal sites (Fig. 1a): an eight-coordinate site, with square antiprismatic geometry, in which egta wraps around the cadmium center to form the dianion $[Cd(egta)]^{2-}$, and an octahedral site in which the manganese is surrounded by six oxygen atoms from three water molecules and three carboxylate groups belonging to three different egta ligands. In each

dianion three carboxylate groups act as bridging ligands connecting the cadmium ion to three manganese ions. Two of these three carboxylate groups (O3-C4-O4 and O7-C8-O8) are involved in the construction of a tetranuclear centrosymmetrical unit formed by alternating Cd and Mn sites (Fig. 1b). The third carboxylate (O5-C5-O6) connects these basic units to give, as overall structure, the extended layered network showed in Figure 2. This figure reveals parallel layers well separated from each other: the shortest interlayer metal–metal distances are Mn–Mn = 11.808(2), Mn–Cd = 9.965(2), and Cd–Cd = 8.680(1) Å, while within the layer the nearest neighbor Mn–Cd distances are d_1 = 5.752(2), d_2 = 6.148(2), and d_3 = 5.553(2) Å (corresponding to the three carboxylate bridges).

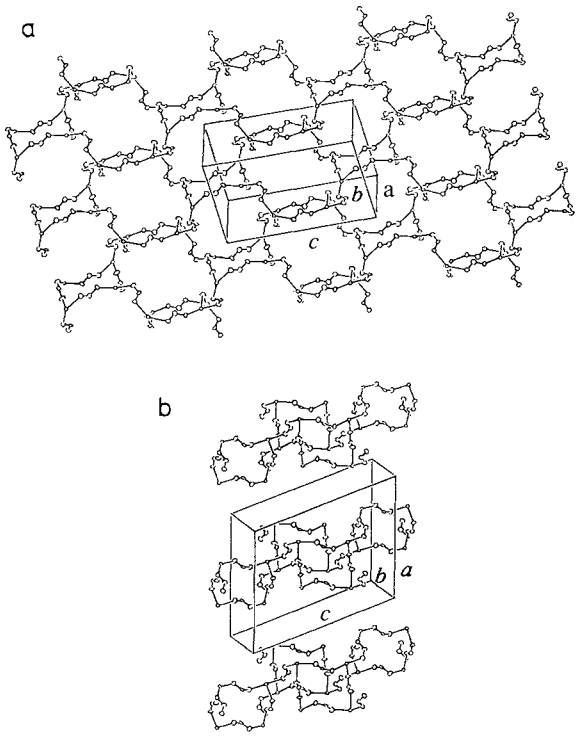

Fig. 2. a) View onto the bc plane of a bimetallic layer. b) The stacking of the layers.

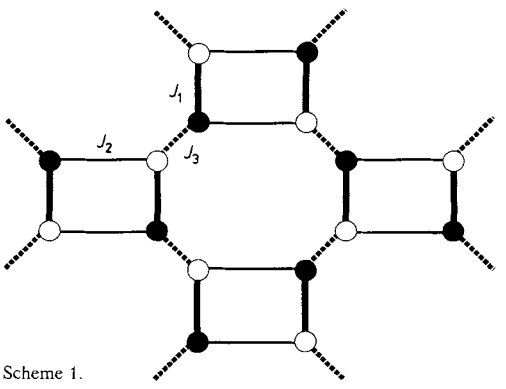
When both sites are occupied by manganese, this unusual structure should give rise to the two-dimensional magnetic lattice sketched in Scheme 1. In this lattice the two magnetic sites (indicated as open and filled circles) alternate in both directions and are coupled by three different exchange interactions (J_1, J_2, and J_3), in accordance with the three different carboxylate bridges. The magnetic behavior for this compound has been investigated with a SQUID susceptometer in a magnetic field of 0.1 T between 298 and 2 K, and is compared in Figure 3 with that obtained for the Mn–Cd compound. While in the Cd-containing compound the product



Scheme 1.

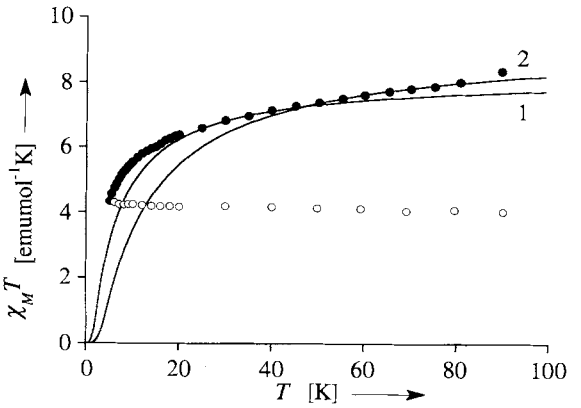


Fig. 3. Plot of $\chi_m T$ versus T for [MnMn(egta)] · 8 H_2O (solid circles) and [MnCd(egta)] · 8 H_2O (open circles). Solid lines correspond to the behaviors of a square S = 5/2 Heisenberg lattice with $J = -0.35\ cm^{-1}$ and $g = 2.14$ (curve 1), and $J = -0.7\ cm^{-1}$ and $g = 2.02$ (curve 2).

$\chi_m T$ is almost temperature-independent, as expected for isolated Mn^{II} ions, the Mn–Mn compound shows a continuous decrease of $\chi_m T$ with decreasing temperature and no evidence of transition to a long-range order in the investigated temperature range. Such behavior is consistent with the presence of short-range antiferromagnetic interactions between Mn^{II} ions through the carboxylate bridges. The lack of a theoretical model for this kind of 2-D system precludes a quantitative analysis of the magnetic data. However, an estimate of the nearest neighbor exchange interactions may be deduced from the model developed for a square spin lattice with a single interaction J.[9] As expected, this model does not give an overall fit to the data, but from the fits obtained by using the low and high temperature data (see curves 1 and 2 in Fig. 3), antiferromagnetic exchange constants in the range 0.35–0.70 cm^{-1} may be derived. These values are similar to that found in the related manganese chain compound [MnMn(edta)] · 9 H_2O[10] for which $J = -0.5\ cm^{-1}$, in agreement with the similar arrangements of the carboxylate bridges. However, it is interesting to notice that whereas the compound with the edta chain undergoes a long-range magnetic ordering at T_c = 1.5 K, no indication of ordering is found down to 2 K in the egta compound despite its higher dimensionality. This result emphasizes the good magnetic isolation of its 2-D lattice.

This preliminary work demonstrates the feasibility of preparing structurally ordered bimetallic layers containing the egta ligand. The versatility of this lattice opens quite interesting possibilities in magnetochemistry, since by variation in the two interacting paramagnetic ions, 2-D ferrimagnetic materials should be isolated. This includes the preparation of compounds formed by rare earth elements and transition metal ions, since the egta ligand has been shown to form very stable complexes with lanthanides. Attempts are in progress.

Experimental Procedure

Synthesis of [MnMn(egta)] · 8 H_2O: $MnCO_3$ (0.3448 g, 3.0 mmol) was added to a warm solution of H_4egta (0.5534 g, 1.5 mmol) in 40 mL of H_2O (final

pH = 5.33). This solution was filtered through paper to remove any insoluble material. A portion (10 mL) of this solution was diluted with 20 mL of H_2O and placed in a U-shaped cell with acetone. After several weeks, slow diffusion of acetone vapor caused a white crystalline powder to deposit.

[MnCd(egta)] · $8H_2O$ was synthesised by a similar procedure. $Cd(NO_3)_2$ (0.3085 g, 1 mmol) was added to a solution of H_4egta (0.3690 g, 1.0 mmol) in 25 mL of H_2O. The pH of this solution was adjusted to 2.5 by adding about 2 mL of 1 M NaOH (2 mmol). $MnCO_3$ (0.1149 g, 1.0 mmol) was then added, and the resulting solution was gently heated for 1 hour (final pH = 4.2). Finally, this solution was allowed to cool at room temperature and placed in a U-shaped cell with acetone. After several weeks of slow diffusion of acetone vapor, white needles formed. IR spectra show the presence of the egta ligand in the white powder and in the single crystals. Both compounds provided a correct elemental analysis and show quite similar X-ray powder patterns.

The Seven-Component Reaction**

By *Alexander Dömling* and *Ivar Ugi**

Dedicated to Professor Friedrich Asinger on the occasion of his 90th birthday

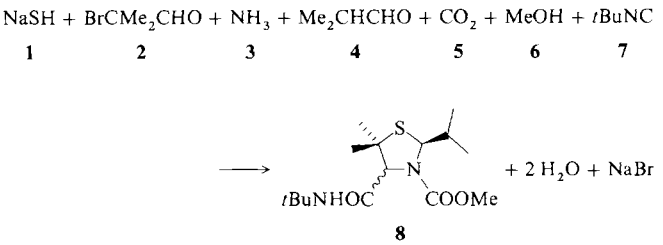
One-pot reactions that form products from at least three different starting materials and incorporate substantial portions of these reagents are termed multicomponent reactions (MCR). This name includes reactions involving at least three different functional groups, some of which may, however, be parts of the same reagent molecule. In general, the MCR are sequences of bimolecular reaction steps that proceed according to the zipper principle, that is, each reaction step is prerequisite for the following stage. The best known examples of MCR are the α-aminoalkylations,[1] to which belong, for example, the Mannich condensation,[2] the Bucherer–Bergs reaction,[3] and formally also the one-pot synthesis of α-ferrocenylalkylamines,[4] as well the Passerini and Ugi reaction (four-component condensation, 4CC).[5] A more recent example of an MCR is the Pauson–Khand reaction.[6]

MCR offer substantial advantages over other synthesis reactions, because most often they use less of the reagents and save time and effort.

In the five-component condensation of primary amines, aldehydes, carbon dioxide, alcohols, and isocyanides to form α-acylaminocarbonamides[7] the highest number of different components were condensed. This reaction is a 4CC in which one of the components, the alkyl carboxylate, is synthesized from two starting materials, alcohol and carbon dioxide.

What is the highest number of different starting materials that can be involved in an MCR?[8] In our opinion a MCR with more than seven reaction partners is scarcely feasible.

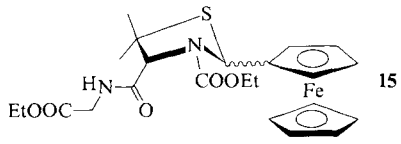
Through a combination of an Asinger condensation,[9] whose α-mercaptoaldehyde component is formed from an α-haloaldehyde and SH^-, and a 4CC with a monoalkyl carboxylate according to Scheme 1, it is possible to condense seven different starting materials (7CC) to afford **8** in 43% yield (see Experimental Procedure). Initially in this reaction,



Scheme 1. Stoichiometry of the 7CC.

9 is formed from sodium hydrogen sulfide (**1**) and α-bromoisobutyraldehyde (**2**) and reacts further with ammonia (**3**) and isobutyraldehyde (**4**) in an Asinger condensation to furnish **10**. Compound **11** is formed in an equilibrium with carbon dioxide (**5**)[10] and methanol (**6**). The thiazoline **10** is protonated by **11** to yield **12**, that together with **13** adds to *tert*-butylisocyanide (**7**) to form the α-adduct **14**, which rearranges to **8** by an O to N migration (see Experimental Procedure and Scheme 2).

An analogous 7CC affording **15** (see Experimental Procedure) is possible in 18% yield with the seven components **1**–**3**, **5**, ferrocenaldehyde, ethyl isocyanoacetate, and ethanol.



15

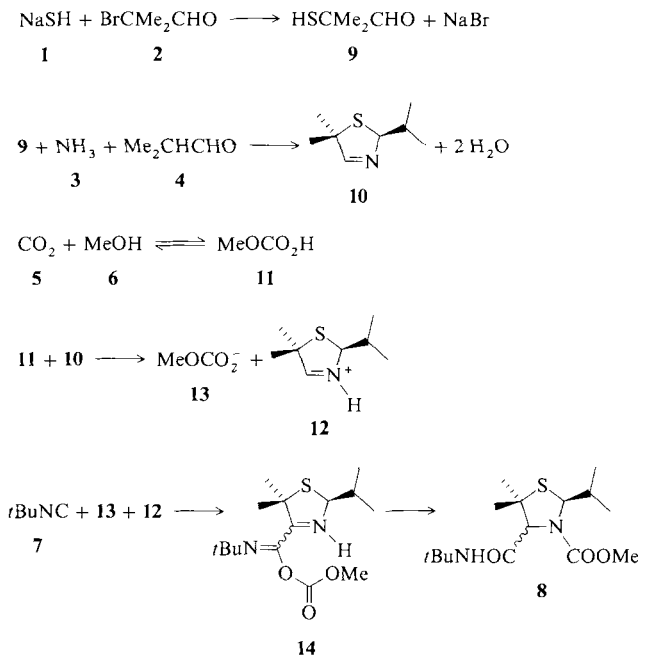
Product	Conversion [%] [a]	Yield [%] [b]	Diastereomeric ratio [c]	Solvent [d]	*p* [bar]
8	70	43	2:1	MeOH	16
15	58	18	14:9	EtOH	48

[a] Based on unchanged Asinger product (determined from the ^{1}H NMR spectrum of the reaction mixture). [b] Pure substance after flash chromatography. [c] Determined from the ^{1}H NMR spectrum of the reaction mixture. [d] Alcoholic component.

[*] Prof. Dr. I. Ugi, Dipl.-Chem. A. Dömling
Organisch-chemisches Institut I der Technischen Universität München
Lichtenbergstrasse 4, D-W-8046 Garching (FRG)

The diastereomeric ratios determined by GC-MS analysis and ^{1}H NMR spectroscopy of the crude mixture (Table 1) are low, in accord with the suggested reaction sequence (Scheme 2). The relative configuration of the two stereocenters could not be determined. We assume from the mechanism, however, that the substituents of the major diastereoisomer in 2- and 4-positions are *trans* to each other.



Scheme 2. Mechanism of the 7CC.

Further studies are in progress to extend the seven-component reaction to oxazole,[12] imidazole, 1,3-thiazine, 1,3-oxazine, and 1,3-pyrimidine ring systems.

Experimental Procedure

General procedure for a 10 mmol batch: To a solution of anhydrous sodium hydrogen sulfide (0.56 g) in alcohol (50 mL) at -10 °C are added α-bromoisobutyraldehyde (1.51 g) and aldehyde (10 mmol), and ammonia is bubbled through the solution for 15 min. This solution was treated with isocyanide (10 mmol) and stirred for 6 days under the pressure of CO_2 given in Table 1. As workup the alcohol was removed, the residue was taken up in ethyl acetate (20 mL), washed with 20 mL water, the organic phase was separated off and dried with magnesium sulfate, and the solvent was removed in vacuum. The residue was separated by flash chromatography with hexane/ethyl acetate as eluent.

Selected physical data of the major diastereomers: **8**: colorless powder, m.p. = 148 °C. ^{1}H NMR ($CDCl_3$, 360 MHz): δ = 0..92 (d, 3H, J = 6.89 Hz), 0.95 (d, 3H, J = 6.64 Hz), 1.34 (s, 9H), 1.41 (s, 3H), 1.62 (s, 3H), 2.67–2.72 (m, 1H), 3.68 (s, 3H), 4.1 (s, 1H), 5.17 (d, 1H, J = 5.49 Hz), 5.45 (s, br, 1H); ^{13}C NMR ($CDCl_3$, 90 MHz): δ = 17.5, 20.5, 26.7, 28.7, 32.5, 33.4, 51.4, 52.7, 71.7, 77.1, 156.2, 169.0. MS (CI): m/z 317 (MH^+). IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1728(s), 1662(s).

15: yellow powder, m.p. = 160 °C (decomp.). ^{1}H NMR ($CDCl_3$, 360 MHz): δ = 1.18 (tr, 3H, J = 7.10 Hz), 1.30 (tr, 3H, J = 7.13 Hz), 1.46 (s, 3H), 1.68 (s, 3H), 4.0–4.28 (m, 13H, –Fc, twice CH2), 4.33 (s, 1H), 4.53 (s, 1H), 4.71 (s, 1H), 6.40 (m, 2H); ^{13}C NMR ($CDCl_3$, 90 MHz): δ = 14.1, 14.3, 24.7, 33.5, 41.0, 61.5, 61.9, 63.6, 67.8, 68.9, 69.0, 71.7, 75.9, 88.5, 154.9, 166.8, 169.6. MS (CI): m/z 503 (MH^+). IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1761(s), 1700(s, br). Correct C,H,N analysis for **8** and **15**.

Tetranuclear Cuboidal and Hexanuclear Prismatic Iron–Sulfur–Nitrosyl Clusters**

By *Michael J. Scott* and *Richard H. Holm**

Homometallic $[Fe_4(\mu_3\text{-}S)_4]$ and heterometallic $[MFe_3(\mu_3\text{-}S)_4]$ cubane-type clusters and the cuboidal $[Fe_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3]$ cluster are now familiar entities in iron–sulfur chemistry and biochemistry.[1] $[MFe_3S_4]$ clusters provide the best current simulations of the *immediate* coordination environments of Mo and V atoms in the corresponding cofactors of nitrogenase.[1, 2] However, cuboidal clusters with the inverted core atom population $[Fe_4(\mu_3\text{-}S)_3]$ and its heterometal analogues $[MFe_3(\mu_3\text{-}S)_3]$ assume new significance in view of the Kim–Rees model of the FeMo-cofactor of the nitrogenase from *Azotobacter vinelandii*, which consists of the cuboidal units $[Fe_4S_3]$ and $[MoFe_3S_3]$ bridged by two μ_2-S atoms and a third unidentified atom in an assembly of trigonal pseudosymmetry.[3] Recognizing that the only structurally authenticated example of $[Fe_4S_3]$ is found in Roussin's black anion $[Fe_4S_3(NO)_7]^-$ and noting an unpublished report of a related Fe_4Se_3 species,[4–7] we have explored certain tetranuclear Fe clusters with nitrosyl and sulfido ligands **1**–**5**.

$[Fe_4S_3(NO)_7]^-$	**1**	$[Fe_4S_3(NO)_4(PPh_3)_3]$	**4**
$[Fe_4S_4(NO)_4]$	**2**	$[Fe_4S_3(NO)_4(PPh_3)_3]^+$	**5**
$[Fe_4S_4(NO)_4]^-$	**3**	$[Fe_6S_6(NO)_6]^{2-}$	**6**

In reaction (a), electron-precise **2**[8] in refluxing dichloromethane is rapidly converted to **4**. The structure of **4**

$$[Fe_4S_4(NO)_4]\ (\mathbf{2}) + 4Ph_3P \longrightarrow [Fe_4S_3(NO)_4(PPh_3)_3]\ (\mathbf{4}) + Ph_3PS \qquad (a)$$

[**] This work was supported by National Institutes of Health (Grant GM 28856; X-ray equipment was obtained through NIH Grant 1 S10 RR 02247).

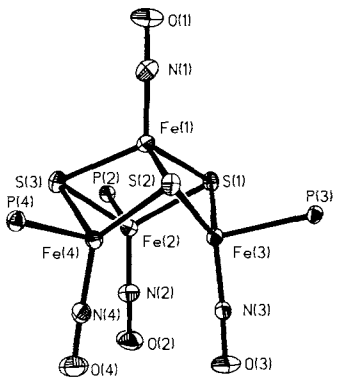

Fig. 1. The structure of **4** (phenyl groups omitted, 30% probability ellipsoids). Selected interatomic distances [pm] and angles [°]: Fe(1)-Fe(2) 257.1(2), Fe(1)-Fe(3) 261.4(2), Fe(1)-Fe(4) 262.8(2), Fe(2)-Fe(3) 277.1(2), Fe(2)-Fe(4) 278.0(2), Fe(3)-Fe(4) 267.8(2), Fe(1)-S 224.3(17), Fe_b-S 221.4(7), Fe-P 224.8(5), S-Fe(1)-S 105.5(16), S-Fe(1)-N(1) 113.2(7), Fe(1)-S-Fe_b 71.5(7), Fe_b-S-Fe_b 76.6(18), S-Fe_b-S 107.5(14), S-Fe_b-N 124(6), S-Fe_b-P 95.7(20), N-Fe_b-P 98.1(5), Fe(1)-N(1)-O(1) 177.9(7), Fe_b-N-O 177.0(6). Except for the unique angle, data involving P, S, and N atoms are mean values under idealized trigonal symmetry (Fe_b = Fe2–Fe4).

(Fig. 1)[9a] demonstrates that desulfurization of the initial $[Fe_4S_4]^{4-}$ core leads to cuboidal $[Fe_4S_3]^{4-}$;[10] **4** has idealized C_{3v} symmetry with basal Fe–Fe distances in the 2.678(2)–2.780(2) Å range and basal–apical (to Fe1) distances of 2.571(2)–2.628(2) Å. In dichloromethane, electron-rich **4** exhibits two reversible ($i_p/i_a \approx 1$) one-electron oxidation steps at 0.00 and +1.03 V vs. saturated calomel electrode (SCE). Reaction (b) afforded the $[Fe_4S_3]^{3-}$ monocation cluster **5** in isolable form. Reaction of **4** with 0.5 equivalents of I_2 also gave **5**, but as a solvated salt **[5][I]** owing to partial conversion of **5** to **1** over longer reaction times than that of reaction (b). In **[5][I]** and **[5][PF_6]**

$$\underset{\mathbf{4}}{[Fe_4S_3(NO)_4(PPh_3)_3]} + NOPF_6 \longrightarrow \underset{\mathbf{[5][PF_6]}}{[Fe_4S_3(NO)_4(PPh_3)_3][PF_6]} + NO \qquad (b)$$

(Fig. 2),[9b,c] the stereochemistry of the cation core is nearly C_{3v}. Analogous to the clusters **2** and **3**,[8] comparative structures allow qualitative identification of the electroactive molecular orbital. The Fe–Fe distances to the apical Fe1 atoms in **4** and **5** are only slightly altered. The most significant change upon oxidation occurs in the basal (Fe_b) atom separations which decrease by 7–19 pm, resulting in a more nearly regular Fe_4 tetrahedron in **5**. Consequently, the HOMO of **4** has considerable antibonding character amongst the three basal Fe atoms.

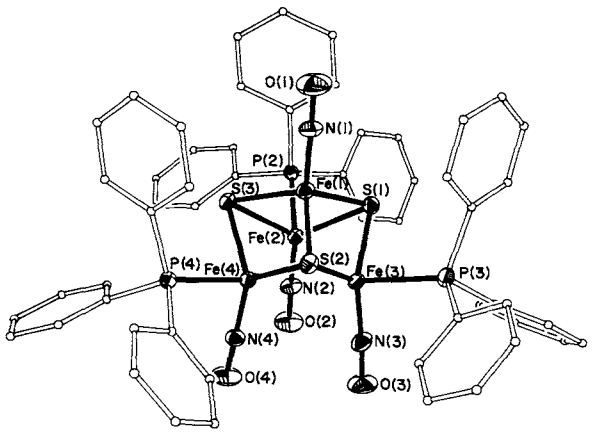

Fig. 2. The structure of **5** in the solvated **[5][I]** salt (30%) probability ellipsoids). Selected interatomic distances [pm]and angles [°]: Fe(1)-Fe(2) 258.8(2), Fe(1)-Fe(3) 260.6(2), Fe(1)-Fe(4) 258.7(2), Fe(2)-Fe(3) 260.6(2), Fe(2)-Fe(4) 262.2(2), Fe(3)-Fe(4) 259.0(2), Fe(1)-S 224.0(9), Fe_b-S 220.6(9), Fe-P 228.0(6), S-Fe(1)-S 103(2), S-Fe(1)-N(1) 113.6(3), Fe(1)-S-Fe_b 71.4(4), Fe_b-S-Fe_b 72.4(7), S-Fe_b-S 107.4(9), S-Fe_b-N 125.4(17), S-Fe_b-P 92.3(4), N-Fe_b-P 98(3). Data involving P, S, and N atoms are mean values under idealized trigonal symmetry (Fe_b = Fe2–Fe4). Phenyl group orientations in this cluster and **4** are similar. The structure of **5** in this compounds as in the PF_6^- salt are essentially identical.

In addition to its oxidative reactions, **4** is an immediate precursor to another cluster type by treatment with excess Ph_3P in DMF at 80 °C [Eq. (c)]. The cluster salt was precipitated by ether addition; the mononuclear species was obtained from the filtrate and identified by its IR spectrum[11] (THF, $\tilde{\nu}$ [cm^{-1}] = 1721, 1677). In the presence of Et_4NCl, pure $[Et_4N]_2$**[6]** could be isolated directly upon addition of ether.[12] The structures of this compound and $[Fe(dmf)_6]$**[6]** demonstrate the existence of the prismane dianion **6** (Fig. 3),[9e,f,13] stereochemically analogous to $[Fe_6S_6L_6]^{2-}$ and $[Fe_6S_6L_6]^{3-}$.[14] Cluster **6** is the first example of this

$$2\underset{\mathbf{4}}{[Fe_4S_3(NO)_4(PPh_3)_3]} \longrightarrow [Fe(NO)_2(PPh_3)_2] + [Fe(dmf)_6][Fe_6S_6(NO)_6] \qquad (c)$$
$$\mathbf{[Fe(dmf)_6][6]}$$

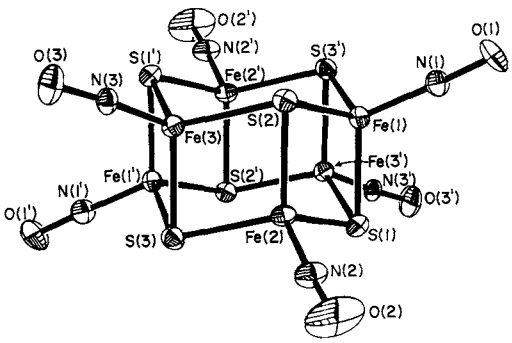

Fig. 3. The structure of **6** as its Et_4N^+ salt (30% probability ellipsoids); Selected interatomic distances [pm] and angles [°]: Fe(1)-Fe(2) 266.3(2). Fe(1)-Fe(3)' 265.6(2), Fe(2)-Fe(3) 265.9(2), mean Fe-S 222.1(5), mean Fe-N 166(1), mean Fe-N-O 176(1); within the Fe_3S_3 cyclohexane-type ring mean values are S-Fe-S 113.2(9), Fe-S-Fe 111.9(8); within the Fe_2S_2 rhombuses mean values are S-Fe-S 106.3(2) and Fe-S-Fe 73.6(2). Primed and unprimed atoms are related by an inversion center.

architecture with L ≠ RS^-, RO^-, or halide. The $[Fe_6S_6]^{8-}$ core in **6** is compressed relative to those in other species of this type; the Fe–Fe and Fe–S distances are about 0.1 and 0.05 Å shorter, respectively. The most remarkable property of **6** is the formation of an extensive electron transfer series. Four sequential reversible reductions are observed in the interval −0.7 to −1.7 V, and a quasi-reversible ($i_{pa}/i_{pc} < 1$), probable two-electron oxidation step near 0 V (Fig. 4). The relatively large potential difference between the second and third reductions is suggestive of an intervening structural change. In contrast to **6** prismatic $[Fe_6S_6]^{4+}$ and $[Fe_6S_6]^{3+}$ clusters exhibit at most a three-membered redox series.[14]

Clusters **1**, **4**, and **5** provide the initial entry to cuboidal $[Fe_4S_3]$ chemistry, albeit significantly modulated by nitrosyl ligation. The latter, with its attendant π-electron reservior potential, low oxidation state stabilization, and enhancement of metal–metal bonding, is undoubtedly responsible for these features: 1) *reductive* desulfurization of the cluster core (**2** → **4**); 2) the reductive five-membered electron transfer series **6** ⇌ $Fe_6S_6(NO)_6]^{6-}$; 3) small or irregular ^{57}Fe

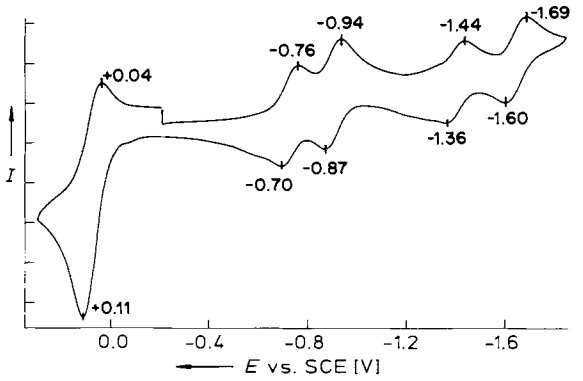

Fig. 4. Cyclic voltammogram of **6** in acetonitrile solution using a scan rate of 50 mVs^{-1} and a Pt working electrode; peak potentials vs. SCE are indicated. For the five redox steps, $E_{1/2} = +0.07$, -0.73, -0.90, -1.40, and -1.64 V.

isomer shift responses to core oxidation state changes at parity of coordination ($[FeS_3(NO)]$);[15] 4) large $\tilde{\nu}_{NO}$ responses to these changes in the oxidation states as in the comparisons **2**/**3**, (1788/1787(m), 1725(vs) cm^{-1}), **2**/**6** (1788/1698 cm^{-1}), and **4**/**5** (Experimental Procedure in dichloromethane). Although dimensionally similar to cofactor clusters,[2] the foregoing species are obviously not models of them. However, they may be synthetic precursors to $[Fe_4S_3]$ clusters with physiologically realistic oxidation levels by oxidative removal of NO ligands with retention of core structure. Such reactions are currently under investigation.

Experimental Procedure

All procedures were carried out under a pure dinitrogen atmosphere with freshly degassed solvents; the FAB-MS matrix was 3-nitrobenzyl alcohol.

4:**2**[8] (5.00 g, 10.6 mmol) and Ph_3P (11.1 g, 42.4 mmol) were refluxed in dichloromethane for 3 h. The precipitate was collected, washed with cold dichloromethane (2 × 50 mL), hexane, and ether which afforded 7.20 g (55%) of product as a black microcrystalline solid. IR (CH_2Cl_2) $\tilde{\nu}$[cm^{-1}] = 1757(s), 1730(vs), 1695(m). FAB-MS: *m/z* 1226(**5**).

[5][1]:**4** (50 mg, 0.041 mmol) in 15 mL of dichloromethane was treated with solid I_2 (6.0 mg, 0.024 mmol). The reaction mixture was stirred for 30 min and 70 mL of ether was added dropwise. One hour after the addition of I_2 the conversion of **4** to **5** was complete (by IR spectroscopy); at longer times peaks of **1** grow in. The solution was stored at 0 °C overnight (ca. 15 h). Single crystals of black **[5][1]** · $0.5CH_2Cl_2$ · $0.5Et_2O$ were isolated in moderate yield. IR (CH_2Cl_2) $\tilde{\nu}$[cm^{-1}] = 1801(m), 1782(vs), 1738(m).

[5][PF_6]:**4** (175 mg, 0.143 mmol) in 10 mL of dichloromethane was treated with solid $NOPF_6$ (25 mg, 0.14 mmol). The reaction mixture was stirred for 30 min and 60 mL of ether was added dropwise. The precipitate was collected and washed with ether which afforded 87 mg (44%) of product as a black microcrystalline solid. IR (CH_2Cl_2), $\tilde{\nu}$[cm^{-1}] = 1803(m), 1781(vs), 1735(m). FAB-MS: *m/z* 1226 (**5**).

[Et_4N]$_2$[6]:**4** (1.00 g, 0.815 mmol) and Ph_3P (0.428 g, 1.63 mmol) in 25 mL of DMF were heated at 80 °C for 12 h, and the solution was filtered. Et_4NCl (0.135 g, 0.815 mmol) was added to filtrate followed by dropwise addition of 300 mL of ether. The precipitate was collected, washed with CH_2Cl_2 (3 × 20 mL) and ether (2 × 20 mL), and was dried in vacuo to yield 0.242 g (56%) of black microcrystals. IR (MeCN), $\tilde{\nu}$[cm^{-1}] = 1698(vs). FAB-MS: *m/z* 707 ($[Fe_6S_6(NO)_6]^-$).

Chiral Phosphinoaryldihydrooxazoles as Ligands in Asymmetric Catalysis: Pd-Catalyzed Allylic Substitution**

By *Peter von Matt* and *Andreas Pfaltz**

Palladium-catalyzed allylic substitution is a versatile, widely used process in organic synthesis,[1] and the development of efficient enantioselective catalysts for this reaction is an important goal of current research in this area.[2, 3] It has been shown that chiral phosphane ligands can induce substantial enantiomeric excesses in Pd-catalyzed reactions of racemic or achiral allylic substrates with nucleophiles.[2a–g] Recently, promising results have also been obtained with chiral bidentate nitrogen ligands.[2h, 3] We have found that palladium complexes of azasemicorrins **1** or methylenebis(dihydrooxazoles) **2** are effective catalysts for the enantioselective allylic alkylation of **5** or related substrates with dimethyl malonate (with **1** (R = $CH_2OSitBuMe_2$), **6a** was obtained in 95% *ee*).[3b] Analogous 1,3-dialkyl-2-propenyl acetates **7**, on the other hand, react very slowly and with poor enantioselectivity. Herein, we report a new class of ligands, chiral 2-(2-phosphinoaryl)dihydrooxazoles of type **3**, which overcome this limitation. With palladium complexes of these readily available ligands, high yields and remarkable enantioselectivities could be realized in allylic alkylations of aryl- and alkylsubstituted allyl acetates.

2-(2-Phosphinophenyl)dihydrooxazoles such as **3**[4] or **4** can be easily prepared in two steps from 2-bromobenzonitrile (1. BuLi; Ph_2PCl; 2. amino alcohol, $ZnCl_2$, PhCl, reflux[5]; 10–30% overall yield). An alternative route involves dihydrooxazole formation from benzonitrile and an amino alcohol, followed by orthometallation with BuLi[6] and subsequent reaction with Ph_2PCl (**3c**: 35% overall yield). Starting from commercially available optically active amino alcohols, a variety of differently substituted enantiomerically pure ligands is readily accessible.[7] The corresponding allylpalladium(II) complexes, which we used as catalysts, were generated in situ from $[\{Pd(\mu\text{-}C_3H_5)Cl\}_2]$ and the corresponding ligands (1.3 equiv/[Pd]).[8]

The complexes derived from ligands **3** and **4** were found to be effective catalysts for allylic alkylations with stabilized carbanions. Under standard conditions[8] (2 mol% of catalyst and a mixture of *N,O*-bis(trimethylsilyl)acetamide (BSA)[2a] and catalytic amounts of KOAc as base[3b]) racemic 1,3-diphenyl-2-propenyl acetate **5** reacts smoothly with dimethyl malonate or acetylacetone affording optically active substitution products [Eq. (a), Table 1]. The phenyl

c: H-Nu = H-C(NHAc)(COOEt)$_2$

derivative **3d** proved to be the optimal ligand for this substrate. After a remarkably short reaction time of 1 h at room temperature (c(**5**) = 0.3 M), the products (−)-**6a** and (+)-**6b** were isolated in essentially quantitative yields with enantiomeric excesses of 99% and 97%, respectively. These values compare favorably to the selectivities obtained with other ligands (**6a**/**b**: 48/96% *ee* with ferrocenyl phosphanes,[2e] 90/63% *ee* with chiraphos,[2e] 30/90% *ee* with BINAP;[2e] nitrogen ligands:[2h, 3]). The reaction with diethyl acetaminomalonate is slower but, after 3–4 d at 23 °C, also affords the desired product (+)-**6c** with excellent enantioselectivity and in essentially quantitative yield.

Table 2 summarizes the results obtained for the reaction of 1,3-dialkyl-2-propenyl acetates **7** with dimethyl malonate

[c] The enantiomeric excess was determined by ^1H NMR spectroscopy ($CDCl_3$/0.25 equiv $[Eu(hfc)_3]$; splitting of the signals for the methoxy groups). [d] $[\alpha]_D = -19.8$ (c = 1.1, $CHCl_3$, 23 °C). [e] $[\alpha]_D = -9.1$ (c = 1.6, $CHCl_3$, 23 °C). [f] $[\alpha]_D = -19.9$ (c = 1.7, $CHCl_3$, 23 °C).

with a *tert*-butyl group at the stereogenic center gave the best enantioselectivities. The dimethyl and di-*n*-propyl derivatives **7a** and **7b**, respectively, reacted with dimethyl malonate under mild conditions, affording the expected products (−)-**8a/b** in high yields with about 70% *ee*. The diisopropyl derivative **7c** was found to be much less reactive (< 20% conversion under these conditions). However, under more vigorous conditions with $NaCH(COOMe)_2$ in DMF at 65 °C, **8c** was formed in good yield and high enantiomeric purity.

At present, no simple mechanistic rationale for the observed enantioselectivity can be offered. Compared to analogous reactions with C_2-symmetric ligands of type **1** or

2, which may be rationalized in a straightforward manner,[3e] the situation here is more complex. With non-symmetric phosphinoaryldihydrooxazoles, two diastereomeric allyl palladium intermediates must be considered, and in addition to steric interactions, electronic effects may play a role as well (differing *trans*-influence of the coordinating N and P atom; see, e.g., ref. [1d]).

Further studies, exploring the scope of these promising catalysts and the mechanism of enantioselection, are in progress. We are also examining the use of phosphinoaryldihydrooxazoles in other metal-catalyzed reactions.

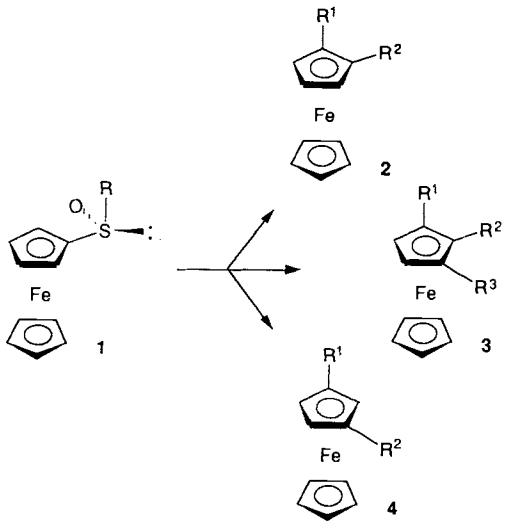
Asymmetric Synthesis and Highly Diastereoselective *ortho*-Lithiation of Ferrocenyl Sulfoxides. Application to the Synthesis of Ferrocenyl Derivatives with Planar Chirality**

By *François Rebière, Olivier Riant, Louis Ricard,* and *Henri B. Kagan**

There are only a few convenient ways to prepare enantiomerically pure ferrocenyl compounds like **2** with planar chirality. The most popular method, based on the pioneering work of Ugi et al.,[1] is the resolution of (1-ferrocenylethyldimethylamine and its subsequent *ortho*-lithiation (92% *de*). This approach has been widely used, for example in the preparation of chiral mono- and diphosphanes with the ferrocene skeleton.[2a, b] A useful asymmetric synthesis of (1-ferrocenylethyl)dimethylamine was described in 1990 by asymmetric reduction of a ferrocenyl imine.[2c] We present here an alternate route to ferrocenyl compounds with planar chirality which is based on an efficient asymmetric synthesis of ferrocenylsulfoxides **1** and avoids a resolution step (Scheme 1).



Scheme 1. Possible syntheses of ferrocenyl derivatives with planar chirality from chiral ferrocenyl sulfoxides **1**.

We recently devised a general method for the synthesis of sulfoxides with very high enantiomeric excesses.[3] In this "sulfite route" an enantiomerically pure cyclic sulfite (S_C,R_S)-**5**[4] was converted into a sulfinate which was then transformed into a sulfoxide (Scheme 2). Enantiomerically pure *tert*-butylsulfinate (S_C,S_S)-**6** could thus be prepared in 70% yield. We found that the reaction of **6** with ferrocenyllithium (conveniently obtained from ferrocene and *tert*-butyllithium[5]) gave *tert*-butylferrocenyl sulfoxide **1a** ($[\alpha]_D = +339$ ($c = 0.8$, $CHCl_3$), m.p. 156–157 °C) in 75% yield. This compound must have (S_S) configuration in analogy to the previously established configuration of sulfinate **6**.[3] It has been found that attack of organometallic compounds on **6** gives sulfoxides with full inversion of the configuration at sulfur.[3] The X-ray structure of sulfoxide **11** (vide infra) fully confirms this assignment. We could not detect traces of the enantiomer of **1a** by ^{1}H NMR spectrosopy using (3,5-dinitrobenzoyl)(1-phenylethyl)amine as a solvating agent.[6] Moreover, the specific rotation remained unchanged after recrystallization. It seems clear that sulfoxide **1a** is enantiomerically pure as were the other sulfoxides previously prepared by the sulfite method. Using the oxidant system we previously described,[7] cumene hydroperoxide (1 equiv) in the presence of 1 equivalent of the combination $Ti(OiPr)_4/(S,S)$-DET/H_2O (1:2:1) (DET = diethyl tartrate), we converted *tert*-butyl ferrocenyl sulfide **9** into sulfoxide **1a**. Flash chromatography on silica gel afforded sulfoxide (+)-**1a** (90% *ee*) in 55% yield. The (*S*) configuration is also predicted by the scheme of asymmetric induction that we had proposed[7] when the ferrocene group is viewed as an arene unit. The sulfite route is superior here to asymmetric oxidation for synthetic purposes.

Sulfoxide **1a** was easily deprotonated with one equivalent of *n*BuLi in THF at 0 °C to give **7**. Subsequent treatment

with methyl iodide at 20 °C gave *tert*-butyl (2-methylferrocenyl) sulfoxide **11** in 80% yield. Only traces of the minor diastereomer were detected by ^1H NMR spectroscopy (*de* > 96%). Crystallization in cyclohexane led to sulfoxide **11** which was suitable for X-ray analysis.[8] Figure 1 shows the (*S*) configuration at sulfur, as expected from the reaction mechanism, and the (*S*) configuration for the planar chirality.[9] It is also apparent that the *tert*-butyl group prefers the

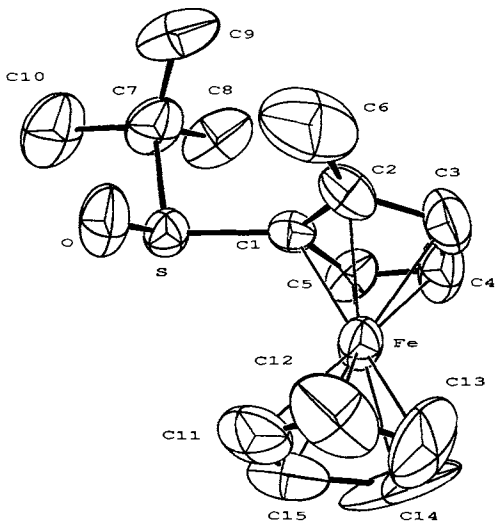

Fig. 1. Crystal structure of **11** (ORTEP, ellipsoids at the 50% probability level). Selected distances [Å], and bond and torsion angles [°] (the numbers in parentheses are estimated standard deviations in the last digits): S-O 1.492(6), S-C1 1.777(6), S-C7 1.860(7), C2-C6 1.54(1), C1-C5 1.371(9), C11-C15 1.36(1); O-S-C1 109.6(3), C1-C2-C6 129.1(8), O-S-C7 107.9(4), C1-S-C7 101.3(3); C7-S-C1-C2 93.51(70), O-S-C1-C2 −20.17(71).

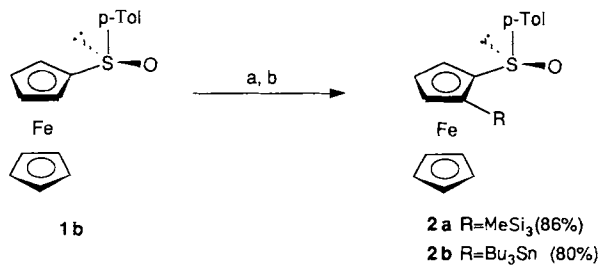
anti orientation with respect to the iron atom, forcing the oxygen substituent to face the (pro-*S*) *ortho* position (even though this is occupied by a methyl group). The *ortho*-lithio compound **7** reacts with many electrophiles to give a large range of chiral ferrocenes. For example, ferrocenyl alcohol **8** was obtained by condensation with acetone (85% yield) ($[\alpha]_D = -29$ ($c = 0.8$, $CHCl_3$)). Deprotonation of **1a** with two equivalents of *n*BuLi followed by quenching with two equivalents of $ClPPh_2$ at room temperature gave diphosphanosulfoxide **10** in 80% yield ($[\alpha]_D = +437$ ($c = 0.5$, $CHCl_3$)).

We previously prepared (*R*)-ferrocenyl *p*-tolyl sulfoxide **1b** by the reaction of ferrocenyllithium with (+)-(R_S,1*S*) menthyl *p*-tolylsulfinate.[5] First attempts at the *ortho*-substitution of **1b** by the sequential addition of *n*BuLi at 0 °C and an electrophile had given a mixture of products. We found recently that the selective deprotonation was cleanly achieved by lithium diisopropylamide (LDA) at −78 °C in THF (Scheme 3). Quenching by trimethylsilyl chloride and tri-



Scheme 3. Diastereoselective *ortho*-lithiation (≥98% *de*) of (*R*)-**1b**. a: LDA, THF, −78 °C. b: RCl.

butylstannyl chloride gave **2a** and **2b**, respectively, in high yield and with a very high diastereomeric excess (≥98%).[10] We tentatively propose that the ferrocenyl unit in **2a** and **2b** has an (*S*) configuration. Based on the assumption of the preferred conformation of **1b**, in which the *p*-tolyl group is *anti* to the iron atom (similar to the conformation of **11** shown in Fig. 1), the observed diastereoselectivity in the lithiation arises from the *ortho*-directing effect of the sulfinyl group.

We are currently investigating the catalytic properties of metal complexes with diphosphane **10** as a ligand. We are also trying to replace the sulfoxide group with other functional groups or remove it completely to set up a general route to enantiomerically pure ferrocenes with planar chirality (Scheme 1).[12, 13, 18]

Experimental Procedure

11: To a solution of (*S*)-**1a** (290 mg, 1 mmol) in dry THF (10 mL) at 0 °C was added dropwise *n*BuLi (0.7 mL of a 1.6 M solution, 1.1 mmol) under argon. The dark solution was stirred at 0 °C for 15 min and 2 h at room temperature. The mixture was cooled to 0 °C and iodomethane (120 μL, 2 mmol) was injected. The reaction mixture was stirred at room temperature for 1 h, then quenched with water, and extracted with diethyl ether. Pure **11** (270 mg, 80%) was isolated as an orange solid after flash chromatography on silica (cyclohexane/EtOAc 1:1) and recrystallized from cyclohexane ($[\alpha]_D = +274$ ($c = 1.5$, $CHCl_3$), m.p. = 104–106 °C).

2a: (*R*)-**1b** (87% *ee*) ($[\alpha]_D = -257$ ($c = 0.46$, $CHCl_3$)) was prepared in 75% yield according to ref. [5] but with a limited amount of ferrocenyllithium (1.0 equiv) at −35 °C in order to prevent the in situ racemization of **1b** (P. Diter, unpublished results). (*R*)-**1b** was recrystallized from hexane/cyclohexane (3:1) until the specific rotation ($[\alpha]_D = -295$ ($c = 0.3$, $CHCl_3$)) was constant. To a solution of (*R*)-**1b** (648 mg, 2 mmol) in dry THF (15 mL) was added dropwise LDA (1.2 mL of a 2 M solution, 2.4 mmol) at −78 °C under argon causing the formation of a light brown precipitate. The suspension was stirred for 15 min at this temperature before treatment with Me_3SiCl (380 μL, 3 mmol). After 10 min of stirring at −78 °C and warming to room temperature over 1 h, the reaction mixture was quenched with 2 N aqueous sodium hydroxide solution and extracted with diethyl ether. The pure sulfoxide **2a** was isolated as a bright orange solid (680 mg, 86%) after flash chromatography on silica (cyclohexane/diethyl ether 7:3). ($[\alpha]_D = +333$ ($c = 0.88$, $CHCl_3$). The enantiomeric excess of **1b** and **2a** (≥ 99%) was determined by HPLC on a chiral column (OD-H, Daicel Co.).

[8] Crystals of **11** ($C_{15}H_{20}FeOS$) were grown at room temperature from cyclohexane solution. Data were collected at 23 ± 1 °C on an Enraf-Nonius CAD4 diffractometer. The crystal structure was solved and refined using the SDP package from Enraf-Nonius. The compound crystallizes in space group $P2_12_12_1$; $a = 10.049(1)$, $b = 11.362(1)$, $c = 13.298(1)$ Å, $V = 1518.30(39)$ Å^3; $Z = 4$; $\rho_{calc} = 1.332$ g cm^{-3}; $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), graphite monochromator; $\mu = 11.1$ cm^{-1}; $F(000) = 640$. A total of 2502 unique reflections were recorded in the range $2° < 2\theta < 60°$ of which 1187 were considered as unobserved ($F^2 > 3.0\sigma(F^2)$), leaving 1315 for solution and refinement. The structure was solved by direct methods, yielding a solution for iron, sulfur, and the Me and Cp carbon atoms. The hydrogen atoms were included as fixed contribution in the final stages of least-squares refinement; anisotropic temperature factors were used for all other atoms. A non-Poisson weighting scheme was applied with a *p*-factor equal to 0.08. $R = 0.049$, $R_w = 0.078$, G.O.F. = 1.62. The analysis confirms the (*S*) configuration at sulfur (agreement factors for the enantiomeric structure: $R = 0.054$, $R = 0.085$, G.O.F. = 1.755). Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB21EZ (UK), on quoting the full journal citation.

A New Type of Hexanuclear Iron(III) Hydroxo(oxo) Cluster

By *Charlie J. Harding, Richard K. Henderson,* and *Anne K. Powell**

In recent years the interest in oxo/hydroxo-bridged iron(III) compunds has increased because of their importance in natural systems. The hydrolytic polymerization of Fe^{III} compounds is recognised as a central feature in natural iron mineralization processes.[1–3] In aqueous solution Fe^{III} salts rapidly form a mixture of insoluble hydroxo(oxo) minerals, collectively described as "$Fe(OH)_3$", once the pH exceeds a value of 3. However, chelating ligands can slow or suppress this hydrolysis, offering the possibility of trapping intermediate oligomeric hydroxo(oxo) species. Many of the oligomeric iron(III) hydroxo(oxo) compounds previously reported, and most recently reviewed by K. S. Hagen,[4] have been prepared in nonaqueous solvents from precursors such as the trinuclear "basic iron carboxylates" $[Fe_3(\mu_3\text{-}O)(RCOO)_6(L)_3]^+$ (e.g. R = H, Cl, CH_3, C_6H_5, *t*Bu; L = H_2O, py), because of the ready hydrolysis of iron(III) compounds and the formation of thermodynamically stable "$Fe(OH)_3$" in aqueous media. As a result the oxo-bridged iron(III) centers of such compounds often have carboxylato bridges as well.[5–8] However, as was recently reported from this laboratory for the interaction of Fe^{3+} with the polycarboxylato ligand "heidi" (H_3heidi = $N(CH_2COOH)_2(CH_2CH_2OH)$), the polyiron hydroxo(oxo) compounds formed in aqueous solution display core structures in which only oxo and hydroxo bridges bind the iron centers together.[9] A related structure was found for an octanuclear iron(III) compound reported by Wieghardt et al., which has an $[Fe_8(\mu\text{-}O)_2(\mu\text{-}OH)_{12}]^{8+}$ core and was prepared by the hydrolysis of Fe^{III}/tacn (tacn = 1,4,7-triazacyclononane) in the absence of carboxylate ions.[10]

Here we report the preparation, isolation, and magnetic properties of a new type of hexanuclear iron(III) hydroxo(oxo) cluster anion in **1** and **2**, which is formed in aqueous

$M_4[Fe_6(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_6(ida)_6] \cdot n H_2O$ **1**, M = Na; **2**, M = K

$H_2ida = HN(CH_2COOH)_2$

solution in the presence of the tridentate iminodiacetato ligand ida^{2-}. A single-crystal X-ray structure determination

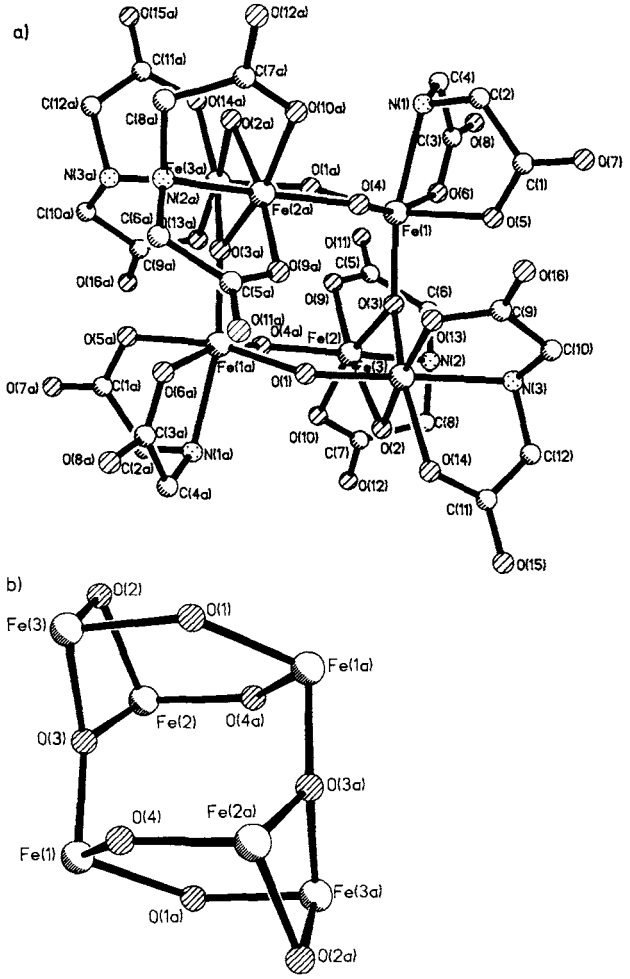

Fig. 1. The structures of a) the anion in **1**, b) the $[Fe_6(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_6]^{8+}$ core of this anion.

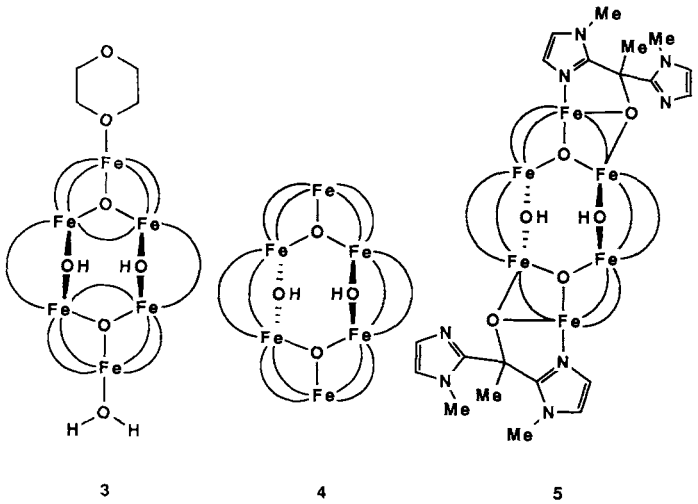
of the sodium salt reveals that the anion in **1** (Fig. 1a) contains an $[Fe_6(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_6]^{8+}$ core (Fig. 1b) with a structure unlike that observed for the three hydroxo(oxo)-hexairon compounds **3**–**5** previously reported (the curves in the formulas represent μ_2-carboxolato ligands).[6–8] Those



3 4 5

clusters are all derived from further reactions of basic iron carboxylate trimers in nonaqueous solvents, which result in two trimer units joining together by carboxylato and hydroxido bridges. Our new hexamer **1** is different for several reasons: firstly it is synthesized directly in an aqueous environment without the formation of intermediate trimer units, and secondly, none of the hydroxido bridges are supported by any other bridging ligand. As a result there are ten close iron–iron separations in **1** less than 3.7 Å, two more than in **3**–**5** (Fig. 2). The two other known types of Fe^{III} hexanuclear clusters form in methanolic solutions, and their iron centers are connected by alkoxido rather than hydroxido bridges.[11]

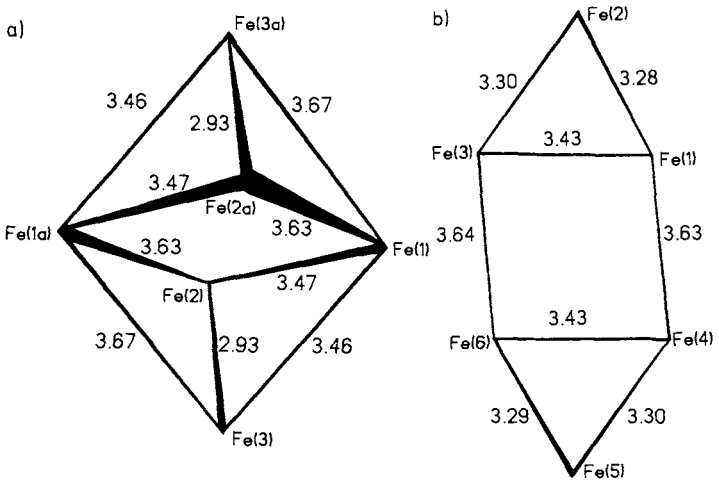


Fig. 2. Comparison of the iron–iron distances in **1** (a) and **3** (b).

The X-ray structure determination[12] of **1** shows that in the anion each iron center is octahedral and has a facially coordinated tridentate ida^{2-} ligand, and one μ_3-oxo and two μ_2-hydroxo bridges. In compounds **3**–**5**, the four central octahedral iron centers are coordinated by one μ_3-oxo and one μ_2-hydroxo bridge, and four other supporting ligands. The core of **1**, by analogy with compounds **3**–**5**, can be regarded as consisting of two μ_3-oxo-bridged Fe_3 triangles defined by Fe(1), Fe(2), Fe(3), O(3), and Fe(1a), Fe(2a), Fe(3a), O(3a). These triangles are in two parallel planes; the apical iron of one triangle (Fe(1)) is connected to the base iron atoms of the triangle opposite (Fe(2a) and Fe(3a)) by two intertrimer μ_2-hydroxo bridges. The two remaining μ_2-hydroxo bridges can be described as intratrimer bridges across the bases of the two triangles between Fe(2) and Fe(3), and Fe(2a) and Fe(3a). These μ_2-hydroxo bridges are in the same plane as the iron atoms of each triangle formed with O(3) or O(3a); the angles Fe(2)-O(2)-Fe(3) and Fe(2)-O(3)-Fe(3) (ideally 120°) are 95.7(5)° and 97.8(5)°, respectively. Consequently Fe(2) and Fe(3) are only 2.934 Å apart, whereas the Fe(1)–Fe(2) and Fe(1)–Fe(3) distances are 3.470 and 3.459 Å, respectively. In other words, the triangles cannot be described as equilateral, unlike in the classic basic iron carboxylate compounds.[13]

In contrast, compounds **3**–**5** possess structures that are derived from two μ_3-oxo-bridged trimers of the basic iron carboxylate type. These Fe_3 triangles are joined by two μ_2-hydroxo bridges and two or four carboxylato bridges to give an essentially planar hexanuclear framework. In **3** the two μ_2-hydroxo bridges are on the same side of this plane,[6] in **4** and **5** on opposite sides.[7,8]

Alternatively, the geometry of the iron core of **1** can be described in terms of two Fe_4 butterfly structures that share the atoms Fe(1) and Fe(1a) at the tips of the wings as illustrated in Figure 2a. Besides the ten Fe–Fe distances < 3.7 Å

in **1**, there are three further interactions <4.7 Å (Fe(1)–Fe(1a) = 4.51 Å, Fe(2)–Fe(3a) = Fe(2a)–Fe(3) = 4.66 Å); the next shortest distance in **3** (Fig. 2b) is between Fe(3) and Fe(4) at 4.76 Å.

The magnetic susceptibilities of **1** and **2** measured against temperature show the same behavior. The effective magnetic moment per iron atom, μ_{eff}/Fe, of **1** increases from 4.02 μ_B at room temperature to a maximum value of 4.81 μ_B at 5 K. (Fig. 3) The variation of χ and μ are parallel in **1** and **2**; the χ_m values are about 6% higher for **1**. The coincidence of the data for **1** and **2** seems to rule out monomeric impurities which can cause large increases in χ_m and μ at low temperatures in compounds that interact antiferromagnetically. Therefore the variation observed is a property of the hexameric ion. This is especially important at low temperature, where a sharp increase in μ is observed.

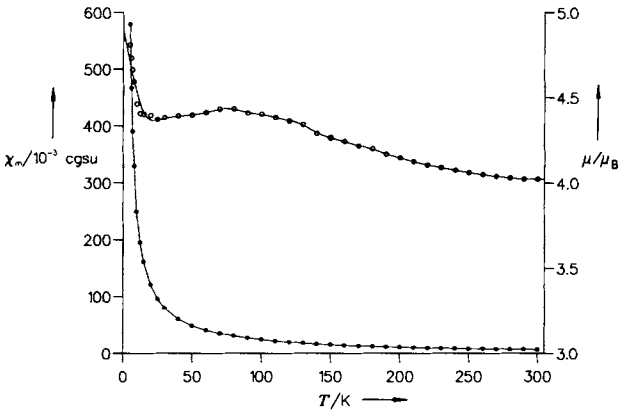

Fig. 3. The variation of the magnetic behavior of **1** between 5 K and 300 K. Upper curve: the fitted curve through the experimentally determined μ values (open circles). Lower curve: experimentally determined χ_m values. χ_m(S.I.) = χ_m(cgsu) $\times 4\pi \times 10^{-6}$ m^3 mol^{-1}.

The interpretation of magnetic data for Fe^{III} hexamers is certainly difficult.[8] The large number of possible pairwise interactions leads to the phenomenon of spin frustration. In our hexamers the high-temperature value of μ of 4 μ_B/Fe clearly shows that antiferromagnetic coupling occurs. If the structure is viewed as two trimers, the sharp rise in μ at low temperatures could be explained by intertrimer ferromagnetic exchange. A similar explanation is given by Hagen[11c] for the hexanuclear compound $[Fe_6(\mu_4\text{-}O)(\mu\text{-}OH)_8(OR)_4(tren)_2\}]^{2+}$ (tren = 2,2′,2″-triaminotriethylamine), although the room-temperature value of μ of 3.55 μ_B/Fe indicates a larger antiferromagnetic exchange than in our system.

Compounds such as **1** and **2** are precursors for mineralized iron(III) compounds (e.g. the core of ferritin) and may be representative of the speciation of iron in the "low molecular weight iron pool". The hexanuclear hydroxo(oxo)iron(III) clusters in **1** and **2** not only illustrate a new structural type, they also give rise to unusual magnetic properties. The interpretation of these properties will lead to advances in understanding the interactions in small anion-bridged cluster compounds.

Experimental Procedure

Compound **1**, $n = 14.5$, is prepared by the addition of a solution of H_2ida (7.5 mmol) and NaOH (17.5 mmol) in water (10 mL) to a solution of $FeCl_3$ (2.5 mmol) in water (10 mL) giving a clear dark red solution of pH ca. 7.5. Solid **1** can be obtained by slow evaporation of the aqueous solution. However, as **1** is very soluble, the addition of excess ethanol is preferable for its isolation. Crystals of **1** suitable for X-ray diffraction were obtained from a water/ethanol mixture. Correct C,H,N,Fe,Na analysis.

Compound **2**, $n = 12$, is synthesized in the same way as **1** with KOH (17.5 mmol) instead of NaOH. Correct C,H,N,Fe,K analysis.

E/*Z* Diastereoselective Enzymatic Hydrolysis of Esters and Diesters**

By *Tanja Schirmeister* and *Hans-Hartwig Otto**

Porcine liver esterase (PLE, E.C. 3.1.1.1) has been used frequently over the last few years for the enantioselective hydrolysis of *meso*- and prochiral diesters as well as for racemic monoesters.[1] The diastereoselectivity of this enzyme was studied among others on cyclopropane derivatives.[2] The ester groups in compounds which contain other labile structure elements could also be hydrolyzed,[3] such as those in β-lactams.[4] However, to our knowledge, there are no reports about enzymatic saponifications of *E*/*Z* diastereomeric monoesters and *E*/*Z* diastereotopic diesters. We report here for the first time about such hydrolyses exem-

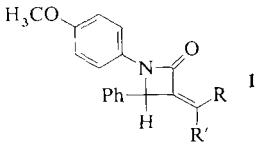
plified by compounds of the type **1**, mono- and dicarboxylates with an azetidine-3-ylide unit in an α position. These



1

compounds cannot be hydrolyzed by conventional methods, since they are stable towards acids, and bases cause a retro-aldol reaction. The hydrolysis described here is therefore the method of choice, even more so since the free acids may be valuable intermediates in the synthesis of antibiotics, and since the method is also applicable for a great number of further arylidene and alkylidene malonates.[16]

The *Z*-positioned ester group in the diester **1**[5] is hydrolyzed selectively with PLE (experiment 1, Table 1). Experiments with other commonly used hydrolases failed with the exception of esterase from rabbit liver. The configuration was determined by a comparison of the chemical shifts in the ^{1}H NMR spectra.[5] The hemiester cannot be reacted further with PLE, however, the hydrolysis to the dicarboxylic acid is achieved with aqueous NaOH at room temperature (experiment 12). The diastereomeric compounds of experiments 4–11 revealed that the *Z* isomers are considerably better substrates for PLE. The acids of the *Z* isomers were obtained selectively from diastereomeric mixtures when the reaction was interrupted after the consumption of the equivalent amount of NaOH (pH-stat method).[6] The reaction course can be followed by thin-layer chromatography (TLC) (silica gel 60, cyclohexane/ethyl acetate/formic acid 49 : 49 : 2) because of the different R_F values of the substrates and products. The hydrolysis of the *E* isomers could not be achieved successfully; the reaction stops after the conversion of several percent (experiments 3, 5, 7, 9, 11). The product could only be isolated from experiments 7 and 9. No reaction was observed in experiment 11.

Table 1. Comparison of the enzymatic hydrolysis of the substrates **1** under the same conditions (see Experimental Procedure).

Experiment no.	**1** R	R'	*t* [h] [a]	Conversion [%] [a]	Product R	R'
1	COOEt	COOEt	72	100	COOH	COOEt
2	COOEt	Me	26	100	COOH	Me
3	Me	COOEt	168	11	Me	COOH [b]
4	COOMe	Me	48	100	COOH	Me
5	Me	COOMe	144	5	Me	COOH [b]
6	COOEt	H	21	100	COOH	H
7	H	COOEt	192	14	H	COOH
8	COOMe	H	18	100	COOH	H
9	H	COOMe	216	13	H	COOH
10	COOMe	Ph	312	100	COOH	Ph
11	Ph	COOMe	219	0	Ph	COOH
12	COOH	COOEt	240	0	COOH	COOH [c]

[a] Reaction time, average values from three or four experiments. [b] Conversions determined by consumption of NaOH. [c] Product (b.p. 131–133 °C, decomp) is obtained by hydrolysis with 0.1 N NaOH (2 h, 25 °C) in over 90% yield.

Evidently, the size of the group R' plays a role in the different reaction times necessary for the complete hydrolysis of the *Z* isomers under the same conditions. This assumption is also confirmed by a comparison of the achieved maximum conversions of the *E* isomers. Thus, the reaction rate decreases with the increasing size of the substituent (H > CH_3 > COOR > Ph). Another influence on the reaction rate is the varying solubility of the substrates. The very poor solubility of the substrates in water was a big problem at the beginning of our investigations.

Although it has been shown that many enzymes are still active in organic solvents,[7] the use of *nonpolar* solvents, apart from a few exceptions,[8] for reactions with hydrolases remained limited to esterifications and transesterifications. The addition of *polar* solvents for the better solubilization of the substrates is only possible to a certain degree without decreasing the activity of the enzymes, in particular for PLE. Thus, hydrolysis occurred for the substrates we used with addition of dimethylsulfoxide,[9] acetone,[4b] EtOH, *t*BuOH, dioxane, or THF; however, only conversions of up to approximately 15% could be achieved.[10] Only following the use of aqueous surfactant-buffer systems, that is by insertion of the substrate molecules into micelles, could all substrates be dissolved sufficiently. Nonionic surfactants were used since these have a high acid–base stability and do not denature proteins.[11] The choice of surfactant did not influence the reaction rate for similar micelle concentrations.[12]

Experimental Procedure

Substrate **1** (0.25 mmol) was dissolved under vigorous stirring by slow dropwise addition of 0.1 M phosphate surfactant buffer (pH 8.0), 0.07 M surfactant Triton X 100 (for other surfactants depending on molecular weight, critical micelle concentration (CMC), and aggregation number N_a 0.009–0.15 M) [13]. Thereafter PLE suspension 200 μL (= 1380 U mmol^{-1})[14] (for experiment 10, however, 500 μL = 3460 U mmol^{-1}) was added. The temperature (32 °C) and pH value were kept constant (pH-stat method, 0.1 N NaOH). After the reaction (see Table 1), the reaction mixture was brought to pH 2 with 2 N HCl and extracted with dichloromethane. The organic phase was dried with sodium sulfate and the solvent was removed under vacuum. The degree of conversion could be determined from the ^{1}H NMR spectrum of the residue. For the isolation, the organic phase was extracted with saturated $NaHCO_3$ solution, acidified (pH 2) with concentrated HCl, and extracted again with dichloromethane. The organic phase was washed several times with water (pH 2) to remove [15] the surfactant completely. After the organic phase had been dried and the solvent had been removed the residue was recrystallized from ethanol/petroleum ether. The separation of phases during the extractions was accelerated by centrifugation (10 min, 7000 U min^{-1}). Yields of up to 85% were obtained. The following surfactants were used: Nonidet P 40 (Fluka), Triton X 100, Brij 35, Pluronic F 68, Myrj 45 (Sigma).

Reduction of Geminal Dihalocyclopropanes with Lithium 4,4′-Di-*tert*-butylbiphenyl; Cyclopropyl Derivatives of Dilithiomethane and 1,2-Dilithioethane; Inferences Regarding the Intermediate Carbenoids

By *Cornelis P. Vlaar*, and *Gerhard W. Klumpp**

While alkyllithium compounds **1**[1] including 1,*n*-dilithioalkanes ($n \geq 4$) are common and thoroughly studied, only few geminal (**2**) and vicinal (**3**) dilithium compounds have been reported and their chemistry is largely terra incognita.[2] Repulsion between neighboring like charges in **2** and **3** is expected to lead to increased energies.[3] Accordingly,

$R^1R^2R^3CLi$ **1** $\quad R^1R^2CLi_2$ **2** $\quad R^1R^2LiC\text{-}CLiR^3R^4$ **3**

formation of **2** and **3** is found to be difficult,[4] and they decompose very easily.[5] Access to **2** and **3** is also restricted by a serious methodological limitation: the easiest route to organolithium compounds, RHal → RLi, proceeds in two steps for these compounds; only rarely can the second step providing **2** and **3** compete with the α- and β-elimination of LiHal from the intermediate α- and β-halolithium compounds.[6] The reduction of geminal dihalides with four equivalents of lithium 4,4′-di-*tert*-butylbiphenyl (LiDBB) at −80 °C (Scheme 1) can lead to compounds of types **2** (**2**-LiHal [Eq.(3)]) and **3**. **3**-LiHal is formed by the dimerization of **4** [Eq.(4)] or the reaction of $R^1R^2CLiHal$–LiHal with **2**-LiHal [Eq.(5)]. As an extension of our previous studies[7] we have subjected dihalonorcaranes (**5a,b**) and related compounds to LiDBB. Besides the expected products **7** and **8**, a new compound of type **3**, **9**-LiCl was found. This derivative of labile cyclopropylmethyllithium[8] is remarkably stable. First conclusions on the aggregation of carbenoids $R^1R^2CLiHal$–LiHal [Scheme 1, Eq.(1)] could be drawn from the observed dependence of the ratio (**7** + **8**):**9** on the reaction conditions.

To a stirred solution of 0.2 mmol **5a** (**5b**) in 10 mL diethyl ether at −95 °C was added by syringe 2 mL of a 0.45 M solution of LiDBB in THF. The reagent was allowed to flow slowly down the inner surface of the reaction vessel, which was maintained at −95 °C. After 5 min at the temperature given in Table 1, the reaction was quenched by addition of MeOD. The product mixture obtained after aqueous workup was analyzed by gas chromatography. Based on their respective deuterolysis (protonolysis) products (7-deuterio- and 7,7-dideuterionorcarane, and compounds **10** and **12**[9]) lithium compounds of types **7**–**9** and dilithium compound **11**, formed from **9** upon warming, were identified. In addition alkyne **15** arising from **11** via **14** was obtained. The results are listed in Table 1.

$$R^1R^2CHal_2 + 2\,LiDBB \longrightarrow R^1R^2CLiHal\text{-}LiHal + 2\,DBB \quad (1)$$

$$R^1R^2CLiHal\text{-}LiHal + LiDBB \longrightarrow \underset{\mathbf{4}}{(R^1R^2CLi)^{\cdot}\text{-}LiHal} + LiHal + DBB \quad (2)$$

$$\mathbf{4} + LiDBB \longrightarrow \underset{\mathbf{2}\text{-LiHal}}{R^1R^2CLi_2\text{-}LiHal} + DBB \quad (3)$$

$$2\,\mathbf{4} \longrightarrow \underset{\mathbf{3}\text{-LiHal}}{R^1R^2CLi\text{-}CLiR^1R^2\text{-}LiHal} \quad (4)$$

$$\mathbf{2}\text{-LiHal} + R^1R^2CLiHal\text{-}LiHal \longrightarrow \mathbf{3}\text{-LiHal} \quad (5)$$

Scheme 1. DBB = 4,4′-di-*tert*-butylbiphenyl. The structures of the compounds listed here are unknown. However, it is well established that organolithium compounds are modified by lithium halide[7c, 13, 16]. This is expressed here and in the text by the addition of -LiHal (no stoichiometry is implied) to the formulas and compound numbers or by expressions such as "lithium compounds of type..." Several proposed structures are discussed in the text.

Table 1. Reduction of **5a** and **5b** with LiDBB. The yields [%] of the lithium compounds of types **7**–**9** and other compounds are based on analysis by gas chromatography (internal standard: *n*-decane) after deuterolysis[a].

Run	**5a,b** Y	*T* [°C]	Additive [b]	**7** [c]	**8** [c]	**9** [d]	Other cmpds. yield [%]
1	Cl	−95		1 [e]		9	**6a**, 50
2	Cl	−75		6 [e]		71

13	Br	−95 [n]		24	55	1 <	

[a] All detected components are listed. The material missing from the mass balance cannot be accounted for. [b] Added to **5a,b**. [c] From the ratio of 7,7-dideuterio- and 7-deuterionorcarane obtained by ^{1}H NMR spectroscopy. [d] According to ^{1}H NMR spectroscopy only dideuterated material was present. [e] Sum of **7** and **8**. The deuterium distribution could not be determined precisely by ^{1}H NMR spectroscopy. [f] Equivalents, based on **5a** (**5b**). [g] TMEDA: *N,N,N′,N′*-tetramethylethylenediamine. [h] PMDTA: *N,N,N′,N″,N″*-pentamethyldiethylenetriamine. [i] TMTAN: *N,N′,N″*-trimethyl-1,4,7-triazacyclononane. [j] After the usual reaction time the reaction mixture was cooled to −90 °C, and a cold solution of *t*BuCl in THF was added until the color changed from blue to red. Deuterolysis followed. [k] Dimethylsulfate was added. The reaction mixture was allowed to warm to room temperature and subjected to aqueous workup. Yield of 7,7′-dimethyl-7,7′-dinorcarane. [l] Origin unknown. [m] Quenched with MeOH after 2.5 h. [n] Inverse addition. A solution of **5b** was added to 8 equiv LiDBB.

Run 1 shows that **5a** is initially transformed into carbenoid **6a**-LiCl, which at −95 °C reacts very slowly with LiDBB. At −75 °C (Run 2) **6a**-LiCl is converted completely into a mixture of lithium compounds of types **7**, **8**, and **9** [(**7** + **8**):**9** ≈ 1:12]. When a polydentate nitrogen base such as TMEDA, PMDTA, and TMTAN (for abbreviations see footnotes [g]–[i] in Table 1) is added to the starting solution of **5a** (Runs 3–5), the ratio (**7** + **8**):**9** inverts to a value of

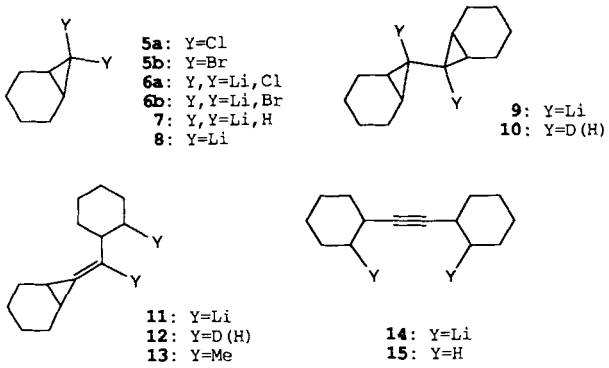
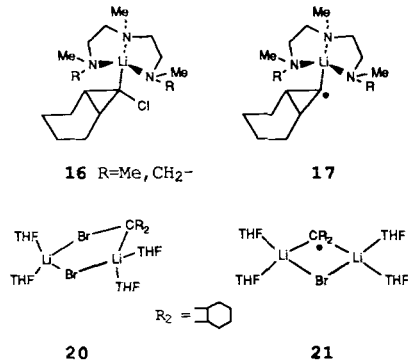
Scheikundig Laboratorium Vrije Universiteit
De Boelelaan 1083, NL-1081 Hv Amsterdam (The Netherlands)

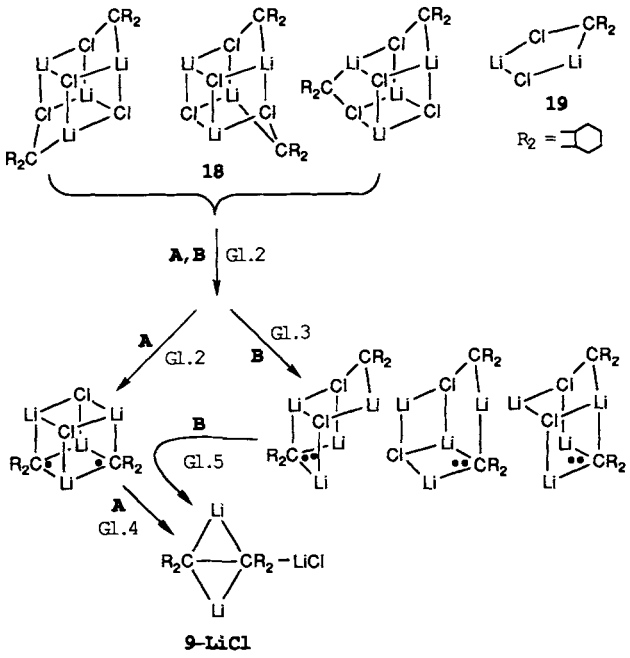


approximately 4:1 (**7**:**8** ≈ 5:1). These Lewis bases cleave aggregates of organolithium compounds in the order of activity TMEDA < PMDTA < TMTAN.[12] Their influence on the ratio (**7** + **8**):**9** may be explained most simply by the assumption that in the presence of PMDTA and TMTAN complexes **16** of the monomeric carbenoid **6a** are reduced by LiDBB to the corresponding α-lithioradicals **17**. The dominant reaction of **17** is hydrogen abstraction to give lithium compounds of type **7**. Only to a minor degree does LiDBB



reduction of **17** lead to dilithium compounds of type **8**. For the reactions conducted without PMDTA and TMTAN (Runs 2(6) and 7–9) we propose a dimer of type **18** (Scheme 2) as the simplest aggregate of **6a**-LiCl that could lead predominantly to **9**-LiCl (and in Runs 9 and 10, to **11** and **14**). The proposal is based on the following assumptions: 1) **6a**-LiCl has structure **19**, which corresponds to the one calculated for CH_2LiF–LiF.[13] 2) In line with the common structural relationship between Li_2X_2 and Li_4X_4 systems (X = C, O, Hal),[14] two units of **19** combine to give aggregate **18**. In Run 6 the unreacted LiDBB was destroyed by addition of *t*BuCl before deuterolysis. No change in the composition of the product mixture was observed (cf. Run 2). This excludes the possibility that the reaction with the fourth equivalent of LiDBB takes place only after the addition of the first equivalent of electrophile. Therefore, processes A [Scheme 1, Eqs.(2),(4)] and B [Scheme 1, Eqs.(2),(3),(5)] shown in Scheme 2 are proposed as possible paths for the transformation of **18** into **9**-LiCl.[15]

Whereas cyclopropylmethyllithium rearranges into 4-lithiobutene already at −70 °C, **9**-LiCl is persistent at this temperature. As shown in Run 7, it is stable even at −30 °C in THF for several minutes. The reasons for the slower ring opening of **9**-LiCl are not known, but may be related to the bonding in (aggregated) 1,2-dilithioethane derivatives.[3b] After 5 min at 0 °C most of **9**-LiCl had rearranged to **11**-LiCl (Run 9, see also the formation of **13** in Run 8). When the reaction temperature is kept at 25 °C for a longer time (Run 10), only **12** and alkyne **15** are isolated in the ratio 1:5.



Scheme 2. For clarity, the complexation of lithium by THF is not shown. The representation of **9**-LiCl is based on the structure found for **3** ($R^1 = R^2 = R^3 = R^4 = SiMe_3$) (Sekiguchi et al.[4b]).

In Runs 11 and 12 the proportion of **7** + **8** is higher than in Runs 2 and 3. This suggests that the less stable[16] α-bromolithium compounds **5b**-LiBr (possible structure in THF: **20**, see ref.[13]) have a lower tendency toward aggregation than their chloro analogues **5a**-LiCl. Support of our hypothesis that compounds **7** and **8** arise from monomeric carbenoid presursors is provided by Run 13. When **5b** is added to an excess of LiDBB, **20** should be trapped by reduction to **21** before dimerization can take place. The α-lithio radical **21** is probably more stable and therefore less aggressive than **17**. Besides the product of hydrogen abstraction, **7**-LiBr, it forms the dilithium compound **8**-LiBr predominantly.

Several other geminal dihalocyclopropanes were examined under the conditions of Run 2(11). The deuterolysis results indicate that the reaction of 8,8-dichlorobicyclo[5.1.0]octane produces homologues of **7**-LiCl, **8**-LiCl, and **9**-LiCl in yields of 8, 22, and 31%, respectively. 1,1-Dibromo-2,2,3,3-tetramethylcyclopropane might lead to a carbenoid with greater steric hindrance and a reduced tendency toward dimerization. Accordingly it forms only traces (<1%) of the 1,2-dilithioethane derivative. After the reaction mixture was worked up with dimethylsulfate, pentamethylcyclopropane (20%) and hexamethylcyclopropane (47%) were obtained. For some obscure reason cyclopropylmethyltin was the sole product (20%) obtained from the reaction of 1,1-dibromocyclopropane after workup with trimethyltin chloride. However, the reaction of a 1:1 mixture of 1,1-dibromocyclopropane and **5a** yielded among other

products the 7-lithio-7-(1-lithiocyclopropyl)norcarane corresponding to **9**.

$[Tc_6X_8]$ Clusters in ternary Technetium Chalcogenides**

By *Welf Bronger,* Martin Kanert, Markus Loevenich, Dieter Schmitz,* and *Klaus Schwochau*

Octahedral structural units composed of six niobium, tantalum, molybdenum, or tungsten atoms have been known for more than four decades. The anions X which surround these M_6 octahedra as a first coordination sphere reveal two different configurations: the $[M_6X_{12}]$ cluster in which the X atoms coordinate the M_6 octahedron over the edges, and the $[M_6X_8]$ cluster in which the M_6 octahedron is coordinated by X atoms over its faces. The former composition occurs preferably in niobium and tantalum compounds and the latter in molybdenum and tungsten compounds. In the crystalline solid, the clusters are generally linked to one another through M atoms by anionic bridges.

The corresponding rhenium clusters whose existence was previously discussed in the sixties[1] were established for the first time in 1978 in ternary sulfides such as $Na_4Re_6S_{12}$.[2] $[Re_6S_8]$ clusters are found as the characteristic structural units which are bridged by additional S atoms or S_2 groups to build anionic frameworks. The alkali metal ions occupy vacancies which have suitable sulfur coordination spheres.

Are there analogous technetium clusters? To answer this question we have investigated the preparation and structural characterization of ternary technetium chalcogenides and the results of our findings are described herein.

The syntheses of the desired compounds were carried out in a radiochemical laboratory at the Institut für Nuklearchemie des Forschungszentrums Jülich. The technetium isotope ^{99}Tc was utilized, which among the long-lived nuclides is the only one accessible in weighable quantities through the induced fission of ^{235}U with thermal neutrons. ^{99}Tc decays with β^- emission ($t_{1/2} = 2.12 \times 10^5$ a, $E_{max} = 0.29$ MeV). Technetium and its compounds were handled in Plexiglass boxes which retain β radiation to the most part.

We have successfully prepared the ternary technetium chalcogenides **1**–**6**. The sulfides were synthesized by heating

$K_4Tc_6S_{12}$	$K_4Tc_6Se_{12}$	$Rb_4Tc_6S_{13}$	$Rb_4Tc_6Se_{12}$	$Cs_4Tc_6S_{13}$	$Cs_4Tc_6Se_{13}$
1	**2**	**3**	**4**	**5**	**6**

alkali metal carbonates, elemental technetium, and sulfur under an argon atmosphere at 800 °C for about 8 h. Well-formed, black, shiny crystals were obtained by extracting the cooled melt with water and ethanol. The synthesis of the selenides was achieved in an analogous manner under a hydrogen atmosphere. During attempts to produce sulfur compounds under a hydrogen stream, a new type of cluster compound was obtained; the structure determination is currently in progress.

All six chalcogenides are isolated phase-pure and crystallize with monoclinic cells in the space group $C2/c$. The lattice constants are listed in Table 1; compounds with the same composition are isostructural. Single crystal structure deter-

Table 1. Dimensions of the monoclinic unit cells (space group $C2/c$) for the ternary technetium chalcogenides **1**–**6**. The lattice constants as determined from Guinier photographs are given in Å and degrees (standard deviations in parentheses).

Compound	a	b	c	β
$K_4Tc_6S_{12}$ **1**	16.463(4)	9.667(3)	11.841(2)	91.40(2)
$K_4Tc_6Se_{12}$ **2**	17.165(2)	10.019(2)	12.301(2)	91.42(1)
$Rb_4Tc_6S_{13}$ **3**	9.745(2)	16.595(4)	13.913(3)	99.83(2)
$Rb_4Tc_6Se_{12}$ **4**	17.640(4)	10.092(1)	12.464(1)	91.30(1)
$Cs_4Tc_6S_{13}$ **5**	9.983(1)	17.120(4)	13.643(3)	100.68(1)
$Cs_4Tc_6Se_{13}$ **6**	10.275(2)	17.826(3)	14.161(4)	100.89(2)

minations[3] show that $[Tc_6X_8]$ clusters are found in both structure types as the structural units (Fig. 1). The six technetium atoms form in each case nearly regular octahedra; their average dimensions are given in Table 2. The eight chalcogen atoms are found over the octahedral faces. The resulting cube is again nearly regular (Table 2). The Tc_6 octahedron of every $[Tc_6X_8]$ unit is linked in all three directions in space to neighboring octahedra through additional X atoms or X_2 groups. The alkali metal ions are inserted in suitable interstices found within the anionic framework, whereby allowances are obviously made for the spatial requirement of the cations through a variation of the bridges linking the $[Tc_6X_8]$ units. The construction of the framework for the potassium compounds **1** and **2** is accomplished by connecting the $[Tc_6X_8]$ clusters through four X and two X_2 bridges each, according to the scheme $K_4[Tc_6X_8]X_{4/2}(X_2)_{2/2}$ (Fig. 2). In contrast, the larger interstices of the cesium compounds **5** and **6** are made possible through the formation of only two X but four X_2 bridges between adjacent $[Tc_6X_8]$ units, so that the formula $Cs_4[Tc_6X_8]X_{2/2}(X_2)_{4/2}$ results (Fig. 3).

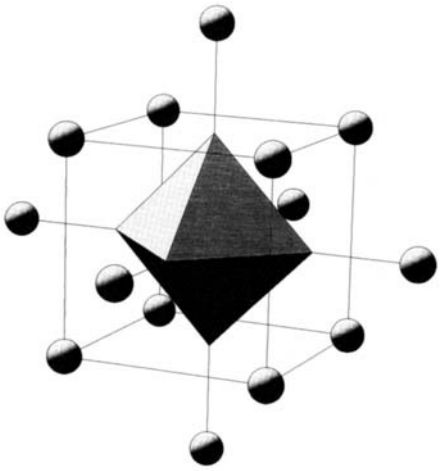

Fig. 1. The $[Tc_6X_8]$ structural unit and bridging chalcogen atoms.

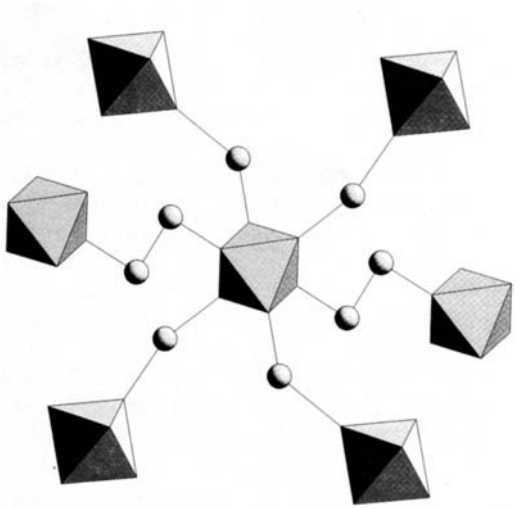

Fig. 2. Linkage of Tc_6 octahedra within the framework structure $\{[Tc_6X_8]X_{4/2}(X_2)_{2/2}\}^{4-}$. The X_8 cubes surrounding the Tc_6 octahedra were omitted for clarity.

Accordingly, in the structure of **4**, due to the relatively large selenium atoms, linkage through four Se^{2-} and two Se_2^{2-} bridges is sufficient to create the required space for the Rb^+ ions to be inserted, whereas in the sulfide **5**, two S^{2-} and four S_2^{2-} bridges are necessary. In the corresponding rhenium compounds, some of which are isostructural with the technetium compounds presented here, we observed an analogous trend.[4–8]

Table 2. Average values of comparable interatomic distances d [Å] and angles [°] (the real values are within the specified interval) [a].

[a] X^i: chalcogen atoms within the $[Tc_6X_8]$ units, X^a: chalcogen atoms bridging Tc_6 clusters. [b] In the $A_4Tc_6X_{12}$ compounds the X^a atoms composing the X_2 bridges occupy special positions, so that the values listed here represent real distances rather than the average.

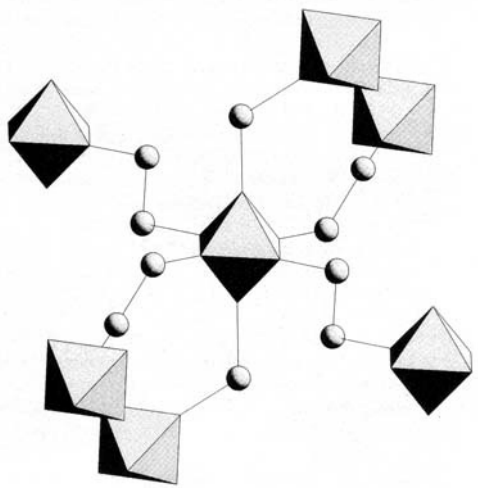

Fig. 3. Linkage of Tc_6 octahedra within the framework structure $\{[Tc_6X_8]X_{2/2}(X_2)_{4/2}\}^{4-}$. The X_8 cubes surrounding the Tc_6 octahedra were omitted for clarity.

Until now, the existence of $[M_6X_8]$ clusters in technetium chemistry was not shown conclusively. Structural entities

described as $\{[Tc_6Br_5]Br_6\}^{2-}$ anions appear to be structurally related.[9, 10] Here it is assumed that the five bromide ions are statistically distributed over the eight positions of the X_8 cube. However, the analytically determined composition, which points to a mixed-valent compound, contradicts the observed magnetism and high symmetry of the Tc_6 octahedron (see the following section).

In the ternary technetium chalcogenides we have presented here, technetium is found in each case in a +3 oxidation state, which indicates that there are 24 valence electrons per Tc_6 unit. According to MO calculations all the bonding states are occupied to give a stable electron configuration.[11] This is in accordance with the observation that all the Tc_6 octahedra are nearly regular, that is a collective Jahn–Teller effect does not occur.[12] The magnetic behavior is also in agreement with this. All six compounds reveal down to low temperatures nearly temperature-independent susceptibilities from -490 to $-665 \times 10^{-6}\ cm^3 mol^{-1}$. After diamagnetic correction [13] a weak temperature-independent paramagnetism is found; such paramagnetism is often observed in cluster compounds.[14–16]

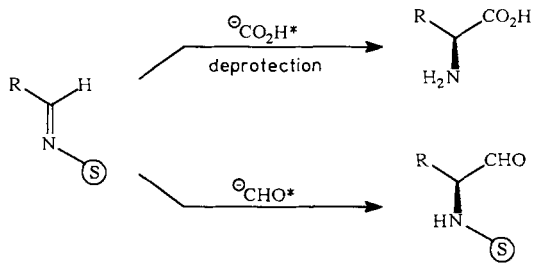
Asymmetric Synthesis of α-Amino Acids and N-Protected α-Amino Aldehydes by Addition of Chiral Vinyl Anions to Sulfonylimines**

By *Manfred Braun** and *Kersten Opdenbusch*

The diversity of methods for the synthesis of α-amino carboxylic acids at our disposal today is based on only a few fundamental concepts. In addition to enzymatic procedures, these include, in particular, asymmetric hydrogenation of dehydroamino acids, alkylation of chiral glycine enolates, electrophilic and nucleophilic amination, addition of C nucleophiles to imino esters, and nucleophilic addition of CO_2H equivalents to chiral imines.[1] Herein we report for the first time on the stereoselective addition of chiral $^{\ominus}CO_2H$ and $^{\ominus}CHO$ synthons to prochiral sulfonylimines, providing access to nonracemic α-amino acids and the N-protected α-amino aldehydes, which are valuable synthetic building blocks (Scheme 1).



Scheme 1. Ⓢ: protecting group.

The dibromoolefin (*S*)-**1**, readily accessible from *S*-ethyl lactate in three steps, is converted into the vinyl anion **2** (*E*:*Z* > 99:1) by stereoselective bromine/lithium exchange with *n*-butyllithium (Scheme 2).[2] Subsequent addition of the mesityl sulfonylimines **3** at −110°C resulted mainly in the

adducts **4**, whose diastereomeric excesses (*de*) and chemical yields are given in Table 1.[3] After column chromatography

Table 1. Adducts **4** prepared by addition of the vinyl anion **2** to mesityl sulfonylimines **3**.

Compound **3**–**4**	R	Yield [%] [a] **4**	(*de*) [%] [b] **4**
a	C_6H_5	62	92
b	4-$CH_3OC_6H_4$	63	92
c	4-(ThexMe$_2$SiO)C_6H_4	54	92
d	$(CH_3)_2CHCH_2$	20	94
e	$(CH_3)_2CH$	40	94
f	$(CH_3)_3C$	52	96

[a] Yields of products purified by column chromatography. [b] Each determined in the crude product by NMR spectroscopy.

of the adducts **4** the excess diastereomers are obtained with > 98% *de* each. The aryl-substituted imines **3a, b** were produced by heating a mixture of mesityl sulfonamide and the dimethyl acetal of the corresponding arylaldehyde.[4a] In contrast, the imines **3c–f** are prepared from the reaction of mesityl sulfonamide with thionyl chloride and the subsequent reaction of the *N*-sulfinyl arylsulfonamide Ar-$SO_2N{=}S{=}O$ formed with the corresponding aldehyde in the presence of boron trifluoride etherate.[4b] However, the sulfonylimines **3d** and **3e** derived from isobutyraldehyde and 3-methylbutanal, respectively, cannot be obtained free from the corresponding tautomeric enamine; thus, lower chemical yields are obtained for the adducts **4d** and **4e** (cf. Table 1; spectroscopic data of **4a–f** see Table 2).

Table 2. Characteristic spectroscopic data of the compounds **4a–f** and **12a–c**.

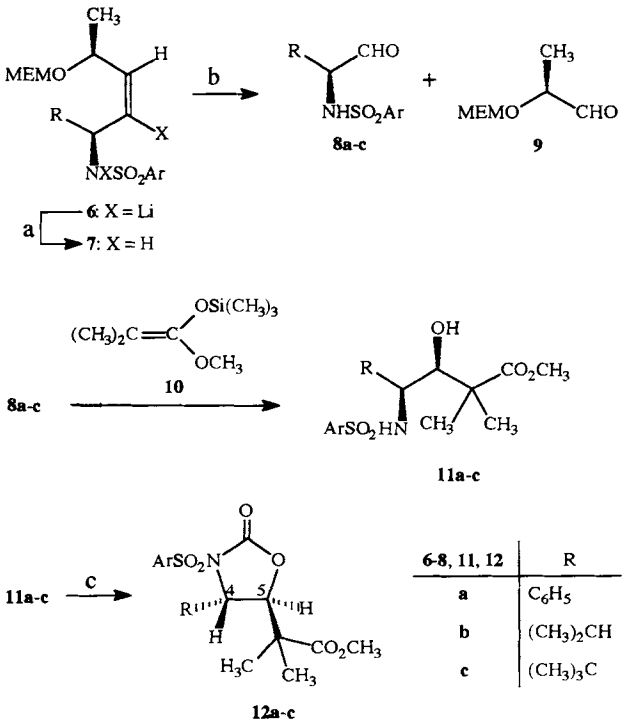
12c: ^{1}H NMR (300 MHz, $CDCl_3$, TMS int.): δ = 0.99 (s, 9H, C$(CH_3)_3$), 1.18 (s, 3H, CH_3), 1.24 (s, 3H, CH_3), 2.30 (s, 3H, ArCH_3), 2.72 (s, 6H, ArCH_3), 3.70 (s, 3H, OCH_3), 4.10 (d, J = 2.0 Hz, 1H, CH(N-)), 4.55 (d, J = 2.0 Hz, 1H, CH(O-)), 6.97 (s, 2H, ArH)

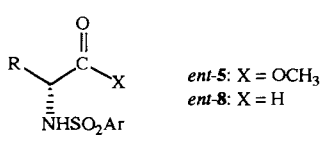
The ozonolysis of the bromoolefins **4a–c** in methanol/dichloromethane[5] leads directly to the N-protected amino acid methyl esters **5a–c** (70 to 80%). These can be converted into the free amino acids as exemplified by **5a**: saponification (LiOH, CH_3OH, H_2O) and subsequent cleavage of the sulfonamide protecting group with sodium naphthalenide in 1,2-dimethoxyethane at −40° C[6] affords phenylglycine in 78% yield (*ee* > 98%).

To obtain the N-protected amino aldehydes **8a–c** first the adducts **4a, e, f** are again lithiated (*tert*-butyllithium, THF) under bromine/lithium exchange. The dilithium compounds **6a–c** formed can then be protonated to give the *Z* alkenes **7a–c**, whose ozonolysis after workup with dimethyl sulfide affords the aldehydes **8a–c** in almost quantitative yields (Scheme 3). The MEM-protected lactaldehyde **9** formed at



Scheme 3. Synthesis and diastereoselective Mukaiyama reaction of the N-protected amino aldehydes **8**. a) NH_4Cl, H_2O. b) O_3, CH_2Cl_2, $(CH_3)_2S$. c) $COCl_2$, toluene, pyridine or Et_3N.

the same time is condensed under high vacuum (10^{-4} Torr/25° C) in a trap cooled with liquid nitrogen and can be reused for the synthesis of the dibromoolefin **1**.[2] Under these conditions a racemization of the remaining N-protected amino aldehyde **8a–c** can be largely suppressed. Starting from the *R*-dibromoolefin **1**[2] obtained from *R*-2-methypropyl lactate, analogous sequences lead to the enantiomeric *N*-sulfonylated amino aldehydes *ent*-**8** or to the esters *ent*-**5**.



To test the applicability of the N-protected amino aldehydes **8a–c** as a starting material for further stereoselective

C–C couplings,[7] they were allowed to react with the ketene silyl acetal **10** in the presence of titanium tetrachloride ("Mukaiyama–aldol reaction"[8]). The *syn*-configurated adducts **11a–c** (72–76% yield based on **7**) are formed with a remarkable stereoselectivity (*de* > 98%), which can be interpreted as arising from a chelate-controlled reaction.[9] The relative configuration of the β-hydroxy esters **11a–c** is determined by its conversion into the oxazolidinones **12a–c** ($COCl_2$, pydridine, toluene). In the ^1H NMR spectra of **12a–c** the coupling constant (4.5 Hz) of the protons H4 and H5 allows an unambiguous assignment of the *trans* configuration (Table 2).[11, 12] Furthermore, ^1H NMR shift experiments with [Eu(hfc)$_3$][12] indicate an enantiomeric excess of the heterocycles **12a–c** of 93–96%.[13] The optical purity of **12a–c** lies only slightly below the diastereomeric excess of the corresponding purified adducts **4a, e, f**, which shows that the *N*-sulfonylated amino aldehydes **8** retain their configurations under the conditions of their formation, isolation, and conversion in the Mukaiyama reaction. However, as expected, heating the aldehydes **8** leads to racemization. The addition of the chiral vinyl anions (*S*)- and (*R*)-**2** to sulfonylimines **3** allows, in particular, an easy access to arylglycines[14] and N-protected arylglycine aldehydes with high enantioselectivity. In the latter case the mesityl sulfonyl protecting group proves to be an efficient stereoregulating element for nucleophilic additions to the aldehyde group.

Structures of Classical Reagents in Chemical Synthesis: $(n\text{BuLi})_6$, $(t\text{BuLi})_4$, and the Metastable $(t\text{BuLi} \cdot Et_2O)_2$**

By *Thomas Kottke* and *Dietmar Stalke**

Alkyllithium compounds are particularly important in synthetic chemistry as deprotonating and substituting reagents and as catalysts in polymerization.[1, 2] As long ago as 1917, Schlenk and Holtz reported the first synthesis of alkyllithium compounds;[3] in 1963 the first solid-state structural analysis of a substance of this class, namely tetrameric ethyllithium, was achieved by Dietrich.[4] Subsequently, numerous RLi compounds have been characterized by X-ray structure investigations.[5–12] The degree of oligomerization of the compounds of this class most commonly used in synthesis, *n*BuLi and *t*BuLi, have long been established by cryoscopic and spectroscopic measurements. In hydrocarbons *n*BuLi is hexameric[13–16] and *t*BuLi is tetrameric;[17–20] in donor solvents a lower degree of aggregation is preferred.[21–23] Until now, however, no information about the crystal structures of *t*BuLi and of donor-free *n*BuLi have been available. This is probably due to the fact that these compounds (especially *t*BuLi) are pyrophoric and that *n*BuLi is an oil at room temperature. Herein we describe the crystallization and the X-ray single-crystal structures[24] of donor-free *n*BuLi and *t*BuLi and also of the metastable adduct of *t*BuLi with one equivalent of diethyl ether.

For the crystallization, a temperature was chosen at which the nearly saturated solutions could be prepared; this should be as low as possible to avoid phase transitions during low temperature data collection (here: −90 °C). The limiting values taken into account were the melting point of *n*BuLi (−76 °C according to reference [1]; the melting point of the crystals investigated here, however, was −34(2) °C) and the temperature at which decomposition of $t\text{BuLi} \cdot Et_2O$ might occur (−40 °C[25] and −35 °C[26] for $t\text{BuLi} \cdot Et_2O$). To achieve a gradual and controlled crystallization, all solutions were prepared at −80 °C. The crystallization period was extended to one week by redissolving crystals formed initially, thus leaving a small number of nucleation sites in the solution. This technique appears to increase the probability of forming single crystals suitable for X-ray crystallography.[27] During the preparation of crystals for data collection (selecting and mounting a crystal and transporting it to the diffractometer) the temperature of a sample never exceeded −45 °C. This was facilitated by using apparatus developed for mounting crystals at low temperatures.[28] Thus the crystals could be kept at −60 °C on the polarization microscope slide, and then transferred to the diffractometer with a portable liquid nitrogen evaporator (see also ref. [29]). The use of inert gas Schlenk techniques and sealing with inert oil[28] were necessary to prevent the extremely oxygen and moisture-sensitive crystals from reacting with air.

All three compounds are discrete aggregates and no interactions between oligomers were found such as have been observed, for example, in the solid-state structure of MeLi (the shortest Li–C distance between two oligomeric units is 382 pm found in *n*BuLi; in MeLi it is 252 pm[5]). The framework of *n*BuLi consists of six Li atoms in a trigonal anti-prismatic (distorted octahedral) conformation (approximately D_{3d} symmetry) with six short (241.3(3)–243.7(3), average

242.9 pm), and six long (289.8(3)–297.0(3), average 293.9 pm) Li–Li distances (Fig. 1). Analogous to cyclohexyllithium,[8] isotypic cyclopentyllithium,[12] and a lithiomethylcyclopropane derivative,[10] six faces of the octahedron are each capped by a single *n*Bu unit; two almost equilateral (and opposite) triangular faces with the longest edges remain unoccupied. Each α-carbon atom is coordinat-

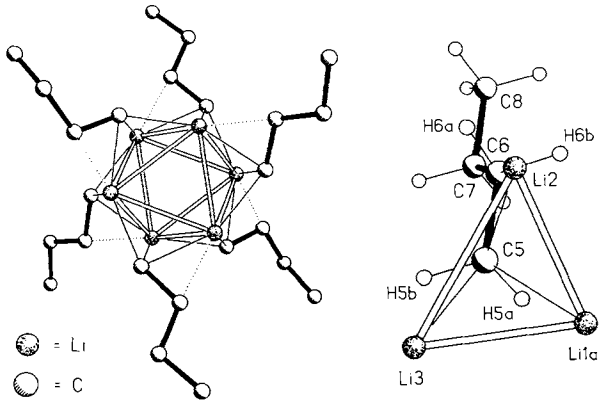

Fig. 1. Left: Crystal structure of *n*BuLi. Right: The projection perpendicular to one of the Li triangles of the distorted octahedron with a coordinated *n*Bu group. Selected bond lengths [pm] and angles [°] (average values): C_α–C_β 153.3(2), C_β–C_γ 152.1(5), C_γ–C_δ 150.5(6); C_α-C_β-C_γ 117.4(5), C_β-C_γ-C_δ 113.7(1).

ed to two Li atoms positioned at the corners of one of these (noncapped) triangles through short bonds (213.7(3)–217.5(3), average 215.9 pm), whereas the bond to the Li atom at the corner of the opposite triangle is significantly longer (226.2(3)–227.7(3), average 227.0 pm). Hence, the *n*Bu moieties do not lie centrally over the isosceles Li triangles but are shifted to one edge (Fig. 1 right). As a result of this, short distances occur between the β-C atoms and the Li atoms, which may be interpreted as electrostatic interactions (Li–C distance: 228.0(3)–229.5(3), average 228.7 pm; though they are in the range of the longer Li–C_α bonds). At the same time this conformation has short Li–H_α and Li–H_β distances (Fig. 1 right: 204(2) pm for Li3–H5b and 203(2) pm for Li2–H6a). The hydrogen atoms at the α–C and β–C atoms are arranged staggered with respect to the nearest Li atom. In conclusion, *n*BuLi shows similar structural characteristics to the cyclic alkyllithium compounds mentioned above. Even in the complex (*n*BuLi · LiO*t*Bu)$_4$ remarkably short Li–C_β distances are observed (234(1) pm[30]). Apparently a fourfold coordination of the Li atoms by including β–C atoms is preferred in spite of the elongation of a Li–C_α bond.

*t*BuLi consists of tetrameric units of almost T_d symmetry (Fig. 2) in the crystal. The asymmetric unit is made up of 4.5 tetramers; one tetramer is crystallographically generated through a twofold axis. Each face of the Li_4 tetrahedron is capped by a *t*Bu group such that the (terminal) Me groups are eclipsed with respect to the corresponding Li atoms of the (within the standard deviation) equilateral triangles (Fig. 2 right). This conformation again involves comparatively short Li–C_β distances (227.5(8)–256.6(9), average 237.4 pm). Thus, the structure of *t*BuLi is essentially different from that of MeLi in which the hydrogen atoms of the Me groups (in contrast to the conformation of C_β atoms in *t*BuLi) are staggered relative to the Li atoms.[6] As in *n*BuLi Li–C_β interactions may participate in determining the conformation of *t*BuLi, especially since the β-C atoms would

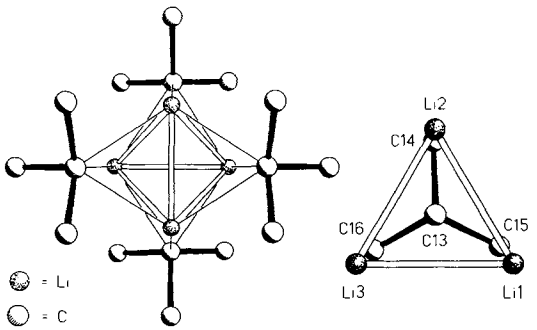

Fig. 2. Left: Crystal structure of *t*BuLi. Right: The projection perpendicular to one of the Li triangles of the tetrahedron with coordinated *t*Bu group. Selected bond lengths [pm] and angles [°] (minimum/maximum/average): C_α–C_β 150.9(5)/157.9(9)/153.4; C_β-C_α-C'_β 104.1(4)/108.5(5)/105.9, Li-C_α-Li' 62.1(4)/66.7(4)/64.9.

preferentially be staggered for steric reasons. The Li-C_α bond lenghts (214.7(17)–237.0(14), average 224.6 pm) are in the range of the values observed in similar compounds, while the Li–Li distances in *t*BuLi (238.3(9)–243.1(8), average 241.2 pm) are significantly shorter (Li–Li and Li–C [pm] in EtLi:[4] 255 and 225, respectively, in MeLi:[6] 256 and 227, respectively). The relatively large variation of the C–C and Li–C distances in *t*BuLi is caused by disorders of the *t*Bu groups.

*t*BuLi · Et_2O is a dimer which is generated crystallographically from the monomeric unit through a twofold axis (Fig. 3). The central four-membered ring consisting of two

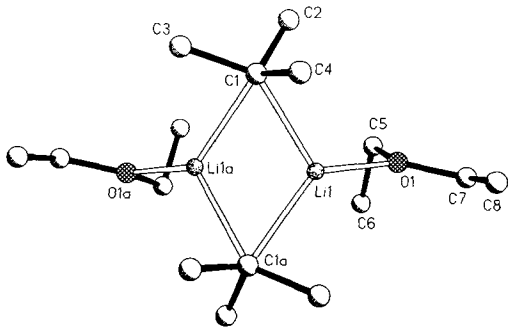

Fig. 3. Crystal structure of (*t*BuLi · Et_2O)$_2$. Selected bond lengths [pm] and angles [°]: Li1–C1 217.4(6), Li1–C1a 219.4(6), Li1–O1 194.0(5); Li1-C1-Li1a 63.6(2), C1-Li1-C1a 110.7(2).

Li and two bridging α–C atoms of the *t*Bu groups is strongly distorted about the Li–Li axis (the angle between the planes Li1–C1–Li1a and Li1–C1a–Li1a is 29.1(4)°), which is consistent with the steric demand of the Et_2O molecules and the *t*Bu groups. This steric hindrance provides a possible explanation for the absence of a second donating Et_2O molecule per Li atom as postulated for *t*BuLi in ether.[26] In connection with this it should be noted that solutions of *t*BuLi in ether are stable even with a large excess of ether (Et_2O:*t*BuLi ≈ 6:1) over a wider temperature range (up to about −40 °C), as observed in NMR studies.[26]

Experimental Procedure

All three compounds were prepared starting with commercially available solutions (in hexane or pentane); solvent was removed from these solutions under vacuum.

*n*BuLi: To *n*BuLi (2.9 g, 46 mmol), constantly stirred at −80 °C, precooled pentane was added dropwise until a homogeneous solution was obtained (ca. 20 mL). After one week at −90 °C colorless blocks crystallized with a melting point of −34(2) °C.

*t*BuLi: *t*BuLi (2.2 g, 34 mmol) was treated as described for *n*BuLi (ca. 18 mL pentane added). Crystallization over one week yielded colorless elongated blocks.

(*t*BuLi · Et_2O)$_2$: From various pentane/Et_2O ratios the best results were obtained by first adding 5 mL pentane and then 12 mL Et_2O (each precooled to −60 °C) dropwise to solid *t*BuLi (2.2 g, 34 mmol) at −80 °C. At −90 °C colorless blocks with a melting point of −38(2) °C were formed from the pale yellow solution.

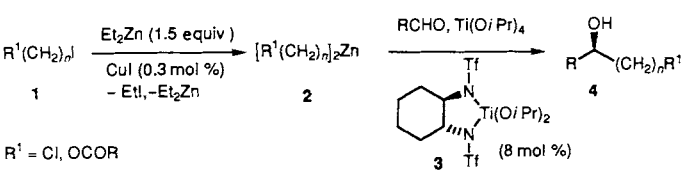
Enantioselective Catalytic Addition of Functionalized Dialkylzinc Compounds to β-Stannylated Aldehydes: A Convenient Preparation of Chiral β- and γ-Functionalized Secondary Alcohols**

By *Walter Brieden, Roswitha Ostwald*, and *Paul Knochel**

Recently we described a general method for the preparation of dialkylzinc compounds of the type **2** from the corresponding alkyl iodides **1**.[1] These functionalized organozinc reagents proved to be extremely useful for the catalytic asymmetric addition to aldehydes in the presence of the chiral catalyst **3**.[1, 2]. The method allows an easy access to polyfunctional secondary alcohols **4** in both enantiomeric forms with excellent enantioselectivity.[2m] Unfortunately, as we



tried to extend this reaction to functionalized aldehydes bearing, for example, an oxygen functionality in the γ-position, stoichiometric amounts of the catalyst **3** were necessary.[1] In addition, acceptable chemical yields could only be obtained with *unfunctionalized* diorganozinc compounds **1**. We report now that this problem does not arise if β-stannylated aldehydes such as **5**[3] or **6**,[4] are used, and that with these aldehydes polyfunctionalized alcohols are readily accessible, which, in a second step, can be converted into polyoxygenated molecules.

The aldehydes **5** and **6** react readily under mild conditions (−35 to −25 °C, 16 h for **5a**, **b** and −60 to −50 °C, 2 h for **6**) with the functionalized diorganozinc compounds **2**, and afford good to excellent yields (67–89%) and enantioselectivities (90–97% *ee*)[5] of the stannylated alcohols **7**–**9** (Table 1). All reactions have been performed with a catalytic amount of **3** (ca. 8 mol%). Remarkably, the presence of an ester or halide functionality does not interfere in these reactions, even if the ester group is relatively close to the metal center (γ position), as is the case in the formation of **9f**. This method allows a one-step enantioselective synthesis of the

allylic alcohol **9b** (88% yield, 92% *ee*), a building block for the preparation of prostaglandins and leucotrienes.[6] The alcohols **7**–**9** can be readily destannylated and thus open the way to several important classes of functionalized alcohols.

Table 1. Stannylated secondary alcohols of type **7**–**9**, obtained by the catalytic asymmetric addition of $[R^1(CH_2)_n]_2Zn$ **2** to the aldehydes **5** and **6**.

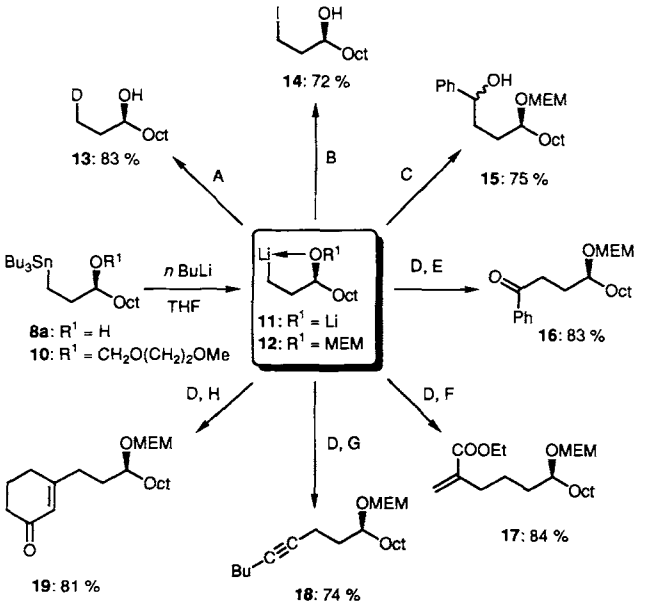
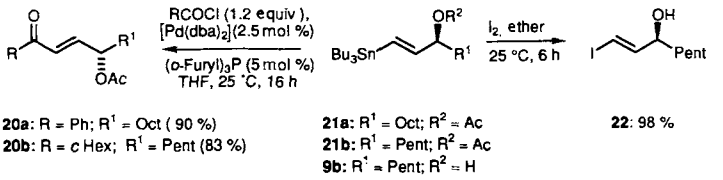
[a] The reported yields are yields of isolated analytically pure product with the expected spectroscopic data (^1H NMR, ^{13}C NMR, IR and MS). [b] The optical rotations were measured in benzene.

The treatment of **8a** with *n*-BuLi (3 equiv, THF, −25 °C, 12 h) provides the γ-lithiated lithium alcoholate **11** (R^1 = Li) in good yields (Scheme 1). The deuterolysis of **11** gives the deuterated alcohol **13** (83% yield, degree of deuteration > 95%) and its iodolysis leads to 1-iodo-3-undecanol **14** (72%). However, because of the low reactivity of **11**, which may be due to the chelation of the γ-lithium atom with the OLi group,[7] this compound only reacted with a few electrophiles. The conversion of **8a** to the methoxyethoxymethyl (MEM) ether **10** allows the preparation of the reactive organolithium compound **12**, which reacts with benzaldehyde leading to the 1,4-diol derivative **15** as a 1:1 mixture of two diastereoisomers (75%). Interestingly, the transmetallation of **12** with the THF-soluble copper salt CuCN · 2 LiCl[8] affords a copper reagent (20 °C, 5 min), which reacts in good yield with various electrophiles. The benzoylation of **12** is of particular interest, providing the homoaldol product **16** (83%). The allylation of the copper derivative of **12** with ethyl α-(bromomethly)acrylate[9] gives the unsaturated ester **17** (84%), whereas its reaction with 1-iodohexyne furnishes the acetylenic ether **18** (74%). Finally, the unsaturated ketone **19** (81%) is accessible by an addition–elimination sequence with the copper derivative of **12** and 3-iodo-2-cyclohexen-1-one.[10] These reactions demonstrate that the chiral stannylated alcohol derivatives **10** can be used for the preparation of a variety of polyfunctionalized secondary alcohols in optically active form.[11]



Scheme 1. A: D_2O, −25 °C; B: 1) $MgBr_2$; 2) I_2, −25 °C; C: PhCHO (2 equiv), −25 °C; D: CuCN · 2 LiCl (2 equiv), −20 to 20 °C; E: PhCOCl (2.5 equiv), −25 °C, 1 h; F: Ethyl α-(brommethyl)acrylate (3 equiv), −25 °C, 0.5 h, G: 1-Iodohexyne (2.5 equiv), −25 °C, 8 h; H: 3-Iodo-2-cyclohexen-1-one (2.5 equiv), −25 °C, 1 h.

The unsaturated alcohols **9** are versatile intermediates and lead to a range of interesting *polyfunctional* alcohols. After acylation of **9c**, the resulting acetate **21a** reacts with benzoyl chloride in the presence of bis-(dibenzylideneacetone)-palladium $[Pd(dba)_2]$ (2.5 mol%)[12] and tri-*o*-furylphosphane (5 mol%)[13] to give the γ-acetoxy ketone **20a** in 90% yield ($[\alpha]_D^{20}$ = − 8,5). Similarly, the reaction of **21b** with cyclohexanecarbonyl chloride furnishes the ketone **20b** (83%; *E*/*Z* ratio ca. 9:1). Thus, our method provides a highly enantioselective entry to nonracemic γ-alkoxy-α,β unsaturated carbonyl derivatives of type **20** which are useful building blocks in organic synthesis and are known to add various nucleophiles with excellent diastereoselectivity.[14] An iodolysis of the alcohol **9b** (I_2, ether, 20 °C, 5 h)[15] affords the iodide **22**[6] in excellent yield (98%, $[\alpha]_D^{20}$ = + 4,0).



20a: R = Ph; R^1 = Oct (90 %)
20b: R = *c*Hex; R^1 = Pent (83 %)

21a: R^1 = Oct; R^2 = Ac
21b: R^1 = Pent; R^2 = Ac
9b: R^1 = Pent; R^2 = H

22: 98 %

In summary we have shown that the catalytic enantioselective addition of dialkylzinc compounds to the stannylated aldehydes **5** and **6** affords chiral alcohols, which, after standard transformations of the carbon–tin bond, leads to chiral polyfunctional alcohols.

Experimental Procedure

A 100 mL three-neck flask equipped with an argon inlet, a thermometer, and a septum cap was charged with dry toluene (3 mL), $Ti(OiPr)_4$ (3.8 mL, 13 mmol), and (1*R*,2*R*)-1,2-bis-(trifluorosulfonamido)cyclohexane (0.2 g, 0.53 mmol). The reaction was heated to 40–45 °C for 0.5 h, and then cooled to −60 °C. Bis(4-chlorobutyl)zinc (ca. 15 mmol; prepared from 1-chloro-4-iodobutane (8.20 g, 38 mmol, 50 °C, 16 h) [1], Et_2Zn (6.0 mL, 59 mmol), and a catalytic amount of CuI (20 mg, 0.11 mmol) were dissolved in dry toluene (16 mL) and added to the cooled reaction mixture. After a few minutes the aldehyde **5b** (1.96 g, 5.65 mmol) was added. The reaction mixture was stirred for 16 h at −35 °C (2 h at −60 °C for **6**) and was worked up in the usual way. The crude oil was purified by flash chromatography (hexane:ether 4:1), which afforded the pure alcohol **8d** as a colorless oil (1.97 g, 79%, $[\alpha]_D^{20}$ = 2.0 (*c* = 8.95, C_6H_6). In the case of the aldehyde **6**, an excess of only two equiv of $[R^1(CH_2)_n]_2Zn$ was required.

Transfer Hydrogenation and Deuteration of Buckminsterfullerene C_{60} by 9,10-Dihydroanthracene and 9,9′,10,10′[D_4]Dihydroanthracene**

By *Christoph Rüchardt,* Matthias Gerst, Jochen Ebenhoch, Hans-Dieter Beckhaus, Eleanor E. B. Campbell, Ralf Tellgmann, Helmut Schwarz, Thomas Weiske,* and *Stephan Pitter*

Since the discovery and characterization of buckminsterfullerene C_{60} many attempts have been made at its derivatization.[1] The hydrogenated fullerenes $C_{60}H_x$ have been the subject of numerous, mostly theoretical publications,[2] which led to the conclusion that initially an exothermic 1,2-addition of hydrogen takes place. Only from the Birch reduction of C_{60}[3] could a homogeneous product $C_{60}H_{36}$ be isolated after thin-layer chromatography (TLC); however, the electron impact (EI) mass spectra indicated the presence of a second component with the empirical formula $C_{60}H_{18}$. At the time it was not possible to decide whether the $C_{60}H_{18}$ (not isolated) was a product of the Birch reduction or a pyrolysis product of $C_{60}H_{36}$.

We have now found that buckminsterfullerene C_{60} can be converted quantitatively into two hydrogenation products, $C_{60}H_{36}$ or $C_{60}H_{18}$, in a reproducible way with the new method of transfer hydrogenation[4, 5] recently described by us. The method is also suitable for the synthesis of $C_{60}D_{18}$ and $C_{60}D_{36}$. Since the first step of this reaction is a molecule-induced radical formation[6] by H addition, C_{60} is a particularly suitable candidate for the reaction because of its "radical sponge" properties.[7]

If C_{60} is heated to 350°C with 120-fold molar excess of dihydroanthracene (DHA) in a glass ampoule sealed under a nitrogen atmosphere, the H transfer to C_{60} can be followed from the changes in color. The initially dark violet melt, probably dissolved C_{60} in DHA, turns rust-brown, ruby-red, orange, yellow, and finally colorless within a few minutes. After the mixture had been cooled to room temperature (after ca. 30 min), the ampoule opened, and the anthracene derivatives sublimed off at 60–110°C (0.2 Torr), a white, solid product **A** ($C_{60}H_{36}$) could be isolated.[8] If the reaction time at 350°C is increased to 24 h, the degree of hydrogenation decreases accompanied by a darkening of the color and the formation of a second product **B** ($C_{60}H_{18}$), which likewise could be isolated.[8] In addition, C_{60} itself can again be identified. If the reaction is carried out in a sealed ESR tube at about 350°C, it is possible to record ESR spectra of the intermediary 9-hydroanthryl radicals. Correspondingly, deuterated products **C** and **D** are obtained from 9,9′,10,10′-[D_4]dihydroanthracene (degree of deuteration of the methylene protons of DHA 95%) after longer reaction times.

[**] Bimolecular radical formation through H transfer, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. F. Diederich, ETH Zürich for samples of pure C_{60}, and Dr. W. Deck, Dipl.-Chem. R. Neuber, and Dipl.-Chem. A. Meissner for ^1H NMR and FT-IR spectra, and Prof. Dr. H. Grützmacher for stimulating discussions.

The homogeneous composition of the products is revealed by the clear separation by TLC and by field desorption mass spectra.[8] Figure 1 shows that the mass spectra, which were recorded by different methods, vary considerably in the amount of information they provide. The EI and the FD mass spectra can be interpreted most clearly.

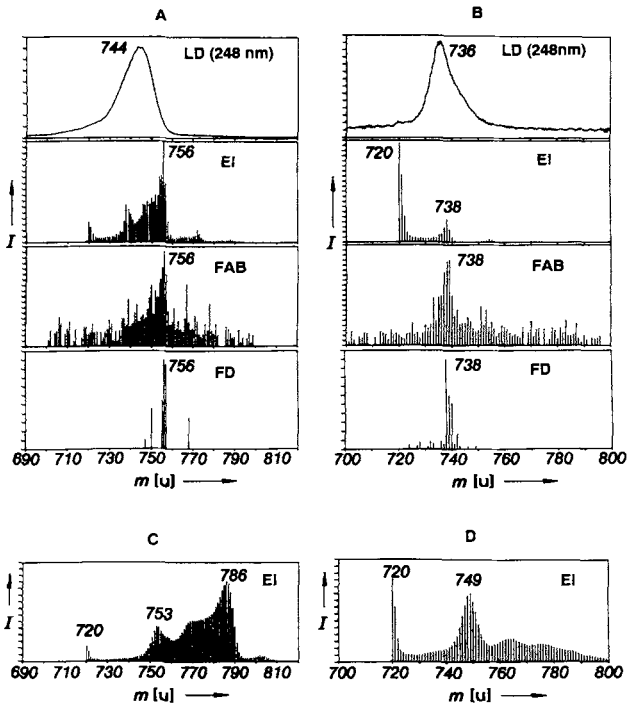

Fig. 1. Mass spectra of the products **A**, **B**, **C**, and **D** recorded with different techniques (see text). I = intensity in arbitrary units, m = mass in atomic mass units.

In the EI (70–100 eV, heating rate 5–100 $K s^{-1}$), FAB (Ar, 8 keV, matrix: *o*-nitrobenzyl alcohol), and FD spectra (field voltage 4 kV) the M^+ peak was always found and the M^{2+} peak was observed sometimes ($C_{60}H_{36}$, $C_{60}D_{36}$, and $C_{60}H_{18}$, $C_{60}D_{18}$, respectively[9]); in the laser desorption (LD) mass spectra (λ = 308 and 254 nm)[10] masses that were too small were observed. The reason for the shift is not yet known, but it seems to be due to the ionization steps in the LD experiment. The common feature of the EI mass spectra is the fragmentation in the spectrometer with the loss of H and D, respectively down to C_{60}. For the products **A** and **C** more intense mass peaks occur with the degree of substitution $x = 18$. Similar spectra but with more lines at higher masses through H and D addition, respectively, are obtained with the FAB method, whereas the FD spectra show almost only the M^+ peak. With the mass spectra of the products **C** and **D** it could be shown that the derivatives **A** and **B** really are hydrogenated fullerenes and not the oxides $C_{60}O_xH_y$, because the molecular weight increased accordingly with the degree of substitution.

The ^{1}H NMR spectra of $C_{60}H_{36}$ in $CDCl_3$, CD_2Cl_2, [D_6]benzene, and [D_8]THF at 25°C as well as in [D_6]dimethylsulfoxide (DMSO) at 25–100°C showed a broad group of signals between δ = 2.5 and 4.2 with three distinct maxima at δ = 3.3, 3.7, and 4.0.[3] In the originally clear solutions a precipitate formed after one hour at the most, in spite of an inert gas atmosphere.

In the FT-IR spectrum of **A** (KBr) bands were detected at $\tilde{\nu}$ = 2913(s), 2850(s), 1733(w), 1606(w), 1511(w), 1257(m), 1198(m), 1169(m), 1076(w), and 745(w) cm^{-1}. These bands could be clearly assigned to **A** following a comparison of the IR spectra with those of the starting materials. The bands of the C–H vibrations between $\tilde{\nu}$ = 2850 and 2920 cm^{-1} were clearly visible, whereas the bands at $\tilde{\nu}$ = 1511 and 1606 cm^{-1} indicate C=C bonds; for product **B** (KBr), the C–H bands, among others, were situated at $\tilde{\nu}$ = 2854(s), 2897(s), and 2925(s) cm^{-1}. The deuterated product **C** (KBr) showed, among others, a broad band at $\tilde{\nu}$ = 2128 cm^{-1}, characteristic for C–D vibrations. In the UV spectrum an absorption at λ = 230 nm was measured for **A** (CH_2Cl_2).

When **A** and **B** were heated they both showed a darkening of color at temperatures above 200°C, but no melting point up to 260°C. Both substances were dehydrogenated quantitatively to C_{60} (LD-MS) at 550°C within 15 min in ampoules sealed under an inert gas atmosphere. The chemical dehydrogenation of **A** with the H acceptors α-methylstyrene and anthracene was also successful (evidence of cumene from gas chromatography as well as LD-MS evidence of **B** and C_{60}). Evidently, the cage structure of C_{60} was retained during the reductions to give **A** and **B**. Consequently, the formation of the product **B**, which has a lower degree of hydrogenation (50%) than **A** with longer reaction time, can be understood as a dehydrogenation of **A** by the coproduct anthracene. From this reaction, among other products, the inert 1,2,3,4-tetrahydroanthracene is formed.

So far all attempts to obtain ESR spectra of the radical anions of the hydrogenated and deuterated fullerenes **A**–**D** by reduction (potassium in dimethoxyethane) have failed.[11] This indicates that there are only discrete double bonds present in $C_{60}H_{36}$, as expected from previous experiments on transfer hydrogenation[4, 5] and the Birch reduction.[3] Figure 2 depicts a probable structure of $C_{60}H_{36}$ minimized according to MM2 calculations (H_s = 159.91 kcal mol^{-1}, $\Delta H^0_{f,g}$ = 333.63 kcal mol^{-1}).

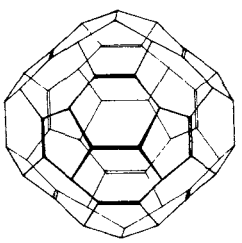

Fig. 2. Possible structure of $C_{60}H_{36}$.

Recent experiments reveal that 1,4-cyclohexadiene is also suitable for the transfer hydrogenation from C_{60} to $C_{60}H_{36}$ (LD-MS). The hydrogenation of C_{60} with DHA is superior to the Birch reduction as a synthetic method because of its simple execution (exactly reproducible), control to give $C_{60}H_{18}$ *or* $C_{60}H_{36}$, and the possibility of deuteration. It seems possible that further fullerenes may be synthesized with other H donors,[5, 12] and different degrees of hydrogenation.

[11] A highly resolved ESR spectrum, produced by eight and four differently coupling protons, was caused by traces of an impurity, which also occurred in the sublimate in higher concentrations after the workup.
[12] Also for the reaction of C_{70} with DHA several hydrogenated products could be identified in the LD-MS, which are being examined more closely at present.

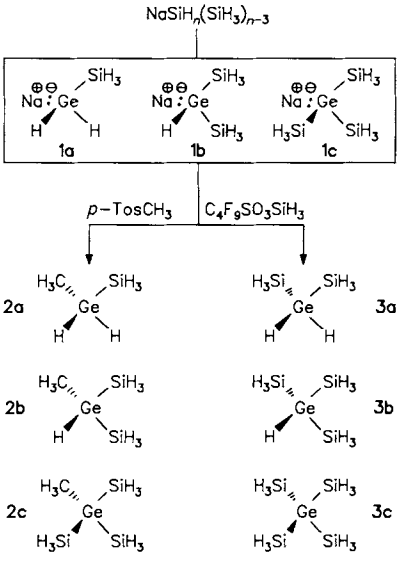
Synthesis and Structure of Tetrasilylgermane, $Ge(SiH_3)_4$, and Other Silylgermanes**

By *Thomas Lobreyer, Heinz Oberhammer,* and *Wolfgang Sundermeyer**

Amorphous alloy or mixed semiconductors (a-SiGe:H, a-SiC:H) seem to be particularly suitable for a more efficient use of the various spectral ranges of sunlight and thus for an increase of the energy yielded from thin-film solar cells.[1] The mixtures of SiH_4/GeH_4 and SiH_4/CH_4 used for the plasma-enhanced chemical vapor deposition (PE-CVD) so far have not led to a satisfactory optoelectronic film quality over the total relevant energy range because of the different deposition behavior of GeH_4, CH_4, and SiH_4.[2] A significant improvement of the films is expected from such chemical compounds, in which some of the bonds of the amorphous network of the alloy semiconductor are already formed within the molecule. Thus, silylgermanes of the composition $GeH_n(SiH_3)_{4-n}$ ($n = 0-3$) would be suitable process gases for the deposition of a-SiGe:H mixed-semiconductor films. We report herein on the first synthesis of tetrasilylgermane and other silylgermanes.

In the reaction of monosilane and monogermane with dispersed alkali metals we observed[3,4] that SiH_4 reacts with sodium to give discrete sodium silylsilanides $NaSiH_n(SiH_3)_{3-n}$ ($n = 0-3$).[5] The first experiments aimed at explaining the mechanism of the Si–Si bond formation, which occurs with the evolution of hydrogen, were carried out with monogermane, in order to investigate the build-up reaction with a view to a possible Si–Ge coupling. If GeH_4 is introduced into the freshly prepared solution of the sodium silylsilanides in diglyme, kept at 100°C, a vigorous evolution of hydrogen and the loss of SiH_4 is observed. Surprisingly, the typical signals[6] of the negatively charged central Si atoms in the ^{29}Si NMR spectrum disappear. In contrast, only three signals, which are shifted to slightly higher field in comparison to the signals of the sodium silanides, occur for the SiH_3 substituents at $\delta = -88.1$, -84.9, and -79.3. These can be assigned to the novel sodium silylgermanides $NaGeH_n(SiH_3)_{3-n}$ ($n = 2,1,0$), **1a–c**.

This is confirmed, in particular, by the subsequent reaction of **1a–c** with methyl *p*-toluenesulfonate (*p*-$TosCH_3$), whose products, the methylsilylgermanes **2a**,[7] **2b**, and **2c**,[5] were isolated by preparative gas chromatography. Methylsilanes as subsequent products of the sodium silanides, which possibly did not react with GeH_4, could not be detected. Further studies aimed at explaining the reaction mechanism of the two formation reactions are currently in progress. The silylation of the sodium silylgermanides **1a–c** with silyl nonafluorobutanesulfonate, $C_4F_9SO_3SiH_3$, about which we reported recently,[3] has proven to be particularly interesting for the synthesis of Si–Ge-containing process gases. Depending on the content of **1a–c** in the solution from this reaction the silylgermanes $GeH_n(SiH_3)_{4-n}$ ($n = 2,1,0$) **3a–c** are obtained in good yields.



Our interest was intitally centered on the symmetrically built $Ge(SiH_3)_4$ (**3c**), which could be isolated in a two-step synthesis after purification by preparative gas chromatography in a yield of 47% (together with **3a** (15%)[8] and **3b** (24%)) as a clear, pyrophonic liquid which melts at −54°C and boils at 86.6°C/193 Torr. The vapor pressure curve was recorded for the CVD. The curve is described by $\lg p = -1348\,T^{-1} + 6.02$ (measured over the range of 28.9°C/36 Torr to 86.6°C/193 Torr). Both the proton-coupled ^{29}Si NMR spectrum (Fig. 1) and the mass spectrum clearly prove the existence of **3c**; the coupling of the Si atoms with the neighboring H atoms results in a quartet at $\delta = -85.18$ ($^1J_{Si,H}$) 203.75 Hz), which is split by the other nine protons to a deciplet ($^3J_{H,H}$) = 3.66 Hz).

[**] This work was supported by the Bundesministerium für Forschung und Technologie (project no. 0328980 A) and the Fonds der Chemischen Industrie. We thank Degussa AG, Messer-Griesheim AG, and BASF AG for chemicals, and Dr. R. Geist, and M. Steiner and O. Walter for recording the mass spectra and the ^{29}Si NMR spectra, respectively.

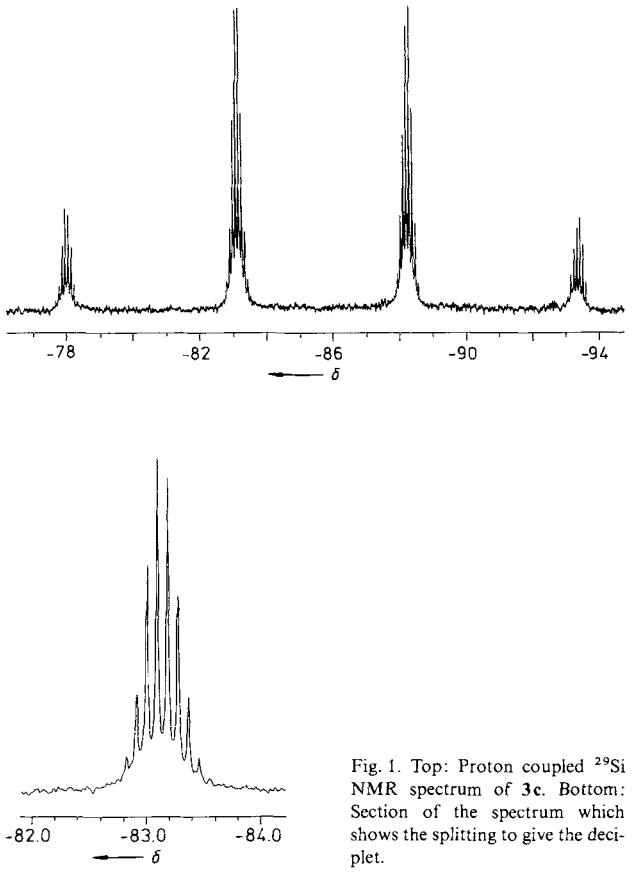

Fig. 1. Top: Proton coupled ^{29}Si NMR spectrum of **3c**. Bottom: Section of the spectrum which shows the splitting to give the deciplet.

The structure of $Ge(SiH_3)_4$ in the gas phase was determined by electron diffraction analysis.[9] The molecule has the expected T_d symmetry, and the silyl groups can rotate almost freely. The structure is depicted in Figure 2. The Ge–

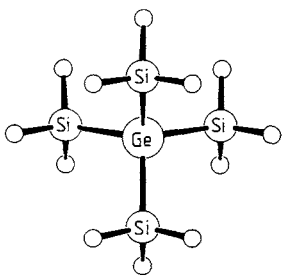

Fig. 2. Molecular structure of $Ge(SiH_3)_4$ **3c** in the gas phase (Distances [Å] and angles [°], limits of error are 3σ values) Ge–Si 2.370(1), Si–H 1.497(7); H–Si–H 106.8(11).

Si bond length (2.370(1) Å) is slightly longer than in $CH_3Ge(SiH_3)_4$ (2.366(2) Å[5]) and is in agreement (within the limits of error) with the value reported for H_3GeSiH_3 (2.357(20) Å[10]).

Experimental Procedure

1a–c: In a reactor fitted with a hollow stirrer (to intensify the contact between the gas and the dispersion) and a baffle plate (to break up the vortex and allow better dispersion) [3], sodium (10 g, 0.44 mol) was dispersed in diglyme (500 mL) at 100°C and allowed to react with monosilane, which was added continuously, to give sodium silanides of the composition $NaSiH_n(SiH_3)_{3-n}$ (n = 0–3) [5]. After 3 h monosilane was replaced, without interrupting the inflow of gas, by monogermane, which was added for 50 min under the same reaction conditions. The hydrogen, which was formed throughout the whole reaction escaped into a cold trap (−196°C), in which monosilane formed at the same time was trapped; this monosilane could be reused. After the reaction was interrupted the reddish solution formed was filtered through a G4 frit. The solution contained a mixture of silylgermanides $NaGeH_n(SiH_3)_{3-n}$ (n = 0–2) with a total yield of 70% (based on the amount of sodium used).

2a–c: In a 500 mL flask filled with nitrogen and fitted with a septum and a cold trap, methyl p-toluenesulfonate (30 g, 104 mmol), dissolved in diglyme (100 mL), was quickly added dropwise with a syringe to the solution containing **1a–c** (150 mL, 87 mmol) at −50°C. The completely decolored suspension formed was stirred for 10 min at −50°C. This was then allowed to warm to room temperature, during which time the volatile reaction products were trapped under vacuum in the cold trap (−196°C) and the mixture of substances was purified by fractionating condensation. The isolation of **2a–c** was achieved by preparative gas chromatography [11].

3a–c: The solution containing **1a–c** (150 mL, 87 mmol) was allowed to react with freshly prepared silyl nonafluorobutanesulfonate [3] (29.7 g, 90 mmol) in a 500 mL flask filled with nitrogen and fitted with a septum and a cold trap at −50°C. The suspension formed remained pale yellow. After removal of the cooling bath the volatile products were condensed under vacuum into the cold trap (−196°C) and separated from the monosilane formed by fractionating condensation. The isolation of **3a–c** was achieved by preparative gas chromatography [11].

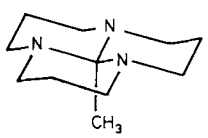
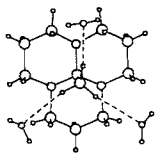
On the Strength of the C–H···O Hydrogen Bond and the Eclipsed Arrangement of the Methyl Group in a Tricyclic Orthoamide Trihydrate**

By *Juan J. Novoa,* Pere Constans,*
and *Myung-Hwan Whangbo**

In the thousands of compounds whose crystal structures have been determined by X-ray or neutron diffraction the conformation about the C_{sp^3}–CH_3 bonds is staggered. The only exception was reported for a crystalline trihydrate of tricyclic orthoamide **1** (i.e., **1** · $3H_2O$), in which the conformation about the C_{sp^3}–CH_3 bond is nearly eclipsed (N-C-C-H dihedral angle of 8.0°).[1, 2] Since in a single crystal of *anhydrous* **1** the conformation about the C_{sp^3}–CH_3 bond is staggered, the eclipsed arrangement in **1** · $3H_2O$ is attributed to the three C–H···O hydrogen bonds between the methyl group of **1** and the three water molecules surrounding **1**.[1] (In the schematic representation **2** the H···O contacts are represented by dashed lines. In addition to the C–H···O hydrogen bond, each water molecule makes a O–H···N hydrogen bond with one of the nitrogen atoms of an adjacent molecule **1**.)



1



2

To explain this striking observation, Seiler et al.[1] carried out theoretical evaluations of the rotational barrier of the methyl group in **1** and the energy of the C–H···O hydrogen bond. Their ab initio SCF calculations for CH_3–$C(NH_2)_3$ (with the N lone pair antiperiplanar (*app*) to the C–CH_3 bond, structural parameters from the crystallographic study) show the staggered conformation to be more stable than the eclipsed by 5.52 kcal mol^{-1}. Thus, the minimum strength of each of the three C–H···O hydrogen bonds in **1** · $3H_2O$ must be about 1.8 kcal mol^{-1} to produce the eclipsed conformation (under the implicit assumption that the energies of the C(methyl)–H···O hydrogen bonds are additive). On the basis of their MP2-level calculations on model complexes CH_4···OH_2 and CH_4···OH_2···NH_3, Seiler et al.[1] concluded that the C–H···O hydrogen bond has this strength. In this evaluation, however, the basis set superposition errors[3] (BSSEs) were not corrected. According to our recent study,[4] the energy of the C–H···O hydrogen bond is at most 0.59 kcal mol^{-1} (based on MP2-level calculations for CH_4···OH_2 with a near Hartree–Fock limit (NHFL) basis set), and the large values reported by Seiler et al.[1] (1.45–1.94 kcal mol^{-1}) are due mainly to the BSSEs. Consequently, the explanation for the eclipsed conformation about the C_{sp^3}–CH_3 bond of **1** · $3H_2O$ remains a challenge to theoreticians, which prompted us to carry out systematic theoretical calculations aimed at understanding this unusual observations.

To estimate the rotational barrier for the methyl group of **1**, ab initio 6-31 + +G** SCF calculations were performed for the model compounds CH_3–$C(NH_2)_3$ and CH_3–$C[N(CH_3)_2]_3$ (with the N lone pair *app* to the C–C bond) with full geometry optimizations. These calculations show that the staggered conformation is more stable than the eclipsed by 5.44 kcal mol^{-1} in CH_3–$C(NH_2)_3$, and by 5.48 kcal mol^{-1} in CH_3–$C[N(CH_3)_2]_3$. These values are very close to that estimated by Seiler et al.[1] In addition, ab initio 6-31 + +G** SCF calculations for CH_3–CH_3 predict a rotational barrier of 2.98 kcal mol^{-1}, in good agreement with experiment. As already pointed out by Seiler et al., therefore, the rotational barrier of the methyl group in **1** is 5.4–5.5 kcal mol^{-1}, and this barrier should be overcome in **1** · $3H_2O$ by the stabilization energy associated with the three C–H···O hydrogen bonds.

The most accurate estimate of the energy of the C–H···O hydrogen bond, 0.59 kcal mol^{-1}, is based on the model CH_4···OH_2 in which one methane hydrogen atom forms a C–H···O hydrogen bond.[4] In **1** · $3H_2O$ all three hydrogen atoms of the methyl group participate in C–H···O hydrogen bonds. Thus, one might speculate that the energy of the C–H···O hydrogen bonding in **1** · $3H_2O$ is enhanced by a cooperative effect of the three C–H···O bonds of the methyl group. To test this hypothesis, we carried out MP2 calculations on the model compounds CH_4···OH_2, CH_4···$(OH_2)_2$ and CH_4···$(OH_2)_3$, whose geometries were chosen to have one, two, and three C–H···O hydrogen bonds, respectively.[5] According to our previous study of CH_4···OH_2,[4] use of diffuse functions is crucial in reducing the BSSEs. Our 6-31 + +G** MP2 calculations show that after correction of the BSSEs by the counterpoise method,[6] the energies of the hydrogen-bonding in CH_4···OH_2, CH_4···$(OH_2)_2$, and CH_4···$(OH_2)_3$ are 0.37,[7] 0.61, and 0.86 kcal mol^{-1}, respectively. Thus, the total energy of the hydrogen bonds of CH_4···$(OH_2)_n$ (n = 2, 3) is not larger but rather somewhat smaller than the value predicted by n times the C–H···O hydrogen-bond energy of CH_4···OH_2. Our 6-31 + +G** MP2 calculations for CH_4···OH_2···NH_3 (geometry of the C–H···O–H···N arrangement as found in **1** · $3H_2O$) show that the energy of the C–H···O hydrogen bond in CH_4···OH_2···NH_3 is 0.52 kcal mol^{-1} after BSSE correction; this is larger than that of CH_4···OH_2 by about 40% (0.52 vs. 0.37 kcal mol^{-1}). Thus, even if C–H···O–H···N hydrogen bonding is assumed to increase the energy of the C–H···O hydrogen bond by about 40%, the stabilization energy expected from the three C–H···O hydrogen bonds in **1** · $3H_2O$ (roughly $2.5 = 3 \times 0.59 \times 1.4$ kcal mol^{-1}) is much smaller than the rotational barrier of the methyl group in **1**.

Another estimate of the stabilization energy for the three C–H···O hydrogen bonds in **1** · $3H_2O$ was made by determining the rotational barriers of the methyl groups in **1** and **1** · $3H_2O$ (the three H_2O molecules were arranged around **1** as in crystalline **1** · $3H_2O$) on the basis of semiempirical AM1 SCF-MO calculations.[8] (AM1 calculations for CH_3–$C(NH_2)_3$ give a rotational barrier of 2.62 kcal mol^{-1}, which is about 2.8 kcal mol^{-1} lower than the ab initio value.) For the rigid rotation of the methyl group based on the experimental geometries, AM1 calculations show that the staggered conformation about the C_{sp^3}–CH_3 bond is more stable than the eclipsed by 1.53 kcal mol^{-1} in **1**, and by 0.27 kcal mol^{-1} in **1** · $3H_2O$. Namely, the three C–H···O hydrogen bonds in **1** · $3H_2O$ provide the stabilization energy of about 1.3 kcal mol^{-1}. The latter suggests a stabilization energy of about 1.8 kcal mol^{-1} for crystalline **1** · $3H_2O$ if we allow for

a 40% increase as a result of the cooperative C–H···O–H···N hydrogen bonding effect. This estimate is consistent with the results of our ab initio calculations.

In the above estimates of the stabilization energy associated with the three C–H···O hydrogen bonds in $\mathbf{1} \cdot 3H_2O$, possible crystal effects were not taken into consideration. To remedy this situation, we calculated the energies of crystalline $\mathbf{1} \cdot 3H_2O$ by employing empirical atom–atom potentials.[9] The structure found in the crystal and the hypothetical structure resulting from it when the conformation about the C_{sp^3}–CH_3 bond is made staggered by rigid rotation are of interest. Our atom–atom potential calculations employed the potential parameters of Williams and Houpt[10] and those of Mirsky.[11] The Madelung energy was calculated by employing the point charges of the atoms that best simulate the electrostatic potentials[12] of **1** and H_2O calculated by the AM1 method. In addition to the usual atom–atom potential terms,[10, 11] the C–H···O hydrogen bond potentials of Cox et al.[13] were employed to calculate the energies of the C–H···O hydrogen bonds for all the H···O contacts shorter than 2.7 Å. Our calculations show that the energy of the interaction between one methyl group and the rest of the crystal is more favorable for the eclipsed than for the staggered arrangement by 2.97 kcal mol^{-1} with the the parameters of Williams and Houpt, and by 1.87 kcal mol^{-1} with the parameters of Mirsky. These values are comparable with the stabilization energies estimated by the present ab initio and AM1 calculations on model compounds.

To maintain the eclipsed arrangement about the C_{sp^3}–CH_3 bond of $\mathbf{1} \cdot 3H_2O$, the stabilization energy associated with the three C–H···O hydrogen bonds of each methyl group should be larger than 5.4–5.5 kcal mol^{-1}, but all our calculations suggest that this energy does not exceed 3 kcal mol^{-1}. Our results do not support the explanation of Seiler et al.[1] for the eclipsed conformation of $\mathbf{1} \cdot 3H_2O$ and lead us to wonder why an eclipsed arrangement is found about the C_{sp^3}–CH_3 bond of $\mathbf{1} \cdot 3H_2O$. It is possible that the observed structure of $\mathbf{1} \cdot 3H_2O$ is not a global but a local energy minimum. It is noted that organic conducting salts often have different phases with identical chemical compositions.[14]

Structural Variations Observed in the $[Bi(O_2CCF_3)_4Ph]^{2-}$ Anion: Selective Cation–Anion Interactions through Hydrogen Bonds**

By *Steven R. Breeze* and *Suning Wang**

Hydrogen bonds are known to play an essential role in determining the shape and function of molecules,[1] and their influence on the structures of solids is widely recognized.[2] The controlled assembly of molecules by hydrogen bonding is a frequently used strategy in the synthesis of supramolecules and inorganic precursor compounds for solid-state materials.[3] However, systematic examinations on the effect of hydrogen bonds on the geometry and stability of inorganic complexes are scarce. We report here on the anionic bismuth complex $[Bi(O_2CCF_3)_4Ph]^{2-}$, whose solid-state structure can be dramatically influenced by interactions with its counterion by the formation of hydrogen bonds.

The reaction of $BiPh_3$ with trifuoroacetic acid and *N,N,N',N'*-tetramethyl-1,3-propanediamine (tmpda) in a 1:4:1 ratio produced **1** in good yield. The anion in com-

$[Me_2NH(CH_2)_3NHMe_2][Bi(O_2CCF_3)_4Ph]$ **1**

pound **1** displays an cuplike structure[4] in the solid state as shown in Figure 1. The Bi^{3+} ion is coordinated by one carbon atom of the phenyl group and four oxygen atoms of the acetate ligands with normal bond lengths and a square-pyramidal geometry. The lone pair of electrons probably occupies the vertex of the octahedron. The bismuth atom is 0.27 Å above the O1-O3-O1'-O3' plane. Compound **1** has a twofold proper rotation axis; the diammonium cation is disordered over this axis. The most unusual feature of the anion is the orientation of the four trifluoroacetato ligands—they

[**] This work was supported by the Natural Sciences and Engineering Research Council of Canada.

all point up to form a cuplike shape. One would expect these acetato ligands to orient away from each other to minimize the repulsion between the negatively charged oxygen centers. We believe that this unusual orientation of the acetato ligands is caused by the interactions between the diammonium cations and the trifluoroacetato ligands through hydrogen bonds. The N–O2 and N–O4 distances, (2.82(4) and 3.01(4) Å, respectively) are comparable to the sum of van der Waals radii (3.05 Å) and indicative of weak hydrogen bonds.[5] Although the positions of the protons were not located by the X-ray diffraction experiment, we believe that they are bonded to the nitrogen atoms of the diamine and form hydrogen bonds to the oxygen atoms of the acetato ligands, since the amine is a much stronger Lewis base than the trifluoroacetato ligand. The C1-O2···N and C3-O4···N angles are 173(3) and 139(3)°, respectively. The two protons act as a "glue" to hold the four oxygen atoms and two nitrogen atoms together. In addition to the hydrogen bonds, the perfect match of the shape of the diammonium cation to that of the $[Bi(O_2CCF_3)_4Ph]^{2-}$ anion also appears to play an important role. For example, the largest separations between the oxygen atoms of the acetato ligands in the anion of **1** are 5.62(3) Å for O2···O2′ and 5.51(3) Å for O4···O4′, which are comparable to the N···N separation (4.92(3) Å) of the tmpda cation. When the tmpda cation in **1** was replaced by the tetramethylethylenediammonium (tmeda) cation, in which the span between the two ammonium groups is one CH_2 group shorter than that of tmpda (N···N = 3.67(7) Å), a dramatic structural change was observed, as is evident in Figure 2.[4]

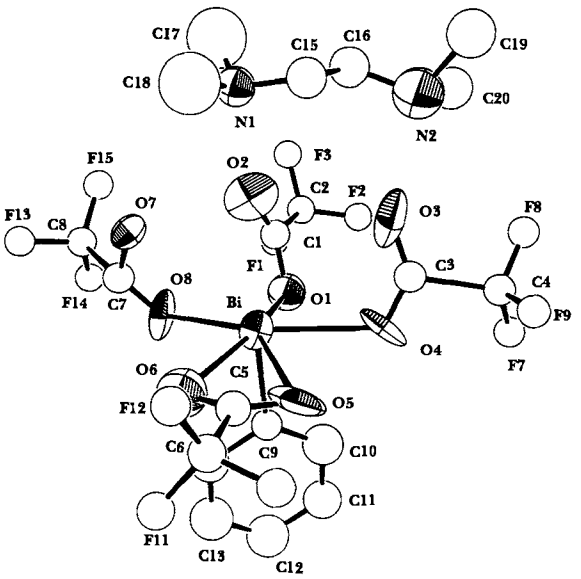

Fig. 2. Crystal structure of **2**; ellipsoids at the 50% probability level. Selected distances [Å] and angles [°]: Bi-O1 2.62(3), Bi-O4 2.50(4), Bi-O5 2.59(4), Bi-O6 2.34(4), Bi-O8 2.32(3), Bi-C9 2.20; O1-Bi-O4 71(1), O1-Bi-O8 71(1), O8-Bi-O6 87(1), O6-Bi-O5 52(1), O5-Bi-O4 78(1).

In contrast to **1** in compound **2** three of the four acetato ligands point up with respect to the phenyl ring; the fourth

$[Me_2NH(CH_2)_2NHMe_2][Bi(O_2CCF_3)_4Ph]$ **2**

acetato ligand chelates the Bi^{3+} ion and is in the equatorial plane. The five oxygen atoms coordinated to the bismuth center are coplanar, and the bismuth atom is 0.23 Å above the plane. The dihedral angle between the equatorial plane and the phenyl ring is 92.4°. Therefore, the coordination sphere of the Bi^{3+} ion could be described as pentagonal-pyramidal. Although such coordination geometry is uncommon for bismuth, it has been observed in some antimony compounds.[6] The ammonium groups are hydrogen-bonded to O2 and O3 only, as indicated by the N1–O2 and N2–O3 distances, 2.72(6) and 2.61(7) Å, respectively. The span between the two ammonium groups in tmeda in **2** is apparently too short for the formation of hydrogen bonds to all four oxygen atoms of the acetato ligands. Consequently, the $[Bi(O_2CCF_3)_4Ph]^{2-}$ anion no longer has a cuplike shape.

The effect of the shape of the diammonium cation on hydrogen bonds and the geometry of the $[Bi(O_2CCF_3)_4Ph]^{2-}$ anion can be further illustrated by the structure[4] of **3**.

$[Me_2NHCH_2CH(OH)CH_2NHMe_2][Bi(O_2CCF_3)_4Ph]$ **3**

Compound **3** was obtained in good yield by the reaction of $BiPh_3$ with trifluoroacetic acid and 1,3-bis(dimethylamino)-2-propanol (bdmap) in a 1:4:1 ratio. The bdmap diammonium cation in **3** is very similar to tmpda in **1** except that the middle CH_2 group in the tmpda is replaced by a CH(OH) group. Crystals of **3** are isomorphous with those of **1**. The structure of the anion in **3** (Fig. 3) resembles that of **1**—a cuplike structure—except that this "cup" is no longer empty, but hosting an OH group. The two ammonium groups are

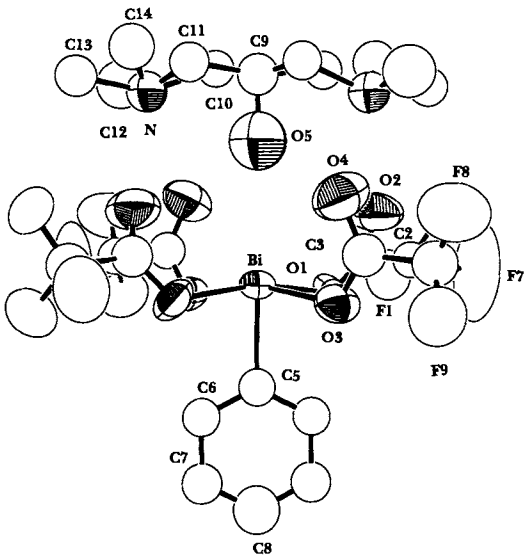

Fig. 3. Crystal structure of **3**; ellipsoids at the 50% probability level. Selected distances [Å] and angles [°]: Bi-O1 2.39(1), Bi-O3 2.40(1), Bi-C5 2.26(3); O1-Bi-O1′ 168.2(7), O3-Bi-O3′ 165.5(7).

hydrogen-bonded to the four oxygen atoms of the acetato ligands in a similar fashion as found in **1** (N–O2 = 2.76(2), N–O4 = 3.26(3) Å). The OH group shares its proton with the four oxygen atoms of the acetato ligands, as evidenced by the distances of O5–O2 = 3.19(2), O5–O4 = 3.03(2) Å. The suitable size of the cavity in the anion and the formation of hydrogen bonds between the OH group and the acetato oxygen atoms are apparently responsible for enclosure of the OH group. However, they are not the dominating factors in determining the cuplike shape of the anion, since **1** has a

similar structure to that of **3** and no OH group. We believe that hydrogen-bonding interactions between the ammonium group and the acetato ligands in **3** play a critical role in shaping the molecule as they do in **1**. Bi^{III} complexes are known to display versatile structural features in the solid state as a result of the presence of a lone pair of electrons.[6-9] However, the structural variations of the $[Bi(O_2CCF_3)_4Ph]^{2-}$ anion observed in compounds **1**–**3** are unprecedented and can only be explained by selective cation–anion interactions through hydrogen bonds. Such phenomena could also exist in other inorganic complex systems. The hydrogen bonds between the cation and anion appear to influence the stability of bismuth complexes in this system. For example, the neutral compound $Bi(O_2CCF_3)_2Ph$ could not be isolated due to its poor stability,[9] whereas the compounds described here with the $[Bi(O_2CCF_3)_4Ph]^{2-}$ anion were obtained readily in the presence of aliphatic diamines. Furthermore, compounds **1** and **2** are stable in solution for days while **3** decomposes rapidly upon dissolution. Further investigation of these cation-dependent salts is in progress.

Experimental Procedure

1: $BiPh_3$ (200 mg, 0.45 mmol) was dissolved in 15 mL of THF. 0.14 mL (1.87 mmol) of trifluoroacetic acid was added to the solution. After the reaction mixture was stirred for 1 h, 78 mg (0.45 mmol) of tmpa was added. After 1 h the solution was concentrated to about 5 mL, and hexane was added to crystallize the product. The colorless crystals of **1** were collected after 24 h (250 mg, 0.26 mmol, 63% yield). Correct C,H,N analysis. ^1H NMR ([D$_6$]acetone): δ = 2.52 (m, CH_2, 2H), 3.07 (s, CH_3, 12H), 3.47 (t, CH_2, 4H), 7.37 (m, CH, 1H), 7.91 (m, CH, 2H), 8.90 (m, CH, 2H).

Compounds **2** and **3** were obtained by the similar procedure. Satisfactory C,H,N analysis for **2**, correct C,H,N analysis for **3**. 1H NMR ([D$_8$]acetone) for **2**: δ = 3.16 (s, CH_3, 12H), 3.98 (s, CH_2, 4H), 7.38 (m, CH, 1H), 7.92 (m, CH, 2H), 8.86 (m, CH, 2H); for **3**: δ = 3.14 (s, CH_3, 12H), 3.42 (q, CH, 2H), 3.53 (q, CH, 2H), 4.88 (m, CH, 1H), 7.39 (m, CH, 1H), 7.90 (m, CH, 2H), 8.88 (m, CH, 2H).

Colorless single crystals of **1**–**3** were obtained from THF by slow diffusion of hexane at 23 °C. The crystals were mounted on glass fibers and sealed from air with epoxy glue. Data were collected over the range $2° < 2\theta < 48°$ for all compounds on a Rigaku AFC6-S diffractometer ($Mo_{K\alpha}$ radiation, 50 kV, 35 mA, graphite monochromator). All data were processed on a VAX workstation 3520 by using the TEXSAN crystallographic package (version 5.0) and corrected for Lorentz-polarization effects. Empirical absorption corrections were applied for all crystals. The position of the *Bi* atom in all structures was determined by direct methods. The refinements converged at final R and R_w values of 0.082 and 0.087 for **1** (150 variables and 970 reflections), 0.072 and 0.072 for **2** (170 variables and 1190 reflections), 0.057 and 0.054 for **3** (152 variables and 1054 reflections), ($F_0^2 \geq 3\sigma(F_0^2)$), respectively. The high R factors for **1** and **2** were caused by the poor quality of the crystals which showed severe twinning problems. In all compounds the CF_3 groups displayed varied degrees of disorders which could also contribute to the poor quality of the structure determinations of **1** and **2**. The positions of hydrogen atoms in **2** were calculated. Their contributions were included in the final structural factors calculation. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-56897, the names of the authors, and the journal citation.

Novel Triselenidotantalum Halfsandwich Complexes**

By *Kazuyuki Tatsumi*,* *Hiroyuki Kawaguchi*, and *Kazuhide Tani*

The chemistry of soluble transition metal selenides is of interest to both material scientists and coordination chemists.[1] Selenides of electron-deficient group 4 and 5 transition metals are rare, however, because of the propensity of chalcogenides to form insoluble polymers. Recently, solid-state reactions[2] and unusual hydrothermal syntheses[3] provided an interesting series of early transition metal selenides. If these reactions are to be conducted at room temperature and in solution, a solubilizing coligand such as C_5Me_5(Cp*) must be employed. In exploring the chemistry of tantalum selenides with organic ligands we have discovered the novel triselenido halfsandwich complexes **1** and **2**.

$[Cp^*Ta(Se)_3Li_3Cl(thf)_3]$ **1**
$[Cp^*Ta(Se)_3Li_2(tmeda)_2]$ **2**

tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine

Reaction of $[Cp^*TaCl_4]$ and 4–5 equiv "Li_2Se_2"[4a] in THF under argon gave an orange solution. Removal of the solvent in vacuo, extraction of the resulting orange solid residue with benzene, and recrystallization from THF/hexane afforded **1** as yellow crystals in 43% yield.[5a] In contrast, the analogous reaction of $[Cp^*TaCl_4]$ with 4–5 equiv "Li_2Se"[4b] in THF gave a deep-red solution from which **1** could not be isolated. The LiCl unit in **1** could be removed by treatment with excess tmeda in toluene to produce **2** as yellow crystals in 86% yield.[5b] The highly hygroscopic and

[**] This research was supported in part by the Asahi Glass Foundation.

moderately air-sensitive complexes **1** and **2** were characterized by spectroscopy and X-ray structure analysis. Sharp ^{1}H NMR resonances in the expected range for Cp* indicate that **1** and **2** are diamagnetic, consistent with the d^0 electronic configuration of the tantalum center.

The molecular structures of **1** and **2** are shown in Figures 1 and 2, respectively.[6] The most important feature of these first organometallic compounds with three monoselenide anions is the common $[Cp^*Ta(Se)_3]^{2-}$ unit. There are no

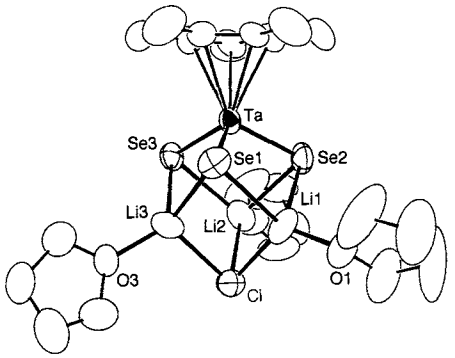

Fig. 1. Molecular structure of **1** (thermal ellipsoids at the 30% probability level). Selected bond lengths [Å]: Ta-Se1 2.406(2), Ta-Se2 2.395(2), Ta-Se3 2.407(2), Se1-Li1 2.64(2), Se1-Li3 2.64(5), Se2-Li1 2.54(4), Se2-Li2 2.57(3), Se3-Li2 2.62(3), Se3-Li3 2.59(4), Cl-Li1 2.38(3), Cl-Li2 2.36(3), Cl-Li3 2.39(4).

well-characterized examples of soluble tantalum selenides, and the $[TaSe_4]^{3-}$ ion is found only in extended solid-state structures. Examples of molecules with isostructural $[Cp^*Ta(E)_3]^{2-}$ units are limited to the hexagonal-prismatic cluster $[\{Cp^*Ta(S)_3Li_2(thf)_2\}_2]$ (**3**)[7] (E = S) and the trioxorhenium complex $[Cp^*Re(O)_3]$ (E = O).[8, 9] Group 5 metal selenides that have been structurally characterized include $[Cp'_2V_2Se_5]$ (Cp' = C_5H_4Me)[10] and $[Cp_3Nb_3(Se)_3(Se_2)Cl_2]$.[11]

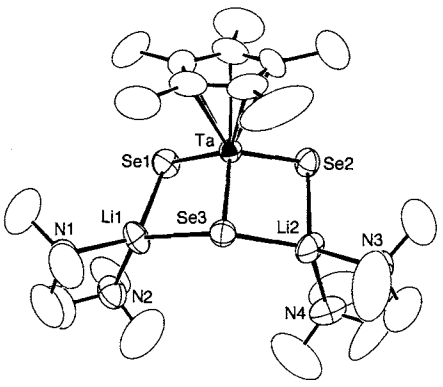

Fig. 2. Molecular structure of **2** (thermal ellipsoids at the 50% probability level). Selected bond lengths [Å] and angles [°]: Ta-Se1, 2.389(2); Ta-Se2, 2.384(2); Ta-Se3, 2.441(2); Se1-Li1, 2.60(3); Se2-Li2, 2.55(3); Se3-Li1, 2.56(3); Se3-Li2, 2.54(3); Se1-Li1-Se3, 94.7(8); Se2-Li2-Se3, 97.1(9).

In **1**, three Li atoms are bound to the $[Cp^*TaSe_3]$ fragment and each bridges two selenido ligands. A Cl atom caps the Li atoms, completing the $TaSe_3Li_3Cl$ cubane framework. Each Li atom is also bound to a THF molecule. The three Ta–Se distances are nearly the same, and the Cl atom is approximately equidistant from three Li atoms. Since all the bond lengths within the cubane core fall in a relatively narrow range (2.36–2.64 Å), the geometry is close to ideal except for the somewhat large Se-Ta-Se angles (103.68(7)–103.87(7)°). In comparison, the sulfur analogue $[Cp^*Ta(S)_3Li_3Cl(tmeda)_2(\mu\text{-tmeda})]$ (**4**) has an open cubane core.[7b] As the Li atoms in **4** are coordinated by tmeda instead of THF, two edges (a Li–S bond and a Li–Cl bond) are missing from the cubane core, probably because of the preferred tetrahedral coordination of the Li atoms.[12]

The two lithium atoms in **2** bridge two selenido ligands and are further coordinated by two nitrogen atoms of the tmeda ligands. The structure of **2** is less symmetrical than that of **1** because of the missing LiCl unit. The Se1-Ta-Se2 angle opens up to 106.26(8)°; the other Se-Ta-Se angles are 103.63(5)° and 104.54(6)°. The Ta–Se3 bond is longer than the Ta–Se1(Se2) bond by 0.05 Å.

The average Ta–Se bond lengths of 2.403 Å (**1**) and 2.405 Å (**2**) are slightly longer than that in $K_3[TaSe_4]$ (2.368 Å),[2d] but they are significantly shorter than the sum of the ionic radii of Ta^V and Se^{2-} (2.62 Å).[13] On the other hand, the Raman spectra of **1** and **2** exhibit bands at 265 cm^{-1} and 263 cm^{-1}, respectively, arising from Ta–Se stretching vibrations, which are at higher frequencies than the A_1 mode stretch (249 cm^{-1}) of $[TaSe_4]^{3-}$.[14] These observations indicate some Ta–Se π bonding in **1** and **2**.

Compounds **1** and **2** are readily soluble in THF, whereas they decompose gradually in acetonitrile to form red precipitates. Although the crystals of **1** are hardly soluble in nonpolar solvents, those of the tmeda adduct **2** are soluble in benzene and toluene. In THF, both **1** and **2** form yellow solutions that exhibit a UV/VIS absorption band at 341 nm. The sulfur analogues **3** and **4** form light-yellow solutions in THF that absorb at 302 nm and 301 nm. The lowest energy bands are assigned to charge-transfer transitions from orbitals of the chalcogenide lone pair to the lowest vacant d orbital of tantalum. The sulfide-to-selenide red shift (0.46 eV) is comparable to the difference in the first ionization potentials of these chalcogens (0.59 eV).[15]

Our synthesis of **1** and **2** provides a convenient entry to soluble tantalum selenides. The lithium cations bound to the selenium atoms may be easily replaced by suitable heteroelements to form a variety of heteronuclear selenide clusters.

[4] a) "Li_2Se_2" was made from the stoichiometric reaction of Li metal with elemental Se in liquid ammonia. The liquid ammonia was evaporated off under a flow of dry oxygen-free Ar to give a reddish-brown powder. Before it was used, this powder was washed a few times with THF to give a flesh colored powder. The Se/Li ratio of the red THF washings is presumably higher than in "Li_2Se_2", and the resulting flesh-colored powder most likely contains Li_2Se. b) "Li_2Se" was prepared as white powder from the reaction of Li and Se_8 (16:1) in liquid ammonia.

[5] All manipulations were carried out under an argon atmosphere with dry solvents. Complexes **1** and **2** gave satisfactory elemental analysis. a) $[Cp^*Ta(Se)_3Li_3Cl(thf)_3]$ **1**: yellow crystals; ^{1}H NMR (270 MHz, $[D_8]$THF, 30 °C): δ = 2.40 (s, Cp*); UV/VIS (THF): $\lambda_{max}(\varepsilon)$ = 341 nm

(19000); Raman (crystals): $\tilde{\nu} = 265\ cm^{-1}$ (s, Ta = Se). b) [Cp*Ta(Se)$_3$Li$_2$(tmeda)$_2$] **2**: yellow crystals; ^{1}H NMR (270 MHz, C_6D_6, 30 °C): $\delta = 2.51$ (s, 15H, Cp*), 2.34 (s, 24H, $(CH_3)_2NCH_2CH_2N(CH_3)_2$), 2.15 (s, 8H, $(CH_3)_2NCH_2CH_2N(CH_3)_2$); UV/VIS (benzene): $\lambda_{max}(\varepsilon) = 341$ nm (21000); Raman (crystals): $\tilde{\nu} = 263\ cm^{-1}$ (s, Ta = Se).

[6] A single crystal of **1** or **2** was mounted in a thin-walled glass capillary and sealed under Ar. Reflection data were measured on a Rigaku AFC5R diffractometer at ambient temperature using the ω-2θ scan technique. The intensity data were corrected for Lorentz and polarization effects, and empirical absorption corrections were applied. The structure was solved and refined by using a TEXSAN program package. a) Crystal data for **1**, monoclinic, $P2_1/n$ (No. 14), $a = 8.681(2)$, $b = 16.600(9)$, $c = 21.817(5)$ Å, $\beta = 90.29(2)°$, $V = 3144(2)$ Å^3, $Z = 4$, $\varrho_{calc} = 1.744\ g\,cm^{-3}$, $2\theta_{max}(Mo_{K\alpha}) = 50.1°$. The structure was solved by direct methods and was refined to $R = 0.051$ and $R_w = 0.056$ by the full-matrix least-squares method for 2961 observed reflections with $I > 3.0\,\sigma(I)$ (298 variables, GOF = 2.03). b) Crystal data for **2**, orthorhombic, $Pna2_1$ (No. 33), $a = 23.484(5)$, $b = 9.949(2)$, $c = 13.676(2)$ Å, $V = 3195(2)$ Å^3, $Z = 4$, $\varrho_{calc} = 1.661\ g\,cm^{-3}$, $2\theta_{max}(Mo_{K\alpha}) = 50.8°$. The structure was solved by the Patterson method and was refined to $R = 0.034$ and $R_w = 0.043$ using the full-matrix least squares method for 2407 observed reflections with $I > 3.0\,\sigma(I)$ (288 variables, GOF = 1.83). $[Cr(CO)_5PCl_3]$—A P_1 Building Block for the Formation of Complexes with *cyclo*-P_x Ligands ($x = 3, 5$)**

By *Manfred Scheer,* Gabriele Friedrich*, and *Kay Schuster*

Coordination compounds with "naked" P_x ligands ($x > 2$) are obtained mainly from white phosphorus and the corresponding metal complex fragment.[1] Only two references of P–P bond-forming reactions starting from PX_3 (X = Cl, Br), in which P_2 ligands are formed, have been reported, namely the formation of $[Co_2(CO)_6(\mu,\eta^2\text{-}P_2)]$[4] and $[Co_2(CO)_6\{(\mu,\eta^2\text{-}P_2)(ML_n)_2\}]$ ($ML_n = M(CO)_5$, $CpMn(CO)_2$; M = Cr, W).[5]

Thus, we were surprised to find that from $[Cr(CO)_5PCl_3]$ and $K[MoCp^x(CO)_3]$ (Cp^x = Cp, Cp′, Cp″; Cp′ = η^5-C_5H_4-*t*Bu, Cp″ = η^5-1,3-C_5H_3tBu$_2$) [Eq. (a)] the main products formed were the complexes **1a–c** which contained *cyclo*-P_3 ligands. If $K[FeCp''(CO)_2]$ is used, the pentaphosphaferrocene derivative **3** is formed [Eq. (b)].

$$[Cr(CO)_5PCl_3] + K[MoCp^x(CO)_3] \xrightarrow[-KCl,\ -[Cr(CO)_6],\ -[MoCp^x(CO)_3]_2]{-78\,°C,\ THF} \mathbf{1a}, Cp^x = Cp;\ \mathbf{1b}, Cp^x = Cp';\ \mathbf{1c}, Cp^x = Cp'' \quad (a)$$

$$[Cr(CO)_5PCl_3] + K[FeCp''(CO)_2] \xrightarrow[-KCl,\ -[Cr(CO)_6],\ -[\{FeCp''(CO)_2\}_2]]{-78\,°C,\ THF} \mathbf{3} \quad (b)$$

According to the results of ^{31}P NMR spectroscopic investigations on the crude reaction mixtures, complexes **1a–c**, which have MoP_3 frameworks, are formed as the main products (**1a, b**: 92%, **1c**: 70%) as shown in (a). The only by-products are the Mo_2P_2 complexes **2a–c** and $[Mo_2Cp''_2(CO)_2(\mu,\eta^2\text{-}P_2)_2]$. Because the oxidized product

$[Mo_2Cp^x_2(CO)_4(\mu,\eta^2\text{-}P_2)]$ **2a**, Cp^x = Cp; **2b**, Cp^x = Cp′; **2c**, Cp^x = Cp″

$[\{Mo(CO)_3Cp^x\}_2]$ is formed in large amounts workup by column chromatography is necessary, leading to a loss in yield. The isolated yields amount to approximately 25% and are thus greater than that reported for $[MoCp^x(CO)_2(\eta^3\text{-}P_3)]$ (Cp^x = Cp, Cp*; Cp* = η^5-C_5Me_5).[6] The pentaphosphaferrocene derivative **3** was formed in 30% yield together with $[FeCp''(CO)_2PCl_2]$ ($\delta(^{31}P) = 369.2$). Compound **3** is isolated after sublimation in 10% yield.

The complexes formed are yellow (**1**), orange (**2**), and green (**3**) crystalline solids, which are sparingly soluble in *n*-pentane but readily soluble in CH_2Cl_2, benzene, and THF. Their properties and spectroscopic data (Table 1) are similar to those of isostructural compounds, which were prepared with other Cp^x ligands by the cothermolysis of P_4 with $[\{MCp^x(CO)_2\}_2]$ (M = Mo; Cp^x = Cp, Cp*;[6] M = Fe, Cp^x = Cp*[7]).

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Deutsche Akademische Austauschdienst. We thank Prof. Dr. O. J. Scherer for his support of this work.

The influence of the $[Cr(CO)_5]$ complex fragment on the reactions (a) and (b) is of decisive importance. If these reactions are carried out starting from noncomplexed PCl_3, the percentage of P_2 derivatives formed increases considerably, and in the case of the reaction of PCl_3 with Cp″Mo complexes, **2c** is afforded as the main product. In the corresponding reaction (b) **3** is no longer formed. Thus, the pentacarbonylchromium(0) unit supports the multiple P–P linkage in the coordination sphere of transition metals. Assumptions that metallaphosphaacetylenes of the type $L_nM{\equiv}P$[8] ($ML_n = [Cr(CO)_n]$ ($n = 3-5$) or $[MCp^x(CO)_n]$, M = Mo or Fe ($n = 3$ or 2)) are intermediates of reactions (a) and (b) were not confirmed by experiments. If the reaction (a) is carried out at various temperatures (−78°C, −40°C, 25°C) in the presence of 2,3-dimethylbutadiene, the same products are formed as from the corresponding reactions without dimethylbutadiene. Thus, a greater importance must be attached to the description of the formation pathway of a stepwise P–P linkage through di- and triphosphorus compounds. The ability of the $[Cr(CO)_5]$ complex fragments to abstract CO,[9] leading to the formation of $[Cr(CO)_6]$ and thus to the production of $[MoCp^x(CO)_2]$ or [FeCp″] units is also of decisive importance. The results of the reaction of $[Cr(CO)_5PCl_3]$ with $Na_2[Cr_2(CO)_{10}]$ indicate P–P bond formation since, in addition to $[\{Cr(CO)_5\}_2PCl]$,[10] the diphosphane **4** is obtained as the main product [Eq. (c)].

$$3[Cr(CO)_5PCl_3] + 2Na_2[Cr_2(CO)_{10}] \xrightarrow[-[Cr(CO)_6]\ -[\{Cr(CO)_5\}_2PCl]\ -4NaCl]{-78\,^\circ C,\ THF} [\{Cr(CO)_5\}Cl_2PPCl_2\{Cr(CO)_5\}] \quad (c)$$

4

The yellow microcrystalline compound **4** is sparingly soluble in *n*-pentane but readily soluble in CH_2Cl_2, toluene, and THF. Compound **4** is stable in air for a limited period but should be stored in the dark under an inert gas atmosphere. The spectroscopic data of **4** (Table 1) are in accordance with those given by Fritz et al., who prepared **4** by electrochemical reduction of $[Cr(CO)_5PCl_3]$.[11]

Further investigations starting from $[Cr(CO)_5PCl_3]$ have shown that P_x ligands are also formed by reactions with other transition metallates. Furthermore, this method of synthesis also appears to be applicable to the heavier homologues of Group 15.

Experimental Procedure

1–3: $K[MCp^x(CO)_n]$ (M = Mo: Cp^x = Cp, Cp′, Cp″, $n = 3$; M = Fe: Cp^x = Cp″, $n = 2$) (3.75 mmol) was added to a solution of $[Cr(CO)_5PCl_3]$ (1.25 mmol) (prepared from $[Cr(CO)_5(thf)]$ and PCl_3 at room temperature) in THF (15 mL) and cooled to −78°C. The solution turned red. It was stirred for one hour at this temperature and then slowly allowed to warm up to room temperature. The solvent was then removed under vacuum and the residue was taken up in benzene (15 mL). Subsequently, KCl was filtered off and the solvent was again removed under vacuum.

For the workup of the molybdenum complexes the solid was taken up in CH_2Cl_2 (15 mL) and adsorbed onto silica gel (10 cm^3). This mixture was dried under vacuum and then applied to a column (silica gel, 35 × 2.5 cm). The *cyclo*-P_3 complexes **1a–c** were eluted as yellow fractions with *n*-hexane or *n*-hexane/toluene (2:1). After recrystallization from *n*-pentane these fractions precipitated in the form of yellow needles (**1a**: 30 mg (23%), m.p. 125°C; **1b**: 43 mg (22%), m.p. 112°C; **1c**: 60 mg (26%), m.p. 98°C). With *n*-hexane/toluene (1:1) **2a–c** were obtained as a mixture with $[\{MoCp^x(CO)_2\}_2]$. Compound **2c** could be isolated from this mixture by recrystallization from *n*-pentane in the form of orange crystals (15 mg; 4%).

To isolate the green needlelike crystals of **3**, the *n*-pentane extract from the reaction mixture was evaporated to dryness and sublimed at 120°C/10^{-4} Torr (**3**: 25 mg (10%), m.p. 115–118°C).

4: $[Cr(CO)_5PCl_3]$ (6 mmol) was allowed to react with $Na_2[Cr_2(CO)_{10}]$ (1.7 g, 4 mmol) as described above and then worked up. The residue was suspended in *n*-pentane (30 mL), transferred to a frit and extracted with hot *n*-pentane until the filtered extracts were colorless. 0.6 g of a mixture of **4** and $[Cr(CO)_6]$ was recrystallized from this solution at 5°C. This mixture was filtered and the solid dried. The chromium hexacarbonyl was sublimed off at 40°C/10^{-3} Torr, leaving microcrystalline, yellow **4** (0.55 g, 30%). The filtrate contained $[\{Cr(CO)_5\}_2PCl]$ as the main component.

Novel V^{III} Complexes with a Central $[V_3(\mu_3\text{-}S)(\mu\text{-}S_2)_3]^+$ or $[V_2(\mu\text{-}O)(\mu\text{-}SPh)_2]^{2+}$ Unit**

By *Norman S. Dean, Kirsten Folting, Emil Lobkovsky,* and *George Christou**

There are two main reasons for our continuing interest in V–S and V–O chemistry. Firstly, the mechanistic details behind the conversion of vanadyl impurities in crude oil into polymeric V^{III} sulfides during hydrodemetallation (HDM) and hydrodesulfurization (HDS) in the processing of crude oil is not understood.[1] Oxo-bridged V^{III} compounds and multinuclear V^{III}–S aggregates are likely intermediates in the early and late stages, respectively, of this transformation. Secondly, the comparison of V–S chemistry with the much better explored Mo–S chemistry is instructive. Despite the many similarities, V–S chemistry is proving sufficiently different from Mo–S chemistry that the study of the former is not a routine extension of the latter. In this report we describe two new structural types for vanadium compounds and contrast them with Mo compounds.

Treatment of $[V(SPh)_2(bpy)_2]PF_6$ (bpy = 2,2′-bipyridine) with four equivalents of sulfur in hot MeCN gives a dark

green solution from which complex **1**[2, 16] can be isolated in 35–40% yield. The structure of the cation of **1** (Fig. 1) consists of a $[V_3(\mu_3\text{-}S)]$ unit with three edge-bridging $\eta^2:\eta^2:\mu\ S_2^{2-}$ groups and three chelating bipyridine ligands.

$[V_3S_7(bpy)_3]PF_6 \cdot 2MeCN$ **1**

The asymmetrically bridging S_2^{2-} units are found to have one longer (ave. 2.479 Å) and one shorter (ave. 2.372 Å) bond to each V atom; the longer V–S bonds are to the sulfur atoms that are almost coplanar with the V_3 triangle (Fig. 1). The idealized symmetry is C_{3v}, and the metals have the rare coordination number 7. Complex **1** is the first vanadium compound with a central $[M_3S(S_2)_3]$ unit,[3] although a complex with a $[V_3(\mu_3\text{-}S)(\mu\text{-}S)_3]$ framework is known.[4] Several complexes with a central $[Mo_3S(S_2)_3]$ unit have been characterized,[5] but none analogous to **1** with terminal bipyridine groups have been reported. The $[M_3E(S_2)_3]$ framework is also known for M = W, E = S[6] and M = Ti, E = O.[7]

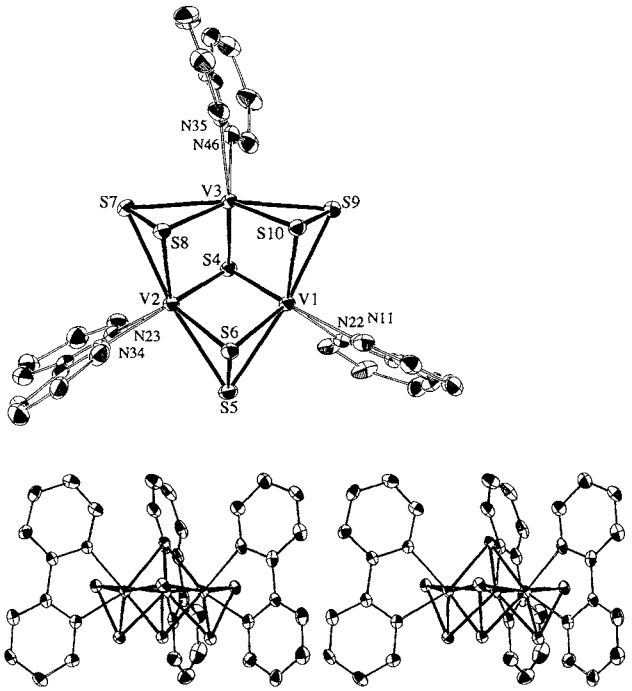

Fig. 1. ORTEP representation and stereoview of the cation of complex **1** (ellipsoids at the 50% probability level). Selected interatomic distances [Å] and angles [°]: V1-V2 2.770(1), V1-V3 2.767(1), V2-V3 2.750(1), S5-S6 2.040(2), S7-S8 2.034(2), S9-S10 2.032(2), V1-S4 2.329(2), V1-S5 2.470(2), V1-S6 2.381(2), V1-S9 2.483(2), V1-S10 2.354(2), V1-N11 2.204(4), V1-N22 2.210(4), V2-S4 2.329(2), V2-S5 2.497(2), V2-S6 2.361(2), V2-S7 2.467(2), V2-S8 2.392(2), V2-N23 2.183(4), V2-N34 2.189(4), V3-S4 2.314(2), V3-S7 2.484(2), V3-S8 2.357(2), V3-S9 2.473(2), V3-S10 2.386(2), V3-N35 2.181(4), V3-N46 2.190(4); V2-V1-V3 59.56(3), V1-V2-V3 60.17(3), V2-V3-V1 60.27(3), V1-S4-V2 72.97(5), V1-S4-V3 73.15(5), V2-S4-V3 72.63(5), V1-S5-V1 67.80(4), V1-S6-V2 71.49(5), V1-S9-V3 67.88(4), V1-S10-V3 71.44(5), V2-S7-V3 67.49(4), V2-S8-V3 70.76(5).

The V^{III} and Mo^{IV} units are isoelectronic. In analogy to the Mo complexes, **1** is diamagnetic in both the solid state and in solution, exhibiting a sharp ^1H NMR spectrum in CD_3CN. An EHMO calculation on the model system $[V_3S_7(NH_3)_6]^+$ also supports a diamagnetic nature for **1**. The calculated HOMO is a filled *e* set with metal–metal bonding character which is composed primarily (≈70%) of metal d orbitals. The LUMO of a_2 symmetry lies 1.3 eV above the HOMO and is composed (≈80%) of an antibonding combination of metal d orbitals.

The cyclic voltamogram of **1** in MeCN displays a reversible one-electron oxidation at −0.47 V (vs. Fc/Fc^+). The oxidized species, generated by controlled potential electrolysis, shows no EPR signal at 298 K or 77 K. On cooling to 5 K a broad, ill-defined EPR signal in the region $g \approx 2$ is observed. This behavior indicating rapid relaxation is consistent with the oxidized species being in a ^2E state, as suggested by the EHMO calculation, with low-lying excited states arising from the expected Jahn–Teller distortion. Coupling of the electron to all three vanadium nuclei would also contribute to further broadening of the EPR signal.

Hydrolysis of a solution of $NEt_4[V(Me_2bpy)(SPh)_4]$ (Me_2bpy = 4,4′-dimethylbipyridine) by adventitious H_2O in the MeCN solvent gave small amounts of the green complex **2**.[8, 16] The complex can be synthesized rationally and

$[V_2O(SPh)_4(Me_2bpy)_2]$ **2**

in adequate yield (40–50%) by controlled hydrolysis of a mixture of $[VCl_3(thf)_3]$, NaSPh, and Me_2bpy in THF. The structure of **2** (Fig. 2) consists of two face-sharing octahedra; the bridging ligands are an oxo and two PhS^- groups. The

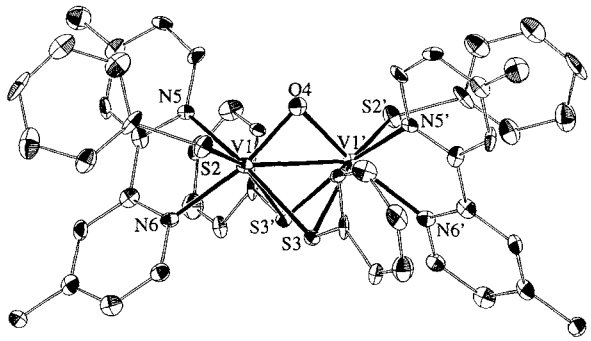

Fig. 2. ORTEP representation of complex **2** (ellipsoids at the 50% probability level). Primed and unprimed atoms are related by a crystallographic C_2 axis. Selected distances [Å] and angles [°]: V1-V1′ 2.579(3), V1-S2 2.394(3), V1-S3 2.432(2), V1-S3′ 2.493(3) V1-O4 1.841(6), V1-N5 2.152(6), V1-N6 2.184(7); V1-O4-V1′ 88.9(3), V1-S3-V1′ 63.15(8).

central $[M_2(\mu\text{-}O)(\mu\text{-}SPh)_2]^{2+}$ unit is unique for vanadium and extremely rare for any other metal; it has been found only in two Mo^{VI} dimers in a highly unsymmetrical form.[9] An M_2 unit bridged by hydroxo and bis-thiolato ligands is found in $[Cp_2Cl_3Mo_2(OH)(SMe)_2]$,[10] and a few examples of sulfido/bisthiolato bridged units are known.[11] The confacial bioctahedral arrangement is new for V^{III}–O compounds, in which the singly bridged $[V\text{-}O\text{-}V]^{4+}$ unit is common[12] and in general linear (or nearly so). In $[V_2O(OAc)_2(tacn)_2]^{2+}$ (tacn = 1,4,7-triazacyclononane) the V-O-V unit is bent with an angle of 130.2°.[13] The V···V distance in **2** (2.579(3) Å) is shorter than in **1** and comparable with that in **3** (2.60 Å) (edt = ethane-1,2-dithiolate).[14]

$[V_2(edt)_4]^{2-}$ **3**

EHMO calculations on the model complex $[V_2O(SH)_4(NH_3)_4]$ suggest the presence of a V–V single

bond in **2** in analogy to **3**. This is also supported by the acute V1-S3-V1′ angle ($\approx 63°$). The small magnetic moment of the complex ($\approx 0.6\ \mu_B$/V) is thus taken as indicating the coupling of the remaining two electrons by bridge-mediated antiferromagnetic exchange interactions (again in analogy to **3**) to give a singlet ground state and a triplet excited state. Thus, **2** is a rare example of a V^{III} compound with a V–V bond.[14, 15]

In summary, V–S chemistry continues to be the source of interesting new structural types and new V^{III} compounds with V–V bonds and/or strong interactions. The described work emphasizes both the similarities and differences between V and Mo chemistry. The framework of complex **1** is both structurally and electronically analogous to that of a well-known class of Mo–S compounds, whereas **2** has no exact structural or electronic Mo counterparts.

Experimental Procedure

1: Sulfur (0.128 g, 4.00 mmol) was added to a solution of $[V(SPh)_2(bpy)_2](PF_6)$ [17] (0.722 g, 1.00 mmol) in MeCN (35 mL), and the solution was heated to 65° for 2–3 h. The initial dark red color gradually changed to dark green and a tan precipitate formed. The solution was filtered and the filtrate volume reduced by 50%. After the addition of Et_2O (30 mL), storage of the solution at 0 °C overnight resulted in the precipitation of **1** as a green powder (0.12 g, 37% yield).

2: $[VCl_3(thf)_3]$ (0.711 g, 2.00 mmol), NaSPh (0.798 g, 6.00 mmol), and Me_2bpy (0.368 g, 2.00 mmol) were dissolved with stirring in THF (40 mL). Water (0.018 mL, 1.0 mmol) was added after 1 h, causing the solution to rapidly change color from red/purple to a dark green. After a further hour the solution was filtered and the filtrate volume reduced to 10 mL. Et_2O (40 mL) was added to precipitate **2** as a dark green powder (0.380 g, 41.2% yield).

The First Unsolvated Chelate and Cubane-Type Barium Complexes: Effective Compounds for the Sol–Gel Process

By *Sushil K. Pandey, Alexander Steiner, Herbert W. Roesky,** and *Dietmar Stalke*

Dedicated to Professor Ulrich Wannagat on the occasion of his 70th birthday

Cyclophosphazenes[1] are an important class of compounds employed as precursors in polymer chemistry.[2] Little is known on the chemistry of these compounds, in particular of cyclophosphazenes with Ba–N bonds. To our knowledge, no phosphazene–barium compounds have been reported to date. Before 1990,[3] molecular barium amides were totally unknown. We were particularly interested in these compounds because they can serve as precursors in the synthesis of complex oxides, which are used in high-temperature superconductors.[4] The metal oxide hydrates can be prepared by the sol–gel process.

We report here on the first unsolvated chelate and cubane-type barium complexes, which were prepared from barium bis(trimethylsilyl)amide.[5] Chelate complex **3** was prepared quantitatively from the reaction of amide **1** with **2**[6] (mol ratio 1:2) in *n*-hexane at 25 °C with elimination of $HN(SiMe_3)_2$. Compound **3** is a white, moisture-sensitive, nonvolatile solid. When **3** was heated to 110 °C at 0.01 bar it decomposed to **2** ($\delta(^{31}P) = 18.5$) and further decomposition products in low yield. Single crystals suitable for X-ray crystallography were obtained by storing a supersaturated solu-

3

tion of **3** in toluene at 0 °C for two days and then at ambient temperature another two days.

Figure 1 shows the crystal structure of **3**. The monomeric compound contains a central six-coordinate barium atom located in the two planes defined by the almost planar backbones of the two tridentate phosphazene ligands. These two planes are perpendicular with respect to one another. Ba1 is surrounded by N1, N3, N4, and N6 in a tetrahedral fashion and linearly coordinated to N2 and N5. The distances from Ba1 to N2 and N5 are shorter (276 pm) than those to the silyl-substituted N atoms (285 pm). These distances are comparable to those observed in dimeric barium bis(trimethylsilyl)amide derivatives[5] with both bridging and terminal amido groups. There the distances between Ba and the bridging N atoms are longer, the distances to the terminal N atoms are shorter than those in **3**.

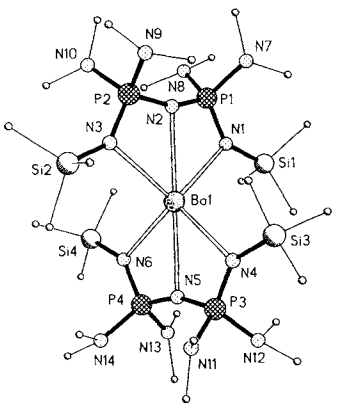

Fig. 1. Crystal structure of **3**. Selected bond lengths [pm] and angles [°] (ave.): Ba1-N1, N3, N4, N6 285, Ba1-N2, N5 276, P-NP 158, P-NSi 155, N-Si 168; P-N-P 158, N-P-N 108, Si-N-P 141.

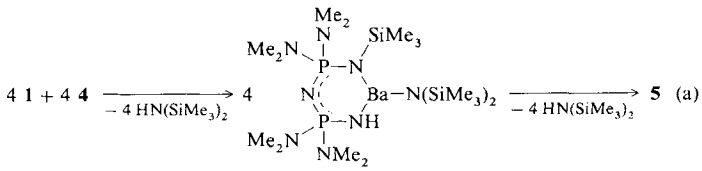
Compound **5** was obtained from the reaction of amide **1** and the acyclic monosilylated ligand **4**[6] (mol ratio 1:1) in *n*-hexane at 25 °C. The reaction mechanism leading to the formation of heterocubane **5** can be described as follows: In a first step a lower-coordinated monocyclic intermediate is formed, which is stabilized in a second step by elimination of one equivalent of bis(trimethylsilyl)amine and simultaneous oligomerization [Eq. (a)].

$$4\,\mathbf{1} + 4\,H_2NP(NMe_2)_2NP(NMe_2)_2NSiMe_3 \xrightarrow{6\text{ h, }n\text{-hexane}} \underset{\mathbf{4}}{} \xrightarrow[-\,8\,HN(SiMe_3)_2]{} [\{BaNP(NMe_2)_2NP(NMe_2)_2NSiMe_3\}_4]$$

5



Compound **5** is a white, moisture-sensitive solid, which is extremely soluble in organic solvents. Single crystals suitable for X-ray crystallography were obtained by storing a saturated solution of **5** in *n*-hexane at 0 °C for a week. Compound **5** is tetrameric (Fig. 2), and the backbone of the structure consists of a barium–nitrogen heterocubane. Veith reports similar cagelike structures with main group elements.[7] The phosphazene ligands have different modes of coordination; two are tetradentate, the other two are tri- or pentadentate, (Fig. 3a–d). In all cases, the imido nitrogen atoms occupy four of the corners of the cubane and, thus, coordinate to three barium atoms (Ba–N: 271 pm (ave.); 259.4 to 283.1 pm), whereas each silylamido nitrogen atom coordinates to one barium atom (Ba–N: 290 pm (ave.); 286.8 to 297.9 pm). The other donor sites are occupied by either dimethylamino nitrogen atoms and solely phosphorus-bound nitrogen atoms. The barium atoms thus exhibit different coordination numbers (Ba1 and Ba4: 6, Ba3: 7, Ba2: 5). The coordination gap at Ba2 is filled by a close contact to a trimethylsilyl group of another tetrameric unit (Ba2–C: 334 pm).[8]

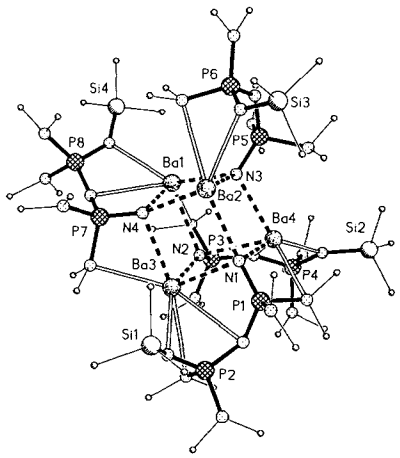


Fig. 2. Crystal structure of **5**. Bond lengths [pm] in the Ba–N cubane: Ba1-N2 274.3(6), Ba1-N3 267.9(6), Ba1-N4 283.1(6), Ba2-N1 266.6(7), Ba2-N3 261.8(6), Ba2-N4 262.4(7), Ba3-N1 272.3(7), Ba3-N2 259.4(6), Ba3-N4 275.6(6), Ba3-N1 282.5(6), Ba4-N2 280.6(6), Ba4-N3 267.1(6).

The formation of the Ba_4N_4 cluster is particularly surprising and gives reason to expect more new results. The compounds presented here may find interesting applications in high-tech material development. Sol–gel investigations on **3** and **5** have already given promising results in the preparation of metal oxide precursors. A white gel, consisting of $Ba(OH)_2 \cdot xH_2O$, can be easily prepared by hydrolysis of a

solution of the barium compounds in toluene with water in methanol or ethanol.

Experimental Procedure

3: A solution of 1.5 g (3.5 mmol) of **2** in 20 mL *n*-hexane was added dropwise to a solution of 1.0 g (1.7 mmol) of **1** in 20 mL *n*-hexane. The reaction mixture was stirred at ambient temperature for 4 h. A pale yellow solution was obtained. After evacuation of all volatile compounds the spectroscopically pure compound was obtained in quantitative yield. Further purification can be achieved by recrystallization in *n*-hexane at 0 °C. M.p. 220 °C; ^{1}H NMR ($CDCl_3$, TMS ext.): $\delta = 0.1$ (s, 36H, $SiMe_3$), 2.5 (d, $J = 10.7$ Hz, 48H, NMe_2); ^{31}P NMR ($CDCl_3$, 85% H_3PO_4 ext.) $\delta = 5.2$ (s); ^{29}Si NMR (*n*-hexane/$CDCl_3$) $\delta = 7.1$ (s); IR (nujol): $\tilde{\nu}$[cm^{-1}] = 1284b, 1256s, 1100s, 1063s, 979vs, 857s, 826s, 740s, 719s, 671m, 626m, 503vs; MS(EI): *m/z* 990 (M^+, 20%), 564 (M^+ minus one ligand, 100%); satisfactory C,H,N analysis for $C_{28}H_{84}N_{14}P_4Si_4Ba$ (990.41).

5: A solution of 1.0 g (2.8 mmol) of **4** in 20 mL *n*-hexane was added dropwise to a solution of 1.7 g (2.8 mmol) of **1** in 20 mL *n*-hexane and stirred at ambient temperature for 6 h. A clear, pale yellow solution was obtained. After evacuation of all volatile compounds the white, foamy product remained in the reaction vessel (quantitative yield). M.p. 110 °C; ^{1}H NMR (C_6D_6, TMS ext.): $\delta = 0.4$ (s, 36H, $SiMe_3$), 2.5–2.7 (m, 96H, NMe_2); ^{31}P NMR (C_6D_6, 85% H_3PO_4 ext.) $\delta = 9.8$ (d), 26.4 (d); IR (nujol): $\tilde{\nu}$[cm^{-1}] = 1305s, 1244m, 1172s, 1080m, 969vs, 933m, 854s, 817s, 747m, 505vs; MS(EI): *m/z* 247 (M^+ minus two ligands; 50%), 355 (ligand; 100%).

Diastereo- and Enantioselective Synthesis of 2-Substituted 3-Trialkylstannylcyclohexanones by Michael Addition of Trialkylstannyllithium to Cyclohexenone SAMP Hydrazone**

By *Dieter Enders,* Klaus-Jürgen Heider,* and *Gerhard Raabe*

Organotin compounds have been shown to be valuable building blocks for the construction of complex organic molecules.[1] The 1,4-addition of trialkylstannyllithium to α,β-unsaturated carbonyl compounds described by Still et al.[2] is a simple and efficient entry to functionalized tetraorganostannanes. In this reaction the enolate formed as an intermediate can be trapped by protons to give the simple adducts, and by alkyl iodides to give the *anti* tandem adduct stereoselectively.[2, 3] In the reactions with enones and trialkylsilylchloride silylenolethers are obtained,[4] and additions to aldehydes provide the aldol products.[5] The trialkylstannylketones formed are homoenolate equivalents[6] and can be easily converted into interesting synthetic building blocks, for example, 1,3-diols and dihydroxyketones,[7] cyclopropanes,[5, 8] enones,[9] unsaturated macrolides,[10] isoxazolines,[11] bicyclo[3.1.0]hexanes,[12] and spiroacetals.[13]

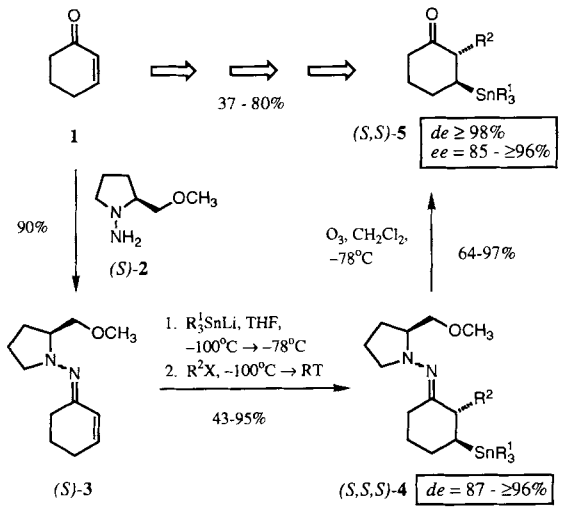
In the Michael addition of trialkylstannyl metal compounds[14] or trialkylstannylcuprates[15] to α,β-unsaturated ketones and the subsequent reaction with alkyl iodides, the *trans* products containing two new stereogenic centers are formed diastereoselectively. Until now optically active 3-trialkylstannylketones have only been prepared by diastereoselective addition to enantiomerically pure cyclohexenones.[15a, b, 16]

We report here for the first time on the regio-, diastereo-, and enantioselective synthesis of 2-substituted 3-trialkylstannylcyclohexanones. The key step is the Michael addition of trialkylstannyllithium to cyclohexenone SAMP or RAMP hydrazone, (*S*)-**3** and (*R*)-**3**, respectively, which are readily available from (*S*)- or (*R*)-1-amino-2-methoxymethylpyrrolidine (SAMP (*S*)-**2** or RAMP (*R*)-**2**, respectively) and cyclohexenone in 90% yield (Scheme 1).

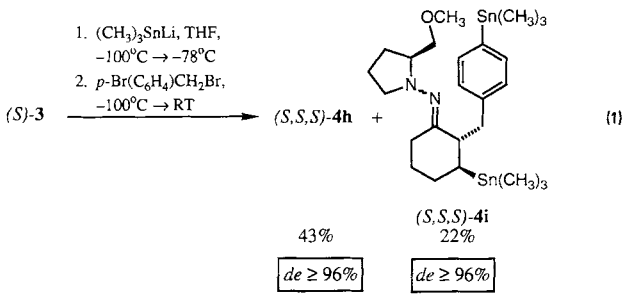


Scheme 1. Diastereo- and enantioselective synthesis of 2-substituted *trans*-3-trialkylstannylcyclohexanones (*S,S*)-**5**. RT = room temperature.

In tetrahydrofuran at −100 °C trimethylstannyllithium and tributylstannyllithium add to (*S*)-**3** regioselectively at the 4-position.[17] Trapping the resulting azaenolate with a saturated solution of ammonium chloride leads to the simple adducts (*S,S*)-**4a** and (*S,S*)-**4b** in only modest diastereomeric excess (*de* = 42–44%), whereas the *trans* tandem adducts (*S,S,S*)-**4c–h** with equatorial substituents are obtained in very good diastereomeric excess (*de* = 87–≥96%) in the reaction with alkyl iodides or bromides (Table 1). In this regard addition of trimethylstannyl anions gives poorer chemical yields (43–82%) and better induction (*de* = 44–≥96%) than the addition of tributylstannyl anions (yields 94–97%, *de* = 42–87%). In the case of 2-alkyl-3-trimethylstannylcyclohexanone SAMP hydrazones the isomer formed in excess can be enriched by chromatography.

The stannylated hydrazones **4** are subsequently converted to 3-trialkylstannylketones **5** by oxidative cleavage with ozone in very good yield without epimerization and racemization (64–93%, *de* ≥ 98%, *ee* = 42–≥96%). Ketones **5a–e** separate as colorless oils and ketones **5f–h** as colorless solids that can be recrystallized from ethanol, *n*-hexane, or diethyl ether.

When *para*-bromobenzylbromide is used as electrophile the bromine atom of (*S,S,S*)-**4a** is exchanged for a trimethylstannyl group in a side reaction. In addition to (*S,S,S*)-**4h** (43%) the stannylated product (*S,S,S*)-**4i** is obtained in a yield of 22% [Eq.(1)]. The conjugate addition of cyano-



(tributylstannyl)methylcuprate[15c] as nucleophile to (*S*)-**3** and trapping of the resulting azaenolate with methyl iodide leads, after oxidative cleavage, to the Michael–Michael adduct (*S,S,S,R*)-**6** as the major product (yield 75%, *de* ≥ 75%), together with the simple tandem adduct (*S,S*)-**4d** (yield 16%, *de* ≥ 98%, *ee* = 88%) [Eq.(2)]

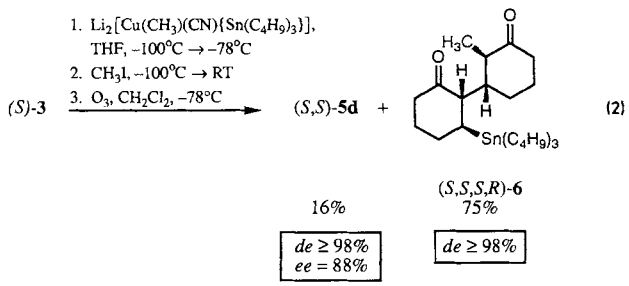


Table 1. 2-Substituted 3-trialkylstannylcyclohexanones **5** prepared by asymmetric Michael addition.

[a] Determined by ^{13}C NMR spectroscopy (absolute configuration in parentheses). [b] Determined by ^1H NMR spectroscopy. [c] The value for *ee* corresponds to the *de* value for hydrazone **4** (absolute configuration in parentheses). [d] Neat. [e] RAMP used as chiral auxiliary. [f] Determined by ^{19}F NMR spectroscopy after reduction to the alcohol and esterification to the MTPA ester (see text). [g] After chromatography. [h] Measured by ^1H NMR shift experiment with $[Eu(hfc)_3]$. [i] After crystallization from ethanol. [j] Contains 22% **4i** as by-product.

The enantiomeric excess of **5f** was determined from its ^{1}H NMR spectrum with [Eu(hfc)$_3$] (hfc = tris[3-(heptafluoropropyl(hydroxymethylene-*d*-camphorato]) and that of **5c–e** and **5g,h** from the ^{19}F NMR spectra of the MTPA esters (MTPA = 3,3,3-trifluoro-2-methoxy-2-phenylpropionic acid), obtained by diastereoselective reduction with potassium tri-*sec*-butylhydroborate (K-Selectride)[18] to the (*S,S,S*)-2-alkyl-3-trialkylstannylcyclohexanol derivatives[19] and subsequent reaction with MTPA-Cl.[20] The racemic reference compounds were obtained by addition of the tin nucleophiles to cyclohexenone. The enantiomeric excesses determined in this fashion are in good agreement with the diasteromeric excesses obtained from ^{13}C NMR spectra at the stage of the hydrazone. Assignment of the absolute configurations (2*S*,3*S*) and (2*R*,3*R*) are based on X-ray crystal analyses of the compounds **5f**[21] and **5g**[22] (Fig. 1) obtained by tandem addition to (*S*)-**3**, and by circular dichroism (CD) measurements.[16a] All the 3-trialkylstannylketones **5** prepared with SAMP as auxiliary show a negative Cotton effect at $\lambda = 300$ nm, whereas the RAMP auxiliary leads to stannylketones with a positive Cotton effect.

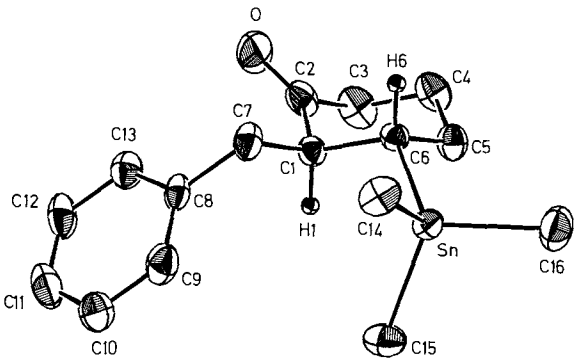

Fig. 1. Crystal structure of **5g**[22] (ORTEP[24], ellipsoids with 30% probability).

To our knowledge this is the first report of the asymmetric Michael addition of tin nucleophiles and provides a diastereo- and enantioselective entry to both enantiomeric series of *trans*-2-alkyl-3-trimethylstannylcyclohexanones.[25] Initial results show that this process can also be applied to open-chain α,β-unsaturated aldehyde SAMP hydrazones.

Experimental Procedure

A commercial 1.5 N solution of *n*-butyllithium in *n*-hexane (3 mL) was concentrated to dryness under vacuum. The residual yellow oil was dissolved in 4 mL anhydrous THF at 0 °C under inert gas, and 4.5 mmol hexaalkyldistannane (degassed under high vacuum or distilled) was added. After 15 min (hexabutyldistannane) or 2 h (hexamethyldistannane), the solution was cooled to −100 °C, and after a further 10 min 3 mmol (*S*)-3 was added dropwise. After the suspension was allowed to warm up to −78 °C over 3 h, an intensely yellow solution was obtained and stirred at this temperature for 2 h. At −100 °C a solution of 6 mmol electrophile in 4 mL THF was slowly added dropwise. The resulting solution was allowed to warm to room temperature within 15 min. The volatile components were condensed under vacuum into a trap cooled in liquid nitrogen, the residue was taken up in diethyl ether, washed with water and saturated NaCl solution, dried over magnesium sulfate, and concentrated to dryness. The crude product obtained can be used directly for the ozonolysis. The 3-trialkylstannyl SAMP hydrazones (*S,S,S*)-**4** were purified by column chromatography (silica gel, petroleum ether/diethyl ether 5:1 + 5% triethylamine).

Ozone was passed through a solution of (*S,S,S*)-**4** in dichloromethane at −78 °C until no more hydrazone could be detected by thin-layer chromatography (silica gel, petroleum ether/diethyl ether 5:1). After the excess ozone was driven off by a stream of argon, the reaction mixture was allowed to warm up, the solvent removed, and the product (*S,S*)-**5** purified by column chromatography (silica gel, petroleum ether/diethyl ether 20:1).

[21] A crystal of suitable quality formed in diethyl ether at −20 °C. The compound crystallizes in the orthorhombic space group $P2_12_12_1$ (no. 19) $a = 6.637(1)$, $b = 9.480(2)$, $c = 23.977(2)$ Å. A cell volume of 1508.7 Å^3, $Z = 4$, and $M_r = 333.0$, leads to a density of $\rho_{calc} = 1.466$ g cm^{-3}. Total number of electrons per unit cell $F(000) = 672$. Enraf-Nonius CAD4 four-circle diffractometer, graphite monochromator, $\Omega/2\theta$-scans, 20 °C, $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $\mu = 16.91$ cm^{-1}. A total of 3432 unique reflections were recorded ($+h+k+l$, $-h-k-l$ Friedel pairs), of which 3183 were observed ($I > 2\sigma(I)$), $R_m = 0.016$, $\sin\theta/\lambda_{max} = 0.649$. The structure was solved by the heavy-atom method (XTAL3.0[23]). Hydrogen atom positions were calculated. A total of 146 parameters were refined, $R = 0.046$ ($R_w = 0.044$). The maximum residual electron density was 1.3 e Å^{-3}. $X_{abs} = -0.04(6)$.

[22] Suitable crystals formed at −20 °C in diethyl ether. The substance crystallizes in the orthorhombic space group $P2_12_12_1$ (no. 19) $a = 7.645(1)$, $b = 16.255(3)$, $c = 13.078(1)$ Å. The cell volume of 1625.2 Å^3, $Z = 4$, and $M_r = 351.1$, leads to a density of $\rho_{calc} = 1.435$ g cm^{-3}. Overall number of electrons per unit cell $F(000) = 712$. Enraf-Nonius CAD4 four-circle diffractometer, graphite monochromator, $\Omega/2\theta$-scans, 0 °C, $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $\mu = 15.66$ cm^{-1}. A total of 3679 independent reflections were recorded ($\pm h + k + l$), of which 3524 were observed ($I > 2\sigma(I)$), $R_m = 0.027$, $\sin\theta/\lambda_{max} = 0.649$. The structure was solved by the heavy-atom method (XTAL3.0 [23]). Some of the hydrogen atom positions could be located, the remainder were calculated. A total of 164 parameters were refined. $R = 0.025$ ($R_w = 0.030$). The maximum residual electron density was 0.3 e Å^{-3} and $X_{abs} = -0.03(3)$. [25] All compounds gave correct elemental analyses and spectra (^{1}H NMR, ^{13}C NMR, IR, UV) in agreement with their structures.

Molecular Tweezers with a Hydrocarbon Skeleton and Convergent Carboxyl Groups

By *Ralf Güther*, *Martin Nieger*, and *Fritz Vögtle**

As preorganized, acyclic host compounds "molecular tweezers" are distinguished by convergent functional groups that can "grasp" guest molecules.[1] To date only a few types of compounds have been reported to be efficient molecular tweezers; those prepared by Rebek et al. are the best known.[2] We have been trying for a number of years[1c, g] to utilize the characteristic features of cyclophane building blocks for the convergent arrangement of functional groups.[3] By linking two suitable cyclophane frameworks we have now been able to preorganize the functional groups so precisely that they are directly opposite each other when the guest molecule is enclosed (Fig. 1). The stereochemistry of [3.3]- and particularly [2.2]metacyclophanes offer interesting possibilities, which we will describe here.

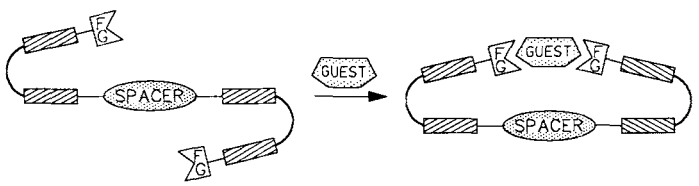

Fig. 1. Schematic representation of host–guest recognition with the new type of tweezer compounds (FG = functional group).

The double dithia[3.3]metacyclophane **5**, which has a stiff diyne bridge holding the two halves apart, exists exclusively in the double *syn* conformation shown in Figure 2, in which the two carboxyl groups are forced to face each other. Compound **5** was prepared in the following manner: 3,5-Dimethylbromobenzene and 3,5-dimethylbenzoic acid were converted into 2,11-dithia[3.3]metacyclophane **1** in a few steps.[5] Subsequent palladium-catalyzed ethynylation (a in Scheme 1) furnished the trimethylsilyl(TMS)-protected cyclophane **2**. The TMS groups were cleaved (b) to give **3**, and coupling of the alkyne moieties (c) led to diyne **4**, which could be hydrolyzed with trifluoroacetic acid (d) to yield **5**.

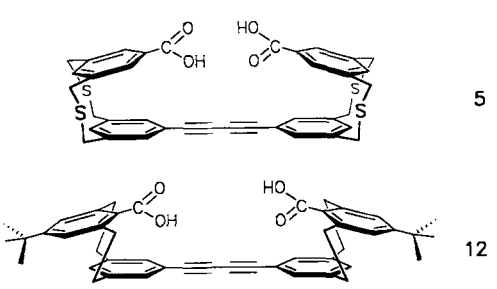

Fig. 2. Target molecule **5** based on the stereochemistry of [3.3]metacyclophanes with proven *syn* conformation of the [3.3]phane units; target molecule **12** based on the stereochemistry of [2.2]metacyclophanes with fixed *anti* conformation of the [2.2]phane units.

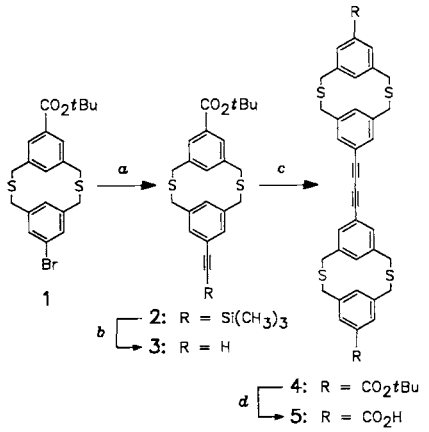

Scheme 1. Synthesis of **5**. a) Trimethylsilylacetylene/[$(Ph_3P)_2PdCl_2$]/CuI, triethylamine, 8 h at 80 °C, 90%; b) K_2CO_3, abs. methanol, 5 h at room temperature (RT), 92%; c) CuCl/$CuCl_2$, pyridine, 5 d at RT, 66%; d) CF_3COOH, 30 min at RT, > 90%.

Figure 2 also shows the rigidly fixed, "double" [2.2]metacyclophane **12** in the *anti* conformation, which was prepared as follows (the *tert*-butyl groups proved to be essential for increased solubility):[1g] 2,6-Dimethylaniline and 5-*tert*-butyl-1,3-dimethylbenzene were converted into dithia[3.3]metacyclophane **6**[5] in a few steps. Oxidation (a in Scheme 2) led to sulfone **7**, subsequent vacuum pyrolysis (b) provided [2.2]metacyclophane **8**. Palladium-catalyzed ethynylation (c) furnished the TMS-protected cyclophane **9**; the TMS groups were cleaved (d) to provide **10**, which could be coupled directly giving diyne **11**. Hydrolysis of the methyl ester groups in the interior of the cyclophane, which are blocked by the adjacent methylene groups, was possible only with LiI in pyridine.[7] In addition to the target molecule **12**, the monocarboxylic acid **13** was also always obtained.

Figure 3 shows the X-ray structure of the crystalline diester tweezer compound **11**.[8] It can be seen that both [2.2]metacyclophane units are in the desired *anti* conformation but twisted 180° to each other about the diyne axis. Since the molecule can twist freely about this axis in solution, the desired conformation in which the two functional groups face each other is possible.[9]

The molecular recognition possible with the two new types of tweezer compounds was tested first with diamines as guest

Synthesis of **12** and **13** (reference compound **14** is shown on the right). a) H_2O_2/glacial acetic acid, benzene, 8 h at 60 °C, > 90%; b) Δ (pyrolysis), 87%; c) trimethylsilylacetylene/$[(Ph_3P)_2PdCl_2]$/CuI, triethylamine, 8 h at 70 °C, 26%; d) K_2CO_3, abs. methanol, 5 h at RT, > 90%; e) CuI, triethylamine, 6 h at 80 °C, 58%; f) LiI, abs. pyridine, 8 d reflux, 27%.

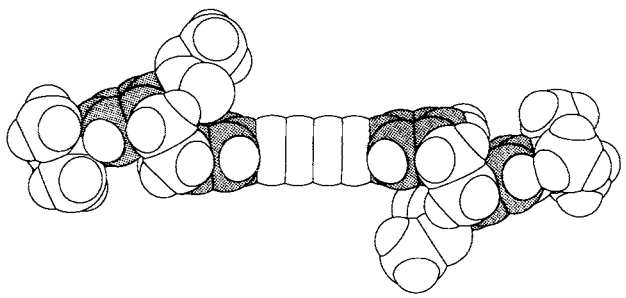

Fig. 3. X-ray structure of diester **11** with two *anti*-[2.2]metacyclophane units. The linearity of the diacetylene spacer is evident.

compounds. When 1,4-diazabicyclo[2.2.2]octane (DABCO, **15**) or piperazine (**16**) (Fig. 4) was added to a suspension of either of the host compounds **5** or **12** in trichloromethane, the mixture dissolved completely at a host–guest ratio of 1:1. In ^{1}H NMR experiments the signals of the protons of the guest, which are shifted to lower fields because of the magnetic anisotropy of the triple bonds, are not observed in the spectrum of the reference host compound **14** with DABCO (shifts of the signals as a result of proton transfers between the tweezer molecules **5** and **12** with DABCO and piperazine

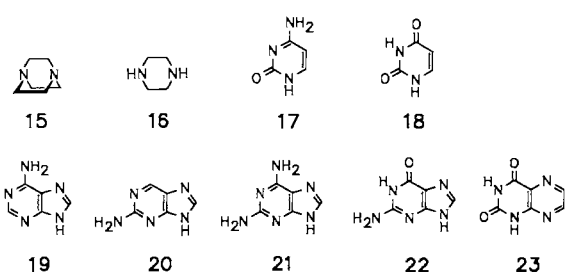

Fig. 4. List of the guest compounds examined.

MS (70 eV): *m/z* 676.3568 ($M^{\oplus}$, 63%, $C_{47}H_{48}O_4$, calc.: 676.3553)

can thus be discounted almost completely). The host compound and DABCO crystallize out of trichloromethane as a 1:1 complex, as ^{1}H NMR and FAB mass spectra prove; the latter shows an intense peak for the 1:1 complex. No indications were given for formation of a 1:2 complex.

We also investigated the host properties of tweezer molecule **12** towards pyrimidine and purine bases (Fig. 4). Using the method described in ref.[10], we found distinctive selectivities in the host–guest recognition. 2,6-Diaminopurine (**21**) is bound more tightly (higher association constants) than adenine (**19**) or 2-aminopurine (**20**). The preference of guest **21** can be explained by its higher basicity and the better spatial complementarity between the host and guest as a result of the additional amino group. The association constants K_{assoc} of the complexes formed by **12** and 2,6-diaminopurine (**21**) and adenine (**19**) determined from the increase in solubility are $6.6(\pm 1.4) \times 10^4$ and $4.1(\pm 1.5) \times 10^4$ M^{-1}, respectively. Given a choice between uracil (**18**) and cytosine (**17**) host **12** shows a preference for uracil, $K_{assoc} = 1.4(\pm 0.6) \times 10^4$ M^{-1} (no definite host–guest effects were observed within experimental limitations with 2-aminopurine (**20**), cytosine (**17**), guanine (**22**), and 2,4-dihydroxypteridine (**23**)). In accord with this successful proof of the host properties of the tweezer compounds, no association was observed when **12** was replaced by the simple cyclophane **14**,[12] "half" of the molecular tweezers (Fig. 5).

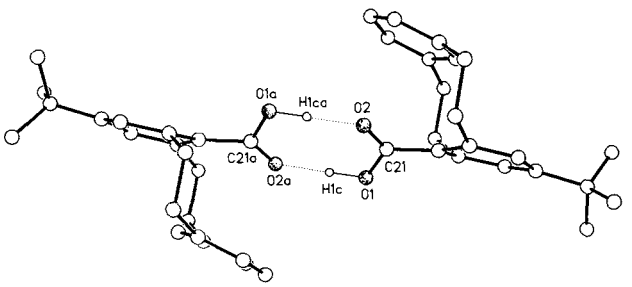

Fig. 5. X-ray structure of the reference compound **14** ("half of the tweezers"). The carboxyl groups are not separated by a spacer and form a dimer, as expected[14], by hydrogen bonding.

The 1:1 composition of the host–guest complexes of **12** and the high association constants suggest that the guest molecules are bound, as planned,[3] by hydrogen bonds in the noncollapsible molecular niche between the two functional groups. Remarkably, in earlier investigations of host compounds for nucleobases, for example tri- and bis(catechol) macrocycles,[10b-d] the same order of bonding strengths was found for this type of guest.

In conclusion, these tweezer molecules, the first constructed from cyclophanes, are strongly binding and selective hosts. The synthesis of other molecular tweezers of this type with various spacers, other functional groups, and with more than two convergent fixed functions appears to be worthwhile.

Experimental Procedure

11: Compound **10** (121 mg, 0.35 mmol) and copper(I) iodide (100 mg, 0.52 mmol) were dissolved in degassed triethylamine (30 mL) under inert gas and heated at 80 °C for 6 h. After the reaction mixture had cooled, the solvent was distilled off under vacuum and the residue purified by chromatography ($R_f = 0.76$; SiO_2, particle size 60–100 μm, dichloromethane/petroleum ether 40–60 (1:1)) to give colorless crystals (70 mg, 58%).

12/13: Compound **11** (69 mg, 0.1 mmol) was dissolved in anhydrous pyridine (30 mL), treated with anhydrous lithium iodide (403 mg, 3 mmol), and heated at reflux for 8 d. The solvent was distilled off under vacuum and the residue taken up in trichloromethane (20 mL) and 2N HCl (20 mL) and extracted repeatedly with trichloromethane. The combined organic phases were washed three times with 6N HCl and dried over Na_2SO_4. The solvent was removed under vacuum and the residue purified by flash chromatography (SiO_2, particle size 30–60 μm, trichloromethane/methanol (50:1)). Fraction 1 ($R_f = 0.45$): 36 mg (53%) monocarboxylic acid **13**; fraction 2 ($R_f = 0.22$); 18 mg, biscarboxylic acid **12**.

Structure and Symmetry of the Benzene Cation**

By *Reiner Lindner, Hiroshi Sekiya, Bernhard Beyl,* and *Klaus Müller-Dethlefs**

The structure and symmetry of the benzene molecule, already a theme of early research in organic chemistry, was not completely clarified until recently, despite many attempts. In particular, the symmetry of the equilibrium structure in the electronic ground state has continually stimulated discussion.[1, 2] Only a few years ago Ermer[1] made clear that although D_{6h} symmetry was compatible with many experi-

mental results and ab initio calculations, D_{3h} symmetry cannot be definitely rejected. D_{6h} symmetry for the electronic ground state $S_0\,^1A_{1g}$ of benzene was proved only with the help of microwave spectra with completely resolved rotational lines (of singly and doubly deuterated benzene) *in the gas phase*, since an analysis of these clearly rules out D_{3h} symmetry.[3] Also for the first excited state $S_1\,^1B_{2u}$, the speculation on a deviation from the hexagonal, planar structure was finally convincingly ended by high-resolution spectroscopy in the gas phase, in this case by Doppler-free rotationally resolved fluorescence-excitation spectra of the $S_1 \leftarrow S_0$ transition.[4]

The perturbation of the π electron system by the removal of an electron to form the benzene cation is expected to cause a deviation from the structure and symmetry of the neutral molecule. Reduction to threefold symmetry is conceivable, which would correspond to a "localization" of the double bonds, either to D_{3h} in which the planar structure is maintained, or to C_{3v} and a chairlike structure similar to the chair conformation of cyclohexane. However, an in-plane symmetry reduction to D_{2h} is also feasible, as can be concluded from theoretical considerations.[5] The analysis of Rydberg series converging to the electronic ground state of the cation, and also of photoelectron spectra, point more towards the maintenance of a planar structure in the cation.[6] Nevertheless, the ground-state geometry cannot be deduced exactly because of the poor resolution of conventional photoelectron (PE) spectroscopy. In this communication, completely rotationally resolved ZEKE (*ze*ro *k*inetic *e*nergy) PE spectra are presented for the first time; through an analysis of these spectra, the symmetry group and structure of the cation could be determined.

In the neutral ground state S_0 of the benzene molecule the π electronic configuration is $(a_{2u})^2(e_{1g})^4$ and thus $^1A_{1g}$. On the transition to the cation an electron is removed from a degenerate bonding e_{1g} orbital. The resulting ionic ground state D_0 is degenerate ($^2E_{1g}$). The Jahn–Teller coupling that accompanies the electronic degeneracy causes a distortion along a non-totally symmetric normal coordinate that lifts the degeneracy.[7, 8] Model calculations therefore predict a D_{2h} symmetry for the cation for which there are three equivalent structures.[5] This distortion to D_{2h} can be detected experimentally in a matrix at low temperatures. The ESR spectra of $C_6H_6^+$ in a freon matrix indicate an increased spin density at C1 and C4 at 4.2 K but an equivalent spin density at 100 K.[9] Thus the question arises whether the D_{2h} structure is *static* and destabilized at higher temperatures by collisions with the matrix or whether a *dynamic* D_{2h} structure is stabilized by the matrix lattice. For weak Jahn–Teller coupling the stabilization energy for the distorted symmetry is smaller than the zero point energy of the Jahn–Teller active mode. Isolated—that is, under collision-free conditions—the three equivalent D_{2h} structures of the cation would dynamically interconvert rapidly, and the ground state of the cation would still be described in the D_{6h} symmetry group.[10] For strong Jahn–Teller coupling the cation would spend much time in one of the three structures, and would therefore be described in D_{2h}.

Rotationally resolved photoelectron spectroscopy as described in this paper allows an unambiguous structure determination. The symmetry of the cation can be deduced from the rotational transitions that occur, together with group theoretical considerations. The knowledge of the structure and the symmetry of the isolated benzene cation is desirable not only for testing quantum mechanical model calculations; it also has a not inconsiderable fundamental importance for organic chemistry.

As the usual methods of ion spectroscopy, such as laser-induced fluorescence, are not applicable to the benzene cation because of the extremely low fluorescence yields, the rotationally resolved PES offers an attractive alternative method. In the past few years the ZEKE-PE technique has established itself as a high-resolution spectroscopic method ($0.2-0.4\ cm^{-1} \approx 25-50\ \mu eV$) for molecular ions,[11–14] and recently has also been applied in studies of microsolvation of larger molecular clusters.[15, 16] ZEKE-PE spectroscopy of molecules and the ZEKE photodetachment of anions[17] are now recognized spectroscopic methods in chemistry.[18–20] For larger molecules combination with a supersonic molecular beam is particularly suitable. The intense cooling of the internal degrees of freedom in this case leads to significantly increased selectivity of excitation and to less complicated spectra.

The benzene molecule is an oblate symmetric rotor, whose rotational energy is described in the first approximation by the two constants B and C and the quantum numbers J and K. The quantum number J describes the total angular momentum of the molecule, K its projection along a quantization direction fixed with respect to the molecule, namely the principal axis. In a vibronically or electronically degenerate state, the influence of the vibronic or electronic angular momentum on the rotational energy must also be taken into account. This Coriolis coupling is described by the constant ζ_{eff}.[8]

The benzene molecules are ionized in a two-photon, two-color process via the first electronically excited state $S_1 6^1$ as intermediate resonance (the symbol 6^1 here represents a vibrational state in which the normal vibrational mode ν_6 is excited with one quantum). The first laser selects a rovibronic state in $S_1 6^1$ and from this state the second laser ionizes the molecule. Depending on the symmetry of the intermediate state, different rovibronic states of the ion are populated. The conservation of the symmetry of the nuclear spin wavefunction on transition, and the symmetry selection rules and rules for coupling of angular momenta severely restrict the number of possible transitions. From the assignment of the transitions and the rotational progressions that occur, the symmetry and structure of the cation can be deduced.

Figure 1 shows the spectra for the transitions from the intermediate states $S_1 6^1$ ($J' = 1$, $K' = 1, +l$) and $S_1 6^1$ ($J' = 2$, $K' = 2, +l$); the rotational states in $S_1 6^1$ are assigned according to ref. [24b]. The most notable feature is the appearance of progressions in the total angular momentum quantum number N^+ (without electron spin) of the ionic core. For transitions between bound states the selection rules $\Delta J = 0, \pm 1$ and $\Delta K = 0, \pm 1$ are valid. Here, however, on transition from a bound to an unbound state the leaving electron can compensate for the angular momentum by vector coupling depending on the partial wavefunction type (s, p, d,...), thus enabling higher rotational angular momentum changes.[21, 22]

A model to explain the observed transitions was formed on considering the following: Starting from the rovibronic symmetry of the intermediate state the symmetry of the final state that can be reached in a one-photon transition is determined. The symmetry of this state is dictated by the rovibronic symmetry of the ion core and the symmetry of the leaving electron. Since the symmetry of the nuclear spin wavefunction is not changed by the transition, the rovibronic symmetry of the ion core, and therefore also the symmetry of the leaving electron is fixed. From the correlation of the symmetry group of the cation with the group $D_{\infty h}$ the partial wavefunction type of the electron is obtained and thereby the possible rotational states of the ion core.[22] Those transi-

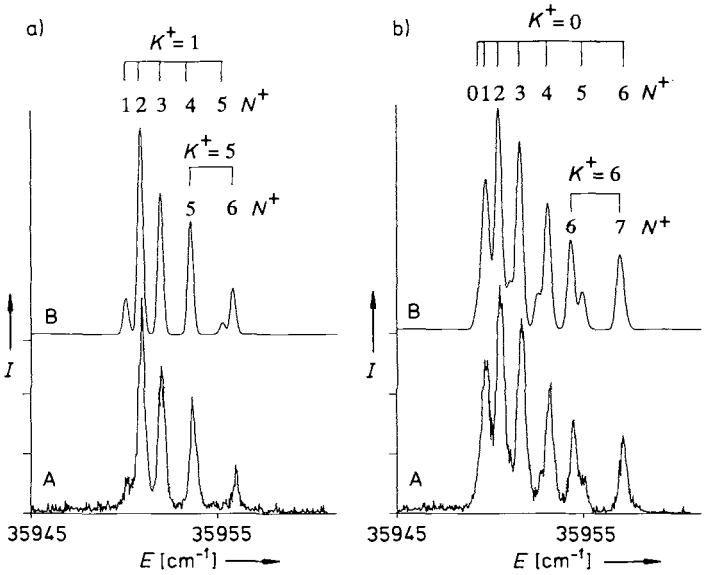

Fig. 1. Recorded (A) and simulated ZEKE spectra (B) of the transitions $D_0\,^2E_{1g} \leftarrow S_1\,6^1\,^1E_{1u}$ ($J'=1$, $K'=1$, + l) (a) and $D_0\,^2E_{1g} \leftarrow S_1\,6^1\,^1E_{1u}$ ($J'=2$, $K'=2$, + l) (b). Gaussian bands with a width of 0.3 cm^{-1} (FWHM) were assumed for the simulation. The intensities I of the ZEKE signals were taken from the spectra. E = energy of the ionizing laser.

tions for which the partial wavefunctions of the ZEKE electron correlate with symmetries that are allowed in a purely electronic transition are expected to be the strongest. For D_{6h} symmetry of the benzene cation, that is the symmetry species e_{2g} with partial wavefunctions $|l=2, \lambda=2\rangle$, $|l=4, \lambda=2\rangle$, and $|l=4, \lambda=4>$ (λ is the projection of the orbital angular momentum l of the ZEKE electron on the principal axis). Analogously one obtains for D_{3h} the species e' with the additional partial wavefunction $|l=1, \lambda=1\rangle$ and for D_{2h} the species $a_g + b_{1g}$ with the additional partial wavefunction $|l=0, \lambda=0\rangle$. In all three cases only the lowest electron angular momentum partial waves from s to g are considered. A determination of the symmetry of the cation is thus possible through the assignment of the rotational transitions in the ZEKE spectrum. On the basis of the above-mentioned model, all the lines are consistent with the assumption of D_{6h} symmetry. None of the intense lines expected from the additional partial wavefunctions for D_{3h} or D_{2h} are observed in the spectra. In the electronic ground state the benzene cation may thus be described as having D_{6h} symmetry. The conclusion is therefore that the stabilization by Jahn–Teller distortion is smaller than the energy of the zero point vibration, and the reduction in symmetry induced by the distortion has therefore no influence on the observed rotational transitions.

With ten rotational states in the P and R branches of the intermediate resonance $S_1\,6^1$ as initial state, 44 lines could be assigned in the ZEKE PE spectrum. This enabled a fit of rotational constants of the benzene cation by the method of least squares.[23] The standard deviation of 0.034 cm^{-1} represent only an eighth of the line width and are an indication of the good quality of the fit. In Table 1 these constants and also the values for the ground state S_0 and the intermediate resonance state $S_1\,6^1$ of the neutral molecule are listed.[24] A comparison of the ground state constants of the neutral and the ionized molecule reveals that the benzene ring is only marginally influenced by the removal of an electron. In particular the values of the rotational constant C, corresponding to the moment of inertia about the axis perpendicular to the ring, are almost identical.

Table 1. Spectroscopic constants for the ground state $S_0\,^1A_{1g}$ and the excited state $S_0\,6^1\,^1E_{1u}$ (Γ_{ev}) of benzene and the ground state $D_0\,^2E_{1g}$ of the cation, for a fit without the restriction $C = B/2$.

[a] This work.

A slight contraction or expansion of the ring on ionization is compatible with the error limits. The deviation from the planarity condition $C = B/2$ lies within the error limits for the rotational constants of the cation. This is consistent with the determined symmetry D_{6h}, which requires a planar structure. The rotational constants were therefore also fitted under the assumption of planarity, and the constants obtained thus were given preference. These values are given in Table 2 and contrasted with the results of an ab initio calculation.[5]

Table 2. Spectroscopic constants for the benzene cation in the ground state $D_0\,^2E_{1g}$, for a fit with the restriction $C = B/2$, and, for comparison, the values derived from the bond lengths obtained in an ab initio calculation.

[a] This work.

The pairs of values suggest a stretching of the ring bonds, which agrees with the intuitive expectation of what happens when an electron is removed from a bonding orbital. The experimentally obtained stretching of approximately 0.1% is, however, about a factor 5 smaller than that predicted by theory. The strength of the bond in the benzene molecule is apparently affected less by the removal of one of the four e_{1g} electrons than previously assumed. An exact statement on the lengths of the C–C and the C–H bonds will only be possible after additional measurements on the perdeuterated benzene C_6D_6.

Experimental Procedure

The principle of the ZEKE PE spectroscopy relies on the extraction of electrons from the ionization volume with an electrical pulse temporally delayed from the ionization process. Two slightly different variations of the method are in present use. In the first, free electrons with a vanishingly small kinetic energy are detected. In the second, which is applied here, high-lying, long-lived Rydberg states that have a lifetime in the µs range because of their high principal quantum number ($n > 150$) are ionized by a delayed field, and the extracted electrons are detected resolved in time (*P*ulsed *F*ield *I*onization, PFI). An exact description of the method may be found in refs. [13, 25]. An energy resolution of about 0.25 cm^{-1} is achieved in the PFI–ZEKE measurements reported here.

Benzene vapor (Aldrich, 99%) with a vapor pressure of approximately 70 mbar pulsed together with 4 bar argon as carrier gas (Messer-Griesheim, 4.5) was expanded through a piezovalve (nozzle diameter 500 µm) into a vacuum. The central region of the supersonic molecular beam obtained thus was skimmed with a cone-shaped skimmer before entering the ionization and extraction volume. The laser system for the ionization of the benzene molecule (1 + 1′ resonance-enhanced two-photon two-color ionization) comprises two dye lasers (Lumonics HD-500) pumped by a Nd:YAG laser (Continuum NY-82/20). The two laser beams pass through the ionization chamber antiparallel and intercept the molecular beam there. The photoelectrons are accelerated in the direction of the detectors by means of an extraction pulse delayed in time relative to the light pulse and are detected there, resolved in time (Fig. 2). The dependence of

the detected ZEKE signal on the laser wavelength gives information on the rovibronic states of the ionized molecule.

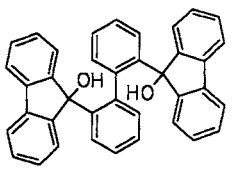
A New Atropisomeric Molecular Structure for Efficient Enantiodifferentiation**

By *Edwin Weber,** *Konstantinos Skobridis, Andreas Wierig, Stavroula Stathi, Luigi R. Nassimbeni,* and *Margaret L. Niven*

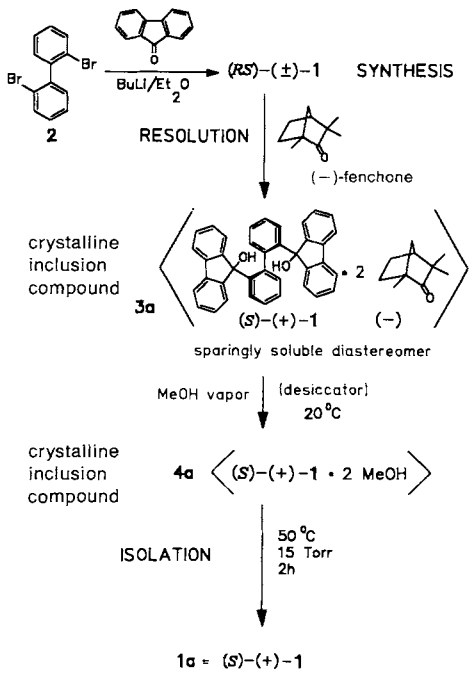
Axial chiral structural elements are extremely interesting for the construction of optically active auxiliaries (reagents, catalysts) for efficient asymmetric syntheses and the resolution of racemates.[1] Important examples of this class contain a biaryl unit, often the atropisomeric group 2,2′-substituted 1,1′-binaphthyl.[2] Recently chiral alcohols bearing bulky substituents (but not the characteristic biaryl unit) have proved themselves for the same purpose.[3]

We report here on the synthesis, optical resolution, structure, and potential applications of the atropisomeric compound **1** that combines the two structural characteristics



1

(biaryl unit and bulky alcohol group), which is therefore a promising reagent for enantiodiscrimination of organic com-



Scheme 1. (+)-Fenchone affords **1b** (= (*R*)-(−)-**1**) analogously.

pounds for a wide variety of applications. This prediction is further supported by the favorable properties of the fluorene group for the formation of crystalline inclusion compounds.[4] Remarkably, chiral auxiliaries of the diol type have not before incorporated the 9-fluorenyl group, which has excellent shielding potential through its large surface area.

Racemic **1** was obtained in 70% yield by lithiation (*n*Bu-Li/Et_2O) of 2,2'-dibromobiphenyl (**2**) and subsequent reaction with fluorenone (Scheme 1).[5] In order to resolve **1**, it was recrystallized from naturally occurring (−)-fenchone. The crystals that form are a 1:2 inclusion complex between (*S*)-(+)-**1** (=**1a**) and (−)-fenchone (the sparingly soluble diastereomer **3a**).

The absolute configuration (*S*) of the host **1a** was confirmed by X-ray structural analysis[6] of the inclusion complex **3a** by using the known configuration of the guest (−)-fenchone (Fig. 1). The host molecule has a conformation

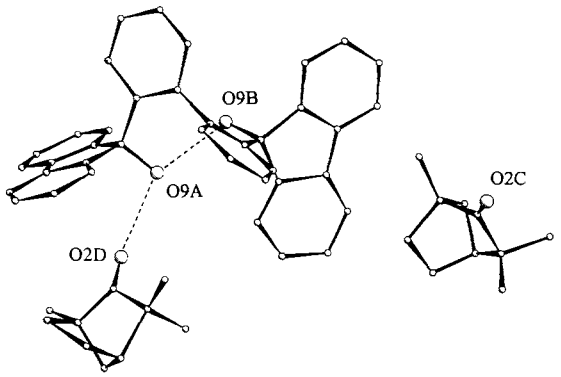

Fig. 1. Crystal structure of **3a** [**1a**·(−)-fenchone (1:2)]. For clarity the hydrogen atoms are omitted. Dashed lines specify hydrogen bonds.

characterized by an orthogonal twisting at the central biphenyl unit (torsional angle C10A-C11A-C11B-C10B = 89(2)°C). The fluorene units are also orthogonal to each other, and each fluorene unit is perpendicular to the phenyl ring to which it is bound. An intramolecular hydrogen-bond contact exists between the hydroxyl groups (O9A···O9B = 2.783 Å). In addition, one of the hydroxyl groups (O9A) forms a hydrogen bond to one of the two fenchone molecules (O9A···O2D = 2.756 Å). The other fenchone molecule in the 1:2 complex has no specific contacts and is situated between the host molecules in a lattice interstice (Fig. 2). Apparently this provides favorable conditions for a good fit between the particular enantiomers **1a** and (−)-fenchone in the crystalline inclusion complex **3a**.

The release of the optically pure host compound **1a** from the complex **3a** is not trivial. High temperatures must be avoided because of the potential racemization of **1a**. However, at low temperatures (−)-fenchone cannot be removed. We therefore used the following indirect route: Initially the firmly bound complex was exposed to an atmosphere saturated with MeOH vapor to exchange (−)-fenchone for MeOH. The new 1:2 inclusion complex with MeOH (**4a**) was dried in vacuum (50°C, 15 Torr) to conveniently afford the pure optically active host compound **1a**. The optical purity of **1a** was confirmed by HPLC on an Okamoto column. Compound **1a** has an optical rotation $[\alpha]_D^{20}$ of 334.2 (c = 0.5 in $CHCl_3$) and displays a positive Cotton effect at 269 nm. The racemization barrier for atropisomeric rearrangement **1a** → **1b** [= (*R*)-(−)-**1**] was determined to be 24 kcal mol^{-1}.[7]

The antipode **1b** was obtained by a similar process on use of (+)-fenchone instead of (−)-fenchone. The release of **1b** from the very soluble (and therefore isolable only with difficulty) diastereomeric inclusion complex **3b** [=**1b**·(−)-fenchone (1:2)] that is present in the mother liquor after crystallization of **3a**, is not as worthwhile.

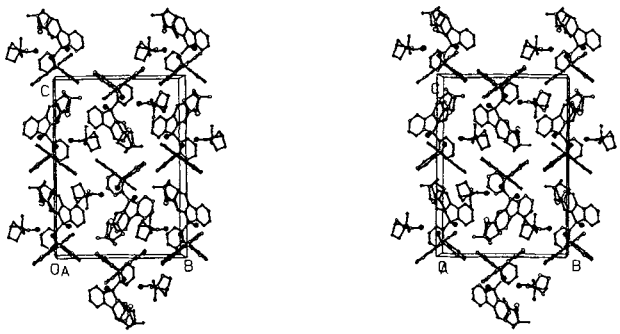

Fig. 2. Packing of **3a** [**1a**·(−)-fenchone (1:2)] in the crystal (stereoview). The hydrogen-bonded oxygen atoms are indicated as filled circles.

Compounds **1a** and **1b** (like racemic **1**) form inclusion complexes efficiently on crystallization with many organic amines and ketones, as well as with other classes of compounds, and form well-defined clathrates with 1:2 stoichiometry.[8] On separate use of **1a** or **1b**, the clathrate formation is enantioselective; for example, 3-methylpiperidine is included with *ee* > 99%, 2-methylpiperidine with *ee* = 40%, and 2-methylcyclohexanone with *ee* = 52%. On heating the isolated crystals of the inclusion complex, the freed guest compound distills off in optically active form, even on preparative scale. A reasonable assumption, therefore, is that **1a** and **1b** can also be used for resolution of racemates of other substances (such as chiral building blocks) by cocrystallization.

If the solid host substance is exposed to an atmosphere saturated with a racemic guest compound, enantioselective sorption takes place. Thus the chances that **1a** (and **1b**) may be developed as chemical sensors for enantioselection are good.[9] Applications as chiral catalysts—for example, in the addition of Grignard reagents to ketones[10a] or of alkylzinc compounds to aldehydes[10b]—or as chiral auxiliaries (aluminum hydride or borohydride reagents)[1, 2a] and NMR shift reagents[11] also seem possible.[12]

Since **1** can be modified in a variety of ways, for example by introducing substituents or varying the bridge, a broad use of this new atropisomeric molecular framework in enantiodifferentiation is expected.

Experimental Procedure

Racemic **1** [5]: A solution of *n*BuLi (53.1 mL, 85 mmol, 1.6N in *n*-hexane) was added slowly under argon at 0°C to 2,2'-dibromobiphenyl [13] (10.5 g, 38 mmol) in dry diethyl ether (70 mL). After the reaction mixture had been stirred for another 2 h at the same temperature, a solution of fluorenone (13.8 g, 77 mmol) in dry diethyl ether was added dropwise within 0.5 h. The mixture was stirred for a further 2 h at room temperature, heated at reflux for 15 h, and subsequently hydrolyzed (NH_4Cl solution). The major portion of the product precipitated and was isolated by filtration. The ethereal phase was separated

off, dried ($MgSO_4$), and evaporated to dryness in vacuum. Methanol was added to the oily residue, which caused more product to precipitate. Yield: 13.8 g (70%). M.p. 292–294 °C (phase change at 248–250 °C) [5]. IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3650 (OH), 3110 (Ar), 1205, 1120, 1060 (C-O, OH), 780, 750, 740 (Ar). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 4.12, 4.13 (2s, 2H; OH), 6.60 (dd, ^3J(H,H) = 8 Hz, ^4J(H,H) = 1.2 Hz, 2H; ArH), 7.05 (dt, ^3J(H,H) = 7.8 Hz, ^4J(H,H) = 2 Hz, 2H; ArH), 7.15–7.55 (m, 16H; ArH), 7.65–7.75 (m, 4H; ArH); ^{13}C NMR (250 MHz, $CDCl_3$): δ = 152.45, 150.68, 142.15, 140.57, 140.15, 139.37, 132.44, 129.37, 129.08, 128.98, 128.59, 128.37, 127.07, 126.20, 125.16, 124.87, 120.44, 119.89, 87.29. MS: m/z 514.1930 (M^+). Correct C,H analysis.

Resolution of **1**: Racemic **1** (10 g, 19.5 mmol) were dissolved in (−)-fenchone (120 mL) with heating. In an open flask colorless crystals of **3a**, the 1:2 inclusion complex between **1a** and (−)-fenchone, formed at room temperature within 1–2 days. These were isolated, washed with petroleum ether (40–60°), and dried. Yield: 70–90%, m.p. >150 °C (decomp.). Thereafter the crystals were exposed to an atmosphere saturated with MeOH in a desiccator at room temperature overnight. The included (−)-fenchone was completely exchanged for MeOH. The methanol was removed from this 1:2 inclusion complex (**4a**) by heating in vacuum (2 h, 50 °C, 15 Torr). Yield: 70–90%, colorless powder, m.p. 150–160 °C (racemization occurs); $[\alpha]_D^{20}$ = 334.2 (c = 0.5 in $CHCl_3$). Spectroscopic data conform to racemic **1**. The use of (+)-fenchone in the same procedure yielded **1b**.

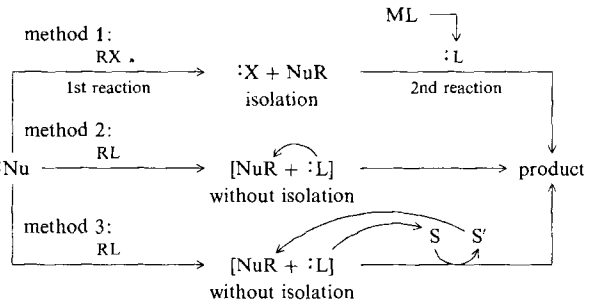
One-Flask Synthesis of Propargylic Alcohols from Organolithium Reagents, *N,N*-Disubstituted Amides, and Acetylenes**

By *Jih Ru Hwu,* Gholam Hosein Hakimelahi, Fung Fuh Wong,* and *Chun Chieh Lin*

Dedicated to Professor Alex Nickon on the occasion of his 65th birthday

Two-step synthetic sequences following standard methods often require two individual reactions. Method 1 in Scheme 1 shows an example in which a nucleophile :Nu is treated with the reagent RX to give :X and NuR in the first reaction. After being isolated, the intermediate NuR is allowed to react with nucleophile :L (from other source) to give the desired product in the second reaction. These two reactions could be combined into one by use of the "counterattack strategy"[1] (method 2), in which the reagent RL is first attacked by :Nu to give NuR and :L. The leaving group :L then counterattacks the intermediate NuR in situ to afford the desired product. Use of this method can simplify chemical transformations and minimize manipulations. With these advantages in mind we developed method 3, another type of efficient method that also combines two reactions.



Scheme 1. Comparison of synthetic methods 1–3; 1 = traditional method, 2 = counterattack method, 3 = pseudo-counterattack method.

The first step in method 3, analogous to that in method 2, is the reaction between :Nu and RL to give NuR and the leaving group :L. This leaving group then reacts with compound S to generate an active species S', which subsequently attacks the intermediate NuR in situ. Because :L does not counterattack NuR directly as in method 2, we may refer to the compound RL as a "pseudo-counterattack reagent". Herein we report a novel way to synthesize propargylic alcohols by this "pseudo-counterattack strategy".

In our new, one-flask synthesis (Scheme 2) an organolithium reagent, an amide (also the solvent), and phenylacetylene were used to prepare the desired propargylic alcohols in 74–93% yields (Table 1). Propargylic alcohols can be used in the synthesis of the ω chain in prostaglandins[2] and for the preparation of pheromone components.[3] To obtain a high yield by this new method, we found it crucial to add the

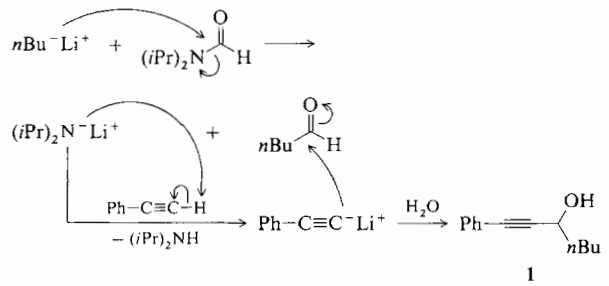
[a] Grignard reagent EtMgBr was used instead of an organolithium reagent.

The mechanism of this reaction is shown in Scheme 3 for *n*BuLi, *N,N*-diisopropylformamide, and phenylacetylene. In the first step *N,N*-diisopropylformamide is attacked by *n*BuLi to give the stable intermediate valeraldehyde. The $(iPr)_2N^-$ anion formed from the amide reacts with phenylacetylene to generate the nucleophile lithium phenylacetylide. This acetylide attacks the intermediate valeraldehyde in situ to afford the desired propargylic alcohol **1**. Thus, in the entire transformation, *N,N*-diisopropylformamide can be considered a pseudo-counterattack reagent (Scheme 1).



1

Scheme 3. Reaction mechanism of the new pseudo-counterattack method. *N,N*-diisopropylformamide functions as a pseudo-counterattack reagent synthetic method.

Smith et al.[4] reported a method for the preparation of α-hydroxy- and α-oxoamides by treating aldehydes, ketones, or esters with diisopropylcarbamoyl lithium, which is generated from *N,N*-diisopropylformamide and an alkyllithium reagent. The alkyllithium reagent functions as a base removing the formyl proton from *N,N*-diisopropylformamide. A mixed-solvent system of Et_2O, THF, and pentane is employed. In our method, the alkyllithium reagent acts as a nucleophile and replaces a dialkylamino group in the amide substrate. We believe that the different roles played by the organolithium reagents in these two methods arise, in part, from solvent effects. In our method the amide serves both as a substrate for the organolithium reagent and as the solvent. These polar aprotic solvents may enhance the nucleophilicity of an organolithium reagent by complexation.[5] Thus nucleophilic addition prevails over deprotonation. To reconfirm this point, we carried out a control experiment by treating *n*BuLi with *N,N*-dimethylformamide at 25 °C. The expected product, valeraldehyde, was isolated in 98% yield after 10 min. The yield gradually dropped to 0% within 1.5 h because of the instability of valeraldehyde in the presence of the base $LiNMe_2$ generated in situ.

The results in Table 1 (entries 1–7) indicate that many *N,N*-disubstituted amides can be employed in the newly developed method, including *N,N*-dimethyl-, *N,N*-diethyl- and *N,N*-diisopropylformamide, 1-formylpyrrolidine, 1-formylpiperidine, *N,N*-dimethylacetamide, and *N,N*-diethyldodecanamide. Although a number of organolithium reagents gave propargylic alcohols in good to excellent yields, Grignard reagents often gave inconsistent results. The best yield we ever obtained was 71% for propargylic alcohol **7**, which came from the reaction of EtMgBr with *N,N*-diisopropylformamide and phenylacetylene (entry 12).

Phenylacetylene was the most suitable alkyne, providing the desired propargylic alcohols (**1**–**7**) in 71–93% yields. 1-Hexyne and 1-octyne reacted with *N,N*-diisopropylformamide and *n*BuLi to afford the corresponding propargylic alcohols undec-6-yn-5-ol and tridec-6-yn-5-ol, respectively, in yields of only 30–33%. The difference in yield may be related to the acidity of the terminal acetylenic proton: phenylacetylene is more acidic than alkylacetylenes by about two pK units.[6] Inefficient proton transfer from an alkylacetylene to $(iPr)_2N^-$ generated in situ allows the latter species to enolize the aldehyde intermediates.

Experimental Procedure

Representative procedure: To a stirred solution containing *N,N*-diisopropylformamide (1.5 mL) and phenylacetylene (141 mg, 1.37 mmol, 1.0 equiv) was added *n*BuLi (1.4 M, 0.856 mL, 1.37 mmol, 1.0 equiv). After being stirred at room temperature under an atmosphere of nitrogen for 3 h, the reaction mixture was diluted with water, neutralized with 10% HCl, and extracted with Et_2O three times. The combined ethereal extracts were washed with water and brine, then dried over $MgSO_4$, filtered, and concentrated under reduced pressure. The residue was chromatographed on a column packed with silica gel to give 1-phenylhept-1-yn-3-ol (**1**) as a pale yellow oil in 87% yield (224 mg, 1.19 mmol).

Spectroscopic data for **1** [7]: ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.96 (t, ^3J(H,H) = 7.2 Hz, 3H, CH_3), 1.38–1.56 (m, 4H), 1.80–1.88 (m, 2H), 2.18 (br, 1H; OH), 4.63 (t, ^3J(H,H) = 6.6 Hz, 1H; C≡CCH), 7.31–7.35 (m, 3H; PhH), 7.45–7.48 (m, 2H; PhH); ^{13}C NMR ($CDCl_3$, 75 MHz, 25 °C): δ = 13.75, 22.16, 27.16, 37.45, 62.92, 84.80, 90.27, 122.84, 128.43, 128.51, 131.85; IR (neat): $\tilde{\nu}$[cm^{-1}] = 3358 (OH), 2223 (C≡C), 1601 (C=C), 1028 (C–O). **2** [8]: ^{1}H NMR: δ = 0.97 (t, ^3J(H,H) = 7.3 Hz, 3H; CH_3), 1.38–1.45 (m, 2H), 1.54–1.63 (m, 2H), 1.59 (s, $OCCH_3$), 1.75–1.81 (m, 2H), 2.15 (s, 1H; OH), 7.32–7.34 (m, 3H; PhH), 7.43–7.47 (m, 2H; PhH); ^{13}C NMR: δ = 13.79, 22.60, 26.73, 43.38, 68.58, 83.25, 93.00, 122.96, 128.38, 131.81; IR (neat): $\tilde{\nu}$[cm^{-1}] = 3381 (OH), 2208 (C≡C), 1584 (C=C), 1142 (C–O). **3**: ^{1}H NMR: δ = 0.91 (t, ^3J(H,H) = 6.6 Hz, 3H; CH_3), 0.97 (t, ^3J(H,H) = 7.2 Hz, 3H; CH_3), 1.24–1.76 (m, 26H), 2.11 (br, s, 1H; OH), 7.32–7.34 (m, 3H; PhH), 7.43–7.46 (m, 2H; PhH); ^{13}C NMR: δ = 13.82, 22.45, 22.69, 24.11, 26.32, 29.15, 29.38, 29.42, 29.63, 31.39, 31.72, 41.71, 41.99, 42.09, 42.11, 71.57, 84.21, 92.42, 123.13, 128.26, 128.35, 131.82; IR (neat): $\tilde{\nu}$[cm^{-1}] = 3408 (OH), 2203 (C≡C), 1599 (C=C), 1248 (C–O). **4** [9]: ^{1}H NMR: δ = 1.66 (s, 6H; $2CH_3$), 2.37 (br, s, 1H; OH), 7.32–7.34 (m, 3H; PhH), 7.44–7.47 (m, 2H; PhH); ^{13}C NMR: δ = 31.23, 65.45, 82.03, 93.78, 122.82, 128.18, 128.33, 131.74; IR (neat): $\tilde{\nu}$[cm^{-1}] = 3367 (OH), 2208 (C≡C), 1598 (C=C), 1158 (C–O). **5** [10]: ^{1}H NMR: δ = 2.54 (d, ^3J(H,H) = 4.9 Hz, 1H; OH), 5.70 (d, ^3J(H,H) = 4.9 Hz, 1H; C≡CCH), 7.26–7.51 (m, 8H; PhH), 7.63 (d, ^3J(H,H) = 7.4 Hz, 2H; PhH); ^{13}C NMR: δ = 64.06, 89.76, 122.58, 126.88, 128.46, 128.57, 128.74, 128.84, 129.03, 131.95, 140.84; IR (neat): $\tilde{\nu}$[cm^{-1}] = 3367 (OH), 2223 (C≡C), 1589 (C=C), 1029 (C–O). **6**: ^{1}H NMR: δ = 0.89 (t, ^3J(H,H) = 7.1 Hz, 3H; CH_3), 0.98–2.14 (m, 20H), 2.48 (s, 1H; OH), 7.22–7.48 (m, 6H; PhH), 7.48–7.52 (m, 2H; PhH), 7.72 (d,

Vanadium Phosphate Framework Solid Constructed of Octahedra, Square Pyramids, and Tetrahedra with a Cavity Diameter of 18.4 Å**

By *Victoria Soghomonian, Qin Chen, Robert C. Haushalter,* and Jon Zubieta**

The intense contemporary interest in the chemistry of vanadium oxide phosphate (V-P-O) compounds reflects the catalytic relevance of the V-P-O system[1, 2] and the astonishing structural variability of the networks of connected vanadium and phosphorus polyhedra that are found in these compounds.[3–10] This structural diversity is associated in part with the ability of vanadium–oxygen compounds to form tetrahedral, square-pyramidal, and octahedral coordination polyhedra and to build larger aggregates by condensation of polyhedra through shared oxygen atoms.[11] Our objective has been the preparation of V-P-O framework solids that encapsulate organic guests to produce large cavities or tunnels. After the organic template is removed by ion exchange or thermal methods, the solid may sorb substrate molecules in a size- and shape-selective fashion.[12] We have exploited hydrophobic/hydrophilic interactions to fashion materials with segregated polar and nonpolar cavities[13] and introduced lower valent vanadium sites into the V-P-O networks to reduce the polarity of the framework and to disrupt the tendency to form the lamellar backbones so common to $MO(PO_4)$ networks.[14] Our efforts have now culminated in the isolation of the unique V-P-O phase **1**.

$(H_3NCH_2CH_2NH_3)_2(H_3NCH_2CH_2NH_2)[V^{III}(H_2O)_2\text{-}(V^{IV}O)_8(OH)_4(HPO_4)_4(PO_4)_4(H_2O)_2]\cdot 2H_2O$ **1**

The hydrothermal reaction of V_2O_5, vanadium metal, ethylenediamine, methylphosphonic acid, and phosphoric acid gave blue crystals of **1** in 80% yield.[15] X-ray structural analysis of **1**[16] revealed a complex three-dimensional structure with a large cavity occupied by the organic cations (Fig. 1). Compound **1** is constructed from corner-sharing

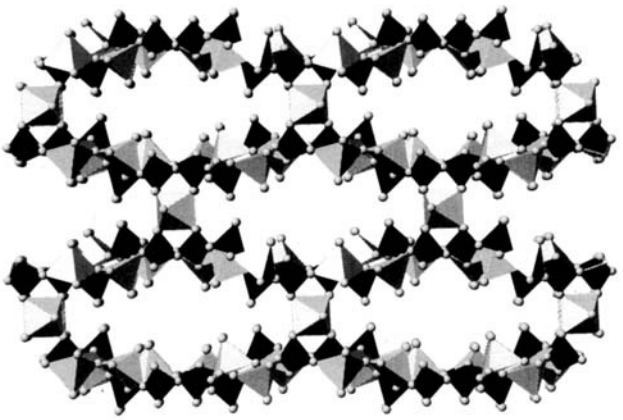

Fig. 1. A view of the structure of **1** down the crystallographic *b* axis showing the elliptically shaped tunnels which have an atom-to-atom diameter of 18.4 Å.

V^{IV} square pyramids, V^{III} octahedra,[17] and PO_4^{3-} and HPO_4^{2-} tetrahedra and displays a number of structural motifs common to V-P-O phases. There are two types of binuclear V^{IV} units in the V^{IV}-P-O lamellar framework: $[V_2(\mu_2\text{-}PO_4)_2]$ and $[V_2(\mu\text{-}OH)(\mu_2\text{-}PO_4)]$ groups.[18] As these motifs alternate within the V^{IV}-P-O planes, {V-O-V} units are found rather than the $\{V\text{-}O\text{-}V\}_\infty$ chains more generally observed in V-P-O phases.

The overall structure may be described as undulating layers constructed of corner-sharing (through a μ^2-OH group) V^{IV} square pyramids and HPO_4^{2-} and PO_4^{3-} tetrahedra connected by V^{III} octahedra. The fundamental building blocks of the layers are domed rings made up of eight polyhedra: four VO_5 square pyramids, and two HPO_4^{2-} and two PO_4^{3-} tetrahedra (Fig. 2 top). These rings are amphiphilic; the four less polar vanadyl groups are on one side of the plane defined by the V and P atoms and four P–O groups are on the opposite side (Fig. 2 bottom). Two of these four P–O groups are strongly polar P–OH groups, the other two are bound to interlamellar diaqua V^{III} center. Each ring exhibits the V=O and P–OH groups in an *anti* orientation and is surrounded by six other rings. In two of the neighboring rings the V=O groups are oriented up and the P–OH groups down along the *b* axis (V=O up/P–OH down); the other four rings have the arrangement V=O down/P–OH up. Within each layer, strips

formed from rings with V=O up/P–OH down alternate with parallel strips with V=O down/P–OH up. The two types of rings in the parallel strips are offset from one another by 0.5 *b*. This up–down connectivity of the domed rings gives rise to the undulations in the layers and large holes (diameter ca. 6.2–7.2 Å atom to atom) within the layers.

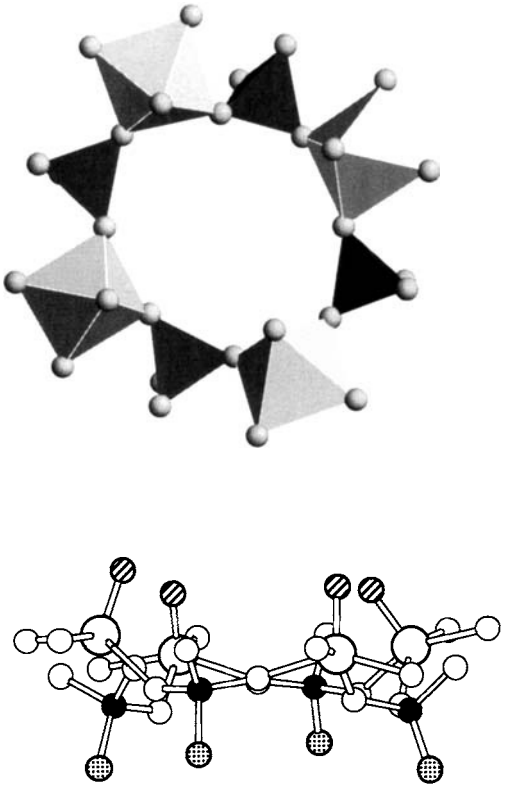

Fig. 2. The ring building block in **1** constructed from eight polyhedra. Top: View perpendicular, and bottom: View parallel to the plane of the ring. Note in the bottom picture that the less polar V=O groups lie on one face of the ring (striped circles) and the more polar P–O groups (stippled circles) on the opposite face. The largest circles are V atoms, the black circles are P atoms.

The three-dimensional structure is formed by the connection of these layers through $V^{III}(H_2O)_2$ centers. These V^{III} atoms serve to produce elliptical cross sections in the large cavities by drawing together the polar regions of the layer while the nonpolar regions of the layers are pushed away from the organic cations. The V^{III}–V^{III} distance of the long axis of the elliptical channels, 18.4 Å, is the same as length of the unit cell along *c*. The polar NH_3+ ends of the organic cations and the water of crystallization are situated within the cavities so as to maximize hydrogen-bonding interactions with the polar P–OH and $V(H_2O)_2$ portions of the framework; the less polar carbon backbones of the organic templates are associated with the V=O groups.

As was found in the case of the microporous molybdenum phosphates,[12] hydrophilic/hydrophobic interactions appear to be an important factor in determining how this type of mixed organic–inorganic compound can crystallize. In compound **1** a potentially labile aqua ligand occupies an incipient vacant coordination site within a micropore. Although we have not yet performed experiments to study the sorption properties of **1**, such microporous oxides displaying shape-selective access to a transition element side could prove useful.[12]

The successful incorporation of a relatively large organic template into a V-P-O solid phase described in this work demonstrates several emerging themes in the development of synthetic routes to such designed materials.[12] Since the structures adopted by V-P-O phases are dependent on the templates employed, hydrophobic/hydrophilic interactions can exploited in the self-assembly of the frameworks by proper choice of templating inorganic and organic cations. Incorporation of both inorganic and organic cations into the V-P-O framework induces segregation of polar and nonpolar regions with the production of large incipient void volumes. When reduced vanadium centers are introduced, specifically V^{III}, a framework with reduced polarity is created. The octahedral (oxo-deficient) geometry preferred by V^{III} leads to a more flexible connectivity, which dramatically extends the structural chemistry of the system. Finally, when the V/P ratio is increased above 1.0, the relative vanadyl (V=O) content of the structure is enhanced. Since M=O moieties are considerably less polar than P–O groups, the tendency of solids rich in M=O units to encapsulate organic templates should be enhanced.

[15] The reaction of V_2O_5, V (−325 mesh), $CH_3PO_3H_2$, H_3PO_4, $H_2N(CH_2)_2NH_2$, and H_2O in a mol ratio of 0.95:1:2.79:7.33:6.73:1056.5 for 4 d at 200 °C in a 23 mL Teflon-lined Parr acid digestion bomb (30% fill volume) gaves two products. Phosphate **1** formed as dark blue, diamond-shaped plates in over 80% yield (based on total V), while the amorphous white product was formed in less than 20% yield. We were unable to optimize these reaction conditions to reduce the amount of the side product.
[16] **1**: Monoclinic, space group $P2_1/n$ with $a = 14.313(3)$, $b = 10.151(2)$, $c = 18.374(4)$ Å, $\beta = 90.39(2)°$, $V = 2669.5(10)$ Å^3, $Z = 2$, $\rho_{calc} = 2.086$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 20.4$ cm^{-1}, $R = 0.0565$ for 2084 reflections with $2\theta < 45°$ and $I < 3\sigma(I)$ (248 parameters); Rigaku AFC5S diffractometer, graphite monochromator. The structure was solved by using the direct-methods routine of the SHELXTL program package. One of the $(H_3NCH_2CH_2NH_3)^{2+}$ ions exhibits disorder of one of the terminal NH_3

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1993 0570-0833/93/0404-0611 $ 10.00+.25/0

groups over two positions; the disorder was modelled by fixing the N-population parameters at each site as 0.75 and 0.25, respectively. The other organic cations were disordered at the inversion centers and modelled as rigid groups with C–C distances of 1.48(2) Å and C–N distances of 1.41(2) Å. The disorder of the groups is evident in the large thermal parameters associated with these cations. Such behavior is not uncommon in structures of this type since the cations reside in large cavities and possess considerable freedom of motion. All other parameters are unexceptional. Hydrogen atom positions could not be located on the final difference Fourier maps. Hydrogen atoms, excluding those of the phosphate OH groups, which have not been introduced either in calculated or observed positions, were placed in their calculated positions and constrained to ride on their associated carbon or nitrogen atoms. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-56810, the names of the authors, and the journal citation.

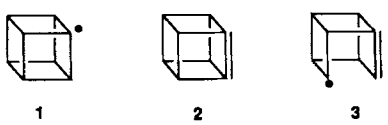
Photochemical Carboxylation of Cubanes**

By *A. Bashir-Hashemi**

Dedicated to Professor Harold Hart

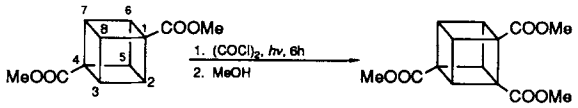
Multiple functionalization of the cubane framework has remained a formidable synthetic task requiring the sequential introduction and stepwise manipulation of substituents.[1] *ortho*-Metalation of amidocubanes[2] has until now been the method of choice for the synthesis of the polycarboxylcubanes.[3] In this communication we report a new methodology for introducing one or more carboxyl groups selectively on the cubane skeleton.

Fifty years ago, Kharasch and Brown reported the photochemical reaction of cyclohexane with oxalyl chloride to give cyclohexane carboxylic acid.[4] This little-known reaction has had limited synthetic application since rearrangements of the radical intermediates result in lower yields of the desired products.[5] By virtue of the cubane geometry, the cubyl radical **1** is an exception.[6] The cubane skeleton constrains the tertiary bridgehead radical to a pyramidal structure. Both hydrogen abstraction and β-scission in this species are unfavorable because these processes lead to intermediates of even higher energy, such as cubene **2**,[7] or **3**, a radical which is exceptionally strained because it is also a bridgehead alkene. Related reports indicate that the cubyl radical has been generated at high temperatures without rearrangement.[6] Also, the observation that cubane can be polyiodinated by means of radical reactions[8] supports the view that photochemical carboxylation of the cubane skeleton could be synthetically useful.



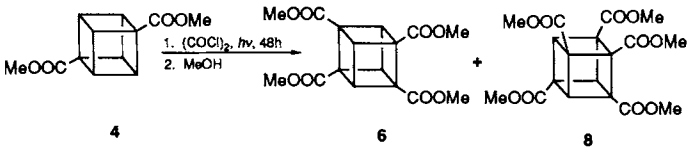
1 **2** **3**

Indeed, the reaction of commercially available 1,4-dimethoxycarbonylcubane (**4**)[9] with oxalyl chloride under irradiation from a sunlamp for 6 h produced,[10] after esterification with MeOH, 1,2,4-trimethoxycarbonylcubane (**5**) in 72% yield.[11]



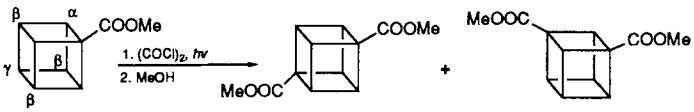
4 **5**

Extension of the reaction time to 48 h led to formation of 1,2,4,7-tetramethoxycarbonylcubane (**6**) in 55% yield and the pentacarboxylated derivative **8** in which chlorocarbonylation of the 1,2,4,6-tetrasubstituted precursor **7** occurred at the positions adjacent to only one of the methoxycarbonyl groups. The ^{1}H NMR spectrum of compound **8** shows only one resonance for the three identical cubyl protons at $\delta = 4.64$. The formation of isomer **7** was observed after 10 h of irradiation. Other isomers of tetra- or pentasubstituted cubanes in which chlorocarbonylation had occurred at positions *ortho* to two carbonyl groups were absent.



4 **6** **8**

These observations indicate a remarkable degree of regioselectivity which results from the reduced reactivity of the C–H bonds adjacent to the carbonyl groups. Therefore, it was predicted that the initial photochemical carbonylation of methoxycarbonylcubane (**9**) should occur at the β and γ positions since α positions would be deactivated by the electronic effect of the methoxycarbonyl group. Statistical considerations (three β positions as compared to one γ position) favor the formation of the 1,3 isomer **10**[12] as the dominant product.



9 **4** **10**

The photochemical chlorocarbonylation of **9** with oxalyl chloride was followed by ^{1}H NMR spectroscopy. In the spectra recorded after 6, 18, and 36 h, the formation of 1,3- and 1,4-disubstituted cubanes and their transformation to higher substituted cubanes was monitored. After 36 h the 1,3,5-trisubstituted **11** had been converted into the 1,3,5,7-tetrasubstituted cubane **12**. Minor amounts of compounds **6′** and **7′**, which originated from the 1,4-disubstituted intermediate **4′**, were also detected.

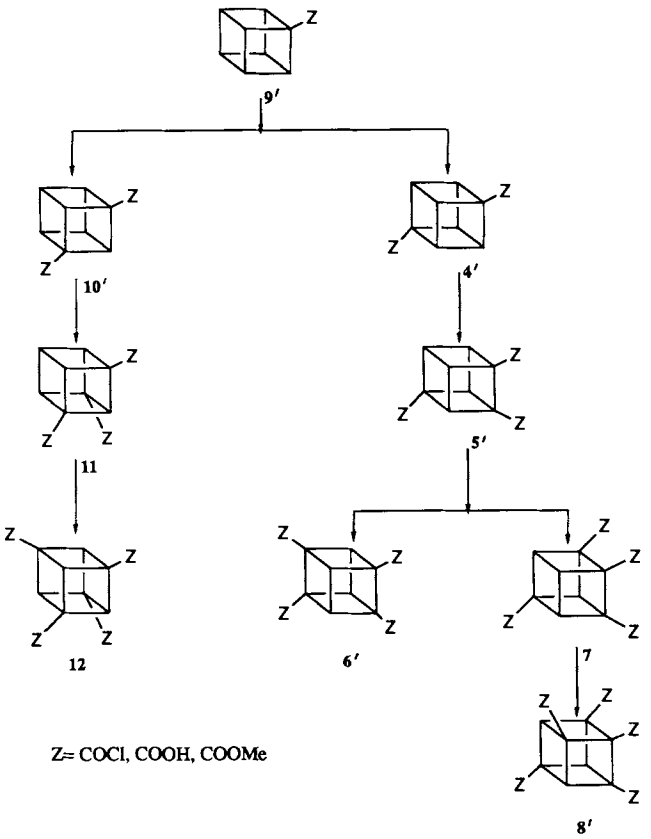
[**] Drs. G. Doyle, T. Axenrod, and J. R. Hardee are thanked for their contributions and N. Gelber and Dr. T. H. Chen for their technical assistance. Useful discussions with Prof. P. E. Eaton are greatly appreciated. This research was supported by Armament Research, Development, and Engineering Center (ARDEC).



On a preparative scale, the irradition of cubane carboxylic acid **9** (with H instead of Me) (1.0 g) with oxalyl chloride (20 mL) in a quartz flask with a Rayonet photochemical reactor (1849 Å–2537 Å) for 4 h produced, after hydrolysis, **12** (Z = COOH) in 60% yield. In contrast, the original synthesis of the T_d-symmetric tetracarboxylic acid **12** by *ortho*-metalation required multiple synthetic steps.[1]

In conclusion, a simple and efficient photochemical procedure for the direct carboxylation of cubane has been demonstrated. In contrast to *ortho*-metalation, this methodology places the new functionalities at remote sites (β and γ) and makes possible the synthesis of a wide range of cubanes.

2,2′-Bipyrimidineoxalatocopper(II) Complexes: From the Mononuclear Complex to the 2D Sheetlike Polymer**

By *Giovanni De Munno, Miguel Julve,* Francesco Nicolo', Francesc Lloret, Juan Faus, Rafael Ruiz,* and *Ekkehard Sinn*

The preparation and chemistry of oxalato transition metal complexes, we restrict ourselves here to Cu^{II} complexes, have been thoroughly investigated.[1] The coordination modes of the oxalato (ox) ligand are well characterized both in solution[2] and in the solid state.[3] Polynuclear bischelate oxalato complexes have attracted the interest of magnetochemists in the last fifteen years[3, 4] because of their remarkable ability to transmit electronic effects between paramagnetic centers separated from each other by more than 5 Å. In fact, oxalato-bridged Cu^{II} complexes provided the first examples of complexes with orbital reversal[5] and tunable exchange interactions.[6] The possibility of tuning the singlet–triplet energy gap (J) between 0 and $-386\ cm^{-1}$ in dinuclear μ-oxalatocopper(II) complexes by varying the terminal ligands is a very striking result.[6]

2,2′-Bipyrimidine (bpym) can also act as a bidentate[7] or a bisbidentate[8] ligand. Strong antiferromagnetic coupling has been achieved between Cu^{II} ions separated by more than 5.5 Å in bpym-bridged Cu^{II} complexes (J ranges from -236

to $-191\ cm^{-1}$).[8b,c] The exchange coupling in both oxalato- and bpym-bridged complexes was explained with a simple orbital model by the large σ in-plane overlap of the $d_{x^2-y^2}$ magnetic metal orbitals through the oxalato or bpym bridge.[6, 8b, 9]

We tried to prepare the mononuclear mixed-ligand complex [Cu(bpym)(ox)], intending to use it as a "complex ligand" to obtain homo- and heteropolymetallic species with exchange interactions. Our first attempts resulted in the isolation and structural characterization[10] of the novel mononuclear complex **1** as well as the polymeric compound **2**.

$[Cu(bpym)(ox)(H_2O)_2] \cdot 5H_2O$ **1**
$[Cu_2(bpym)(ox)_2] \cdot 5H_2O$ **2**

The crystal structure of **1** is composed of neutral $[Cu(bpym)(ox)(H_2O)_2]$ units and uncoordinated water molecules. The copper atom is hexacoordinate (Fig. 1); two nitrogen atom of bpym and two oxygen atoms of the oxalato ligand are found in the equatorial plane, whereas the two axial positions are occupied by oxygen atoms of aqua ligands. The bonds between the copper center and the equatorial atoms (2.002(6)–1.934(6) Å) are shorter than those to the axial oxygen atoms (average 2.529(7) Å), as expected for a six-coordinate Cu^{II} complex. The equatorial atoms N(1), N(2), O(1), O(2) are almost coplanar, and the copper atom is only 0.020(1) Å out of the equatorial mean plane in the direction of the O(5) atom. The oxygen atoms of the five waters of crystallization are reasonably close together (2.742–2.913 Å) indicating the existence of medium-strength hydrogen bonds.

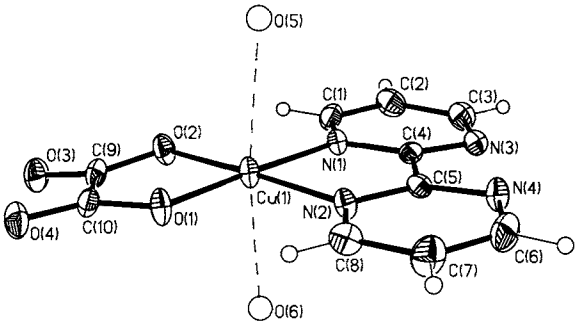

Fig. 1. Molecular structure of **1** (ellipsoids at the 30% probability level) with the atom numbering. Selected distances [Å] and angles [°] with standard deviations in parentheses: Cu(1)-O(1) 1.934(6), Cu(1)-O(2) 1.936(5), Cu(1)-N(1) 2.002(6), Cu(1)-N(2) 1.976(6), Cu(1)-O(5) 2.554(7), Cu(1)-O(6) 2.503(7); O(1)-Cu(1)-O(2) 85.5(2), O(1)-Cu(1)-N(1) 176.7(2), O(1)-Cu(1)-N(2) 95.1(2), O(1)-Cu(1)-O(5) 97.8(2), O(1)-Cu(1)-O(6) 93.4(2), O(2)-Cu(1)-N(1) 97.9(2), O(2)-Cu(1)-N(2) 177.3(3), O(2)-Cu(1)-O(5) 91.5(3), O(2)-Cu(1)-O(6) 89.8(3), N(1)-Cu(1)-N(2) 81.5(3), N(1)-Cu(1)-O(5) 83.2(2), N(1)-Cu(1)-O(6) 86.6(3), N(2)-Cu(1)-O(5) 91.0(3), N(2)-Cu(1)-O(6), 87.6 [13].

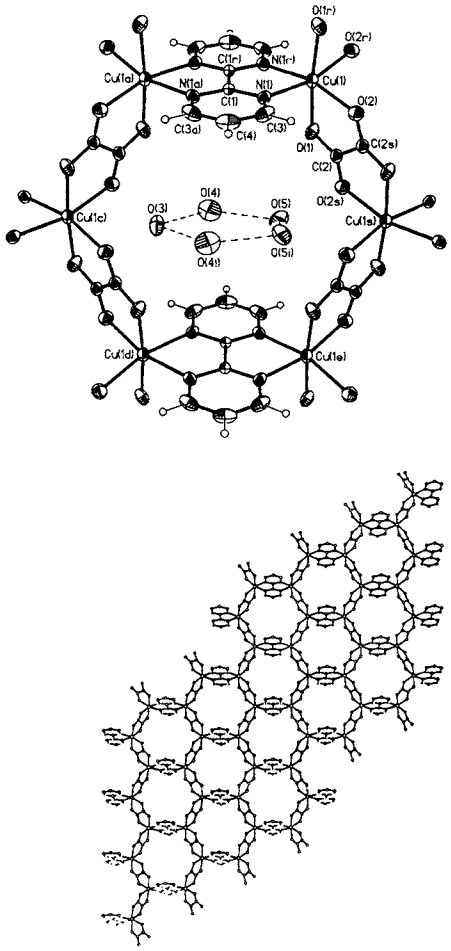

Fig. 2. Crystal structure of **2** (ellipsoids at the 30% probability level). Top: Hexameric repeating unit showing the atom numbering and the inclusion of water molecules. Bottom: View of a sheet of **2** perpendicular to the *xy* plane (hydrogen atoms and water molecules have been omitted for clarity). Selected distances [Å] and angles [°] with standard deviations in parentheses: Cu(1)-O(1) 2.076(3), Cu(1)-O(2) 2.086(3), Cu(1)-N(1) 2.129(3); O(1)-Cu(1)-O(2) 79.7(1), O(1)-Cu(1)-N(1) 97.0(1), O(2)-Cu(1)-N(1) 95.2(1), O(1)-Cu(1)-O(1r) 173.8(1), O(2)-Cu(1)-O(1r) 96.0(1), N(1)-Cu(1)-O(1r) 87.8(1), O(2)-Cu(1)-O(2r) 94.6(1), N(1)-Cu(1)-O(2r) 164.9(1) (symmetry code: (r) $1-x, y, -z$) [14].

The crystal structure of **2** is made up of parallel sheets each consisting of an infinite hexagonal array of copper atoms bridged by bisbidentate oxalato and bpym ligands; the copper atom exhibits a six-coordinate CuN_2O_4 chromophore (Fig. 2). A lengthening of the Cu–O and Cu–N equatorial distances is observed in **2** with respect to **1**: their average values increase from 1.989(6) and 1.935(6) Å in **1** to 2.129(3) and 2.086(3) Å in **2**. In contrast the Cu–O axial distances decrease remarkably (average values 2.076(3) and 2.529(6) Å in **2** and **1**, respectively). As a consequence of these geometrical variations, the coordination environment at the copper center does not show significant octahedral distortion. As shown in Figure 2, this two-dimensional polymer extending in the *xy* plane is formed by the repetition of almost circular rings. The intraring Cu···Cu distances are 5.680(1) [Cu(1)···Cu(1a)], 5.406(1) [Cu(1)···Cu(1s)], 9.559(2) [Cu(1)···Cu(1c)], 9.445(2) [Cu(1)···Cu(1e)], 11.022(2) [Cu(1)···Cu(1d)] and 10.942(2) [Cu(1c)···Cu(1s)] Å. These layers are stacked by graphite-like interactions between bpym rings of different layers; the C(4)···C(4′) distance [(′) $= 1-x, y, -1-z$] is 3.839 Å. The five disordered water molecules accomodated in each hole of the sheetlike polymer are linked together by means of hydrogen bonds to form a planar ring.[15] In each water ring at the center of the cavity the O(4) atom is linked by hydrogen bonds to the equivalent O(4′) atoms (2.59(2) Å for O(4)···O(4′)) of the rings in the cavities above and below, resulting in columns of H_2O rings inserted in the channels delimited by the cavities along the *z* direction. These hydrogen bonds, directed almost along the *z*-axis, dictate the crystal packing in that direction more strongly than the above-mentioned intralayer hydrogen bonds. Furthermore, the water cluster is attached to the wall of the channel by hydrogen bonds between each O(3) atom and two equivalent O(2) atoms of the adjacent layers (2.936(6) Å for O(3)···O(2)).

The temperature dependence of the magnetic susceptibility per Cu^{II} ion of complex **2** between 4.2 and 300 K is indica-

tive of a relatively weak antiferromagnetic interaction. At room temperature the value of χ_M (per mol of Cu^{II}) is 1.20×10^{-3} cm^3 mol^{-1}. Upon cooling χ_M increases until a sharp maximum is achieved at 16 K, then it decreases. Heat capacity measurements reveals no three-dimensional magnetic order for **2** on the low-temperature side of the curve down to 2 K (absence of λ-type peak). Thus the susceptibility maximum arises from two-dimensional magnetic interactions. It is not possible to fit the experimental data satisfactorily with one-dimensional models. This result is not surprising because the magnetic orbitals of Cu^{II} in **2** can be described in principle by both $d_{x^2-y^2}$ and d_{z^2} orbitals, indicating a possible exchange pathway through both oxalato and bpym bridging ligands. Moreover, the different efficiency of these bridges in transmitting exchange coupling would lead to an alternating magnetic plane. This last assumption is supported by the fact that the observed magnetic behavior cannot be reproduced by a model of a regular two-dimensional hexagonal array. The lack of a theoretical law for an alternating magnetic plane precludes a correct analysis of the magnetic data of such a new material.

Experimental Procedure

1: 2,2'-Bipyrimidine (0.158 g, 1 mmol) dissolved in a minimum amount of ethanol was added to an aqueous solution (80 mL) containing $Cu(NO_3)_2 \cdot 3H_2O$ (0.242 g, 1 mmol) yielding a blue-green solution. Solid sodium oxalate (0.134 g, 1 mmol) was added slowly with stirring and gentle warming. The solvents were allowed to evaporate at room temperature over several days to give blue hexagonal crystals of **1** which were filtered off and dried on filter paper. **1** provided a correct elemental analysis (C, H, N, Cu).

2: A solution of $Cu(NO_3)_2 \cdot 3H_2O$ (0.060 g, 0.25 mmol) in a minimum amount of water was added to an aqueous solution (100 mL) of **1** (0.436 g, 1 mmol). Slow evaporation of the resulting green solution gave cubic green crystals of **2** after a few days, and a mixture of crystals of **1** and **2** when the solution was allowed to evaporate nearly to dryness. **2** provided a correct elemental analysis (C, H, N, Cu).

[10] X-ray structure analyses: Siemens R3m/V automatic diffractometer, $Mo_{K\alpha}$, $\lambda = 0.71073$ Å, graphite monochromator, 298 K. Data collection, solution and refinement: ω-2θ, standard Patterson methods with subsequent Fourier recycling, SHELXTL-PLUS [11]. **1**: $C_{10}H_{20}N_4CuO_{11}$ ($M_r = 435.6$), orthorhombic, space group $P2_12_12_1$, $a = 6.544(2)$, $b = 13.838(4)$, $c = 19.319(7)$ Å, $V = 1749.4(10)$ Å^3, $Z = 4$, $\rho_{calcd.} = 1.655$ g cm^{-3}, $\mu = 13.1$ cm^{-1}, 2θ range 3–50°, crystal size $0.35 \times 0.38 \times 0.20$ mm^3, $F(000) = 900$. 1803 unique reflections, and 1475 assumed as observed with $I > 3\sigma(I)$. Refinement of 199 variables with anisotropic thermal parameters for all non-hydrogen atoms (except the oxygen atoms of water molecules) gave $R(F_o) = 0.0525$, $R_w(F_o) = 0.0613$ and $S = 1.49$ with $w^{-1} = \sigma^2(F_o) + 0.002395(F_o)^2$. **2**: $C_{12}H_{16}N_4Cu_2O_{13}$ ($M_r = 551.4$), monoclinic, space group $C2/m$, $a = 9.445(2)$, $b = 16.622(3)$, $c = 6.202(1)$ Å, $\beta = 101.4(1)$°, $V = 954.6(3)$ Å^3, $Z = 2$, $\rho_{calcd.} = 1.918$ g cm^{-3}, $\mu = 23.1$ cm^{-1}, 2θ range 3–55°, crystal size $0.34 \times 0.19 \times 0.23$ mm^3, $F(000) = 556$. 1147 unique reflections, and 981 assumed as observed with $I > 3\sigma(I)$. Ψ-scan absorption correction was applied (max. and min. transmission factors 0.355/0.472) [12]. Refinement of 86 variables with anisotropic thermal parameters for all non-hydrogen atoms gave $R(F_o) = 0.0420$, $R_w(F_o) = 0.0470$ and $S = 1.67$ with $w^{-1} = \sigma^2(F_o) + 0.001000(F_o)^2$. The space group of **2** cannot be uniquely determined from the systematic absences, which only indicate the presence of a *C*-centered cell; the choice is between the acentric *C*2 or *Cm* groups and the centric *C*2/*m* one. The latter was favored by the intensities statistics, and consequently the structure solution and refinement were carried out in the centrosymmetric space group. The analysis of the residual electronic density in a final difference-Fourier map revealed three distinct peaks (two, O(4) and O(5), in general positions and one, O(3), in special position on a twofold axis), which could be interpreted as crystallization water molecules. The elemental analysis indicated a 5:2 ratio between the crystallization water and copper. Five oxygen atoms of the water molecules may be obtained by applying the twofold axis operation to the three peaks, while 10 positions are obtained when also the mirror operation is also applied. Then, we tried to refine the structure in *C*2 and *Cm*, but all our attempts gave worse results with large correlations between atomic positional parameters. Therefore, the refinement was completed in *C*2/*m* by assuming a disordered disposition of the water molecules in which 10 half oxygen atoms are arranged as two staggered five-membered rings. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-56958, the names of the authors, and the journal citation.

[13] Bond lengths and angles in the bpym and oxalato ligands are in agreement with those reported in the literature. Although the pyrimidyl rings of bpym are planar, the ligand as a whole is not planar (the dihedral angle between the six-membered pyrimidyl rings is 4.4(3)°). The oxalato ligand is quite planar; the maximum deviation from the mean plane is 0.077(7) Å at O(2). The dihedral angle between the mean planes of the bpym and oxalato ligands is 7.1(2)°. The O–C bond lengths of oxalate occur in two sets (1.281(9) and 1.267(9) Å for O(2)–C(9) and O(1)–C(10), and 1.248(10) and 1.212(12) Å for O(3)–C(9) and O(4)–C(10)) as a result of its bidentate coordination to copper.
[14] The bpym and oxalato ligands are planar and form a dihedral angle of 99.4(1)°. The O–C bond lengths in the oxalato ligand in **2** are all identical (1.242(4) Å) on account of its quasi-symmetrical bischelating coordination to copper.
[15] The disorder is such that two sets of five half oxygen atoms are arranged as a ten-membered ring (O···O separation ca. 1.4 Å) formed by two staggered pentagons. For clarity, only one set of five atoms is shown in the top picture in Figure 2, where it should be noted that O(3) lies on the twofold axis. The five water molecules are almost planar (the largest deviation from the mean plane is 0.07(1) Å. The dihedral angle between this plane ant that of bpym is 15.7(2)°.

Reaction Tuning in Zeolites: An in situ MAS NMR Study of Acetaldehyde on HZSM-5**

By *Eric J. Munson* and *James F. Haw**

Zeolites have found widespread use in the petroleum industry as catalysts, for example, for the catalytic cracking of vacuum gas oil into gasoline[1] and the conversion of methanol to gasoline on zeolite HZSM-5.[2, 3] A relatively recent application of zeolites is as solid catalysts in synthetic organic chemistry.[4–6] One advantage of zeolites over conventional homogeneous catalysts is that the pores of the zeolite can act as tiny microreactors that dictate the maximum size of the reagent and product molecules. In addition,

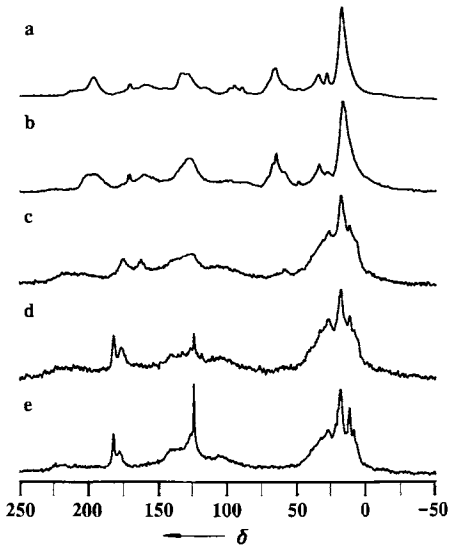

Fig. 1. ^{13}C MAS NMR spectra of [1,2-^{13}C]acetaldehyde on HZSM-5. a) 298 K; b) 20 min at 353 K; c) 20 min at 433 K; d) 20 min at 473 K; e) 10 min at 523 K. Complex aldol reactions occurred at low temperatures; CO ($\delta = 184$) and CO_2 ($\delta = 126$) formed at 523 K.

a number of zeolites with acidic, basic, or redox centers are available. We demonstrate here that the reactions of acetaldehyde in zeolite HZSM-5 can be tuned to give different products depending on whether water and/or oxygen are coabsorbed in the catalyst.

These reactions were carried out inside sealed zirconia rotors that were heated in an NMR probe to temperatures up to 523 K; the products were detected by using solid-state NMR with magic-angle spinning (MAS).[7–10] Figure 1 shows ^{13}C MAS NMR spectra of [1,2-^{13}C]acetaldehyde as it was heated to 523 K on zeolite HZSM-5. Following adsorption at 298 K (Fig. 1a) almost all of the acetaldehyde condensed to form a complex mixture of products. After heating to 433 K, these products began to crack, and CO ($\delta = 184$) and CO_2 ($\delta = 126$) were formed at 523 K.

As shown in Figure 2, absorption of water moderated the activity of the catalyst and permitted the selective conversion

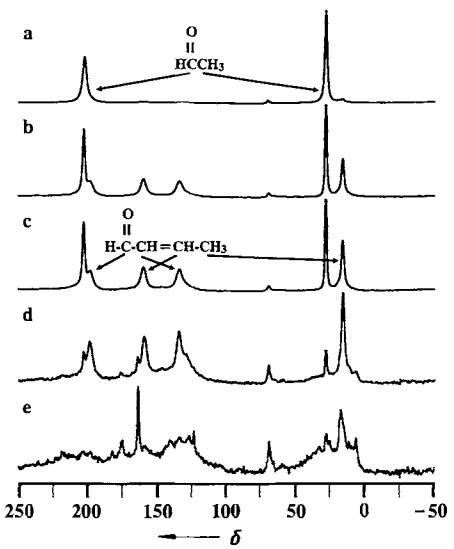

Fig. 2. ^{13}C MAS NMR spectra of [1,2-^{13}C]acetaldehyde on HZSM-5 that had been saturated with water. a) 298 K; b) 10 min at 353 K; c) 30 min at 353 K; d) 20 min at 393 K; e) 20 min at 433 K. Crotonaldehyde ($\delta = 199, 160, 135$, and 19) was produced selectively at 353–393 K.

of acetaldehyde (which was stable at 298 K) to crotonaldehyde at 353–393 K. This product was stable up to ca. 433 K. One way to view the effect of the coadsorbed water is that it reduces the acidity of the strong acid sites of HZSM-5 to that of the less acidic hydronium-ZSM-5; this affects the acid-catalyzed aldol reaction. The environment in the zeolite is still acidic, as reflected in the moderate downfield shifts of the signals of C-1 and C-3.[11] The selective formation of crotonaldehyde from acetaldehyde on basic zeolite NaZSM-5 in a flow reactor was previously reported in the patent literature by Dessau.[12]

Moderating the acidity of HZSM-5 by coadsorption of water also permitted other selective reactions. In the presence of water *and* oxygen, [1,2-^{13}C]acetaldehyde was converted to [1,2-^{13}C]acetic acid in high yields as verified by both the ^{13}C chemical shifts (Fig. 3) and the $^{1}J_{C,C}$ coupling constant of 56 Hz.[13] A separate control experiment con-

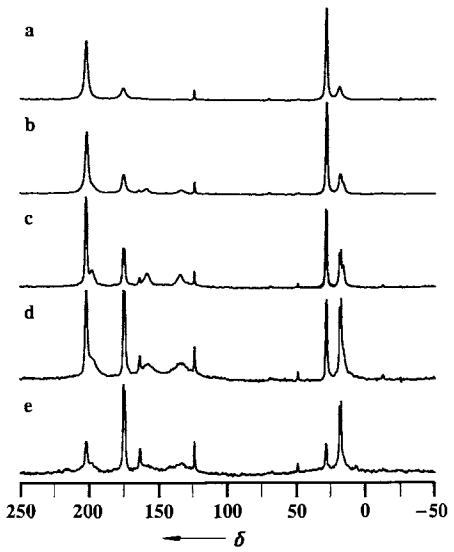

Fig. 3. ^{13}C MAS NMR spectra of [1,2-^{13}C]acetaldehyde and oxygen on HZSM-5 that had been saturated with water. a) 1 h at 298 K; b) 10 h at 298 K; c) 10 min at 393 K; d) 30 min at 393 K; e) 10 min at 433 K. The major product was acetic acid ($\delta = 176$ and 21). A small amount of crotonaldehyde also formed.

firmed that acetic acid is unreactive on the zeolite under these conditions. The oxidation of aldehydes to carboxylic acids by molecular oxygen is a well-characterized reaction in solution,[14] and provided that the acidity is tuned by coadsorption of water, it is the predominant reaction in HZSM-5 under these conditions.

This study has shown that the product selectivity of organic synthetic reactions in zeolites can be tuned by coadsorbates. This effect must be kept in mind when the solvent or other reaction conditions for organic synthesis with zeolite catalysts are selected.

Experimental Procedure

HZSM-5 was obtained from UOP Corporation and [1,2-^{13}C]acetaldehyde from Cambridge Isotopes. The protocol for the experiment depicted in Figure 1 is described in ref. [8]. For the experiments in Figures 2 and 3, the catalyst was first heated at 393 K for 1 h under vacuum and subsequently exposed to water vapor until saturation. The catalyst then packed into a glass ampule in a dry-box, attached to a vacuum line, and evacuated to 10^{-2} Torr. After adsorption of acetaldehyde with or without oxygen, the ampule was sealed to ensure sample integrity and placed into a zirconia rotor in which the reactions and NMR studies were conducted.

^{13}C NMR spectra were acquired on a modified Chemagnetics CMC-200 spectrometer operating at 50.06 MHz and with a MAS frequency of 3–4.5 kHz. Single-pulse ^{13}C excitation (Bloch decay) with proton decoupling (pulse delay = 1 4 s, 100 400 transients) was used to obtain the spectra presented in this contribution.

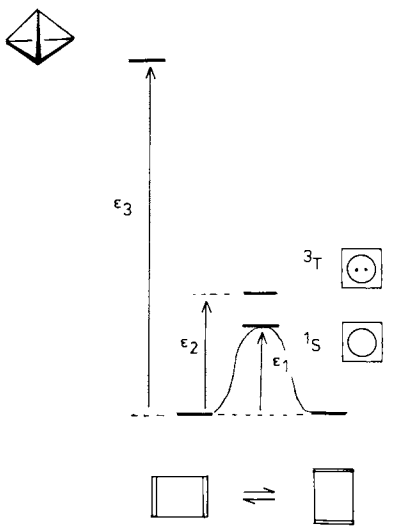

Scheme 1. Schematic energy diagram for the valence isomerization of cyclobutadiene.

Aza- versus Phospha-Substitution in Cyclobutadiene: A Theoretical Evaluation of Bonding Properties

By *Wolfgang W. Schoeller** and *Thilo Busch*

While the chemistry and bonding properties of cyclobutadiene (**1**) have been explored in detail,[1, 2] studies on analogous aza compounds are rare and on phospha compounds completely lacking. Regitz et al.[3a–c] recently reported on the synthesis and structural investigation of monoazacyclobutadiene (azete). Suitable precursors for the synthesis of phosphacyclobutadiene have been prepared in the past few years as well.[4] We determined the structures and energies of the parent compound **1** and the aza and phospha analogues by quantum chemical calculations at the MCSCF level[5] and report our results here. Our investigations may serve as a basis for understanding the effect of Group 5 element substitution on the structure and bonding in **1**.

Cyclobutadiene (**1**) adopts a rectangular geometry with localized π bonds.[6] The following aspects of its chemistry are important (Scheme 1):
a) the valence isomerization of rectangular **1** through a square (open-shell) singlet transition state (^1S), as determined by the energy barrier ε_1;
b) a low-lying triplet state with a small energy separation (ε_2) with respect to the singlet ground state, since cyclobutadiene is an antiaromatic cyclic conjugated π system. The triplet state of **1** lowest in energy (^3T) adopts a square geometry;
c) the energy difference (ε_3) between **1** and its structural isomer tetrahedrane.

We investigated these aspects of the analogous heterocyclobutadienes. These π systems are expected to adopt trapezoidal geometries. We also studied the total energy (ΔE) of fragmentation of the tetrahedranes (e.g., T_d-$C_4H_4 \rightarrow 2\,C_2H_2$).

In the two extreme cases all of the CH groups of **1** are replaced by the heteroatoms P or N to give cyclic P_4 and cyclic N_4, respectively. The former structure corresponding to white phosphorus should be particularly stable, whereas cyclic N_4 is expected to fragment readily to give two N_2 molecules. Consequently, the effect of mono- and disubstitution of **1** on the stability of the corresponding tetrahedranes is of particular interest. The ground state geometries of the structures examined are shown in Figure 1 and their energies

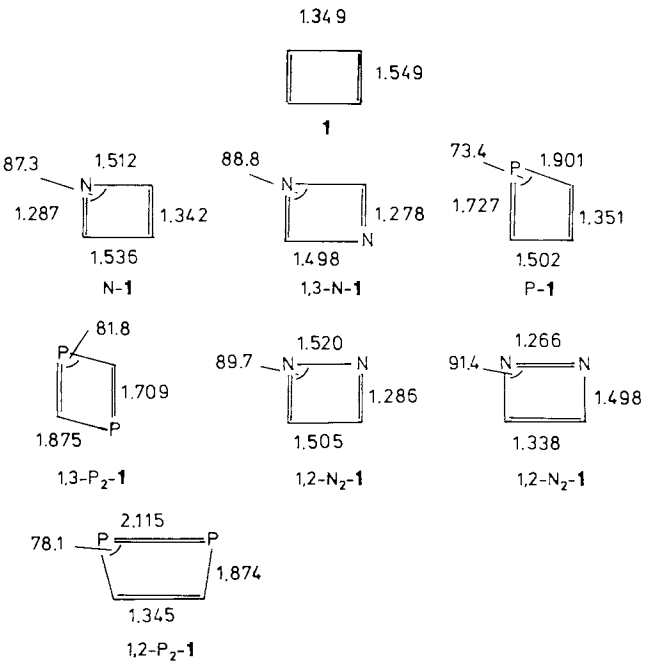

Fig. 1. Bonding parameters of cyclobutadiene and some of its aza and phospha analogues; bond lengths in Å units, bond angles in °.

are listed in Table 1. Positive values (in kcal mol^{-1}) refer to endothermic and negative values to exothermic energies.

For the parent compound **1** the calculated energy barrier for valence isomerization proceeding through the open-shell singlet state (ε_1, Table 1) is slightly higher than the value determined experimentally by Maier et al. (6.6 kcal mol^{-1}).[7] The energy difference is on the order of the expected zero-point vibrational energy, which was not explicitly accounted for in our work, and which may slightly lower the energy barrier ε_1, as was shown for cyclobutadiene.[8] In general, valence isomerization in the phospha derivatives is more facile than in the aza derivatives, since the PC double bond is weaker than the NC double bond.[9] In other words, the delocalization of the π electrons benefits from the weaker double bonds. The energy barrier decreases further with increasing phospha substitution and is almost zero for the P_4 cyclobutadiene ($\varepsilon_1 = 1.7$ kcal mol^{-1}). Thus it can be expected that the phosphacyclobutadienes react preferentially as biradicals rather than as olefinic compounds. Concomitant with the weak double bond localization is the decreased singlet–triplet energy separation (ε_2). Nevertheless for all phosphacyclobutadienes the triplet state is always above the singlet state in energy. In contrast, aza substitution in **1** causes an increase in the energy barrier (ε_1) for valence isomerization. 1,3-Diazacyclobutadiene can be considered a "push–pull"[6] cyclobutadiene; its singlet ground state is stabilized relative to that of **1**. Its valence isomerization proceeds through a nonplanar transition structure with C_{2v} symmetry (see Table 1).

Table 1. Relative energy values (in kcal mol^{-1}) of cyclobutadiene and some of its aza and phospha analogues at the MCSCF level.

Compound	Symmetry [a]	ε_1	ε_2	ε_3	ΔE [b]
1	D_{2h} (D_{4h})	8.4	14.8	36.4	−27.2
N-**1**	C_s (C_{2v})	12.1	18.9	30.1	−54.9
1,3-N_2-**1**	C_{2h} (C_{2v})	18.9 (12.8) [c]	26.9	36.1	−93.2
P-**1**	C_s (C_{2v})	7.2	7.4	13.6	−1.5
1,3-P_2-**1**	C_{2h} (D_{2h})	3.1	8.2	−11.8	−21.5
P_4-**1**	D_{2h} [d] (D_{4h}) [d]	1.7	6.8	−47.2	−26.0

[a] Symmetry in parentheses refers to transition state geometries for valence isomerization. [b] Values for fragmentation of the (substituted) tetrahedranes into (from top to bottom) 2 C_2H_2, C_2H_2 + HCN, 2 HCN, C_2H_2 + HCP, 2 HCP, and 2 P_2, respectively. [c] Value in parentheses is relative to the dipolar nonplanar transition state. [d] Planarity was assumed.

The 1,2-diazacyclobutadienes are higher in energy than their 1,3 isomers, the isomer with two C=N bonds (1,2-N_2-**1**) by 12.1 kcal mol^{-1} and the other isomer with one N=N and one C=C bond (1,2-N_2-**1'**) by 22.5 kcal mol^{-1} (at the MRCI/MCSCF level). In contrast, only one 1,2-diphosphacyclobutadiene having a P=P and a C=C double bond (1,2-P_2-**1**) is stable. Relative to its 1,3 isomer it is 10.6 kcal mole^{-1} lower in energy.

Cyclobutadiene (**1**) and its aza analogues are all lower in energy than the corresponding tetrahedranes (ε_3, Table 1), and their tendency to fragment (ΔE) increases with increasing aza substitution. In addition to the data in Table 1 it should be noted that the fragmentation of triazatetrahedrane and tetrazatetrahedrane into HCN + N_2 and 2 N_2, respectively, is exothermic ($\Delta E = -135.9$ and -191.0 kcal mol^{-1}, respectively). This indicates that their corresponding cyclobutadiene derivatives once generated would also easily undergo retro-[2 + 2] addition. For the azete only flash pyrolysis (700 °C, 5×10^{-6} mbar) leads to retrocyclization.[3b,c] Similar behavior has been observed for cyclobutadienes.[1] In contrast, the introduction of phosphorus rather than nitrogen to **1** makes the tetrahedrane isomers more stable.[10,11] 1,3-Diphosphacyclobutadiene is already less stable than its corresponding tetrahedrane isomer. Our results indicate that the heterocyclobutadienes are interesting targets for matrix isolation studies.[12]

[5] a) All the quantum chemical calculations were carried out at the ab initio double-ζ level with polarization functions at the heavy atoms. The corresponding basis sets were constructed from Huzinaga type functions (S. Huzinaga, *Approximate Atomic Functions. II*, Technical Report, The University of Alberta, Edmonton, Alberta, Canada, **1971**) as follows: C, N: (9,5) in the contraction [5, 4 × 1/3, 2 × 1]; P: (11,7) in the contraction [5, 6 × 1/4, 3 × 1]; H: (4) [3,1]. One set of polarization functions was added to the heavy atoms: ζ_d for C,N, and P = 0.8, 0.95, and 0.5, respectively. The MCSCF [5b], MRCI [5c], and CEPA-1 calculations were carried out with the MOLPRO program systems [5d]. MCSCF wave functions were used in the geometry optimization with inclusion of the full π space. Corrections for higher excitations were performed with the Davidson procedure [5e]. The frozen core approximation was applied in the MCSCF and MRCI calculations. The accuracy of optimization is $\lesssim 10^{-7}$ Hartree. After optimization each point on the potential energy surface was refined by the MRCI calculations with the MCSCF wavefunction given as reference. Further investigations indicate that the lone pairs (on P, N) have no effect on the equilibrium geometries. This was tested by inclusion of these electron pairs in the active space of the MCSCF treatment and reoptimization. For the configuration interaction all of the singly and doubly excited configurations with respect to the MCSCF wavefunction were considered; the inner shells were not correlated. For the tetrahedrane structures (calculations of ε_3) we utilized RHF-optimized geometries in an MCSCF calculation, in which the active space consisted of four orbitals, to obtain the reference wavefunction for the subsequent MRCI calculation. Perfect closed-shell systems result for the tetrahedranes, as evident from the expansion coefficients of the MSCF wavefunction. For the computations of the ΔE values the CEPA-1 electron correlation approach was utilized, based on the RHF geometries of the tetrahedranes and their fragments C_2H_2, HCN, HCP, N_2, and P_2. b) H. [9] W. W. Schoeller in ref. [4a], Table 1.

[10] For a detailed analysis of the energy differences between P_4 (T_d), P_8 (O_h), and P_2 see a) R. Ahlrichs, S. Brode, C. Ehrhardt, *J. Amer. Chem. Soc.* **1985**, *107*, 7260–7264; b) G. Trinquier, J.-P. Daudey, N. Komiha, *J. Amer. Chem. Soc.* **1985**, *107*, 7210–7212.

[11] In addition to the values of ε_3 and ΔE listed in Table 1 for **1** and its mono- and disubstituted derivatives the following quantities (in kcal mol^{-1}) were obtained (at MP4/6-311g(2d,p)//MP2/6-31g(d) level): **1** 31.7 (ε_3), −27.3 (ΔE); N-**1** 26.2, −55.5; 1,3-N_2-**1** 29.1, −90.0; P-**1** 9.3, −3.2; 1,3-P_2-**1** −17.3, −18.3. 1,2,3-N_3-**1** -135.3 (ΔE); N_4-**1** -188.5; 1,2,3-P_3-**1** -29.4; P_4-**1** −39.5. These values are in good accord with the results of the more involved MCSCF calculations (see Table 1). The calculations were conducted with the GAUSSIAN 90 set of programs (M. J. Frisch, M. Head-Gordon, G. W. Trucks, J. B. Foresman, H. B. Schlegel, K. Raghavachari, M. A. Robb, J. S. Binkley, C. Gonzalez, D. J. Defrees, F. J. Fox, R. A. Whiteside, R. Seeger, C. F. Melius, J. Baker, R. L. Martin, L. R. Kahn, J. J. P. Stewart, S. Topiol, J. A. Pople, Gaussian Inc., Pittsburgh, PA, **1990**).

[12] We have computed the IR spectra of **1** and its mono- and disubstituted derivatives, as they have the best prospects for experimental verification. The vibrational analyses were performed within the harmonic approximation at MP2/6-31G* level. Details of the computed spectra are available on request and we will comment on them only briefly here. For example, an inversion center in **1** and its 1,3-heteroderivatives simplifies the expected IR spectra. For **1** seven IR-active bands [12a] and for 1,3-P_2-**1** six IR-active bands [12b] are predicted. For P-**1** the situation is more complicated since it has no inversion center. Here all 15 vibrations are IR-active. a) For **1** these values are in excellent agreement with experiment [1] (values in cm^{-1}): 559 (b_{3u}), 750 (b_{2u}), 1081 (b_{1u}), 1293 (b_{2u}), 1619 (b_{1u}), 3281 (b_{2u}), 3300 (b_{1u}). b) For 1,3-P_2-**1** (values in cm^{-1}): 275 (a_u), 581 (b_u), 672 (a_u), 946 (b_u), 1168 (b_u), 3267 (b_u).

BOOKS

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Book Reviews

Kirk/Othmer Encyclopedia of Chemical Technology. Vol. 1: A to Alkaloids. Vol. 2: Alkanolamines to Antibiotics (Glycopeptides). 4th Edition. (Series editor: *J. J. Kroschwik.*) Edited by *M. Howe-Grant.* Wiley, Chichester. Vol. 1: 1991. XXII, 1087 pp., hardcover £ 135.00.—ISBN 0-471-52669-X; Vol. 2: 1992. XXVIII, 1018 pp., hardcover £ 135.00.—ISBN 0-471-52670-3

In September 1991 a new edition of "Kirk/Othmer" started to appear from the publishers John Wiley and Sons. The fourth edition of this standard Encyclopedia of Chemical Technology will consist of 27 volumes (25 on topics in alphabetical order, together with a supplementary volume and a keyword index), which is one more than in the third edition. Up to now Volumes 1 and 2 have appeared. The rest are to follow at three-monthly intervals, so that the entire work should be completed by the end of 1998.

Volume 1 (33 articles) extends from "Ablative Materials" to "Alkaloids", and Volume 2 (27 articles) from "Alkanolamines" to "Antibiotics". Scanning through the articles it is evident that the new Kirk/Othmer continues the excellent tradition of earlier editions. The contributions have again been written by acknowledged experts, and despite this (or perhaps because of it) they can be understood even by the interested non-specialist. The literature citations are carefully chosen and very up-to-date; some of the articles even cite sources as recent as 1991.

The choice of topics reflects recent progress in science and technology. For example, separate articles are now dedicated to key technologies such as "Advanced Ceramics" (for electronic and engineering components), to developing fields with high growth potential such as "Antiaging Agents", and to technologies that have increased in importance such as "Aeration" (in biotechnology and effluent treatment). On the other hand product areas that have stagnated or become less important (e.g., acetylene, anthraquinone derivatives) have now been relegated to subsections. Other articles have been revised and updated. A high standard of treatment has been maintained throughout. This applies not only to bulk commodity products but also to products in the middle or at the end of the value-added chain. Thus, on the one hand new developments in large-scale processes such as the production of cyclohexanol by addition of water to cyclohexene, or of adipic acid from butadiene as a cheap feedstock, and on the other hand advances in specialized areas, for example the synthesis of special amines such as *tert*-butylamine, where the Ritter reaction is being replaced by the more environmentally acceptable direct catalytic amination of isobutene, are treated with equal thoroughness.

The articles that are concerned not with products but with basic science (e.g., absorption and adsorption), with working techniques (e.g., analytical methods), or with environmental topics (e.g., atmospheric pollution) also reflect the latest knowledge. For example, in the article on "Air Pollution" we find not only data from measurements in 1990 and values for the ozone-depleting potential and greenhouse-effect potential of important atmospheric pollutants, but also an informative section on "Indoor Air Pollution", which puts this topic into perspective without playing down the risks. Whereas in "Ullmann" the topics of a more fundamental nature are treated in a separate series, in the new Kirk/Othmer these are integrated into the main volumes.

Unlike previous editions this new edition consistently uses SI units in the tables and figures (although in the text the American units are occasionally added in parentheses—not surprisingly, some conversion errors have crept in here, but on the whole these are comparatively rare).

Some of the articles contain many abbreviations, which can be rather troublesome. Headings such as "UOP MRU–ORU Processes" (Vol. 1, p. 593) convey hardly anything to the reader who wants to find information quickly. On encountering a sentence such as "The related simple design concepts of WES, WUB, and LUB for constant-pattern adsorption are discussed later" (Vol. 1, p. 540, "Adsorption Dynamics"), the reader who is new to the subject but wants to find out more will be deterred rather than encouraged to read on, especially as the meaning of WES, WUB, and LUB can only be discovered by first turning back to page 517 (for

LUB) then further on (!) to page 564 (for WES and WUB). On the other hand, in cases where abbreviations are listed at the end of an article, when one no longer needs them, it is simply a waste of space (e.g., "IARC", Vol. 1, p. 310, and "ADI", Vol. 2, p. 578.

In the articles concerned with products one finds that the information given in the section "Economic Aspects" in each case varies greatly in the amount of detail and sometimes in quality. For example, under "Ammonia", "Adipic Acid", and "Acrylonitrile" one finds a considerable amount of information about production capacities, consumption, and market growth, not only for the USA but also for Europe and Asia. In contrast, under "Anthraquinones" (Vol. 2, p. 811) the section "Economic Aspects" gives only one quantitative item, the price. Under "Alkyl Phenols" (Vol. 2, p. 128) the "Economic Aspects" amount to no more than a breakdown of the production costs, and under "Amino Resins and Plastics" (Vol. 2, p. 635) they consist essentially of a list of manufacturers occupying nearly half a page. Here the work could certainly have been improved by some systematization and unification of treatment, like that found in the corresponding sections of "Ullmann".

However, despite the few shortcomings the new Kirk/Othmer, like its predecessors, is a work of reference in the top rank worldwide, and it is essential to every scientific and technical library as a complementary work to "Ullmann".

Computational Chemistry. Structure, Interactions and Reactivity. (Series: Studies in Physical and Theoretical Chemistry.) Edited by *S. Fraga*. Elsevier, Amsterdam, 1992. Part A: XXXII, 744 pp., Part B: XIX, 661 pp., hardcover HFl 995.00.—ISBN 0-444-88512-9

This two-volume work of altogether more than 1400 pages is the result of the efforts of 111 authors. More than half of these are Spanish; moreover, the make-up of nationalities in the rest is significant, as it is dominated by countries such as Argentina, Cuba, and Mexico. Thus the work is in effect a literary demonstration by the Hispanic countries. The editor has exercised little, if any, control over the authors, and has also succumbed to the temptation of assuming that one can never have too much content and variety. It therefore comes as no surprise to find that the majority of the 52 chapters have turned out to be neither "computational" nor "chemistry". It is not possible here, nor even necessary, to describe in detail and evaluate all the chapters. Instead this review will offer some general comments on the contributions, will identify those chapters that are in the nature of a general overview of a particular topic, and will discuss the extent to which they present results relating to theories that are described.

Unfortunately a good many of the authors seem unable (or unwilling) to present review articles of general interest such as one expects to find in a book of this kind. These authors assume that their own work and very individual views will be of interest to the reader, and they give numerous references to their own publications. For example, in the report on excited states of simple molecules it is not clear why one should want to systematically calculate the excited states of molecules with two, three, and four atoms. Who is interested in this apart from the author? What is sadly missing here is a review of the current situation in theoretical photochemistry. Another example is the article on configurational interaction, which is in fact very well written, but leaves one at the end wondering what it all adds up to. What are the capabilities and limitations of the computational methods described? To discuss such methods without including the sets of basis functions is like having a vessel without a bottom. Moreover, the article fails to give any experimental results, and without these one cannot evaluate the theories. The authors of a chapter on basis sets have even managed to discuss the topic entirely in verbal terms, giving neither basis sets nor any results derived from them. One also feels regret for what is missing in the chapter on molecular integrals based on Slater functions, in which the final climax is a closely printed list of pointless integral formulas. A chapter entitled "Geometries, Energies and Molecular Properties" includes, in addition to the properties mentioned here, calculations of dipole and quadrupole moments, field gradients, and electron densities for many molecules such as H_2O, NH_3, CH_4, C_6H_6, etc., with six basis sets in each case. However, the 19 enormous tables amount to nothing more than a large occupational therapy exercise, as the discussion of the basis set dependence at the Hartree–Fock level, without taking into account electron correlations, has long since ceased to be of interest to anyone. Regrettably, this antiquated article is not an isolated example; to conclude these adverse comments the prize for this must go to Cuba for the contribution on "Approximate Methods for Polyatomic Systems", in which a whole group of authors introduces the reader to the basic equations of the elementary Hartree–Fock theory and to the NDO approximation—and this in 1992!

The transition from the barren wastes to the more worthwhile contributions is smooth. A chapter on photoelectron spectroscopy contains not only an up-to-date account of the theory but also many examples, in which different methods of calculation are compared with each other and with experimental results. The literature on this topic is extensively reviewed. In this respect one should also mention the article by Moccia which is an introduction to calculations on multiphoton processes, including a detailed account of the theory and of methods of calculation together with results. Leaving the area of spectroscopy the reader's attention may be caught, for example, by a chapter on solvent effects in reacting systems. The theories of the self-consistent reaction field are clearly described, but unfortunately their applications are only indicated sketchily. This situation could quickly change, as these methods are already included in the latest versions of readily available program packages. The reader concerned with applications will also certainly appreciate the analysis of the concepts of basicity and acidity using reliable ab-initio calculations. This excellent article is hidden away under the rather uninformative title "Organic Molecules". The chapter by Smeyers on "Non-Rigid Molecules" meets the criteria for a good and easily understandable review article. The applications described are mainly to calculations on IR spectra of systems with internal rotation. The contribution by Strausz et al. on the Wolff rearrangement of α-diazoketones is worth mentioning as a classic example of the application of modern ab-initio methods of calculation to a chemical problem. Ventura gives an excellent review of chemical reactivity, with a pithy discussion in which formulas are kept to a minimum; the aspects covered range from the energy hypersurface through modern quantum chemical methods of calculation to reaction dynamics, concluding with kinetics and thermodynamics. The concise style continues in the section on applications, without leaving out any of the essentials. The examples chosen range from gas phase reactions to enzyme reactions. This very informative review,

which does not overload the reader with irrelevant details, is one of the highlights of the two volumes, as also is the account by Barthelat and Durand of the theory of the effective Hamiltonian operator. Such operators provide the theoretical basis for calculations on heavy atoms, and consequently their importance can hardly be overstated. Such a readable and full account of this topic is unlikely to be found elsewhere.

Other topics treated in these two volumes include mathematical fundamentals, atomic scattering experiments, biochemistry, quantum electrodynamics, NMR spectroscopy, statistical mechanics, models of liquids, superconductivity, crystal physics, and metallurgy. However, these topics are so far removed from the title of the work that it is not possible to review them here. Paradoxically, in contrast to this one searches in vain for contributions on modern semiempirical methods of calculation. It is unfortunate that readers interested in computational chemistry will have to load their bookshelves with so much ballast in order to have access to the few articles that are relevant.

Photodissociation of Simple Molecules in the Gas Phase. By *H. Sato*. Bunshin, Tokyo, 1992. V, 158 pp., paperback Yen 1100.—ISBN 4-89390-092-7-C3543-P1100E

For some years now H. Sato of Mi'e University has been monitoring the literature on photodissociation processes of small molecules in the gas phase, and at annual intervals people interested in this field have received from him a booklet listing publications during the past year. All these references covering the years from 1970 to 1991 have now been collected together into a book. This is the period that has seen the laser become firmly established as a tool for photolytic studies and analysis. The book consists of two tables, together with an associated list of over 1000 references. Altogether the compilation covers about 280 simple molecules and more than 70 van der Waals molecules. Recently the survey has also included organometallic compounds that are of importance in chemical vapor deposition studies. The structure of the tables is very simple, with entries listing the initial molecular species, the photolyzing wavelength (or generating source), method used to identify the breakdown fragments, and final products, as well as the literature citation and a few brief comments. The entries are arranged according to the initial species.

This is not a textbook, nor is it a monograph along the lines of H. Okabe's book *Photochemistry of Small Molecules*. As Okabe notes in the foreword, it has more in common with the much costlier spectroscopic data collection *Constants of Diatomic Molecules*, by Huber and Herzberg. It is a book to refer to when one is setting out to photolyze a new molecule and wishes to find out what relevant work has been published recently. Thus it is intended for the active researcher, for whom it can be thoroughly recommended. In my own laboratory the booklets that were its forerunners have proved invaluable when planning experiments. I would like to have these data available on a floppy disk, which should also make it possible to search according to reaction products.

According to the publishers, the price, including postage, is \$ 17.50 in the USA and \$ 19.50 in Europe. I have just learnt from Dr. Sato that Supplement VI of his collection "Photodissociation of Simple Molecules in the Gas Phase" has been published in *Research Reports of the Faculty of Engineering, Mi'e University*, Vol. 17, December 1992.

Entropy Analysis. An Introduction to Chemical Thermodynamics. By *N. C. Craig*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1992. XI, 208 pp., hardcover DM 72.00.—ISBN 1-56081-539-6/3-527-89539-6

This book aims to provide students in their first semester with an introduction to thermodynamics along new lines. The author sets out to develop the fundamental laws of thermodynamics from a global perspective instead of the usual system-orientated viewpoint. As the title of the book indicates, the treatment focuses on entropy as the key variable, since the first law (the conservation of energy) can be regarded as being automatically fulfilled from the global standpoint. The book consists of ten chapters and an appendix. After an introduction the author deals with the fundamental principles of thermodynamics (the first law, the concept of enthalpy, the second law), then with their application to heat engines, the molecular significance of entropy, applications to chemical reactions (the definition of the Gibbs energy, chemical equilibria, electrochemical reactions), and the interconversion between different forms of energy. Each chapter ends with a detailed summary of its contents. The appendix consists of four sections. The first short one (three pages) discusses the relationship between the global and system-orientated approaches to thermodynamics. Two further sections contain examples to illustrate the interpretation of the proposed concepts from the molecular (microscopic) point of view. The last section consists of 30 pages of tables listing standard enthalpies and entropies of formation and Gibbs energies, and specific heats of the elements and of more than a thousand compounds, mostly inorganic.

The global approach chosen here undoubtedly has advantages in some parts of the subject. For example, it is found that beginners often have great difficulty with problems where, in order to apply the second law, one has to combine the "system" and the "surroundings" to form a new "supersystem". The global approach avoids the complications associated with systems that are not closed. Also the description of irreversible processes is simplified. The introduction of the molecular significance of entropy at an early stage is a welcome feature.

However, the author incurs a penalty for his approach, since for each process he has to consider a number of systems, each with its own internal energy. The first law takes the form:

$$\Delta U_{\text{total}} = \Delta U_{\sigma} + \Delta U_{\theta} + \Delta U_{\text{wt}} + \ldots = 0$$

in which the suffix σ denotes the reacting system under consideration, θ denotes a heat reservoir system, and wt a mechanical system. These systems are illustrated by diagrams. The processes that are analyzed involve an exchange of energy between the partial systems. However, in physical terms this compartmentalization often breaks down; to take the simple case of an exothermic reaction in solution, the latter is also the heat reservoir. This is an abstract idea that the beginner will not always find easy. The fundamental difference between the internal energy as a state function on the one hand, and on the other hand the concepts of work

 © *VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1993* *0570-0833/93/0404-0621 \$ 10.00+.25/0*

input and heat introduced or removed, which are not state functions, does not clearly emerge. The concepts of work and heat are replaced by the energies of the mechanical system and of the heat reservoir system, respectively. For the relationship between the two approaches one has to go to the appendix. It seems very doubtful whether the approach adopted here will really help the student to gain a deeper understanding of thermodynamics and apply it to practical situations later on.

The avoidance of using the methods of differential and integral calculus will certainly be helpful to first-semester students, who do not usually have a sufficient mathematical background at this stage. However, by the second semester at the latest, a more exact mathematical formulation becomes essential; the usual level of thermodynamics lecture courses in Germany at this stage goes beyond that of the book. In many cases, therefore, the student will then need to switch to a different approach, and there is a risk that the earlier simplifications will become a hindrance to a deeper understanding.

Within the intended scope of the book, the treatment is, on the whole, rigorous. Nevertheless, it seemed to this reviewer that in some places the author makes statements, in anticipation of later discussions, that could be misunderstood. Although these are later corrected when the topics are treated in detail, there is a risk that by then the reader has the misconceptions so firmly in his or her head that it is difficult to correct them. For example, the statement in Chapter 4 (p. 42) that entropy is a measure of disorder is inappropriate in relation to the subsequent more detailed treatment in Chapter 6. In Chapter 3 reference is made to the heat capacity of the thermal reservoir before the specific heat c_p has been defined. Also the short section on "the molecular basis of the reaction enthalpy" is not very helpful.

There are many exercise problems at the end of each chapter, sometimes with hints on the method of solution. The consistent use of SI units throughout is a good feature. The high price of the book will deter students from buying it, especially since it scarcely goes far enough to cover the first semester of study.

Organic Synthesis with Oxidative Enzymes. By *H. L. Holland.* VCH Verlagsgesellschaft, Weinheim, 1992. XI, 463 pp., hardcover DM 168.00.—ISBN 3-527-27956-3

Biocatalysis techniques are increasingly developing as attractive alternatives to well established conventional chemical methods for many chemical transformations. This applies also to oxidations, as is impressively shown by H. L. Holland in this book. The applications of oxidoreductases in organic synthesis are summarized here in ten chapters, each plentifully illustrated with formula schemes and supported by a comprehensive and up-to-date bibliography (up to May 1990). Although alcohol dehydrogenases can also be used oxidatively, these are not covered. The book is intended for organic chemists who wish to learn about the capabilities of oxidative biotransformations and their use on a preparative scale. Some of these can be performed using isolated enzymes, which are even commercially available in a few cases, but the majority of the transformations described are only possible by using whole cells, i.e. living microorganisms. Although this whole cell technology has already been established in industry for several decades, e.g. for the hydroxylation of steroids, its applications to organic syntheses in other fields has so far been minimal compared with the use of isolated biocatalysts. One reason for this is that up to now the majority of oxidases have been difficult or impossible to obtain in active form together with the necessary cofactors and activators. A second reason is that many organic chemists still feel a great aversion and reluctance to use methods that are "too biological", and are therefore not very amenable to being controlled and—even more importantly—rationalized. Mindful of this obstacle to getting started, Holland has followed his introductory chapter, in which he describes the basic mechanisms of enzymic catalysis by mono- and dioxygenases, peroxidases, and also reductases, with a chapter on general laboratory techniques for performing biotransformations. In this he describes briefly how one goes about obtaining the microorganism needed for the purpose, and then how the actual transformation is carried out.

The following seven chapters present the current state of the art regarding the most important organic biotransformations. Chapter 3 describes hydroxylations at saturated carbon atoms; the main emphasis is on steroids and terpenes, but also included are hydroxylations at the benzylic position in a wide variety of arenes, and applications to *N*-dealkylations. Chapter 4 deals with oxidations of unsaturated CC bonds, describing biocatalytic epoxidations of olefins and arenes, and the currently very interesting conversion of aromatic hydrocarbons to enantiomerically pure *cis*-dihydrodiols as useful synthetic building blocks. Chapter 5 is concerned with biocatalytic Baeyer–Villiger oxidations, and Chapter 6 with oxidations at heteroatoms such as nitrogen and sulfur to give *N*-oxides, sulfoxides, sulfones, etc. Chapter 7 describes the conversion of CC single bonds to double bonds, with special reference to steroids and fatty acids, then in the following chapter the author collects together all the reactions that cannot be categorized under the previous headings. These include, for example, the oxidative coupling of phenols and their oxidation to quinones, and the biocatalytic breakdown of alkyl chains. In the penultimate chapter, which is very long in keeping with its importance, Holland describes reductive biotransformations, including the enzymic removal of hydroxy groups and halogens, the reduction of sulfoxides to sulfides and of *N*-oxides to amines, and especially the conversion of isolated double bonds and α,β-unsaturated carbonyl compounds to the corresponding saturated hydrocarbons. Lastly, Chapter 10 contains a survey of the many different types of enzyme-catalyzed syntheses described in the foregoing chapters, and with this as the theme the author gives advice, especially for the non-specialist, regarding criteria for identifying a suitable microorganism to perform a particular conversion. After also discussing the possibility of applying genetic engineering methods, the book ends with a brief, but optimistic, review of future prospects.

H. L. Holland has produced here a book that sets new standards. He informs the reader expertly, comprehensively, and without unnecessarily lengthy detail, about the capabilities and range of applications of the various biocatalysts described. He has wisely resisted the temptation to view his special subject through rose-colored spectacles and praise it to the skies. In every case he presents a critical evaluation, indicates perspectives, and points out examples where biocatalysis offers no advantages compared with conventional methods. In accordance with his self-imposed task of addressing organic chemists and helping them to make decisions and overcome fears, whenever possible Holland gives topical examples illustrating how the products from biosyn-

theses can be used in subsequent organic syntheses (e.g., as in the dioxygenases and the Baeyer–Villiger oxidation).

The book can be recommended unreservedly both for the specialist in academia or industry who wants detailed information and for the synthetic chemist who is keen to learn about these methods but has little previous knowledge. It is likely to earn a place as a standard work in the bioorganic literature.

der Universität Bonn (FRG)

Salt Effects in Organic and Organometallic Chemistry. By *A. Loupy* and *B. Tchoubar*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. XVI, 315 pp., hardcover DM 164.00.—ISBN 3-527-28025-1/0-89573-954-2

We have all met these problems! A reaction fails to proceed at the necessary rate, or does not give the desired selectivity. One obvious way around this kind of everyday problem is to change the solvent. It is less well known that reaction rates, equilibria, and regio- and stereoselectivities can be dramatically altered by adding chemically inert salts. Specific salt effects, i.e. those that depend not only on the concentration and charge of the ions but also on the chemical nature of the salt, have not yet been accepted into the preparative chemist's armory to any significant extent. Probably one reason for this is that the relevant information is widely scattered throughout the literature and has not previously been collected together. This monograph on salt effects in organic and organometallic chemistry by the French authors Loupy and Tchoubar is probably the first of its kind, and its dust-cover promises a gold-mine of information, experience, and ideas. Does the book live up to this claim? Yes, to a large extent it does.

After a brief introduction to the classification of salt effects, the authors describe the effects of salts on the rates of substitution and addition reactions. This is followed by a survey of how the regio- and stereochemical course of a reaction can be influenced by adding salts. Lastly the book deals with the effects of salts on the positions of equilibria, and discusses the importance of salt effects in organometallic chemistry. This last part is much shorter than the book's title leads one to expect. The work ends with an appendix summarizing some of the general concepts used in the foregoing chapters (e.g., the classification of solvents, hard and soft acids and bases).

This monograph is an English translation of the book published in France in 1988 under the same title. Regrettably, the opportunity to update it by including recent developments has been allowed to pass, and thus in general the literature references only extend up to 1988; a few papers from the period 1988–1990 are mentioned only in the appendix. There are very few factual errors (e.g., Eqn. 7–94 on p. 270), and those that have crept in scarcely affect the meaning. The salt effect referred to on page 175, namely the effect of adding a cuprate to a chiral Michael acceptor, is correctly described but is shown for the wrong stereoisomer. The subject index of only five pages is of little help when one is looking for specific subject areas (instead the reader should refer to the very detailed list of contents), and there is no author index (an omission that has unfortunately become too common nowadays). If these shortcomings could be remedied in a new edition it would considerably improve the book's usefulness.

The authors have been largely successful in their efforts to achieve a useful organization of the information contained in well over a thousand publications. In describing the effects observed they have mainly avoided including mathematical derivations. In view of the large mass of data it is hardly surprising that occasionally the guiding theme is lost and gives way to a mere list of observations. However, this is not a disadvantage insofar as it has enabled the authors to include some related areas that would otherwise have been left out. The extensive sections on salt effects in regio- and stereoselective reactions are likely to be especially useful; chemists working on these topics will find here a wealth of stimulating ideas, and they may well find it worthwhile to buy a personal copy. Libraries, despite their tight budgets, cannot afford to be without the book.

Norbert Krause and *Robert Wagner*
Institut für Organische Chemie
der Technischen Hochschule Darmstadt (FRG)

Hydrogen Bonding in Biological Structures. By *G. A. Jeffrey* and *W. Saenger*. Springer, Berlin, 1991. XIV, 569 pp., hardcover DM 198.00.—ISBN 3-540-50839-2

In the living world of biomolecules hydrogen bonds are the most important of all noncovalent bond types. They play an essential role in the formation of biological macromolecules such as the globular proteins and the DNA double helix, and in the mechanism of enzyme-substrate recognition. This area of study is the subject of a new monograph by G. A. Jeffrey and W. Saenger, which places special emphasis on the geometrical aspects.

The first part begins with a short historical survey, followed by an account of the characteristics and functions of hydrogen bonding. The authors describe the possible types of geometries and effects on the molecular structure, cooperativity, ordering, and statistics, and discuss experimental and computational methods for studying these effects.

In the second part the patterns of intra- and intermolecular hydrogen bonding in small molecules are discussed on the basis of available structural data. In particular the authors consider hydrogen bonding in alcohols and saccharides, which often form crystal structures with extended cooperative networks. This is followed by detailed discussions of the structures of purines and pyrimidines and the possible base pairings in these compounds, and of the crystal structures of nucleosides and nucleotides. There is also a short section on amino acids.

Part 3 of the book is concerned with hydrogen bonding in biological macromolecules. The structures of oligosaccharides and cyclodextrins are discussed very thoroughly, leading to general conclusions about cooperativity and dynamics in extended hydrogen-bonded networks. A further section deals with internal hydrogen bonding in proteins, describing the types of geometries and patterns that are found. The flexibility of protein molecules and their hydrogen bonds has been investigated by hydrogen–deuterium exchange experiments. Nucleic acids and their possible base pairings are also discussed from the standpoint of hydrogen bonding. There is also a section on protein–nucleic acid recognition mechanisms.

Part 4 is concerned mainly with aggregates formed by water molecules. First the authors introduce the models used to

describe water, ice, clathrates, and the hydrate and layer hydrate compounds formed by small molecules. They then go on to discuss the hydration of proteins and nucleic acids, describing in detail the arrangement of water molecules on the surfaces of these macromolecules, and the formation of water clusters in the region of the transition to the bulk solvent.

Taken as a whole this is a comprehensive standard work on hydrogen bonding in biological systems. However, owing to the difficulty of obtaining data for hydrogen atoms in large structures the main emphasis is on small molecules such as saccharides and nucleic acid bases, for which adequate structural data are available. The energies of hydrogen bonds are difficult to analyze, and consequently they are not treated to any significant extent here. The same also applies to entropy effects, such as are involved in the stabilization of structures by hydration. The schemes and tables contain a wealth of experimentally determined structural data, and the discussions in the text are supported throughout by clear diagrams. The introductions to the individual chapters give sufficient information to ease the way for readers new to the subject. The author's aim was certainly not to write a short compendium on the subject, but nevertheless the book contains a wealth of useful information not only for the specialist but also for the reader with more general interests, and this will ensure that it appeals to a wide readership.

Ulrich Abele and *Georg E. Schulz*
Institut für Organische Chemie und Biochemie
der Universität Freiburg (FRG)

Rapid Reactions in Solution. By *H. Strehlow*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. XIV, 341 pp., hardcover DM 176.00.—ISBN 3-527-28260-2/1-56081-126-9

Any student or researcher who has needed to find out about fast reactions will know that since the publication in 1964 of Edward Caldin's book *Fast Reactions in Solution* there has been no more recent treatment of the methods and results of this area of research. This book by Hans Strehlow now fills that gap.

In the language of chemists, "rapid" reactions are those with time-scales in the range from nanoseconds to several seconds. Although even faster processes in the femtosecond range can nowadays be studied, and there is speculation concerning what information of interest to the chemist this can yield, such processes are not the subject of this book. As Strehlow emphasizes in his introduction, the investigator concerned with the dynamics of chemical processes is not primarily interested in obtaining numerical values of rate constants with the highest possible accuracy; instead the aim is to elucidate reaction mechanisms and to observe and characterize the elementary steps in complex systems. Strehlow has set out to provide the investigator, by means of examples of applications, with as comprehensive an understanding as possible, so that he or she can choose the most suitable method for a given problem. Reading the book is certainly not enough by itself to reach that goal, but it provides a firm basis for more detailed discussions with the experts, of whom Strehlow is indisputably one of the most competent. He has used nearly all the methods himself, has been involved in their development in some cases, and he and his research group at the Max-Planck-Institut in Göttingen have made numerous contributions to the understanding of reactions in solution.

The subject matter is arranged according to the various methods, beginning with flow techniques, which have now developed to the point where they can be applied even to reactions in the microsecond range. Then relaxation methods and NMR techniques are both treated at some length. The book ends by describing flash photolysis and pulse radiolysis methods. The area with which Strehlow is most closely associated is electrochemistry, as might be guessed from the fact that the modern and highly successful NMR methods are given only about the same amount of space as polarography, a highly specialized method limited to homogeneous reactions. From this it can be seen that the author is concerned to present the methods in a way that reflects their historical development. Regrettably, fluorescence quenching is only briefly mentioned under the heading of "Other Methods". In recent years this technique has yielded much valuable information, especially in colloid chemistry; the technology is now highly developed, and advances in the theoretical understanding of fluorescence quenching in compartmentalized systems (extension of the Perrin theory) have led to new ways of interpreting the data.

Many of the applications chosen as examples belong to the early investigations that yielded basic information about the elementary steps of proton transfer, metal complex formation, and enzyme–substrate interactions; most of the systems discussed here are those that have been extensively studied by the author's own group. However, developments of other kinds have not been ignored. An example of these is fluctuation analysis, which has become important in membranes research and other areas. Nevertheless, Strehlow's book contains few examples of applications in biophysical chemistry, or references to such work.

Strehlow introduces the theoretical aspects in a way that reveals him to be an outstanding teacher who can explain the principles clearly and understandably. The introduction to the kinetics of micelle formation is a prime example of how the discussion of a simplified system can serve to prepare the reader for a more abstract formulation. Likewise the introduction to NMR methods, where the Bloch equations and the relationships based thereon are of special interest for applications in physical chemistry, is excellent from a learning standpoint—my students have already had much amusement from the illustration of the spin-echo experiment. The occasional cartoons are probably even more effective in contributing to a better understanding. Moreover, the book shows evidence of careful editorial planning, with a clear layout.

The book is accompanied by a floppy disk containing computation programs. This may be useful to many readers, but nowadays many statistical and graphics programs are widely available, and most research groups whose work involves relaxation curves or correlation functions already have the "Discrete" program installed in their computer systems so that exponential functions can be fitted to data.

Many scientists working in this field are members of the "Discussion Group on Fast Reactions in Solution" run by the Royal Society (London), and attend the Group's annual discussion meeting. One of the founder members of this Group was Edward Caldin, who is also still an active participant in these annual discussions, and at this year's meeting I talked with him about Strehlow's book. He reacted quite spontaneously by saying "I am delighted that my book has been replaced by Professor Strehlow's book, which I

have read and greatly admire." I can certainly endorse that view.

Georg Ilgenfritz
Institut für Physikalische Chemie
der Universität Köln (FRG)

Carbocyclic Cage Compounds: Chemistry and Applications. (Series: Methods in Stereochemical Analysis. Series editor: *A. P. Marchand.*) Edited by *E. Osawa* and *O. Yonemitsu.* VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. XIV, 409 pp., hardcover DM 168.00. – ISBN 3-527-27933-4/0-89573-728-0.

This is the third major work on carbopolycyclic compounds to appear within the last four years. Whereas Haufe and Mann (*Chemistry of Alicyclic Compounds,* **1989**; see *Angew. Chem.* **1991**, *103*, 111; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1191) approach the subject in a systematic way, the multiauthor volume edited by Olah (*Cage Hydrocarbons,* **1990**) and the book reviewed here are unstructured collections of review articles in a style similar to that of *Chemical Reviews*. The latter journal did in fact include an issue in 1989 containing 17 reviews on the same subject area. Despite this there is little overlapping of the contents, which gives an indication of the wide-ranging nature and high level of activity in polycycles chemistry.

We learn from the preface that this book arose from a series of symposia on cage compounds that took place in Japan in the 1980s, extending to the beginning of the 1990s. As one might expect from this, the articles vary considerably in their breadth of subject matter, length, readability, up-to-dateness, and so on. Nevertheless, most of the older contributions appear to have been revised to bring them up to date, so that in general the articles take into account work published up to 1989, with a few references to publications in 1990 and 1991. A lamentable exception is Chapter 11 in which, out of about 110 references, the most recent are one from 1981, two from 1982, and one from 1983.

The subtitle should be regarded with caution. Anyone who expects to find applications of cage compounds in fields other than chemistry will be disappointed. Apart from a mention in the preface, applications are only seriously addressed in the last chapter (solar energy storage). It is a sad commentary on the present situation regarding support for basic research that it is felt necessary and realistic to justify it by citing potential applications of doubtful validity; here, for example, research on cubane is justified by dubious references to possibilities for explosives or pharmaceuticals.

Most of the book's contents are concerned with down-to-earth organic chemistry. In Chapter 1 A. P. Marchand gives a very readable review of the use of cage compounds as intermediates in organic synthesis, and as rigid structures within which reactive intermediates that could not exist otherwise may be prepared, observed, or identified from the stable products that result from them. The reaction schemes are clear and well annotated, a virtue not shared by some of the other articles.

Chapter 2 (K. Naemura) deals with cage compounds that are highly symmetrical but nevertheless chiral (an example is D_3-trishomocubane). Many of the schemes show several structural formulas together, identified only by numbers, which necessitates much turning of pages and spoils the clarity of the presentation.

Chapter 3 (H. W. Kroto and D. R. M. Walton) is a short one on "Postfullerene Organic Chemistry", and is rather out of place here in several respects. Firstly, the aromatic C_{60} soccerball structure (according to the preface a "fantastic superstar", which rather misleadingly appears in several copies, sadly shrunken, on the front cover) is fundamentally different from the small saturated molecules treated in the rest of the book. Secondly, this article consists not so much of research results as of speculations about possible synthetic routes to individual fullerenes (at the time when this chapter was written the flood of publications on C_{60} chemistry was only just beginning).

Chapter 4 (F. Matsuda and H. Shirahama) on "Natural Products Chemistry in Three Dimensions" discusses the observation that unsaturated macrocycles often adopt a preferred conformation in which the plane of a double bond is perpendicular to the plane of the macrocycle, with important consequences for the reactivity. Chapters 5 (propellanes, Y. Tobe), 6 (cyclophanes derived from vinyl arenes, J. Nishimura), 7 (prismanes, G. Mehta and S. Padma – very lucid and worth reading), 8 (cubanes, H. Higuchi and I. Ueda), and 9 (bishomocubanes, W. L. Dilling) review recent developments in the chemistry of these compound classes, with the emphasis in each case on the work of the authors.

In Chapter 10 C. Ganter describes in detail the elegant methods and results of his cartography of "Adamantaneland". Chapter 11 (J. Fournier and B. Waegell) discusses the reflex and anti-reflex effects, which are concerned with the influence of axial substituents at the 3- and 5-positions on the conformations of cyclohexanones. In Chapter 12 T. Miyashi, Y. Yamashita, and T. Mukai give a concise description of photochemical methods for synthesizing cage compounds, and the photochemical reactions that these undergo in the presence of electron transfer catalysts. Lastly, Chapter 13 (K. Hirao, A. Yamashita, and O. Yonemitsu) discusses the problems that still remain to be overcome in trying to apply a simple reaction (norbornadiene$\rightleftharpoons$quadricyclane) on a technical scale.

The overall impression from these articles is of thoroughly sound contributions to the field. The rather nonsensical statement "Asymmetry is a necessary but insufficient criterion for a chiral molecule to have a nonsuperposable enantiomer" (p. 62) is, fortunately, not typical. When dimethyldioxirane is wrongly described as "dimethyldioxolane" (p. 241) and Meldrum's acid (isopropylidene malonate) as a "glutaric acid derivative" (p. 280), one might well excuse these as no more than minor slips. Unfortunately there are also some annoying errors in the formula diagrams. For example, in pagodane (p. 36) two bonds are missing from the "waist" of the molecule, the stick projection of the C_{60} football on page 98 is not successful, and in the alleged conformational equilibrium shown at the top of page 324 the two formulas actually represent a pair of constitutional isomers. The repeated appearance of certain topics, such as 2 + 2-photocycloaddition and the Favorsky ring contraction, was probably unavoidable. I would have preferred a more definite continuity of theme in several of the articles, and even throughout the book.

The technical quality (typography, binding, etc.) is good, and the number of printing errors is acceptably small. Libraries and specialists in the field should buy the book, but most other chemists are unlikely to wish to do so, in view of its specialized nature and the fact that parts of it are no longer completely up-to-date.

The Synthesis of Insect Pheromones, 1979–1989. (Series: The Total Synthesis of Natural Products, Vol. 9. Series editor: *J. ApSimon.*) By *K. Mori.* Wiley, Chichester, 1992. IX, 534 pp., hardcover, £ 98.00.—ISBN 0-471-55189-9

Insect pheromones, a group of natural products that modify insect behavior, have attracted the attention of many synthetic chemists during the last two decades because of their importance in biology, ecology, and biological plant protection. In this volume of over 500 pages on the synthesis of insect pheromones, Kenji Mori single-handedly and skillfully reviews the literature on the subject for the years 1979–1989, and describes in detail an enormous variety of new methods, as well as variations and improvements on already known methods. It is intended as a continuation from an article by the same author that appeared in Volume 4 of this series "The Total Synthesis of Natural Products". As one of the most successful and best known synthetic pheromone chemists, Mori can justly be described as the guru of pheromone synthesis, especially in the area of chiral and enantiomeric compounds. Understandably, therefore, a considerable part of the book is concerned with enantioselective methods of synthesis.

Probably every pheromone chemist of this period is represented in the literature references, of which there are over 1200. These cover all the leading international and national journals, but also include some publications in rather unusual journals that are not easily accessible to most readers. A very impressive feature of the book is the formula schemes, which probably account for a high proportion of the work that has gone into the book; the author makes a special point of thanking his colleagues in Tokyo for their help in preparing them. With over 1000 (!) formula schemes the volume is a picture-book of pheromone synthesis and a striking example of the art of clear presentation. The book is an especially valuable resource for the chemist who needs a quick survey of all the existing synthetic methods for particular pheromone structures, and wants to avoid too much laborious reading of descriptions of syntheses.

However, the volume also deserves careful reading. After a brief summary of the most important monographs and reviews on pheromones research during the period covered, which is almost a tabulation in its format, there follows a short introduction (Chapter 2) describing general synthetic and analytical methods. Chapters 3 onwards deal with actual syntheses. The chapters are arranged according to structural types, starting with hydrocarbons then continuing through alcohols, esters, etc., up to heterocyclic pheromones containing nitrogen and sulfur. However, any desired compound can easily be located by means of a molecular formula index at the end of the book. Alternatively the reader can look up a given pheromone-producing insect species in the usual way by using the contents list.

As a result of the above arrangement of subject matter, the first half of the book is mainly concerned with the sex attractants that have relatively simple structures, and are produced by butterflies and moths. This is followed in the second half of the book by the more complex pheromones produced by other insect species. Altogether the syntheses of 260 pheromones are described and illustrated by formula schemes. The text relating to a particular synthesis is only one or two sentences in most cases, usually giving just the key reaction and the starting materials. However, the amount of detail in the formula schemes fully makes up for the brevity of the text. In each case the relationship to the insect that produces the substance is explained, and sometimes details of the analysis and structure determination are given; often also the biological activity of the compound is described. For some optically active chiral pheromones the relationship between absolute configuration and biological activity is briefly discussed. The question of stereobiology is considered from a more general standpoint in the final chapter.

To sum up, this book is essential reading for synthetic organic chemists, and is an excellent work of reference that no laboratory involved with pheromones should be without.

Data Fitting in the Chemical Sciences. By *P. Gans.* XII, 258 pp., hardcover £ 29.95.—ISBN 0-471-93412-7

This book explains the mathematical fundamentals of the most commonly used methods of data fitting. In view of the growing use of microcomputers and program libraries in the recording and presentation of data, the book should prove a valuable aid, as it contains a critical survey of the use of statistical methods and the limitations of the various mathematical techniques. The introductory chapter begins by describing an example to illustrate the need for a model as a basis for interpreting experimental data and presenting results. Chapter 2 is concerned with experimentally measured quantities, errors in data, and the propagation of errors. The author uses an example to illustrate the difference between random and systematic errors, pointing out that only random errors can be handled by statistical methods. The following two chapters deal in turn with linear and nonlinear least-squares fitting methods. The author also describes the derivation of the formulas that are used in most application programs, so that the interested reader can follow these through to their final form. Although not every chemist is as familiar as P. Gans is with the matrix notation used, the treatment of some simple examples helps the reader to feel more at ease with the otherwise tedious mathematical derivations. Chapters 5 and 6 deal with the empirical and theoretical models needed for the interpretation or presentation of experimental data. Here the author first considers the limiting conditions affecting the model parameters that are to be determined. This is followed by a discussion of methods for controlling experiments so as to improve the quality of the data. Here the author again makes a special point of warning the reader about systematic errors that cannot be analyzed by statistical methods: "Sometimes a factor may be unsuspected until after the experiment has been performed and the data analyzed. In that case it is better to repeat the experiments with that factor under control than to try to extract information from flawed data." Chapter 6 addresses the question of when it is appropriate to use least-squares fitting methods, and suggests criteria for deciding, on the basis of the statistical properties of the experimental data, whether a model can be rejected. Here it is repeatedly emphasized that, even under the best statistical conditions, one can never prove the correctness of a model.

The second half of the book is devoted to some special types of data fitting problems. Chapter 7 is concerned with the representation of data by polynomials and with smoothing and differentiation methods. Chapter 8 deals with the fitting of data to spline functions, single and multiple exponential functions, Gaussian and Lorentzian functions, trigonometric functions, and surface functions. Chapter 9 summarizes those aspects of the Fourier transformation that are relevant to data fitting. Chapter 10 treats a special topic

with which the author has been concerned in the past, the application of statistical methods to potentiometric titration. The book ends with an appendix consisting of seven short sections, which include definitions of the most important terms used in statistics and brief explanations of matrix algebra, partial differentiation, the calculation of expectation values, and various minor mathematical theorems.

The author has set out to describe the processes of data compilation and analysis that take place inside the "black box" (the microcomputer and associated application programs), and in particular to draw attention to the problems and difficulties of data handling. The reader is specifically warned about the possible pitfalls that await the inexperienced user when data are interpreted with the help of such a "black box". The book fulfills this task very well, and it should be of considerable value to all who use microcomputers and application programs for statistical data analysis. I can recommend it unreservedly for such readers.

Spectrochemical Analysis by Atomic Absorption and Emission. By *L. H. J. Lajunen*. The Royal Society of Chemistry, London, 1992. XII, 242 pp., paperback £ 18.50.—ISBN 0-86186-873-8

This book, which is intended for students and teachers of analytical chemistry, describes the state of knowledge in atomic spectroscopy in the early 1990s. Following a short historical sketch and a general explanation of the terms used, the fundamental theory is presented. This forms the basis for a clearly understandable description of various analytical techniques, ranging from flame atomic absorption spectroscopy (flame-AAS) through graphite furnace AAS (GFAAS) and other AAS methods, inductively coupled plasma atomic emission spectroscopy (ICP-AES), and ICP-mass spectrometry (ICP-MS), to atomic fluorescence spectroscopy. For each technique the basic instrumentation is described first, followed by the capabilities, problems, and ways of solving them. The lengths of the chapters reflect the relative importance of the different methods. Thus the most extensive chapters are those on the three most important routine techniques, namely flame-AAS, graphite furnace AAS, and plasma-AES. Also included, however, are short descriptions of recently developed techniques such as ICP-MS and the different types of sample introduction systems used (although here the book does not go into much detail, and also some small errors have crept in, such as an incorrect figure showing a mass spectrum on page 197).

A very positive feature of the book is that the author does not waste time on trivia but concentrates on important relationships and an overall view, though without neglecting the problems. For example, a separate chapter is devoted to sample preparation, ranging from sample acquisition through digestion techniques to methods of separation and enrichment. The clear presentation of the material is also greatly helped by the detailed and well-arranged list of contents and the many figures (148) and tables (46), which both support and amplify the information in the text. To round off the book there is a section in which the different atomic spectroscopy methods are summarized and compared, together with a list of books for further reading and of the most important relevant journals.

The book can be recommended for everyone who wishes to learn about the capabilities and limitations of analysis by atomic spectroscopy. It is especially suitable for students with interests in analytical chemistry, for whom it offers a clearly understandable and thorough grounding in modern atomic spectroscopy. It is to be hoped that it will reach a wide readership, as it covers a broad range of subject matter in a very readable form.

Capillary Electrophoresis: Methods and Scope

New Analytical Methods (44)

By Heinz Engelhardt,* Wolfgang Beck, Jörg Kohr, and Thomas Schmitt

Capillary electrophoresis is a new analytical technique that has seen a great upswing in recent years, because this adaptation of electrophoresis may be automated and simple, direct quantification is possible. As in conventional electrophoresis, samples with a large range of molecular weights, from inorganic ions to biopolymers such as DNA and proteins, can be separated. Uncharged molecules can also be separated when micelle-forming detergents are added to the buffer; the distribution mechanism that then comes into play increases the separation efficiency of this micellar electrokinetic chromatography. Chiral additives such as cyclodextrins make the separation of enantiomers possible. The rapid increase in the popularity of capillary electrophoresis is reflected in instrument sales and the growing number of scientific publications dealing with the method, and it seems that the future of this technique is assured.

1. Introduction[**]

Analytical separation methods such as chromatography and electrophoresis have played an important role in the determination of the composition of complex biological, environmentally relevant, and industrial samples. Gas-liquid chromatography (GLC) and high-performance liquid chromatography (HPLC) allow the separation, identification, and quantification of the components of complex mixtures in a very short time. The combination of the high-performance separation systems with sensitive, selective, and specific detectors, such as UV/VIS diode array detectors (DAD), mass spectrometers, and Fourier transform infrared (FTIR) spectrometers makes it possible to identify the separated substances unequivocally. Development in instrumentation is so far advanced that chromatographic analysis is now almost fully automated.

The areas of application of GLC and HPLC are clearly defined by the demands made by the analytical method on the sample. In view of the vast number of nonvolatile compounds it is not surprising that HPLC is today the most widely used separation technique with a continuing high growth rate. (The market for HPLC instruments is at present growing at over 10% per year.) Problems always arise with HPLC when polar and ionogenic (and in particular basic) samples or biopolymers are to be analyzed rapidly and efficiently. This is an inherent problem of chromatography with stationary phases based on silica gel. Although phases are now available for which such problems are hardly noticeable (polymer-based stationary phases have not been applied widely because of their swelling capacity, lower efficiency, and limited pressure stability), the development of a technique for the separation of ionogenic substances still requires great skill and a detailed knowledge of the multifarious sorption and exchange processes involved.

Charged particles migrate at different rates in solution under the influence of an electric field. In the first half of the century the terms "electrophoresis" or "electrical transportation" were introduced for this behavior.[1-4] Differences in the rate of migration can have two causes: either the molecules have different charges and are thus accelerated to different extents by the applied field, or the migrations of the molecules are slowed down to differing degrees as a result of their individual frictional resistances. In the simplest case the separation of a solution of an electrolyte can be carried out in a tube, since here no interactions with a stationary phase can occur. In practice, however, distortions of the substance zones occur on account of differing densities of the electrolyte and convection currents originating from the transport of Joule heat to the capillary wall. In classical electrophoresis, as introduced by Tiselius,[5] gels or strips of paper impregnated with solutions of electrolytes are used to reduce the distortions arising from convection. In addition, frictional resistance introduced for macromolecules with low charge differences increases the separation efficiency. Polyacrylamide gel electrophoresis (PAGE) makes possible the efficient separation of DNA molecules and proteins. The separation performance can be optimized by varying the degree of cross-linking of the gels. Gel electrophoresis can be used for direct determination of the molecular weight of proteins denatured by sodium dodecyl sulfate (SDS). In this case the separation is due solely to the hindrance of the migration by the gel (in the absence of a gel all proteins denatured by SDS would migrate at almost equal rates).

Classical electrophoresis (with gels or paper) unfortunately has two significant disadvantages. Firstly, quantitative analysis is possible only with reflection measurements; proteins must first be dyed, and the results are subject to considerable errors. Secondly, the voltage gradient that can be applied across the gel bed is limited. Since the heat evolved increases with the square of the voltage, efficient cooling is necessary to prevent the gel from drying out. The time required for an analysis using a gel bed 10 cm in length can thus be as much as several hours. The advantage with respect to modern automated separation processes is that several separations can be carried out simultaneously in one gel by using separate tracks; the sample throughput is thus greatly increased. In

Thomas Schmitt

Heinz Engelhardt, born in Nuremberg in 1936, studied chemistry at the University of Erlangen-Nuremberg and gained his doctorate in 1965. He was a postdoctoral fellow at Northeastern University in Boston in 1969–1970. In 1971 he obtained his "Habilitation" in analytical organic chemistry, and in that year accepted a chair at the University of the Saarland, where he is currently Professor of Applied Physical Chemistry. Engelhardt has published more than 130 papers on chromatography and is the author of the book "Hochdruck-Flüssigkeits-Chromatographie", which was also published in English, Russian, and Chinese. He is editor of several journals, chairman of the Arbeitskreis Chromatographie of the Gesellschaft Deutscher Chemiker (GDCh), and a member of the board of the Subdivision of Analytical Chemistry of the GDCh. In 1992 he obtained the Dal Nogare Award and in 1993, the A. J. P. Martin Award of the Chromatographic Society of Great Britain.

Wolfgang Beck was born in 1964 in Fürth/Bavaria and studied chemistry at the University of the Saarland from 1985 to 1990. In his diploma thesis with H. Engelhardt he synthesized and characterized HPLC stationary phases for the separation of chiral compounds. Since 1990 he has been working towards his doctorate. His work deals with the improvement of detection methods and the optimization of UV detection, diode array detection, and indirect UV detection.

Jörg Kohr, born in 1963 in Saarlouis/Saarland, studied chemistry at the University of the Saarland (diploma 1989) and received his doctorate in 1992 for his research with H. Engelhardt on the application of polymer-coated quartz capillaries in capillary electrophoresis.

Thomas Schmitt was born in 1964 in Quierschied/Saar and studied chemistry from 1985 to 1991 at the University of the Saarland. His diploma thesis dealt with the separation of DNA restriction fragments by capillary gel electrophoresis. Since 1991 he has been working towards his doctorate in Saarbrücken on the separation of chiral compounds by capillary electrophoresis.

addition, the flatbed method readily allows two-dimensional (2D) operation in which different separation mechanisms are employed. The excellent separation performance of 2D gel electrophoresis in protein analysis will be mentioned here only briefly.

2. Principles of Capillary Electrophoresis

Various attempts have been made to reduce convection currents in free electrolytes when open tubes are used, for example, by rotating the tube about its axis.[6] The use of thin capillaries, either of glass[6, 7] or Teflon,[8] with an internal diameter between 200 and 500 μm was found to be successful. Quartz capillaries[9–12] with internal diameters of 25–200 μm made it possible to carry out highly efficient separations of proteins and dansyl amino acids. The negative influence of thermally induced convection was greatly reduced with these capillaries because of the relatively large surface to volume ratio. Quartz capillaries of the type used in GLC make it possible to use detectors for the on-line detection of the separated substances within the capillary. In the second half of the 1980s the simplicity of the apparatus required led to an increased interest in capillary electrophoresis (CE), often referred to as capillary zone electrophoresis (CZE). Since in all separations the substances are injected as discrete zones at the beginning of the capillary and the components of the samples migrate as discrete zones, we shall refer to this simple case simply as capillary electrophoresis (CE).

The basic construction of a CE apparatus is shown schematically in Figure 1. The thin quartz capillary (25–100 μm

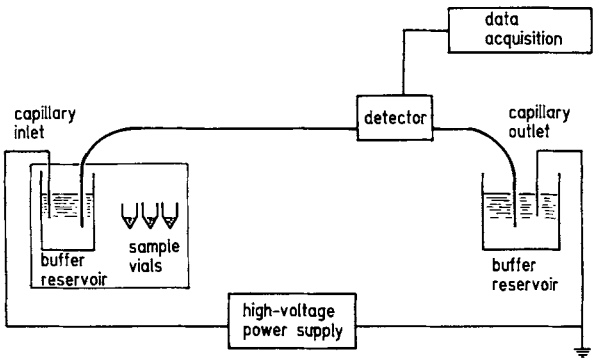

Fig. 1. Schematic diagram of a CE apparatus.

in diameter), 20 to 100 cm in length, bridges the two buffer vessels, between which a voltage of up to about 30000 V is applied. A relatively small "slug" of the sample (a few nL!) is introduced at the anodic end of the capillary. This is done by replacing the buffer vessel by a sample vial; in other words, the end of the capillary is dipped into the sample solution. The advantages and disadvantages of the various methods of sample introduction are discussed in detail in Section 3 "Apparatus".

The migration of the sample is induced by the applied voltage. The electrophoretic migration is always accompanied by an electroosmotic flow (EOF) of a certain magnitude, which contributes in a passive manner to the transport of the sample zones but not to their separation. This EOF depends strongly on the pH value of the buffer and the surface properties of the capillary. It can be so large that not only neutral molecules but even negative ions are transported to the detector, that is, in the opposite direction to that of their electrophoretic migration. Since in most buffers dissociation of silanol groups leads to the presence of negative charges at the surface of the quartz capillaries, in turn inducing positive charges in the vicinity of the surface, the EOF is directed towards the cathode; thus the detector is usually positioned near the cathode. The EOF helps in the transport of the sample zones to the detector, so that when the EOF is sufficiently large anions can also be transported to the cathode. The result of a separation of cationic, anionic, and neutral substances by means of CE is shown in Figure 2. Under these conditions all uncharged molecules migrate with the same velocity, that of the EOF, and cannot be separated, whereas the separation of the ions is possible because of their differing electrophoretic mobilities.

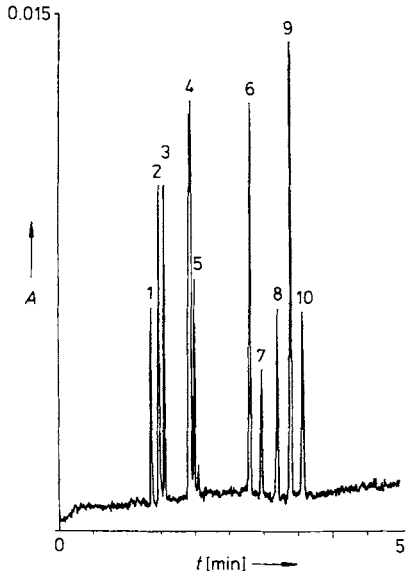

Fig. 2. Demonstration of a separation of positive and negative ions using capillary electrophoresis. Conditions capillary: L (length) = 30/37 cm, ID (inner diameter) = 75 μm; buffer: 33 mM borate, pH 9.5; field: E = 350 Vcm^{-1}, UV detection at 214 nm. Sample: 1 = trimethylphenylammonium bromide, 2 = histamine, 3 = 4-aminopyridine, 4 = benzyl alcohol, 5 = phenol, 6 = syringaldehyde, 7 = 2-(*p*-hydroxyphenyl)acetic acid, 8 = benzoic acid, 9 = vanillic acid, 10 = *p*-hydroxybenzoic acid.

Apart from this simplest form of CZE in which the separation depends only on mobility differences, numerous variations have been introduced: in capillary gel electrophoresis (CGE) the capillary is filled with a gel; the electrophoretic migration of macromolecules is influenced by the gel matrix, leading to a separation according to molecular size. Uncharged molecules can be separated by means of micellar electrokinetic chromatography (MEC). When detergents are added to the buffer, the neutral molecules are distributed between the buffer and the micelles according to their hydrophobic properties. Since a distribution process is involved, this is a chromatographic technique. The separation is due to the mobility of the micelles, which are generally negatively charged. In the case of isoelectric focusing (IEF) the separa-

tion is carried out in a pH gradient, which is formed in the electric field when ampholytes are added to the buffer. Of less importance is electrochromatography (EC), in which HPLC stationary phases are used and the transport of the samples is brought about only by the electroosmotic flow. Finally we should mention the oldest capillary separation technique, isotachophoresis (ITP), which has recently become more important because of its use in CE for sample concentration.

2.1. Electrophoretic Migration

An increase in voltage and consequently an increase in the field strength E leads to an increase in the electrophoretic migration velocity u of the ions and thus to a faster analysis. The applied voltage decreases over the total length L_{tot} of the capillary. The velocity and hence the electrophoretic mobility μ is determined from the time t the sample stays in the capillary between sampling (usually at the anodic end of the capillary) and detection, and the effective capillary length L_{eff}. With commercial equipment the capillary length between detection window and capillary end (usually the cathodic end) can be between 5 and 20 cm. This additional length must be considered when determining mobilities. The correlation between these values is given by Equation (1). A single ion experiences an accelerating force K_B [Eq. (2)],

$$\mu = \frac{u}{E} = \frac{L_{eff}}{Et} = \frac{L_{eff} L_{tot}}{Ut} \quad (1)$$

$$K_B = zFE \quad (2)$$

F is the Faraday constant (96 500 C mol^{-1}) and z the effective charge of the ion. This force is opposed by the frictional force K_R, which is approximated by Stokes' Law [Eq. (3)]; η is the dynamic viscosity [Pa s] and r the Stokes radius [cm].

$$K_R = 6\pi\eta r \quad (3)$$

The electrophoretic migration velocity u is thus defined by Equation (4). Electrophoretic separations are possible only

$$u = \frac{zFE}{6\pi\eta r} \quad (4)$$

when the ions have different mobilities. The effective charge equals the formal charge minus the charge contribution of the surrounding oppositely charged *rigid* double layer.[14] During the migration the ion takes this fraction of the double layer with it and thus migrates more slowly than expected on the basis of its formal charge. This is known as the electrophoretic effect and is greatest for a thin *diffuse* double layer surrounding the ion. This characteristic double layer can be calculated by Debye–Hückel theory, and its thickness is inversely proportional to the square root of the electrolyte concentration. It can be shown that the effective ionic charge, and thus the migration velocity, decreases with increasing ionic strength.

In the case of large molecules with radii greater than the thickness of the double layer, their mobility is independent of their size (provided that they have similar compositions);[14] this makes the electrophoretic separation of large molecules more difficult, as the migration rate of DNA molecules and proteins denatured by SDS is identical in pure electrolytes. Separation can only be achieved when the migration is influenced by sieve effects (e.g. in gels) or exclusion effects.

2.2. Electroosmotic Flow

While electrophoresis is responsible for the separation of molecules with differing mobilities, electroosmosis causes a flow of the buffer solution in the electric field. In most cases the electrophoretic migration of the ions in CE is reinforced by the electroosmotic flow (EOF), which depends on the distribution of the charges in the vicinity of the capillary surface. Almost every surface carries charges; in the case of quartz capillaries these are negative and induced by dissociation of the silanol groups. The surface charges are balanced by corresponding opposite charges in the buffer. In a quartz capillary this double layer, shown schematically in Figure 3, is dominated by positive ions arranged in a static and a diffuse layer at the surface. If a field is applied parallel to the

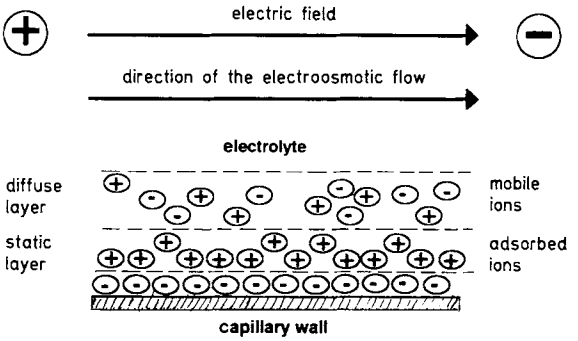

Fig. 3. Schematic diagram of the charge distribution at the capillary surface.

surface, the counterions in the mobile layer are pulled parallel to its axis along with the liquid in the capillary. Thus for quartz capillaries the induced EOF is in the direction of the cathode. An extremely flat piston-shaped flow profile results. This leads to considerably less band broadening than obtained with hydrodynamic flow with applied pressure, for which a parabolic Hagen–Poisseuille flow profile is observed, which depends strongly on the radius of the capillary and the flow velocity. In capillaries packed with glass beads or silica gel particles the EOF should be independent of the particle diameter of the packing material and should lie in the same direction as in the empty capillary. It is thus theoretically possible to use either very small particles (1 μm or less in diameter) or long columns in a chromatographic separation. The procedure known as electrochromatography (EC) is thus a subject of increasing interest,[15] since it should combine the selectivity of HPLC with the separation efficiency of CE. By using nonporous particles it is possible to eliminate the contribution to the band broadening caused by diffusion within the pores.

The magnitude of the EOF can be described simply by the Helmholtz equation [Eq. (5)]. It is inversely proportional to

$$\mu = \frac{\varepsilon E \zeta}{4 \pi \eta} \tag{5}$$

the viscosity η of the electrolyte and proportional to its dielectric constant ε, to the applied field strength E, and to the number of charges at the capillary wall (and thus to ζ, the "zeta potential" they induce). In the case of quartz capillaries the EOF decreases with the concentration of the electrolyte and the amount of organic components added, and increases with the degree of dissociation of the silanol groups at the surface; in other words, it increases with increasing pH. The pH dependence of the EOF for quartz capillaries and the corresponding reproducibility of the mobility is shown in Figure 4. The largest variations occur at intermediate pH values in the vicinity of the pK value of silicic acid. The deviations can be reduced, however, by increasing the conditioning time following a change in the pH value of the buffer; the hysteresis effects are then decreased. For reproducible analyses conducted with untreated capillaries the rinsing and conditioning times following a change in the buffer must be standardized; this can reduce hysteresis effects in the EOF.[16]

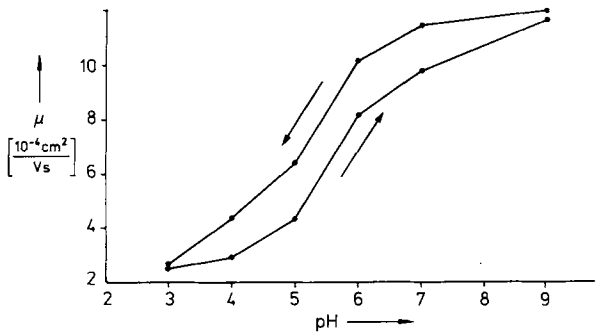

Fig. 4. pH Dependence of the electroosmotic flow μ. Conditions: capillary: $L = 40/47$ cm, $ID = 75$ μm; buffer: 10 mM phosphate; neutral marker: benzyl alcohol; $E = 425\ \mathrm{Vcm^{-1}}$.

Electroosmotic flow is observed for all electrophoretic separation techniques, since surface charges can never be completely eliminated. On the one hand it can lead to a convective mixing of the electrophoretic zones, while on the other it plays an important role in the transport of the zones through the capillary. In capillary electrophoresis the detector is generally situated near the cathode because of the omnipresent EOF. Since anions are also transported to the cathode when the velocity of their electrophoretic migration is less than the EOF, it is possible to separate cations and anions in one single analysis. In other CE techniques (e.g. in MEC) the EOF is used solely for the transport of the (in part uncharged) samples to the detector. The capillary surface can be chemically modified to control, eliminate, and even reverse the EOF. Measuring the magnitude of the EOF is the single means of determining changes at the capillary surface, for example, the irreversible adsorption of components of the sample. All other methods for the characterization of the surface fail because of the very low surface area ($< 10\ \mathrm{cm^2}$). Surface-modified capillaries show hardly any hysteresis effects when the buffer is changed, and because of the reduced adsorption they are extremely well suited for the analysis of proteins (see Section 4.2.2 "Chemically Modified Capillaries").

The addition of long-chain cationic detergents such as cetyltrimethylammonium salts, which are adsorbed at the silanol groups of the surface, makes a reversal of the EOF possible.[17] A detergent double layer is formed in which the positive charges are arranged in the direction of the electrolyte. Capillaries thus coated can be used for the separation of rapidly migrating inorganic ions.[18]

2.3. Band Broadening

The main contribution to band broadening in capillary chromatography is that due to the Hagen–Poiseuille flow profile. This contribution increases with the square of the diameter of the capillary and is inversely proportional to the diffusion coefficient of the sample in the electrolyte (Aris–Taylor equation or mass transfer term of the Golay equation[19]). Because of the slow radial diffusion in liquids the flow profile is not balanced, and capillary liquid chromatography is thus not possible with capillaries > 50 μm in diameter. The diffusion coefficients of samples in gases are larger by a factor of 10^4, however, and the parabolic flow profile is rapidly balanced out by radial diffusion. Capillary gas chromatography is thus a highly efficient separation technique. Since in CE the flow profile is piston-shaped as a result of the electroosmotic flow, the contribution of the flow profile to band broadening can be neglected, and only the longitudinal diffusion term must be taken into account.

The band broadening H can be calculated from Equation (6), where D is the diffusion coefficient of the sample in

$$H = \frac{2D}{u} = \frac{2D}{\mu E} \tag{6}$$

the electrolyte. Using the relation $H = L/N$ we can calculate the number of theoretical plates from Equation (7). U is the

$$N = \frac{\mu U}{2D} \tag{7}$$

voltage, which decreases along the length L of the column. It should be mentioned that the mobility μ of the ions is a combination of the electrophoretic mobility μ_{ep} and the electroosmotic mobility μ_{eo}. The number of plates increases with increasing voltage and decreasing diffusion coefficients of the samples (in contrast to HPLC, where the number of plates decreases rapidly with decreasing diffusion coefficients). Giddings[14] showed that at room temperature and across a wide range this relationship can be reduced to Equation (8). When voltages between 100 and 50000 V are em-

$$N = 20\ z\ U \tag{8}$$

ployed for the separation of ions with effective charges z between 1 and 10, it is possible to achieve up to 10 million

theoretical plates per meter. In this respect CE is clearly superior to HPLC. The mathematical expressions derived for chromatography have been adapted for the description of the band broadening in CE and can as such also be used to describe transport phenomena in the capillary. It should be mentioned, however, that in chromatography samples are always transported through the detector (after elution from the column and the consequent dilution) with the same velocity. In CE with on-column detection the migration rate of the samples at the detector window can vary. A comparison of the number of theoretical plates is thus not completely valid.

The high numbers of theoretical plates predicted have indeed been realized for the analysis of DNA molecules in gel-filled capillaries.[20] However, DNA molecules are a special case, since they do not interact with the capillary surface because of their negative charges. Such high numbers of plates have not yet been achieved for separations of proteins, although up to 500000 plates per meter have been obtained with coated capillaries. A slight degree of adsorption at the surface leads to local changes in the EOF and thus to a distortion of the piston-shaped profile. In addition, any adsorption leads to a decrease in mass transfer. The mass transfer term of the Golay equation can no longer be neglected, and the band broadening increases.

As mobility and the EOF increase with increasing voltage, the analysis time can be decreased. Because the sample spends less time in the column, band broadening decreases and the number of plates increases. When the voltage is increased, however, the buffer solution warms due to Joule heating. Heat transport occurs solely across the capillary wall, and a radial temperature (and thus viscosity) gradient is built up at right angles to the electrophoretic migration.[21, 22] Cooling the capillary increases the temperature gradient, but this is necessary in order to avoid degassing and local overheating. Viscosity differences between the center of the capillary and the capillary wall lead to migration differences, and thus to band broadening and loss of resolution.

The negative influence of this radial temperature gradient can only be reduced by reducing the inner diameter of the capillary. In a cylindrical tube the temperature difference between the center and the wall of the capillary increases with the square of the capillary diameter. This is the reason for the use of extremely narrow capillaries (diameter 25–100 μm) in CE. However, a decrease in the capillary diameter implies a reduction in the length of the light path and thus in the detection sensitivity (Lambert–Beer Law). Alternatively, Joule heating can also be reduced by reducing the buffer concentration and/or using buffers with lower ionic conductivity.

The reduction in the conductivity of the buffer is subject to limits. If there is a large difference between the conductivity in the buffer and sample zones, the induced local variations in the electrical field will lead to distortion of the zones and thus to a decrease in the separation efficiency. If the conductivity in the sample zone is greater than that in the carrier electrolyte, the diminished resistance will lead to a reduction in the field strength. The molecules at the maximum sample concentration will thus migrate more slowly than at the flanks of the peak. This leads to an extreme distortion of the zones, with a slow increase and a rapid falloff (leading). When conductivity in the buffer is greater than in the sample zone, peaks with a high degree of tailing are observed. Symmetrical peaks are obtained only when the conductivities are identical. The buffer concentration must thus be adjusted for the given separation problem (dissociation and mobility of the samples). In addition, mobility differences between sample ions and buffer ions can lead to isotachophoretic effects, which generally result in triangular peak forms that may cause integration problems.

The buffer concentration can be varied only within narrow limits. An increase in the buffer concentration leads to more Joule heating, which can be compensated for by lowering the voltage. This, however, increases the time required for the analysis and thus the time the sample spends in the capillary. As a result the increase in the longitudinal diffusion leads to a greater band broadening. In the optimization of the separation efficiency in CE it is thus necessary to take into account the influence of Joule heating, the conductivity differences between samples zones and electrolytes, and the detection sensitivity that can be achieved, in order to obtain high resolution with short analysis times.

3. Apparatus

Commercial capillary electrophoresis instruments have been available since 1988, and the number of suppliers is increasing. The various instruments are quite similar, since the actual separation system is very simple. Slight differences are found in the way in which the sample is introduced and in the number and type of detectors offered. We have no intention of surveying the market but intend to emphasize the typical requirements made on the various components of the apparatus.

3.1. Voltage Source

The voltage should be adjustable within the range from -30 to $+30$ kV and should remain constant at the value required. In addition it is useful to be able to adjust the voltage and current separately. When the voltage, or better the current, is monitored during the analysis it may be possible to localize any problems that may occur. In commercial instruments the high-voltage source shuts off automatically when the analysis compartment is opened to prevent accidents due to high voltage. Similar precautions must be taken when an apparatus is constructed in the laboratory.

3.2. Sample Introduction

The most difficult problem in capillary electrophoresis is reproducible sample introduction. The sample zone must be kept small to avoid band broadening; this requires the injection of very small sample volumes in the range 5–50 nL.[23–25] Excessively large sample volumes rapidly lead to peak distortions and loss of resolution.[26, 27] To meet these extreme requirements and for the manipulation of such small sample volumes, miniaturized[28, 30] and automated sample introduction[29–31] is indispensable. Reproducible introduc-

Table 1. Types of injection used in capillary electrophoresis.

	Electrokinetic injection	Hydrostatic injection	Hydrodynamic injection	Injection by sample splitting
Injection by	electric field	siphoning effect	pressure or vaccum	electrical sample splitter and split-flow systems
Automatization	yes	yes	yes	no
Smallest sample volume	$<10\,\mu L$ (multiple injection)	$<10\,\mu L$ (multiple injection)	$\approx 10\,\mu L$ (multiple injection)	$>10\,\mu L$ by dosing capillary or HPLC syringe (no multiple injection)
Discrimination effects with sample introduction	yes	no	no	yes (for electrical splitters) no (for flow split systems)
RSD values	4.1% (from ref. [30])	<2.9% (from refs. [30, 33])	2–3% (experimentally found)	<3% (ideal case for electrical splitter) (from ref. [34]) ≈2% (for split flow systems) (from ref. [35])

tion of the small sample volumes is an important requirement for quantitative analysis with acceptable standard deviations. The most important types of sample injection used in various commercial instruments are summarized in Table 1.

3.2.1. Electrokinetic Injection

In this injection method the sample vial into which the capillary dips is connected to the voltage source; a voltage is applied for a short interval causing the components of the sample to migrate into the separation capillary. The amount Q of the sample depends on the magnitude of the applied voltage U_i, the time t_i during which the voltage is applied, and the mobility of the components of the sample according to Equation (9),[30] where c is the concentration of the sample

$$Q = \frac{(\mu_p + \mu_{eo})\,\pi r^2 U_i t_i c}{8\eta L} \tag{9}$$

in the solution. This relationship makes clear the problem of this method of injection—the discrimination between sample components of differing mobilities. The electrical resistance of the sample solution (the ionic strength) relative to that of the electrolyte solution also affects the reproducibility of the procedure.[32] A relative standard deviation (RSD) of 4.1% for peak area measurements has been determined for automatic electrokinetic sample introduction.[30] In general it is possible to improve the reproducibility of quantitative analysis greatly by using an internal standard, as is the case for all procedures which are accompanied by problems with sample introduction (e.g. capillary gas chromatography).

3.2.2. Hydrostatic Injection

This method takes advantage of a difference in level between the buffer reservoir and the sample vial for the introduction of small sample volumes; the sample solution is introduced into the capillary by siphoning. The sample volume introduced depends on the difference in levels (generally 5–10 cm), the time, and the hydrodynamic properties (viscosity η, density ρ) of the electrolyte solution. Density and viscosity differences between the sample and the electrolyte solution can thus be neglected. The amount of sample introduced can be calculated by using Equation (10). The amount injected

$$Q = \frac{\rho g \pi r^4 \Delta h t_i c}{8\eta L} \tag{10}$$

thus depends only on the difference in levels and the injection time. Injection times of several seconds are normally used, and the level difference must be adjusted accordingly. Manual injection leads to poor reproducibility in quantification (RSD 10%), while with automatic, computer-aided injection RSDs of 2%[30] or better[33] can be achieved.

3.2.3. Pressure Injection

In this method the sample is injected by applying a pressure difference between the sample vial and the end of the capillary; to achieve this the pressure is either increased in the sample vial or reduced at the end of the capillary. These two possibilities also make it easy to rinse the capillary with fresh buffer solutions. The amount of sample introduced is calculated from Equation (11) and depends only on the pressure difference and the injection time. This is the most commonly used technique in commercial instruments. According to our experience the RSD lies between 2 and 3%; it can be reduced to below 1% when an internal standard is used.

$$Q = \frac{\Delta p \pi r^4 t_i c}{8\eta L} \tag{11}$$

3.2.4. Sample Splitters

Splitting systems analogous to those used in capillary gas chromatography have also been described for CE sample introduction; we can distinguish between electrical and hydrodynamic splitting systems. In the case of the electrical sample splitter (Fig. 5) the junction with the separation capillary is situated at the center of the dosage capillary. Since the field strengths applied to the two capillaries are unequal, the sample moves within two different current circuits; the splitting ratio is determined by the ratio of the two currents

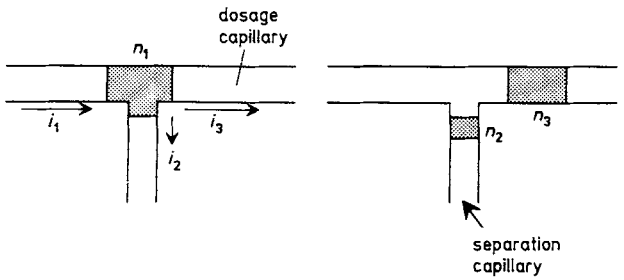

Fig. 5. Schematic diagram of an electric sample splitter. i_1, i_2, and i_3 denote the currents in the corresponding sections of the capillary; n_1 is the amount of sample prior to sample splitting, n_2 the amount introduced, and n_3 the remainder. Left: during sample splitting. Right: after the sample is split.

in the capillaries. The RSD for this method has been reported to be $<3\%$.[34] In the hydrodynamic splitting system an HPLC syringe is used to introduce the sample volume into a T-piece. The splitting ratio is determined by the ratios of diameter and length of the separation capillary and overflow capillary.[35] An RSD of approximately 2% has been reported for this technique, which requires, however, relatively large sample volumes. Other splitting systems, some of which use HPLC pumps,[36] have been described, but they have not provided better reproducibility.

3.2.5. Reproducibility of Sample Introduction

The reproducibility of sample introduction is influenced by a number of factors. Conductivity differences between the separation electrolyte and the sample solution,[37] large differences in the concentrations of the various components of the sample[33] and their electrophoretic mobilities,[38] and differences in the sample matrix[32] all affect the reproducibility. CE is the method of choice, however, when only very small sample volumes are available, for example, in the analysis of ions in drops of rainwater.[39] In commercial, automated instruments miniaturization of sample introduction is so advanced that a sample volume of 3 μL suffices for several injections.

The problems with the reproducibility of sample introduction in CE are due to the small pressure differences and short injection times required. When larger volumes are injected, the efficiency of the separation rapidly decreases. Attempts have therefore been made to introduce larger volumes and to sharpen the zones prior to the actual separation. This can be done by making use of isotachophoresis effects (ITP) prior to the actual CE separation, as will be described in Section 4.6. Samples may also be concentrated by means of transient increases in the field strength. This can be carried out most easily when a water "plug" is injected into the capillary prior to the actual sample introduction ("sample stacking").[40] The voltage decrease across the "nonconductor" water is so great that the following sample zone is concentrated in the much larger field present there. Enrichment factors of up to 100 have been achieved.

3.3. Thermostatting

The main purpose of thermostatting is to remove Joule heat. Both air and liquid thermostats are used in commercial instruments and allow the temperature to be controlled in the range from 15 to roughly 60 °C. For most applications intensive air cooling suffices.[41] The influence of temperature on efficiency and selectivity is at present still a subject of discussion.One reason for this is that in commercial instruments only the capillary (or sections thereof) is thermostatted, while the buffer reservoir is not always kept at the same temperature as the capillary. It has been shown, however, that for the separation of DNA fragments in gel-filled capillaries the actual separation performance decreases with increasing temperature, although the relative migrations, in other words the selectivity of the separations, can be increased.[42]

3.4. Capillaries

Polyimide-coated quartz capillaries 25 to 100 μm in diameter are generally used in CE. In principle glass or plastic capillaries could be used, though these are not sufficiently transparent in the short-wave UV range. The polyimide layer of the quartz capillaries must be removed at the site of the detector either mechanically or by burning off before the capillary is coated or used.[13] Capillaries with UV-transparent coatings have recently become available. Untreated and unmodified capillaries are used for most applications. The quartz capillaries obtained from different suppliers differ with respect to the precision and constancy of their internal diameter as well as to the treatment of the inner surface and the optical transmission in the lower wavelength region. It is thus advisable to treat new capillaries with 1 M NaOH prior to their initial use in order to obtain complete hydroxylation of the surface.

Surface modification of the capillaries can be carried out with the same methods described for the modification of silica gels for the preparation of stationary phases for HPLC or for coating capillary columns for gas chromatography. As already mentioned, changes in the EOF can be used to characterize modified capillary surfaces; characterization by gas-chromatographic techniques has also been described.[43] The advantages and disadvantages of modified capillaries and gel-filled capillaries will be discussed in combination with the various separation techniques for which they are used.

3.5. Detection

Detection is still the greatest technical problem in CE. Because of the short cell length (mean capillary diameter) the demands made on the detectors with respect to sensitivity, noise, stray light effects, etc. are extremely high. Nevertheless, modified UV detectors designed for HPLC are most frequently used. Detection is carried out directly in the capillary in order to avoid efficiency loss due to peak broadening outside the capillary. Typical bandwidths of the zone in the capillary are around 5 mm ($N = 500000$), which corresponds to a volume of 10 nL (for a 50 μm capillary). These extremely small volumes are also the reason for the mass sensitivity, which has often been referred to as astounding. The world record at present is a reported detection limit of 300 molecules with a signal-to-noise ratio of 3:1[44] for derivatized

amino acids detected by laser-induced fluorescence. Although concentration sensitivity is more important for routine use, it is restricted by the short absorption path (mean capillary diameter!). UV Detection in CE gives concentration limits that are 30 to 100 times lower than those in HPLC.[45] In the case of irradiation at right angles to the capillary axis the limit depends on the detector noise and the effective cell length, which is lower than the nominal value (the inner diameter of the capillary). Stray light effects due to inefficient focusing (light from the capillary wall!) and nonideal cylindrical capillary geometry[46] increase the background noise; these effects can be largely eliminated by optimization of the optics (slit, lens, etc.). The detector most often used is a UV detector with a fixed or variable wavelength. In spite of the short path length it is also possible to record UV spectra with sensitive diode array detectors[47,48] (see Fig. 14).

Samples that do not absorb in the UV can be detected with commercial instruments by means of indirect UV detection.[18,49-53] An electrolyte that absorbs in the UV whose mobility is similar to that of the sample to be separated is added to the buffer or is used as a buffer component. Because of the necessity for electroneutrality the amount of added electrolyte must be less where the sample migrates (displacement mechanism). As a result the buffer has a higher transmission, and a negative peak, as shown schematically in Figure 6, is recorded. Examples are given in Sections 4.1.4 and 4.2.1 in the description of ion analysis (Figs. 12 and 17). The detection sensitivity in indirect UV detection depends on the molar extinction coefficient of the added UV-absorbent background electrolyte and corresponds to that of normal UV absorption.[54]

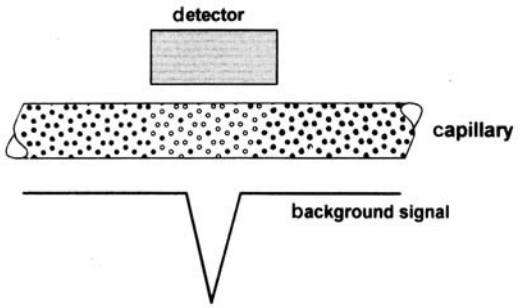

Fig. 6. Principle of indirect UV detection. • = UV-absorbing buffer ions; ○ = ionic sample components that are not UV absorbing.

In addition to UV detectors, fluorescence detectors have also recently become commercially available. The main difference between the two is the light source. Besides the usual deuterium and xenon flashlamps, much more complex laser systems are on the market. Since in the latter the excitation lies in visible range, samples must be derivatized accordingly. Indirect fluorescence detection is also possible and should become universally applicable when suitable fluorophores without quenching effects become available.[55-57]

Conductivity detection and other electrochemically based techniques appear promising but are as yet not commercially available. As a highlight we should mention the trace analysis of alkali metal and alkaline earth ions directly in the capillary by using microelectrodes.[58] The problem with conductivity detection is that the conductivity in the zone containing the substance to be analyzed is only slightly higher than that of the electrolyte. Suppression techniques for the reduction of the buffer conductivity such as those used in HPLC cannot be applied here. Conductivity detection in CE has already been described by a number of workers.[59-64] It has, for example, been possible by using amperometric detection to analyze neurotransmitters in nerve cells directly; the separation was carried out in 5 μm capillaries.[65-68]

Because of the low flow rates (100 nL min^{-1}), coupling CE with mass spectrometry also appears feasible. The main problem is that the transition from the capillary to the ion source, where high vacuum is necessarily present, must be constructed in such a way that the eluent is not sucked out of the capillary. A pressure drop of 1 bar leads to a linear flow velocity of 1 cm s^{-1} when applied to a capillary 1 m in length and with an internal diameter of 50 μm. The laminar parabolic flow profile thus induced would lead to a noticeable loss of efficiency; a "protective flow" must thus be applied around the capillary prior to ionization. Electrospray MS permits mass spectrometric detection of biopolymers by multiple ionization.[69-72]

Table 2. Detection methods in capillary electrophoresis.

Detection method	Detection limits absolute amount [mol]	concentration [mol/l]	Typical applications	Remarks
UV absorption	10^{-15}–10^{-13}	10^{-7}–10^{-4}	aromatic compounds, proteins, nucleic acids, ...	standard detection in CE (available in all commercial instruments)
Indirect UV absorption	10^{-16}–10^{-13}	10^{-8}–10^{-4}	metal ions, amines, organic and inorganic ions, sugars	possible with commercial instruments
Fluorescence	10^{-18}–10^{-13}	10^{-9}–10^{-4}	derivatized amino acids, DNA, peptides, proteins	derivatization necessary for many samples
Laser-induced fluorescence	10^{-21}–10^{-17}	10^{-13}–10^{-7}	DNA fragments, derivatized amino acids	lasers are still very expensive (use in VIS and near-UV)
Indirect fluorescence	10^{-16}–10^{-14}	10^{-7}–10^{-5}	alcohols, amines, anions, cations, sugars	only a few applications described
Amperometry	10^{-16}–10^{-14}	10^{-8}–10^{-6}	reducible or oxidizable substances, e.g., neurotransmitters	capillaries with inner diameters up to 2 μm can be used
Conductometry	10^{-18}–10^{-16}	10^{-7}–10^{-5}	ionic samples, e.g., metal ions, amines, carboxylic acids	changing capillaries is difficult
Potentiometry	10^{-19}	10^{-8}	alkali metal and alkaline earth ions; selective detection by ion-selective microelectrodes	use and preparation of microelectrodes difficult
Mass spectrometry	10^{-17}	10^{-8}	proteins, peptides, drug monitoring	interfaces commercially available, coupling with automated systems possible
On-line radioactivity measurements	10^{-18}–10^{-16}	10^{-10}–10^{-8}	^{32}P and ^{14}C in biochemically relevant compounds	good detection sensitivity using stop-flow systems

ism,[75] refractive index,[76] and capillary vibration[77]) have been described in the literature. It is not possible at present to estimate their suitability for routine use.

The limits of detection for the most frequently used detection systems are listed in Table 2. It is clear that excellent mass sensitivities can be achieved because of the small volumes involved. The concentration sensitivities lie in the range of those found for HPLC.

Chromophores can naturally be introduced into non-UV-active and nonfluorescing samples prior to the separation by using the standard derivatization reagents. Special reagents for electrophoresis that permit the simultaneous introduction of charges are a topic of discussion.[78-81]

4. Separation Techniques in Capillary Electrophoresis

4.1. Capillary Electrophoresis in Uncoated Capillaries

4.1.1. The Influence of the pH Value

The influence of the pH value on the transport of samples to the detector has two causes. Firstly, as already mentioned, a separation based on electrophoretic migration is dominated more or less by the EOF, whose magnitude is determined by the dissociation of the surface silanol groups. Secondly, the mobility of the ions is determined by their degree of dissociation in the carrier electrolyte and thus by its pH value. The separation can therefore be optimized by changing the pH value and the buffer. In the case of weak electrolytes the greatest migration differences, in other words the highest selectivities, are obtained when the pH value of the buffer lies between the pK_s values of the sample components, as is already known from classical electrophoresis. Nondissociated samples migrate through the capillary at the velocity of the EOF. As has been shown, the EOF also depends on the pH value and the other properties of the electrolyte, in particular on its ionic strength. The dependence of the EOF on the pH value in quartz capillaries is shown in Figure 4.

The possibilities provided by the combination of electrophoretic migration and EOF can be demonstrated on nucleotides. The EOF is directed towards the cathode, and the nucleotides migrate to the anode; triphosphates are the fastest because of their high charge. Even at high pH values (pH > 10) the EOF does not suffice to transport the triphosphates to the detector at the cathode. If the electrophoretic mobilities of the mono- and diphosphates are lower than the EOF, they will be transported to the detector and will reach it at different times. The separation of this type of sample is shown in Figure 7. Under these experimental conditions the vector component of the EOF is insufficient to transport the triphosphates, which migrate to the anode compartment. The triphosphates can be analyzed by reversing the polarity, while the di- and monophosphates are driven by the EOF in the opposite direction. The mobility can be varied by the addition of ion pair-forming substances in such a manner that all the nucleotides can be separated in one run.[82] The separation of anions with greatly different mobilities in one single analysis is also possible when the EOF is reversed by surface modification and simultaneous field reversal (see Fig. 16).

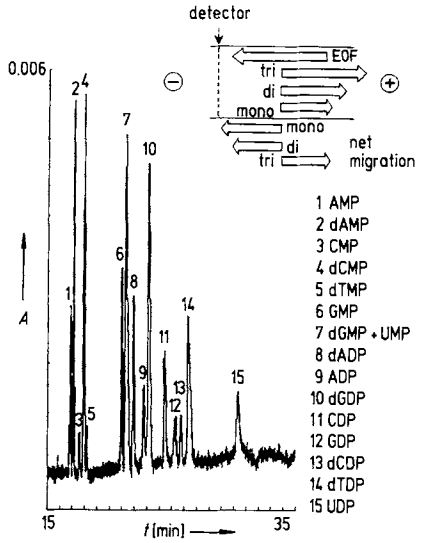

Fig. 7. Separation of mono- and dinucleotides with an untreated capillary. Conditions: capillary: $L = 75$ cm, $ID = 75$ μm, buffer: 100 mM CAPS (3-(cyclohexylamino)-1-propanesulfonic acid), pH 10.5; field: $E = 200$ V cm^{-1}, $I = 35$ μA; sample concentration: 100–250 mM. Trinucleotides migrate faster to the anode and cannot be detected.

4.1.2. The Influence of Ionic Strength

The lower the ionic strength, the lower the Joule heating of the electrolyte. On the other hand, the differences in the conductivity between the sample zone and the carrier electrolyte should be negligible. The larger the ionic strength of the electrolyte, the lower the EOF.

The influence of the ionic strength on the EOF and the mobility of the ions is shown in Figure 8a. In all cases the current is held constant. The neutral marker (benzyl alcohol) is eluted after about 15 minutes at a concentration of 100 mM,

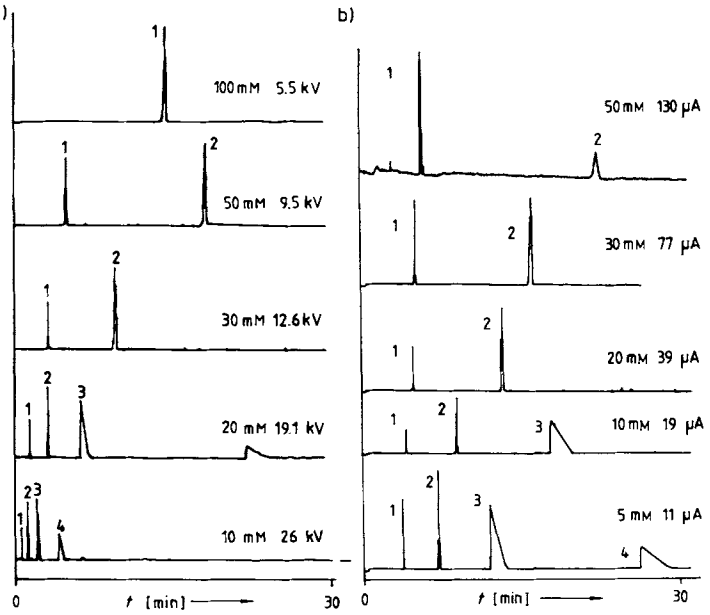

Fig. 8. Dependence of the EOF on the ionic strength of the buffer. Conditions: capillary: $L = 44$ cm, $ID = 75$ μm; buffer: borate solutions of various concentrations, pH 9.5; a) constant current (100 μA); b) constant field (230 V cm^{-1}). Sample: 1 = benzyl alcohol, 2 = benzoic acid, 3 = benzene-1,2-dicarboxylic acid, 4 = benzene-1,3,5-tricarboxylic acid.

while the carboxylic acids which migrate to the anode are not eluted. If the ion concentration is reduced to 20 mM the separation is complete after about 20 minutes, at 10 mM after 5 minutes. The analysis time is determined here by the size of the EOF, since the effective sample migration is almost independent of the buffer concentration. Because of their lower mobility with respect to the borate ions of the buffer, the di- and tricarboxylic acids migrate as asymmetrical peaks with tailing. Such triangular peaks are always observed when the mobility difference between the carrier electrolyte and the sample is too great.[8] Samples with mobilities greater than that of the buffer ion exhibit leading. Symmetrical peaks, and thus high numbers of theoretical plates, are obtained only when the mobilities of the sample and carrier electrolyte are equal. Analogous effects are observed when a constant voltage is used, as shown in Figure 8b. Comparison of Figures 8a and 8b clearly demonstrates the advantages of low buffer concentrations and high possible voltages: the analysis time can be reduced tremendously (Fig. 8a). Thus low buffer concentrations and high field strength are optimal.

Figure 9 shows the influence of the buffer concentration on the band broadening H of samples with different mobilities. Low band-broadening and high separation performance are observed for the neutral marker benzyl alcohol (breakthrough of the zone with EOF) and for the only weakly dissociated *p*-hydroxybenzoic acid even at a low buffer concentration (50 mM). At this buffer concentration the band broadening for the di- and tricarboxylic acids is intolerably high. Even at higher buffer concentrations the band broadening is not as low as that obtained for nondissociated or weakly dissociated samples.

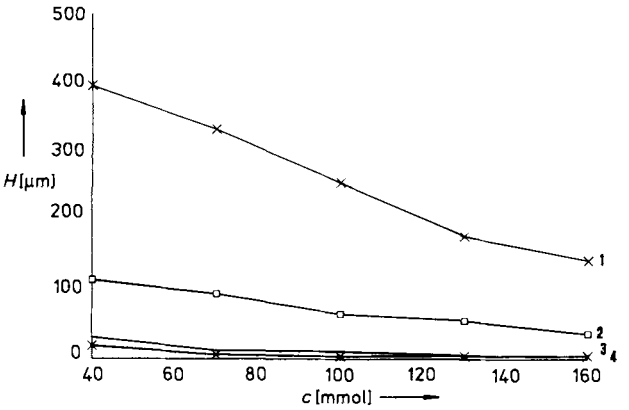

Fig. 9. Influence of the buffer concentration on the band width H. Conditions: capillary: L = 50/54 cm, ID = 50 µm; buffer: borate solutions of various concentrations, pH 8.5; field: E = 560 Vcm^{-1}; UV detection at 214 nm. Sample: 1 = benzene-1,3,5-tricarboxylic acid, 2 = benzene-1,2-dicarboxylic acid, 3 = *p*-hydroxybenzoic acid, 4 = benzyl alcohol.

4.1.3. Choice of the Buffer
