Several factors must be taken into consideration when choosing the buffer. As shown above, the mobilities must be equal in order to obtain a high separation performance. The concentrations of the buffer ions should be greater than the concentration of the ions in the sample solution; this also leads to sharply defined, symmetrical zones. However, high ionic strength implies a high current density for a given voltage gradient, and thus an increase in Joule heating. These effects can be simply measured in the form of deviations from Ohm's law, as shown in Figure 10 for two buffer systems and capillaries with different inner diameters. The advantage of organic buffers, which have low conductivities, can clearly be seen. Even for the thicker capillary Ohm's law is obeyed throughout the whole range for the buffer 3-(cyclohexylamino)-1-propanesulfonic acid (CAPS), while with the same capillary and a borate buffer the range of linearity only extends up to 10 kV. The advantages of the thinner capillaries for heat transport can also be seen for the borate buffer; it is still possible to work at 25 kV with the 50 µm capillary. It is also possible to achieve shorter analysis times, since these are inversely proportional to the applied field strength.

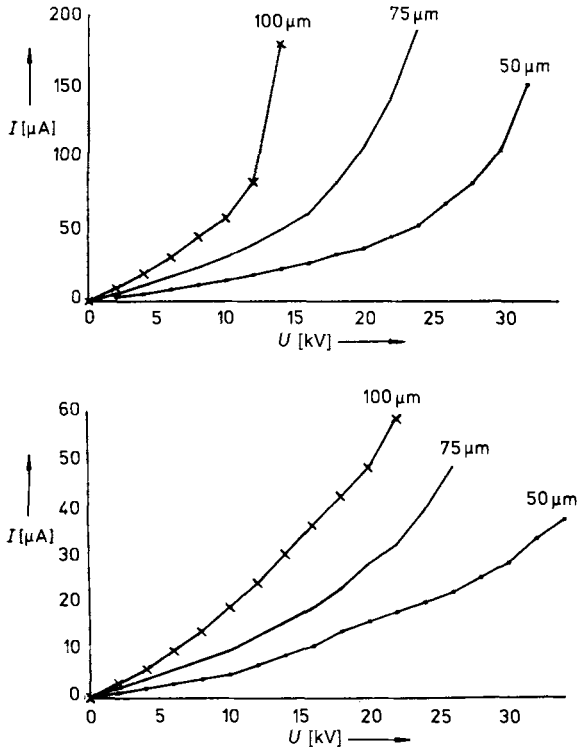

Fig. 10. Current–voltage dependence as a function of the capillary diameter and the buffer concentration. Top: buffer: 20 mM borate, pH 9.5. Bottom: buffer: 25 mM CAPS, pH 11.0.

4.1.4. Areas of Application

Electrophoresis in uncoated capillaries is the standard technique particularly suitable for the separation of small molecules with permanent charges. Thus it is possible to separate aliphatic and aromatic carboxylic acids, sulfonic acids, amino acids, phenols, nucleotides, and amines without great difficulty. A good survey of recent applicatons is available in the two articles written by Kuhr.[83, 84] An example of a separation of sugars and sugar acids is shown in Fig-

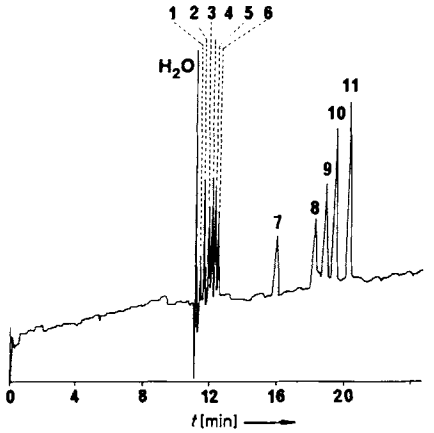

Fig. 11. Separation of carbohydrates by CZE. Conditions: capillary: $L = 100/122$ cm, $ID = 50$ μm; buffer: 6 mM sorbate, pH 12.1; field: $E = 203$ Vcm^{-1}, $I = 13$ μA; $T = 30$ °C; UV detection at 256 nm; CE instrument: ABI model 270A. Sample: 1 = raffinose, 2 = 2-deoxy-D-ribose, 3 = galactose, 4 = glucose, 5 = rhamnose, 6 = mannose, 7 = *N*-acetylneuraminic acid, 8 = gluconic acid, 9 = galacturonic acid, 10 = glucuronic acid, 11 = mannuronic acid (from ref. [85]).

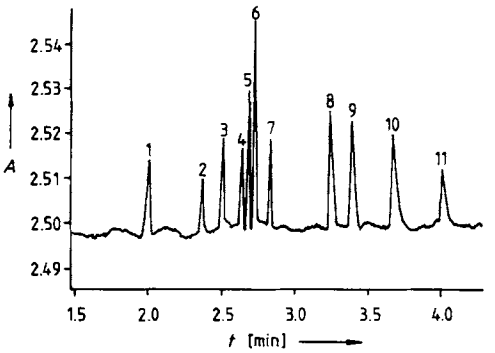

Fig. 12. Separation of metal ions, amines, and amino alcohols (indirect UV detection). Conditions: capillary: $L = 50/58$ cm, $ID = 75$ μm; buffer: 5 mM imidazole, pH 4.5; field: $E = 430$ Vcm^{-1}, $I = 9$ μA. Sample: 1 = NH_4^+, K^+, 2 = Na^+, 3 = dimethylamine, 4 = Ca^+, 5 = trimethylamine, 6 = Mg^{2+}, 7 = Li^+, 8 = diethylamine, 9 = triethylamine, 10 = diethanolamine, 11 = triethanolamine. Sample concentrations: 1–3 ppm (from ref. [51]).

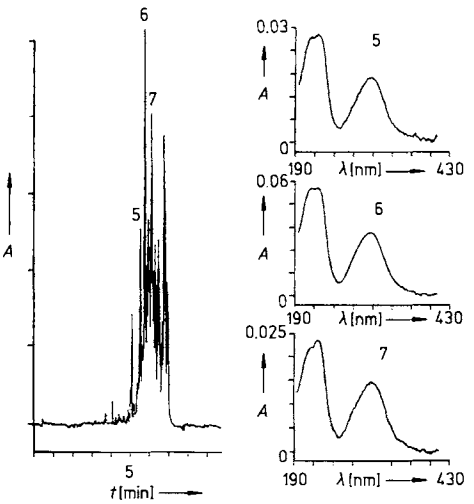

Fig. 13. Separation of tannic acids and their characterization (diode array detection). Spectra are shown for the marked peaks. Conditions: capillary: $L = 50/80$ cm, $ID = 75$ μm; buffer: 50 mM borate, pH 9.5; field: $E = 375$ Vcm^{-1}, $I = 32$ μA. Detection: Perkin Elmer LC-480.

ure 11;[85] Figure 12 shows the separation of cations and lower aliphatic amines with indirect UV detection. Imidazole is used here as both an electrolyte component and a UV absorber.[51] Figure 13 shows the CE of a natural tannin mixture. The separation of charged molecules with relatively large hydrophobic residues can be improved by the addition of SDS, as is demonstrated in Figure 14a with aromatic sulfonic acids. The resolution of the fast migrating components is only possible in the presence of SDS; the migration of the letter acids is, as expected, not influenced by the SDS. The scope for the optimization of CE separations by adding detergents will be discussed in detail in Section 4.5, which deals with micellar electrokinetic chromatography. The per-

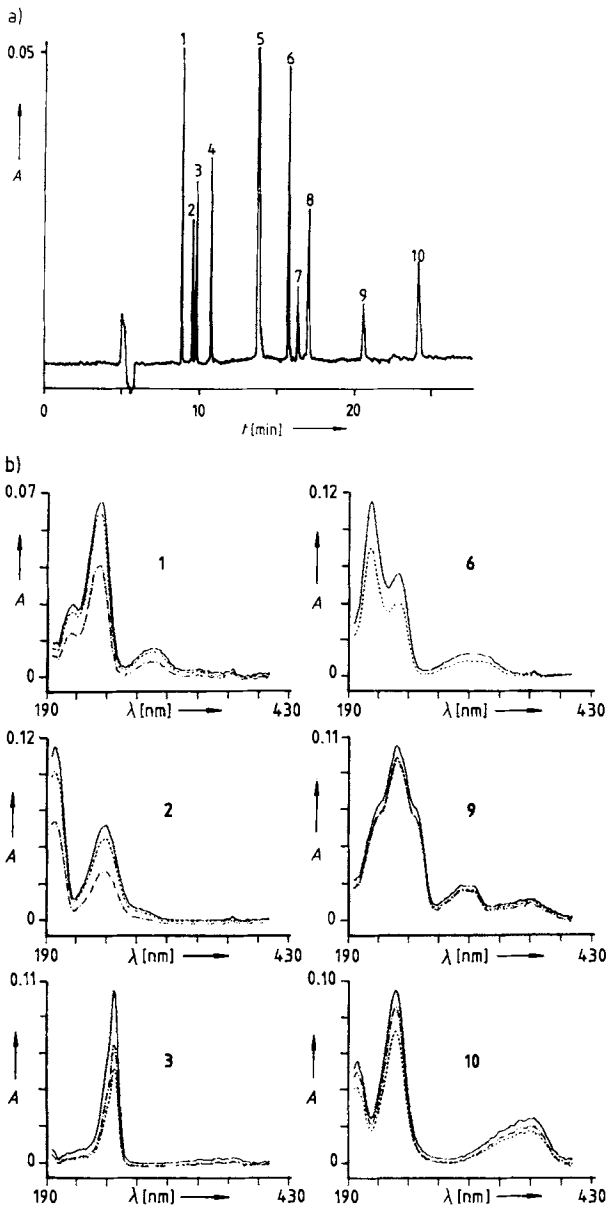

Fig. 14. Separation of aromatic sulfonic acids and their characterization (diode array detection). a) Conditions: capillary: $L = 50/80$ cm, $ID = 75$ μm; buffer: 59 mM borate, 50 mM SDS, pH 9.5; field: $E = 310$ Vcm^{-1}, $I = 39$ μA. Sample: 1 = 2-naphthylamine-6-sulfonic acid, 2 = sulfanilic acid, 3 = benzenesulfonic acid, 4 = anthracene-2-sulfonic acid, 5 = 1-naphthylamine and 2-methylnaphthylene, 6 = 1-hydroxymethyl-2-naphthol-6-sulfonic acid, 7 = 2-naphthol-6-sulfonic acid, 8 = R-acid, 9 = G-acid, 10 = H-acid. b) Spectra for the given components. Detection was carried out using a Perkin Elmer LC-480 adapted for capillary electrophoresis.

formance of diode array detectors (DAD) in capillary electrophoresis is also demonstrated in Figures 13 and 14b. Purity determination by means of UV spectra recorded at the peak maxima and (for overlapping peaks) at the points of inflection is possible even for the sharp, narrow peaks obtained in CE; Figure 14b shows the overlap observed for the on-line UV spectra of the acids.

4.2. Capillary Electrophoresis in Surface-Modified Capillaries

The EOF can be controlled by chemical modification or dynamic coating of the capillary surface. The possibility of the absorption of sample components at the capillary surface is simultaneously reduced and the reproducibility of the analysis improved. Surface-modified capillaries are, for example, absolutely necessary for the analysis of proteins.

4.2.1. Dynamically Modified Capillaries

The simplest method of modifying the surface of quartz capillaries is to add to the buffer solution a component which will be preferentially adsorbed by the surface silanol groups. The resulting layer influences the EOF and also reduces the absorption due to hydrophobic or electrostatic repulsion.

As shown in Figure 15, the use of cationic detergents leads to the formation of a double layer in which the positive charges are directed towards the interior of the capillary; the EOF is reversed as a result. This technique also permits the

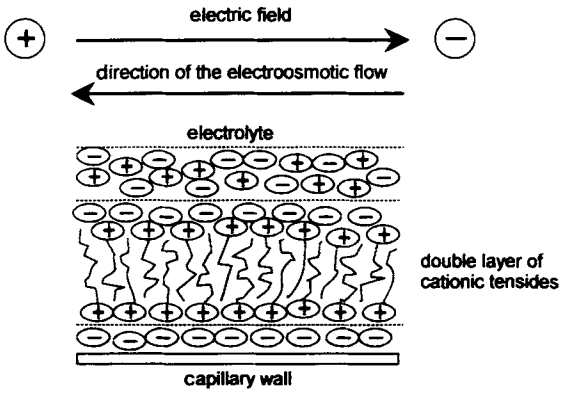

Fig. 15. Schematic representation of EOF reversal induced by cationic detergents.

separation of rapidly migrating anions when the field is also reversed,[117] as is shown schematically in Figure 16; this should be compared with the case demonstrated in Figure 7, in which the EOF is directed towards the cathode and the rapidly migrating triphosphates migrate to the anode. It was possible to detect the latter by means of polarity reversal, though the slowly migrating anions were no longer observed. If the EOF is also reversed, both rapidly and slowly migrating anions can be detected and determined in one single analysis. Figure 17 demonstrates this for the analysis of inorganic and organic anions in the ppm range with indirect UV

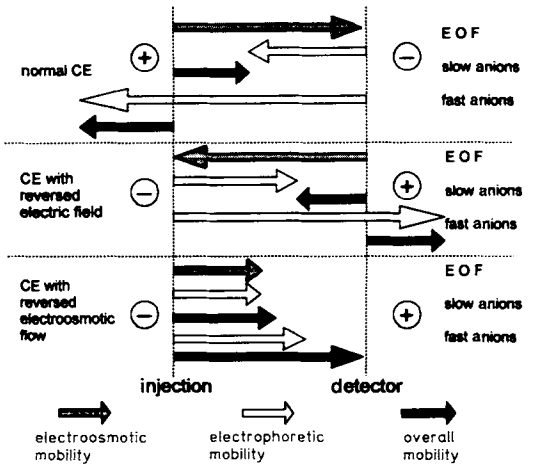

Fig. 16. Migration of ions with normal and with reversed EOF.

detection. Chromate is used as the UV absorber,[118] and the capillary is coated with cetyl trimethylammonium bromide, for example. Care must be taken that the critical micellar concentration is not exceeded when the detergent is present.

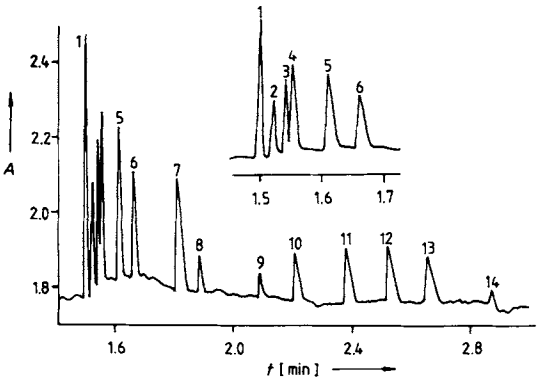

Fig. 17. Separation of inorganic and organic anions. Conditions: capillary: $L = 42/50$ cm, $ID = 75$ μm; buffer: 5 mM chromate, 0.5 mM hexadecyltrimethylammonium bromide (dynamic coating), pH 8.1; field: $E = 600$ Vcm^{-1}. Sample: 1 = bromide, 2 = chloride, 3 = sulfate, 4 = nitrite, 5 = nitrate, 6 = azide, 7 = fluoride, 8 = phosphate, 9 = carbonate, 10 = acetate, 11 = propionate, 12 = butyrate, 13 = valeriate, 14 = D-gluconate.

Positive surface charges are also used in the separation of proteins. The adsorption of cationic proteins is hindered by the electrostatic repulsion achieved either by adding detergents[92] or by coating the capillary surface with ethylene imine, which can also be cross-linked at the surface.[108] A high number of theoretical plates is achieved, and symmetrical peaks are observed for basic proteins. When lower polyamines are added to the buffer[90] the adsorption of proteins at the capillary surface can be reduced. The efficiencies are high, though the field strength must be kept low because of the high intrinsic conductivity of the buffer. Since the EOF is also decreased, the analysis times are relatively high. Figure 18 shows, as an example, the separation of standard proteins. Table 3 lists the separation systems generally used for the separation of proteins in uncoated capillaries.

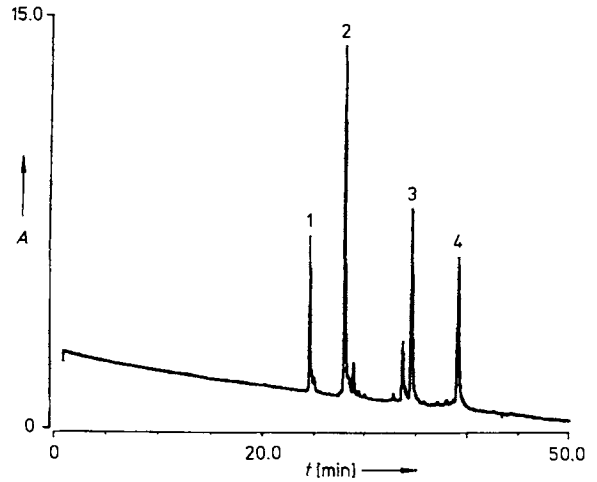

Fig. 18. Separation of basic proteins in an untreated capillary. Conditions: capillary: Polymicro, $L = 55/75$ cm, $ID = 50$ μm; buffer: 50 mM phosphate, 40mM 1,3-diaminopropane, 20mM K_2SO_4, pH 3.5; field: $E = 200$ Vcm^{-1} (from refs. [90, 113]). Sample: 1 = cytochrome C, 2 = lysozyme, 3 = ribonuclease, 4 = chymotrypsinogen.

4.2.2. Chemically Modified Capillaries

The techniques developed for gas chromatography (polymer coating) and methods used for the modification of silica gel surfaces (silylation reactions, surface polymerization) have been applied to the modification of capillaries for use in electrophoresis. Table 4 contains a list of the most important coating methods, and their main areas of application, and the stability ranges of the coatings. The greatest limitation of the coatings prepared by silanization is their limited stability at higher pH values, a fact which is painfully well known from HPLC. The disadvantage of polymer coatings is their extreme hydrophobicity, which has led to the widespread use of such phases for protein separation in the presence of nonionic or zwitterionic[91] detergents. As already mentioned, the coating and its stability can be most easily characterized by the reduction or constancy of the EOF.

In analogy to classical electrophoresis, acrylamide coatings have often been used for the separation of proteins by CE;[16, 103–105] these coatings are often described as "linear acrylamide". Figure 19 shows the separation of the same standard proteins as in Figure 18 with a polyacrylamide-coated capillary. In spite of the considerably reduced EOF it

is possible to work at normal field strengths, so that the separation is complete after about 5 minutes. A further advantage of coated capillaries lies in the greater constancy and reproducibility of the EOF. A disadvantage is their reduced stability at high pH values (pH > 7). The use of ionic coatings[108, 113] can in addition lead to a pH-independent flow or to a reversal of the EOF.

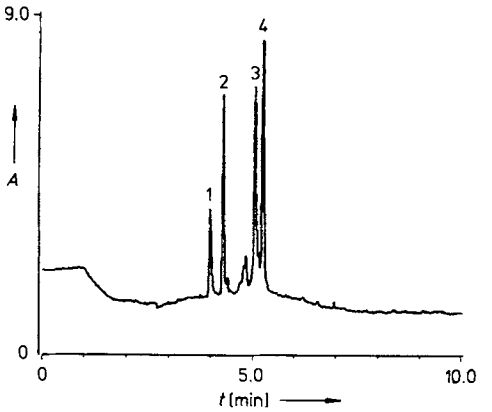

Fig. 19. Separation of basic standard proteins in a capillary coated with linear polyacrylamide. Conditions: capillary: $L = 31/48$ cm; buffer: 30 mM citrate, pH 3.0; field: $E = 410$ Vcm^{-1}. Sample: 1 = cytochrome C, 2 = lysozyme, 3 = ribonuclease A, 4 = chymotrypsinogen [$c = 0.2$ mg mL^{-1}].

As shown in Figures 18 and 19, the separation of proteins can be carried out successfully with both dynamically and permanently coated capillaries. Apart from the general remarks made here, no conclusion as to the advantages and disadvantages of the two separation techniques is possible at present.

Apart from protein separation, the main area of application of coated capillaries is in micellar electrokinetic chromatography (MEC), where the EOF must be reduced to

obtain long residence times in the capillary.[100, 111] When gel-filled capillaries are used, the EOF must be eliminated by capillary coatings in order to keep the gel stationary. Enantiomers could be separated with a capillary coated with a polysiloxane containing cyclodextrin groups,[112] although interactions with the capillary surface otherwise always lead to extreme losses in efficiency.

4.3. Isoelectric Focusing (IEF)

In classical electrophoresis, IEF is a highly efficient separation process, and it can also be used for the determination of the isoelectric points of proteins. A pH gradient is established along the separation pathway in an ampholyte-stabilized gel.[114] In this pH gradient a protein migrates only as long as it is charged and stops at the pH value corresponding to its isoelectric point (pI). The ampholytes are either added to the buffer or covalently bound to the gel.[115–118] This is necessary for the stabilization of the pH gradient because of the relatively long analysis times. The pH gradient is established before the sample is introduced by applying a voltage. Stabilizing gels are not required for the transfer of IEF in the capillary; however, the EOF must be reduced or completely eliminated in order to allow formation of the pH gradient.[119–122] This can be done either by coating the capillary surface or by increasing the viscosity of the buffer solution by adding highly viscous polymers (e.g. hydroxymethylcellulose).[123] The latter is particularly useful, since IEF requires the use of very high pH values.

In contrast to flatbed IEF, in CE the formation of the pH gradient in the capillary and the focusing of the proteins is carried out in one step. The capillary is filled with the solution of the samples in the ampholyte mixture; dilute sodium hydroxide is introduced into the capillary at the anode side and phosphoric acid at the cathode side. A high current flows when the voltage is first applied. The end of the focusing is evident by the reduction in the current to a constant low value. After the sample has been focused (and thus separated) in the capillary, it must be transported to the detector. This is generally carried out by exchanging the cathode electrolyte for a NaOH–NaCl solution, which destroys the pH gradient, mobilizes the focused proteins, and allows their transport to the detector.[124] Since the focusing occurs throughout the whole capillary, also between the detector and the cathode, proteins with extremely high pI values cannot be detected by this method. This can be prevented by filling the capillary with NaOH beyond the detection site. An example demonstrating the scope of IEF in capillaries is shown in Figure 20.

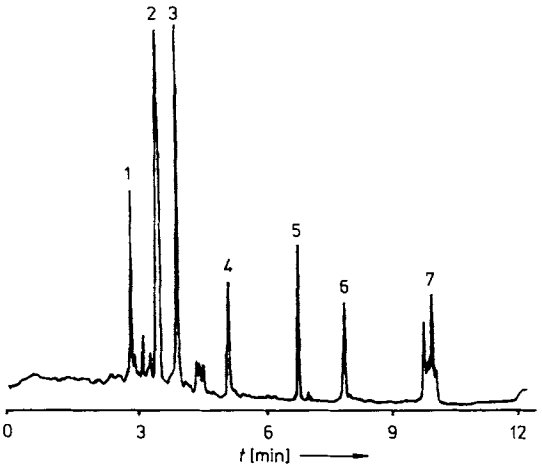

Fig. 20. Isoelectric focusing of a protein standard mixture (pI 5.1–7.5). Conditions: capillary: $L = 12$ cm, $ID = 25$ mm, coated capillary; buffer: Bio-Lyte ampholyte, pH 3–10 (catholyte: 0.01 M phosphoric acid, anolyte: 0.02 M NaOH); mobilization with 0.08 M NaCl and 0.02 M NaOH; voltage for focusing and mobilization: 7 kV; UV detection at 280 nm (0.1 AUFS) (Application Note 31, BioRad). Sample: 1 = human hemoglobin C, 2 = human hemoglobin A, 3 = equine myoglobin, 4 = equine myoglobin (minor band), 5 = human carbonic anhydrase, 6 = bovine carbonic anhydrase, 7 = β-lactoglobulin B.

4.4. Capillary Gel Electrophoresis (CGE)

The enormous growth in popularity of capillary electrophoresis and the introduction of commercial instruments were induced by the American Human Genome Project. DNA fragments from sequencing reactions, restriction fragments, etc. have been separated almost solely by CGE.[20, 125, 126] Of the various types of gels used in classical flatbed gel electrophoresis, acrylamide,[127] agarose,[128, 130] and cellulose[129] are generally used as the matrix in CGE. The prerequisite for the stability of the gel in the capillary is the complete elimination of the EOF. This can be achieved by coating or chemically modifying the capillary wall.[103, 104] Initially the gel was often cross-linked with the surface coating during the polymerization in the capillary.[20, 131] The selectivity of the gels was varied by changing the ratio of the acrylamide monomer concentration (% T) to the concentration of the cross-linker (% C). The remarkable separation performance of these capillaries is demonstrated in Figure 21.[132, 133] The number of theoretical plates amounts to several million and increases with increasing migration time.[133] This apparent contrast to the situation in chromatography shows that apparently only the longitudinal diffusion contributes to the band broadening, and that at least for CGE Equation (6) correctly describes the dependence of the number of plates on the diffusion coefficient.

In practice these fixed gels had some disadvantages. They dried out very rapidly at the ends of the capillary (bubble formation) and were thus of no further use. An exchange of the buffer in the capillaries was either impossible or required a great deal of time. The thermal stability of such gels was also poor, and commercial applications could not be realized. The preparation of these capillaries requires a great deal of skill in the modification of the surface and, in particular, in carrying out the polymerization in the capillary.[132, 134]

These problems can be avoided when the capillary is filled with a solution of a high molecular weight, water-soluble polymer instead of polymerizing cross-linked gels directly in the capillary.[135, 136] "Linear polyacrylamide" (0% C) is also used for this purpose.[42] The polymers are introduced into the buffer reservoir, and the capillaries are filled by the application of pressure. The EOF must, of course, also be eliminated, so that the gel remains stationary in the capillary during the separation; any flow reduces the efficiency of the separation. The selectivity of very high molecular weight "linear gels" (e.g. 12% T) is similar to that of cross-linked gels

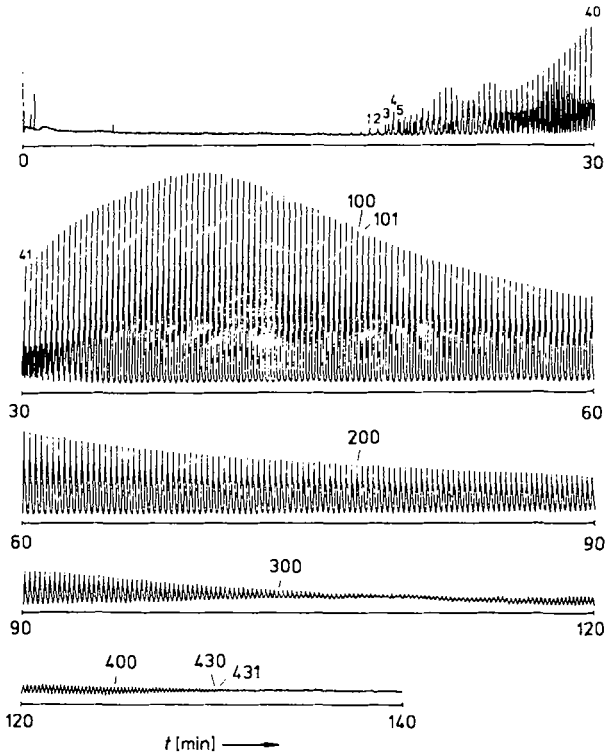

Fig. 21. Separation of poly(uridine-5'-phosphate). Conditions: capillary: L_{eff} = 45 cm, ID = 100 μm; gel: polyacrylamide 6% T, 5% C; buffer: 0.1 M Tris/0.25 M boric acid/7 M urea; field: E = 300 Vcm^{-1}, I = 12 μA; injection: 5000 V, 2 s; UV detection at 260 nm (taken from ref. [132]).

polymerized in the capillary. Figure 22 shows the separation of restriction fragments (PBR 322) in a capillary filled with "linear gel" (3% T, 0% C).[137] Here the number of theoretical plates is greater than 600000 plates per meter. At such high plate numbers the capillaries should not be coiled, since this reduces the efficiency.[138] As already mentioned, the separation of DNA fragments in gels is temperature dependent. As a comparison between Figures 22 and 23 (the same separation carried out at 20 and 50 °C) shows, the selectivity increases with temperature, particularly for higher molecular

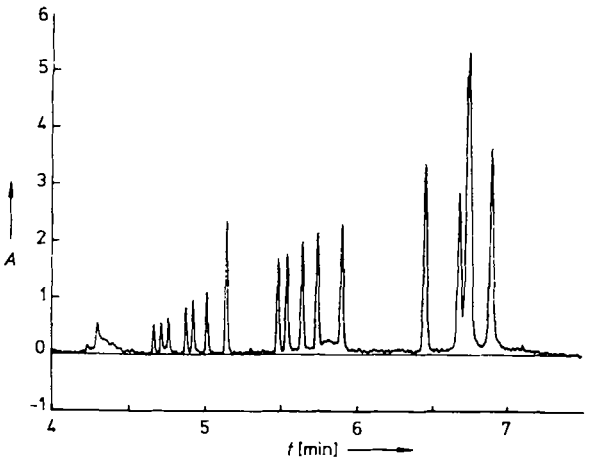

Fig. 22. Separation of DNA restriction fragments with "liquid gels". Conditions: capillary: L = 20/27 cm; buffer: 100 mM Tris-borate buffer, pH 8.3, 3% (w/v) linear polyacrylamide, capillary coated with linear polyacrylamide; field: E = 300 Vcm^{-1}; UV detection at 254 nm, T = 20 °C. Sample: pBR 322 Hae III restriction fragments. Apparatus: Pace System, Beckman Instruments.

weight fragments, and the separation improves although the number of plates decreases with increasing temperature. Theory and practice agree here, too. Apart from linear polyacrylamides, hydroxyethylcellulose has also been used successfully for the separation of restriction fragments.[135, 139]

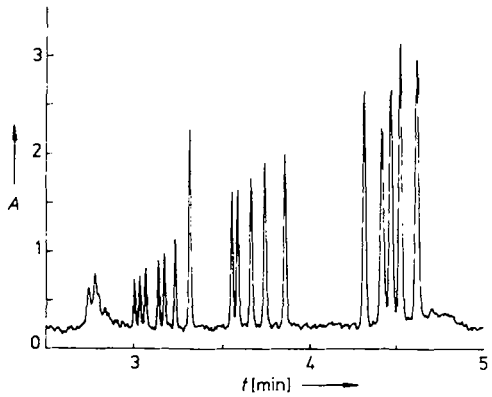

Fig. 23. Temperature influence on the separation of DNA restriction fragments. Conditions as in Figure 22; T = 50 °C.

CGE has been used almost solely for the separation of DNA fragments. The sensitive detection of proteins in gel-filled capillaries at low wavelengths (< 230 nm) in the UV is not possible, as acrylamides are not optically transparent below 250 nm; cellulose derivatives should be useful here. Interactions between the proteins and the gels may also play a role, since until now only the successful separation of proteins denatured with SDS in gel-filled capillaries has been described.[138, 140, 141] Only laser-induced fluorescence has been used for detection in the DNA sequencing, because the amounts of sample available are very small; the limit of detection lies at 10^{-11} M.

4.5. Micellar Electrokinetic Chromatography (MEC)

In CE any uncharged molecules present are eluted between the cations and the anions and are not separated. The addition of anionic detergents to the buffer (SDS is generally used) leads to the formation of micelles around the uncharged molecules; since the micelles carry a negative charge, they migrate to the anode.[142, 143] If the capillaries are not coated, and the EOF is larger than the rate of migration of the micelles, they will also be transported to the detector at the cathode. In this case the effective rate of migration of the sample components is equal to the vector sum of the electrophoretic migration to the anode and the electroosmotic velocity. Since micelles always migrate with almost the same rate, the separation is due to the distribution of the uncharged molecules between the buffer solution and the interior of the micelles; this is shown schematically in Figure 24. Chromatography is indeed the correct term here, as the mechanism leading to the separation of the uncharged molecules is based on a distribution equilibrium. In the case of ions this distribution process is superimposed on the actual electrophoretic migration.

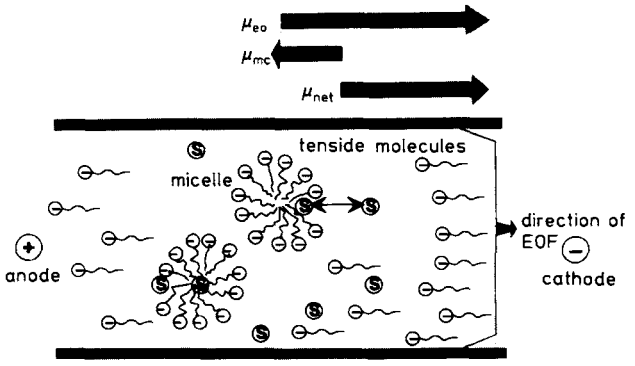

Fig. 24. Schematic representation of micellar electrokinetic chromatography (MEC). S = sample components. μ_{eo} = electroosmotic mobility, μ_{mc} = micelle mobility; μ_{net} = net mobility.

Optimization strategies for the MEC method will be demonstrated below with the example of the separation of fluorenylmethyloxycarbonyl (Fmoc) derivatives of amino acids. The separation of eleven Fmoc amino acids is shown in Figure 25. Because of the relatively large contribution made by the neutral derivatizing reagent, which is the same for all the samples, the electrophoretic mobility of the derivatives is very similar and almost no separation is observed. The addition of SDS to the buffer leads to a much better separation of the Fmoc amino acids (Fig. 26) under otherwise identical conditions. The addition of an organic component to this buffer can lead to a further improvement in the separation. The separation shown in Figure 27 was carried out under conditions identical to those in Figure 26 but with methanol added to the buffer. This additive has an influence on the distribution equilibrium of the sample between the buffer and the micelles, changes the EOF, and affects the solubility of the sample in the buffer.[144]

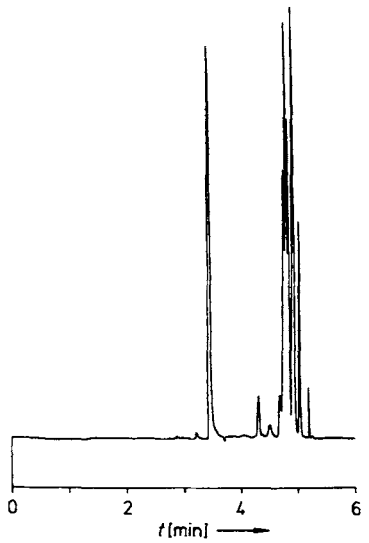

Fig. 25. Separation of eleven Fmoc amino acids by CZE. Conditions: capillary: Chrompack, L = 50/75 cm, ID = 50 μm; buffer: 50 mM borate, pH 9.5; field: E = 330 Vcm^{-1}; UV detection at 200 nm. Sample: Fmoc amino acids.

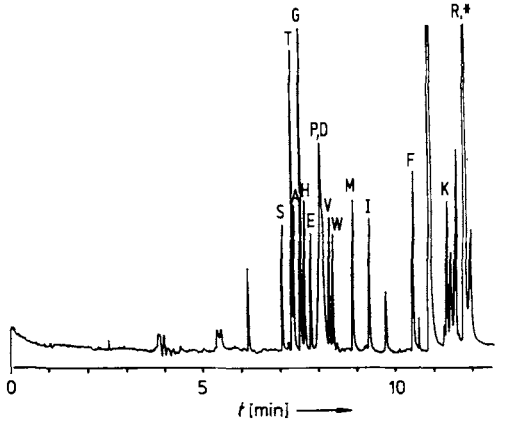

Fig. 26. Separation of 16 Fmoc amino acids by MEC. The peaks are identified by the one-letter-code for amino acids; * = system peak. Conditions: buffer: 50 mM borate, pH 9.5, 50 mM SDS; otherwise as in Figure 25.

Besides anionic detergents and organic solvents, neutral or charged components such as urea, zwitterions, and other sources of ion pairs may be added to the buffer. As the separation is based on distribution equilibria, it is naturally also temperature-dependent. Of course high concentrations of organic components cannot be used, since hardly any micelles will be formed. However, separation is still possible when the concentration of the detergent is in the submicellar range. It was possible to separate chiral compounds by adding chiral components such as alkylated amino acid derivatives and cyclodextrins to the SDS-containing buffer.[145-147] Such a system was also used to separate polycyclic aromatic hydrocarbons by MEC.[148] High concentrations of urea and cyclodextrins were used to improve the solubility of the aromatic compounds in the aqueous buffer. A typical example of the application of MEC for the separation of neutral molecules is shown in Figure 28. Since the variations with respect to both the samples to be separated and the organic additives to the aqueous buffer system appear to be unlimited, MEC is an extremely versatile technique. A very

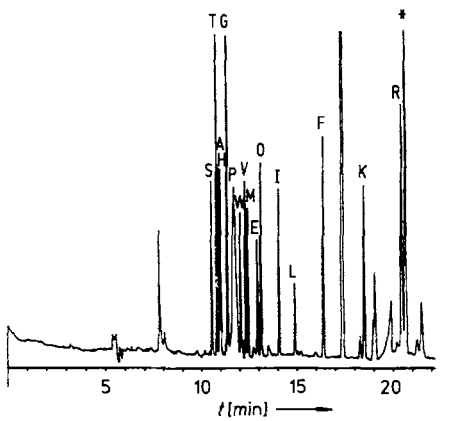

Fig. 27. Separation of 16 Fmoc amino acids by MEC with methanol as buffer additive. For peak identification see Figure 26. Conditions: buffer: 50 mM borate, pH 9.5, 50 mM SDS, 10% methanol (v/v); otherwise as in Figure 25.

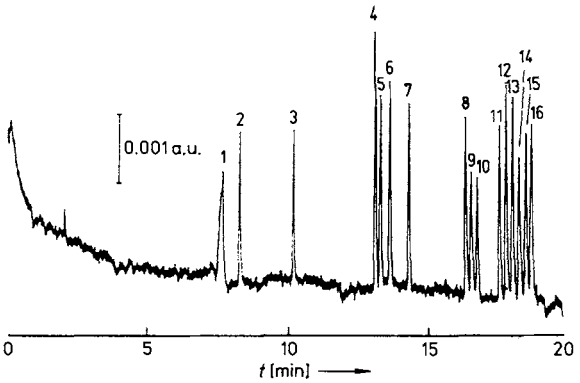

Fig. 28. Separation of phenols by MEC. Conditions: capillary: $L = 65$ cm, $ID = 50$ µm; buffer: 1 mmol SDS in 20 mM borate-phosphate buffer, pH = 7.0; field: $E = 300$ Vcm^{-1}, $I = 28$ µA; UV detection at 270 nm, $T \approx 25$ °C. Sample: 1 = water, 2 = acetylacetone, 3 = phenol, 4 = *o*-cresol, 5 = *m*-cresol, 6 = *p*-cresol, 7 = *o*-chlorophenol, 8 = *m*-chlorophenol, 9 = *p*-chlorophenol, 10 = 2,6-xylenol, 11 = 2,3-xylenol, 12 = 2,5-xylenol, 13 = 3,4-xylenol, 14 = 3,5-xylenol, 15 = 2,4-xylenol, 16 = *p*-ethylphenol (from ref. [142]). a.u. = absorption units fall scale.

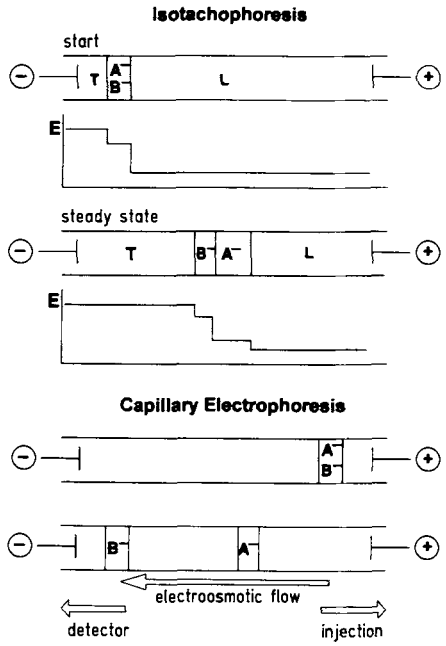

Fig. 29. Schematic comparison of ITP and CZE.

recent monograph[149] provides an excellent survey of its wide range of applications.

4.6. Isotachophoresis (ITP)

While the electrophoretic separation techniques with capillaries that we have described so far correspond to elution chromatography (discontinuous sample introduction, constant eluent composition, different rates of migration for the sample components), ITP[150] corresponds to displacement chromatography. In both cases all the components of the sample migrate with the same velocity. ITP was described many years ago and was at that time carried out in Teflon tubes. The method did not find wide use as an analytical technique because of the problems associated with the selection of suitable electrolytes. In ITP the sample is introduced between two electrolytes of different ionic mobility; these must be chosen in such a way that they limit the mobility range of the components of the sample. In general the lead electrolyte has the highest and the terminating electrolyte the lowest mobility of all the migrating ions. All ions with the same charge migrate at an equal rate when the stationary state is achieved.[151, 152] This is shown schematically in Figure 29 and compared with the potential variation in CE. For ITP the field strength is different in each zone but constant within each zone; the field jumps suddenly at the zone boundary. Thus in ITP only ions with the same charge are separated. The concentration dependence of the sample zones can be described by a square-wave function. As in displacement chromatography, the zones follow one another directly. A step-shaped signal is obtained when a conductivity detector is used.

ITP has been used mainly for the separation of inorganic ions and of organic carboxylic acids. The method is not widely used because of detection problems and the difficulty of finding suitable electrolytes for samples of unknown composition. One specific problem is that the separation of proteins and other complex mixtures requires suitable spacers, electrolytes with migration rates between those of the sample components, for better separation of the zones. Because suitable spacers are not available, ITP has hardly been used in bioanalytical work. Like displacement chromatography, ITP causes dilute samples to be concentrated and is thus useful as a concentration process prior to a CE separation.[153–156] Problems arising from the dosage of relatively large volumes of dilute samples can thus be overcome. The concentration step can be carried out directly in the separation capillary used for CE. A short zone of the lead electrolyte is introduced into the capillary filled with the separation electrolyte; then the sample is injected. Sample volumes

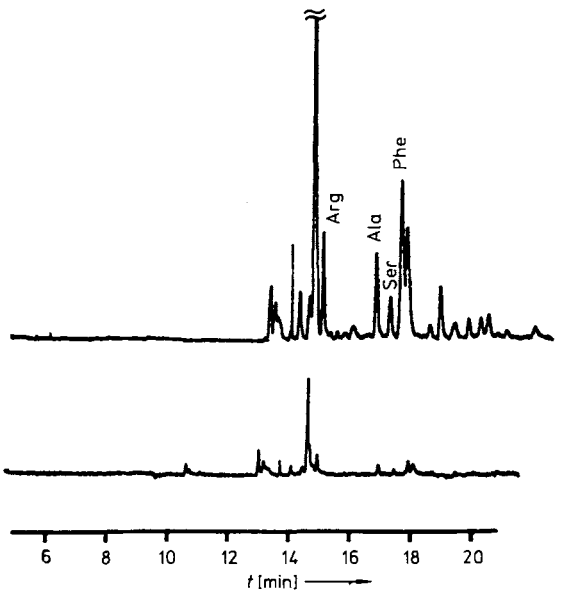

Fig. 30. Isotachophoresis for sample enrichment in CZE. Lower electropherogram: fluoresceinisothiocyanate (Fitc)-derivatized amino acids (without enrichment by ITP), injection: 2 s/5 kV, separation voltage 25 kV. Upper electropherogram: coupling of an ITP capillary to the CZE capillary. Voltage in ITP: 10 kV, in CZE: 25 kV, injection and sample as above, detection: laser-induced fluorescence at 488/514 nm (from ref. [153]).

in the μL range can be applied. The normal electrolyte is then introduced as a terminating electrolyte. The enrichment takes place in the direction of the lead electrolyte with enrichment factors of up to 100.[153, 156] It has been shown that with proteins the addition of ammonium acetate to the sample solution[157] can have the same effect; the acetate ion acts as the lead electrolyte. The coupling of two instruments, ITP for enrichment and CE for separation, each with a UV detector, has also been described.[153] When the enriched ITP zone reaches the first detector, the system is switched over to CE separation. The enrichment and subsequent CE separation achieved by such an arrangement is demonstrated in Figure 30.

4.7. Electrochromatography (EC)

Band broadening in HPLC results primarily from the parabolic flow profile and diffusion into and out of the pores of the stationary phase. Attempts have been made to reduce this contribution to band broadening by reducing the particle diameter; this reduction is opposed by the high pressure drop required. In the ideal case the EOF is independent of the particle diameter of the material used to pack the capillaries. In addition the piston-shaped flow profile of the EOF leads us to expect high separation performance. It thus appears possible in principle to combine the high selectivity of HPLC with the efficiency of CE by using packed columns.[21, 158] The separation principles and stationary phases used are those of HPLC, but the transport of ionic components is due to electric migration. Extremely small nonporous particles (1 μm in diameter) are used in order to reduce the contribution of the sorption process to band broadening. The favorable theoretical predictions for this technique have not yet been verified experimentally. The reduced plate heights achieved are not much better than those attained in HPLC.[15] One reason for this is the detection problem: in CE detection is carried out directly through the separation capillary; this is no longer possible when packed columns are used. Thus the problems known from micro-HPLC resulting from the coupling of the detector to the separation capillary also occur here.

5. Outlook

The separation systems discussed above based on electric migration are summarized in Table 5. The technique most often used is certainly CE in uncoated or surface-modified quartz capillaries (open tubes). Neutral molecules can also be separated in this system when a micelle-forming agent is added.

CE has several advantages over classical electrophoresis:
- extremely high separation efficiency,
- simple on-line detection and quantification,
- simple operation,
- short analysis times,
- simple automation,
- low consumption of buffers.

The advantages compared with HPLC are
- the high separation efficiency,
- the rapid establishment of equilibrium when the analytical conditions are changed,
- short analysis times,
- low consumption of buffers,
- minimal sample preparation (suspensions can be injected directly).

The disadvantages of CE lie in
- the use of UV detectors because of their low concentration sensitivity,
- the poor reproducibility and control of the electroosmotic flow,
- the adsorption of the analytes at the surface of the capillary, which is always accompanied by a loss of efficiency.

Commercial instruments, some already second-generation, are presently available for the routine CE analysis. This is also reflected in the nature of publications appearing, where practice-oriented papers are slowly outnumbering those describing theory and methods. Whereas in 1990 only 225 papers were listed under the heading "capillary electrophoresis" in the review volume of *Analytical Chemistry*[83] (more than half of these dating from 1988/89), the literature survey for the two following years[84] contains 523 publications. It was not our intention when compiling this article to provide a complete literature survey, but to give an objective overview (although personal preferences have certainly played a part)

Table 5. Separation systems driven by an electric field in a capillary.

Capillary zone electrophoresis	Capillary gel electrophoresis	Micellar electrokinetic chromatography	Electro-chromatography	Isotachophoresis in capillaries	Isoelectric focusing in capillaries
modified/ unmodified capillaries	modified and gel-filled capillaries	unmodified capillaries	packed capillaries	unmodified capillaries	modified/ unmodified capillaries
EOF controlled/ uncontrolled	EOF suppressed	with EOF	with EOF	with EOF	EOF suppressed/ very low
separation by electrophoretic migration; influence of EOF	separation by electrophoretic migration with sieve effect; no EOF	separation by electrophoretic migration and distribution of the sample between micelle and buffer; influence of EOF	separation by interaction with a stationary phase (LC separation system); EOF functions as pump	separation by electrophoretic migration; influence of EOF	separation according to the isoelectric point of the sample; mobilization of the sample zone towards detector not necessary when small EOF present
many applications for small and large charged molecules	separation according to molecular size of DNA molecules and SDS-denatured proteins	wide application range for small, neutral, and charged molecules	application range as for HPLC (no practical use so far)	limited application range sample preconcentration technique for CE	separation of zwitterionic samples according to their pI values

of the current scope and limiations of CE. CE complements the established separation techniques, HPLC and GC; its advantages are found in situations where the latter reach their limits, that is, in the separation of polar and ionogenic, low molecular weight materials and in the analysis of proteins and other biopolymers.

As the history of the development of the established separation techniques has shown, method-oriented publications are typically followed by those dealing with applications in various areas. The tendency of the analytical chemist to test as many separations as possible with the new technique can also be observed here. Even polycyclic aromatic hydrocarbons have been separated with CE; however, we make no comment as to whether this is a worthwhile application (see Section 4.5). Further developments are possible by coupling CE with other separation techniques and with spectroscopic techniques, in particular mass spectrometry.

The first monographs and collected editions dealing with CE have appeared or been announced.[159, 160]

Our own work in this area has been supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and by graduate scholarships provided by the Saarland to J. Kohr and T. Schmitt. We thank friends and colleagues for an intensive and fruitful exchange of ideas. T. Schmitt thanks Prof. B. L. Karger, Northeastern University, Boston, for allowing him to carry out experimental work in his laboratories. We also thank Beckman and Millipore for providing us with instruments.

The Coordination Chemistry of Multidentate Isocyanide Ligands

By F. Ekkehardt Hahn*

In spite of the excellent ligation properties of isocyanides, until a few years ago there was only a small number of known multidentate ligands of this type. One of the reasons for this lack of interest, when compared to monodentate isocyanides, was the linear arrangement of the M–C≡N–R group, which usually inhibits the formation of mononuclear chelate complexes and leads to the formation of multinuclear or polymeric metal complexes. In these, the multidentate ligand acts in a monodentate fashion towards each metal atom. Only recently has a series of polyisocyanides with large ligand backbones been synthesized successfully. Bidentate isocyanides can bridge two metal atoms or react to give chelates with only one metal center. Tripodal ligands form mono- or binuclear complexes, in which the largest organometallic rings observed to date occur (up to 36 atoms). This class of ligands promises to be interesting for the synthesis of stable, diagnostically important technetium complexes of the type $[Tc(CNR)_6]^+$. There also appear to be applications for tripodal isocyanides in catalysis. A facial, chiral $Cr(CNR^*)_3$ unit might be able to catalyze the hydrogenation or isomerization of prochiral double bonds. It is even possible to bind triisocyanides with suitable backbones to carbonyl trimetal clusters, thereby stabilizing them, or making selective cluster formation possible. Coordinated isocyanides can be transformed readily into carbene ligands, which, in the future, could lead to complexes with polycarbene ligation.

1. Introduction

The almost simultaneous discovery of isocyanides by Gautier[1] and Hoffmann[2] more than one hundred years ago posed a series of interesting questions for chemists of the time. Was it indeed possible that in the case of the newly synthesized ethylisocyanide, in contrast to the known propionitrile, "the carbon of the ethyl group is soldered to the molecule by attachment to the nitrogen"?[1b] and could the carbon be present in these compounds in the divalent state? It was probably not the "very uncomfortable odor"[3] of volatile isocyanides, described by one of the discoverers, which hindered further investigations, but rather the fact that these compounds were only accessible by the difficult and frequently low-yield transformation of metal cyanides with alkyl iodides.[4] Only the fundamental work by Ugi et al.[5] regarding the dehydration of formamides with phosgene led to a convenient and versatile method for the synthesis of isocyanides[4] and opened the door for the study of these interesting compounds and their metal complexes.[6]

Today, an almost countless number of isocyanides is known, some of which have significant synthetic potential. An example are the alkylisocyanides, which can be α-metalated, and have been shown to be synthons for α-metalated primary amines.[7] However, even today simple isocyanides such as isocyanogen[8a] and diisocyan[8b] are a challenge for the synthetic chemist. A further simple isocyanide that is difficult to prepare is ethynyl isocyanide (**1**),[9] which has been shown to exist in interstellar space.[10] A number of isocyanides with fluorinated side chains[11] or even naturally occurring isocyanides have since become known, for example, the antibiotic xanthocillin (**2**),[12] or (±)-9-isocyanopupukeanane (**3**), for which an X-ray structure analysis[13] and a total synthesis[14] have been performed.

Isocyanides have also achieved importance in coordination and organometallic chemistry. Their excellent ligation properties, as well as the wide potential for substitution at the side chain, have led to a substantial chemistry of isocyanide metal complexes.[6] Coordinated isocyanides can be transformed into carbenes[15] (even hexacarbene complexes are possible[15a]) and can be used for forming C–C bonds.[16] Trichloromethylisocyanide complexes[17] and anionic transition metal complexes of isocyanides[18] have been prepared and shown to have valuable synthetic applications. Even the structure of an isocyanide deprotonated at the α-carbon atom has been characterized by X-ray crystallography.[19] The use of monodentate isocyanide ligands shows great promise in medical diagnostic applications. For instance, hexaisocyanide complexes of the monochromatic γ emitter ^{99m}Tc **4**[20] are very useful for radiological diagnoses because of the excellent radiophysical properties of this technetium isotope,[21] in particular, for the imaging of blood flow in the heart.[22]

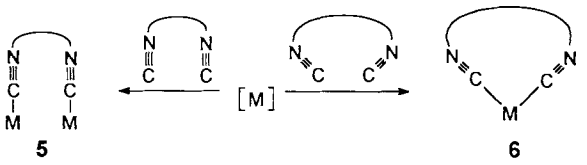
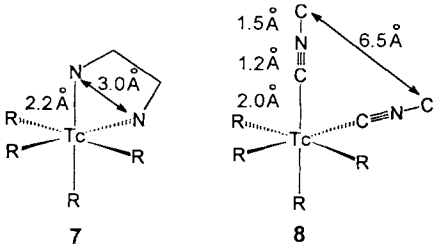
The reactivity and coordination chemistry of multidentate isocyanides are relatively unexplored, in comparison with the corresponding knowledge about monodentate isocyanide ligands. This is unfortunate insofar as multidentate ligands are expected to exhibit special properties, for instance the chelate effect. For multidentate isocyanides, however, the rigid linear M–C≡N–R unit usually prohibits the formation of chelates and leads instead to di- or multinuclear metal complexes **5**. In these complexes, the multidentate isocyanide ligand functions only as a monodentate base towards each metal atom. Only ligands with a sufficiently large number of atoms in the backbone between the isocyanide groups satisfy the stereochemical requirements for the formation of chelate complexes **6**.



5 **6**

Model studies with rhodium complexes of bidentate aliphatic isocyanide ligands[23, 24] have shown that at least seven methylene groups between the isocyanide functionalities are necessary for chelate formation. The reasons for this special situation become clear when the structural parameters of an ethylenediamine complex (**7**) are compared with those of two *cis*-oriented isocyanide units in an octahedral or square-planar complex (**8**; Scheme 1).



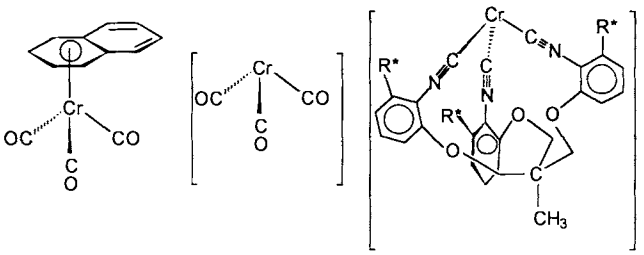
7 **8**

Scheme 1. Selected bond lengths in ethylenediamine and isocyanide technetium complexes (average values). Left: in the $Tc(H_2NCH_2CH_2NH_2)_2$ unit of *trans*-$[TcO_2(en)_2]^+$ [25]; right: in the $[Tc(CN\text{-}t\text{Bu})_4(bpy)]^+$ ion [26].

If ideal geometry is assumed, the distance between the nitrogen atoms in **7** is about 3.0 Å, whereas in the isocyanide complex **8** the carbon atoms that need to be linked for chelate formation are separated by more than 6.5 Å. Even when a nonideal geometry (C-Tc-C < 90°) is assumed, the distance to be bridged is still about 6 Å. The necessity of a large number of atoms in the backbone between two isocyanide functionalities leads to large chelate rings (a 12-membered ring would form in a chelate complex with 1,7-heptanediisocyanide), which in turn diminishes the chelate effect. This sterically unfavorable situation is the reason for the underdeveloped state of the coordination chemistry of multidentate, potentially chelating, isocyanide ligands.

However, recently there has been an increase in the interest in coordination compounds with polyisocyanide ligands. Apart from the academic interest in the formation of chelate complexes despite the mentioned steric obstacles, other aspects related to the application of this chemistry have surfaced. For instance, for the complexation of ^{99m}Tc, chelating isocyanide ligands are an interesting alternative to the currently employed monodentate ligands.

Furthermore, there are potential applications for tripodal triisocyanide ligands in organic synthesis. Labile [(arene)Cr-$(CO)_3$] complexes **9** (arene = naphthalene, phenanthrene) are effective catalyst precursors for hydrogenation[27] and isomerization[28] reactions. The catalytically active $Cr(CO)_3$ fragment **10a**, which has three open coordination sites, is generated by the dissociation of the arene ligand from **9**. In spite



9 **10a** **10b**

of a number of attempts to obtain a chiral CrL_3 fragment corresponding to $Cr(CO)_3$,[29] it has so far been impossible to prepare a chiral catalyst. To achieve high catalyst activity,

F. Ekkehardt Hahn was born in Jena in 1955. He studied chemistry up to the Vordiplom (1978–1981) at the Technischen Universität (TU) Berlin, and thereafter he was awarded a Fullbright travel grant and continued his studies at the University of Oklahoma (Prof. J. J. Zuckermann). After obtaining his Master of Science he returned to Berlin in 1982, where he completed his Diplom in 1983 and his dissertation in 1985 on the synthesis and X-ray structures of organolanthanide compounds with Prof. H. Schumann. From 1985–88 he was a postdoctoral fellow with Prof. K. N. Raymond at the University of California, Berkeley (initially with a NATO research fellowship). 1988–1990 he completed his habilitation at the TU Berlin with studies on the use of technetium complexes for radiodiagnostic applications. In 1991 he was appointed Privatdozent and awarded a Karl Winnacker fellowship. Since March 1992 he has been a Professor of Inorganic Chemistry at the Freien Universität Berlin. His main areas of research are the development of multidentate ligands and their use for the selective complexation of technetium, gadolinium, and copper, as well as the organometallic chemistry of isocyanides and carbenes.

the ligands of the CrL_3 units must be good π acids and be facially oriented. These conditions should be fulfilled by complexes of chiral-substituted tripodal triisocyanides **10b**, in which the function and positions of the three facial CO groups in **10a**[30] are assumed by the linked isocyanide units.

2. Bidentate Isocyanide Ligands

The coordination compounds of bidentate isocyanide ligands can be separated into three general categories. The first contains multinuclear complexes without direct metal–metal interactions between the complexed metal atoms. The second category encompasses those metal complexes in which the bidentate isocyanide ligand bridges two metals in such a fashion that direct metal–metal interactions are possible after complexation by the ligands, and the third category comprises mononuclear chelate complexes with diisocyanide ligands.

2.1. Binuclear and Polymeric Complexes without Metal–Metal Interactions

The bidentate, "rigid" isocyanides 1,3-phenyldiisocyanide, 2,4-tolyldiisocyanide, or 4,4'-diphenylmethanediisocyanide employ bent bridges to link the metal atoms. These ligands react with $[\{Rh(CO)_2Cl_2\}_2]$, yielding two-dimensional, insoluble coordination polymers $[Rh(bridge)_2Cl \cdot xH_2O]_n$ (Fig. 1) with an interlayer distance between 3.21 and 3.36 Å. The

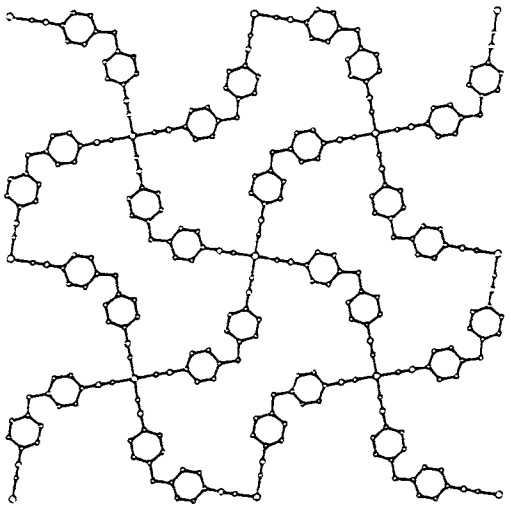


Fig. 1. Structural model of the two-dimensional, layer-type coordination polymer $[Rh(4,4'\text{-diphenylmethanediisocyanide})_2Cl \cdot H_2O]_n$ [31].

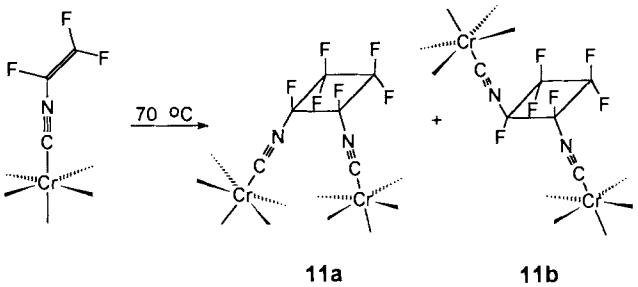
term template polymerization has been coined to describe this type of reaction.[31] When 1,4-phenyldiisocyanide or 4,4'-biphenyldiisocyanide are used as ligands, linearly bridged coordination polymers can be obtained.[32] The reaction of the linear ligand 1,4-phenyldiisocyanide with metallamacrocycles such as tetrabenzylphorphyrin iron, yields linear dimers, trimers, and polymers.[33] These polymers are formed by the use of the two axial coordination sites at the metal center. Compounds of this type were developed in the hope of obtaining one-dimensional polymers with cofacial π systems for semiconductor applications.

By using appropriate starting materials, bidentate phenyldiisocyanide ligands can also be used to prepare monomeric complexes. For instance, 1,4-phenyldiisocyanide reacts with two equivalents of $[Et_4N]^+[W(CO)_4(PR_3)Cl]^-$ to give the binuclear complex $[(CO)_4(PR_3)W\text{–}CNC_6H_4NC\text{–}W(CO)_4(PR_3)]$.[34] The reaction of 1,2-phenyldiisocyanide, which has only recently become available in good yields,[35] with $[ClAuSMe_2]$ affords the binuclear complex $[C_6H_4(NC\text{–}AuCl)_2]$.[36] A completely different path to binuclear diisocyanide-bridged complexes has been reported by D. Lentz et al. They found that, when heated, $[(CO)_5Cr(CN\text{–}CF{=}CF_2)]$ dimerizes to give the 1,2-substituted hexafluorocyclobutane complexes **11a,b** (Scheme 2).[37]

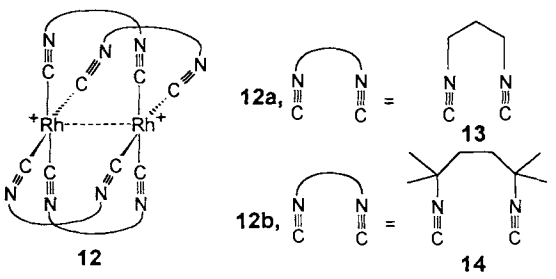


Scheme 2. Dimerization of $[(CO)_5Cr\{CNC(F){=}CF_2\}]$.

A multitude of other [M-CN-R-NC-M] complexes of type **5** with different metals and bridging groups R, are known.[6] Their complete enumeration here, however, would exceed the scope of this survey.

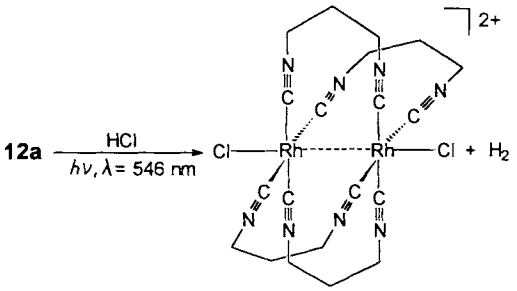
2.2. Bidentate Complexes with Metal–Metal Interactions

Tetra(arylisocyanide)rhodium(I) complexes aggregate in solution to give higher oligomers with $Rh^I\text{–}Rh^I$ bonds.[38] This leads to the possibility of a two-center oxidative addition. To investigate this aspect in more detail, bridged $Rh^I\text{–}Rh^I$ complexes of type **12** with four diisocyanide ligands (with 1,3-propanediisocyanide **13**[39] and 2,5-dimethylhexane-2,5-diisocyanide **14** as ligands) were synthesized and structurally characterized.[40]



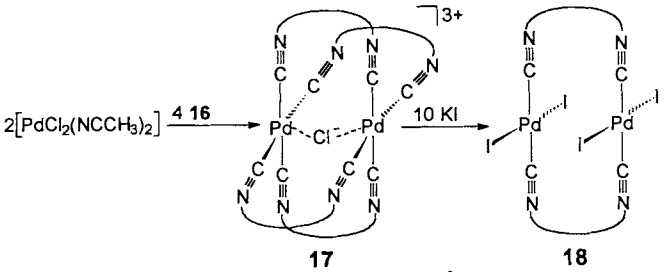
The ligand geometry was chosen so that chelate formation with a single metal atom was impossible, but that a Rh–Rh'

unit could be "clamped" together. Despite the increase in the length of the bridge between the isocyanide functionalities in **14** compared to **13**, the Rh–Rh distances in **12a** (3.242(1) Å) and **12b** (3.262(1) Å) are nearly identical. The expected interaction between the two Rh^{I} centers is confirmed by the Rh–Rh distance, the dark blue color of **12a**, and by the fact that CH_3I is oxidatively added, forming yellow $[Rh_2(\mathbf{13})_4(CH_3)(I)]^{2+}$. The reaction of **12a** with HCl yields a similar complex, which, upon irradiation (546 nm, 12 M HCl) forms the yellow Rh_2^{II} complex **15** and one equivalent of H_2. While the importance of this photoinduced redox reaction was recognized immediately, the storage of solar energy by using **12a** is still a long way away.[41] The X-ray crystal structure of **15**, which is more readily obtained by the oxidation of **12a** with Cl_2, confirms the expected shortening of the Rh–Rh distance in comparison to that in **12a,b** to 2.837(1) Å; the structure of **15** is built from two square-pyramidal $Rh^{II}C_4Cl$ units.[42]

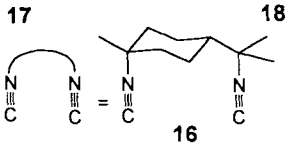


15

The span width of the diisocyanide ligand was further increased by the use of 1,8-*p*-menthanediisocyanide **16**. This ligand also forms a rhodium complex of type **12**, but with a large (4.479(2) Å) Rh–Rh separation.[43] The more interesting reaction is that of **16** with divalent transition metals. In the binuclear Pd^{II} complex **17**[44] the metal–metal distance is large enough for Cl^- or Br^-, but not the larger thiocyanate, to be inserted. Iodine is also not inserted in the Pd–Pd bond, but reacts with **17** to give the doubly bridged complex **18**.



17 **18**

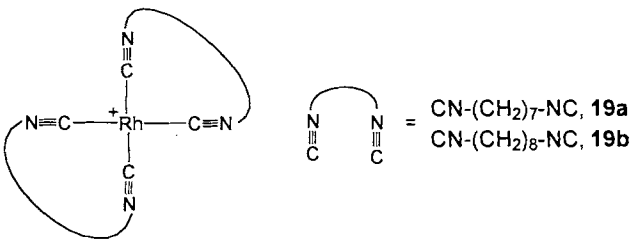


16

Halides are also inserted in the reaction of NiX_2 (X = Cl, Br) with **16**.[45] In the binuclear rhodium(I) or iridium(I) complexes of **16** this is not the case, even though structurally they are in a position to do so. This observation is most likely due to the lower charge compared to Ni^{II} or Pd^{II} complexes.[44]

2.3. Chelate Complexes with Diisocyanide Ligands

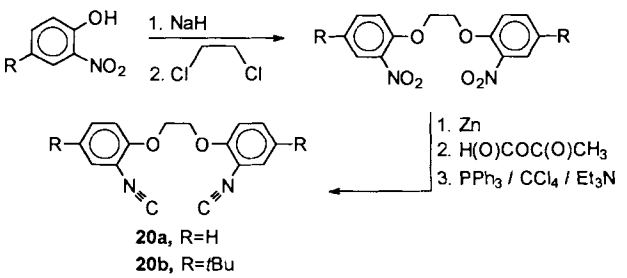
The isocyanides presented in Sections 2.1 and 2.2 do not fulfill the structural requirements for the coordination of both CN groups to a single metal center. As early as 1978, a number of research groups began work on the problem of whether diisocyanides can be constructed in such a manner as to allow the formation of mononuclear chelate complexes. Early model studies gave indications that 1,7-heptanediisocyanide should be capable of this coordination behavior.[23] The formed metallacycle would then be 12-membered. The first experiments led to the postulation of compounds of type **19**, in which two diisocyanide ligands form a square-planar Rh^{I} chelate complex. When present in suitable concentrations the metal complexes aggregate in solution to give oligomers, as has also been observed for mononuclear complexes of the type $[Rh(CNR)_4]^+$.[38] Chelate formation was proposed based on geometric considerations and the electronic spectra of the compounds.[23]



19

Another early report deals with substitution reactions on complexes of type **19b**.[24] One of the bidentate diisocyanide ligands in **19b** can be substituted by PPh_3 or $Ph_2PCH_2CH_2PPh_2$, leading to phosphane-substituted chelate complexes with only one coordinated bidentate diisocyanide.[24] So far, it has not been possible to characterize one of these complexes by X-ray structure analysis.

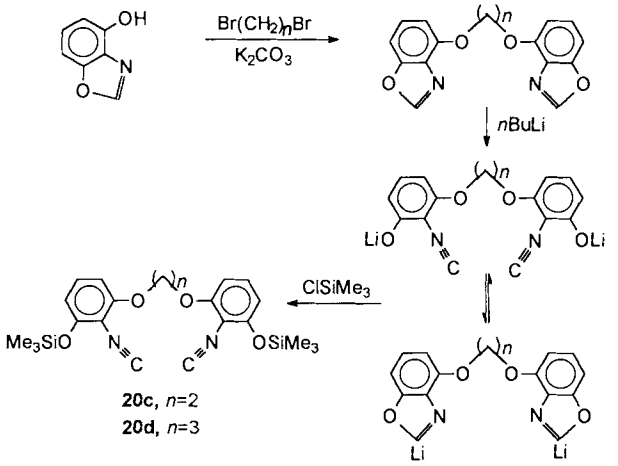
The first unambiguous proof for the formation of chelate complexes by bidentate diisocyanides was provided by R. J. Angelici et al. in 1982 by using aromatic diisocyanides. The ligands **20a** and **20b** have eight atoms between the isocyanide groups (roughly equivalent to the eight methylene groups in **19b**). They were prepared by etherification of the correspond-



20a, R=H
20b, R=*t*Bu

ing nitrophenols with 1,2-dichloroethane, reduction and formylation of the nitro group, and finally dehydration of the obtained diformamides.[46]

The trimethylsiloxy-substituted compounds **20c** and **20d** were prepared by an interesting variation of this synthesis. First, two 4-hydroxybenzoxazole units were linked by an ethylene (**20c**) or trimethylene (**20d**) group. The isocyanide functionalities were deprotected by lithiation and subsequent silation of the benzoxazole oxygen atom.[47] The use of $ClSiMe_3$ led to exclusive silation of the oxygen atom. The reverse reaction (Si–O cleavage with KF) for coordinated 2-siloxyphenylisocyanides leads to carbene complexes in high yields, by a nucleophilic attack of the oxygen atom at the isocyanide nitrogen atom (see Section 3.4).



The reaction of **20b** with $[\{Rh(cod)Cl\}_2]$, followed by anion exchange with $NaBPh_4$, leads in good yield (81%) to crystalline $[Rh(\mathbf{20b})_2]BPh_4 \cdot 1.5\,CH_3CN$.[48] The X-ray structure analysis shows that the Rh^I ion is surrounded in a square-planar fashion by two chelating ligands (Fig. 2).[47] The 13-membered chelate rings formed in this complex are among the largest known for organometallic compounds. In solution the Rh complex forms oligomers, while in the crystal two cations form a dimer with a Rh^I–Rh^I distance of 3.384 Å.[48]

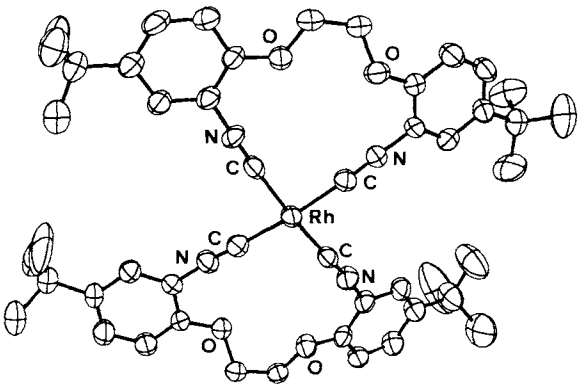


Fig. 2. Molecular structure of the cation in $[Rh(\mathbf{20b})]BPh_4 \cdot 1.5CH_3CN$ [47]. The Rh^I ion is in a square-planar environment.

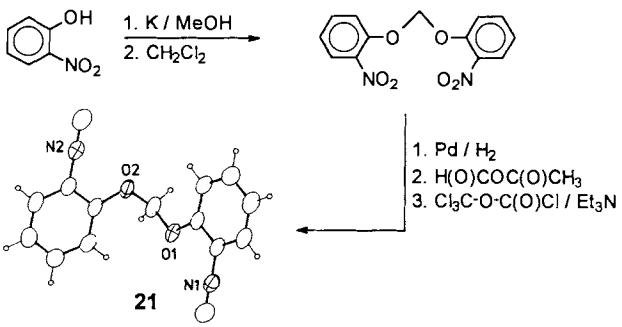
Analogous, but crystallographically uncharacterized cationic Rh^I complexes are formed with the ligand **20a**.[48] Ligand **20c** does not form chelates, but binuclear cations with four diisocyanide bridges $[Rh_2(\mathbf{20c})_4]^{2+}$, which are structurally equivalent to complex **12**. In a rigid chelate complex, it is probably impossible to arrange the sterically demanding trimethylsiloxy groups in a noninterfering manner. In contrast the slightly bigger ligand **20d** forms monomeric Rh^I chelate complexes. In this case, the trimethylsiloxy groups inhibit the formation of oligomers in solution.

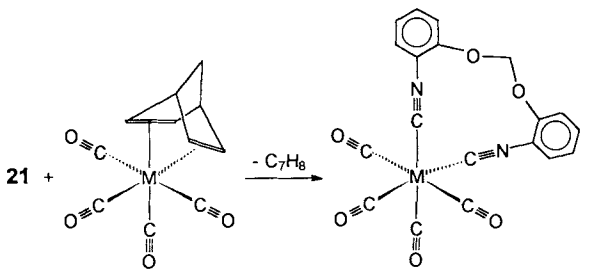
Ligand **20a** can be used to obtain complexes like $[(CO)_4M(\mathbf{20a})]$ (M = Cr, Mo, W),[46] as well as *cis* and *trans* isomers of $[Fe(\mathbf{20a})_2Cl_2]$.[49] Even though these complexes have not been structurally characterized, a multitude of spectroscopic data in addition to the proven ability of **20b** for chelate formation makes the likelihood that these compounds are also chelate complexes very high.

Even a reduction in the number of atoms in the backbone between the isocyanide groups still allows chelate complex formation. While **20a–c** have eight and **20d** even nine atoms in the backbone, **21** has only seven atoms between the isocyanide groups. This is approximately equivalent to seven methylene groups and corresponds to the smallest proposed potentially chelating diisocyanide so far.[23]



Compound **21** was obtained in 45% yield by the etherification of two equivalents of *o*-nitrophenol with dichloromethane,[50] reduction of the nitro group by Pd/H_2, formylation of the resulting amine, and finally dehydration of the diformamide according to the method of Ugi et al.[51] The X-ray structure analysis of the free ligand shows no abnormalities. The bond lengths in the phenoxyisocyanide groups ($d(C{\equiv}N)$ = 1.150(3) and 1.153(3) Å) correspond to those found in monodentate phenylisocyanides.[52]

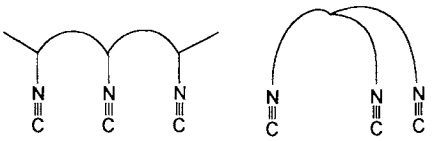
In analogy to **20a,b**, **21** reacts with $[(C_7H_8)M(CO)_4]$ (C_7H_8 = norbornadiene, M = Cr,Mo) to form the chelates **22**.[51] The evidence for the formation of mononuclear chelate complexes includes the good solubility in dichloromethane,



the appearance of the molecular ion in the mass spectrum, as well as spectroscopic data. The IR spectra are very similar to those of [(CO)$_4$M(**20a**)].[46] The spectrum of **22a** exhibits fewer than the four allowed CO absorption bands, but the broadness and intensity of bands at lower wavenumbers make the overlap of two absorption bands in this region quite probable. A similar situation is found with *cis*-[(CO)$_4$M(CN-*p*-tol)$_2$] (M = Cr, Mo; tol = tolyl).[53] Furthermore, two CN absorption bands are found for **22**, while only one is expected for a binuclear complex [{(CO)$_5$M}$_2$**22**].

3. Tridentate Isocyanide Ligands

Until the beginning of the 1990s, almost nothing was known about the synthesis or the coordination chemistry of triisocyanides. Such ligands could in principle have either linear topology such as **23** or a tripodal topology such as **24**. A report describing the synthesis of a linear triisocyanide was published in 1990. The ligand was obtained by coupling of α-metalated diphenylmethylisocyanide[7] with 1,3-dibromopropane.[54] The coordination chemistry of this ligand has not yet been explored.

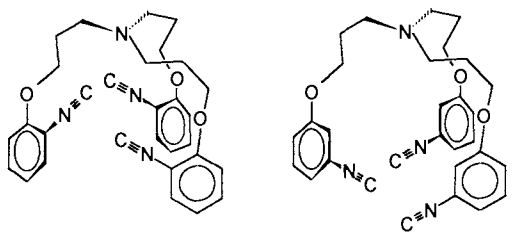


23 **24**

Tripodal isocyanides were unknown until 1990, with the exception of a few compounds that did not act as tripods.[5b, 55] However, more recently, the synthesis of a number of such ligands has been completed.[56–64] They exhibit an interesting coordination chemistry and are, in some instances, capable of forming mononuclear chelate complexes despite the linear M–C≡N–R unit in the metal complex. In some cases this leads to very large organometallic rings. Also a triangular M_3 plane in carbonyl trimetal clusters like [$Os_3(CO)_{12}$] can be bridged. The coordination chemistry of tripodal triisocyanides will be presented in the following sections.

3.1. Chelate Complexes with Tripodal Aromatic Triisocyanide Ligands

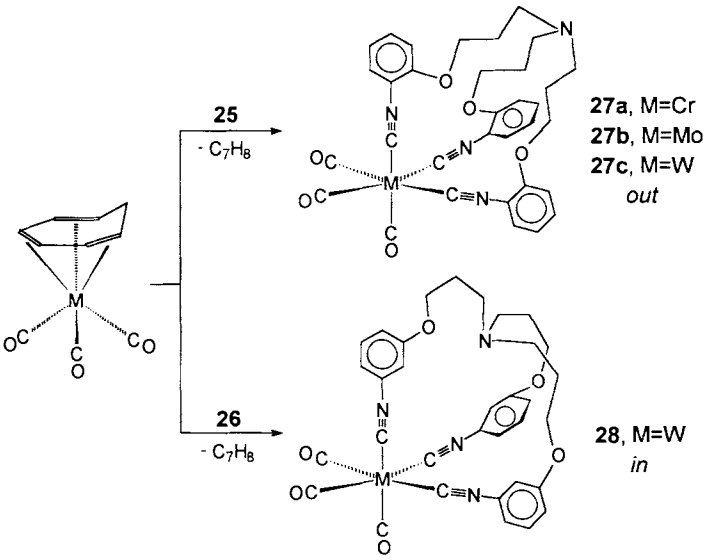
The driving force for the development of chelating tripodal aromatic triisocyanides was the search for new ligands for the complexation of ^{99m}Tc. In the first successful synthesis three *o*- or *m*-nitrophenol units were linked with tris-(3-chloropropyl)amine by a Williamson etherification. This backbone topology had been successful in the synthesis of tricatechol ligands,[65, 66] while neither tris(2-chloroethyl)amine nor tris-(4-chlorobutyl)amine are suitable for backbone construction due to their tendency for ring formation. The obtained trinitro compounds can be transformed into the tripodal aromatic triisocyanides **25**[56, 57] and **26**[58] by reduction of the nitro



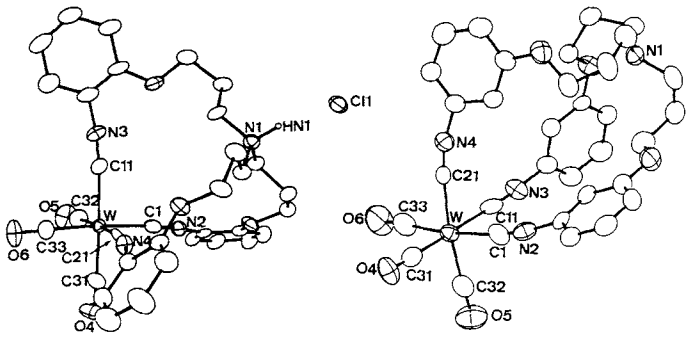
25 **26**

groups to primary amines, subsequent formylation, and dehydration according to Ugi et al.[5]

The crucial question was then whether these triisocyanides could indeed form chelate complexes. One possible problem is the formation of three 18-membered rings in a facial complex with **25** as a ligand while a complex with **26** would even contain three 20-membered rings. Ligands **25** and **26** were allowed to react with [(C_7H_8)M(CO)$_3$] (C_7H_8 = cycloheptatriene, M = Cr, Mo, W) in dichloromethane. These reactions proceed by the facile replacement of the cycloheptatriene ligand by the tripodal triisocyanide, forming the complexes **27** and **28** in 69–87% yield.[56, 58] Attempts to obtain crystalline samples of **27c** and **28** led to an interesting observation. Compound **28** crystallizes from dichloromethane as well-formed rhombuses, which can be recrystallized as often as needed from this solvent. In contrast, the complexes **27a–c** do not crystallize readily from dichloromethane. Once crystals (of, for example, **27c**) have formed, however, they do not redissolve, and their combustion analyses show marked deviations from calculated values for *fac*-[(CO)$_3$W(**25**)]. To explain these deviations, X-ray crystal structure determinations of **27c** and **28** were undertaken. The results indicate that facial chelate complexes have formed with both ligands (Fig. 3). The 18- and 20-membered rings obtained thereby were at that time the largest of their kind known for organometallic compounds.



The main difference between **27c** and **28** is the conformation and configuration of the central nitrogen atom of the ligand backbone. In **27c** the nitrogen atom is protonated and the unit is present in the *out* configuration. Most likely, in-



27c·HCl, *out* **28**, *in*

Fig. 3. Molecular structures of the chelate complexes **27c** · HCl and **28**.

version at the nitrogen is inhibited by the coordination of the ligand to the metal atom. Hence, the nitrogen atom is fixed in the *out* configuration and is subsequently protonated by HCl—which is either present as solvent impurities or formed by dichloromethane cleavage—to form the hydrochloride **27c** · HCl. Complexes **27a,b** behave similarly and are assumed to have analogous structures. In the soluble complex **28** the central nitrogen atom adopts the *in* conformation and remains unprotonated.

Analogous bond lengths and angles in **27c** and **28** are identical within error limits. The C≡N bond lengths are longer than in uncoordinated ligands such as **21** (Table 1), due to π back bonding in the metal complex. The IR spectra

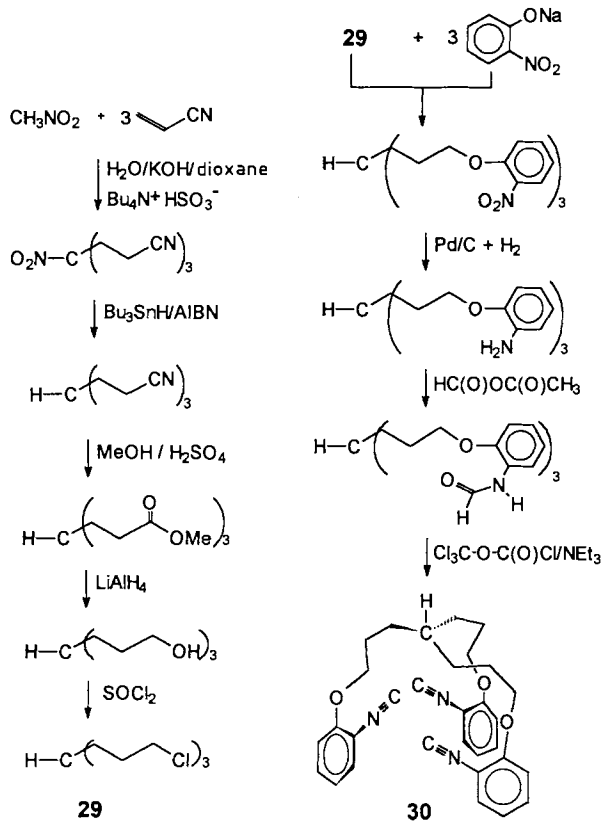
of **27a–c**, which are not substantially different, exhibit the expected A_1 and E bands for complexes with C_{3v} symmetry. These bands are found in the same energy range as in complexes of the type *fac*-[$(CO)_3$W(aromatic isocyanide)$_3$].[53, 67] The *m*-substituted ligand in **28** is a weaker σ donor, but a better π acceptor than the *o*-substituted ligand in **27a–c** (see Table 2). This substitution dependence of IR spectra of aromatic isocyanides was already mentioned by Ugi et al.[5a]

The protonation of the ligands in **27** and the unfavorable solubility of the formed hydrochlorides led to the development of tripodal, aromatic triisocyanides that have a methine group which cannot be protonated as the central group in the backbone.[61] The key step in the synthesis of **30** was the formation of the trichloride **29**.

The reaction of **30** with [(C_7H_8)W$(CO)_3$] leads to a soluble chelate complex (see Table 2).[61] Attempts to obtain this



compound in crystalline form have so far been unsuccessful. Therefore it could not be determined whether the methine group is in the *in* or *out* configuration. The ^{13}C NMR spectrum (Fig. 4), however, is very informative in this regard. The doubling of all signals indicates that the reaction leads to a mixture of *in*-**31a** and *out*-**31b** configurational isomers

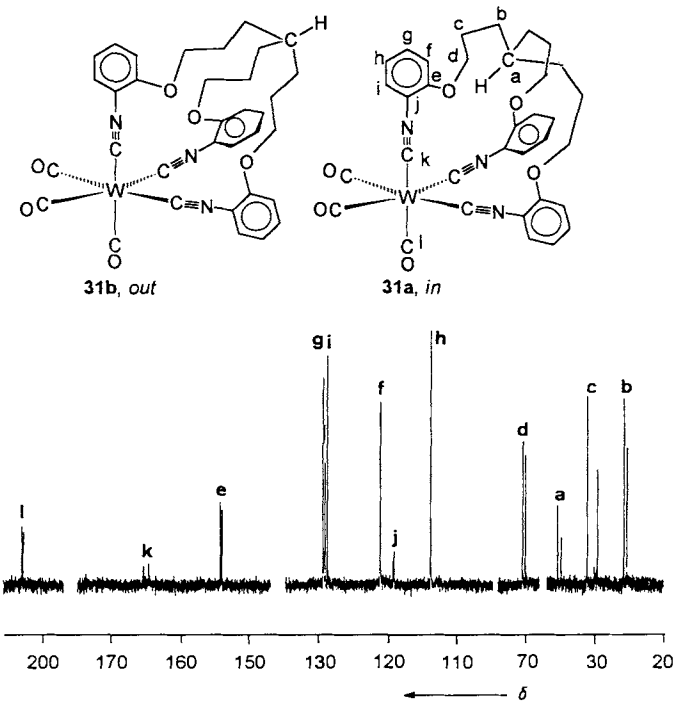


Fig. 4. ^{13}C NMR spectrum of a 5:3 mixture of complexes **31a** and **31b**.

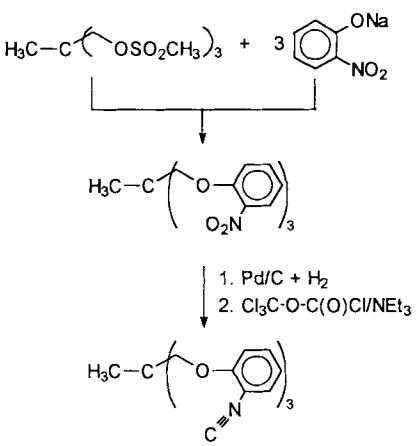
(5:3 ratio). The *in* isomer is easily identifiable in the ^{1}H NMR spectrum by a septet for the proton of the central methine shifted downfield to $\delta = 2.50$. This is due to the penetration by the proton on the central carbon atom a into the deshielding region of the anisotropy cones of the C≡N bonds (see Section 3.2). Attempts at separating the isomers chromatographically have so far been unsuccessful.

The results obtained led to the synthesis of ligand **32** (see Table 2).[61] This ligand also contains a bridgehead carbon atom which cannot be protonated, and the number of atoms in the backbone is reduced. The methyl substituent at the bridgehead was introduced to sterically encumber the formation of *in* isomers in order to obtain homogeneous, crystallizable samples of *out* isomers.



32

The reaction of **32** with $[(C_7H_8)W(CO)_3]$ in dichloromethane leads indeed to the soluble complex *fac*-$[(CO)_3W(\mathbf{32})]$ **33** in good yield. The X-ray structure analysis of **33** confirms the formation of the desired chelate complex (Fig. 5, see Table 1).[61] The decrease in the number of backbone atoms between the isocyanide functionalities from thirteen to nine has apparently no effect on the chelating ability. The introduction of the methyl group at the central carbon atom successfully inhibited the formation of *in* isomers, forcing an exclusive *out* configuration.

Apparently, tripodal triisocyanides are very well suited for the preparation of facial chelate complexes. The configuration or conformation of the central backbone atom can be influenced by the ligand design. The size of the ligand backbone can be varied over a broad range without appreciably affecting either the ligand's ability for chelate formation or the linear geometry of the M–C≡N–R unit (see Table 1).

In some instances, it was found that during complex formation, small amounts (5–7%) of higher oligomers were isolated along with the desired monomeric products. During the course of the preparation of **27c** it was possible to separate a dimer in 5% yield from the main product by fractional crystallization and to characterize this species by X-ray structure analysis. In *fac,fac*-$[\{(\mathbf{25})W(CO)_3\}_2] \cdot 2HCl \cdot 2CH_2Cl_2$ **(27d)** (Fig. 6), the two $W(CO)_3$ units are bridged by two ligands **25**.[59] Each ligand binds to one metal atom through two of its isocyanide groups, while the third isocyanide group bridges to the other metal atom. This creates a chelate ring composed of 36 atoms, which is, to the best of our knowledge, the largest one of its kind in organometallic compounds. The central nitrogen atoms of both ligands are protonated and adopt the *out* configuration. The positions of the hydrogen atoms on the central backbone atoms were not determined.

33, *out*

Fig. 5. Molecular structure of *out*-$[(CO)_3W(\mathbf{32})]$ **33**.

Preliminary investigations showed that homoleptic complexes of the type *fac*-$[Cr(\mathbf{32})_2]$ **34** can be obtained by the reaction of the tripodal ligand with bisnaphthalenechromium.[68] The bright red compound **34** was isolated in 60% yield (Table 2).[69] Cr(0) complexes with six monodentate aliphatic isocyanide ligands have already been obtained from bisnaphthalenechromium in analogous ways.[68] The classic method for the synthesis of hexaisocyanidechromium(0) compounds using chromium(II) acetate[70] leads with **32** to higher oligomers, whose molecular structures have so far not been elucidated.[69]

The reaction of **25** with $^{99m}TcO_4^-$ leads to the incorporation of ^{99m}Tc into the ligand. In this case, the ligand is present in large excess and acts as the reducing agent as well as the complexing agent. This behavior was observed previously in

the synthesis of hexaisocyanide complexes with monodentate isocyanide ligands.[71] The technetium(I) complex of **25** is assumed to have a structure analogous to that of the complex of **34**.[57] It is so far unclear whether the coordinated ligands are protonated on the backbone nitrogen atom, or if the complex is a monocationic $^{99m}Tc^I$ compound.

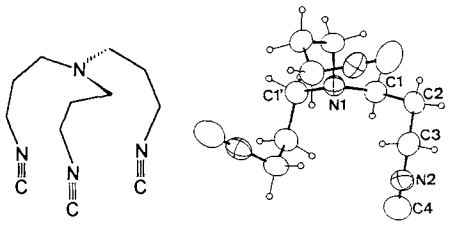
3.2. Chelate Complexes with Tripodal Aliphatic Triisocyanide Ligands

Further experiments were carried out to investigate if it is possible to prepare complexes with aliphatic triisocyanides. It was also of interest to determine the mimimum number of atoms in the backbone of the ligand necessary for chelate formation. For these purposes, the ligand **35** was prepared by the dehydration of 3,3',3''-nitrilotripropionamide[72] (Fig. 7).[56] At room temperature **35** is a viscous oil, which can be crystallized from methanol at low temperatures. Its X-ray structure, the first to be determined for a saturated aliphatic triisocyanide, shows a molecule with C_3 symmetry. The length of the N≡C bond (1.135(3) Å) determined by X-ray crystallography is significantly shorter than the N≡C bond lengths in aliphatic isocyanides determined by using electron diffraction.[73] The reasons behind the differences in these results, as well as the necessary corrections, have been



35

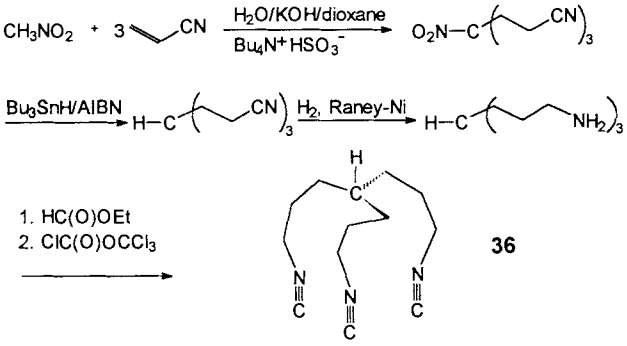
Fig. 7. Schematic representation and molecular structure of ligand **35**.

discussed, for example, in the case of 1,4-phenyldiisocyanide.[52a]

The ^{1}H NMR spectrum of the ligand **35** shows $^2J(^{14}N,^1H)$ and $^3J(^{14}N,^1H)$ coupling with the isocyanide nitrogen atom.[56] This has been described previously for aliphatic isocyanides.[74] The ^{13}C NMR spectrum also shows coupling between the isocyanide nitrogen atom and the neighboring carbon atoms.[56, 75] All coupling with the isocyanide nitrogen atom disappears upon complex formation, an important aid for the identification of metal complexes with isocyanide ligands.

Unfortunately, this aid cannot be used in the investigation of the product of the reaction of **35** with $[(C_7H_8)W(CO)_3]$, as the formed complex is too insoluble. The IR spectrum of this product, however, indicates at least local C_{3v} symmetry (Table 2). This observation and the elemental analysis[56] indicated that higher, insoluble oligomers were formed.[58] However, protonation of the ligand, as observed during the formation of **27c** (see Fig. 3) cannot be ruled out conclusively, even though the product is free of chloride.

To eliminate the factors that might cause the insolubility of complexes containing **35**, the ligand **36** was prepared with an all carbon backbone.[60] This ligand cannot be protonated at the central methine group and it allows the investigation of the coordination chemistry of aliphatic, tripodal triisocyanides with a small number of backbone atoms. The backbones of the ligands **35** and **36** are nearly identical and, in the case of chelate formation, would lead to the smallest rings (12 atoms) observed so far.



36

The ^{1}H NMR spectrum of **36** (Fig. 8 top) shows the previously mentioned ^2J(N,H) coupling for the CH_2 protons neighboring the isocyanide functionalities. The signal of the proton of the methine group overlaps with that of the methylene group B at $\delta = 1.45$. The reaction of **36** with $[(C_7H_8)$-

$Cr(CO)_3$] in dichloromethane yields the highly soluble complex *fac*-[$(CO)_3$Cr(**36**)] (**37a**) (see Table 2). The multiplicity of the signal of the methylene group D in the ^{1}H NMR spectrum of **37a** has been reduced from a triplet of triplets in the free ligand to the expected triplet by the coordination of the isocyanide group. The methine signal is strongly shifted downfield to $\delta = 2.43$. This allows the distinction between the two configurational isomers (*in* and *out*, Fig. 8 bottom). The downfield shift can only be explained by the presence of the *in* isomer, as only then can the proton of the methine group penetrate the deshielding region of the anisotropy cones of the N≡C bonds.

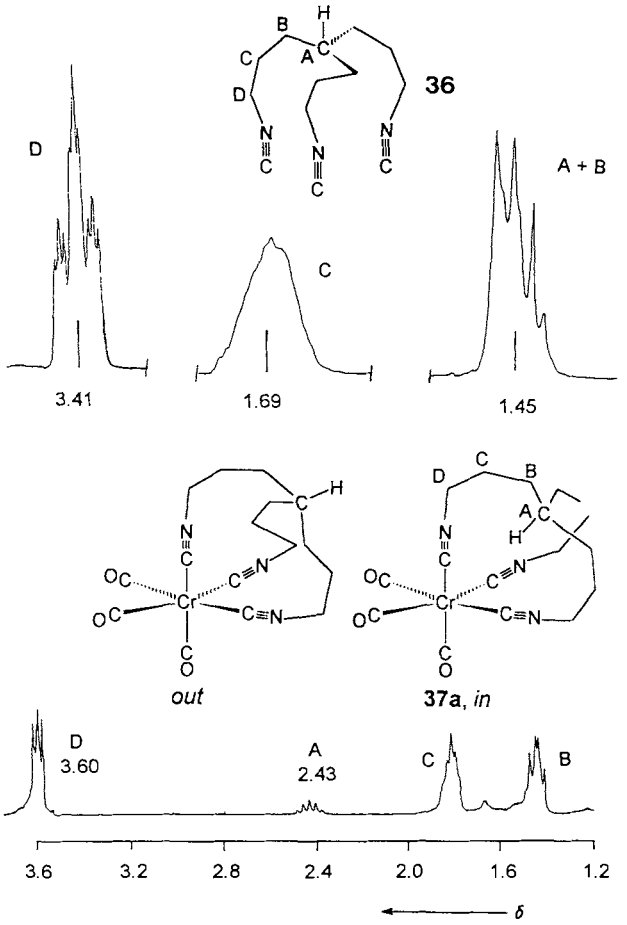


Fig. 8. ^{1}H NMR spectrum of **36** and its tricarbonylchromium complex **37a**.

The structure analysis of the isostructural complex *fac*-[$(CO)_3$W(**36**)] (**37b**) shows that the above assumptions are correct (Fig. 9, see Table 1). All three ligand branches coordinate to the same tungsten atom, which leads to the formation of 12-membered chelate rings. The central methine group adopts the *in* configuration.[60]

The structure analysis of **37b** shows that aliphatic, tripodal triisocyanides with only seven atoms between the isocyanide functionalities are also capable of forming chelate complexes. Hence it should be possible to obtain monomeric chelate complexes with the nitrogen-containing ligand **35**. This ligand indeed reacts with [(C_7H_8)W$(CO)_3$] under high dilution conditions to yield *fac*-[$(CO)_3$W(**35**)] (**38a**), which was characterized by X-ray diffraction (Fig. 9, Table 1).[60] Apparently

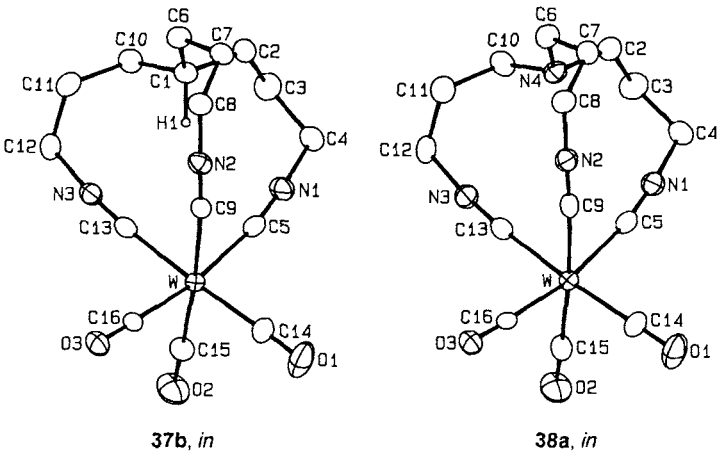

Fig. 9. Molecular structures of **37b** (left) and **38a** (right).

the formation of larger oligomers is favorable at higher concentrations, leading to the previously described insoluble compounds.[58] This assumption is supported by the isolation of the dimeric species *fac,fac*-[{$(CO)_3$W(**35**)}$_2$] (**38b**), which is formed in small amounts (ca. 5%) during the preparation of **38a**.[61] The structure of **38b** (Fig. 10) shows two $W(CO)_3$ units bridged by two ligands **35**. As was the case for **27d** (see Fig. 6) each ligand coordinates one metal center with two isocyanide groups, while the third isocyanide branch forms the bridge to the other metal atom. The nitrogen atom in the backbone of the complexes **27c** · HCl and **27d** are protonated and in the *out* configuration, while in **38a** and its dimer **38b** the nitrogen atoms are not protonated and exhibit the *in* conformation.

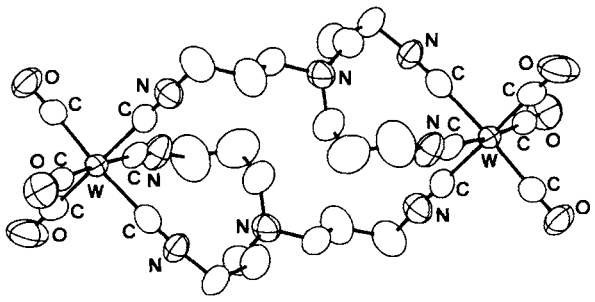

Fig. 10. Molecular structure of the dimer *fac,fac*-[{[$N(CH_2CH_2CH_2NC)_3$]-$W(CO)_3$}$_2$] **38b**.

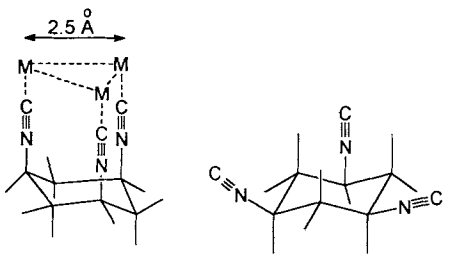
The IR spectra of the monomeric complexes **37a,b** and **38a** (see Table 2) are in accordance with those found for complexes with monodentate aliphatic isocyanides like *fac*-[$(CO)_3$W-$(CNR)_3$].[76] The spectra indicate that **35** and **36** are better σ donors and weaker π acceptors than aromatic triisocyanides such as **25**, **26**, **30**, or **32**. The M–CN and M–CO bond lengths, however, are only mildly affected by this (Table 1). Apparently the structural parameters reflect the electronic conditions much less accurately than the IR spectra.

It is noteworthy that the triisocyanides **32**, **35**, and **36** with fewer backbone atoms do not cause any larger deviations

from the linearity of the M-C-N or C-N-C angles than were observed for ligands with larger backbones. This occurs despite the fact that isocyanide complexes are known which are bent at the nitrogen atom.[77] This means that a large ligand backbone, with many atoms between the isocyanide functionalities, is not absolutely necessary for chelate formation.

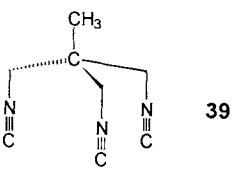
3.3. Reactions with $[M_3(CO)_{12}]$ Clusters

Low molecular weight carbonyl metal clusters act as catalysts and, in some instances, can serve as model systems for the investigation of reaction sequences on catalytically active metal surfaces.[78] One prerequisite for these studies is cluster stability (that is, the lack of any propensity for decomposition into smaller fragments). This condition is not fulfilled particularly in carbonyl clusters of the first transition metal series, since the M–M bonds there are generally weak. One method for the stabilization of clusters lies in bridging the metal atoms with multidentate ligands. Many clusters have trimetallic planes bridged by main group elements.[79] Other clusters are reinforced by tridentate phosphane[80a–c] or arene[80d] ligands. As early as 1980 an attempt was made to bridge a triangular plane in clusters of the type $[M_3(CO)_{12}]$ (M = Fe, Ru, Os) with triisocyanide ligands, making use of the fact that their properties are similar to carbon monoxide.[55] The ligand prepared for this purpose, *cis,cis*-1,3,5-cyclohexanetriisocyanide, proved unsuitable. Even though in form A (CN axial) the three isocyanide carbon atoms form an equilateral triangle with an edge length of about 2.5 Å, the ligand assumes the unfavorable form B (CN equatorial), in contrast to the analogous triamine.[81]



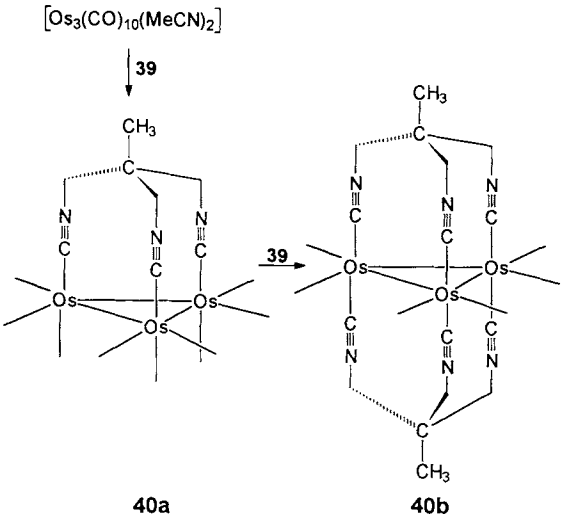
A B

The tripodal ligands presented in Sections 3.1 and 3.2 do not have this type of conformational problem. They do not, however, possess an ideal topology, since they react with trimetal clusters by chelating only one metal atom, thereby destroying the cluster framework. The ideal ligand would be a tailor-made triisocyanide with a small enough backbone to preclude chelate formation with a single metal atom. The ligand **39**, developed nearly simultaneously by two research groups,[62, 63] fulfills these requirements. If the isocyanide groups are parallel, the distance between the isocyanide carbon atoms is calculated to be 2.55 Å, assuming an angle of 109° at the quaternary carbon atom and a C–CH_2 distance of 1.54 Å. When further considering that the M–C≡N–CH_2 unit can deviate from linearity, it becomes apparent that **39** should be able to bridge trimetallic planes in $[M_3(CO)_{12}]$ clusters (M = Fe, d(M–M) = 2.69, 2.55 Å;[82] M=Ru, d(M–M) = 2.848 Å;[83] M = Os, d(M–M) = 2.881 Å[84]).



39

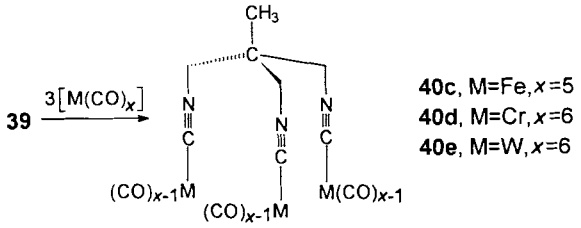
It proved indeed possible to obtain the bridged clusters **40a** (yield 55%) and **40b**[62] by allowing **39** to react with $[Os_3(CO)_{10}(NCCH_3)_2]$.[85] Compared to the starting material, the X-ray crystal structure of **40a** shows a nearly unchanged Os_3 frame (d(Os–Os) = 2.896 Å) and almost linear Os–C≡N and C≡N–CH_2 angles (ca. 170°). The reaction of **40a** with Me_3NO/MeCN and another equivalent of **39** yields the bicapped cluster **40b**.



40a **40b**

The stability of metal–metal bonds in $[M_3(CO)_{12}]$ clusters increases in the order Fe < Ru < Os. For the Os clusters, and, in a more limited way, for the Ru clusters, substitutions of the CO groups are possible without causing cluster fragmentation. The corresponding triiron clusters are significantly less stable. While ruthenium and osmium pentacarbonyl react quickly to give the corresponding dodecacarbonyls, iron pentacarbonyl is more stable than $[Fe_3(CO)_{12}]$. Therefore a different path was chosen for the synthesis of $M_3(CO)_9$ (M = Fe, Ru) units bridged by **39**.[63, 64] In the first step, **39** was ligated to three mononuclear metal carbonyls according to the method of Hieber.[63, 86] The IR spectrum of thus obtained **40c** indicates that the isocyanide groups occupy the axial position on the iron atoms, displaying C_{3v} symmetry.[87] Apart from the shift of the C≡N absorption band in the IR spectrum, the coordination of the isocyanide groups to a metal center can be identified by the downfield shift of the resonance signal for the methylene group in the ^{1}H NMR spectrum ($\Delta\delta$ = 0.22–0.31).[63]

Upon irradiation (high-pressure mercury lamp), highly diluted solutions of **40c** evolve CO, and the slightly yellow reaction mixture turns dark green within 10 minutes. Preliminary analyses indicate the formation of a triisocyanide-bridged cluster which also contains bridging CO ligands.



This cluster, however, fragments very readily, during which a transformation of the triisocyanide ligand is observed as well. This sensitivity has so far precluded a structure analysis. The high reactivity of this triiron cluster is not surprising when considering that the reaction of $[Fe_3(CO)_{12}]$ with MeNC results in cluster fragmentation as soon as more than two CO groups have been replaced.[88]

An interesting property of **39** is the possibility not only to coordinate each isocyanide group separately, but also to different metals (Fig. 11).[64] In this way it is possible for **39** to coordinate one, two, or three $Cr(CO)_5$ fragments to form the complexes **40f–h**. The structure of **40f** (Fig. 11) provides the unique opportunity to compare the N≡C bond lengths of coordinated and free isocyanide functions in the same molecule. Even though the IR absorption band of the coordinated isocyanide group is shifted 45 cm^{-1} to higher energies in comparison with the free isocyanide groups, the bond lengths of all three groups are identical within error limits. Apparently the coordinated isocyanide functionality acts only as σ donor. The complexes **40g** and **h** containing two and three $Cr(CO)_5$ units, respectively, were identified by the downfield shift of the signal for the protons of the methylene group in the ^1H NMR spectrum.[64]

This downfield shift also permitted the identification of complexes with different carbonyl metal fragments. The complex $[H_3CC(CH_2NC)\{CH_2NC\text{-}W(CO)_5\}\{CH_2NC\text{-}Cr(CO)_5\}]$ was characterized by the three signals of the methylene groups at $\delta = 3.45$ (H_2C-NC), 3.70 (H_2C-NC-$Cr(CO)_5$), and 3.91 (H_2C-NC-$W(CO)_5$).[61] It is thus possible to obtain the starting materials for clusters containing different transition metal atoms by preparing correspondingly coordinated triisocyanide ligands such as **39**. The formation of metal–metal bonds can then be initiated by irradiation, as for the triiron complex, or by other methods (oxidation or reduction of the carbonyl metal unit). The most prominent advantage of this method is that the desired cluster can be preformed by using stable mononuclear carbonyl isocyanide metal units.

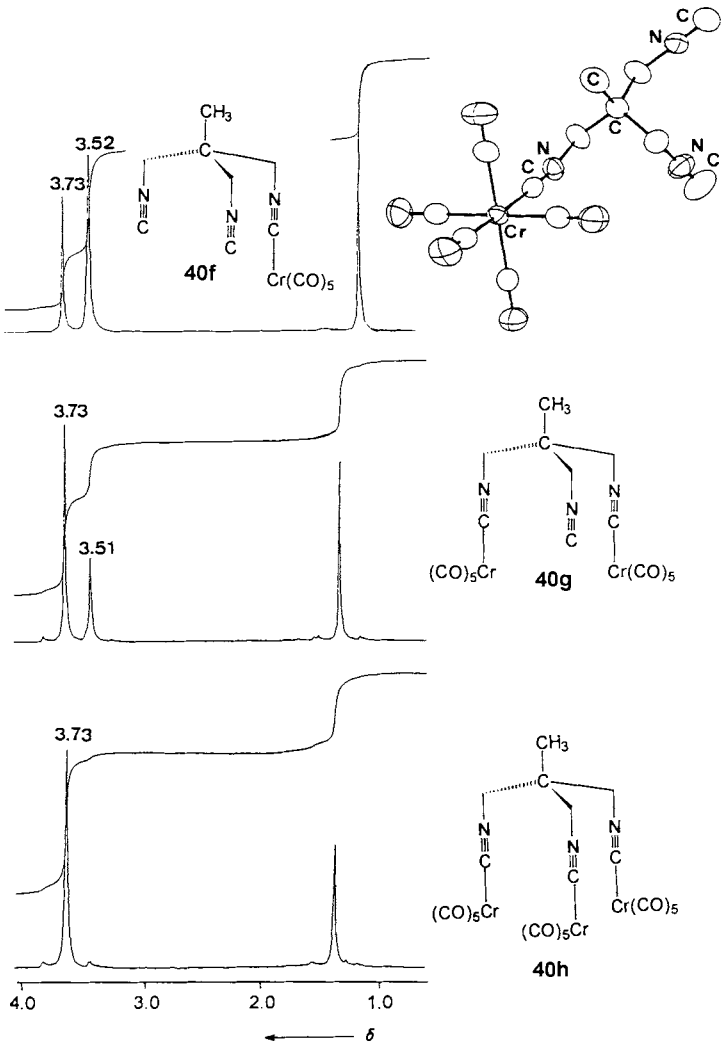


Fig. 11. ^1H NMR spectra of the complex $[CH_3\text{-}C(CH_2NC)_x\{CH_2NCCr(CO)_5\}_{3-x}]$ ($x = 0, 1, 2$) and the molecular structure of $[CH_3\text{-}C(CH_2NC)_2\{CH_2NCCr(CO)_5\}]$ **40f**.

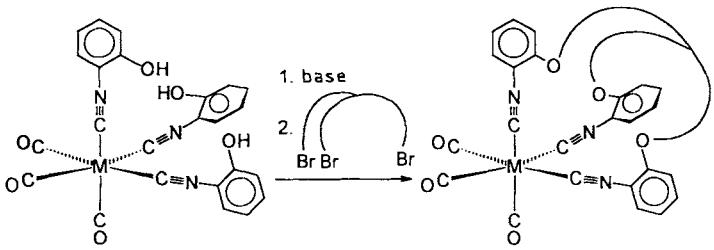
3.4. Experiments for the Construction of Polyisocyanides by Template Synthesis

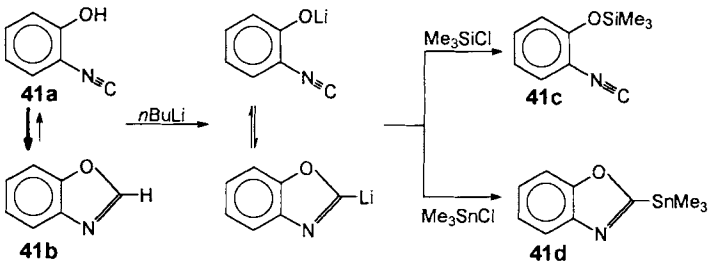
After it had been shown that tripodal isocyanides of varying backbone sizes have the ability to form chelate complexes, an attempt was made to prepare such ligands by template synthesis from monodentate isocyanides already bound to a metal center. A promising starting material for such reactions is coordinated β-hydroxyphenylisocyanide (**41a**). It should be possible to link three of these ligands, when facially coordinated to a metal center, by using the three hydroxyl groups and a suitable tripodal linker. In this way, novel as well as previously described ligands with an ether bridge could be obtained (Scheme 3).



Scheme 3. Construction of tripodal ligands by template synthesis.

Free **41a** is not stable, however, but quantitatively cyclizes to form benzoxazole **41b**.[89] Benzoxazole can be deprotonated by strong bases, such as *n*BuLi. The open ring formed can then be stabilized by regiospecific silylation at the oxygen atom using trimethylchlorosilane, forming β-trimethylsiloxyphenylisocyanide **41c**.[90] With trimethyltin chloride instead exclusively the stannylated benzoxazole **41d** is formed.[90]

In order to study possible alkylations according to Scheme 3, **41c** was allowed to react with $[W(CO)_5(thf)]$,[91]



which yielded complex **42a** (Fig. 12).[61] It is known that aliphatic β-hydroxyalkylisocyanides like $HOCH_2CH_2NC$ can be stabilized by coordination to electron-rich $(CO)_5M$ fragments (M = Cr, Mo, W).[92] Coordination to late transition metals (Pt^{2+}, Pd^{2+}, Au^+), however, leads to the rapid formation of carbene complexes with cyclic oxazolidine-2-ylidene ligands. This reaction proceeds by an intramolecular

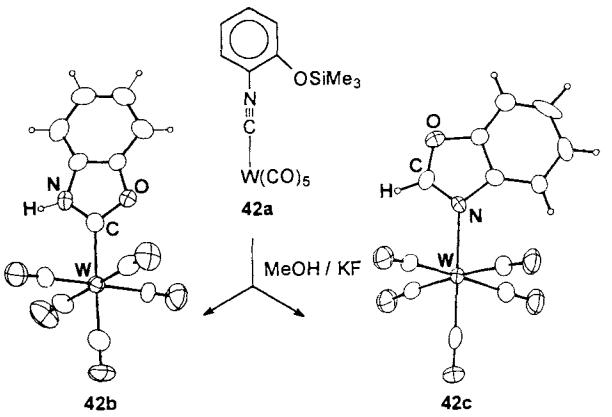


Fig. 12. Molecular structures of (dihydrobenzoxazole-2-ylidene)pentacarbonyltungsten **42b** and (benzoxazole)pentacarbonyltungsten **42c**.

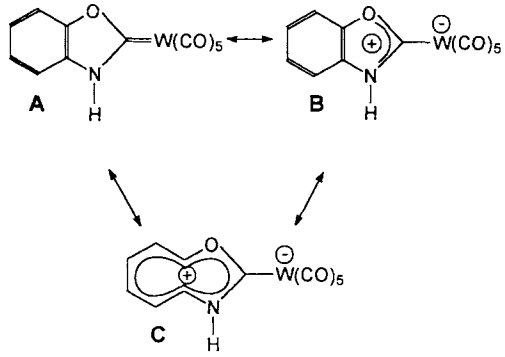
nucleophilic attack of the hydroxy group on the isocyanide, which is activated due to the lack of $(d \rightarrow p)\pi$ back bonding.[93] A stabilization of the isocyanide carbon atom by tungsten(0) was expected for the complex formed by the cleavage of the trimethylsilyl protecting group from **42a**. The silyl group is indeed removed readily by stirring **42a** in methanol in the presence of a catalytic amount of KF.[94] Surprisingly, the product of this Si–O bond cleavage is not the expected $(CO)_5W$ complex with coordinated β-hydroxyphenylisocyanide, but a mixture of the heterocarbene complex **42b**, with coordinated dihydrobenzoxazole-2-ylidene, and the complex **42c** with N-coordinated benzoxazole[95] (Fig. 12).[61] The carbene formation by intramolecular nucleophilic attack on the isocyanide carbon atom was therefore not prevented by the relatively electron-rich tungsten(0) center. Apparently, in addition to the stabilization provided by metal–ligand back bonding (**A**) and by the $(p \rightarrow p)\pi$ bonds of the heteroatoms (**B**), the aromaticity of the carbene ligand (**C**) makes a crucial contribution to the thermodynamic stability of the complex (Scheme 4). This stabilization cannot occur with aliphatic β-hydroxyisocyanides, which are stabilized at W^0.

These assumptions are also supported by a comparison of the structural parameters of **42b** and **42c**. The $W–C_{carbene}$ distance in **42b** (2.185(10) Å) is in the range found for corresponding bonds in other $(CO)_5W$–C(carbene) complexes.[96] The bond lengths in the heterocarbene ring of **42b** are, as expected for an arene, rather similar (from 1.329(14) to 1.399(13) Å). In the N-coordinated benzoxazole ring of **42c**, however, one finds clearly distinguishable single and double bonds (e.g., $d(N–C_{CH}) = 1.271(10)$, $d(N–C_{Ph}) = 1.397(10)$ Å). Analogous behavior has been observed for (dihydrobenzoxazole-2-ylidene)tetracarbonyl iron, which has been structurally characterized.[61]



Scheme 4. Resonance structures for (dihydrobenzoxazole-2-ylidene)pentacarbonyltungsten.

It appears that template syntheses using coordinated β-hydroxyphenylisocyanide are not feasible due to the cyclization of the coordinated ligand. There is, however, the possibility to alkylate the nitrogen atom of the formed dihydrobenzoxazole-2-ylidene ligands. The N-bound proton in **42b** is readily removed by bases, enabling subsequent electrophilic alkylation of this nitrogen atom.[97] After deprotonation by NaH, **42b** reacts with MeI or $H_2C=CHCH_2Br$ to form the complexes **42d** and **42e**, respectively (Fig. 13).[61]

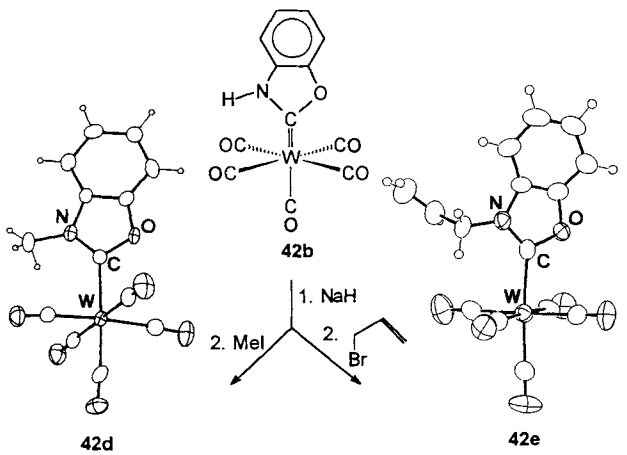


Fig. 13. Molecular structure of (*N*-methyldihydrobenzoxazole-2-ylidene)pentacarbonyltungsten **42d** and (*N*-allyldihydrobenzoxazole-2-ylidene)pentacarbonyltungsten **42e**.

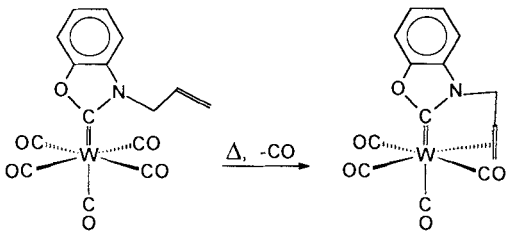
Complex **42e** can be further transformed thermally to give the olefin–carbene complex **42f**. Such complexes are assumed to be of great importance for catalytic processes.[96d, 97, 98] Complex **42f** can be characterized unambiguously by the

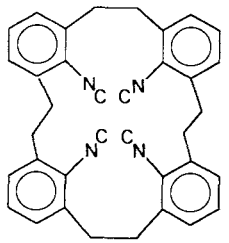
changes in the ^{1}H NMR spectrum. The coordination of the allylic double bond causes an upfield shift, especially for the olefinic methylene protons ($\delta = 2$). The resonance signals for the protons of the N-bound methylene group are also diastereotopically split by the coordination of the double bond.



42e **42f**

4. Tetradentate Isocyanide Ligands

Up to now, only a few tetraisocyanides are known. The synthesis of the cyclic, aliphatic isocyanide **43** was reported in 1981.[99] It was postulated that this ligand forms mononuclear complexes with a number of transition metals. In this case, very small chelate rings would have to form. From the molecular structure of the $[Rh(\mathbf{20b})]^+$ cation (see Fig. 2), it appears that linking two ligand molecules **20b** by an ethylene bridge should be difficult. The formation of mononuclear, planar metal complexes, in which all four isocyanide functionalities of a single **43** ligand are coordinated to the same metal, therefore appears to be unlikely.



43

The synthesis of tetraisocyanides is possible starting from the triisocyanides described in Sections 3.1 and 3.2. If, during the synthesis of **29**, the reductive elimination of the ligand backbone nitro group is not performed, subsequent reduction of this group together with the aromatic nitro functionalities to primary amines leads, after formylation and dehydration, to a tetraisocyanide.[61] Assuming the *in* configuration at the central carbon atom, such ligands are capable of occupying four coordination sites in trigonal-bipyramidal complexes. Only a large ligand backbone, however, allows the transition from O_h (octahedral) to C_{3v} symmetry (trigonal bipyramid) in a metal complex. The coordination chemistry of the only known linear tetraisocyanide has not yet been explored.[54]

5. Summary and Outlook

As is the case in all new areas of research, the investigation of metal complexes of polyisocyanides is currently dominated by the coordination chemistry and the search for synthetic pathways leading to new ligands and complexes. Tripodal triisocyanide ligands are especially characterized by a rich and varied coordination chemistry. Most notable is the fact that the formation of mononuclear chelate complexes is possible with rather different ligands. The composition of the ligand backbone (nitrogen or carbon as central atom) as well as its size can be varied over a wide range. The work with tripodal ligands indicates that, starting from the results of structural analyses, it is possible to influence the structural parameters of the complexes substantially by altering the ligand design.

The future will bring the development of ligands with different backbones, maybe even tetradentate ligands. The investigation of the reactions of coordinated polyisocyanides is also only at its very beginning. The preparation of siloxy-substituted tripodal triisocyanide ligands can be envisioned. After coordination to a metal atom, it then should be feasible to transform these compounds by Si–O bond cleavage and subsequent intramolecular carbene formation into previously nearly unknown polycarbene ligands.[100] The preparation of facial chromium complexes, $[CrL_3^*]$ (L_3^* = chiral-substituted tripodal triisocyanide), should lead to interesting catalytic reactions. Finally, the use of triisocyanides in the preparation of $^{99m}Tc^I$ complexes for medical diagnostic purposes cannot be overlooked. Multidentate ligands, in contrast to their monodentate analogues, raise the possibility of linking the ligands to a molecule with high biospecificity. This, in turn, would influence the in vivo distribution of the subsequently formed technetium isocyanide complexes.

I wish to extend my gratitude to my graduate students for their enthusiastic cooperation. Dr M. Tamm deserves special mention for the synthesis of the tripodal triisocyanides and their metal complexes. I wish to thank Professor H. Schumann for always providing me with support during my habilitation, during which time a large number of the described complexes were prepared. Professor E. P. Künding receives my thanks for bringing the interesting problems of the catalysis with chromium carbonyls and isocyanides to my attention. Past and present support of our work by the Deutsche Forschungsgemeinschaft, the Graduate College "Synthese und Strukturaufklärung niedermolekularer Verbindungen" at the Technischen and the Freien Universität Berlin, as well as the Fonds der chemischen Industrie is gratefully acknowledged. A doctoral fellowship from the BASF AG for Dr. M. Tamm was especially appreciated. Financial support for our work with technetium was provided by the Institut für Diagnostikforschung (a subsidiary of the Schering AG) at the Freien Universität Berlin.

[3] There are differing reports regarding the smell and the physiological properties of isocyanides. While Gautier describes the smell of—probably impure—ethylisocyanide as very uncomfortable and unbearable [1b], Hoffmann reports that vapors of phenylisocyanide leave a bitter taste on the tongue and create "especially in the throat an asphyxiating effect". [2a] Other groups report that pure compounds do not have unpleasant smells (cf. H. Lindemann, L. Wiegrebe, *Ber. Dtsch. Chem. Ges.* **1930**, *63*, 1650–6, in particular, p. 1655). Volatile alkylisocyanides like

MeNC or EtNC have indeed an unpleasant smell, while higher or alkylisocyanides with substituted side chains are practically free of any smell. Polyisocyanides are in general not volatile and are free of smell. In a study by the Bayer AG the toxic effect of isocyanides was tested. It was found that—with some exceptions—mice could tolerate doses of 500–5000 mg per kg body weight (cf. reference [67b] in [5b]).

Sequence-Specific Recognition and Modification of Double-Helical DNA by Oligonucleotides

By Nguyen T. Thuong and Claude Hélène*

Dedicated to Professor Charles Sadron on the occasion of his 90th birthday

Nucleic acids can be selectively recognized by a large number of natural and synthetic ligands. Oligonucleotides provide the highest specificity of recognition. They can bind to a complementary single-stranded sequence by forming Watson–Crick hydrogen bonds. They can also recognize the major groove of double-helical DNA at specific sequences by forming Hoogsteen or reverse Hoogsteen hydrogen bonds with purine bases of the Watson–Crick base pairs, resulting in a triple helix. Triple-helix formation through oligonucleotide binding to DNA is a sequence-specific interaction involving primarily homopurine · homopyrimidine sequences in the double-helical target. Extending the range of recognition sequences remains a challenge to chemists. Both thermodynamic and kinetic parameters for triplex formation have been determined. These parameters indicate, for example, that triple-helix formation is a much slower process than duplex formation. Nuclease-resistant oligonucleotides synthesized with the α-anomers of nucleosides (instead of the natural β-anomers) also form triple helices with double-stranded DNA. Triple-helix-forming oligonucleotides can be modified, for example, by attaching DNA intercalating agents to enhance their binding affinity. They may also be modified with reagents that induce irreversible reactions in their target sequence upon chemical or photochemical activation. Thus, artificial nucleases can be developed with very high sequence specificity on megabase-size DNA. Furthermore, triple-helix-forming oligonucleotides can be used to selectively control gene expression. When bound to the regulatory region(s) of specific genes they may prevent activation (or repression) of transcription. When binding occurs near or downstream from the transcription initiation site, elongation of the transcript may be inhibited. Therefore, the potential exists for developing new gene-blocking agents with therapeutic applications in the treatment of gene disorders.

1. Introduction

The recognition of specific nucleic acid sequences has been the subject of a large number of studies over many years. This interest arises from the early observation that gene expression in all living organisms is controlled by regulatory proteins that bind to specific sequences on single- or double-stranded nucleic acids. During the last ten years, resolution of the X-ray crystallographic structures of several nucleic acid–protein complexes has provided details of the molecular interactions involved in protein–nucleic acid recognition.[1] Despite these advances and the study of model systems[2] we are not yet in a position to predict the oligopeptide sequence that will recognize any given nucleic acid sequence.

Nucleic acids, especially double-stranded DNA, bind a large number of naturally occurring and synthetic ligands, such as antibiotics or antitumor agents. For example, intercalating agents insert their aromatic rings between two adjacent base pairs of double-helical DNA.[3] Minor groove-binding ligands have also been reported to alter biological processes that involve DNA as a substrate.[4] Until very recently there was no ligand available with a high enough selectivity to recognize a single sequence in double-helical DNA within a living cell. The size of the DNA genome in living organisms ranges from a few million base pairs in bacteria (4.5×10^6 in *Escherichia coli*, the bacterium that colonizes the intestinal tract in humans) to a few billion in higher (eukaryotic) systems (about 3×10^9 base pairs in human DNA, which is not the largest genome among all living organisms).[5] Viruses, which after infection rely on the host cell for multiplication, have smaller genomes consisting of either single- or double-stranded ribo- or deoxyribonucleic acids (RNA or DNA). For example, the genetic information (genome) of the human immunodeficiency virus (HIV) is contained within a single-stranded RNA chain of about 9200 ribonucleotides.[6]

In order for a ligand to recognize a single sequence in a nucleic acid it should interact with a number of nucleotides or base pairs; this number depends on the size of the targeted nucleic acid (Fig. 1). The minimum number of base pairs that must be recognized in a bacterium such as *E. coli* (4.5×10^6 base pairs) is about 11, while that in a human cell (3×10^9 base pairs) is approximately 17.[7] These estimations are based on a statistical distribution of base pairs in the DNA genome and an equal number of A · T and G · C base pairs. More sophisticated calculations can be done by using additional parameters such as the nearest neighbor frequencies, which have been determined for many organisms.[7]

The only nucleic acid binding ligands known to date that can achieve such a high degree of specificity are nucleic acids themselves. Since the discovery of the DNA double-helical

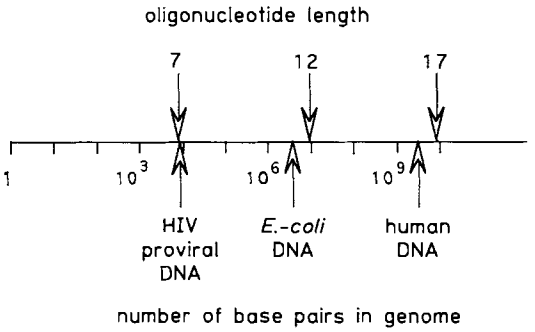

Fig. 1. The required length an oligonucleotide should be in order to recognize a unique DNA sequence in the genome of a living organism has been calculated, assuming a random distribution of base pairs and a fraction of A · T (G · C) base pairs equal to 0.5. There are four possibilities (A, T, G, or C) for each nucleotide position. Due to the complementarity of base pairs (A opposite T, G opposite C) in double-stranded DNA, there are $4^n/2$ different sequences of n base pairs for odd values of n and $4^n/2 + 4^{n/2}/2$ for even values of n [195]. When single-stranded DNA or RNA is the target and, for a site size of n nucleotides, there are 4^n distinguishable sequences. In higher (eukaryotic) organisms, the fraction of A · T base pairs is about 0.6. The nearest neighbor frequency is also known, which allows more detailed calculations to be performed (see ref. [7]). For example, the sequence $^{5'}CG^{3'}$ (but not $^{5'}GC^{3'}$) is underrepresented in eukaryotic genomes (about five times less frequent than calculated on a statistical basis). Sequences containing only C and G with several $^{5'}CG^{3'}$ sequences will have less probability of being found in eukaryotic DNA than sequences rich in A and T. The genome of *E. coli* (4.5×10^6 base pairs) and of human beings (3×10^9 base pairs) is indicated together with that of HIV. The genetic information of HIV is carried by a single-stranded RNA, but following infection, this RNA is reverse transcribed into double-stranded DNA which integrates into the DNA of the infected cell. A minimum length of about 17 bases is therefore required to recognize a unique sequence within the proviral DNA once it is integrated in the genome of the infected cell.

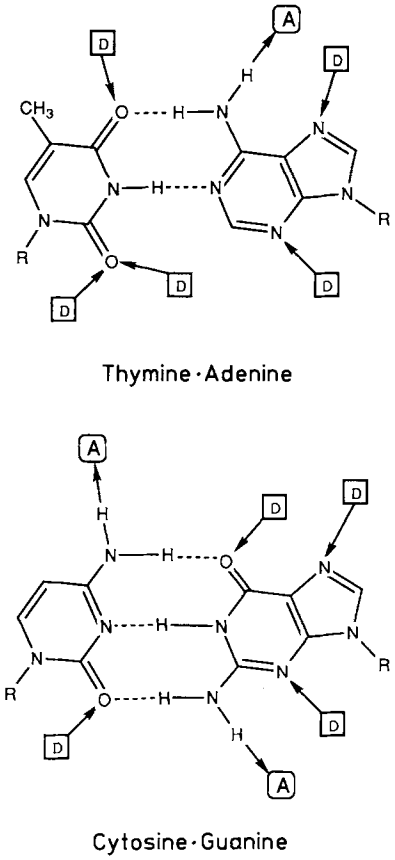

Fig. 2. Watson–Crick base pair formation. Hydrogen bond donor (D) and acceptor (A) sites within both the major and the minor groove are indicated (taken from ref. [2]).

structure in 1953,[8] the Watson–Crick model of base pair formation has provided the code for recognition of any single-stranded nucleic acid sequence. Two hydrogen bonds allow the recognition of adenine (A) by thymine (T) or uracil (U), and three hydrogen bonds are involved in recognition of guanine (G) by cytosine (C) (Fig. 2). Due to these selective recognition rules it is possible to design an oligonucleotide that will recognize any base sequence on a single-stranded nucleic acid target. The isomorphism of purine · pyrimidine

Nguyen Thanh Thuong left Vietnam in 1950, at the age of twenty, came to France, and studied chemistry at Ecole Superieure de Chimie de Mulhouse from 1954 to 1958. In 1960, he received his doctorate in chemistry under the supervision of P. Chabrier in Paris. Until 1978 he worked as an organic chemist in industry, then joined the Centre de Biophysique Moléculaire (CNRS) in Orléans. His fields of interest are the synthesis and application of modified oligonucleotides in molecular biology.

Claude Hélène was born in 1938. After graduating from the Ecole Normale Supérieure de Saint-Cloud, he received his Ph.D. in 1966 from the University of Paris. In 1967 he moved to the Centre de Biophysique Moléculaire, a CNRS Institute, in Orleans as a CNRS researcher. In 1974 he became Director of this institute. In 1976 he was appointed as Professor to the Chair of Biophysics at the Muséum National d'Histoire Naturelle in Paris, where he created a new INSERM and CNRS research unit in 1980. Since 1990 he has also been a Scientific Director at Rhône-Poulenc. In 1988 he was elected a full member of the French Academy of Sciences. Claude Hélène has been involved early on in studies on nucleic acid excited states and photochemistry, and on protein (peptide)–nucleic acid interactions. During the last ten years, he has developed new approaches in the field of antisense and antigene oligonucleotides.

base pairs ensures that there is no major distortion of the phosphodiester backbones of a double helix (the two chains wrap around each other in a regular way). Hydrogen bonding interactions between purines and/or pyrimidines other than A · T(U) or G · C are possible, but the distortion of the backbone introduces an energy penalty that leads to rejection of such interactions in a (perfect) double helix. However, under certain circumstances some base pairs such as G · T ("wobble" base pair) can be accommodated within a double helix. The high fidelity of DNA replication, which ensures that genetic information is not lost during cell division, requires a highly sophisticated proofreading process, thereby eliminating erroneous bases introduced by the enzymatic replication machinery.[9]

It has long been recognized that nucleic acid base pairs of double-helical DNA retain hydrogen bonding capabilities in both the minor and major groove of the double helix. These capabilities may be exploited for sequence-specific recognition (see Fig. 2).[2] A few years after the discovery of the DNA *double helix* structure,[8] it was shown that a *triple helix* could be formed by polynucleotides.[10] Two chains of the polyribonucleotide poly(rU) are able to simultaneously bind to one chain of poly(rA). This was the starting point for a number of studies, showing that double helices containing only purines in one chain could bind a third polynucleotide containing only pyrimidines (e.g., poly(dCT) binding to poly(dGA) · poly(dCT)) or only purines (e.g., poly(dG) binding to poly(dG) · poly(dC)) (Fig. 3).[11-13] The hydrogen bonding interactions involved in triple-helix formation are often referred to as Hoogsteen hydrogen bonds. Hoogsteen discovered that in cocrystals of adenine and thymine derivatives a hydrogen bonding pattern different from that of Watson–Crick base pairs was present.[14] These hydrogen bonds are involved when a (third) strand of poly(dT) binds to a Watson–Crick-paired poly(dA) · poly(dT) double helix.

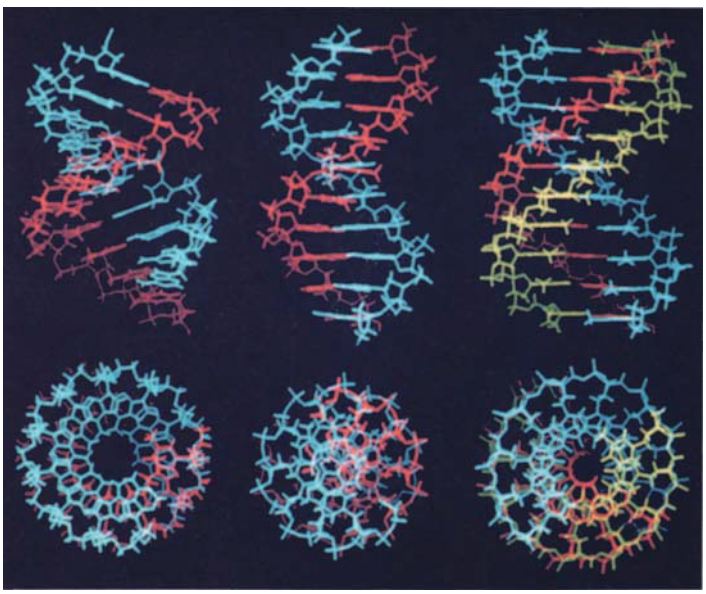

Fig. 3. Model of A-DNA (left), B-DNA (center), and triple-helical DNA (right). End-on views of the structures are shown below. The A- and B-DNA structures were obtained from the atomic coordinates given by Arnott et al. [208]. The triple helix structure was obtained by energy minimization [63] starting from the structure obtained by X-ray diffraction of poly(dA) · 2poly(dT) fibers [50]. In this triple-helical structure, the third strand contains only pyrimidines, which are hydrogen bonded to the purine strand of the double helix according to the Hoogsteen hydrogen bonding mode in Figure 5. The third strand runs parallel to the Watson–Crick purine strand. Other possible triple-helical structures are discussed in the text.

The interest in triple helices was recently rekindled when it was shown that:

1) Mirror-repeat homopurine · homopyrimidine sequences of circular double-stranded DNA could adopt a new structure, called H-DNA, under superhelical stress.[15-17] This structure arises from the concomittant formation of a triple helix and a single-stranded loop (Fig. 4) within superhelical circular DNA.

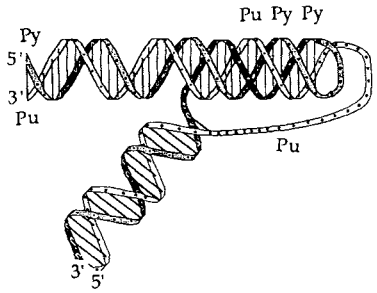

Fig. 4. Structure of H-DNA formed when a mirror-repeat polypurine · polypyrimidine sequence is subjected to supercoiling constraints within circular DNA. Half of the polypyrimidine strand folds back on the pu · py double helix to form a py × pu · py triple helix, and the corresponding complementary half of the polypurine sequence becomes single-stranded. Alternatively, the polypurine sequence can fold back on the pu · py double helix to form a pu × pu · py triple helix and a polypyrimidine single strand (adapted from ref. [16]).

2) Short oligonucleotides could bind to the major groove of double-helical DNA by forming a local triple helix through sequence-specific Hoogsteen hydrogen bond formation.[18-20, 99]

This review will focus mainly on triple-helix formation by short oligonucleotides bound to double-helical DNA. New information has been accumulating during the last few years on the structure, thermodynamics, and kinetics of such interactions. The possibility of designing a new generation of sequence-specific regulators of gene expression based on DNA recognition by triple-helix-forming oligonucleotides has a great deal of interest in the chemistry and biology of oligonucleotide analogues. We have called this approach the "antigene" strategy[21] (a specific gene being the target of a triple-helix-forming oligonucleotide) by analogy with the "antisense" strategy (where the oligonucleotide is targeted to a single-stranded "sense" nucleic acid, such as a messenger RNA (mRNA) or a viral RNA, through formation of Watson–Crick base pairs). Several recent reviews on the antisense strategy have been published,[22-25] and this aspect of oligonucleotide chemistry and biology will not be dealt with in the present review, except when similar chemical modifications have been introduced in both the antigene and antisense approaches.

2. Triple-Helix Formation by Oligonucleotides

2.1. Base Triplets

As stated in the introduction, triple-helix formation relies upon hydrogen bonding interactions between bases in the

third strand and purines already engaged in Watson–Crick hydrogen bonding to pyrimidines. Figure 5 shows the base triplets that could be formed with natural bases.[21] Several features are of importance:

1) All base triplets in Figure 5 involve two hydrogen bonds with the purines of the A · T and G · C base pairs.

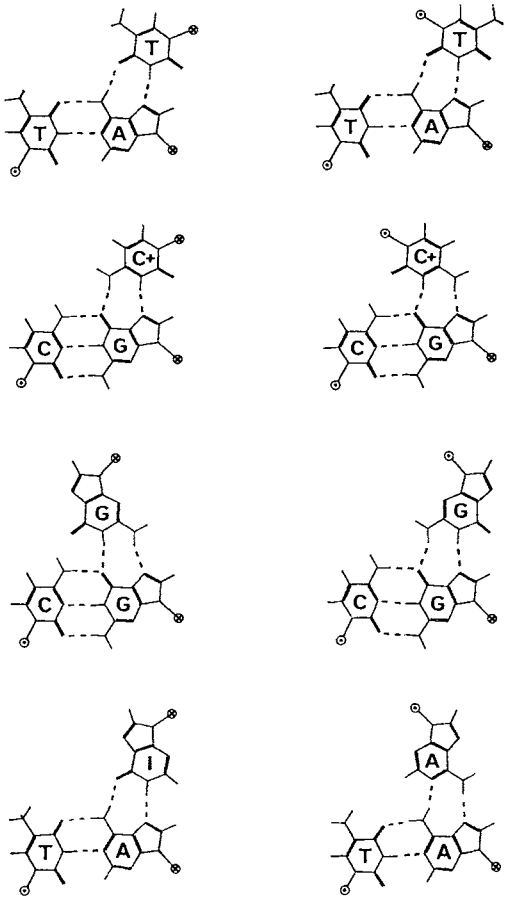

Fig. 5. Base triplets formed by Watson–Crick A · T and G · C base pairs with T, protonated C (C^+), G, A, and I. If bases in the third strand are in the *anti* conformation with respect to the sugar ring, the triplets in the left column correspond to a parallel orientation of the third strand with respect to the homopurine sequence of the DNA target, while those in the right column correspond to the reverse orientation. For the T × A · T triplets, the one on the left corresponds to the Hoogsteen hydrogen bonding pattern, whereas the one on the right corresponds to reverse Hoogsteen (see text). Some of these base triplets have been found in the crystal structures of transfer RNAs [26, 27] [e.g. G × G · C (reverse Hoogsteen bonds) and A × A · U]. Of course, many other possibilities exist where a single hydrogen bond is formed by the base in the third strand with any of the bases in the Watson–Crick base pairs. The structures of the base triplets shown in this figure were obtained from energy-minimized triple helices of ten identical base triplets (see ref. [63]).

2) In order to form two hydrogen bonds with G in a G · C base pair, cytosine must be protonated. The pK value of isolated deoxycytidine is 4.3, but the apparent pK is raised in oligonucleotides and multistranded nucleic acids due to their polyanionic character. Homopyrimidine oligonucleotides can form stable triple helices at acidic pH but, as expected, their stability decreases as the pH increases. However, the pH dependence is affected by the distribution of cytosines within the oligonucleotide sequence. Adjacent cytosines will create an unfavorable situation due to electrostatic repulsions between protonated rings.

3) All base triplets involving T, C, or G in the third strand may adopt two isomeric configurations. One series (left-hand side of Fig. 5) correspond to the hydrogen bonding scheme discovered by Hoogsteen in cocrystals of A and T,[14] and will be referred to as *Hoogsteen base triplets*. The other series (right-hand side on Fig. 5) involves a 180° rotation of the base in the third strand, and will be referred to as *reverse Hoogsteen base triplets*. Adenine in the third strand can adopt only a single configuration for the formation of two hydrogen bonds. The resulting A × A · T base triplet belongs to the reverse Hoogsteen category. Inosine can form two Hoogsteen hydrogen bonds with A · T base pairs (I × A · T).

4) One important parameter in designing oligonucleotides that bind to the major groove of double-helical DNA is the isomorphism of base triplets. When the C-1′ atoms of the Watson–Crick base pairs are fixed, the position of the C-1′ atom of the nucleotide in the third strand depends on the base triplet (Fig. 6). Only two triplets T × A · T and

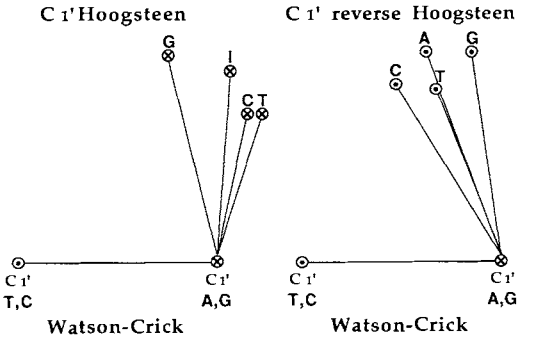

Fig. 6. Isomorphism of base triplets. The C1′ atoms of the three nucleotides belonging to each triplet are shown, with the C1′ atoms of the Watson–Crick base pair T · A or C · G located at a fixed position. The C1′ atoms of the nucleotide in the third strand are shown in either the Hoogsteen mode of hydrogen bonding (left column of Fig. 5) or in the reverse Hoogsteen mode (right column of Fig. 5).

C^+ × G · C are isomorphous. Other combinations lead to a distortion of the backbone(s) of the triple helix in order to minimize the effects of non-isomorphism. Hence, triple helix stability will be reduced when several steps along the triple helix are distorted.

2.2. Orientation of the Third Strand

Accoding to Figure 5, triple helix-forming oligonucleotides can be synthesized from naturally occurring nucleosides. The bases in the third strand bind to the purine bases in the target DNA through hydrogen bonds. To avoid the distortion of the oligonucleotide backbone that would result from switching from one strand of the double helix to the other, triple helices preferentially form at homopurine · homopyrimidine sequences of DNA (i.e. all purines in the target sequence belong to the same strand of the double helix).

As stated previously (Fig. 6), only two base triplets (T × A · T and C^+ × G · C) are isomorphous when Hoogsteen hydrogen bonds are involved. Thus, triple-helix-forming oligonucleotides containing only pyrimidines (T and C)

have been the subject of the majority of recent studies.[21] However, despite the backbone distortion that results from the heteromorphism of other base triplets, oligonucleotides other than those containing only pyrimidines are able to form triple helices with homopurine · homopyrimidine sequences of DNA. Oligonucleotides containing either G and T,[28, 29] G and A,[30, 31] or G, T, and C[32] have been shown to form triple helices. The formation of purine × purine · pyrimidine triplets was also shown to occur with either intramolecularly folded oligonucleotides,[33–35] polynucleotides with repeating units,[36, 37] or polypurine · polypyrimidine sequences in supercoiled plasmids.[38–40]

With all nucleotides in the *anti* conformation,[*] Hoogsteen hydrogen bonds lead to a parallel orientation of the third strand with respect to the homopurine target strand. Reverse Hoogsteen hydrogen bonding corresponds to an antiparallel orientation. If nucleotides in the third strand adopt the *syn* conformation, these orientations are reversed.

The orientation of third-strand oligonucleotides has been verified in several different ways:

1) For oligonucleotides which have a symmetrical base sequence (i.e. when the same base sequence is read in the 5′ → 3′ and 3′ → 5′ directions), attachment to particular positions of a cleaving reagent such as Fe-EDTA[**][19, 30] or a photocross-linking reagent[18, 41] has allowed direct determination of the orientation from an analysis of the location of the cleavage or cross-linking sites (cleavage at cross-linked sites was achieved with alkaline treatment[18, 41]).

2) For asymmetrical sequences optical melting curves (determinations with optical methods),[42] footprinting,[60, 122] or gel retardation experiments[29, 98] carried out with sequences of opposite polarities were used to determine which of the two orientations was bound to the target DNA.

In all cases, the orientation was found to obey the rules presented above. Oligopyrimidines bind in a parallel orientation with respect to the homopurine strand of the target DNA sequence.[18, 19, 41, 42] Oligopurines bind in an antiparallel orientation.[30] For oligonucleotides containing G and T the orientation was originally proposed to be parallel to the homopurine sequence[28] but later shown to be antiparallel.[29]

The intrinsic stability of T × A · T and G × G · C base triplets favors the Hoogsteen mode of hydrogen bonding. However, the energy penalty associated with the distortion of the backbone imposed by the non-isomorphism of these two triplets is less important for the reverse Hoogsteen configuration (Fig. 6). Therefore it might be surmised that the orientation of an oligonucleotide containing G and T should depend on the number of TpG and GpT steps in the third strand. This prediction has been experimentally verified.[43]

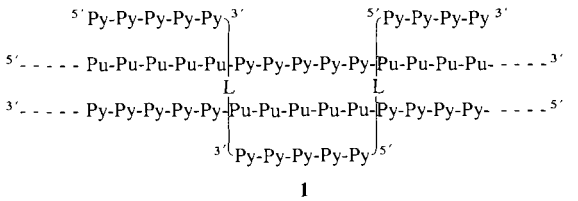
An oligonucleotide containing T, C, and G [$d(T_4CT_4G_6)$] was shown to bind in a parallel orientation with respect to the homopurine sequence.[32] In this complex six adjacent G × G · C Hoogsteen triplets formed together with Hoogsteen T × A · T and C^+ × G · C base triplets.

2.3. Extension of Recognition Sequences for Triple-Helix Formation

Triple-helix formation requires a homopurine · homopyrimidine sequence in the target DNA. A non-natural deoxynucleotide (1-(2-deoxy-β-D-ribofuranosyl)-4-(3-benzamidophenyl)imidazole) was recently shown to bind both T · A and C · G Watson–Crick base pairs when incorporated in an oligopyrimidine.[215] Although this derivative does not discriminate T · A from C · G base pairs, it allows triple helix formation at oligopurine sequences interrupted by one pyrimidine. It remains a challenge to design oligonucleotides that will recognize mixed purine/pyrimidine sequences. Recent work has shown that alternate-strand triple-helix formation can be achieved in different ways. Formation of this structure allows the recognition of a mixed sequence in which homopurine sections alternate on the two strands of DNA.

2.3.1. *Oligonucleotides with Opposite Polarities*

Two homopyrimidine oligonucleotides that bind in a parallel orientation with respect to the homopurine sequence of duplex DNA can be linked to each other at their 3′ or 5′ ends.[44–46] Different linkers have been described which allow simultaneous binding of the homopyrimidine oligonucleotides to adjacent purine tracts on alternate strands of the DNA duplex in parallel but opposite orientations (see **1**).



1

A 3′-3′-oligodeoxynucleotide **2** containing two pyrimidine sequences flanking a 1,2-dideoxy-D-ribose was synthesized on a support **3**, in which the first nucleoside was attached to the CPG through its 5′-hydroxyl group. After the first pyrimidine oligomer in the 5′-3′ direction was assembled by using nucleoside-5′-phosphoramidites **4**, the linker residue was introduced in the opposite orientation through its 3′-phosphoramidite **5**. The second pyrimidine sequence was then assembled in the usual 3′-5′ direction through the classical nucleoside-3′-phosphoramidites.[44]

[*] The fundamentals of the structure of nucleic acids and their building blocks are described in biochemistry textbooks. See for example, D. Voet, J. G. Voet, *Biochemistry*, Wiley, **1990**, Chapter 28.

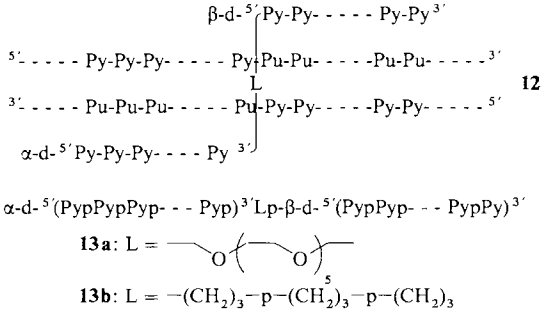
2.3.2. *Oligonucleotides with the Same Polarity*

One can take advantage of the different orientations that third-strand oligonucleotides adopt, depending on the nature of the base triplets involved in triple-helix formation. This should allow oligonucleotides containing only natural 3′-5′ phosphodiester linkages to simultaneously bind both strands of double-helical DNA by switching from one homopurine sequence to another. Sun et al.[43] have shown that the orientation of oligonucleotides containing G and T depends on the number of GpT and TpG steps. Consequently an oligonucleotide containing G and T can be designed to recognize adjacent purine tracts on alternate strands of the duplex. Beal and Dervan[47] have used the opposite orientations of pyrimidine and purine oligonucleotides bound to a homopurine sequence of duplex DNA to design a mixed-sequence oligonucleotide capable of forming an alternate-strand triple helix. The structures depend on whether the target site is 5′-(purine)$_m$(pyrimidine)$_n$-3′ or 5′-(pyrimidine)$_m$(purine)$_n$-3′. The former requires a pyrimidine domain and a purine domain linked by a 3′-5′ phosphodiester, while the latter requires that the third strand has at least two nucleotides as a linker at the site of crossover in the major groove.[47]

2.3.3. *Oligonucleotides Made from α- and β-Oligomers with the Same Polarity*

The reverse orientation of the pyrimidine oligo-α-nucleotide third strand with respect to that of the corresponding β-oligomer[122] (Section 3.3 for α-oligodeoxynucleotides) can be used to construct another set of molecules which are able to bind adjacent homopurine sequences on alternate DNA strands (see **12**). An oligo-α-deoxynucleotide covalent-



12

ly linked to a β-oligomer of the same polarity through either a hexaethylene glycol **13a** or a 1,3-propanediol derivative **13b** were readily synthesized by using the classical solid support **9** and 3′-phosphoramidites of α- and β-deoxynucleosides (V. Roig, N. T. Thuong, unpublished results).

2.4. Structure of Triple Helices

There is no crystal structure yet available for short triple-stranded oligonucleotides which gives a detailed description of the conformation of all nucleotide units in the three strands. Fiber diffraction data are available on polynucleotide structures.[48–51] Triple-helical complexes (either intra- or intermolecular) are the subject of intensive studies by NMR techniques.[52–58] Based on fiber diffraction data it was concluded that the triple-stranded structure poly(dT) × poly(dA) · poly(dT) had a large axial rise per base

triplet with the three strands forming a 12-fold helix of the A-family all containing C3′-*endo* furanose rings. In contrast, two-dimensional ^{1}H NMR studies of a 31-base DNA oligonucleotide, which folds to form a stable intramolecular triplex at acidic pH, have shown that most of the triplex sugars are close to the C2′-*endo* conformation.[54] However, stacking interactions between the purines in an intermolecular complex containing 11 base triplets have suggested that the oligopurine strand exhibits an A-helical base stacking conformation.[52] A molecular dynamics (MD) simulation of the DNA triplex, $d(TC)_5 \cdot d(GA)_5 \cdot d(TC)_5$ has also revealed considerable deviation from the fiber diffraction model.[59]

An assignment of nonexchangeable protons for an intramolecular triple helix with seven base triplets has been proposed on the basis of three-dimensional homonuclear NOESY–TOCSY ^{1}H NMR spectroscopic studies.[58] Exchangeable protons have also been identified for both Watson–Crick and Hoogsteen hydrogen-bonded protons.[52–54] Cytosine and protonated cytosine involved in $C^+ \times G \cdot C$ base triplets can also be distinguished. Future NMR experiments will certainly give more detailed information on local conformations within the triple helix and their sequence dependence.

Conformational changes in DNA induced by triple-helix formation have been characterized by the change in reactivity of bases toward chemical or photochemical reagents. Cleavage by a copper–phenanthroline chelate has been used to obtain a footprint of the triple-helix-forming oligonucleotide on the DNA double helix.[60] The region covered by the oligonucleotide was protected, whereas a strong enhancement of cleavage was observed on the purine-rich strand at the triplex–duplex junction on the 3′-side of the homopyrimidine oligonucleotide. A strong binding site for an ellipticine derivative was detected at the triplex–duplex junction on the 5′-side of the pyrimidine oligonucleotide.[61] Intercalation of ethidium or acridine derivatives at this same junction induces a conformational change that is detected by the hypersensitivity to diethylpyrocarbonate (EtO_2C-O-CO_2Et).[62] Psoralen derivatives (5- or 8-methoxypsoralen) exhibit enhanced reactivity under UV-B irradiation, forming a cross-link between the two duplex strands at the duplex–triplex junction, provided there is a 5′ TpA 3′ sequence (M. Takasugi, C. Hélène, unpublished results). This increased photochemical reactivity was related to enhanced intercalation of the psoralen ring at the triplex–duplex junction.

Molecular modeling and energy minimization studies have also shown that triple-helix formation induces conformational changes, notably at the duplex–triplex junctions.[63, 64] Experimental evidence for bending has been provided by recent electrophoretic mobility studies on DNA fragments containing a triple helix site at different positions.[64] A slight retardation of mobility was observed, which was maximized when the triple-helical region was centrally located. However, similar experiments carried out by Maher et al.[65] showed that DNA restriction fragments carrying a triple-helical region exhibited permutation-dependent acceleration of the mobility rather than retardation in a manner consistent with DNA stiffening rather than bending at the duplex–triplex junction. It can be predicted that triple-stranded DNA helices exhibit a reduced flexibility as compared to a double helix due to the higher radial charge density and the additional constraints arising from the presence of a third strand. Bending at the junction should also occur due to changes in helical parameters of the duplex within the triple-helical region. Energy minimization studies show that bending occurs toward the minor groove at the 5′-junction and toward the major groove at the 3′-junction.[64] In addition, bending is expected to depend on the nucleotide sequence at and near the duplex–triplex junctions.

A conformational distortion in the DNA duplex induced by triplex formation was detected in the regulatory region of human *papilloma* virus type II.[66] Hypermodification by chemical reagents such as dimethylsulfate, diethylpyrocarbonate, and osmium tetroxide were observed at bases flanking the triplex-forming region. An increased accessibility to chemical probes was interpreted as being due to a bend in the DNA duplex at the triplex–duplex junction. As shown by energy minimization studies, the bend induced by intermolecular triple helix formation depends on the sequence at the junction.[64] It is therefore expected that reactivity toward chemical probes will also be sequence-dependent. Clearly, more experimental data is needed to clarify the conformational changes that are expected to occur at and near a triple helix site.

Changes in DNA conformation induced by triple helix formation are also revealed by UV-photofootprinting. Following UV irradiation, adjacent pyrimidines form both pyrimidine dimers (with a cyclobutane ring involving the C5 and C6 carbon atoms on each pyrimidine) and 6,4-photoadducts (with a single bond between the two pyrimidines). The formation of 6,4-photoadducts is prevented by triple helix formation, both in pyrimidine × purine · pyrimidine[67] and purine × purine · pyrimidine[68] triplexes.

Uranyl-mediated photocleavage of phosphodiester bonds has also been used to probe the accessibility of phosphates in the triple helix.[69] Reduced accessibility was found on the purine strand, especially at its 5′-end, whereas enhanced cleavage was observed near the 3′-end of the pyrimidine strand when only $T \times A \cdot T$ triplets were involved.

2.5. Specificity of Triple-Helix Formation

The specificity of triple-helix formation has been probed by different techniques. Dervan et al.[19, 70, 71] used Fe-EDTA attached to a thymine base of the third strand to cleave the target DNA at the specific site of triple-helix formation. This method gives only qualitative information on the extent of binding but allows for a rapid comparison of sequence selectivity. A recent report[206] has shown that the affinity cleavage reaction can be made quantitative. A second method relies upon spectroscopic studies, in which "optical melting curves" are recorded and analyzed according to a two-state (all-or-none) model describing the dissociation of the third strand from the double helix.[72, 73] The precision of thermodynamic measurements from UV melting curves is often limited by the difficulty in obtaining good base lines before and after the melting process. The difference in stability introduced by mismatches has been estimated to be 3.2–4.0 kcal mol^{-1} per mismatch in one study[73] and to range

from 1.8 kcal mol^{-1} for the less destabilizing G × G · C non-canonical triplet to 5.9 kcal mol^{-1} for the most destabilizing C × T · A mismatch in another study.[72] The energy difference between canonical and non-canonical base triplets was estimated to vary between 3 and 6 kcal mol^{-1} from the superhelical density that is required to induce the transition to the triplex H-DNA structure in plasmids.[75] Polyacrylamide gel electrophoresis (PAGE) was also used to investigate base sequence specificity,[74] but no quantitative data on differences in triplex stability were reported. Footprinting techniques using, for example, DNase I or Cu–phenanthroline as cleaving reagents could also be used to analyze sequence specificity of triplex formation.

It should be emphasized that the change in stability due to a mismatch in a triple-helical structure depends on many parameters among which are: the nature of the mismatch, the nearest neighbors flanking the mismatch in the triplex sequence, the pH if one of the base triplets involves protonation of a cytosine (or an adenine in a A × G · C triplet[76]), the ionic strength, and the presence of ligands. Therefore one should be careful in drawing general conclusions from a study where only one set of conditions is used.

Griffin and Dervan[70] observed similar stabilities for the G × T · A and the canonical T × A · T triplet by affinity cleavage experiments. However, this holds true only when the G × T · A triplet is flanked by T × A · T triplets on both sides. The presence of C$^+$ × G · C triplets as nearest neighbors destabilizes this interaction.[71, 72] The G × T · A triplet within intramolecular triplexes was extensively studied by NMR,[76, 77] and was shown to involve a single hydrogen bond between the $NH_2(2)$ proton of G and the C = O(4) group of T. This result was consistent with that proposed on the basis of energy minimization and molecular modeling studies.[72] The structure and stability of X × G · C mismatches in the third strand of intramolecular triplexes was also studied by NMR.[78] The hydrogen-bonding scheme proposed for the G × G · C triplet was again identical to that obtained by energy minimization.[72] This scheme (with a single hydrogen bond) is different from that shown in Figure 5 for G × G · C triplets, in which two hydrogen bonds are formed. This difference probably reflects the backbone distortion due to the lack of base triplet isomorphism when a G × G · C triplet is flanked by two T × A · T triplets in a parallel orientation (Hoogsteen mode). The hydrogen-bonding scheme of Figure 5 is appropriate when adjacent guanines recognize a tract of adjacent G · C base pairs in the double helix.

As yet, only a little data is available on mismatch effects in purine × purine · pyrimidine triple helices.[30] For pyrimidine × purine · pyrimidine triplexes guidelines are emerging for choosing the base in the third strand that will give the highest stability when a purine · pyrimidine Watson–Crick base pair in duplex DNA is replaced by a pyrimidine · purine base pair (i.e. when a homopurine tract is interrupted by a pyrimidine).[63, 71, 72] Mismatches in the duplex itself may lead to enhanced stability.[63] For example, an A · C mismatch in the double helix forms a T × A · C triplet which is more stable than the canonical base triplet T × A · T.

Sequence-selective recognition of homopurine · homopyrimidine sequences within long molecules of duplex DNA was first reported in plasmids of a few thousand base pairs, where a single cut was observed when the triplex-forming oligonucleotide was equiped with either Fe-EDTA[19] or Cu–phenanthroline.[79] With Fe-EDTA as a cleaving reagent, Strobel et al. showed that a triplex-forming 18mer oligomer was able to cut the DNA of bacteriophage λ at a single position within the 48 502 base pair genome,[80] and that a 20mer recognized and cleaved a single site inserted in chromosome III of the yeast *Saccharomyces cerevisiae*, which contains 3.4×10^5 base pairs.[81] Dervan et al. then developed an elegant strategy to cleave long DNA sequences at a single site.[82, 83] They used a triplex-forming oligonucleotide that overlapped a methylation/restriction site. These are sites which are recognized by both endonucleases and methylases. When the sequence is first methylated (e.g. on adenines), the endonuclease is no longer able to cleave. *Eco*RI, *Msp*I, *Hae*III, *Taq*I, *Alu*I, and *Hpa*II methylase/endonucleases recognize symmetric sequences that contain two or three contiguous purines or pyrimidines which may overlap a triplex site. An oligonucleotide recognizing a homopurine · homopyrimidine sequence which overlaps a methylase recognition site prevents methylation at this site, while all other sites are methylated. When the endonuclease partner is added, only the unmethylated site is cleaved; the others are protected by methylation. The technique developed with triplex-forming oligonucleotides is similar to that described by Szybalsky et al.[84, 85] which they called the "Achilles heel" cleavage technique. In this technique a DNA-binding protein (e.g. the lac repressor) is used to protect a DNA sequence from being methylated. The restriction endonuclease then cleaves selectively this protected site.

These results show the high selectivity of triple helix formation in long DNA molecules (chromosomes) and the possible development of triple-helix-forming oligonucleotides for use in gene mapping on intact chromosomes. The possibility of using a degenerate oligonucleotide pool to screen for potential binding and cleavage sites on cosmid clones of chromosomes extends the potentiality of the technique to DNA regions which have not yet been sequenced.[83]

2.6. Thermodynamics and Kinetics of Triple-Helix Formation

Several studies have been devoted to the determination of thermodynamic parameters for Hoogsteen hydrogen bond formation by oligopyrimidines. The ΔH values were obtained from UV melting curves,[42, 73, 86, 89] change in T_m with DNA concentration,[87] differential scanning calorimetry (DSC),[86, 88, 89] and kinetic measurements.[91] The systems that were studied include those containing either three different strands,[87, 89, 91] a Watson–Crick duplex hairpin structure binding a "Hoogsteen oligopyrimidine",[42] or a single-stranded oligopurine bound to an oligopyrimidine with the formation of both Watson–Crick and Hoogsteen hydrogen bonds.[86] The reactions were analyzed according to a two-state model for the transition from triplex to duplex + single strand[42, 87, 88, 91] or to three single strands.[86] Only values obtained from DSC measurements do not rely on a model for the triplex-to-duplex reaction. ΔH

values calculated for different sequences are given in Table 1. The lowest value (2 kcal mol^{-1} per base triplet) has been obtained from calorimetric measurements.[89] However, these authors report van't Hoff ΔH values obtained from optical melting curves or DSC shape analysis that are about three times higher than the calorimetric enthalpy. In another study the van't Hoff and DSC values were nearly identical within experimental error.[86] Clearly, more data are required to obtain a reliable picture of the thermodynamic properties of triple helices, but the results presently available show that triple helices are less stable than double helices. The stability is expected to depend on the base-triplet sequence, the nature (charge) and concentration of cations, and, in the case of cytosine-containing third strands, on pH. The enthalpy of cytidine protonation was estimated to be -2.8 ± 0.3 kcal mol^{-1}.[42]

Table 1. Thermodynamic parameters for the transition from triplex to duplex.

[a] From melting curves (pH 6). [b] pH 6, $\overset{*}{C}$ is 5-methylcytosine. [c] From $1/T_m$ vs. $\ln C_T$ (where C_T is total third-strand concentration). [d] From DSC curves. [e] From UV melting curves, pH 5.0. [f] From $1/T_m$ vs. $\ln C_T$, pH 5.5. [g] From DSC, pH 6.5. [h] From kinetic measurements, pH 6.8.

Kinetic measurements have shown that triple-helix formation is a slower process than double-helix formation.[90, 91] Maher et al.[90] used an *Ava* I restriction endonuclease assay to measure rate constants for the association (pseudo-first order) and for the dissociation (first order) of a triple helix formed by a 21mer containing 5-methylcytosines and a 21 bp double-stranded target within a 6.4 kbp plasmid. Depending on the reaction conditions (salt concentration and pH), k_{ass} values ranged from 8×10^2 to 2.2×10^3 M^{-1} s^{-1} and k_{diss} values from 2.4×10^{-4} to 2.2×10^{-5} s^{-1}. The equilibrium constant (for the association) ranged from 3.3×10^6 to 10^8 M^{-1} depending on salt and pH conditions. The association rate was about three orders of magnitude slower than that of double helices. Increasing the pH led to a large increase in the dissociation rate and a small reduction in the association rate. The presence of Mg^{2+} ions increased the association rate.

Rougée et al.[91] made the observation that in many cases the thermal dissociation (heating) curve, as measured by UV spectroscopy, was shifted toward higher temperatures than the association (cooling) curve. This hysteresis was used to carry out a complete kinetic analysis of triplex formation involving a 21mer oligopyrimidine bound to a double-helical DNA fragment with 21 base pairs. The association constant ranged from 13 to 300 M^{-1} s^{-1} at 15 °C and pH 6.8, when the NaCl concentration was increased from 20 to 300 mM in the absence of Mg^{2+} ions. The reaction rate was greatly increased in the presence of Mg^{2+} ions. The dissociation constant (1.5×10^{-6} s^{-1}) was independent of NaCl concentration. A mismatch X × A · T (X ≠ T) in the center of the triple helix had no effect on the association rate but induced a large increase in the dissociation rate constant (from 1.5×10^{-6} s^{-1} for the canonical T × A · T triplet, to 2×10^{-3} s^{-1} for the more destabilizing C × A · T mismatch). The activation energy for association was found to be negative. These results were explained by a "nucleation-zipping model" in which three to five base triplets constitute the nucleus. The effect of different salts points to the importance of multivalent cations in the stabilization of triple helices, through an increase of the association rate constant. Monovalent cations have the same effect at higher concentrations in the absence of multivalent cations. In the presence of divalent cations (e.g. Mg^{2+}), monovalent cations may decrease the extent of triplex formation through their inhibitory effect on multivalent cation-binding to DNA.

Kinetic studies, and especially the observation that the rate of triple helix formation is slow, have implications for the development of oligonucleotides for use in controlling gene transcription or replication. If the oligonucleotide must compete with a protein or an enzyme for binding to a specific sequence on DNA, kinetic phenomena might become the limiting factor in competition experiments.

2.7. Cooperative Binding of Oligonucleotides to Duplex DNA

The binding of two contiguous oligonucleotides on a single-stranded template is a cooperative phenomenon because of stacking interactions between base pairs at the junction of the two oligonucleotides. The same situation occurs when two homopyrimidine oligonucleotides bind to two adjacent homopurine · homopyrimidine sequences on duplex DNA.[92] Two oligonucleotides which do not bind to adjacent sequences can be made to bind cooperatively if the 3′-end of one oligonucleotide and the 5′-end of the other one are elongated by two complementary sequences that can form Watson–Crick base pairs.[93] These two additional sequences act as dimerization domains. When two oligonucleotides are bound adjacent to each other on a DNA template, they may be ligated by either a phosphodiester[94, 95] or a pyrophosphate[95] linkage. The 5′-terminal phosphate of one of the oligonucleotides can be activated with BrCN, imidazole, and $NiCl_2$ to form a phosphodiester bond with the 3′-OH of the adjacent oligonucleotide.[94] Alternatively, 1-(1-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride may be used as a condensing agent.[95]

Two double-helical DNA fragments can be brought in juxtaposition upon binding to a triple-helix-forming oligonucleotide, which can form Hoogsteen hydrogen bonds with the terminal sequences of the two DNA fragments.[96, 97] Upon chemical activation by *N*-cyanoimidazole, the proximal 3′-hydroxyl and 5′-phosphate termini undergo covalent ligation on one or both strands.[96] The same reaction may be achieved when the oligonucleotide binds to alternate strands to juxtapose the duplex termini into a triple-helical complex.[97]

3. Enhancement of Triplex Stability by Oligonucleotide Modifications

3.1. Base Modifications

Modified bases have been introduced into triple-helix-forming oligonucleotides either to improve binding under physiological conditions or to extend the range of recognition sequences. Replacement of cytosine by 5-methylcytosine was shown to stabilize the triple helix made by polynucleotide chains polyd(CT) × polyd(GA) · polyd(CT) at pH values up to 8.[100] Similarly, 5-methylcytosine was introduced into triple-helix-forming oligonucleotides and shown to extend the pH range over which a triplex was formed with a homopurine · homopyrimidine sequence of duplex DNA.[101, 102, 128] Thermodynamic analysis showed that stabilization is mainly due to entropic effects arising from the formation of a "spine" of hydrophobic methyl groups carried by thymine and 5-methylcytosine in oligopyrimidines.[102] Substitution of 5-bromouracil for thymine also extends triple helix stability towards higher pH, and combination of both substitutions (Br^5U and m^5C) strongly increased the cleavage efficiency of oligonucleotides tethered to Fe-EDTA at higher pH values.[101]

Oligonucleotides containing 5-bromouracil, 5-methylcytosine, and 5-bromocytosine can easily be constructed from the commercially available deoxyribonucleoside-3′-phosphoramidites. However, protonation of the nitrogen atom N(3) of cytosine is still required to form the triplex, which is markedly destabilized with increasing pH when it contains contiguous $C^+ \times G \cdot C$ triplets.

To overcome this limitation, oligonucleotides containing the nucleoside couples (dT, dG),[29, 32, 43] (dA, dG),[30, 31] [dT, 2′-*O*-methylpseudoisocytidine (**14**) (Cm)],[103] [dT, 6-methyl-8-oxo-deoxyadenosine (**15a**) (MODA)],[105] [dT, 8-oxo-deoxyadenosine (**15b**)],[106] [dT, P1 (**16**)][107] (Fig. 7), and [damP (**17**), dG] were constructed. 2′-Deoxyxanthosine and 2′-deoxyinosine have also been introduced into oligonucleotides.[104]

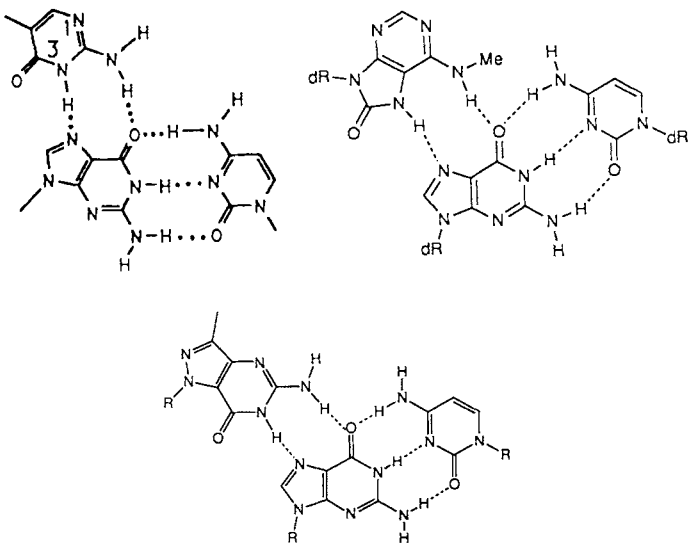

Fig. 7. Base triplets formed by modified bases with G · C base pairs of DNA. Top left: pseudoisocytidine (**14**) [103]; top right: MODA (**15**) [105] (The same hydrogen bonding scheme applies to 8-oxoadenine [106]); bottom: nucleoside P1 (**16a**) [107]. In contrast to cytosine, these modified bases do not require protonation to form two hydrogen bonds (see Fig. 5).

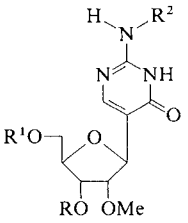
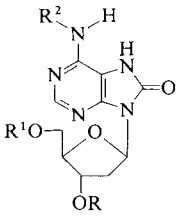


14a: R, R^1, R^2 = H (Cm)

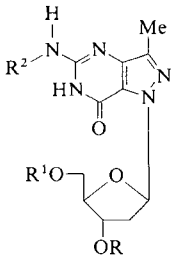
14b: R = $-P(OCH_2CH_2CN)-NiPr_2$, R^1 = DMT, R^2 = Ac



15a: R, R^1 = H, R^2 = CH_3 (MODA)

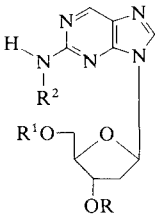
15b: R, R^1, R^2 = H

15c: R = $-P(O^\ominus)(=O)-H$, R^1 = DMT



16a: R, R^1, R^2 = H (P_1)

16b: R = $-P(OCH_2CH_2CN)-NiPr_2$, R^1 = DMT, R^2 = Ibu



17a: R, R^1, R^2 = H (amP)

17b: R, R^1 = 4-NO_2-Bz, R^2 = Bz

17c: R = $-P(OCH_2CH_2CN)-NiPr_2$, R^1 = DMT, R^2 = Bz

Incorporation of Cm **14a** into a pyrimidine oligomer was achieved through its phosphoramidite **14b**, which was obtained in a seven-step synthesis from pseudoisocytidine.[103] In its neutral form, Cm can form two hydrogen bonds (Hoogsteen configuration) with guanine of a G · C base pair (Fig. 7 top left). In contrast to cytidine no protonation is required.

Oligonucleotides containing MODA **15a** were assembled by using the 3′-H-phosphonate derivative **15c**.[105] The nucleoside **15a** was prepared from N^6-methyl-2′-deoxyadenosine by bromination and subsequent displacement of the bromide in the 8-position with acetate, which was then removed by methanolysis.[105] 8-Oxo-2′-deoxyadenosine (**15b**) was also introduced into oligonucleotides through the phosphoramidite[106] of the 8-methoxyadenine derivative. These two derivatives (**15a** and **15b**) can form two hydrogen bonds with G in a G · C base pair, without the need for protonation (Fig. 7 top right).

The deoxyribonucleoside P1 **16a** was synthesized in five steps by construction of the heterocyclic ring and subsequent incorporation into pyrimidine oligodeoxyribonucleotides through its phosphoramidite **16b**.[107] This modified nucleotide can form two hydrogen bonds with G of a G · C base pair (Fig. 7).

Purine oligonucleotides consisting of dG and 2-aminopurine-9β-D-2′-deoxyribofuranoside (**17a**, amP) were assembled by using the phosphoramidite **17c** (V. Roig, N. T. Thuong, unpublished results). Compound **17c** was obtained from **17b**, which was prepared by a transglycosylation reac-

tion using 3′-5′-di-*O*-(4-nitrobenzoyl)thymidine as a glycosyl donor, and subsequent separation of the anomers.

Among the couples of base triplets [(T × A · T, C^+ × G · C), (T × A · T, G × G · C), (A × A · T, G × G · C), (T × A · T, Cm × G · C), (T × A · T, MODA × G · C), (T × A · T, P_1 × G · C), and (amP × A · T, G × G · C)] used to form triple helices, only (T × A · T, C^+ × G · C), (T × A · T, Cm × G · C), and (amP × A · T, G × G · C) are isomorphous couples (see Figs. 5–7). In contrast to cytosine, which must be protonated to form two hydrogen bonds with guanine of G · C Watson–Crick base pairs, the modified bases Cm, MODA, 8-oxoadenine, and P1 were shown to recognize G · C base pairs in a pH-independent manner.

3.2. Backbone Modifications

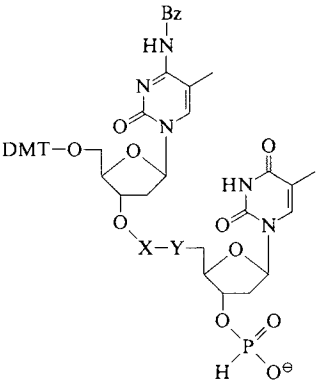
When deoxyribose is replaced by ribose a stabilization of intermolecular triple helices is observed.[210, 214] Pyrimidine oligo*ribo*nucleotides bind more strongly to duplex DNA than corresponding oligo*deoxyribo*nucleotides. 2′-OMe derivatives bind more strongly than unsubstituted oligoribonucleotides.[210, 214]

Incorporation of phosphorothioate groups into polynucleotides has been shown to have a dramatic effect on triplex formation: poly[d(TC)] · poly[d(sGsA)] spontaneously dismutates to a triplex at pH 8, whereas poly[d(sTsC)] · poly(d(GA)] could not form a triplex.[108] As shown with poly[d(GA)] · 2poly[d(sTC)] and poly[d(sGA)] · 2poly-[d(TC)],[108] a phosphorothioate 5′ to a purine increases the T_m of the triplex while at a position 5′ to a pyrimidine it decreases the T_m.

Formation of a triple helix involves strong electrostatic repulsion between the negatively charged partner strands. Metal ions play an important role in the stability of triple helices. Reducing the negative charge of the third strand by introducing neutral backbones is an attractive possibility to enhance triple-helix stability. However, with methylphosphonate backbones, there is no evidence for triplex stabilization. On the contrary, triplex formation was not detected between $d(A)_{19}$ and $d(T)_{19}$ when either strand was replaced by a methylphosphonate strand.[109] Furthermore, triplex formation between $d(CT)_8$ and $d(AG)_8$ in which the pyrimidine strand consisted of methylphosphonates required a lower pH than the phosphodiester analogue.[110] However, in both of these two examples, one of the Watson–Crick strands contained a methylphosphonate backbone. Therefore any conclusion must await data in which only the third strand carries methylphosphonate groups. It should be kept in mind that methylphosphonate groups exist in two diastereoisomeric forms and that 2^n diastereoisomers are present in an oligomer containing *n* such linkages. It is expected that the stereochemistry at the phosphorus atom plays an important role on triple helix formation and stability.

Oligomers with neutral analogues of dinucleoside phosphodiester linkages **18** were synthesized in order to form triple helices with duplex DNA under physiological salt conditions.[111] The incorporation of each analogue linkage was achieved by using the *N*-benzoyl-5-methyl-2′-deoxycytidine-thymidine (5-MeC-T) dimer protected at the 5′-end with dimethoxytrityl (DMT) and derivatized at the 3′-end with a H-phosphonate salt. The methylphosphonate dinucleoside **19a** was obtained by using the 5′-dimethoxytrityl-deoxyribonucleoside-3′-methylphosphonic imidazolide. Reaction of dinucleoside H-phosphonate with carbon tetrachloride in

d-$^{5'}$TpCpTpC^{Me}-TpC^{Me}-TpC^{Me}-TpC^{Me}-TpTpTpT$^{3'}$ **18**



19a: X–Y = Me–P(=O)–O (*R,S*-methylphosphonate)

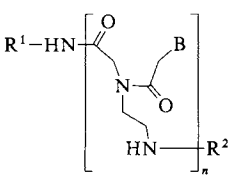
19b: X–Y = NH–$(CH_2)_2$–OMe–P(=O)–O (*R,S*-methoxyethylphosphoramidate)

19c: X–Y = CH_2–O (formacetal)

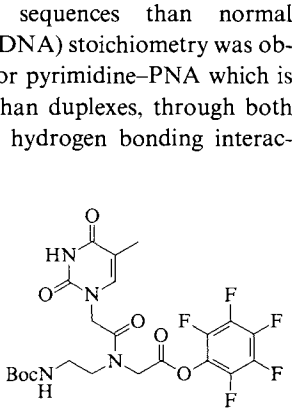
19d: X–Y = CH_2–S (thioformacetal)

the presence of methoxyethylamine led to the precursor of the dinucleoside phosphoramidate **19b**. The precursor of the formacetal dinucleoside **19c** was generated from a 3′-trialkylsilyl-thymidine and a 5′-dimethoxytrityl-deoxynucleoside-3′-methyl thioacetal, activated with *N*-bromosuccinimide. In an analogous manner to the preparation of the formacetal dimer, the thio analogue **19d** was obtained starting from the 5′-thio analogue. The formacetal linkage is suitable for sequence-specific triple-helix formation, whereas oligonucleotides with thioformacetal, methylphosphonate, and methoxyethylamidate linkages exhibited reduced affinity for duplex DNA.[111]

Oligomers with a neutral polyamide backbone (**20**, PNA) were designed by replacing the deoxyribose-phosphodiester linkage of DNA by an oligomer of aminoethylglycine.[112] PNA was constructed with a standard peptide-coupling procedure. The BOC-protected pentafluorophenyl ester of the thymine monomer **21** was synthesized by condensation of the BOC-aminoethylglycine with the pentafluorophenyl ester of thymine acetic acid. PNA binds more strongly to single-stranded complementary sequences than normal oligonucleotides. A 2:1 (PNA:DNA) stoichiometry was obtained. This might hold only for pyrimidine–PNA which is able to form triplexes rather than duplexes, through both Watson–Crick and Hoogsteen hydrogen bonding interactions.



20: R^1 = Lys–NH_2
R^2 = H or acridine derivative



21

PNA also binds to double-stranded DNA by a strand-displacement reaction.[112] In this reaction, the double helix is

locally disrupted and the PNA binds to its complementary strand. This strand displacement reaction is reminiscent of the reaction catalyzed by the Rec A protein from *E. coli*, which allows one polynucleotide chain to invade a double helix containing a homologous sequence to form a D-loop, in which one of the Watson–Crick strands is displaced and replaced by the invading polynucleotide chain.[152–158] If the results obtained with PNA containing only one (T) or two (C and T) bases can be extrapolated to any base sequence, then new possibilities will be open to bind PNAs to any base pair sequence of DNA. This would relieve the constraints that presently limit triple helix formation by oligodeoxynucleotides to homopurine · homopyrimidine sequences of DNA.

3.3. Triplex Formation by α-Oligonucleotides

Natural nucleic acids are constructed with the β-anomers of nucleotide units **22**. It is possible to synthesize the α-anomers **23**[113–116] and subsequently build α-oligonucleotides, in which all units have the α-configuration. These α-oligomers are resistant to both endo- and exonucleases.[115–117]

β-D-deoxyribonucleotides **22** α-D-deoxyribonucleotides **23**

a: B = thymine, **b**: B = cytosine, **c**: B = adenine, **d**: B = guanine, **e**: B = 2-aminopurine, **f**: B = 5-methylcytosine

Pyrimidine α-D-deoxyribonucleosides **23a,b**[118a] can be obtained by an anomerization reaction, while purine α-D-deoxyribonucleosides **23c,d**[118a] and **23e**[118b] were synthesized by a transglycosylation procedure using pyrimidine β-D-deoxyribonucleosides as the glycosyl donor. 5-Methyl-2′-deoxy-α-cytidine **23f** was prepared by activation of the C(4) position of α-thymidine followed by aminolysis.[122]

Starting from α-deoxyribonucleosides, the assembly of the oligo-α-deoxyribonucleotide chain was achieved by adaptation of either the phosphotriester method in solution[114–116] or the phosphoramidite method on solid support.[119–121] The efficiency of the coupling reaction was similar to that obtained for the synthesis of oligo-β-deoxyribonucleotide derivatives. Oligo-α-deoxyribonucleotides containing either 5-methylcytosine (**23f**)[122] or 2-aminopurine (**23e**) (V. Roig, N. T. Thuong, unpublished results) were constructed by using phosphoramidite building blocks.

α-Oligomers bearing an acridine derivative, through a phosphodiester linkage at either their 3′- (**24a**) or 5′-ends (**25a**), were first synthesized in solution.[115,123] The latter (**25a**)[121] and the psoralen derivative **25b** were readily obtained from the phosphoramidites **28a** and **28b** by the solid-phase procedure. With the previously described thiophosphate method,[133–136] oligo-α-deoxynucleotides covalently linked at either their 3′- (**26**) or 5′-ends (**27**) to either acridine, psoralen, orthophenanthroline, azidoproflavine, proflavine, or *para*-azidophenacyl derivatives were obtained (see Fig. 9).[18,41,124]

28a: R = (Acr)–NH–$(CH_2)_5$–
28b: R = (Pso)–O–$(CH_2)_6$–

The binding of α-oligonucleotides to double-stranded DNA was investigated by different techniques, including cross-linking to the target sequence,[18,41,124] absorption spectroscopy,[122] and inhibition of restriction enzyme cleavage.[122] Only oligopyrimidine sequences have been tested for triple helix formation. The orientation of the α-strand with respect to the homopurine · homopyrimidine sequence of duplex DNA depends on the sequence. An α-oligomer containing only thymine was bound in a parallel orientation with respect to the poly(dA) sequence of the target duplex as was the oligonucleotide synthesized with the β-anomers.[18,41] In contrast, α-oligonucleotides containing T and C were bound in an antiparallel orientation with respect to the homopurine sequence of the target.[122] The change in orientation induced by cytosines in the α-strand was explained as a consequence of triple helix stabilization due to formation of isomorphous base triplets. According to energy minimization studies, α-oligo(dT) and α-oligo(dC) prefer to bind in a parallel orientation with respect to the oligo(dA) and oligo(dG) strands, respectively, of the target duplex and engage in reverse Hoogsteen hydrogen bonding interactions.[125] As shown previously (Fig. 5), $T \times A \cdot T$ and $C^+ \times G \cdot C$ base triplets are not isomorphous in the reverse Hoogsteen configuration, but are isomorphous in the Hoogsteen configuration. The net result is that an α-oligonucleotide containing both C and T prefers to bind in an antiparallel orientation in order to avoid the distortion of the backbone that would occur in the parallel orientation. It may be expected that the orientation will depend not only on the number of cytosines in the α-oligonucleotide but also on their distribution within the sequence.

Triple helices formed by α-oligonucleotide binding to natural DNA are slightly less stable than those formed by their β-analogues. However, they can be stabilized by intercalating agents attached to the ends of the α-oligomer.[122] Since an α-oligopyrimidine containing both C and T binds in the reverse orientation as compared to a β-oligonucleotide, an intercalating agent attached to the 3′-end of the α-oligomer will intercalate at the 5′-pyrimidine-purine-3′ step of the duplex–triplex junction, as does an intercalating agent attached to the 5′-end of a β-oligonucleotide. An α-oligonucleotide–psoralen conjugate can be cross-linked under UV irradiation to its target site, provided there are cross-linkable thymines in the vicinity of the triplex–duplex junction (C. Giovannangeli, C. Hélène, unpublished data). The nuclease resistance of α-oligonucleotides make these compounds attractive for development as regulators of gene transcription in vivo.

3.4. Oligonucleotides Covalently Linked to Intercalating Agents

Intercalating agents attached to either the 5′- or 3′-end(s) of oligonucleotides were originally developed in order to increase the affinity of antisense oligonucleotides toward their complementary single-stranded sequence.[126, 127] The same strategy was applied to triple helix-forming oligonucleotides with the expectation that an intercalator attached to one (or both) end(s) of such an oligonucleotide would intercalate at the triplex–duplex junction. In support of this strategy, an oligopyrimidine–intercalator conjugate strongly stabilized the triple helix formed upon binding of the oligomer to duplex DNA.[128, 129] Fluorescence and molecular modeling studies showed that intercalation was strongly favored on the 5′-side of the third-strand oligonucleotide, since the intercalating agent recognizes a 5′-pyrimidine–purine-3′ sequence at the duplex–triplex junction (Fig. 8). Such a sequence is known to be a strong intercalation site for many polycyclic aromatic molecules.[3] The same conclusion was drawn for oligonucleotides carrying a psoralen derivative attached to the 5′-end.[130]

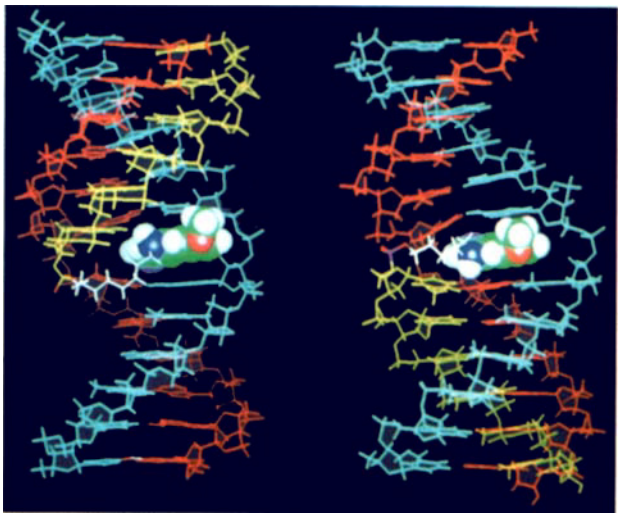

Fig. 8. Molecular models of triple helices formed by oligonucleotide–intercalator conjugates and double-helical DNA. The intercalating agent is 9-amino-6-chloro-2-methoxyacridine tethered either through a pentamethylene linker to the 5′-phosphate (right) or through a nonaethylene linker to the 3′-phosphate (left) of the triplex-forming oligonucleotide (in light green). The acridine derivative is shown intercalated between the last base triplet of the triple helix and the first base pair of the duplex at the duplex–triplex junction (see ref. [209]).

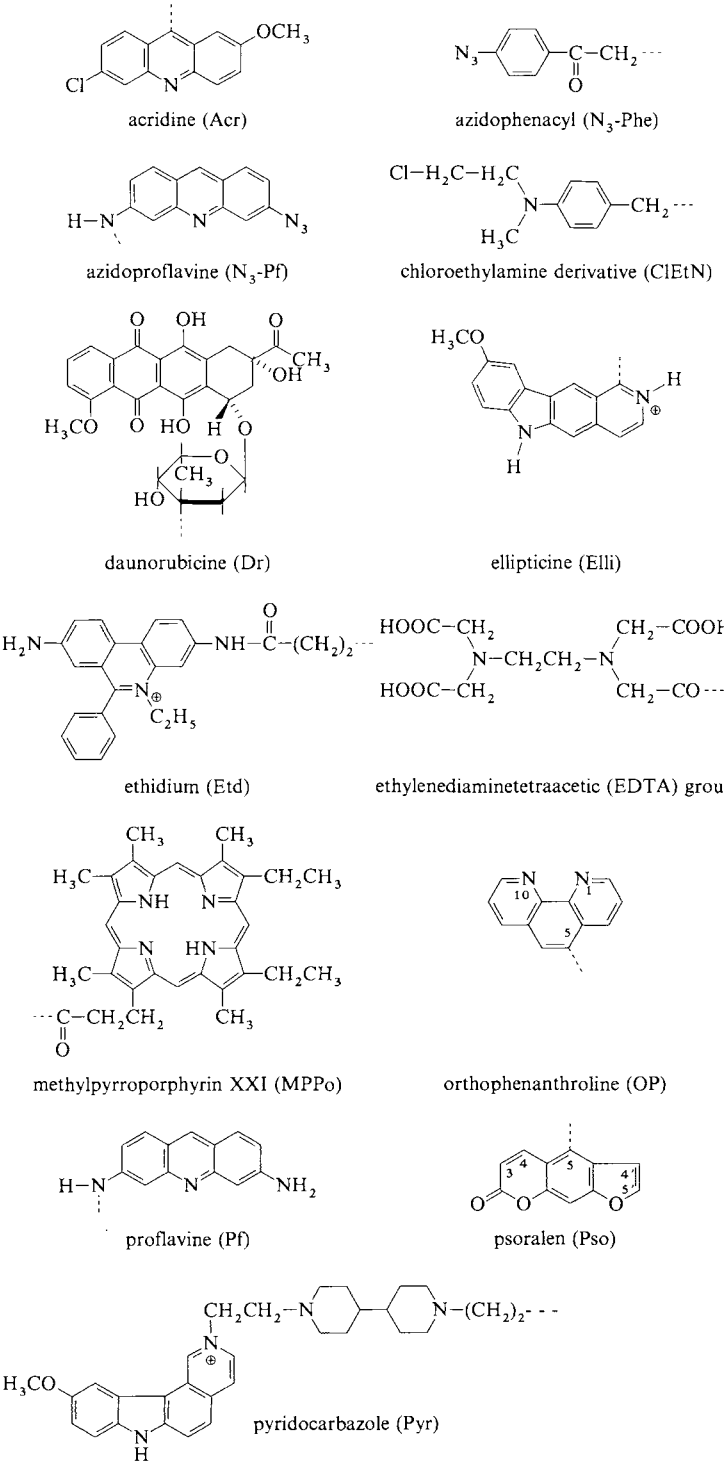

Fig. 9. Structure of different ligands tethered to triple-helix-forming oligonucleotides. The dashed line indicates the site of attachment to the linker (see text and ref. [134]).

3.4.1. Incorporation of Conjugate Groups during the Assembly of Oligonucleotides

The direct incorporation of the conjugate group (see Fig. 9) during the assembly of the oligomers generally involves the following steps: 1) Introduction of a functional group such as a hydroxy group and appropriate protection of the other functional groups not engaged in the coupling reaction. 2) A coupling reaction providing protection to the oligonucleotide conjugates. 3) Use of conditions for the removal of the protecting group (unblocking) which do not affect the conjugated oligomers.

Oligodeoxynucleotides carrying an acridine derivative (9-amino-6-chloro-2-methoxyacridine) at either the 3′- (**29a**) or 5′-end (**30a**) were first synthesized in solution by using the phosphotriester method by coupling the hydroxy group of the acridine derivative **31a** with either the 3′-arylphosphodiester **32** or 5′-arylphosphodiester **33** of the protected oligonucleotide.[126, 127] Unblocking of the nucleic acid bases was carried out by treatment with sodium hydroxide in order to avoid cleavage of the 9-aminoacridine bond. By this

method, an EDTA moiety was tethered to the 3′-phosphate of the oligomer **29b** through the trimethylester of the EDTA derivative **31b**. In the same way, an acridine and an EDTA group were respectively attached to the 3′- and 5′-ends of oligothymidylates.[131]

Solid-phase preparation of oligonucleotides attached through their 5′-ends to either an intercalator **30a** or a photoreactive group **30c** was easily achieved by condensing the phosphoramidite derivative of either an acridine **28a** or psoralen **28b** with the 5′-hydroxy group of an oligonucleotide still fixed to the solid support.[132, 181]

3.4.2. *Incorporation of Conjugate Groups into Unblocked Oligonucleotides*

This strategy involves the introduction of appropriate functional groups in the two unprotected moieties, followed by their specific coupling, thereby providing the conjugated oligodeoxyribonucleotide. Many systems can be used by introducing functional groups into the oligodeoxyribonucleotides, including phosphate, phosphorothioate, amine, thiol, carboxy, and *cis*-diol groups. Among these systems, the *S*-alkylation reaction of the phosphorothioate group by substituted alkyl halides was extensively used to prepare conjugated oligonucleotides utilized in the study of the triple helix.

Introduction of a thiophosphate group at either the 3′- (**34**) or 5′-end (**35**) of the oligonucleotide can be achieved either by the phosphotriester method in solution or through the phosphoramidite on solid phase. Modification of the 5′-end with a phosphorothioate group was easily achieved by condensing bis(cyanoethyl)-*N*,*N*-diisopropylamidophosphite (**36**) activated by tetrazole with the 5′-hydroxy group of the protected oligomer assembled either in solution[133] or on solid support,[134] followed by a sulfurization step. The 5′-thiophosphate group can be unblocked in oligonucleotides by reaction with NH_4OH. Introduction of the thiophosphate group on the 3′-end by solid-phase synthesis involved attachment of the nucleoside through its 3′-(2-cyanoethylthiophosphate) to a solid support by a dithiodiethyl bridge **37**. The latter may be easily obtained by using the dithiodiethanol-derivatized solid phase **38** and the classical nucleoside-3′-cyanoethyl phosphoramidite, and replacing the oxidation step with a sulfurization step. After assembly of the oligonucleotide chains, the 3′-thiophosphate was unblocked and released from the support by treatment with an aqueous solution of dithiothreitol and NaOH.[135, 136] Condensation of the thiophosphate-containing oligonucleotides **34** and **35** with halogenoalkyl ligands, RX, **39**, yields the phosphorothioester of the conjugated oligonucleotides, **40** and **41**, respectively (see Fig. 9 for the nature of R).[133, 134, 136] With the methods described above, an oligothymidylate covalently linked to an acridine at its 3′-phosphate and to orthophenanthroline at its 5′-end (**42**) was synthesized.[159]

Recently the nucleophilicity of the phosphorothioate was also used to conjugate the binuclear platinum II **43** to the 5′-end of oligodeoxynucleotides.[167] Phosphorylation of either 4-(*N*-2-chloroethyl-*N*-methylamino)benzylamine[137] or the amino derivative of ethidium[138] with an oligonucleotide containing a terminal phosphate led to the phosphoramidate oligomers, **44a** and **44b**, respectively.

4. Triple-Helix Ligands

Multivalent cations favor triplex formation at neutral pH. It was mentioned in Section 2.6 that Mg^{2+} ions strongly stabilized py × pu · py triple helices, and it seems that Mg^{2+} or other divalent cations are absolutely necessary for the formation of such triple helices.[17] Polyamines such as spermine and spermidine strongly stabilize triple helices.[19, 128, 139] The concentration of polyamine in the nucleus of eukaryotic cells is in the millimolar range. Therefore triple helices might be stabilized in the cell nucleus. This

potential might be important for the natural regulation of certain genes through intramolecular H-DNA formation as well as for the artificial control of gene expression by triple helix-forming oligonucleotides.

It was of interest to establish whether some well-known ligands of the DNA double helix could also bind to a triple helix. Spectroscopic studies of the classical DNA intercalator ethidium bromide have shown that it does intercalate into triple helices.[140, 141] Ethidium binding to poly(dA) · 2poly(dT) shifts the transition from triplex to duplex + single strand toward higher temperatures.[140] This appears to be due to the low affinity of ethidium for the double helix, poly(dA) · poly(dT), which exists in solution in a nonstandard conformation. The binding of ethidium to short triplex sequences containing both T × A · T and C^+ × G · C base triplets induces a decrease of the temperature for the triplex-to-duplex transition and an increase of that for the duplex-to-single strand transition.[141] This result shows that for the sequence investigated in this study, ethidium binds more strongly to the duplex than to the triplex structure. Energy minimization studies have shown that ethidium, which is a positively charged cation, prefers to bind between T × A · T base triplets to avoid electrostatic repulsion with the positively charged C^+ × G · C base triplet.[142]

Minor groove-binding ligands of double-helical DNA such as netropsin and a distamycin analogue have been shown to bind to triplex structures formed by either polynucleotides poly(dA) · 2poly(dT)[143a] or short oligonucleotides $(dT)_6 \cdot (dA)_6 \cdot (dT)_6$.[143b] In both cases, the ligand binds to the triplex structure without dissociation of the third strand. However, netropsin thermally destabilizes the triplex state, while it stabilizes the corresponding duplex.[143]

The only triple helix-specific ligands reported until now are benzopyridoindole derivatives (Fig. 10),[144] which according to Mergny et al. lead to a strong stabilization of triplexes. The melting temperature of the triplex-to-duplex

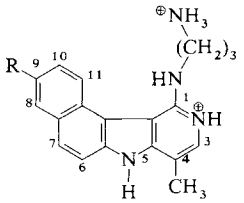

Fig. 10. General structure of benzo[*e*]pyridoindole derivatives which bind to and stabilize triple helices (see ref. [144]). The derivative in which R = OCH_3 gives the best stabilization of the triple helix.

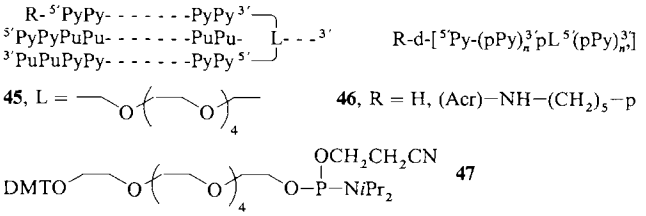
transition was increased by up to 20 K. The stabilization was shown to depend on the base triplet sequence with a strong preference for T × A · T triplets. This dependency is due to the electrostatic repulsion which occurs when the positively charged ligand is close to positively charged C^+ × G · C base triplets. The results of energy transfer experiments have suggested an intercalation of the benzopyridoindole ring between adjacent base triplets. The stabilization provided by these compounds for a triplex formed on the β-lactamase gene of *E. coli* enhanced the inhibitory effect of the triple helix-forming oligonucleotide on transcription by *E. coli* RNA polymerase. It was also reported that upon UV irradiation covalent adducts were formed with the target strand at very low drug concentrations. These studies open the way to designing better ligands for triple helices and to synthesizing oligonucleotide–ligand conjugates that have a high selectivity and strong affinity for duplex DNA sequences.

5. Triple-Helix Formation on a Single-Stranded Nucleic Acid Target

5.1. Recognition of a Polypurine Sequence through both Watson–Crick and Hoogsteen Hydrogen Bonds

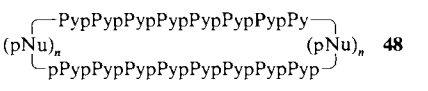
In the preceding discussion, triple-helix formation involved a duplex DNA target, which is recognized by an oligonucleotide, thus providing the third strand. In intramolecular triplexes (H-DNA) formed from polypurine · polypyrimidine sequences, one of the strands folds back on the double helix to form a triple helix.[15–17, 145] Therefore, it should be possible to form a triple helix on a single-stranded DNA fragment. Since in both pu × pu · py and py × pu · py triple helices the third strand binds to the purine strand of the Watson–Crick double helix, a single-stranded homopurine sequence can be chosen as a target. Two approaches have been described thus far:

1) A polypyrimidine sequence may be chosen such that half will form Watson–Crick base pairs, while the other half will form Hoogsteen hydrogen bonds to the Watson–Crick duplex.[86, 146] This configuration is possible because the Watson–Crick and Hoogsteen polypyrimidine sequences are antiparallel in a py × pu · py triple helix (**45**). The linker be-



tween the two polypyrimidine sequences may be a non-nucleotidic chain, such as hexaethylene glycol (**45**, **46**),[146] or a short sequence of three to five nucleotides (C. Giovannangeli, C. Hélène, unpulished results). A similar situation was described by Xodo et al.[86] in the study of triplex formation between a short oligopurine (11mer) and a longer polypyrimidine sequence (24mer) that resembled a H-DNA structure. The hexaethylene glycol oligonucleotides **45** and **46** could be prepared with automatic synthesizers from the phosphoramidite **47**.

2) The Watson–Crick and Hoogsteen polypyrimidine sequences may be incorporated into a circular molecule (as in **48**) by using two short loops (optimum length of five nucleotides) to connect the two polypyrimidine sequences.[147, 148]



Cyclization of linear 5′-phosphorylated oligomers was achieved by a chemical method (BrCN/imidazole/Ni^{2+}), in which short complementary single-stranded DNA templates were used to bring the free 3′-OH and activated 5′-phosphate moities adjacent to each other.

In both approaches, the linear or cyclic polypyrimidine oligonucleotides recognize the polypurine sequence by forming both Watson–Crick and Hoogsteen hydrogen bonds (Fig. 11). Adenines are thus recognized by four hydrogen bonds and guanines by five hydrogen bonds. For example, the 16 nucleotide sequence investigated by Giovannangeli et al.,[146] which is part of the HIV genome, contains nine adenine and seven guanine bases. Therefore, the polypyrimidine ligand is able to form 71 hydrogen bonds with its target. The discrimination of mutant targets, which differ by a single base, is very high as compared to a complementary antisense oligonucleotide, since both Watson–Crick and Hoogsteen hydrogen bonding is perturbed.

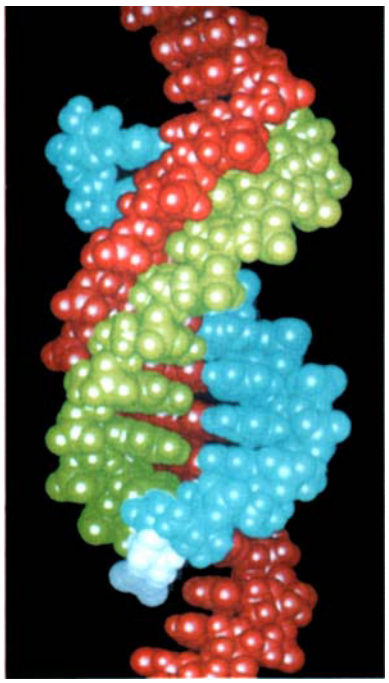


Fig. 11. Space-filling model of a triple helix formed by a single-stranded oligopurine target (red) with a chimeric oligonucleotide consisting of two polypyrimidine sequences attached to each other through a hexaethyleneglycol linker (white). The linker can also be made of an oligonucleotide [211]. One of the polypyrimidine sequence (blue) forms Watson–Crick base pairs with the target, whereas the second forms Hoogsteen base pairs (green) (see ref. [146]). The 3′- and 5′-ends of the polypyrimidine chimeric oligonucleotide can be joined together to generate a circular oligomer [147, 148].

The cyclic oligonucleotides with optimized loops bind with higher affinity to a polypurine target than linear oligomers which contain the same bases.[148] This has been attributed to the entropic benefit of preorganization in the cyclic molecule. Reactive groups can be attached at one or both ends of the linear oligomers. For example, it was shown that attachment of an intercalating agent to the 5′-end of **45** strongly stabilized the triplex structure, provided the Watson–Crick portion of the oligomer was extended by one or two base pairs.[146] The intercalating agent may be made reactive toward the target sequence. We have recently shown that a psoralen derivative attached to the 5′-end of the Hoogsteen strand can be cross-linked to both the target purine and the Watson–Crick pyrimidine strands, thereby "locking" the triplex structure in place. Replication of such irreversibly blocked templates is inhibited.[211] We have called these molecules "oligonucleotide clamps".[211]

5.2. Binding of Oligonucleotides to the Single-Stranded Region which Results from the Formation of Intramolecular Triplexes (H-DNA)

A mirrored polypurine · polypyrimidine sequence of double-helical circular DNA can undergo a transition to form an intramolecular triplex, thereby relaxing some of the constraints imposed by supercoiling.[15–17] During this process, either half of the polypurine sequence folds back on the double helix to form a pu × pu · py triple helix, in which approximately half of the polypyrimidine sequence becomes single-stranded, or half of the polypyrimidine sequence folds back to form a py × pu · py triple helix, in which half of the polypurine sequence becomes single-stranded (Fig. 4). In both cases, an oligonucleotide may be designed to be complementary to the single-stranded sequence. Oligomer binding has been observed in vitro[149, 150] and in vivo[149] and has been shown to favor H-DNA formation by trapping the single-stranded portion of the DNA.[150]

A similar model was proposed to describe effects observed during in vivo transcription of the polypurine-containing strand of the immunoglobulin A (IgA) switch region in a supercoiled plasmid.[151] Nascent RNA transcripts remain associated with their template through RNase H-sensitive, RNA–DNA hybrids, which stabilize an intramolecular triplex and result in the formation of stable, less supercoiled conformers of the plasmid.

6. RecA-Mediated Formation of Three-Stranded Structures

General genetic recombination involves the exchange of genetic information between homologous sequences carried by two chromosomes. A key step in recombination is the alignment and pairing of homologous DNA sequences. Recombinases, such as the RecA protein of *E. coli*, bind cooperatively to single-stranded oligonucleotides. In the presence of homologous double-stranded DNA, they induce the formation of a synaptic complex in which three strands of DNA are associated with recA proteins.[152–155] When a supercoiled circular DNA is used as a substrate, deproteinization of the synaptic complexes leads to the formation of joint molecules, in which the single-stranded oligonucleotide is still bound to the supercoiled DNA. Linearization of the DNA by a restriction endonuclease which relieves the constraints associated with supercoiling, releases the oligonucleotide. When long single-stranded DNA fragments are used instead of short oligonucleotides (and ATP is used instead of non-hydrolyzable ATPγS) strand exchange can take place, for example between a circular single strand and linear duplex DNA.[153, 154]

In the presence of the non-hydrolyzable ATP analogue, 5′-(γ-thio)ATP (ATPγS) and ADP, RecA protein can pair a short single-stranded 15mer with duplex DNA.[155] However, a homology of only eight bases is sufficient to form such synaptic complexes. Association of the oligonucleotide with duplex DNA survives the removal of RecA protein provided that the length of shared homology is at least 26 base pairs.[155] The structure of these three-stranded complexes is not yet known. One strand of duplex DNA can be displaced to form a D-loop, but an alternative structure in which all three strands are hydrogen bonded has been proposed.[152] It should be noted that there is a fundamental difference between the triple helices discussed in the remaining sections of this review and the RecA-mediated three-stranded complexes. This difference resides in the orientation of the third strand. In triple helices [both intramolecular (H-DNA) and intermolecular], the third strand has an opposite polarity with respect to the Watson–Crick strand of the identical base sequence, whereas in RecA-mediated three-stranded complexes the third (invading) strand has the same polarity as the Watson–Crick strand of identical sequence.

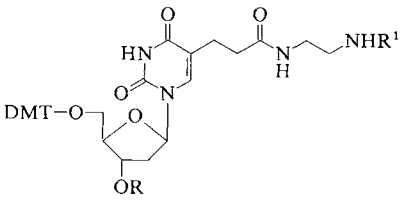
RecA-mediated formation of three-stranded complexes can be used to introduce site-specific lesions in duplex DNA. An oligonucleotide having a psoralen group on the furan ring was used to form a joint molecule with a homologous sequence of duplex DNA in the presence of RecA.[156] Upon UV irradiation, the psoralen was further cross-linked (pyrone side) to a thymine in the complementary strand of the oligonucleotide. Since psoralen cross-linking requires correct positioning of the double bonds which react to form the cyclobutane ring, this result suggests that the oligonucleotide was bound to its complementary sequence through Watson–Crick base pairs. Oligonucleotides of at least 50 residues in length were necessary to observe 50% efficiency of the cross-linking reaction. These complexes were further used to study the mechanism of cross-link repair by *E. coli* ABC excinuclease.[156]

A homologous joint formed by an oligonucleotide with duplex DNA in the presence of RecA was shown to inhibit transcription initiation when the oligonucleotide was homologous to a promoter region and to prevent transcription elongation when it was bound downstream from the promoter.[157] RecA-mediated formation of three-stranded complexes inhibits cleavage by restriction enzymes and methylation by associated methylases when the oligonucleotide covers a restriction site. This observation has been used to develop a new strategy (called RARE for "RecA-assisted restriction endonuclease" cleavage) to make single cuts in long DNA fragments and chromosomes.[158] When a three-stranded complex is formed, methylation is inhibited at this particular site, but takes place at other methylase recognition sites. Upon subsequent addition of the corresponding restriction endonuclease, only the non-methylated site is cleaved. This technique is similar in its principle to the "Achilles heel" method developed by Koob and Szybalsky[84,85] and to that described by Strobel and Dervan,[81–83] which uses triple helix-forming oligonucleotides. However the RARE procedure offers a more general approach, since any double-stranded sequence can be "invaded" by a third strand in the presence of RecA.

7. Sequence-Specific Modifications of DNA

7.1. Sequence-Specific Cleavage of Duplex DNA by Triple-Helix-Forming Oligonucleotides Tethered to Active Reagents

Sequence-specific triple-helix formation by oligodeoxynucleotides has led to the development of artificial nucleases that are able to cleave DNA at specific sites. Under physiological conditions, direct cleavage can be achieved by attaching to the oligonucleotide a reagent capable of generating reactive species, such as hydroxyl radicals, upon *chemical* activation. This strategy has been used with metal complexes, such as Fe-EDTA[19,30,80,81,131] or copper–phenanthroline.[79,159] Alternatively, cleavage can be induced by *photochemical* activation of an aromatic group such as an ellipticine derivative.[61,160] The yields of these reactions are usually low, except with copper–phenanthroline, for which 70% cleavage of double-stranded DNA was reported.[79] The attachment of intercalating agents such as phenanthroline or ellipticine was described in Section 3.4. Oligonucleotides with an EDTA group at the C(5) position of dU were assembled on solid phase via the 3′-phosphoramidite derivative **49c** of the modified nucleoside **49b**. Compound **49b** was obtained by conversion of 2′-deoxyuridine into the amino derivative **49a**, which was acylated with an (EDTA triethylester) hydroxysuccinimide ester.[204]



49a: R, R^1 = H
49b: R = H, R^1 = (EDTA-Et_3)
49c: R = $-P(OCH_2CH_2CN)-NiPr_2$, R^1 = (EDTA-Et_3)

Rather than attaching a chemical reagent to one end of the triplex-forming oligonucleotide, it is also possible to attach an enzyme.[203] An oligonucleotide–staphylococcal nuclease adduct cleaves plasmid DNA with a 75% yield at a specific site. By using two target sequences on the same DNA molecule, it is possible to excise DNA fragments. Even though cleavage by the nuclease does not occur at a single phosphodiester bond, the fragments can be used in cloning studies.[203]

Diffusible reagents, such as OH• radicals, which are generated within one of the double helix grooves, are expected to yield an asymmetric distribution of cleavage patterns on opposite strands. In Figure 12 top a cylindrical projection of the sugar–phosphate backbone of "standard" B-DNA is shown. If one assumes that OH• radicals are generated in the center of one of the grooves, they will attack the deoxyriboses according to their distance distribution. Faster reaction is expected at sugars located in a direction perpendicular to the *groove* axis and not to the *helix* axis. When the reactive sites are plotted on a linear representation of DNA with

arrow lengths proportional to an estimated reactivity, their distribution is clearly asymmetric (Fig. 12 bottom). Cleavage sites are shifted toward the 3'-end when OH• radicals are produced within the minor groove and toward the 5'-end when they are produced in the major groove.

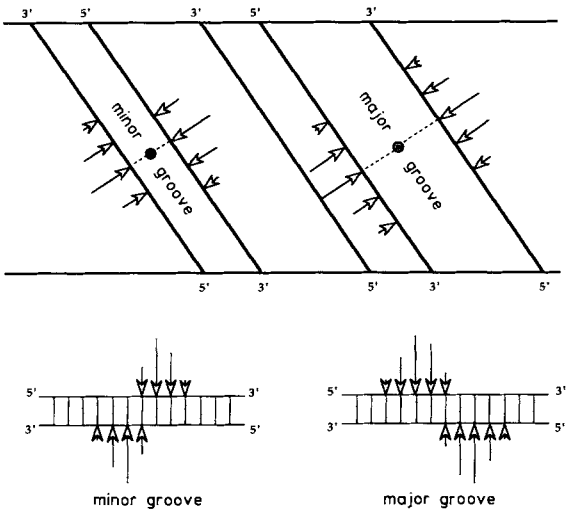


Fig. 12. Asymmetric distribution of the cleavage sites on the two DNA strands generated by a diffusible species (e.g., OH• radicals) within the major or minor groove of the DNA double helix. The upper portion shows a schematic cylindrical projection of the sugar–phosphate backbone of the B-form of DNA [201]. The cylinder was cut open, spread on a flat surface and viewed from the outside. If reactive species (e.g., OH• radicals) are generated in the center of a groove (dot within a circle) they will react the most with sugars which are closest in space (in a direction perpendicular to the groove axis). They do *not* belong to the nucleotides of the same base pair. Reactivity (cleavage) will be related to distance, as shown by the arrows on the cylindrical projection and, in the bottom portion of the figure, on a linear representation of the double helix. The two "waves" of cleavage sites on each strand reveal an asymmetric distribution. They are shifted to the 3'-side when cleavage occurs in the minor groove and to the 5'-side when cleavage occurs in the major groove. The actual location, amplitude, and distribution of the cleavage sites depend on the position of the OH• radical-generating species with respect to the double helix of DNA.

The cleavage patterns observed with Fe-EDTA linked at C(5) of a pyrimidine nucleoside of an oligonucleotide show that this probe is located in the major groove of duplex DNA.[19] When site-specific cleavage with copper–phenanthroline was analyzed the cleavage patterns were found to be shifted to the 3'-side on opposite strands. This indicates that cleavage takes place in the minor groove.[79, 205] Different linkers were used to tether phenanthroline to the triplex-forming oligonucleotide. The results showed that cleavage was due to phenanthroline intercalated at the triplex–duplex junction. Intercalation brought the two nitrogen atoms of phenanthroline into the minor groove where copper chelation occurred, leading to the production of the oxidative species in the presence of a reducing agent (3-mercaptopropionic acid). Therefore binding of the oligonucleotide in the major groove together with phenanthroline intercalation at the triplex–duplex junction, targeted the cleavage reaction to the minor groove, leading to the characteristic asymmetric distribution of cleavage sites to the 3'-side on opposite strands (Fig. 13). Site-specific cleavage occurred at higher temperatures and pH values than anticipated on the basis of the stability of the oligonucleotide–DNA triple helix. The intercalation model provides an explanation for these observations. Oligonucleotide binding to the major groove and copper binding to intercalated phenanthroline in the minor groove should lock the complex in place, with phenanthroline acting as a bridge connecting the two grooves.

7.2. Cross-Linking of Oligonucleotides with Double-Helical DNA

Indirect cleavage of duplex DNA may occur after covalent bond formation between a reactive group tethered to a third-strand oligonucleotide and nucleotides of the target DNA, followed by cleavage of the phosphodiester bonds at the cross-linked sites under alkaline conditions. This method was used by Le Doan et al.[18] and Praseuth et al.[41] to demonstrate sequence-specific triplex formation with both β- and α-oligonucleotides by using azidoproflavine and azidophenacyl, respectively, to photo-induce cross-linking of the oligonucleotides to their target sequence (Fig. 9).

Oligonucleotides covalently linked to alkylating agents, such as *N*-2-chloroethyl-*N*-methylaminobenzylamide, were also shown to cross-link with specific DNA sequences and to undergo site-specific cleavage under alkaline conditions.[161, 162, 164–166] This alkylation is specific for the N(7) position of guanines as is that induced by other reagents,

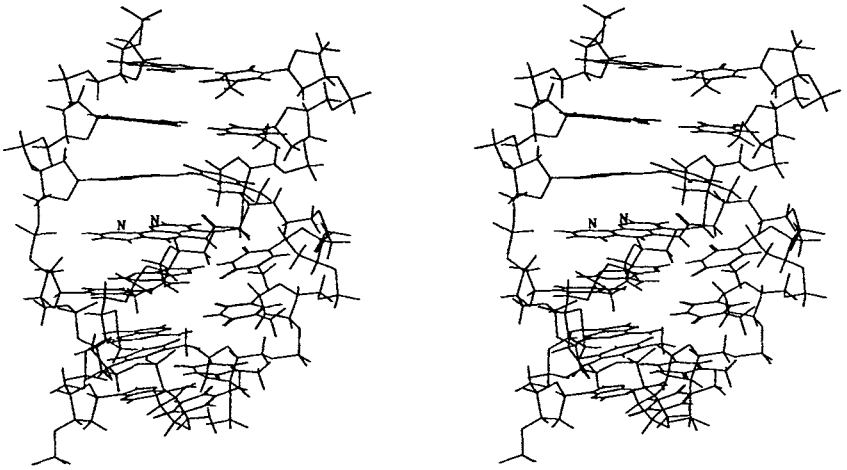

Fig. 13. Stereodiagram of phenanthroline intercalation at the triplex–duplex junction. Three base pairs (top) and three base triplets (bottom) are shown. The 5'-phosphate of the third-strand oligonucleotide is linked through a hexamethylene linker to 5-amino-1,10-phenanthroline. The third strand is bound to the major groove, to where it also brings the linker tethered to phenanthroline. When phenanthroline intercalates, the two nitrogen atoms point into the minor groove, where copper chelation and cleavage take place.

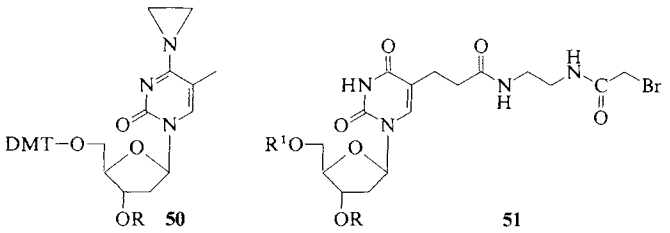
such as N^4,N^4-ethano-5-methyldeoxycytidine (**50**)[163] and thymidine (**51**) with an *N*-bromoacetyl group attached by a



50 **51**

linker to the C(5) position of the pyrimidine ring.[162, 166] Treatment under alkaline conditions results in depurination of the alkylated guanine, followed by β-elimination reactions which result in backbone cleavage and the emergence of 5′- and 3′-phosphate termini with an efficiency of about 95%. In all these reactions, the cross-linking reagent can only react with one of the two DNA strands. The resulting cleavage is therefore limited to one strand. However, two alkylating oligonucleotides can be engineered in such a way as to bind to adjacent inverted sites on double-helical DNA and to alkylate at single guanine positions on opposite strands. If the two alkylated guanines are separated by a few base pairs, the two single-strand breaks can lead to single-site double-strand cleavage of long DNA fragments with an efficiency of up to 90%, as recently demonstrated in a yeast chromosome.[166]

Cross-linking of oligonucleotides with a double-stranded DNA target was also observed with a binuclear platinum derivative **43**.[167] One of the Pt centers was allowed to react with a 5′-phosphorothioate of the oligonucleotide, and the second Pt center formed a covalent adduct with guanines in the target sequence.

7.3. Sequence-Specific Cross-Linking of the Two Strands of Double-Helical DNA by Psoralen–Oligonucleotide Conjugates

Psoralens have been used for many years as photoactive probes of DNA and RNA structures, as photoactive drugs against dermatological diseases such as psoriasis, and as tools for studying the mechanisms of mutagenesis and repair processes.[168] Upon UV irradiation, they react with thymines in DNA, and when intercalation occurs at 5′TpA3′ sites they form a cross-link between the two DNA strands by reacting with the two thymines on opposite strands. Cross-linking involves a [2 + 2] cycloaddition between the 5,6 double bond of the thymine and the 3,4 (pyrone) and/or 4′,5′ (furan) double bonds of psoralen. Structural studies carried out by using NMR spectroscopic techniques have concluded that the psoralen ring at the cross-linked site is oriented with the C(8) position in the minor groove and with a *cis-syn* configuration for each of the adducts.

Triple-helix formation involves binding of the oligonucleotide in the *major* groove. Therefore, in order to bring a psoralen to a 5′TpA3′ site with the appropriate orientation necessary to form a cross-link between the two DNA strands, the psoralen ring should be attached to the oligonucleotide through its C(5) position (see Fig. 9). Experiments with several sequences as targets for the psoralen–oligonucleotide conjugates showed that sequence-specific cross-linking of the two DNA strands could be achieved with a high yield, provided a 5′TpA3′ step is located at the junction between the triplex and duplex structures[130, 202] (Fig. 14). Recent experiments have shown that a psoralen–oligonucleotide conjugate is able to find its site-specific target within the three billion base pairs of human DNA (C. Giovannangeli, L. Perrouault, C. Hélène, unpublished results). The target sequence was carried by the proviral DNA of HIV, which was integrated as a single copy into one of the chromosomes of a chronically infected human cell line.

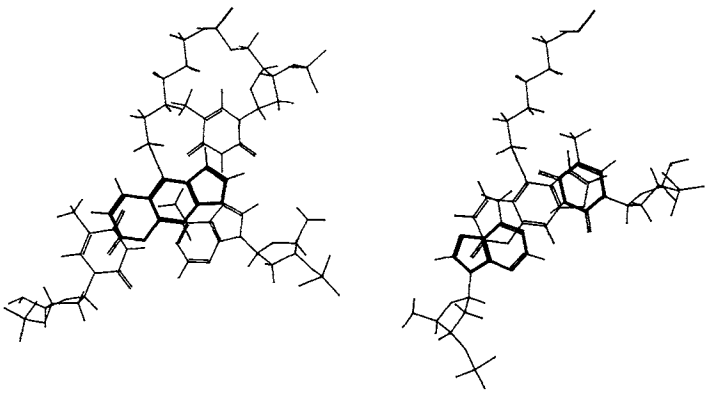


Fig. 14. Energy-minimized structures of an oligonucleotide–psoralen conjugate. The psoralen is attached to the 5′-end of a triplex-forming oligonucleotide and intercalates at the triplex–duplex junction. This figure shows the psoralen ring stacked over the last base triplet of the triple helix (T × A · T) (left) and below the first base pair (T · A) of the duplex (right). Only one position of the psoralen ring is shown, with the furan ring oriented toward the first thymine of the duplex region (the sequence at the duplex–triplex junction is $^{5'}$TpA$^{3'}$). The two reactive double bonds of psoralen [4′,5′-(furan side) and 3,4-(pyrone side)] are close to the 5,6 double bonds of the two thymines that react to form cyclobutane units, leading to a cross-link between the two strands of DNA (see ref. [130] and [202]).

The psoralen ring may a priori adopt two orientations at its intercalation site by rotating 180° around the C(5)–O bond. However, the psoralen derivative at the cross-linked site was shown to be predominantly oriented with its furan side bound to the purine-rich strand.[130] This preferential orientation reflects both the difference in binding energy of the two rotamers and the difference in photochemical reactivity. The second parameter seems to be more important, since the furan ring positioned in close proximity to the homopurine sequence yields an appropriate orientation for the two reactive double bonds of psoralen with respect to the double bonds of the two thymines on opposite strands (Fig. 14).

8. Gene Control by Triplex-Forming Oligonucleotides

The formation of a local triple-helical structure arising from the binding of an oligonucleotide to a specific sequence on the DNA double helix can affect gene expression in several ways (see Fig. 15 for a schematic representation of inhibitory processes in the case of transcription):

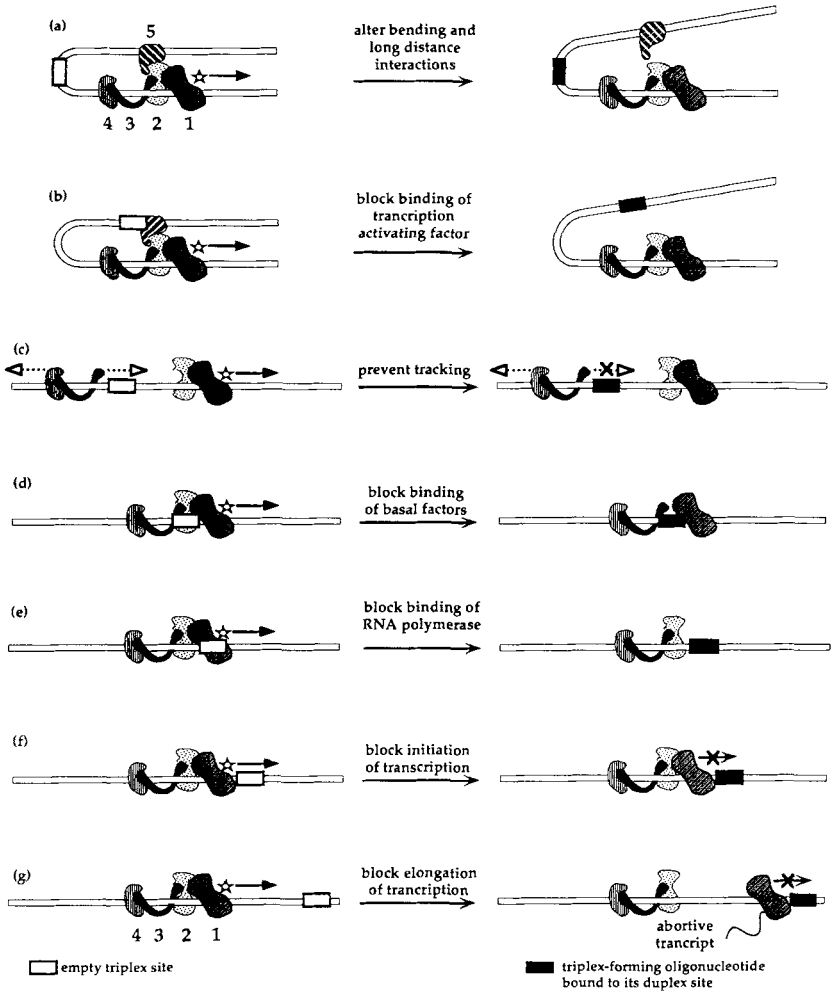

Fig. 15. Schematic representation of different mechanisms by which triple-helix-forming oligonucleotides can block transcription. The transcription machinery involves RNA polymerase and associated factors, activating factors that bind upstream in the promoter region, and activators that bind to enhancer sequences at long distance from the RNA polymerase binding site and act through folding of the double helix. The arrow indicates the direction of transcription, and the star denotes the transcription start site. The open box represents the unoccupied triplex site and the filled box represents the triple helix formed on duplex DNA. Proteins are schematically represented: RNA polymerase (1) with associated basal factors (2) interacting with transcription activating factors, which can bind either within the same promoter region (3,4)—either directly or after sliding along the promoter sequence—or at a long distance and interact with the transcription machinery through folding of the DNA duplex (5). The triple-helix forming oligonucleotide can thus: a) alter bending of the DNA, thereby preventing long distance interactions between enhancer-bound proteins and the transcription machinery; b) block binding of activators, which act either through long distance interactions, or through factors bound next to the RNA polymerase complex (not shown); c) block tracking of transcription factors which bind to an enhancer sequence far away from the promoter and slide along the DNA to contact the polymerase machinery, as shown recently for late T4 genes [172]; d) block binding of basal factors (polypeptides associated with the protein that carries the enzymatic (polymerizing) activity); e) prevent binding of the polypeptide chain (RNA polymerase) which carries the polymerizing activity; f) prevent initiation of transcription upon binding downstream but in contact with the transcription machinery; g) block elongation of transcription when bound within the transcribed region of the gene. Other mechanisms, such as recruiting triple helix-binding proteins that might perturb the fine tuning of interactions between all protein factors involved in the transcription machinery or perturbing the structure of nucleosomes bound upstream or downstream of the promoter region, are not shown. Perturbation of chromatin structure may alter transcription (see ref. [173] for a review).

1) The triplex-forming oligonucleotide can overlap the recognition and binding sites of one of the components of the transcription or replication machinery.[169-173, 196] Competition for binding to the same site is expected to exert a direct effect on the biological process (Fig. 15b,d,e).

2) The DNA conformational change which has been demonstrated to occur upon triplex formation[60-69] may perturb the binding of protein factors and/or enzymes. The perturbation of the double helix extends outside the oligonucleotide binding site, and medium-range effects on protein binding can therefore be expected. Long-range effects may also occur due to triplex-induced bending, change in bending, and/or stiffening of the DNA double helix. These types of conformational perturbations might alter through-space interactions between, for example, two transcription factors bound to different regions of the DNA or may modify the distribution of nucleosomes within the chromatin structure (Fig. 15a,c).

3) A triplex-forming oligonucleotide bound immediately downstream of RNA polymerase attached to its promoter site might prevent initiation of transcription. Inhibition might also occur when an oligonucleotide binds close enough to DNA polymerase at an origin of replication (Fig. 15f).

4) An oligonucleotide bound to DNA might act as a "roadblock" for the transcription or replication enzymes (Fig. 15g). It is likely that short oligonucleotides will not be strong enough ligands to stop the enzymatic machinery once it is launched on the DNA. This phenomenon is reminiscent of antisense oligodeoxynucleotides, which do not prevent translation when bound to the coding sequence of a mRNA, unless ribonuclease H cleaves the target mRNA at the oligodeoxynucleotide binding site. Ribosomes moving along a mRNA will displace a bound oligonucleotide in the same way that they unfold secondary structures in mRNA. Only irreversible reactions, induced by either RNase H or chemical reagents attached to the oligonucleotide, will be able to stop the translation of ribosomes. A similar situation is expected for replication or transcription. Only an irreversible reaction induced at the oligonucleotide binding site is expected to stop the DNA processing enzymes.

The mechanisms described thus far rest upon *inhibition* of an enzymatic process acting on DNA as a template. The binding of an oligonucleotide to the major groove of DNA with the formation of a local triple helix might also lead to an *activation* of the enzymatic process. There are numerous accounts of activating factors, which act positively on transcription, but there are also negatively regulating protein factors that upon binding to a gene control region decrease the efficiency of transcription.[171] Preventing the binding of such factors by triple helix-forming oligonucleotides will relieve their inhibitory effects. Alternatively, changes in DNA

and/or chromatin structure might also enhance the efficiency of transcription and/or replication.[173]

The aforementioned discussion refers only to transcription and replication, two biological processes involving DNA as a matrix, for which there are published reports on the effects of triplex-forming oligonucleotides. However, there are other biological phenomena in which enzymatic systems use DNA as a matrix. For example, DNA repair might be affected by triplex-forming oligonucleotides. The enzymatic machineries responsible for DNA repair have to recognize defects in the DNA double helix arising from either replication errors (mismatches) or damage induced in DNA by exogenous influences (radiation, chemicals, drug metabolites, etc).[9] If the altered site in the double helix is close to, or overlaps a triplex-binding site, then DNA repair might be affected. Other processes, such as recombination, modulation of DNA supercoiling by topoisomerases, and alterations in chromatin superstructure,[173] may be altered by triplex-forming oligonucleotides as well. In addition there might be proteins which specifically bind triple-helical structures within cells.[179] They could stabilize both intramolecular (H-DNA) and intermolecular (oligonucleotide-directed) triple helices.

8.1. Inhibition of Restriction Enzyme Binding and Cleavage

Restriction enzymes and methylases provide interesting tools for demonstrating that triplex-forming oligonucleotides can inhibit protein binding to specific DNA sites.[174–176] Several examples have been described in previous sections. This strategy was used to induce site-specific cleavage of long DNA fragments including chromosomes (see Section 2.5). A triplex-forming oligonucleotide can protect a restriction site from methylation by the corresponding methylase; unprotected sites are methylated. When the restriction enzyme is then added to this partially modified DNA only the protected site is cleaved.[82, 83] Most of the experiments described to date deal with overlapping recognition sites [i.e. the triplex-forming site overlapped (by one or more base pairs) the enzyme recognition site]. However, longer range effects might be observed due to the conformational change induced by triplex formation.

8.2. Inhibition of Eukaryotic Transcription Factor Binding In Vitro

There are several examples described in which oligonucleotide-directed triple-helix formation prevents transcription factor binding. Oligonucleotides containing C and T,[65, 174, 182] G and T,[28, 185–187] and G and C[183] have been used to inhibit transcription factors from binding to specific sites in the promoter regions of several genes. In a few cases, the resulting inhibition of transcription has been documented both in vitro[28, 65, 182] and in cell cultures.[182, 185, 187] Intramolecular triplexes (H-DNA) may also play a similar role. For example, a poly(dG) · poly(dC) sequence was placed at the 5′-end of a thymidine kinase promoter in mouse LTK$^-$ cells.[184] Formation of a triplex (with G × G · C base triplets) was proposed to inhibit binding of a *trans*-activating factor that stimulates transcription when the (dG · dC) tract is double-stranded.

Maher et al. have examined the effects of triple helix-forming oligonucleotides in an eukaryotic (*Drosophila*) cell-free transcription system.[65] Homopurine · homopyrimidine sequences were inserted in various configurations relative to the binding sites of the *trans*-activating factor Sp1 in eukaryotic promoters. Promoter- and oligonucleotide-specific repression of basal transcription was observed in the absence of Sp1. These effects were ascribed to the alteration in DNA flexibility arising from triple helix formation at the promoter region. However, other mechanisms, such as inhibition of DNA tracking (Fig. 15c) may modify the appropriate interactions of activators or basal factors with RNA polymerase by preventing sliding along the DNA double helix. Transcription inhibition by triplex-forming oligonucleotides required the preassembly of triple-helical complexes prior to addition of nuclear extracts. This result might arise from activities present in the nuclear extracts which might decrease DNA accessibility, and/or trap or hydrolyze the oligonucleotide, thereby decreasing its free concentration. We have shown that nuclear extracts contain nuclease activities that hydrolyze oligonucleotides which are not tightly bound to either proteins or DNA. Addition of the *trans*-activating factor Sp1 after the triplex-forming oligonucleotides did not cause derepression, independently of whether Sp1 binding sites overlapped the triple helix sites or not. These results suggest that transcription control could be exerted by triplex-forming oligonucleotides that bind at sites which *do not* overlap known protein binding sites.

8.3. Inhibition of Transcription Initiation and Elongation In Vitro

In 1968 Morgan and Wells[177] demonstrated that transcription of polynucleotide duplexes in which all purines were on the same strand (poly[d(T · C)] · poly[d(G · A)] or poly(dA) · poly(dT)) was inhibited when a third strand RNA (poly[r((U · C)] or poly(rU)) was added prior to addition of RNA polymerase from *E. coli*.

An oligonucleotide bound immediately downstream of *E. coli* RNA polymerase was shown to inhibit transcription of the β-lactamase gene.[181] The triplex-forming site was adjacent to the binding site of RNA polymerase on the β-lactamase promoter, as evidenced by DNase I footprinting experiments. Upon addition of nucleoside triphosphates, transcription did not start immediately when the oligonucleotide was bound. A delay was observed that could be related to the lifetime of the triplex. Dissociation of the oligonucleotide allowed RNA polymerase to initiate transcription. Triple helices can be strongly stabilized by a benzo[*e*]pyridoindole derivative.[144] In the presence of such a ligand, the effect of the triplex-forming oligonucleotide on transcription initiation at the β-lactamase promoter was observed at much lower concentrations of the oligonucleotide. Inhibition was made irreversible when a psoralen–oligonucleotide conjugate was used to cross-link the oligonucleotide with its target sequence following UV irradiation.[181]

An oligonucleotide bound far downstream from the transcription initiation site of a DNA carrying a eukaryotic Pol II promoter was shown to transiently arrest transcription until the oligonucleotide was displaced by RNA polymerase moving along its template.[180] A polymerase complex stalled near a triple helix seems to mediate triple helix dissociation. The oligonucleotide acted as a "roadblock" only when it was cross-linked to its target site.[180] Transcription initiation by T7 RNA polymerase has been inhibited by oligonucleotide-directed triple-helix formation at a site overlapping the polymerase-specific promoter.[207]

8.4. Inhibition of Transcription In Vivo

There have been few reports clearly demonstrating that oligonucleotide-induced effects on transcription inside cells occurred as a result of triplex formation and inhibition of *trans*-activating factors. Postel et al.[185] provided evidence for binding of a triplex-forming oligonucleotide to the *myc* gene by showing that a DNase I-hypersensitive site was masked by the oligonucleotide in cell nuclei. We have used the gene encoding the α subunit of the interleukin 2 receptor (IL2Rα) to demonstrate triplex-specific effects[182, 212, 213]. The target sequence within the promoter of the IL2Rα gene overlaps the recognition site for a transcription factor (NFκB), which strongly activates transcription. A mutant of the target sequence was constructed which could not bind a triplex-forming 15mer oligonucleotide. In transfected cells, whereas the wild-type (natural sequence) gene was inhibited by the 15mer oligonucleotide, the mutant gene was not. This result clearly demonstrated that triplex formation was a prerequisite for the inhibitory effect of the oligonucleotide. In this system, we made use of oligonucleotides carrying either an intercalating agent at the 5′-end (an acridine derivative), which could strongly stabilize the triple-helical structure,[212] or a psoralen derivative which could photo-induce a cross-link between the two strands of DNA at the oligonucleotide binding site.[213] In the latter case, analysis of the target DNA after irradiation of the cells showed that the cross-link was indeed formed at the expected oligonucleotide site within irradiated cells.[213] Chemical probes, such as $KMnO_4$, DMS, and OsO_4/pyridine, can be used in living cells: They might allow the characterization of intermolecular triplexes by in vivo footprinting, as demonstrated recently for intramolecular H-DNA in bacteria.[188]

In several studies, an inhibitory effect on gene transcription of oligonucleotides expected to form triple helices was observed, even though it was not directly demonstrated that inhibition resulted from triple-helix formation. The IL2Rα gene promoter in T-lymphocytes and the HIV-1 promoter region in acutely or chronically infected cells were chosen as targets. A decrease in mRNA synthesis was observed in both cases.[186, 187]

8.5. Inhibition of DNA Replication

Triplex-forming oligonucleotides might prevent the replication machinery from moving through the oligonucleotide binding site. However, it is more likely that the oligonucleotide–DNA complex will be dissociated when replication progresses. An irreversible reaction induced at the oligonucleotide binding site should bring more efficient inhibitory effects.

The binding of an oligonucleotide to an origin of replication might prevent assembly of the replication machinery and therefore inhibit initiation of the biological process. An oligonucleotide–intercalator conjugate targeted at the origin of replication of SV 40 was shown to inhibit viral DNA replication in CV 1 cells.[189] However, there are mechanisms other than triplex formation which might explain these results, as discussed in the original report. There is as yet no other data available on replication inhibition when duplex DNA is used as a template. However, with single-stranded DNA as a template we have recently shown that a chimeric oligonucleotide carrying both the Watson–Crick and Hoogsteen sequences can block replication by T7 DNA polymerase by forming a triple helix on the single-stranded target.[211]

In other experiments in which single-stranded DNA was used as a template for either *E. coli* (Klenow fragment) or *Thermus aquaticus* (Taq) DNA polymerase, replication was shown to stop in the middle of polypurine (or polypyrimidine) tracts.[190] This result was ascribed to the formation of pu × pu · py or py × pu · py triple helices, because of the folding of the second half of the polypurine (or polypyrimidine) tract on the double helix formed by the template and its replicated complementary strand. Such inhibition of replication was relieved when a single-strand binding protein was preincubated with the template.[190]

8.6. Detection of Triple-Stranded Structures within Cells

A monoclonal antibody for triplex DNA was produced by immunizing mice with poly[d(T^mC)] · poly[d(GA)] · poly[d($^mC^+T$)], which forms a stable triple helix under physiological conditions.[192] Binding of this antibody to metaphase chromosomes and interphase nuclei was observed by immunofluorescent microscopy of mouse myeloma cells, which had been fixed in methanol/acetic acid.[192] Immunopositive regions corresponding to condensed chromatin rings were also observed in fixed polytene chromosomes of *Chironomus tentans* and *Drosophila melanogaster*.[193] The abundance of polypurine · polypyrimidine sequences in the DNA of eukaryotes[198, 199] makes it likely that H-DNA (intramolecular triplexes) can form under topological constraints.[178] There is as yet no report on the immunological detection of intermolecular triplexes within living cells.

9. Summary and Outlook

The demonstration[18–20] that short oligonucleotides can form sequence-specific complexes with double-stranded DNA has opened a new field of investigations. Binding occurs in the major groove of the double helix and each base pair is recognized by two hydrogen bonds. Even though triple helix stability is less than that of a double helix, the specificity is at least as good as that of double-helical complexes. Single sites can be recognized in the genomic DNA of

higher organisms, which has opened new possibilities for sequence-specific cleavage of individual chromosomes at a limited number of sites. Oligonucleotide-directed triple helix formation can also be used to fish out double-stranded DNA sequences from a complex mixture.[191]

Triple-helix formation was originally limited to target sequences in which all purines belonged to the same strand. As shown in this review, the range of recognition sequences has been extended, but it still remains a challenge to organic chemists to design new base analogues able to read all four base pairs (A · T, T · A, G · C, C · G). Strand displacement reactions [e.g. with polyamide nucleic acids (PNAs)[112] or by recombinase-mediated reactions][155-158] might represent alternatives to triple-helix formation, which are not limited by the variety of base pair sequences they are able to recognize.

Many genes possess polypurine · polypyrimidine stretches, which appear to be over-represented in the genome of higher organisms.[198-200] Therefore, triple-helix-forming oligonucleotides offer new possibilities of controlling gene expression at the gene level. There are usually only two copies of each gene in a diploid cell. This characteristic might be an advantage in comparison with other targets for oligonucleotides, such as mRNA sequences which are present in large numbers within cells. The "antigene strategy",[21] which targets the oligonucleotide to the gene itself, is therefore an attractive alternative to the "antisense strategy",[22, 194] which targets the oligonucleotide to the mRNAs rather than to the gene.[197]

A fair amount of chemistry is being devoted to improving stability, selectivity, and range of recognition sequences of triple helix-forming oligonucleotides. Some of the problems facing the in vivo use of antigene oligonucleotides are similar to those encountered with antisense oligonucleotides. These problems include stability in biological media, cell uptake, intracellular distribution, pharmacokinetics. The synthesis of oligonucleotide analogues and the study of their physicochemical and biological properties provide the basic principles and the concepts for the development of a new family of therapeutic agents.

We wish to thank all our collaborators whose work is referred to in this review. We also thank Dr. Daniel Pilch for careful reading and comments, and Catherine Alvarez for typing the manuscript. Work in our laboratories has been supported by Rhône-Poulenc.

The Marcus Inverted Region from Theory to Experiment

By *Günter Grampp**

At first the theoretical papers of the 1992 Nobel Prize winner R. A. Marcus were not regarded by the experimentalists as the challenge they actually represented. From the very first publication on electron transfer reactions in May 1956,[1] which contains statements on the dependence of the free energy of activation of such reactions on the participating ions or molecules, their charges, and the solvent, they had the opportunity to put these theoretical predictions to the test. But even the paper on the Marcus cross correlation,[2] a easy-to-apply equation that should predict the rate constants of any redox process from the individual electron self-exchange reactions, attracted little attention from the experimenters.

The most spectacular theoretical prediction, however, applied to the relation between the free energy of activation ΔG^* and the free energy of reaction ΔG^0 of an electron transfer reaction,[**] and postulates the existence of a "Marcus inverted region". This unusual kinetic behavior and its experimental verification is the theme of this highlight.

Two quantities play an important role in every chemical reaction: the free energy of activation ΔG^* and the free energy of reaction ΔG^0. The latter determines whether the reaction is endergonic ($\Delta G^0 > 0$), thermoneutral ($\Delta G^0 = 0$), or exergonic ($\Delta G^0 < 0$). The rate constant of an electron transfer reaction is derived from the usual approach according to Equation (1).

$$k_{et} = A \exp(-\Delta G^*/RT) \tag{1}$$

To compare the experimentally determined rate constants with those calculated from Equation (1), theory must make sound statements on the composition of the free energy of activation ΔG^* and the preexponential factor A. The Marcus theory does both in a form that can be tested by experiment.

Of crucial importance is the reorganizational energy λ (Fig. 1); it describes the required rearrangement of the system of reactants and solvation shell necessary for electron transfer. For the same coordinates of the nuclei, the starting system (R) is differentiated from the final system (P, see Fig. 1) by the energy contribution λ. The reorganization energy λ has two components, the internal reorganization energy λ_i that accounts for the change in the bond lengths and bond angles on electron transfer, and the external reorganization energy λ_o that comprises the energy for the required rearrangement of the solvent shell [Eq. (2)]. The

$$\lambda = \lambda_i + \lambda_o \tag{2}$$

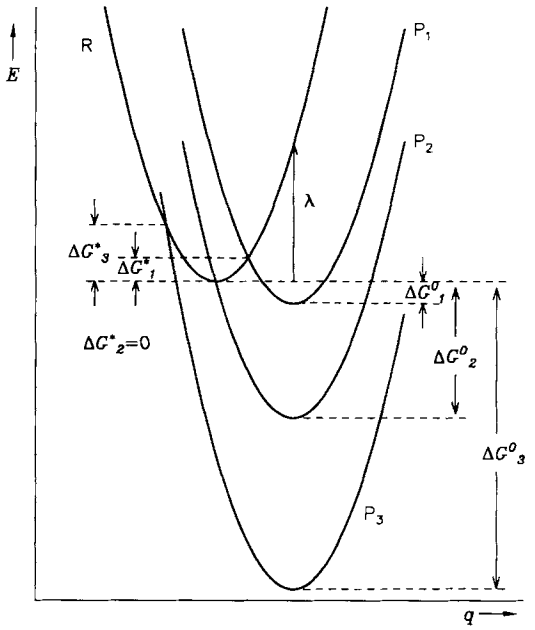

Fig. 1. The potential energies E of the reactants (R) and the products (P_1–P_3) of three systems with different free energies of reaction ΔG^0, as a function of the nuclear configuration q. 1: Exergonic reaction with $|\Delta G_1^0| > 0$ and $\Delta G_1^* > 0$; 2: exergonic reaction with $|\Delta G_2^0| = \lambda$ and $\Delta G_2^* = 0$; 3: $|\Delta G_3^0| > \lambda$ and $\Delta G_3^* > 0$ (Marcus inverted region).

influence of the solvent is described by purely physical properties, namely its refractive index n and its dielectric constant ε_s as combined in the Pekar factor $\gamma = (1/n^2 - 1/\varepsilon_s)$. This means that, in contrast to correlations that rely on empirical solvent parameters, the slope and intercept of graphs of $\lg k_{et}$ versus γ have a physical meaning.[3] The original Marcus theory did not consider dynamic solvent effects, but was later extended to include them.[4]

With Equation (1) and purely algebraic arguments a relationship between the free energy of activation ΔG^* and the free energy of reaction ΔG^0 can be established [Eq. (3)]. This

$$\Delta G^* = \frac{\lambda}{4}\left(1 + \frac{\Delta G^0}{\lambda}\right)^2 \tag{3}$$

is the famous Marcus equation that is strongly contrary to all chemical intuition because of the quadratic dependence of the free energy of activation on the free energy of reaction.

From experience we know that ΔG^* and therefore also the rate constant k of a reaction depend on ΔG^0,[5] and as a result, a number of "linear free energy relatonships" have been formulated that all involve the proportionality expressed in Equation (4). Thus in the beginning the Marcus

$$\lg k \sim -\Delta G^* \sim \Delta G^0 \tag{4}$$

theory had difficulty in gaining acceptance. While the elementary principles, for example that the electron transfer

[**] The Marcus free energy of activation ΔG^* is related to the classical free energy of activation ΔG^+ of Eyring by the following relation: $\Delta G^+ = \Delta G^* - RT\ln(c^* h N_L A/RT)$. That k_{et} is a second order rate constant in Equation (1) is taken into account in the units of concentration c^* (mol L^{-1}). A = preexponential factor.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1993 0570-0833/93/0505-0691 $ 10.00+.25/0

can take place only between isoenergetic states as a consequence of the first law of thermodynamics, were accepted as a matter of course, the implications of Equation (3) appeared obscure to chemists. A close examination of this equation shows that it predicts a decrease in the rate constants with increasing exergonicity, a direct result of the quadratic relationship between ΔG^* and ΔG^0. For a long time experimental confirmation of this phenomenon, which was described by the phrase "Marcus inverted region", was sought intensively. The experimenters soon realized that only for photoinduced electron transfer reactions or for radiochemically generated energetic systems would a reaction have large enough exergonicity to display this behavior.

There are, however, several kinetic studies that show unambiguously that the rate constants of strongly exergonic *inter*molecular electron transfer reactions in solution approach a limiting value k_{diff}, which is the value for diffusion-controlled reactions (Fig. 2). The classic papers of Rehm and Weller[6] on fluorescence quenching by electron transfer have proved this conclusively.

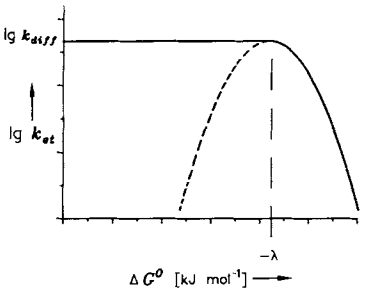

Fig. 2. The logarithm of the rate constants k_{et} of an electron transfer reaction, as function of the free energy of reaction ΔG^0. The solid line represents Rehm–Weller behavior and the broken line the Marcus inverted region. The maximum of this curve lies at $\Delta G^0 = -\lambda$.

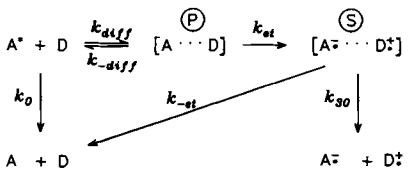
This immense discrepancy between Marcus theory and experiment justifiably caused some skeptical comments in the beginning.[7] The breakthrough for the Marcus theory with regard to the inverted region was made about twenty years after its publication. The first occurrence of an inverted region was observed by J. J. Miller and the late G. L. Closs in a pulse radiolysis induced *intra*molecular electron transfer reaction.[8a] Through a skilful linking of donor and acceptor units by a rigid part of the molecule, the spacer, they could achieve a fixed reaction distance between the two units. Biphenyl served as donor and several aromatic hydrocarbons or quinones as acceptors. Even conformers with axial and equatorial units bound to the spacer were studied.[8b] By variation of the donor and acceptor units, a really phenomenal synthetic achievement, the ΔG^0 values were varied by means of the individual redox potentials to reach the inverted region. A convincing decrease in the rate constants k_{et} was found for values of $|\Delta G^0| > \lambda$.

Since then the existence of the inverted region has been proved conclusively for a series of molecules with bridged donor/acceptor units. Porphyrins were coupled to quinones and the reaction distance between the donor and the acceptor was varied. Remarkable achievements in synthesis were made to prepare diverse saturated six-membered ring systems as bridging units between the donor unit 1,4-dimethoxynaphthalene and acceptor unit dicyanoethylene.[10] Electron transfer reactions in proteins over large distances[11] likewise show the effect, as do photoinduced reactions in organic glasses[12] or the melts of aromatic hydrocarbons.[13] An inverted region has also been detected in inorganic transition metal complexes for the *intra*molecular electron transfer between two ligands.[14]

All examples mentioned thus far, and only a few have been selected, have in common the *intra*molecular electron transfer step. In contrast, up to now Rehm–Weller behavior has been found for all charge separation reactions described by the rate constant k_{et} in Scheme 1.



Scheme 1. Mechanism of a charge separation reaction between donor D and acceptor A. Ⓟ = precursor complex, Ⓢ = successor complex.

This finding invites further investigations on the precursor complex Ⓟ. One must distinguish here between contact ion pairs and solvent-separated ion pairs. Interested readers are referred to reference [15]. Without expanding on the structural differences of these loose complexes, it should be mentioned that combination reactions between the components of these species have certain similarities with intramolecular electron transfer. For example, the diffusion of the reaction partners to one another, which forms the precursor complex Ⓟ in bimolecular reactions, is redundant. Moreover, the distances between the reacting centers are more or less fixed.

As a result it was also possible to find the Marcus inverted region for charge recombinations, for example, for the electron back transfer (rate constant k_{-et}, Scheme 1). Unambiguous experimental proof was found for the existence of the inverted region for the electron back transfer from photoexcited singlet states of preformed radical ion pairs comprising 9,10-dicyano- or 2,6,9,10-tetracyanoanthracene as acceptor and a large number of aromatic hydrocarbons as donor.[16]

This electron back transfer took place from radical ion pairs derived from excited singlet states. Always present as competing reaction is the separation into the free solvatied ions $A^{\bullet -}$ and $D^{\bullet +}$, represented by the rate constant k_{30} ($\triangleq k_{diff}$) (Scheme 1).

In 1989 Russian authors studied the electron back transfer for radical ion pairs in the triplet state and likewise found an inverted effect. Through the use of a solvent with a low dielectric constant ε_s, the diffusion of the components of the radical ion pair away from each other was hindered.

Relatively few publications deal with both the electron transfer reactions discussed above, namely, the charge separation (k_{et}) and the electron back transfer (k_{-et}), in the same system. A new paper by Gray et al. concerns exactly this problem. Through fluorescence quenching experiments the authors succeeded in measuring the rate constant k_{et} of the forward reaction for triplet states of the iridium complex

$[\{Ir(1,5\text{-cyclooctadiene})(\mu\text{-pyrazolyl})\}_2]$ $(= Ir_2)$ with *N*-alkylpyridinium salts (py^+) as donors.[18] Whereas for the forward reaction formulated in Equation (5) the diffusion-

$$^3Ir_2 + py^+ \xrightarrow{k_{et}} Ir_2^{\bullet+} + py^{\bullet} \quad (5)$$

controlled limiting value in the strongly exergonic region is almost achieved (Rehm–Weller behavior), the electron back transfer reaction described in Equation (6) shows distinctly the inverted behavior of Marcus.

$$Ir_2^{\bullet+} + py^{\bullet} \xrightarrow{k_{et}} Ir_2 + py^+ \quad (6)$$

We found exactly the same situation for a purely organic redox system. The forward reaction proceeding from triplet states of the dye thionine with different aromatic hydrocarbons and amines as donors according to Equation (7) clearly

$$^3Th^+ + D \xrightarrow{k_{et}} [Th^{\bullet} \cdots D^{\bullet+}] \quad (7)$$

demonstrated Rehm–Weller characteristics, which has been known for a long time,[19] while the electron back transfer reaction [Eq. (8)] lies just as clearly in the Marcus inverted region.[20]

$$^3[Th^{\bullet} \cdots D^{\bullet+}] \xrightarrow{k_{-et}} Th^+ + D \quad (8)$$

The actual reasons for the different reaction behaviors is still topic of theoretical studies. Several models have been proposed only to be rejcted again. For instance, models that take into account quantum mechanical tunneling for the Marcus inverted region were developed, but they could not satisfactorily explain the quantitative differences between Rehm–Weller and Marcus behavior.[21] Energetically low-lying electronically excited states were thought to explain the absence of the Marcus inverted region for charge separation reactions, as was the dielectric saturation of the solvent molecules in the first solvent coordination sphere.[22] It was also noted that the electron transfer in intermolecular and intra- or pseudo-intramolecular back transfer reactions can also take place for other reaction distances.[23]

All these models are extremely difficult to test by experiment. So the occurrence or absence of the Marcus inverted region is still a field for wide-ranging theoretical deliberation. Interested readers are referred to a recent review.[24]

Nevertheless it can be categorically stated that all the predictions of the Marcus theory on the kinetics of electron transfer have been fully verified,[25] and they also contain explanations for such complex phenomena as the charge separation on photosynthesis, chemiluminescence, the collection of solar energy, and electron penetration reactions. Therefore the justification of the Royal Swedish Academy of Sciences for the award of the Nobel prize for Chemistry to R. A. Marcus in 1992 was singularly apt when they declared that it is a realistic theory.

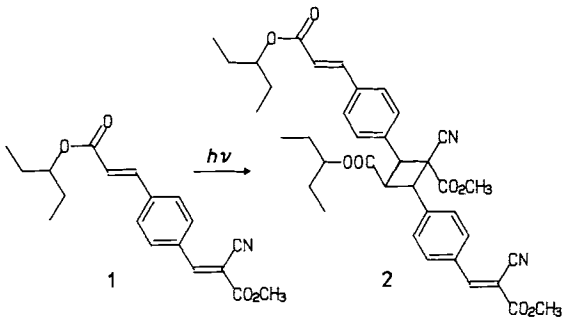
Absolute Asymmetric Synthesis by Irradiation of Chiral Crystals

By *Gerd Kaupp** and *Michael Haak*

The formation of enantiopure optically active biomolecules is an important chapter in the history of evolution. The physical phenomena which can generate and augment asymmetry[1] have been known for a long time. However, since 1975[2] there are also crystal chemical solutions of the problem, which moreover can be used in asymmetric synthesis. When achiral molecules crystallize in chiral space groups and the irradiation of the crystals leads to chiral products, one speaks justly and correctly of "absolute" asymmetric synthesis. For this, the use of chiral agents and thus also the "crystal-selecting" human hand must be dispensed with, even though the latter is useful for syntheses.

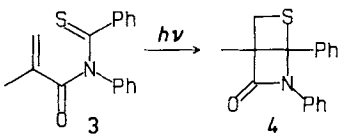
Absolute asymmetric [2 + 2] photodimerizations of achiral compounds in crystals have been known since 1982.[3] Compound **1** (Scheme 1) crystallizes in the chiral space group $P2_1$. Crystals of **1** obtained from the melt and from ethanol on irradiation give either (+)- or (−)-**2** with enantiomeric excesses (*ee* values) of 0 to 95% and higher. The result varies from crystallization batch to crystallization batch; however, 100% *ee* of the (+)- and the (−)-enantiomer **2** were also obtained.[3] This confirms that the photoreaction occurs *stereospecifically* (lattice-controlled or topochemical) and that in the batches with lower optical yields the preceding crystallization leads to mixtures of left- and right-handed chiral crystals. Many asymmetric syntheses of this kind occur with considerably lower optical yields (e.g. <7% *ee*[3]), or they are dependent on the conversion.[3] This is, however, not surprising, even when only crystals of a single chirality are present, because studies by atomic force microscopy (AFM)[4] have shown that photodimerizations proceed from the surface to the interior of the crystal, during which extensive molecular regroupings (on the scale of the lattice constants) take place. The degree of the obtainable stereoselectivities clearly depends on the various mechanisms which are involved in those processes.[4]



Scheme 1. **1** is *achiral*, but forms chiral crystals, which upon irradiation form *chiral* **2**.

The fact that relatively often spontaneous asymmetric crystallization of achiral compounds occurs with the formation of either right- or left-handed crystals is the result of autoseeding with the first crystal formed.[3, 5] Thus, in favorable cases all of the supersaturated solution yields only crystals of one chirality (analogously from melts), which, of course, cannot be predetermined. The chirality can only be influenced by manual seeding with selected crystals.

Enantioselective syntheses with achiral molecules in host crystals constructed from chiral molecules[6] belong as little to absolute asymmetric syntheses as do intramolecular photoreactions (di-π-methane rearrangement or γ-H transfer) following the manual selection of enantiomorphic crystals[7a] or after seeding with such crystals.[8] However, Scheffer, Trotter et al.[7b] developed further their highly selective di-π-methane rearrangement of diisopropyl dibenzobarrelenedicarboxylate to give the dibenzosemibullvalene derivative (quantitative *ee* at conversions of a few percent) into an absolute asymmetric synthesis, and Sakamoto et al.[9] have recently found another intramolecular absolute asymmetric synthesis by irradiation of crystals of achiral **3** (Scheme 2), which also crystallize in the chiral space group $P2_12_12_1$. Optically active **4** is obtained after photolysis of **3** without external seeding for the crystallization. In seven of ten crystallizations from hexane the (+)-enantiomer **4** predominated, in three cases the (−)-enantiomer **4**. The optical yields (10% *ee* at 0 °C, 75% chemical yield) can be improved by reducing the temperature (40% *ee* at −40 °C, 70% yield; no reaction at −78 °C; however, formation of racemic **4** in solution also at −78 °C). This is again a reminder of the necessity of the formation of a new phase by the product, which is accompanied by extensive molecular transports (on the scale of the crystal lattice constants) in all known cases.[4] Evidently, as a result of these, the chiral conformers **3** have—as in solution—the opportunity for racemization and further conformational alterations. Nevertheless, the chirality advantage given by the crystal is retained partly. Although, in principle, it is not necessary for the action of an asymmetric crystal environment that the molecules are arranged as uniform chiral conformers, it is essential for the helical compound **3**[9] that the one enantiomorphic type of crystal contains the molecules **3** in the right-handed helix (*P*), the other in the left-handed helix (*M*).[10]



Scheme 2. **3** is *achiral*, but forms chiral crystals, which upon irradiation form *chiral* **4**.

As long as the absolute configuration of the products (e.g. **2** or **4**) and of the enantiomorphic crystals has not been determined, usually those leading to (+)-products are designated as (+)-crystals and vice versa. Without knowledge of the absolute configurations there is also no correlation between the chirality of the crystal and the helicity of the lat-

[*] Prof. Dr. G. Kaupp, Dipl.-Chem. M. Haak

tice-frozen conformer. To elucidate the principle we arranged the unit cell ($P2_12_12_1$) of **3** with the left-handed helix arbitrarily as left handed. Compound (1*R*,4*S*)-**4** [(−) or (+)] is formed unavoidably from the left-handed helix **3**. Correspondingly, (1*S*,4*R*)-**4** must be formed from the enantiomorphic crystal arranged in the right-handed way. This is represented in Figure 1 on the basis of optimized geometries from semiempirical PM3 calculations. Regardless of whether the adoption of the configurations agrees with reality, it thus becomes clear that the spontaneous asymmetric crystallization determines the chirality of the excess enantiomer **4** exclusively. The energetically most favorable conformer of **3** (Fig. 1; *M* or *P*) is 13 kcal mol^{-1} less stable than **4** according to our calculations,[11] and thus it should show optimal reactivity. According to the X-ray structure analysis,[9] in the crystal the pitch of the helix is reduced. This is evident from the significantly shortened distances between the reactive centers: the semiempirical calculated distances S-1/C-6 and C-2/C-5 in **3** are 4.33 and 3.26 Å, respectively, (where the numbers refer to the sequence of atoms in the chain starting from S);[11] in contrast, in the crystal they were determined to be 3.59 and 3.11 Å, respectively.[9] This compression also contributes to the selectivity of the crystal photolysis.

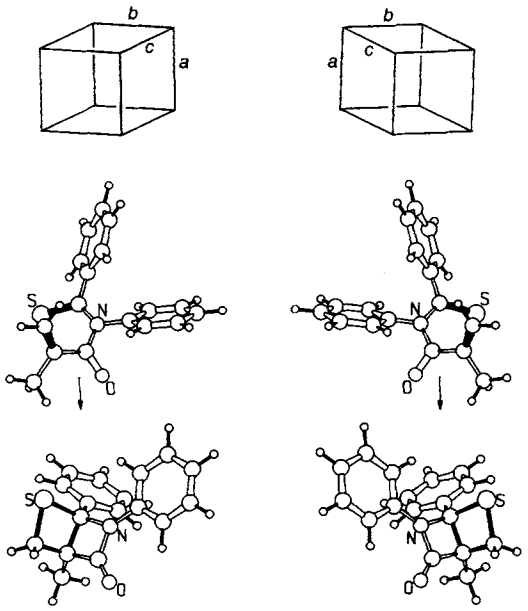

Fig. 1. Top: $P2_12_12_1$ unit cell ($a = 9.535(2)$, $b = 9.782(2)$, $c = 16.428(3)$ Å) of **3**, left- and right-handed arrangement; middle: left-handed (*M*) and right-handed helix (*P*) of **3** where *M* and *P* are descriptors for helicity (*M* = minus and *P* = plus); bottom: (1*R*,4*S*)-**4** and (1*S*,4*R*)-**4**.

Absolute asymmetric synthesis by irradiation of chiral crystals,[10] now extended to intramolecular reactions, supports the assumption of the prebiotic origin of natural chirality. The chemical mechanisms here appear to be so conclusive and efficient that they should in any case be retained besides the complicated physical interpretations.[1] It must be remembered that of the 230 space groups 65 are chiral and that of these $P2_12_12_1$ and $P2_1$ belong to the five most frequent in the organic crystals.

Regardless of these fundamental findings a wide field has opened up for efficient asymmetric syntheses by approved photochemical reactions. Far too little attention has been paid to the phenomenon of the spontaneous asymmetric crystallization to date, with the result that the step to the polarimeter or the use of chiral NMR shift reagents after the photolysis has mostly not been taken; otherwise without doubt many a supposed racemate would have turned out to be optically active.[12]

Ordered Molecular Arrays as Templates: A New Approach to the Synthesis of Mesoporous Materials

By *Peter Behrens** and *Galen D. Stucky*

During the past decade, physicists have discovered a new world in mesoscopic systems, in which classical models collide with quantum effects. It is a world in which electronic transport becomes a coherent process and any change in phase leads to a macroscopic change in conductance. Similarly, small changes in atomic structure or externally applied electromagnetic fields can cause large changes in absorption edges, polarization, optical transparency, and general nonlinear response. Using electrooptic interconnects in this dimension offers the possibilities of decreasing processing times in optical computers, increasing our capabilities to manipulate and store visual images, and a host of other potential applications.

The physicist's and engineer's approach to the mesoscopic world[1] has been by way of molecular beam epitaxy (MBE) and atomic layer epitaxy (ALE) on substrates with an ordered two-dimensional lattice to fabricate ultra-thin (monolayer) semiconductor epitaxial layers. Quantum wires in which carriers and electronic wave functions have only one degree of freedom can be formed in the MBE approach by corrugation of quantum layers or by lateral structuring, but are still a challenge below diameters of about 100 Å.

The chemist's interest in the mesoscopic world has been equally intense, based on a long-held recognition that ultimately all materials and living organisms have their origins in the collective assembly of a small number of atoms or molecules. Whether it be the beginning of life, crystallization, or the natural formation of a complicated biological nanocomposite like a sea shell, the inherent future properties such as shape, mechanical strength, color, conductivity, etc. of an extended structure are established very early as the molecules or atoms assemble and make the critical transition from few units with nanoscale dimensions to mesoscopic arrays. It is at this metamorphosis that macroscopic collective properties are defined and have their birth.

Two chemical approaches to the micro- and mesophase manipulation of atoms and molecules have been most extensively used. The first, in which considerable progress has been made, is the assembly of microcluster atomic arrays. Examples include small chunks of metal[2a] that are solubilized and protected by a coating of ligands, such as $[HNi_{38}Pt_6(CO)_{48}]^{5-}$[2b] and $[Au_{55}(PPh_3)_{126}]^{6+}$[2c] as well as the use of competitive core cluster growth and surface capping (which terminates the cluster growth) of semiconductor clusters.[3] A limitation has been the difficulty in subsequently ordering these clusters into three-dimensional supramolecular lattices.

A second approach has been to use two-dimensional, structure-directing surfaces and three-dimensional porous media for molecular recognition. The chemical growth from solution of superlattice layered structures, giving a periodic array of planes of atoms or molecules with confinement in one dimension (perpendicular to the expitaxial grown layers) has been beautifully developed by the research groups of Mallouk, Marks, and Katz for applications such as enantioselective synthesis and nonlinear optical devices.[4] The separation of the layers in these nanophase materials is generally less than 20 Å.

Microporous phases with three-dimensional framework structures are now routinely synthesized by using molecular units or hydrated alkali or alkaline earth cations as templates. Their well-defined pore structures and pore sizes (3 to 13 Å) reflect the template dimensions. Chronologically the development of this microporous synthesis chemistry has evolved from zeolites that possess crystalline aluminosilicate frameworks to pure silicate phases, and more recently to compounds that exhibit similar framework structures but have compositions in which Al and/or Si are substituted by other elements such as Be, B, Ga, Ge, Zn, and P. The aluminosilicate and silicate microporous solids have found extensive application in the fields of ion exchange (consider the use of zeolite A as water softener in detergents), desiccation, sorption (e.g., gas separation and purification), and catalysis. Especially for the latter two applications, the geometric restrictions imposed by the porous framework are of importance in differentiating between molecules of different size (size exclusion from intraporous sorption); and in the selectivity of starting materials, transition states, and products of catalytic processes ("shape-selective catalysis").[5]

In the last five years, new applications of the precisely defined void structure of zeolite-type microporous solids have been envisaged. In an approach to "supramolecular architecture"[6] and "nanoscale inclusion chemistry"[7] based not on molecular ensembles but on extended solid state structures, they serve as a versatile host medium for assembling and maintaining controlled microstructures of quantum dots and wires,[8] organic molecules and polymers,[9] metal carbonyls and organometallic molecules,[8d, 10] redox systems and electron-transport chains,[11] as well as nanosize reaction vessels.[12a] This type of host–guest chemistry results in synthetic nanocomposite materials that can be described as "expanded" metals and semiconductors, stabilized arrays of aligned molecules or spatially organized redox systems for which applications in optoelectronics,[8a, 8b] nonlinear optics,[9a, 9b] optical data storage and image processing[8a] (for example by spectral hole burning),[9c] and enzyme mimicking[12b] are conceivable.

There has been a growing interest in the extension of the microporous molecular sieve synthesis and applications to mesoscopic dimensions. Typical areas for the application of mesoscopic zeolite-type structures are in separation (e.g., protein separation and selective adsorption of large organic molecues from waste waters) and catalysis (e.g., processing of tar sand and of the high distillates of crude oils to valuable low-boiling products). Another is in the supramolecular as-

sembly of molecular arrays and polymers for electronic and optical applications.

Although there have been numerous attempts to carry over the crystallinity and the well-defined pore structure of zeolites to the mesoporous regime, the direct synthesis of three-dimensional mesoporous[13] materials containing cages and channels with access pores greater than 13 Å has until now been unsuccessful. Other routes to mesoporous solids such as forming pillars of layered compounds have been investigated.[14–16] Although mesoporosity was observed in some of the systems investigated, the pore size distribution was broader than in microporous zeolites.

The usual technique for preparing zeolites is the hydrothermal treatment of aluminosilicate gels or solutions containing metal (alkali or alkali earth) or organic ions (e.g., tetraalkylammonium ions) or molecules (e.g., amines). First progress towards enlarging the pore sizes in zeolite-type compounds was achieved by changing the composition of the gel from that of an aluminosilicate. This led to the discovery of the aluminophosphate VPI-5,[17] a one-dimensional channel structure with channel diameters of ≈13 Å, and of the gallophosphate cloverite,[18] featuring a cavity with a diameter of about 30 Å. Although the windows are about 13 Å at their widest point, their effective kinetic diameter is much smaller because of the clover-leaf shape of the opening.

The ions and molecules present in the hydrothermally treated gel act as templates during its crystallization; that is, they direct the formation of a specific zeolite framework and are usually occluded in the voids of the crystallizing solids. Even today this template effect is not fully understood. One proposal is that the template molecules change the chemistry of the crystallizing gel. Organic templates, on the other hand, may also act merely as "void fillers", preventing the crystallization of thermodynamically more stable dense phases. One obvious way to zeolites with larger pores is the use of large molecular organic templates, which should give large voids. This approach was, of course, followed by many laboratories but over a long period has not led to a definite claim of a mesoporous structure.

Recently, researches of Mobil Oil Company[19, 20] used a new concept in the synthesis of porous material which at long last has led to the first synthesis of mesoporous structures. The templating agent is no longer a single, solvated, organic molecule or metal ion, but rather a self-assembled molecular array. This template leads to mesoporous zeolites with adjustable pore sizes between 16 and >100 Å, covering well the mesoporous range of greatest interest. These compounds, named MCM-41 (MCM stands for Mobil's Composition of Matter), possess a hexagonal arrangement of parallel channels which can be directly visualized by a transmission electron microscope.[20] The arrangement of pores is very regular, and the pore size distribution measured by absorption is nearly as sharp as that of conventional zeolites.[19, 20b] A structural model of an MCM-41 material is given in Figure 1.

Kresge et al.[20a] and Beck et al.[20b] propose that a liquid crystal templating mechanism is operative in the synthesis of their mesoporous materials. Typically, the templates they use are quaternary ammonium ions $C_nH_{2n+1}(CH_3)_3N^+$, which are also useful as surfactants in detergents. These ions are known to form micelles in aqueous solutions (Fig. 2). In a

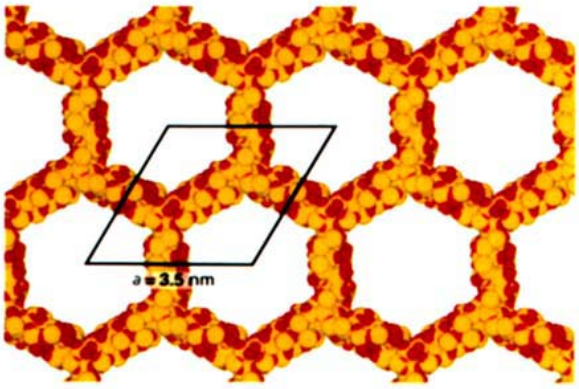

Fig. 1. Schematic representation of the structure of a MCM-41 phase with an interpore distance of ≈35 Å, amorphous wall structure, and hexagonal pores.

picture similar to the recently proposed "can-and-cement" model of the crystallization of microporous zeolites,[21] these template molecules are assumed to be ordered in the aqueous gel; during crystallization, the silicate or aluminosilicate solution present between the template assemblies becomes the "walls" of the porous solid. Different types of order have

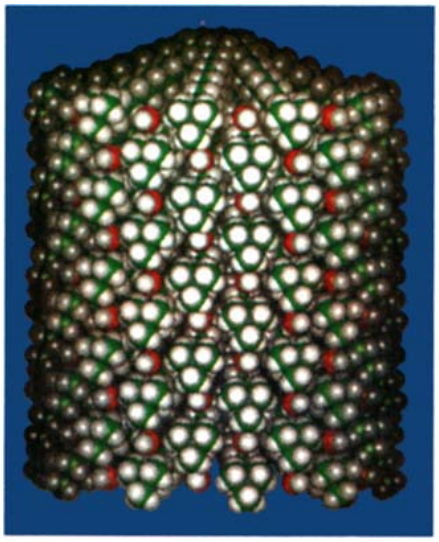

Fig. 2. Schematic representation of the exterior surface of a cylindrical micelle. The ends of the micelle cylinder are probably best visualized as hemispherical.

been found in surfactant–water liquid crystals, including lamellar, hexagonal, and cubic phases.[22] Accordingly, MCM-41 materials, which have a hexagonal arrangement of mesoporous channels are templated by the hexagonal phase. Strong support for the liquid crystal template mechanism comes from the discovery of cubic and layered crystallization products[20, 23] that possibly are templated by the cubic and lamellar liquid crystal phases. According to the templating mechanism, the alkyl chain length n influences the pore size of the MCM-41 material. For example, for $n = 12$, 14 or 16 the pore size is 30 Å, 34 Å, and 38 Å, respectively.[19, 20]

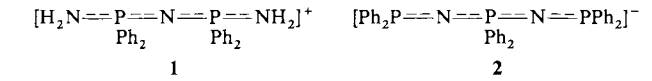
Formation and Complex Stabilization of a New Chainlike Phosphazene Anion by Co^{II}-Assisted Oxidative Scrambling of $[N(PPh_2)_2]^-$**

By *Jochen Ellermann,* Jörg Sutter, Falk A. Knoch,* and *Matthias Moll*

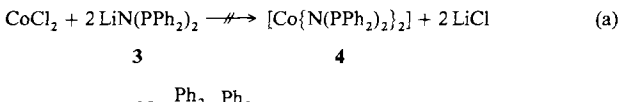
Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

The linear phosphazene cation **1**[1] has a great synthetic potential and is particularly suitable for the preparation of cyclometallaphosphazenes.[2, 3] We report now on the formation of the similar phosphazene anion **2** whose sequence of atoms is reversed and its complexation to give a novel spirocyclic cobaltaphosphazene.

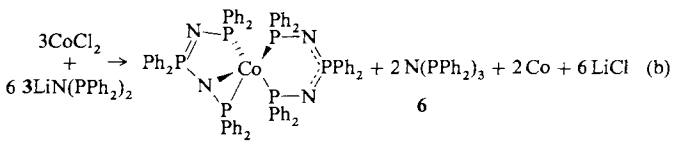


1 **2**

Surprisingly, when anhydrous cobalt(II) chloride is treated with lithium bis(diphenylphosphino)amide (**3**)[4–6] in the molar ratio 1:2 in boiling toluene, no complex **4** is formed [Eq. (a)], but in accordance with Equation (b) the red-black spirocyclic cobaltaphosphazene **5**[7] is obtained with the scrambling of the P-N-P ligand in **3**. As shown by the crystal



3 **4** (a)



5 **6** (b)

structure analysis (Fig. 1) this spirocycle contains three rings of different sizes, that is, in **5**, **2** acts both as a bidentate P ligand and as tridentate P and N chelating ligand. In addition to **5**, tris(diphenylphosphino)amine **6**[8–10] and cobalt metal are formed. Cobalt(0) and **5** could be isolated almost quantitatively in the amounts expected according to Equation (b).

6 **7** (c)

Consequently, it is assumed that the anion of **3** is oxidized to give **6** with the formation of the nitrene **7** according to Equation (c), whereas cobalt(II) chloride is reduced to cobalt metal. The intermediate **7** is trapped by a further anion of **3** with the formation of **2**, which then coordinates the remaining cobalt(II) to give **5**.

The cobalt(II) ion contained in **5** has a distorted coordination polyhedron in the solid state, which can be considered as a N1-capped CoP_4 tetrahedron or as a distorted tetragonal pyramid with an apical P3 and a N1-P1-P4-P6 base (Fig. 1).[11] As expected both forms lead to a d^7 low-spin electronic state.[12]

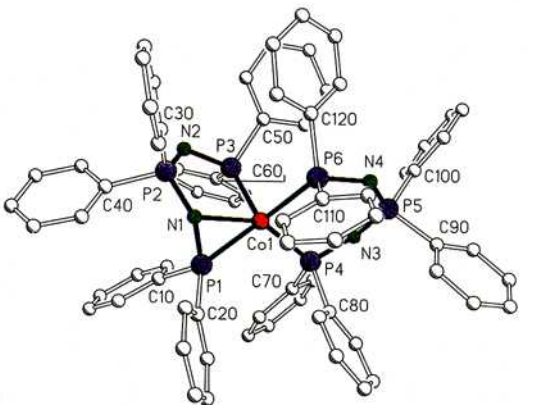


Fig. 1. Crystal structure of **5** (without the H atoms). Important distances [pm] and angles [°]: Co1-P1 217.4(1), Co1-P3 234.2(2), Co1-P4 220.6(1), Co1-P6 231.9(1), Co1-N1 221.2(3), P1-N1 165.3(3), P2-N1 163.6(3), P2-N2 158.1(4), P3-N2 165.9(3), P4-N3 162.6(3), P5-N3 159.5(3), P5-N4 158.9(3), P6-N4 162.3(3); P1-Co1-P3 99.6(1), P1-Co1-P4 106.4(1), P3-Co1-P4 110.8(1), P1-Co1-P6 144.8(1), P3-Co1-P6 101.4(1), P4-Co1-P6 92.1(1), P1-Co1-N1 44.3(1), P3-Co1-N1 86.0(1), P4-Co1-N1 149.6(1), P6-Co1-N1 109.7(1), Co1-P1-N1 69.1(1), N1-P2-N2 117.1(2), Co1-P3-N2 106.4(1), Co1-P4-N3 118.0(1), N3-P5-N4 119.0(1), Co1-P6-N4 120.5(1), Co1-N1-P1 66.7(1), Co1-N1-P2 110.5(2), P1-N1-P2 125.6(2), P2-N2-P3 117.9(2), P4-N3-P5 123.4(2), P5-N4-P6 129.2(2).

The P–N bond lengths all lie between the values of P–N single (177 pm) and P–N double bonds (156 pm),[13] as they occur in phosphazenes. The bonds P2–N2 (158.1 pm), P5–N3 (159.5 pm), and P5–N4 (158.9 pm) are mainly of double bond character, whereas the distances P2–N1 (163.6 pm), P1–N1 (165.3 pm), P3–N2 (165.9 pm), P4–N3 (162.6 pm), and P6–N4 (162.3 pm) correspond rather to bond lengths between single and double bonds.

The UV/VIS spectrum of **5** (solvent: toluene) is very similar to those of comparable cobalt(II) complexes in which the central atom is in a tetragonal-pyramidal environment.[14, 15] One weak and two intense absorptions at 15850 ($^2A_1 \rightarrow {}^2B_2$),[16] and 21250 ($^2A_1 \rightarrow {}^2E$) and 26750 ($^2A_1 \rightarrow {}^2B_1$) cm^{-1}, respectively, are observed (the assignments are tentative).

Experimental Procedure

All operations were carried out under a nitrogen atmosphere in dry, N_2-saturated solvents. Compound **3** was prepared according to refs. [5,6]. Anhydrous $CoCl_2$ was purchased from Merck-Schuchardt, Hohenbrunn near Munich.

To a suspension of **3** (7.625 g, 19.49 mmol) in toluene (75 mL), anhydrous $CoCl_2$ (1.265 g, 9.74 mmol) was added. After the mixture had been heated and stirred under reflux for 5 h, elemental magnetic cobalt and LiCl precipitated from the dark red reaction mixture. The mixture was filtered and the filtrate concentrated to a fifth of its volume. Compound **5**, which precipitated as a red-black, crystalline solid, was purified by recrystallization from hot toluene. Finally, it was dried in vacuo for 48 h. Yield: 3.67 g (92%). Single crystals of **5** were obtained by layering a saturated solution of **5** in CH_2Cl_2 with *n*-pentane at room temperature. Correct elemental analysis (C,H,N,P,Co); decomposition at 227 °C. ^1H NMR (270 MHz, CD_2Cl_2): $\delta = 8.51$ (s, 32H; C_6H_5), 7.70 (s, 4H; C_6H_5), 7.37 (s, 12H; C_6H_5), 2.95 (br. s, 12H; C_6H_5) [12]; $^{13}C\{^1H\}$ NMR (67.94 MHz, CD_2Cl_2): $\delta = 131.0$ (s, C-*ortho*; C_6H_5), 128.2 (s, C-*para*; C_6H_5), 127.2 (s, C-*meta*; C_6H_5), 119.5 (br s, C-*ipso*; C_6H_5) [12]; $^{31}P\{^1H\}$ NMR (109.38 MHz, CD_2Cl_2; H_3PO_4): $\delta = -150$ (s, half-value width 125 ppm) [12]. IR (KBr): $\tilde{\nu}$ [cm^{-1}] [17] = 3070 w–m, 3051 m [ν(CH)], 1584 m, 1478 m–s, 1432 s [ν(CC)], 1303 m [δ(CH)], 1192 vs, 1170 s [ν(P = N)]; 1132 vs [P-sens. q, P^V] [18], 1093 s [P-sens. q, P^{III}] [18], 1046 m–s [ν(P=N)], 1026 m [δ(CH)], 997 m [C_6H_5-ring vibration.]; 807 s [ν(PN)]; 735 s [γ(CH)]; 714 m–s [P-sens. r, P^V] [18], 693 vs [Φ(CC)] [18], 676 m–s [ν(PN)], 568 m, 552 m–s [γ(P-N-P)], 537 s [P-sens. y, P^V] [18], 515 s, 490 m–s [P-sens. y, P^{III}] [18], 427 m [P-sens. t, P-C_6H_5] [18]; 368 m, br [δ(NP_2)]. FD-MS: *m/z* 1225 (M^+).

The LiCl was extracted with THF from the above-mentioned residue of LiCl and pyrophoric cobalt metal and determined qualitatively. After the remaining crude cobalt was dried it weighed 362 mg (6.14 mmol; corresponding to 63% of the amount of Co used) and the content of pure Co was determined complexometrically to be 98.5% after transformation into $CoSO_4$. Identification of **6**: The volatile components of the combined filtrates of **5** were removed under vacuum. The pale brown residue was eluted with toluene (25 mL) and the solution was layered with *n*-pentane (35 mL), leading to a crystal conglomerate of colorless, clear, square crystals of **6**, which were embedded in a microcrystalline thin layer of **5**. Crystals of **6** were removed mechanically, separated, and analyzed [10].

Hypothetical Carbon Modifications Derived from Zeolite Frameworks**

By *Reinhard Nesper,* Karlheinz Vogel,* and *Peter E. Blöchl**

Dedicated to Professor Hartmut Bärnighausen on the occasion of his 60th birthday

The discovery of fullerene modifications of carbon, in particular C_{60}, and their laboratory-scale production have stimulated a large number of theoretical and experimental investigations.[1,2] Interest in the potential of carbon to form new, exotic structures with surprising physical properties has grown. Recent studies[3–8] have concentrated on graphite-related materials such as fullerenes, graphitic microtubules, and negatively curved graphitic carbon—compounds composed of sp^2-hybridized C atoms. Surprisingly, only few reports on modifications with sp^3-hybridized C atoms have appeared.[9] Such compounds are likely to exhibit a structural variety rivaling that of the graphite-related materials that are currently attracting a great deal of attention. The stability of the C–C single bond is manifested in diamond; its bond energy is only 0.02 eV per atom less than that of graphite. Compounds made up of tetrahedral building blocks such as group 14 elements (C, Si, Ge, Sn, Pb) as well as solid H_2O and SiO_2 are known for their complex structural chemistry. The existence of amorphous silicon and carbon and of crystalline and glassy silicates indicates the enormous structural variety and kinetic stability of arrangements of these building blocks.

We investigated ordered carbon modifications with sp^3 C atoms which are derived from structures found in nature, namely zeolites.[10] Zeolite frameworks consist of tetracoordinated $MO_{4/2}$ units (M = Si, Al, etc.). Formal replacement of each $MO_{4/2}$ unit by one carbon atom and appropriate rescaling provides the desired model structures. We took all known zeolite structures[10] into account but have omitted those containing three- and four-membered rings. Six candidates remained for further investigation.

In order to determine the energetic stability of these six carbon allotropes we performed electronic structure calculations. We used the ab initio molecular dynamics method of

Car and Parrinello[11] based on the local density approximation (LDA)[12] in combination with the projector-augmented (plane) wave (PAW) method developed by one of us (P.E.B.).[20] The PAW method overcomes the well-known problems in the application of the pseudopotential method to first-row and transition metal elements by expanding the electronic wave functions in augmented plane waves. It has been successfully applied to several systems such as small and large molecules and surfaces,[13] and the solid-state systems here. The accuracy of the PAW method is comparable to that of state-of-the-art pseudopotential and linear augmented plane wave methods. The Car–Parrinello technique was used here to optimize the trial structures without imposing symmetry or other constraints.

In the present study we used augmented plane waves up to a kinetic energy of 25 Ry (1 Ry = 13.605804 eV). An increase to 35 Ry provided the same results. Our calculations are based on supercells for which the product of the number of atoms and the number of reciprocal lattice points k (N (atoms) × N(k-points)) is between 92 and 136. Table 1 contains selected calculated energies for the zeolite-derived carbon modifications.

Table 1. Hypothetical carbon modifications. The columns contain the designation, the structure type, the energy difference ΔE [eV] in cohesive energy per atom relative to diamond, and the LDA band gaps E_G [eV].

Modification	Structure type	ΔE	E_G
C_{DIA}	diamond	0.00	4.21
C_{MTN}	zeolite ZSM-39	0.07	3.26
C_{MEP}	melanophlogite	0.09	3.96
C_{BIK}	bikitaite	0.21	3.14
C_{MTT}	zeolite ZSM-23	0.27	3.68
C_{TON}	zeolite Theta-1	0.34	3.28
C_{FER}	ferrierite	0.49	2.50

The energy–volume dependence is shown in Figure 1. All but one of the structures investigated are energetically favored over C_{60}, which according to LDA calculations[6] and experiment[14] is higher in energy than diamond by 0.42 eV and 0.38 eV per atom, respectively. C_{MEP} and C_{MTN} have the

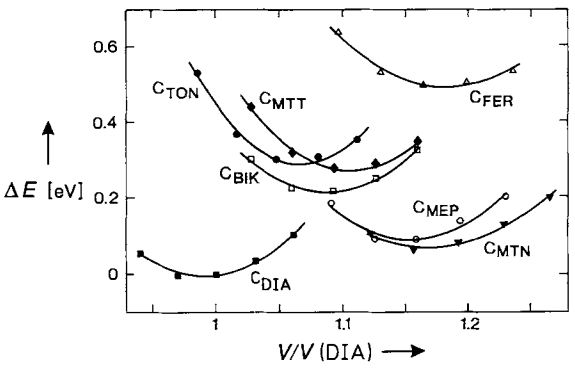

Fig. 1. Energy–volume diagram of hypothetical carbon modifications. Energy differences and volumes are given per C atom and scaled relative to diamond. V (DIA) refers to the experimentally determined volume of diamond.

lowest energies ever calculated for any hypothetical carbon modifications.[3–7] In the following discussion we will concentrate on these two compounds.

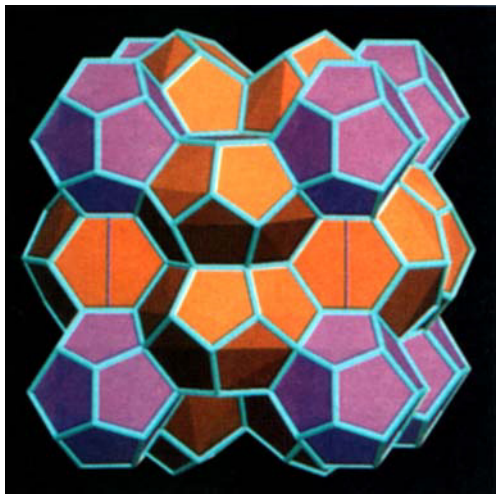

Fig. 2. Structure of C_{MEP}, which correspouds to the clathrate I structure (purple: C_{20} pentagonal dodecahedra, orange: C_{24} cages.)

C_{MEP} and C_{MTN} correspond to the well-known clathrate I and clathrate II structures, respectively (Figs. 2 and 3), which are found in a number of isoelectronic compounds like $[As_8Ge_{38}]I_8$,[15] $[Ge_{46-x}I_x]I_8$ with $x = 8/3$,[16] and $Na_x[Si_{136}]$ with $x = 3-11$.[17][*] Both structures are space-

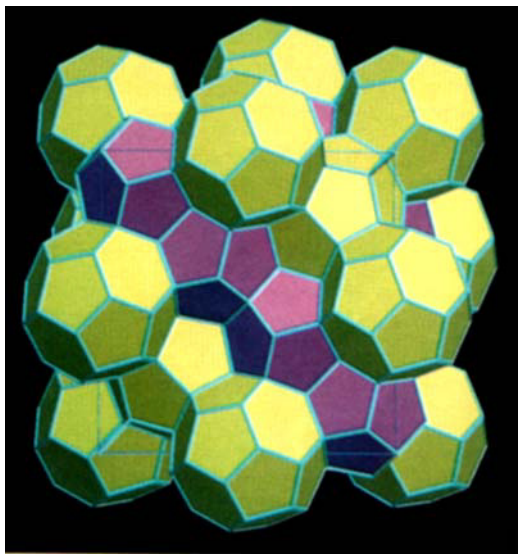

Fig. 3. Structure of C_{MTN}, which corresponds to the clathrate II structure. The large C_{28} cages (yellow) form a superdiamond framework, the pentagonal dodecahedra C_{20} (purple) a supertetrahedron.

filling arrangements of face-sharing fullerene-like cages with twelve pentagons and zero, two, or four hexagons. It is interesting that the structural patterns in C_{MEP} and C_{MTN} are similar to those in the fullerenes despite the grossly different bonding (sp^3 vs. sp^2 hybridization). In these polymeric allotropes the minimal difference between the bond angle in a

[*] Framework atoms in brackets; the counterions I^- and Na^+ occupy the voids.

five-membered ring (108°) and in an ideal tetrahedron (109.47°) accounts for the stability. An ideal structure composed of sp^3 C atoms would therefore contain solely face-sharing pentagonal dodecahedra. However, as it is impossible to build an infinite structure from pentagonal dodecahedra alone, six-membered rings are required even though they introduce greater ring strain. With this general building principle, namely face-sharing fullerene-like cages, it is possible to construct a large class of polymorphic solids that are expected to be similar in energy to the ones we have studied. Recently Guo et al. proposed structures for transition metal carbide clusters forming face-sharing pentagonal dodecahedra.[18] The structures of C_{MEP} and C_{MTN} can be considered extensions of these clusters to bulk structures (cf. Figs. 2,3).

C_{MTN} and C_{MEP} exhibit large band gaps that are even 6 and 23% smaller than that of diamond. (These numbers should be taken with a grain of salt as the LDA does not in principle allow the prediction of excitation energies. Trends, however, are usually well reproduced.) These hypothetical carbon modifications have a number of interesting characteristics. The large cages might accommodate interstitial dopant atoms providing a means to engineer their electronic and optical properties. The nearest-neighbor distances for the interstitial sites within the various fullerene-like cages are 207 and 255 pm for C_{MTN} and 215 and 223 pm for C_{MEP}, compared to 153 pm in diamond. The first value always refers to the nearest-neighbor distance in pentagonal dodecahedron. The average volume per atom is increased by about 15% over diamond but considerably less than in graphite (153%) and in solid C_{60} (205%).

We expect C_{MTN} and C_{MEP} to exhibit high mechanical stability once they are formed, as a result of their low energy difference compared to C_{DIA}, the large energy required to break a C–C bond, and the three-dimensional linkage of the network C atoms.

Currently we are investigating whether the new structures can be identified in the products formed by the Krätschmer process. High-pressure experiments on C_{60} are being performed as well.[19] An alternate synthetic route would the epitaxial growth of these solids on, for example, the carbide clusters of Guo et al.[18]

Self-Assembly, Structure, and Spontaneous Resolution of a Trinuclear Triple Helix from an Oligobipyridine Ligand and Ni^{II} Ions**

By *Roland Krämer, Jean-Marie Lehn,* André De Cian*, and *Jean Fischer*

Double-helical metal complexes, termed helicates, have been shown to form by the spontaneous assembly of oligo-2,2′-bipyridine (bpy) strands and metal ions that favor tetrahedral coordination geometry, such as Cu^{I} and Ag^{I}.[1–3] Complexes containing from two to five metal centers, that is, di- to pentahelicate species, have been obtained thus.[1–4]

Helicate formation is a self-organization process[5] displaying positive cooperativity.[6] It results from the tetrahedral coordination imposed by each $Cu(bpy)_2^+$ site and from the design of the ligands. These two features constitute, respectively, the recognition event and the molecular steric "instruction" that lead to the preferential generation of double-helical structures. In the general context of programmed supramolecular systems,[1] helicate formation may be described as the result of the reading by metal ions of the molecular information stored in the oligo(bpy)strands following a tetrahedral coordination algorithm.[5, 7]

A number of double helical complexes involving other ligand molecules and presenting two metal centers have been reported.[8–13] When the ligand contains two[14–17] or three[17] terpyridine units, double-helical complexes with two or three octahedral metal centers, respectively, may be obtained.

The steric information contained in the oligo(bpy)strands yielding double helicates resides in the disposition of the nitrogen sites and in the 6,6′-disubstitution of the bpy units.[1–7] The latter hinders the binding of metal ions that prefer octahedral coordination geometry, which would be expected to yield triple helicates. This might, however, become possible through a slight modification of the steric instruction by shifting from a 6,6′- to a 5,5′-disubstitution. We now report that the trinuclear triple-helical complex **1** is indeed formed spontaneously by self-assembly from three 5,5′-disubstituted tris(bpy) strands **5** and three Ni^{II} ions.

A triply bridged dinuclear Fe^{II} complex of a bis(bpy) ligand[18] and probably also a related bis(Fe^{II}) complex possess triple-helical features.[12] A triple-helical arrangement has been assigned to dinuclear Fe^{III} complexes of tripodal ligands on the basis of NMR and circular dichroism (CD) data.[19]

Recently, the self-assembly and the triple-helical structure of a dinuclear Co^{II}[13, 20] complex has been described. The present species **1** represents the first triple helicate containing three metal centers.

The tris(bpy) strand **5**[21] was easily accessible in 71% yield by the reaction of monolithiated 5,5′-dimethylbipyridine **3** (obtained by treating **2**[22] with BuLi in THF) with 5,5′-bis(bromomethyl)bipyridine **4**.[23] Reaction of **5** with $NiSO_4$ gave a pink complex, which was isolated as the perchlorate salt $[(\mathbf{5})_3Ni_3](ClO_4)_6$, whose composition was determined by FAB^+ mass spectroscopy and microanalysis. Its UV/VIS spectrum exhibited absorptions at wavelengths similar to those of $[Ni(5,5'\text{-dimethylbipyridine})_3]^{2+}$, but the extinction coefficients were about three times larger.[24] The proton NMR spectrum of the helicate showed very broad signals between $\delta = 5$ and $\delta = 160$, consistent with that of the mononuclear Ni^{II} complex mentioned above.[25]

The structure of $\mathbf{1}(ClO_4)_6$ was determined by X-ray crystallography (Fig. 1).[26] It consists of $[(\mathbf{5})_3Ni_3]^{6+}$ ions in which three strands of ligand **5** are wrapped around each other and held together by three Ni^{II} ions forming a trinuclear triple-helical complex, a trihelicate $^3\mathscr{H}$, as represented schematically by **1**.

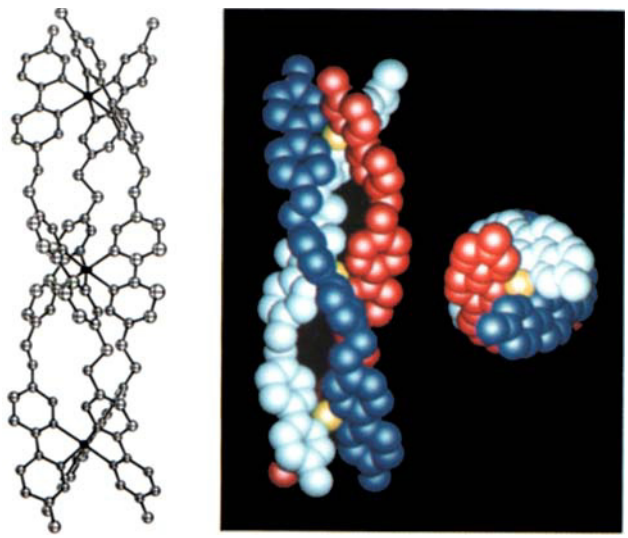

Fig. 1. ORTEP representation of the crystal structure of the self-assembled trinuclear triple helical Ni^{II} complex **1** (left); CPK representations along and perpendicular to the axis of the three metal ions (right).

The helical features of the triple helicate **1** are defined by several parameters. The angle of twist, that is, the angle of rotation of the helix, between two successive Ni centers is about 75° and approximately 149° between the first and third Ni center. This means that a full turn of the helix would involve 5.8 metal centers. Since the Ni ··· Ni distance is 8.6 Å, the helical pitch (length per turn) is about 41 Å. The solid-state structure is, however, not a regular triple helix of D_3 symmetry. It has a C_2 axis perpendicular to the NiNiNi axis and passing through the middle of central C–C bond of the central bpy of one strand; the other two strands are interconverted by this axis. The radius of the circumscribed cylinder measures approximately 5.3 Å. The total length of the triple helix is about 28 Å (distance between the carbon atoms of the terminal CH_3 groups). The C-CH_2-CH_2-C dihedral angle of 158° is much closer to the *trans* than to the *gauche* form. The triple helix **1** is therefore rather elongated, displaying a looser twist than the double helix of nucleic acids and even more so than the cuprohelicates (pitch about 30–35 Å[27] and 12 Å, respectively).[1] In view of this extended structure there is no significant stacking overlap between the bpy groups of two successive Ni centers. One may note that triple helical species are also found in proteins such as collagen,[28] in nucleic acids,[27] and in supramolecular liquid crystals.[29]

The three Ni centers of **1** are so aligned that the structure is linear, whereas the cuprotrihelicate showed a slight bend.[1] The Ni^{II} ions present octahedral coordination with Ni–N distances of 2.04–2.12 Å.

The unit cell contains two complexes **1** and twelve perchlorate counterions. Each species **1** is located in a special position of the space group $C2$. The helices are parallel to each other with their axes perpendicular to the a,b plane of the unit cell. They are arranged in layers in which each helix **1** is

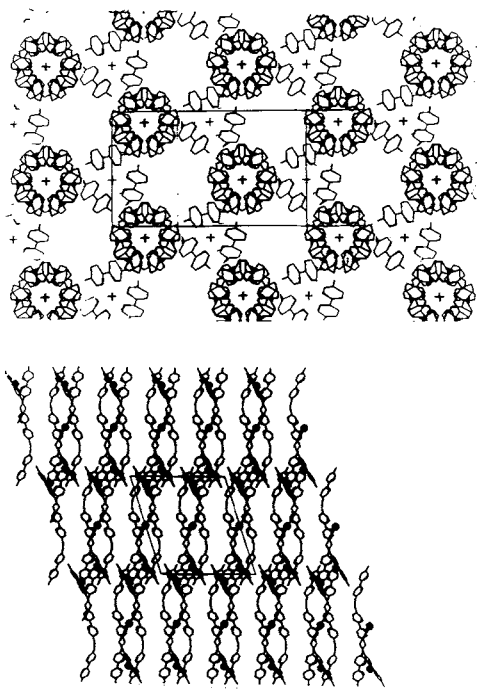

Fig. 2. Hexagonal packing of triple helical species **1** viewed along the axis of the helices with the a and b axes respectively horizontal and vertical in the plane of the figure (top); view of the packing in a plane perpendicular to the top view, showing the layers of helices **1** and the channels present in the structure (bottom).

located at the center of a hexagon of six surrounding helices; the distance between neighboring axes is 13.5 Å (Fig. 2). The layers of helices are stacked along the *c* axis and are shifted along the *a* axis; the projection of the fourth layer perpendicular to the *a*, *b* plane coincides with the first layer. This arrangement creates channels parallel to the *c* axis of the unit cell and tilted by about 19° with respect to the axis of the helices. These channels contain the anions which are partly disordered.[26]

The *C*2 space group of the crystals indicated that they were chiral, which suggested that they contained only one of the two triple-helical enantiomers, either right-handed or left-handed. Several single crystals were selected, and their solutions were subjected to circular dichroism measurements. They showed optical activity, displaying circular dichroism curves of the two opposite types (Fig. 3). Thus, crystallization of the trihelicate **1** $(ClO_4)_6$ occurs with spontaneous resolution, a remarkable feature not presented by the cuprohelicates,[1, 2] where helicity induction has been attained by introducing chiral centers into the oligo(bpy) strand.[30]

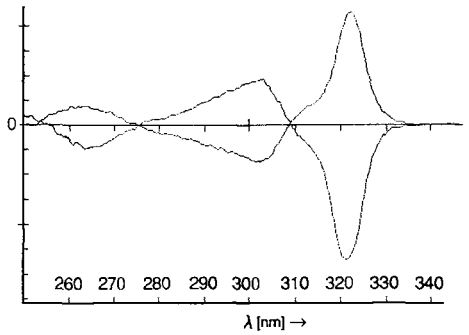

Fig. 3. Circular dichroism curves measured for individual single crystals of **1**$(ClO_4)_6$ in acetonitrile/water (9/1) at room temperature; positive and negative curves of different amplitudes were obtained for different crystal; the ordinates are proportional to molecular ellipsicities; in the present case the curve with negative Cotton effect was recorded for a solution that was 4.5 times more concentrated than that giving a positive Cotton effect.

However, when a number of crystals of **1**$(ClO_4)_6$ were examined, the circular dichroism $\Delta\varepsilon_{323}$ values were not constant but varied from -178 to $+659\ M^{-1}cm^{-1}$. A few presented no optical activity.[31a] A value $\Delta\varepsilon_{308} = -406.6$ has been reported for the $[Ni(bpy)_3](ClO_4)_2 \cdot 2H_2O$ complex.[31b] These variations in $\Delta\varepsilon$ were not due to racemization in solution, since the maximal loss of optical activity of **1**$(ClO_4)_6$ was 23% in 24 hours. Thus, **1** is much more stable against racemization than optically active $[Ni(bpy)_3]^{2+}$.[32] Therefore, the spontaneous resolution was only partial, and apparently each crystal contained different amounts of species of left- and right-handed helicity. This behavior may be attributed to microtwinning of the chiral crystals, each being composed of domains of opposite helicity.[33] Experiments are underway to determine the optical purity of these crystals and the optical properties of the pure enantiomers.

The present results demonstrate the spontaneous formation of a trinuclear triple helix by self-assembly from three ligand molecules and three metal ions. They also represent a successful application of molecular programming[5–7] to the spontaneous but directed generation of desired supramolecular architectures.

In the self-assembly of helicates, three main features that bear structural information determining the nature and shape of the helical species formed may be distinguished: 1) the precise structure of the *binding site*; it determines in particular the ability to coordinate metal ions with a given geometry the number of strands bound; 2) the *spacer* separating the binding sites; as pointed out earlier[1] it must favor interstrand over intrastrand binding, and it influences the tightness of the helix (its pitch) through the rotation of one metal center with respect to the next one; 3) most importantly the *configuration of the coordination centers* determines whether the structure is indeed of helical nature; helicity implies that all metal centers have the same screw sense (see also ref. [30]). As a corollary, helicity induction requires the introduction of elements of asymmetry.[30]

The programme containing these information features is molecular and linear; its operation is supramolecular and takes place through the reading of the information according to the coordination algorithm of the metal ion. More generally, self-assembly may involve interactions other than metal ion coordination, such as hydrogen bonding, stacking, or donor–acceptor effects as found in proteins,[28] nucleic acids,[27] liquid crystals,[29] and molecular complexes.[36]

Further developments involve the investigation of variations in ligand structure on the features of double and triple helicates, the determination of their physico-chemical (thermodynamic, kinetic, electrochemical, photochemical) properties, the exploration of the coordination chemistry of the ligand strands (for instance with cubic metal ions). Beyond these systems lies the investigation of processes involving several ligands and metal ions, that is, multicomponent self-assembly.[37]

Experimental Procedure

5: Lithium diisopropylamide was prepared by addition of butyllithium (7.2 mmol, 1.6 M solution in hexane) to diisopropylamine (1.05 mL, 7.43 mmol) in dry THF (20 mL) under argon at -78 °C. This solution was added slowly by canula to 5,5′-dimethyl-2,2′-bipyridine (**2**)[22] (1.33 g, 7.22 mmol) in dry THF (20 mL) at -78 °C. The dark reddish brown reaction mixture was allowed to reach 0 °C. 5,5′-Bis(bromomethyl)-2,2′-bipyridine (**4**)[23] (408 mg, 1.18 mmol) in THF (30 mL) was added dropwise with stirring within about 40 minutes. Stirring at 0 °C was continued for 30 min, and then water (20 mL) was added to quench the reaction. THF was removed in vacuum, and the yellow precipitate filtered off, suspended in MeOH (50 mL), and filtered off again. The remaining solid was recrystallized from chloroform/methanol. The white, microcrystalline powder was vacuum-dried (50 °C, 3 h). Yield 470 mg (71%). M.p. 275–278 °C. FAB$^+$: *m/z* 549.2 $[M + H^+]^+$. ^{1}H NMR ($CDCl_3$): $\delta = 8.6$–8.3 (m, 12H; bpy-H), 7.8–7.6 (m, 6H; bpy-H), 3.06 (s, 8H; CH_2), 2.43 (s, 6H; CH_3). Correct C, H, N analysis.

$[(\mathbf{5})_3Ni_3](ClO_4)_6$, **1**$(ClO_4)_6$: **5** (60.0 mg, 0.109 mmol) was suspended in 80 mL of an ethanol/water mixture /1/1) and heated under reflux. The ligand was partially dissolved by addition of 0.5 M H_2SO_4 (0.40 mL). After 15 minutes stirring, $NiSO_4 \cdot 6H_2O$ (28.7 mg, 0.109 mmol) in 3 mL water was added dropwise. At the end of the addition, a clear, almost colorless solution was obtained. Heating at reflux was continued for 15 h. Some drops of a saturated $LiClO_4$ solution were added to the hot reaction solution, which was then kept at 5 °C for several hours. The pink precipitate was filtered off, washed with water, and redissolved in acetonitrile (40 mL). Water (24 mL) was added, and the pink solution was allowed to stand in an open beaker. After several days, a gel had formed that contained pink crystals. Water (30 mL) was added with shaking and the liquid was decanted from the crystals. These were successively washed with water, ethanol, and ether, and air dried. Yield 36 mg (38%). FAB$^+$: *m/z* 2317.2 $[M - ClO_4^-]^+$, 2218.4 $[M - 2ClO_4^- + e^-]^+$, 2120.4 $[M - 3\ ClO_4^- + 2e^-]^+$. UV/VIS: λ_{max} [nm] (ε) 258 (113000), 308 (152000), 320 (164000), 525 (53). Correct C, H, N analysis for **1** $(ClO_4)_6 \cdot 12H_2O$.

[26] (a) X-ray structure analysis of **1** $(ClO_4)_6$ ($C_{108}H_{96}N_{18}O_{24}Cl_6Ni_3$), M_r = 2418.9; pink crystals ($0.30 \times 0.25 \times 0.20$ mm^3). The first cell determined was trigonal with a = 24.594 Å, α = 31.90°; a careful check of intensities related by the C_3 axis showed a very high discrepancy (>25%) for a number of strong and medium reflections, therefore **1** $(ClO_4)_6$ was assumed to be monoclinic, space group $C2$ with a = 23.418(4), b = 13.518(3), c = 24.598(4) Å, β = 108.52(2)°, V = 7383.8 Å^3, Z = 2, ϱ_{calcd} = 1.088, $F(000)$ = 2496, μ = 5.471 cm^{-1}. Most of the crystals (obtained by slow evaporation of acetonitrile/water solutions) exhibited cracks either in the mother liquor or within a few minutes in air. One crystal free of cracks was selected and mounted on a rotation free goniometer head. In the attempt to find an orientation matrix and to collect data on an Enraf–Nonius diffractometer (graphite monochromator, $Mo_{K\alpha}$ radiation, λ = 0.70930 Å) at −100 °C, the crystal showed no diffraction power after 12 hours and exhibited cracks. Therefore, data were collected at room temperature ($\theta/2\theta$ scans, $4 < 2\theta < 60°$). Three standard intensities showed a decay of 34% during data collection and were corrected with a linear time-dependent function. Semiempirical absorption corrections based on ψ curves of four reflections were applied. At this stage, data was analyzed for the presumed presence of a C_3 axis; data were transformed by assuming a trigonal cell, and intensities were averaged. The overall $R_{int}(I)$ factor was 0.24, by far higher then normally expected, and therefore the monoclinic system was retained. The systematic absences hkl ($h + k = 2n + 1$) together with E statistics and Nz test suggested space group $C2$ or Cm. With Z = 2, the cation **1** must lie on a special position of the space group; the only possibility is a twofold axis; therefore the true space group is $C2$. The structure was solved by a combination of Patterson, difference Fourier, and full least-squares methods with the Enraf–Nonius Molen/Vax package [26b] (F refinements, $w = 1/\sigma^2, \sigma^2(F^2) = \sigma^2_{counts} + (pI)^2, p$ = 0.08). One anion is well resolved; for the second, only the chlorine atom was found, and the third could not be located (this ClO_4^- anion is probably disordered in the channels of the structure). An attempt was made to determine the absolute configuration by comparing xyz and $-x-y-z$ refinements, but the differences are very small and gave no clear answer. Microtwinning [35] or lamellar twinning [36] are not excluded. $R(F)$ = 0.105, $Rw(F)$ = 0.134 for 2721 reflections having $I > 3\sigma(I)$ and 599 variables. Maximum residual electron density = 0.8 eÅ^{-3}. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Center, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation. Crystals of **1** $(PF_6)_6[Ni(N_6C_{36}H_{32})_3]^{6+} \cdot 6PF_6^-$ were also analyzed by using CuKα graphite monochromated radiation on a Philips PW 1100/16 machine at room temperature. This complex is isostructural with **1** $(ClO_4)_6$, a = 23.454(4), b = 13.535(3), c = 24.619(4) Å, β = 108.45(2)°. The number of usable data was too low, and the results were worse than those for **1** $(ClO_4)_6$. b) B. A. Frenz "The Enraf-Nonius CAD4-SDP" in *Computing in Crystallography* (Eds.: H. Schenk, R. Formation of Interwoven 2-D Networks by the Spontaneous Strict Self-Assembly of $[\{M(CO)_3(\mu_3\text{-}OH)\}_4]$ (M = Mn, Re) and Complementary Angular Spacer Molecules**

By *Steven B. Copp, S. Subramanian,* and *Michael J. Zaworotko**

Predictable self-assembly of supramolecular species by directed covalent or noncovalent bonding is one of the great challenges and opportunities that faces modern chemistry.[1] Nature, with very limited tools, is replete with simple yet elegant examples of self-assembly. Synthetic chemistry, however, has thus far only offered tantalizing suggestions that the limits of synthesis, given the diverse range of tools at our disposal, are perhaps set only by imagination. In this context, symmetry and functionality at the molecular level are not only exploitable but critically important facets of self-assembly.[1, 2] Diamond, ice, and KH_2PO_4 are three well-known[3] examples of how the shape and inherent ability of a moiety to self-assemble can influence the three-dimensional (3-D) solid-state structure; in ice and KH_2PO_4 this is a consequence of noncovalent bonding. It is therefore perhaps surprising that it has only recently been realized that appropriately tetrafunctionalized organic molecules with S_4 symmetry can also self-assemble[4, 5] and generate aesthetically pleasing superdiamondoid 3-D networks, sometimes with open architecture.[4c, d, 5] An alternate and potentially more versatile approach to the construction of 3-D supramolecular architecture is the cocrystallization of complementary molecular components, in other words a "strict self-assembly".[6] This approach has already been demonstrated for 1-D and 2-D structures,[7–9] and we recently extended it to superdiamondoid networks by employing $[\{M(CO)_3(\mu_3\text{-}OH)\}_4]$ (**1**,

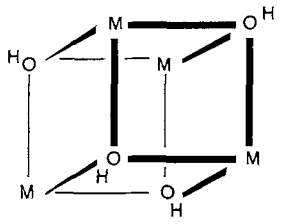
[**] Manifestations of Noncovalent Bonding in the Solid State, Part 4. This work was supported by the NSERC, Canada. Part 3: S. Subramanian, M. J. Zaworotko, *Can. J. Chem.*, in press.



1: M = $Mn(CO)_3$; **2**: M = $Re(CO)_3$

M = Mn[10]; **2** M = Re[11]), cubanelike molecules with T_d or close to T_d symmetry and four rigid hydrogen-bond donors (Fig. 1), and linear difunctional hydrogen-bond acceptor molecules.[12] We explored the generality and versatility of strict self-assembly based upon T_d molecules by exploiting nonlinear spacer groups with **1** and **2** in order to generate 2-D hydrogen-bonded networks of varying but predictable levels of interpenetration and openness.

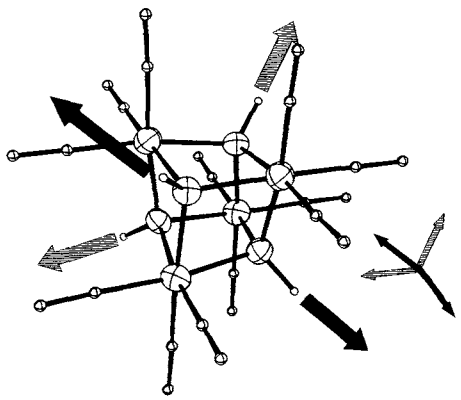


Fig. 1. Perspective view (ORTEP) of a molecule of **1** or **2**. The μ_3-OH groups are oriented (large arrows) towards the vertices of a tetrahedron.

Complex **1** cocrystallizes from acetonitrile with excess 1,3-diaminopropane[13] (DAP) or hexamethylenetetrammine[14] (HMTA) to afford the 2-D "chicken-wire" networks $(\mathbf{1} \cdot 2\,DAP)_n$ and $(\mathbf{1} \cdot 1.5\,HMTA)_n$, respectively. The structure of $(\mathbf{1} \cdot 2\,DAP)_n$ shown in Figure 2 reveals how two independent DAP molecules bridge adjacent molecules of **1** through OH···N hydrogen bonds (O···N separations range from 2.702(7) to 2.782(9)Å). The DAP molecules adopt W conformations and facilitate separations of 10.26 and 11.73 Å between the cubes. The different separations reflect the orientations of the nitrogen lone pairs within the DAP molecules. The space within the network is large enough to hold one ordered acetonitrile molecule per molecule of **1**. The structure of $(\mathbf{1} \cdot 1.5\,HMTA)$ is dramatically different. Since HMTA should be capable of acting as a tetrafunctional H-bond acceptor, a diamondoid network is anticipated when it is cocrystallized with **1** in a 1:1 ratio. However, the solid obtained from the 1:1 cocrystallization has 1.5 molecules of HMTA per molecule of **1**, presumably because HMTA is too small to simultaneously accomodate four molecules of **1**. Two types of HMTA molecules are found in the structure, both of which engage in only two hydrogen bonds: two-thirds of the molecules (i and ii, Fig. 3) are in the tetrameric species $(\mathbf{1} \cdot HMTA)_4$ with N···O distances of 2.863(14) and 2.773(12)Å, respectively; the remainder (iii, Fig. 3) bridge adjacent tetramers (N···O 2.931(13)Å) to form a sheet of 2-D "chicken wire" in the *ab* plane with large cavities. Two

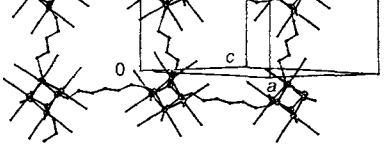

Fig. 2. Perspective view of the "chicken-wire" solid-state structure adopted by $\mathbf{1} \cdot 2\,DAP$. Carbonyl ligands and CH_2 hydrogen atoms are omitted for clarity in this and subsequent figures.

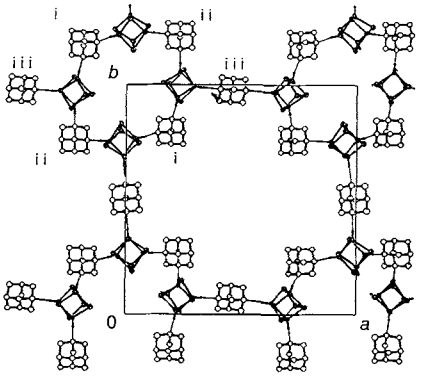

Fig. 3. View onto the *ab* plane in $\mathbf{1} \cdot 1.5\,HMTA$ showing the "chicken-wire" network of the tetrameric units. Crystallographic twofold axes pass through the HMTA molecules.

disordered acetonitrile molecules lie within the tetramer, which, as evident from Figure 4, is thus a type of cavitand. The open spaces in the network are filled by adjacent sheets.

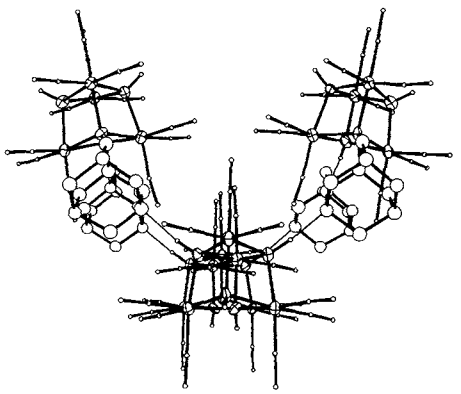

Fig. 4. Perspective view of $[\mathbf{1} \cdot HMTA]_4$. Two disordered solvent molecules are located inside the cavity of the tetramer.

Cocrystallization of **2** with two equivalents of 4,4'-dipyridine (dipy) from methanol/CH_3CN affords colorless crystals of the three-component network $(\mathbf{2} \cdot 2\,dipy \cdot 2\,MeOH)_n$.[15] The methanol molecules are integral components of the resulting hydrogen-bonded network and profoundly influence its structure by acting as angular bridges between molecules

of dipy and **2** (MeOH $\cdots$ dipy, O $\cdots$ N = 2.714(13)Å; μ_3-OH $\cdots$ O(H)Me, O $\cdots$ O = 2.560(10)Å). A 3-D structure is thereby precluded but hydrogen bonding between **2** and the other end of each dipy molecule (μ_3OH $\cdots$ dipy, O $\cdots$ N = 2.606(11)Å) sustains an open 2-D network with large intercube separations of 15.75Å (Fig. 5). The resulting cavities

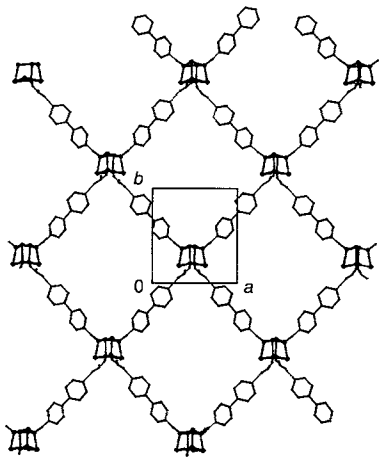

Fig. 5. Perspective view (ORTEP) of one of the two independent 2-D networks of **2** · 2 dipy · MeOH. Alternate cells are occupied in the crystallographic *ab* plane.

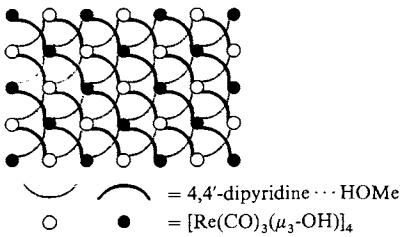
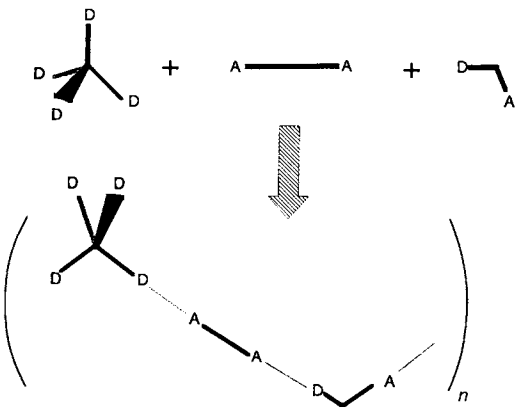
are filled by self-inclusion of a second identical but independent network, affording what is to our knowledge a novel[16] doubly interwoven carpetlike structure (Scheme 1).



Scheme 1. Schematic representation of the interwoven structure of **2** · 2 dipy · 2 MeOH.

In summary, strict self-assembly of **1** or **2** and complementary multifunctional hydrogen-bond acceptor or acceptor/donor molecules leads to aesthetically pleasing supramolecular 2-D or 3-D compounds that are manifestations of directed noncovalent bonding and are therefore predictable,[17] controllable, and readily crystallized. The key to predictability in such networks appears to be quite simple: restrict the geometry and number of strong H-bond donor/acceptor moieties present in each component. The salient feature here is that in principle the concepts are general and should apply to a diverse range of structurally similar (Scheme 2)[17] or even dissimilar[18] components.



Scheme 2. Schematic representation of the general approach to construction of 2-D networks from three complementary molecular components. D = Hydrogen-bond donor; A = hydrogen-bond acceptor.

[12] **1** and **2** cocrystallize with two equivalents of a wide range of linear difunctional hydrogen-bond acceptors to generate diamondoid networks. For example, 1,4-diaminobenzene, 1,2-diaminoethane, and 4,4'-dipyridyl generate two-, three- and fourfold interpenetrated diamondoid networks, respectively: a) S. B. Copp, S. Subramanian, M. J. Zaworotko, *J. Am. Chem. Soc.* **1992**, *114*, 8719. b) S. B. Copp, S. Subramanian, M. J. Zaworotko, unpublished results.
[13] a) Crystals were grown from hot acetonitrile, decompose at ca. 200 °C, and are insoluble in aprotic organic solvents under ambient conditions. IR (KBr)[cm^{-1}]: ν_{OH} = 2859(s); ν_{CO} = 2013(s), 1904(s). Space group $P2_1/n$ (No. 14, nonstandard), a = 17.2454(16), b = 10.2592(8), c = 19.7952(20)Å, β = 101.384(12)°, V = 3343.3(5)Å^3; ρ_{calcd} = 1.57 gcm^{-3} for Z = 4; 2178 (out of 3205) observed ($I > 3\sigma I$, 2θ 2–40°) reflections afforded R = 0.038, R_w = 0.041. OH, CH_3, and one set of NH_2 hydrogen atoms were located by inspection of the difference Fourier map and fixed. CH_2 hydrogen atoms were fixed in calculated positions (d_{C-H} = 1.08 Å); one set of NH_2 hydrogen atoms could not be located. Intramolecular distances and angles were observed to be within expected ranges. b) Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographie Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.
[14] Crystals were grown from hot chloroform, decompose at ca. 150 °C, and are insoluble in aprotic organic solvents. IR (KBr) [cm^{-1}]: ν_{OH} = 3314(s), 2964(s); ν_{CO} = 2019(s), 1929(s). Space group $P4_22_12$ (No. 94), a = 21.4558(18), c = 15.5713(23), V = 7168.3(12)Å^3; ρ_{calcd} = 1.67 g cm^{-3}; 2133 (out of 3001) observed ($I > 3\sigma I$, 2θ 2–40°)) refelctions afforded R = 0.043, R_w = 0.040. Hydrogen atoms were calculated (OH, CH_2) and fixed during least-squares refinement. The enantiomorph was fixed by using Friedel equivalents and the Rogers method. The solvent molecules were observed to be disordered. Refinement of all solvent atoms as carbon with site occupancy as a variable gave two molecules of solvation. All intramolecular distances and angles were observed to be within expected ranges. See also ref. [13b].
[15] Crystals are insoluble in aprotic organic solvents, even hot acetonitrile, become opaque at ca. 150 °C, but show no other signs of decomposition

below 250 °C. IR (KBr)[cm^{-1}]: ν_{OH} = 2744(s); ν_{CO} = 2011(s), 1915(s). Space group $P2/c$ (No. 13), a = 10.5407(10), b = 11.6973(10), c = 17.868(3)Å, β = 94.37(4)°, V = 2196.7(4)Å^3; ρ_{calcd} = 2.31 gcm^{-3} for Z = 2; 2876 (out of 3873) observed ($I > 3\sigma I$) reflections afforded R = 0.033, R_w = 0.038. Hydrogen atoms were calculated (CH) or located by inspection of the difference Fourier map and fixed during least-squares refinement. All intramolecular distances and angles were observed to be within expected ranges. In the absence of MeOH a fourfold superdiamondoid network that enclathrates two molecules of acetonitrile per molecule of **1** or **2** is obtained (see ref. [12]). See also ref. [13b].

[16] Four independent, folded, nonplanar, interpenetrating networks as a consequence of self-assembly were observed in benzene-1,3,5-tricarboxylic acid: a) D. J. Duchamp, R. E. Marsh, *Acta Crystallogr. Sect. B* **1969**, *25*, 5; b) F. H. Herbstein, *Top. Curr. Chem.*, **1987**, *140*, 107.

[17] Whereas the structure of **1** · 1.5 HMTA is the result of serendipity and is unlikely to be general, the molecular "chicken-wire" type structure observed for **1** · 2 DAP is reproducible (**1** · 2 diacetone alcohol) and molecular "carpet" structures with the same dimensions as **2** · 2 dipy · 2 MeOH can be obtained with *n*-BuOH and *i*-PrOH. M. J. Zaworotko, S. B. Copp, S. Subramanian, unpublished results.

[18] As noted by a referee the networks reported herein are not the only hydrogen-bonded networks that can be generated from organometallic molecules that are multifunctional hydrogen-bond donors. For example, $[(Me_3Sn)_4Fe(CN)_6] \cdot 2H_2O$ forms infinite networks when its bound water molecules form hydrogen bonds to bridging water (U. Behrens, A. K. Brimah, R. D. Fischer, *J. Organomet. Chem.*, **1991**, *411*, 325) or dioxane (M. Adam, A. K. Brimah, R. D. Fischer, L. Xing-Fu, *Inorg. Chem.*, **1990**, *29*, 1597) molecules. The hydrogen-bonded chains are crosslinked by covalent Lewis acid–base interactions.

Ca_3AuN: A Calcium Auride Subnitride**

By *Jürgen Jäger, Dagmar Stahl, Peter C. Schmidt,* and *Rüdiger Kniep**

Dedicated to Professor Dietrich Mootz on the occasion of his 60th birthday

Recently with $NaBa_3N$[1] a new subnitride was presented that crystallizes in the hexagonal Perowskite structure (like for example, $CsNiCl_3$[2]) and that is characterized by "spatial separation" of ionic and metallic bonding components. By drawing on the crystal chemistry of the alkali metal suboxides[3] under consideration of the electronegativities of nitrogen, barium, and sodium, the bonding in $NaBa_3N$ is described as follows:[1] $Na^+Ba_3^{2+}N^{3-} \cdot 4e^-$; results of band structure calculation are in accord with these concepts.

In the course of our investigations into ternary and quaternary nitrides with elements of the 11 th group of the periodic system, we have now prepared the compound Ca_3AuN. The product, which according to X-ray powder studies contains one phase (blue-violet crystals of cubic habit with a metallic luster), was obtained as follows: calcium (shot) and gold (wire) were placed in the molar ratio 3:1 in a corundum crucible and heated at a rate of 200 K h^{-1} to 950 °C in a quartz reaction tube under argon, exposed at this temperature to a stream of nitrogen (1 atm) for 24 h, and finally cooled to room temperature at 6 K h^{-1}. In the Ca–Ag–N system an intermediate phase with a brassy luster was obtained in this way;[4] the ductility and perfect cleavability of the layered crystals have as yet prevented a structure determination. The nitridocuprates known today[5] are all shiny black crystals, thin layers of which appear red and transparent.

Ca_3AuN[6] crystallizes in the cubic perowskite structure (Fig. 1). This structural type also occurs in the ternary nitrides Ca_3XN (X = P, As, Sb, Bi, Ge, Sn, Pb),[7] which in agreement with the results of band structure calculations,[8] have the ionic formula $Ca_3^{2+}X^{3-}N^{3-}$. Nitrogen in these compounds is surrounded by an octahedron of calcium atoms; the NCa_6 octahedra share corners and are linked into a three-dimensional framework $^3_\infty[NCa_{6/2}]$. In the crystal structure of Ca_3AuN, calcium and gold together form a cubic face-centered arrangement. The Ca–N bond lengths of 241.1 pm are approximately equal to those in α-Ca_3N_2 (245.1(2)–248.2(2) pm[9]). The Ca–Ca distances (340.9 pm) are shorter than in the metal (394 pm[11]), while the Ca–Au distances (340.9 pm) correspond to the sum of the radii of Ca and Au in the metals (341 pm[11]).

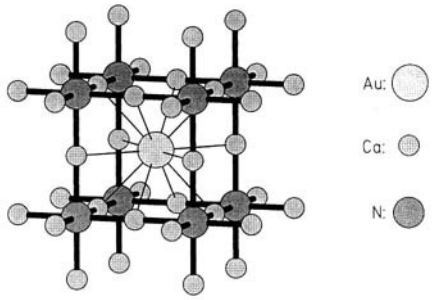

Fig. 1. Section of the crystal structure of Ca_3AuN.

Since the electronegativities[12] of gold (2.54) and nitrogen (3.04) are larger than that of calcium (1.0), the following simple model of the chemical bond in Ca_3AuN can be deduced: $Ca_3^{2+}Au^-N^{3-} \cdot 2e^-$. This agrees with the concept of the chemical bond in $NaBa_3N$,[1] and results in an overall metallic character for Ca_3AuN. The picture was also verified by the results of the band structure calculations according to the ASW method (ASW = *a*ugmented *s*pherical *w*ave).[13] The quantum mechanical calculations in this investigation were not restricted to Ca_3AuN, but to provide suitable comparison, were extended to CsAu[15] (an ionic auride) and Al_2Au[16] (an intermetallic phase with metallic character). Ca_3AuN is shown to have energetically low-lying, filled N 2p and Au 6s and Au 5d bands, while the Fermi level lies in a broad band with Au 6p and Ca character. In Figure 2 the dependence of the charge densities for gold on the radius of

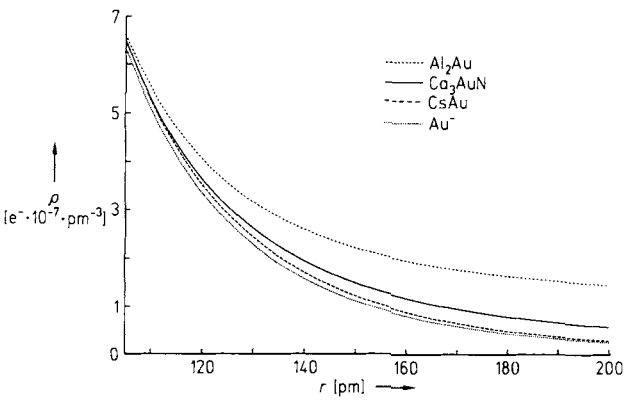

Fig. 2. Dependence of the charge densities at gold on the radius around its central position in the compounds Al_2Au, Ca_3AuN, and CsAu.

its central position is depicted for the compounds Al_2Au, Ca_3AuN, and CsAu. The spherically averaged charge density for Au in CsAu corresponds very well to that for a "free Au^-". In Al_2Au the electron density approaches a high value at large distances from the Au core, characteristic for metallic bonds. The curve for the electron density at gold in Ca_3AuN suggests the presence of an auride.

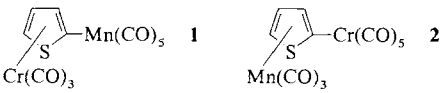
(η^1-tpMn, η^5-tpCr) → (η^1-tpCr, η^5-tpMn) Thiophene (tp) Conversion due to Bimetallic Activation: A Novel Metal-Exchange Reaction**

By *Thomas A. Waldbach, Petrus H. van Rooyen,* and *Simon Lotz**

Reactions of thiophenes (tp) in transition metals complexes are currently a topic of great interest. A variety of coordination modes of thiophene in mono-, bi-, and trimetallic complexes are known and were recently reviewed.[1] Much of the work in this field centers around studies on mechanisms that may be of importance in the hydrodesulfurization of petroleum[2] and in materials with optical or conducting properties.[3] Thiophene, activated by coordination to transition metals, is a very versatile reagent and undergoes many interesting reactions, such as the insertion of transition metals into the C–S bond,[4] dimerization,[5] intermolecular silyl transfer,[6] intramolecular interconversion of η^1-sulfur and η^2-olefin isomers of [Cp*(CO)$_2$Re(benzol[b]tp)],[7] and the remarkable reactions of the two isomeric forms of [Cp*Ir(2,5-Me$_2$tp)] with iron carbonyls[8] and acetylenes.[9] Here we extend this list of novel reactions and report a metal exchange, facilitated by a η^1:η^5-bridging tp ligand, in an activated heterobimetallic complex.

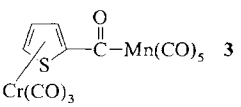
A solution of [(η^5-2-LiC$_4$H$_3$S)Cr(CO)$_3$],[10] prepared by treating *n*-BuLi (10% excess) in THF with [(η^5-tp)Cr(CO)$_3$][11] at −50 °C, was stirred with one equivalent of [Mn(CO)$_5$X] (X = Br, Cl) for 1 h at −90 °C and 0.5 h at room temperature. The reaction mixture was dried under vacuum, and the residue chromatographed in dichloromethane/hexane (1:1) on silica gel. Slow evaporation of the solvent from the first orange band give crystals of the novel complex **2** in about 10% yield. In addition to the main product **2**, apart from [(η^5-tp)Cr(CO)$_3$], [Mn$_2$(CO)$_{10}$], and a polar intractable residue, a second orange product of very different polarity was also collected and afforded **1** in even



1 **2**

lower yield (<2%). Higher yields of **1** (10%) were obtainable by shorter reaction times, lower temperatures, and faster column chromatography.

When crystals of complex **1** were dissolved in polar solvents such as acetone and THF, they spontaneously underwent a metal exchange process to afford the thermodynamically favored compound **2**. The conversion of **1** into **2** was studied by ^{1}H NMR spectroscopy. Intensity measurements reveal that a pure sample of **1** (15 mg) converts almost quantitatively (>85%) into **2** at 30 °C in deuterated acetone over a period of 24 h. The spectra show only signals for **1** or **2** (>99%), which indicates a conversion with no side products. Factors contributing to this facile process include a very labile π-coordinated tp ligand on Cr(CO)$_3$, labile carbonyl ligands on the Mn(CO)$_5$ fragment, the formation of a relatively strong tp–Mn σ bond, solvents with coordinating properties (e.g., THF), and a driving force towards the thermodynamically favored product. However, this irreversible conversion was inhibited in dichloromethane, and analytically pure crystals of both **1** and **2** could therefore be obtained from dichloromethane/hexane mixtures. A novel intramolecular flip of the tp ligand is postulated as mechanism for the metal exchange. Whereas **1** inserts CO to form the stable complex **3**, no reaction was observed for **2** in a CO atmosphere. The complexes were fully characterized by elemental analysis and IR, ^{1}H NMR, ^{13}C NMR, and mass spectra; these data[12] support our formulations of **1** and **2**.



3

The patterns of the bands associated with the carbonyl vibrations in the IR spectrum of **1** are typical for independent Cr(CO)$_3$ and Mn(CO)$_5$ moieties. The tp ligand in **1** places more electron density on the chromium atom than in the precursor [Cr(η^5-tp)(CO)$_3$],[11] which is reflected by the

[**] π-Heteroatom Complexes, Part 1. This work was supported by the Foundation for Research and Development, Pretoria.

shift of the carbonyl frequencies to lower wavenumbers. Although overlapping in the IR spectrum of **2** hampered unique assignments, it can be seen that the $Cr(CO)_5$-fragment displays vibrational frequencies lower than those observed for $[Cr(CO)_5I]$, but higher than those found for $[Cr(CO)_5I]^-$.[13] The ^1H NMR spectra of **1** and **2** show the expected three nonequivalent resonances for the tp protons, with different chemical shifts and coupling constants. The reduction of electron density on the tp ring on going from **1** to **2** is reflected in the spectra by a downfield shift for the protons of **2**. Conclusive spectral evidence for the structural assignment of the bimetallic compounds **1** and **2** are found in their ^{13}C NMR spectra. The broad signal associated with $Mn(CO)_5$ at $\delta = 208$ and the chemical shift for the $Cr(CO)_3$ unit of $\delta = 238$ in **1** is absent in the spectrum of **2**. Instead, a broad signal for the $Mn(CO)_3$ fragment at $\delta = 219$ and two resonances at $\delta = 218$ (*cis*-CO) and 222 (*trans*-CO), typical for $Cr(CO)_5$ fragments, are observed; this is in good agreement with values reported in literature.[14] The relatively high value for the *ipso*-carbon when bonded to chromium may indicate some carbene character in this bond (Scheme 1).

X-ray diffraction studies were performed on suitable crystals of **1** and **2**, obtained by recrystallization from dichloromethane/hexane mixtures. The compounds **1** (orange) and **2** (yellow) crystallized in different space groups.[15] The solid state conformations are essentially identical (Fig. 1 and 2), but with some important differences in the bond distances. The distance between the Mn atom and the center of the tp ring in **2** is 1.720(5) Å, significantly shorter than the distance of 1.850(3) Å observed for the Cr center in **1**. The bond

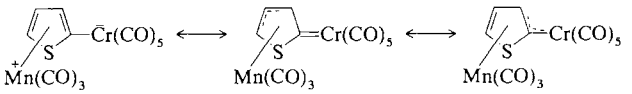
Selected distances [Å] and angles [°]: Mn-tp(center) 1.720(5), Cr-C7 2.112(4), Mn-S 2.330(1), Mn-C4 2.131(4), Mn-C5 2.150(4), Mn-C6 2.252(3), Mn-C7 2.299(4), S-C4 1.729(4), S-C7 1.768(4), C4-C5 1.399(6), C5-C6 1.472(5), C6-C7 1.485(5), C4-C5-C6 115.3(4), C5-C6-C7 109.3(3), C6-C7-S 109.7(3), C7-S-C4 94.5(2), S-C4-C5 110.0(4), S-C7-Cr 122.0(2), C6-C7-Cr 127.7(3).



Scheme 1. Resonance structures of **2**.

lengths of the bridging tp ligand in **1** are typical for η^5-coordinated thiophene ligands: the C4–C5 and C6–C7 distances are clearly shorter than the C5–C6 distance. In contrast, the corresponding C6–C7 distance in **2** is equal to the C5–C6 bond length, which compares with normal $C(sp^2)$–$C(sp^2)$ single bond distances (1.48 Å).[16] Both allylic resonance structures (Scheme 1) are therefore plausible for **2**. The short $Cr(\eta^1)$–C7 bond (2.112(4) Å) in **2** is comparable to values recorded for aminocarbene complexes of chromium[17] and supports the ^{13}C NMR data in indicating some carbene character for C7.[14]

Ligand exchange reactions from the coordination sphere of a complex form the basis of most reactions in organometallic chemistry. By contrast, the exchange of metal atoms each from their own ligand environment to that of the other involves the breaking and making of many bonds and is, as far as we are aware, unprecedented in the literature for simple organometallic compounds. Furthermore, after this $\eta^1 \rightleftarrows \eta^5$ conversion of metal bonding was realized, the displacement of the chromium atom in [(η^5-thiophene)$Cr(CO)_3$] by manganese within the fixed ligand environment became an attractive possibility. The stability of **2** is remarkable, and initial efforts to displace the $Cr(CO)_5$ fragment by a ligand and protonate the thiophene ligand to afford the target compound $[(\eta^5\text{-tp})Mn(CO)_3]^+$ failed. Treatment of **2** with HBF_4 under CO atmosphere and at elevated temperatures afforded an unstable intermediate, which displayed an additional carbonyl frequency at 1658 cm^{-1} in the infrared spectrum, and immediately converts back to **2** during workup.

In conclusion, we report the first example of a metal exchange reaction which we believe will have wider application. Further studies are directed towards investigating the mechanism and kinetics of the exchange process, extending the range of transition metals participating in metal exchange, deducing optimum conditions for the promotion of the exchange process, and expanding the concept to other compounds with cyclic heterodiene and cyclopentadienyl ligands. The above example clearly demonstrates the importance of ligand activation by transition metals in heterobimetallic complexes.

A Novel Synthesis of Pyrrole-2-carboxylic Acid Derivatives by Ring Transformation of 1,2-Thiazolium Salts through Sulfur Extrusion

By *Andreas Rolfs* and *Jürgen Liebscher**

Attention has been directed recently toward pyrrole-2-carboxylic acid derivatives as lead structures for the development of effective anticonvulsants,[1] but these compounds have long been important as analgesics and antiinflammatory agents as well.[2, 3] These types of pyrroles are also employed in the synthesis of natural products and analogous compounds such as porphyrins,[4] oligopyrroles,[5] and nucleosides.[6] Derivatives of pyrrole-2-carboxylic acid have been prepared, for example, by ring-closing reactions and ring transformations, often with restrictions on the substitution pattern.[7] We report here on an efficient route to pyrrole-2-carboxylates and -nitriles based on a novel ring transformation of substituted 2-methyl-1,2-thiazolium salts by sulfur extrusion.

When 2-alkoxycarbonylmethyl- or 2-cyanomethyl-1,2-thiazolium salts **1** were heated in polar solvents in the presence of base, the pyrrole-2-carboxylic acid derivatives **5** formed spontaneously (Method A, see Experimental Procedure and Table 1). The sulfur atom of the 1,2-thiazole ring

was extruded to give elemental sulfur, which could be easily removed from products **5**. In the presumed course of the reaction initial deprotonation of the exocyclic methyl group leads to zwitterion **2**. Electrocyclic ring opening of **2** could provide the 3-alkylidenaminoprop-2-enethiocarbonyl compound **3**, and subsequent ring closure could give the ring-expanded 1,2-dihydro-1,3-thiazine **4**. Compound **4** is then converted to pyrrole **5** by a further deprotonation and extrusion of sulfur, as was shown by R. R. Schmidt in related work.[8] In connection with this proposed mechanism it should be mentioned that the net transformation proceeds much more readily for thiazolium salts with electron-donating substituents (R^2 = NR'_2, SCH_3) than for those with aryl groups (R^2 = aryl).

[*] Prof. Dr. J. Liebscher, Dipl.-Chem. A. Rolfs

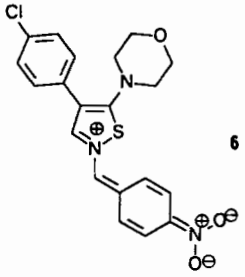
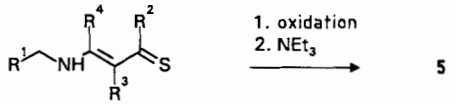
Telefax: Int. code + (30)2846-8343

Very high yields of 1*H*-pyrroles **5** were often obtained. In addition, the choice of substituents is not restricted, which allowed us to prepare a series of previously unknown pyrroles **5** (Table 2). The substituents R^1, however, must be sufficiently electron-withdrawing for the reaction to succeed. In the reactions of 2-benzyl-1,2-thiazolium salts and 2-alkyl-1,2-thiazolium salts **1** (R^1 = phenyl, or H and alkyl, respectively) either no reaction was observed or the corresponding 1,2-thiazoles were obtained in the presence of strong bases by dealkylation. Treatment of the 2-(4-nitrobenzyl)-1,2-thiazolium salt **1** (R^1 = 4-$NO_2C_6H_4$, R^2 = morpholino, R^3 = 4-ClC_6H_4, R^4 = H) with triethylamine gave the deprotonation product **6** (Table 2).



6

Since alkylations of 1,2-thiazoles are not particularly smooth, the 1,2-thiazolium salts **1** were obtained by oxidative cyclization[9] of enaminothiocarbonyl compounds **7**.[10] Products with various substituents R^2–R^4 other than those listed for the compounds in Table 1 can be prepared from the appropriate precursors **7**. The synthesis of starting material **1** and the further ring transformation to the pyrrole-2-carboxylic acid derivatives **5** can often be combined in a one-pot process (Method B).



5

7, R^1 = CO_2alkyl, CN

The ring transformation with sulfur extrusion described here provides a general principle for the preparation of hetarylcarboxylates and -nitriles. Initial investigations with 2-alkoxycarbonylmethyl- and 2-cyanomethyl-1,2,4-thiadiazolium salts demonstrate that imidazole-2-carboxylic acid derivatives can be synthesized analogously.

Experimental Procedure

Method A: To a stirred solution of 10 mmol 1,2-thiazolium salt **1** in 50 mL methanol was added 12 mmol triethylamine in 5 mL methanol. The solution was briefly heated to reflux or was heated for 5 min at reflux (**1a** and **1b**). When the reaction mixture was allowed to cool and pyrrole **5** precipitated, it was filtered off and dissolved in dichloromethane, sulfur removed by filtration, and the crude product recrystallized. Alternatively, the product was purified by column chromatography on silica gel (eluent *n*-hexane/ethyl acetate).

Method B: 10 mmol Enaminothiocarbonyl compound **7** was oxidized by treatment with 10 mmol triethylamine and 10 mmol iodine (**6i**, **6j**) or bromine (**6d**, **6h**) or with 11 mmol H_2O_2 (**6k**) in 50 mL ethanol, chloroform, or methanol. After the oxidation was complete 12 mmol triethylamine in 5 mL methanol was added dropwise, and the reaction mixture was stirred and heated briefly at reflux. The workup was analogous to that in Method A.

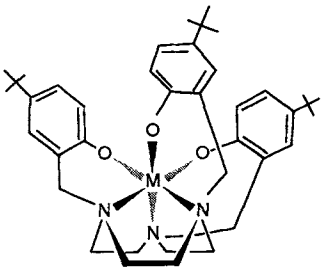
Molecular Recognition of Hexaaqua Transition Metal(II) Ions**

By *Ulf Auerbach, Claudia Stockheim, Thomas Weyhermüller, Karl Wieghardt,** and *Bernhard Nuber*

Dedicated to Professor Heinrich Nöth on the occasion of his 65th Birthday

The significance of noncovalent interactions in the molecular recognition of molecules in solution for biological receptors and for supramolecular assemblies is undisputed. Sterically favorable hydrophobic (e.g. stacking of aromatic building blocks) and hydrophilic interactions (hydrogen bonds) are decisive for the stereognostic properties of molecular assemblies.[1] The term "coordination in the second coordination sphere" is defined by Stoddart et al.[2] as the noncovalent bonding of molecular units to the first coordination sphere of a transition metal complex. This concept is traced back to Werner.[3] The bonding of crown ethers is particularly well documented, for example in the second coordination sphere of ammine complexes through the formation of several N–H···O bonds.[4] In contrast, cyclodextrins[5a] and calix[4]arenes[5b] have so-called hydrophobic pockets, into which complexes with hydrophobic ligands can be inserted. We have now observed that octahedral neutral complexes with a *cis*-trisphenolato metal(III) structural unit can bind hexaaqua transition metal(II) ions in the second coordination sphere with a certain degree of selectivity.

Recently we reported that the ligand 1,4,7-tris(5-*tert*-butyl-2-hyroxybenzyl)-1,4,7-triazacyclononane (LH_3) forms exceptionally stable complexes LM^{III} **1**–**3** with Cr^{III}, Fe^{III}, and Co^{III} ions.[6] These compounds are very soluble in all organic solvents. The three coordinated, *cis*-positioned phenolato oxygen atoms in **1**–**3** still have basic properties, as shown by their reaction with aqueous $HClO_4$ in CH_3OH. In this case twofold O–H···O bridged dinuclear complexes of the type $[(LH)_2M^{III}_2](ClO_4)_2 \cdot 2H_2O$ are formed.[6] This residual basicity of the O donor atoms can also be used for the formation of complexes.



1: M = Cr
2: M = Fe
3: M = Co

The reaction of **3** in acetone with the hexaaqua metal(II) cations $[M^{II}(OH_2)_6](ClO_4)_2$ in the ratio 2:1 leads to the crystalline, trinuclear complexes **4**, **5a**, and **6**–**8**. If

$$2\,\mathbf{3} + [M^{II}(OH_2)_6](ClO_4)_2 \xrightarrow{(CH_3)_2CO} \underset{\mathbf{4-8}}{[(LCo^{III})_2M^{II}](ClO_4 \cdot 2(CH_3)_2CO}$$

$$2\,\mathbf{3} + [Fe^{III}(OH_2)_6](ClO_4)_3 \longrightarrow \underset{\mathbf{5b}}{[(LCo^{III})_2Fe^{III}](ClO_4)_2 \cdot 2(CH_3)_2CO}$$

Scheme 1. **4**: M = Mn; **5a**: M = Fe; **6**: M = Co; **7**: M = Ni; **8**: M = Zn.

$[Fe^{III}(OH_2)_6](ClO_4)_3$ is used, red crystals of **5b** are obtained (Scheme 1). Figure 1 shows the structure of the dication in crystals of **5a**.[7] They are doubly face-sharing, trinuclear

[**] This work was supported by the Fonds der Chemischen Industrie.

cations, in which the six oxygen atoms of the phenolate groups of the two LCo^{III} units are bound to the Fe^{II} ion. Thus, complex **3** is a tridentate ligand, which is coordinated twice in the *first* coordination sphere of the central Fe^{II} ion. The structure of the trication in **5b** is analogous,[7] but with a central Fe^{III} ion.

Interestingly, **1** and **2** do not react under the same reaction conditions to give the above-mentioned complex type. The basicity of the O atoms in **1** and **2** is reduced due to the stronger Lewis acidic character of $Cr^{III}(t_{2g}^3)$ and the high-spin Fe^{III} ion ($t_{2g}^3e_g^2$) in comparison to the low-spin Co^{III} center (t_{2g}^6) in **3**,[6] and is not sufficient to force the substitution of the aqua ligands of the $[M^{II}(OH_2)_6]^{n+}$ ions. If excess $Na[BPh_4]$ is added to a solution of **1** or **2** and $[M^{II}(OH_2)_6](ClO_4)_2$ (2:1) in acetone, crystals of **9**–**16** precipitate (Scheme 2).

$$2\,\mathbf{1}\text{ or }2\,\mathbf{2} + [M^{II}(OH_2)_6](ClO_4)_2 \xrightarrow[(CH_3)_2CO]{Na[BPh_4]} [(LM^{III})_2\{M^{II}(OH_2)_6\}][BPh_4]_2 \cdot 4(CH_3)_2CO$$

9–**16**

Scheme 2. **9**: M^{II}/M^{III} = Mn/Cr; **10**: M^{II}/M^{III} = Co/Cr; **11**: M^{II}/M^{III} = Ni/Cr; **12**: M^{II}/M^{III} = Zn/Cr; **13**: M^{II}/M^{III} = Mn/Fe; **14**: M^{II}/M^{III} = Co/Fe; **15**: M^{II}/M^{III} = Ni/Fe; **16**: M^{II}/M^{III} = Zn/Fe.

Figure 2 shows the structure of the cation in crystals of **16**.[7] The central hexaaqua metal(II) ion is bound through six O–H ··· O contacts to two LFe^{III} neutral molecules; each coordinated H_2O molecule thus forms a hydrogen bond to a phenolate oxygen atom. Thus, chelate complex formation in the *second* coordination sphere of the $[M^{II}(OH_2)_6]^{2+}$ ion is achieved. In addition, the four H_2O molecules in equatorial positions are each bound to one acetone solvent molecule through a weak O–H ··· O contact. The structures of **13** and **9** are analogous to that of **16**.[7] The average Cr–O, Fe–O, Mn–O, and Zn–O distances in **9**, **13**, and **16** correspond to those in the neutral complexes **1** and **2**[6] as well as to those in the salts of the hexaaqua metal(II) cations $[Mn(OH_2)_6]^{2+}$ and $[Zn(OH_2)_6]^{2+}$.[8]

Interestingly, the reaction of $[Cu(OH_2)_6](ClO_4)_2$ with **1** or **2** does *not* lead to the crystallization of products of the type **9**–**16**. The reason for this may be the stretched octahedral structure of $[Cu(OH_2)_6]^{2+}$ (Jahn–Teller distortion), which prevents the double formation of three equivalent O–H ··· O contacts with **1** or **2**. This means that the complex formation in the second coordination sphere leads to a certain selectivity, which is influenced by differing stereochemical details of the $[M^{II}(OH_2)_6]^{2+}$ ions.

We have tested this selectivity qualitatively as follows: the products, which crystallized from reaction solutions and contained **1**, and an equimolar mixture of two different $[M^{II}(OH_2)_6]^{2+}$ ions were analyzed with regard to their divalent metal ion content. The results are summarized in Table 1. From these results it follows that the $[Zn(OH_2)_6]^{2+}$ ion is bound with the greater selectivity (4:1) when in competition with the $[Mn(OH_2)_6]^{2+}$ ion, whereas the $[Co(OH_2)_6]^{2+}$ ion shows hardly any selectivity preference over the $[Ni(OH_2)_6]^{2+}$ ion (1:1). Consequently, the formation of **10** and **11** is favored in Co/Mn and Ni/Mn solutions, respectively. Since the results of the selection experiments in Table 1 are consistent with each other, the possibility that different solubility products of the salts feign this selectivity is unlikely (it is assumed to be the same for all complexes). The crystalline products do not consist of a mixture of two

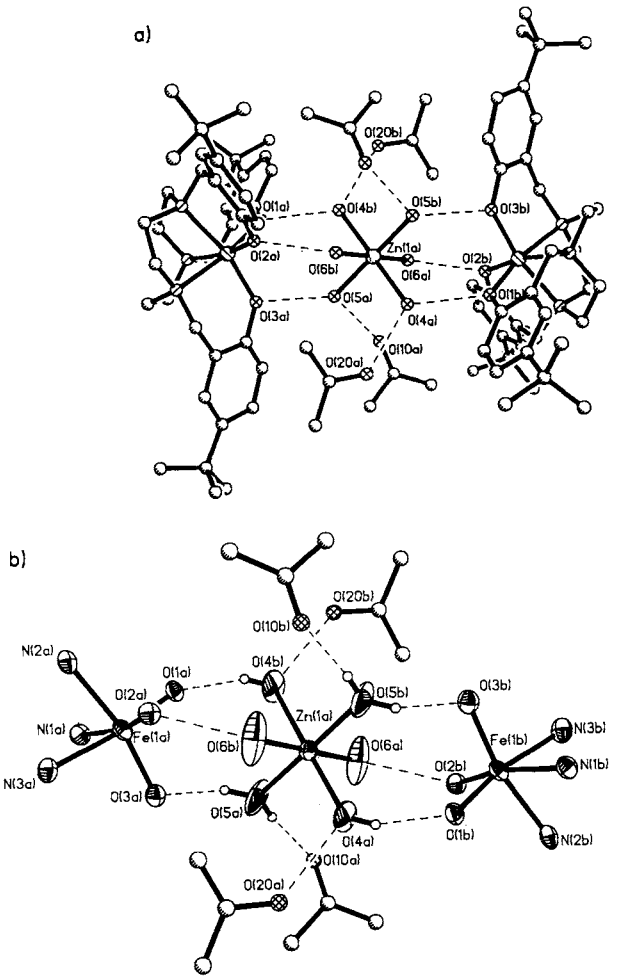

Fig. 2. Structure of $[(LFe)_2\{Zn(OH_2)_6\}]^{2+}$ in **16**: a) overall view of the cation; b) first coordination sphere. The structures of **9** and **11** are analogous. Selected bond lengths [Å] in **16** and in parentheses for **9** and **13**: Fe-O 1.938(7), 1.940(7), 1.921(7), (Cr-O 1.95(1), 1.96(1), 1.95(1); Fe-O 1.930(8), 1.940(8), 1.939(9)); Fe-N 2.212(9), 2.206(9), 2.221(9), (Cr-N 2.10(2), 2.10(1), 2.11(2); Fe-N 2.22(1), 2.19(1), 2.21(1)); Zn-O 2.09(1), 2.081(9), 2.04(1), (Mn-O 2.16(1), 2.19(1), 2.20(1); Mn-O 2.172(9), 2.17(1), 2.196(9)); O1 ··· O4 2.72(1), (2.74; 2.69(1)); O2 ··· O6 2.66(1), (2.68; 2.73(1)); O3 ··· O5 2.62(1), (2.72; 2.68(1)); O5 ··· O(20) 2.81(2), (not found; 2.99(2)); O5 ··· O(10) 2.68(1), (not found; 3.00(2)).

kinds of crystal, but of uniform mixed crystals (homeomorphy).

Thus complexes **9** and **12** are the extremes regarding the stability of the compounds **9**–**12** in solution; **9** is more un-

Table 1. Selectivity experiments [a]. The composition of the solutions ($[M^1(OH_2)_6]^{2+}$:$[M^2(OH_2)_6]^{2+}$ (1:1)) is compared to that of the crystalline products [b].

Solution		Products	
$[M^1(OH_2)_6]$	$[M^2(OH_2)_6]$	M^1 [c]	M^2 [c]
$[Zn(OH_2)_6]^{2+}$	$[Ni(OH_2)_6]^{2+}$	48	52
$[Zn(OH_2)_6]^{2+}$	$[Mn(OH_2)_6]^{2+}$	87	13
$[Ni(OH_2)_6]^{2+}$	$[Mn(OH_2)_6]^{2+}$	83	17
$[Co(OH_2)_6]^{2+}$	$[Mn(OH_2)_6]^{2+}$	80	20
$[Co(OH_2)_6]^{2+}$	$[Mn(OH_2)_6]^{2+}$	80	20
$[Co(OH_2)_6]^{2+}$	$[Ni(OH_2)_6]^{2+}$	47	53

[a] Reaction solution: 1.0 mmol **1** as well as 0.25 mmol each of $[M^1(OH_2)_6](ClO_4)_2$ and $[M^2(OH_2)_6](ClO_4)_2$ in 50 mL acetone, 0.20 g $Na[BPh_4]$. [b] The metal content M^1, M^2 was determined by atomic absorption spectroscopy. [c] The sum of the components [%] of both divalent cations in the crystalline products is 100%.

stable than **12**. Structural reasons for this tendency can be found from the X-ray structure analyses of **9**, **13**, and **16**. In these structures the O–H ··· O distances between the phenolate oxygen atoms and the aqua ligands are 2.72 (**9**), 2.70 (**13**), and 2.68 Å (**16**). The O ··· O distances within one triangular face of the octahedron, in whose corners are situated the phenolate oxygen atoms, are on average in **9**: 2.82, in **13**: 2.89, and in **16**: 2.89 Å, whereas this distance for the surface of the $[M^{II}(OH_2)_6]^{2+}$ octrahedron, which is bound through O–H ··· O contacts to **1** or **2** is in **9**: 3.07, in **13**: 3.07, and in **16**: 2.88 Å. From this it can be concluded that the triangular faces involving the oxygen atoms which lie opposite each other in **16** are better matched with respect to their size than those in **9** and **13**, and thus **16** is more stable in solution. The effects are small and different bond strengths of the O–H ··· O interactions, a result of the differences in basicity of the phenolate and water oxygen atoms, may be a further factor.

We are at present investigating the possibility of binding complexes of the type **1** and **2** with different O ··· O distances and residual basicity of the O atoms to a polymer, in order to achieve the separation and selective enrichment of $[M^{II}(OH_2)_6]^{2+}$ ions in aqueous solutions in very small concentrations.

Experimental Procedure

The synthesis of complexes **1**, **2**, and **3** was recently described [6]. Synthesis of the complexes **4**, **5a**, **6**–**8** and **5b**: To a solution of **3** (1.0 mmol) in acetone (50 mL) was added the hexaaquametal(II) perchlorate $[M(OH_2)_6](ClO_4)_2$ (0.60 mmol) (M = Mn, Fe, Co, Ni, Zn) under exclusion of air at 20 °C. After the mixture had been stirred for 30 min and subsequently filtered, $NaClO_4 \cdot H_2O$ (0.10 g) was added and half of the solvent was removed on a rotary evaporator. Red crystals of the desired complex grew within 12 h (≈75% yield). **5b** was prepared analogously with $[Fe(OH_2)_6](ClO_4)_3$ (0.60 mmol). Temperature-independent magnetic moments (80–295 K; Faraday method): **4**: 5.9, **5**: 5.5, **6**: 4.8, **7**: 3.1 μ_B; **8**: diamagnetic; **5a**: 5.9 μ_B.

Synthesis of the complexes **9**–**16**: To a solution of **1** or **2** (1.0 mmol) in acetone (50 mL) was added $[M(OH_2)_6](ClO_4)_2$ (0.60 mmol) (each of M = Mn, Co, Ni, Zn) at 20 °C and stirred. After the mixtures had been stirred for 30 min, $Na[BPh_4]$ (0.20 g) and ethanol (15 mL) were added to the clear solutions. From these solutions crystals precipitated in an open vessel (≈70% yield) after approximately 3–5 d. From temperature-dependent (4.2–295 K) magnetic susceptibility measurements it followed that the spins in **9**–**11**, and **13**–**15** were weakly coupled in an intramolecular antiferromagnetic manner. Temperature-independent magnetic moments of 3.8 μ_B/Cr and 5.9 μ_B/Fe were found for **12** and **16**. All complexes gave satisfactory elementary analyses (C, H, N, metal).

[7] Crystal structure analyses: The structures of **5a**, **5b**, **9**, **13**, and **16** were determined by X-ray crystallography with $Mo_{K\alpha}$ radiation. The intensities of **5a** and **16** were measured at 163 K, those of the other compounds at 295 K. The diffraction behavior of all crystals was limited; above $2\theta = 45°$ only a few reflections were observed ($I \geq 2.5\sigma(I)$). In all structures problems arose due to the disorder of the butyl groups, which could not be resolved satisfactorily. In **5b**, **9**, and **13** the positions of several acetone solvent molecules could not be determined precisely, because they left the crystal assembly during the measurement. These problems, which are impounded still further by slightly disordered ClO_4^- and BPh_4^- anions, led to relatively poor *R* values. In **16** it was possible to localize several of the positions of the H atoms in the O–H ··· O bridges. Crystal data **5a**: $a = 21.744(4)$, $b = 16.751(3)$, $c = 26.586(5)$ Å, $\beta = 91.13(3)°$; space group $C2/c$; $Z = 4$; $\mu(Mo_{K\alpha}) = 0.60\ mm^{-1}$; 7806 possible reflections, of which 3130 independent, observed ($F \geq 3.0\sigma(F)$); 434 parameters; $R = 0.14$; $R_w = 0.14$. **5b**: $a = 27.03(1)$, $c = 33.81(4)$ Å; space group $R\bar{3}$ (no. 148); $Z = 9$; $\mu(Mo_{K\alpha}) = 0.64\ mm^{-1}$; 6989 possible reflections, of which 2604 independent, observed; 237 parameters; $R = 0.11$; $R_w = 0.10$. **9**: $a = 14.221(3)$, $b = 27.080(7)$, $c = 17.671(4)$ Å, $\beta = 98.33(2)°$; space group $P2_1/n$ (no. 14); $Z = 2$; $\mu(Mo_{K\alpha}) = 0.30\ mm^{-1}$; 14079 possible reflections, of which 5824 independent, observed; 644 parameters; $R = 0.15$, $R_w = 0.13$; **13**: $a = 14.256(4)$, $b = 27.066(7)$, $c = 17.706(5)$ Å, $\beta = 97.87(2)°$; space group $P2_1/n$ (no. 14); $Z = 2$; $\mu(Mo_{K\alpha}) = 0.35\ mm^{-1}$; 11533 possible reflections, of which 6290 independent, observed; 658 parameters; $R = 0.099$; $R_w = 0.096$. **16**: $a = 13.972(3)$, $b = 27.128(5)$, $c = 17.757(4)$ Å, $\beta = 96.76(3)°$; space group $P2_1/n$ (no. 14); $Z = 2$; $\mu(Mo_{K\alpha}) = 0.46\ mm^{-1}$; 11709 possible reflections, of which 5545 independent, observed; ($I \geq 2.0\sigma(I)$); 707 parameters; $R = 0.11$, $R_w = 0.11$. The P4-Phosphazene Base as Part of a New Metal-Free Initiator System for the Anionic Polymerization of Methyl Methacrylate**

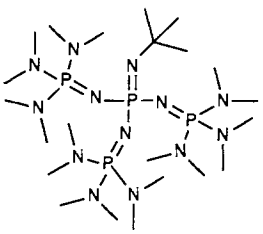
By *Thomas Pietzonka* and *Dieter Seebach**

Anionic polymerization of activated olefins, for which methacrylate is a prototype, leads to products having high molecular weights ($M_n > 10000\ g\,mol^{-1}$) and narrow polydispersities ($M_w/M_n < 1.3$) if either metal-free systems[1,2] or metals with a very bulky ligand sphere are used[3–7] and if the chain-initiating step[8] is irreversible. As counterions large ("soft") cations such as Bu_4N^+ or $(Me_2N)_3S^+$ are preferred. In the protonated form of the P4-phosphazene base **1** developed by Schwesinger and Schlemper[9] the positive charge is delocalized over 17 (!) positions, causing the base to be unusually reactive.[10] As **1** forms an extremely soft cation, we have now checked its ability to catalyze anionic polymerizations.



1

We found that methyl methacrylate (MMA, **2**) may be polymerized in high yields in different solvents at various temperatures with the P4 base **1**. The initiating system was prepared by treating small amounts of ethyl acetate with P4

base. Monomer **2** was continuously added and the reaction quenched after 30 minutes by addition of methanol.

All of the prepared poly(methyl methacrylate)s show molecular weights of $M_n > 10000\ g\,mol^{-1}$,[11] whereas their polydispersities D (M_w/M_n)[11] strongly depend on the reaction conditions; polymerizations carried out in hexane gave broadly distributed mixtures of polymers, whereas in the more polar THF smaller D-values were observed, down to 1.11 (Table 1).

Table 1. Average molecular weights and polydispersities D of poly(methyl methacrylate)s obtained with P4 base/ethyl acetate (EA) as initiator [11]. RT = room temperature.

Expt	Conditions	Molar ratio EA:P4:MMA	$M_n$theor [kg mol^{-1}]	M_n [kg mol^{-1}]	M_w [kg mol^{-1}]	D
1	toluene/RT	1:1:76	7.5	10.5	18.4	1.80
2	hexane/RT	1:1:85	8.4	17.2	35.8	1.82
3	THF/−78 °C	1:1:55	5.5	44.3	101.5	2.29
4	THF/RT	1:1.1:126	11.0	12.2	14.9	1.22
5	THF/60 °C	1:1.1:126	11.0	15.2	16.9	1.11
6	THF/60 °C	1:1.1:378	35.0	22.2	26.3	1.18
7	THF/60 °C	0:1.0:161	16.1	33.0	68.0	2.05

In experiments 1–3 (Table 1) the molecular weights achieved were clearly higher than the ones calculated from the initiator:monomer ratio. Obviously not all of the P4 molecules **1** initiated a chain. For polymerizations in which THF was used as solvent both the $M_n$theor: M_n ratio and the dispersity D strongly depended on the reaction temperature. At −78 °C broadly distributed polymers with too high molecular weights were isolated. At elevated temperatures (experiments 4–6) the determined molecular weights correspond well to those calculated, showing that under these reaction conditions the P4 base is able to initiate an anionic polymerization efficiently. The most narrowly distributed polymers were obtained in THF solution at 60 °C (experiments 5 and 6, Table 1). In contrast to anionic polymerizations with metal-bearing initiators, which lead predominantly to isotactic diads,[13] all poly(methyl methacrylate)s formed in THF contain approximately 80% syndiotactic diads.[12] Preliminary experiments have shown that other monomers, for instance ethyl acrylate, can also be polymerized by using the P4/ethyl acetate initiator system. The polymerization even takes place without addition of ethyl acetate, but the polydispersity of the polymer increases (experiment 7, Table 1).

Further optimizations of this new anionic polymerization with emphasis on the influence of monomer and solvent purity are in progress. Special attention is paid to the question if the polymer prepared with the P4 base is "living", in other words, whether block copolymers with different monomers can be prepared.

Experimental Procedure

Polymerization of MMA with the P4 base: Into an oven-dried 100 mL, two-neck, round-bottomed flask, fitted with a serum cap, were introduced 50 mL of THF and 45 μL (0.49 mmol) of ethyl acetate under argon. At reaction temperature a solution of 325 mg (0.34 mmol) P4 base **1** in 0.2 mL of THF was added, followed by dropwise addition of 20 mL (190 mmol) of methyl methacrylate (**2**) within 20 minutes. The reaction mixture was stirred for 0.5 h, quenched by addition of 1 mL of methanol, and concentrated to dryness. The residue was dissolved in a minimum of THF and precipitated by addition of the resulting solution to 200 mL of MeOH. The solvent was decanted and the residue dried under high vacuum at 50 °C until its weight remained constant to give 16.4 g (87%) PMMA with $M_n = 22200\ g\,mol^{-1}$, $D = 1.18$ [11] as a colorless, brittle powder. ^{1}H NMR (200 MHz, C_6D_5Cl, 80 °C): $\delta = 1.3$ (br. s, CH_3 (syndiotactic triad)), 1.4 (br. s, CH_3 (heterotactic triad)), 1.5 (br. s, CH_3 (isotactic triad)), 2.0–2.5 (br. m, CH_2), 3.7 (br. s, OCH_3) (a commercial sample was used as a reference, see also ref. [12]).

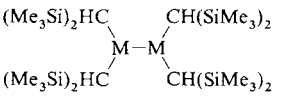
Reduction of a Tetraaryldigallane to Afford a Radical Anion with Ga–Ga Multiple Bonding Character**

By *Xiaoming He, Ruth A. Bartlett, Marilyn M. Olmstead, Karin Ruhlandt-Senge, Bradley E. Sturgeon,* and *Philip P. Power**

Organometallic complexes of heavier main group 3 elements of types **1a**,[1] **1b**,[2] and **1c**[3] have recently been prepared in good yield. These interesting compounds feature



1a, M = Al
1b, M = Ga
1c, M = In

[**] This work was supported by the National Science Foundation and the Petroleum Research Fund.

metal–metal single bonds between the three-coordinate metal centers. Parallel studies have shown that closely related boron compounds can be synthesized by using bulky alkyl or aryl substituents.[4–6] In addition, the reduction of tetraaryldiboranes afforded diborane dianions of types **2**[7]

$[Mes_2BBPhMes]^{2-}$ **2** (Mes = 2,4,6-$Me_3C_6H_2$)

$[Me_2NPhBBPhNMe_2]^{2-}$ **3**

and **3**,[8] which had B–B double bonds that are analogous to C–C double bonds in substituted ethenes. In view of the facility with which the reductions to **2** or **3** occurred, it was decided to attempt to extend this chemistry to aryl derivatives of the heavier members of the group. In this paper some preliminary results concerning the reduction of a tetraaryldigallane are now described.

Tetraaryldigallane **4** was synthesized by the reaction of four equivalents of TripMgBr with $Ga_2Cl_4 \cdot 2$ dioxane. Its structure features a Ga–Ga bond length of 2.515(3) Å and a

$Trip_2GaGaTrip_2$ **4**
Trip = 2,4,6-$iPr_3C_6H_3$

Ga–C distance of 2.008(7) Å. Moreover, there is a torsion angle of 43.8° between the two GaC_2 planes. The Ga–Ga bond length in **4** is similar to that in **1b** (2.541(1) Å[2]); however, the latter compound has an almost planar central Ga_2C_4 unit.

The treatment of a solution of **4** in diethyl ether with an excess of lithium powder affords a dark ochre solution. When [12]crown-4 is added crystals of salt **5** can be obtained. The X-ray crystal structure of **5** (Fig. 1)[9] shows that the

$[Li([12]crown\text{-}4)_2]^+ \left[\begin{array}{c} Trip \quad\quad Trip \\ \diagdown \quad\quad \diagup \\ Ga{=}Ga \\ \diagup \quad\quad \diagdown \\ Trip \quad\quad Trip \end{array} \right]^{\bullet -}$ **5**

neutral precursor **4** has been singly reduced to give the radical anion $[Trip_2Ga{=}GaTrip_2]^{\bullet -}$. This reduction produces dramatic structural changes. The Ga–Ga distance is shortened to 2.343(2) Å, and the torsion angle between the GaC_2 planes is decreased to 15.5°. There is also a slight lengthening in the Ga–C bonds to approximately 2.038(2) Å. The decrease of the Ga–Ga distance by 0.17 Å and the closure of the torsion angle are consistent with the formation of a one-electron π bond between the galliums. In this respect, **5** is analogous to the corresponding boron radical anions $[B_2R_4]^{\bullet -}$ which were generated in solution.[10] The Ga–Ga distance in **5** is the lowest reported to date; the shortest Ga–Ga distance previously known, 2.388(5) Å, was observed in $Ga_2[I_3Ga\text{-}GaI_3]$.[12] The difference in the Ga–Ga distances in **4** and **5** represents a shortening of almost 7%. This value is comparable to the 8–9% difference between single and double bond lengths in the heavier main group elements.

The presence of an unpaired electron in the $[Trip_2Ga\text{-}GaTrip_2]^{\bullet -}$ radical anion is manifested in broad, paramagnetically shifted resonances in the ^1H NMR spectrum. In addition, THF solutions of **5** at room temperature show a strong EPR signal[12] (Fig. 2). This signal is complex since gallium has two major isotopes (^{69}Ga and ^{71}Ga) both with $I = 3/2$, which exist in an approximately 60:40 ratio. A preliminary analysis of the spectrum reveals couplings of approximately 354. and 439. mT between the unpaired electron and the ^{69}Ga and ^{71}Ga nuclei. These values are consistent with the location of the unpaired electron in a π orbital. Although the crystals of **5** appear black, they are dark brown-red in transmitted light. A UV/VIS absorption spectrum displays bands at 360 and 900 nm that are attributable to the radical anion in **5**. Work on **5** and related compounds is continuing.[13]

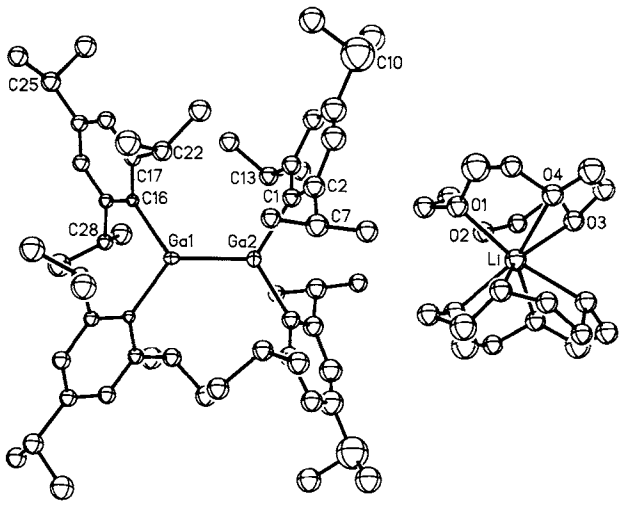

Fig. 1. Crystal structure of **5**. H atoms are omitted for clarity. Bond lengths [Å] and angles [°]: Ga1-Ga2 2.343(2), Ga1-C16 2.036(8), Ga2-C1 2.039(10), Li-O(ave.) 2.36(5); C1-Ga2-C1a 117.4(6), Ga1-Ga2-C1 121.3(3), C16-Ga1-C16a 111.5(5), Ga2-Ga1-C16 124.2(2).

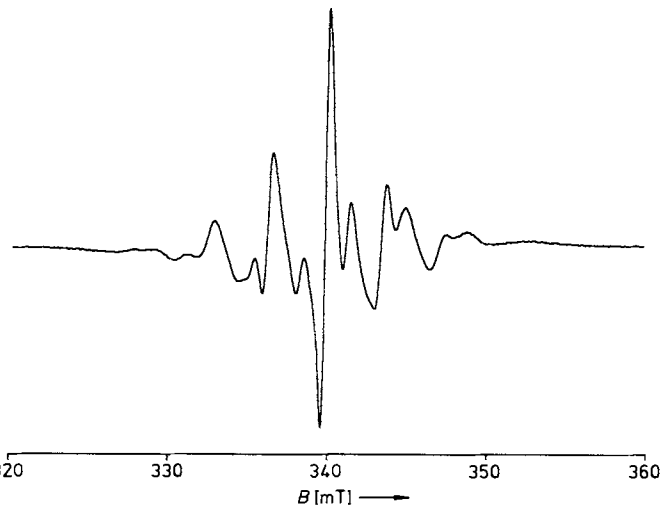

Fig. 2. A plot of the EPR spectrum of **5** in THF at ca. 25 °C. The complexity of the signal is due to coupling to different isotopic pairs of gallium isotopes ($I = 3/2$), which are present in the following percentages: $^{69}Ga/^{71}Ga$ ca. 48%; $^{69}Ga/^{69}Ga$ ca. 36%; $^{71}Ga/^{71}Ga$ ca. 16%.

Experimental Procedure

4: Under anaerobic and anhydrous conditions, 250 mL of 0.105 M diethyl ether solution (26.25 mmol) of TripMgBr was added dropwise to $Ga_2Gl_4 \cdot 2$ dioxane (3.0 g, 6.54 mmol), suspended in diethyl ether (50 mL) and cooled in a dry ice/acetone bath. Stirring was continued for 3 h at this temperature and a further 10 h with cooling by an ice/salt mixture. Filtration and removal of the solvents under reduced pressure gave a yellow-green semisolid residue which was taken up in hexane (250 mL). Filtration, concentration to approximately 50 mL, and storage at 20 °C for 20 h afforded **4** as yellow crystals in 83% yield (5.2 g). M.p. 113–115 °C.

5: A solution of **4** (2 g, 2.1 mmol) in diethyl ether (50 mL) was added to a suspension of lithium powder (0.1 g, 14.4 mmol) in diethyl ether (20 mL) with

cooling in a dry ice/acetone bath. Stirring was continued for 2 h during which time the solution turned dark blue-green. The reaction mixture was warmed to approximately $-10\,^{\circ}C$ in an ice/salt bath and stirred for a further 3 h. Filtration of the now dark-ochre solution was followed by the addition of [12]crown-4 (0.7 mL, 4.2 mmol). The solution was concentrated to ca. 15 mL and stored at -20 C for 48 h to furnish **5** as black crystals in 80% yield (2.2 g) which gave a satisfactory C,H analysis. M.p. 128–129 °C.

Chem.* **1993**, in press. In our laboratory we have also succeeded in isolating $[Trip_2AlAlTrip_2]^{\cdot-}$ which has an Al–Al distance of 2.470(2) Å. An account of this work will be published separately.

5-Dimethylamino-5′-nitro-2,2′-bithiophene—a New Dye with Pronounced Positive Solvatochromism**

By *Franz Effenberger** and *Frank Würthner*

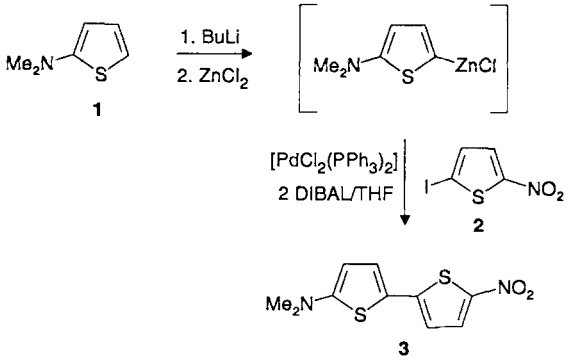
Dedicated to Professor Emanuel Vogel and Professor Klaus Hafner on the occasion of their 65th birthdays

All the significant findings on solvent parameters, their determination, and their respective advantages and disadvantages on application in very diverse reactions have been soundly summarized by C. Reichardt.[1] According to this information the solvatochromism of special compounds, which is easily quantified by UV/VIS spectroscopy, is particularly suitable for the empirical determination of solvent parameters. Of the many types of compounds studied, three have proved to be particularly good models for this purpose because of their pronounced solvatochromic properties: a) the Z values of Kosower obtained from the solvent-dependent (intermolecular) charge-transfer (CT) transitions in pyridinium compounds,[2] b) the $E_T(30)$ values of Dimroth, Reichardt, et al. obtained from the longest wavelength UV/VIS absorption of pyridinium N-phenoxides[3] and c) the π^* values of Taft, Kamlet, et al. derived from the long-wavelength absorption of benzene and styrene derivatives containing both donor and acceptor substituents.[4]

The Z values have a disadvantage over the $E_T(30)$ values: in solvents of higher polarity the CT transition overlaps with the strong $\pi \rightarrow \pi^*$ absorption, which restricts the range of application considerably. Another advantage of the $E_T(30)$ values over the Z values is the enormous width of the absorption region covered by the solvatochromism, which in addition is largely in the visible spectrum. A disadvantage of the $E_T(30)$ values is that the phenolates used for their determination are strongly basic. $E_T(30)$ values are therefore not available for solvents with high acidity. To a certain extent this disadvantage can be compensated for by the use of more weakly basic pyridinium N-phenoxides.[5] Because of the specific interactions of protic and Lewis acidic solvents with the phenolate group, the $E_T(30)$ values of these solvents are not a general measure for the solvent polarity.[6] These specific solvation effects[3, 8] occur in all betaine dyes that display negative[7] solvatochromism because of their negatively charged phenolate group in the electronic ground state. Dyes displaying positive[7] solvatochromism show smaller specific interactions and are therefore generally better suited for the description of solvent polarity parameters in terms of unspecific electrostatic interactions.

As hitherto no universally applicable positive solvatochromic dye was known,[9] Kamlet and Taft defined an "averaged" π^* scale from the solvatochromic behavior of seven standard and about forty auxiliary compounds. Although this scale in essence reproduces the stabilization of the excited state by electrostatic interactions correctly, in contrast to the $E_T(30)$ and Z scales it has no clear, well-understood reference process as basis.[10] In addition, the tabulation of other solvents or solvent mixtures proved troublesome.

In the context of studies on conjugated polyenes[11] and oligothiophenes[12] containing donor and acceptor substituents, we have prepared several amino- and nitro-substituted oligothiophenes that display exceptionally strong solvatochromic properties. Here we report on the solvato-



Scheme 1. 1) **1** and BuLi in *n*-hexane/THF; 2) addition to $ZnCl_2$ in THF; 3) addition of Zn-metalated **1** and **2** in THF to 5 mol% $[PdCl_2(PPh_3)_2]$/2 DIBAL (diisobutylaluminium hydride, 1 M in *n*-hexane) in THF, 3 h at room temperature.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 329) and the Fonds der Chemischen Industrie. We thank Prof. W. Liptay, Mainz, for his program SOLVDEPE, Dr. R. Wortmann and Mr. P. Krämer for the EFISH and electrooptical absorption measurements, and Ms. S. Henkel for the crystal structure determination.

chromic behavior of 5-dimethylamino-5'-nitro-2,2'-bithiophene (**3**) and its suitability for the establishment of a π^* scale that is based on only *one* model compound and whose absorption wavelengths lie in the easily detectable visible spectral range.

Bithiophene **3** was synthesized by a transition metal catalyzed coupling reaction[13] from the aminothiophene **1** and 2-iodo-5-nitrothiophene (**2**) according to Scheme 1 and is obtained in pure form as violet crystals (m.p. 176–177 °C). It is readily soluble in all organic solvents and displays unusually large solvatochromic shifts, which extend almost over the whole visible range, from $\lambda = 466$ nm (*n*-hexane) to $\lambda = 597$ nm (formamide/water) (Fig. 1).

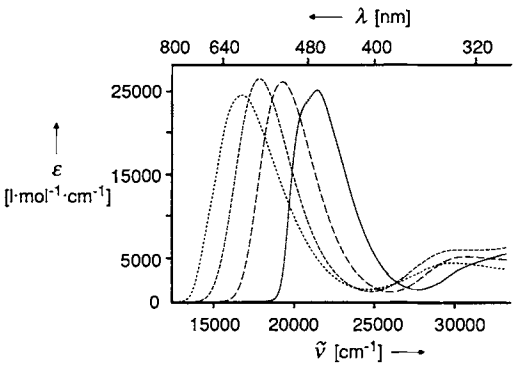

Fig. 1. UV/VIS absorption spectrum of **3** (4×10^{-5} M) in *n*-hexane (——), THF (– – –), dimethylsulfoxide (----), and formamide/water (1:1) (·····).

The X-ray structure analysis[14] shows that bithiophene **3**—in contrast to comparable biphenyl derivatives[15]—is almost completely planar; therefore conjugation is not reduced by twisting of the end groups and the thienyl system or of the thienyl groups themselves (Fig. 2). A further indication of the good electron delocalization in **3** is the distinct equalization of the C–C bond lengths within both thiophene units. As a result the electron distribution in **3** resembles that of merocyanines.[16]

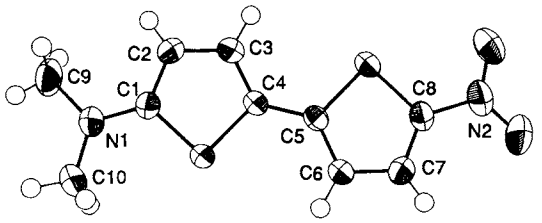

Fig. 2. Crystal structure of **3** (ORTEP projection). Selected distances [Å]: C1–N1 1.356(3), C1–C2 1.383(4), C2–C3 1.402(3), C3–C4 1.372(3), C4–C5 1.438(2), C5–C6 1.385(3), C6–C7 1.399(3), C7–C8 1.363(4), N2–C8 1.417(3); bond angles [°]: C9-N1-C10 120.2; dihedral angle [°]: Me_2N-thienyl 4.5, thienyl-thienyl 3.7, thienyl-NO_2 2.1.

The large electronic interaction between the two end groups is not only evident in the pronounced solvatochromism, but also in other physical properties that suggest that the donor- and acceptor-substituted oligothiophenes could find application in nonlinear optics.[17] According to EFISH measurements, the static hyperpolarizability of the donor- and acceptor-substituted bithiophenes is almost twice as large as that of the corresponding biphenyls. The agreement between these experimentally determined hyperpolarizabilities and the values calculated from solvatochromic data for this class of compounds is excellent.[12]

The electrooptic absorption measurements[12b] showed that the change in dipole moment on electronic excitation is oriented parallel to the transition dipole and is constant over the whole CT band. Thus the entire long-wavelength absorption band of **3** arises from a single electronic transition.

Table 1. Physical molecular properties of 5-dimethylamino-5'-nitro-2,2'-bithiophene (**3**) and 4-dimethylamino-4'-nitrobiphenyl (DNB) [12b].

Measured quantities	**3**	DNB
dipole moment in the ground state μ_g [D] [a]	7.95	6.72
dipole moment in the excited state μ_e [D] [b]	22	24
hyperpolarizability β_z (1064 nm) [esu] [c]	318×10^{-30}	89×10^{-30}
static hyperpolarizability β_0 [esu] [d]	54×10^{-30}	33×10^{-30}
absorption maximum λ_{max} (*n*-hexane) [nm]	466	375
absorption maximum λ_{max} (formamide) [nm]	577	420
extinction coefficient ε_{max} [$L\,mol^{-1}\,cm^{-1}$] [e]	25000	20000
oscillator strength *f* [e]	0.46	0.47

[a] According to Debye–Guggenheim–Smith (in benzene). [b] Electrooptical absorption measurements. [c] EFISH measurement, reference quartz $d_{11} = 1.2 \times 10^{-9}$ esu. [d] Calculated according to the two-level model from EFISH data (1064 nm). [e] In *n*-hexane, $f = 4.32 \times 10^{-9} \int \varepsilon d\tilde{\nu}$.

Prompted by these physical quantities, we examined the solvatochromic properties of **3** by recording its absorption spectrum in three aliphatic, eleven dipolar-aprotic, seven aromatic, five chlorinated, and six protic solvents.

Solvatochromism can either be described empirically[1–8] or be based on physical properties which quantify the solvent effect on the absorption behavior.[18] For **3** an excellent correlation ($r = 0.9923$) is established with the solvent function defined by dielectric constant ε and the refractive index n_D according to the method of Liptay for the 13 aliphatic and dipolar–aprotic solvents (excluding dioxan).[18, 19] The aromatic solvents and dioxan deviate substantially from the regression line, because their large quadrupole moments cannot be described by the macroscopic solvent parameters ε and *n*. The empirical representation of the solvent polarity by suitable molecules like **3**, however, encompasses all operative effects on the molecular microscopic level.

Since the π^* scale was set up with dyes that do not enter into specific interactions with dipolar-aprotic solvents, it is not surprising that a very good correlation between the absorption wavenumbers of **3** and the π^* values of the relevant solvents was obtained [Eq. (a)].

$$\tilde{\nu}_{max}(\mathbf{3}) = 21\,166\ cm^{-1} - 3323\ cm^{-1} \cdot \pi^* \quad (r = 0.9979) \quad (a)$$

In aromatic and in chlorinated hydrocarbons the absorption transitions of **3** occur at shorter wavelengths than calculated on the basis of the π^* values according to Equation (a). Kamlet, Taft, et al. have introduced a correction parameter δ for these solvents to account for the different contributions of the polarization and dispersion forces[4, 20] [Eq. (b)];

$$\tilde{\nu}_{max}(\mathbf{3}) = 21\,126\ cm^{-1} - 3337\ cm^{-1} \cdot (\pi^* - 0.1 \cdot \delta) \quad (r = 0.9936) \quad (b)$$

$\delta = 0$ for aliphatic and dipolar–aprotic solvents, 0.5 for chlorinated aliphatic solvents, and 1 for aromatic solvents (and dioxan). When the correction term $d \cdot \delta$ is taken into account for a *d* value of -0.1 for the bithiophene **3**, we also obtained

a very good correlation between the absorption wavelengths and the known π^* values including those for all the chlorinated and aromatic solvents we studied (Fig. 3).

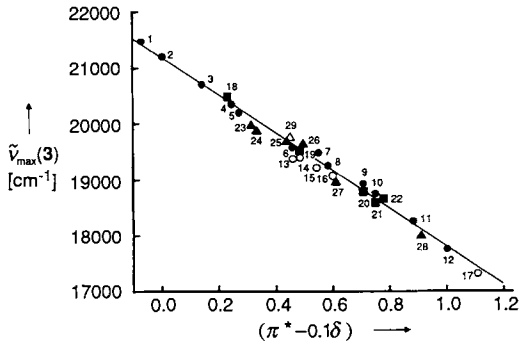

Fig. 3. Correlation of the absorption wavenumbers with the π^* scale according to Taft, Kamlet et al. and including the correction term δ. Aliphatic and dipolar-aprotic solvents (●) [1 *n*-hexane, 2 cyclohexane, 3 triethylamine, 4 dibutyl ether, 5 diethyl ether, 6 butyl acetate, 7 ethyl acetate, 8 THF, 9 acetone, 10 acetonitrile, 11 DMF, 12 DMSO]; protic solvents (○) [13 *n*-butanol, 14 2-propanol, 15 ethanol, 16 methanol, 17 formamide]; chlorinated solvents (■) [18 CCl_4, 19 trichloroethylene, 20 chloroform, 21 1,2-dichloroethane, 22 dichloromethane]; aromatic solvents (▲) [23 mesitylene, 24 *p*-xylene, 25 toluene, 26 benzene, 27 chlorobenzene, 28 nitrobenzene]. 29 Dioxan (Δ) was treated like an aromatic solvent ($\delta = 1$); for formamide and chloroform the π^* values were taken from ref. [4a].

Thus in terms of Equation (b), reliable π^* values can be determined simply and fast with only *one* indicator dye, because bithiophene **3**, in contrast to the indicator dyes used till now,[4] fulfills *all* criteria for establishing solvent parameters: namely, good spectral sensitivity, absorption in the visible range in which all solvents are transparent, high intensity of the CT transition not masked by other electronic transitions, and good solubility in all organic solvents.

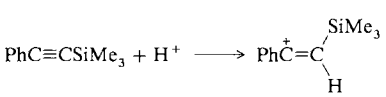
Protonation of Phenyl(trimethylsilyl)acetylene: A Surprisingly Weak Stabilization of a Carbocation by a β-Trimethylsilyl Group**

By *A. Jerry Kresge** and *John B. Tobin*

Carbocations are strongly stabilized by β-trimethylsilyl substituents:[1] effects amounting to several tens of kcal mol^{-1} have been calculated[2] and observed[3] in the gas phase, and an acceleration by a factor of 10^{12} has been determined for a reaction in solution;[4] β-silyl-substituted carbocations have also been observed directly quite recently and their stability has been assessed by NMR spectroscopy.[5] We were surprised, therefore, to find that the β-trimethylsilyl substituent in phenyl(trimethylsilyl)acetylene (**1**) speeds up the protonation of this substance to give the phenyl β-trimethylsilylvinyl cation (**2**) [Eq. (a)] by a factor of only 300.



(a)

1 **2**

Phenyl(trimethylsilyl)acetylene is converted cleanly into acetophenone by moderately concentrated aqueous perchloric acid (45 wt%); during which phenylacetylene can be detected as an intermediate. The first stage of this reaction may therefore be formulated as the protodesilylation [Eq. (b)]; the phenylacetylene so produced is then hydrated more slow-

[*] Prof. A. J. Kresge, Dr. J. B. Tobin
Department of Chemistry, University of Toronto
Toronto, Ontario M5S 1A1 (Canada)

[**] This work was supported by the Natural Sciences and Engineering Research Council of Canada and the donors of the Petroleum Research Fund administered by the American Chemical Society.

ly by the well-known acid-catalyzed reaction to give acetophenone [Eq. (c)].

$$PhC{\equiv}CSiMe_3 + H^+ \xrightarrow[-H^+]{H_2O} PhC{\equiv}CH + HOSiMe_3 \quad (b)$$

$$PhC{\equiv}CH \xrightarrow[H_2O]{H^+} PhC(OH)=CH_2 \longrightarrow PhCCH_3 \quad (c)$$

Although the UV spectra of **1** and phenylacetylene are quite similar, there is a difference in the region $\lambda = 250$–260 nm, and this can be used to monitor the protodesilylation spectroscopically. Conveniently measurable rates are obtained for the acid concentrations 10–40 wt% aqueous $HClO_4$. The reaction is first-order, and the rate constants increase sharply with increasing acidity. These rate constants give a good linear correlation when treated by the Cox–Yates method[6] by using the X_0 acidity function.[7] This correlation provides the catalytic coefficient for dilute solution $k_H^+ = (8.93 \pm 0.35) \times 10^{-5}\ M^{-1} s^{-1}$. Comparison of rates of reaction in 0.79 M perchloric acid in H_2O and D_2O also gives the isotope effect $k_H^+/k_D^+ = 1.79 \pm 0.06$. This isotope effect is characteristic of a process that involves rate-determining hydron transfer (hydron = H^+, D^+, or T^+) from the hydronium ion to a carbon base.[8] Similar isotope effects have been obtained for the hydration of other acetylenes,[9] a reaction known to occur by rate-determining protonation of the acetylenic carbon atom to give a vinyl cation.[9, 10] The slope of the present Cox–Yates correlation is also similar to that obtained for the hydration of other acetylenes.[9b, 11] The accumulated evidence thus indicates that the protodesilylation of **1** likewise occurs by rate-determining proton transfer to acetylenic carbon atom [Eq. (a)]; this step is then presumably followed by rapid nucleophilic displacement of the trimethylsilyl group from the vinyl cation **2** [Eq. (d)].

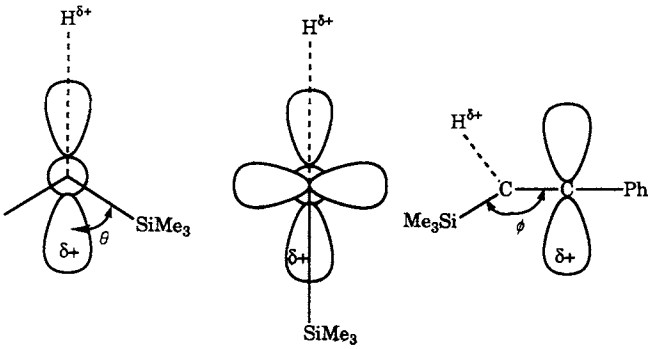
$$PhC^+(H)=C(SiMe_3) \xrightarrow[-H^+]{H_2O} PhC{\equiv}CH + HOSiMe_3 \quad (d)$$

2

Since the rate-determining steps for the hydration and protodesilylation of acetylene are the same, an assessment of the cation-stabilizing effect of β-trimethylsilyl substituents can be made by comparing the rate of the protodesilylation of **1** with the rate of hydration of phenylacetylene. Use of $k_H^+ = 2.86 \times 10^{-7}\ M^{-1} s^{-1}$ for phenylacetylene[9b] then leads to an acceleration of the reaction by a factor of 312 ± 16, which is equivalent to a β-silyl stabilization, relative to hydrogen, of $\Delta\Delta G^{\neq} = 3.4$ kcal mol^{-1}. This value is very much smaller than the large stabilization energies, ranging from 20 to 50 kcal mol^{-1}, which have been calculated[2] and observed[3] for the β-silyl effect in the gas phase, as well as the stabiliztion energy of 17 kcal mol^{-1} observed in solution for the solvolysis of a cyclohexyl substrate with optimal conformation.[4] The present $\Delta\Delta G^{\neq}$ value is similar, however, to the β-silyl stabilization energy found for proton addition to ethyl β-trimethylsilylvinyl ether in aqueous solution (2.9 kcal mol^{-1})[12] [Eq. (e)]. In that case the low stabilization energy was attributed to a nonoptimum transition state geometry **3**, in which the dihedral angle θ between the C–$SiMe_3$ bond and the vacant p orbital of the positively charged carbon atom deviates significantly from the value, $\theta = 0$, required for the maximum hyperconjugative interaction of this bond with the cationic center; this caused a considerable reduction of the hyperconjugative component of the stabilization, which constitutes the major part of the β-silyl effect.[2, 4]

$$Me_3SiCH{=}CHOEt + H^+ \longrightarrow Me_3SiCH_2\overset{+}{C}HOEt \quad (e)$$

This dihedral angle does have its optimum value in the transition state of the present reaction (**4**) inasmuch as the C–$SiMe_3$ bond and the vacant p orbital lie in the same plane throughout the protonation process and consequently $\theta = 0$. In the present case, however, another angle, that between the C–$SiMe_3$ bond and the adjacent C–C bond, designated ϕ in structure **5**, has a value that is probably far from optimal. Hyperconjugative interaction will be maximum when the C–$SiMe_3$ bond and the vacant cationic p orbital are parallel and $\phi = 90°$ but, as protonation of the acetylenic carbon atom takes place, this angle begins with an initial-state value of $\phi =$ is 180° and then reaches a final-state value of only $\varphi = 120°$ in the fully formed vinyl cation. In the transition



3 **4** **5**

state, this angle will of course be considerably greater than $\varphi = 120°$; and that will lead to a sizeable reduction in the hyperconjugative interaction, consistent with the weak β-silyl effect found here. This analysis implies that substantially stronger β-silyl effects should be observed in systems, such as solvolysis of vinyl substrates, where a near-optimum value of ϕ is already present in the reaction's initial state.

New Chiral Porphyrins—Syntheses and Molecular Recognition of Amino Acid Esters

By *Yasuhisa Kuroda,* Yusuke Kato, Takuji Higashioji,* and *Hisanobu Ogoshi**

Synthetic chiral porphyrins have attracted much interest as model compounds for the chiral environments of heme proteins.[1] We report herein a new synthetic route to chiral porphyrins and their chiral recognition behavior. Since the required synthetic building blocks are achiral atropisomeric tetraarylporphyrins with *ortho*-substituted phenyl groups and simple bridging reagents, the route is suitable for the preparation of a series of chiral porphyrins for the systematic investigation of molecular recognition properties. Our synthetic scheme is based on the following strategy (Fig. 1).

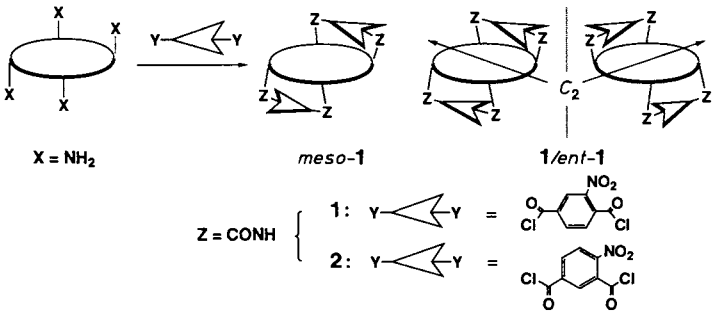

Fig. 1. Schematic representation of the synthesis of chiral porphyrins.

When the $\alpha,\alpha,\beta,\beta$ atropisomers of tetraarylporphyrins are doubly bridged with an unsymmetric, difunctionalized reagent, a mixture of a *meso* porphyrin and a pair of enantiomeric porphyrins with a C_2 symmetry axis parallel to the porphyrin plane may result,[2] which may be separated by chromatography. For example, the reaction of $\alpha,\alpha,\beta,\beta$-tetrakis(*ortho*-aminophenyl) porphyrin with nitroterephthaloloyl chloride in THF gave two doubly bridged porphyrins, *meso*-**1** and **1**/*ent*-**1**, which could be purified by silica gel chromatography.[3] The product with the larger R_f value on a silica gel TLC plate was further resolved into the enantiomers **1** and *ent*-**1** on a chiral HPLC column. The chirality of these products is clearly demonstrated by their circular dichroism (CD) spectra, which show completely symmetric Cotton effects in the region of the Soret bands. The analogous reaction with 4-nitroisophthaloyl chloride gave, following chromatographic separation, *meso*-**2** and **2**/*ent*-**2**; the enantiomers could be separated again by HPLC.[4] All compounds were characterized by ^{1}H NMR spectroscopy and fast atom bombardment mass spectrometry (FAB-MS).

In spite of the slight difference between the bridging positions of **1** (*para*) and **2** (*meta*), the topological structures of these porphyrins were expected to be quite different; the angles between planes of the porphyrin and the bridging benzene units in **1** and **2** are predicted by calculations to be approximately 0° and 70–80°, respectively (see Fig. 2).[5]

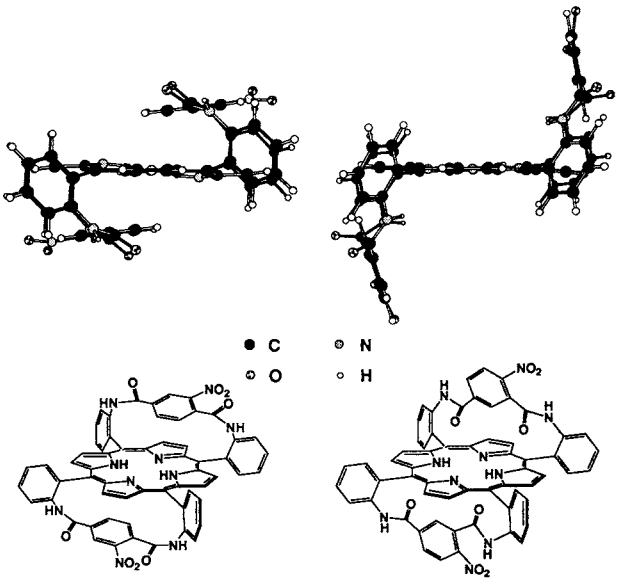

Fig. 2. Ball-and-stick molecular models of one each of the sets of enantiomers **1**/*ent*-**1** (left) and **2**/*ent*-**2** (right) (see ref. [5]).

We attempted to evaluate the chiral recognition abilities of **1** and **2** by determining the association constants of the adducts formed by their Zn complexes and amino acid methyl esters.[6] Titration experiments indicate that various types of amino acid methyl esters form 1:1 complexes with **1**-Zn and **2**-Zn (Table 1). The following interesting aspects of the molecular recognition are clear: a) coordination of the amino acid to *meso*-**1**-Zn is hindered significantly compared with that to TPP-Zn, by the benzene bridge; b) in contrast, *meso*-**2**-Zn shows a high affinity for amino acids, while the affinity for corresponding simple amines is low; c) the chiral porphyrins **2** and *ent*-**2** show significant chiral recognition for amino acids.

Upon complex formation, the ^{1}H NMR signals of the protons of the amino acid ester exhibit upfield shifts that are dependent on their distance from the amino group. For example, valine shows upfield shifts of $\Delta\delta$ = 6.2, 2.2, 2.2, and 0.9 for C_α-H, C_β-H, CH_3 (*i*Pr), and CH_3 (ester), respectively. The electronic spectra of these Zn porphyrins also show a clear redshift of the Soret bands (ca. 8 nm) upon addition of the amino acid, while the corresponding uncomplexed porphyrins do not. These observations strongly indicate coordination of the amino group on the Zn atom. Comparison of association constants for amino acids esters and the corresponding amines strongly indicates that the methoxycar-

[c] Absolute configurations of these enantiomeric porphyrins were not determined. The signs (+) and (−) are based on the CD spectra in the Soret region (see ref. [4]). [d] All amino acids used in this work have L configuration.

bonyl group participates in the attractive interaction between **2**-Zn and the substrate. This attractive interaction is best explained by a hydrogen bond between the carbonyl oxygen atom of the amino acid ester and amide hydrogen atom of **2**-Zn; upon coordination of the amino group to the Zn atom these two atoms are only 1.9 Å apart. This hydrogen bonding is confirmed by the observation in the ^1H NMR titration experiments that two signals for amide NH protons shift upon addition of valine methyl ester from $\delta = 6.76/7.34$ to 7.45/7.65. Existence of the hydrogen bond is further supported by a result from preliminary IR spectroscopic measurements: upon addition of the amino acid, the NH stretching bond of the amide groups in **2**/*ent*-**2**-Zn, originally observed 3403 cm^{-1}, shifts to 3305 cm^{-1}; this can be explained by the formation of a NH···O hydrogen bond.[7]

Since chiral recognition logically requires at least a *spatially oriented* three-point interaction, the observed chiral recognition for amino acid esters suggests that there is a significant difference between the hydrogen-bonding abilities of the two amide groups at the 1- and 3-positions of the bridging benzene ring in **2**/*ent*-**2**-Zn. Thus, the amino acid receptor **2**/*ent*-**2**-Zn utilizes three kinds of interactions: coordination of the Zn atom, hydrogen bonding, and steric repulsion. Interestingly, these three interactions correspond to three characteristic elements of amino acids: the amino group (coordination), the carboxyl group (hydrogen bonding), and the side chain (steric repulsion).

The new synthetic route to chiral porphyrins reported here is expected to be widely applicable for various structural variations. Preliminary studies on chiral recognition show that, in contrast with chiral crown ethers,[8] chiral porphyrins differentiate between neutral amino acid esters.

The Synthesis and Ab Initio Structure Determination of $Zn_4O(BO_3)_2$, a Microporous Zincoborate Constructed of "Fused" Subunits of Three- and Five-Membered Rings**

By *William T. A. Harrison,** *Thurman E. Gier,* and *Galen D. Stucky*

Substitution of boron for aluminum and/or silicon in zeolite molecular sieves has long been a topic of interest.[1–3] A rare example of complete boron substitution for both Si and Al is provided by "boralite", $Zn_4O(BO_2)_6$,[4] a direct topological analogue of the aluminosilicate sodalite-type framework found in, for example, $Na_4OH(AlSiO_4)_3$.[5] In general, however, boron atoms, which usually substitute for aluminum atoms, have only been introduced into aluminosilicate molecular sieves in small quantities, although the technological implications of such doping reactions are extremely important, as in the boron/MFI zeolite.[6]

[**] This work was supported in part by the Office of Naval Research and the National Science Foundation (Grant No. DMR 9208511). We thank Dr. V. I. Srdanov (UCSB) for carrying out the powder-second-harmonic-generation test.

We describe here one result of our exploratory syntheses in the area of zincoborates that complements the rapidly growing family of zincophosphate and related (Be/Zn)(P/As) molecular sieves,[7, 8] consisting of framework elements from groups 2, 12, and 15 of the periodic table. $Zn_4O(BO_3)_2$ is a novel neutral-framework material containing micropores, built up from "fused", vertex-sharing tetrahedral ZnO_4 and triangular BO_3 units. Several other zincoborate compounds are known,[9] but none are similar to the phase described herein.

The final atomic coordinates for $Zn_4O(BO_3)_2$ are listed in Table 1, selected geometrical data in Table 2. $Zn_4O(BO_3)_2$

Table 1. Atomic coordinates and isotropic temperature factors for $Zn_4O(BO_3)_2$. Rhombohedral, $R\bar{3}c$, $a = 9.9115(4)$ Å, $\alpha = 48.602(1)°$.

[a] The crystallographically distinct atom is primed.

has a three-dimensional structure built up from five atoms per asymmetric unit (1 Zn, 1 B, 3 O), forming vertex-sharing tetrahedral ZnO_4 and triangular BO_3 subunits, which enclose small, elongated cavities (Fig. 1) and a three-dimen-

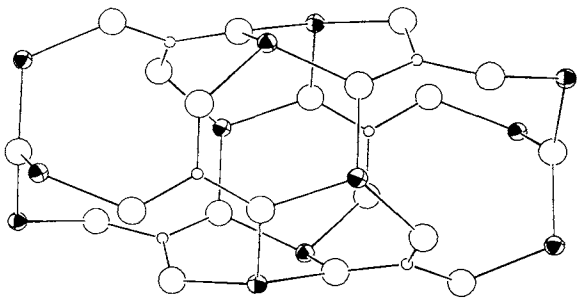

Fig. 1. ORTEP plot of the cage configuration in $Zn_4O(BO_3)_2$ viewed perpendicular to [111], showing the fused three- and five-membered rings. B: small empty circles; Zn: filled circles; O: large empty circles. Atom radii are arbitrary.

sional network of channels (Fig. 2). These channels propagate in the crystallographic [100], [010], and [001] directions; their estimated diameter is 3.5 Å. Each oxygen atom is bound to three neighbors—two zinc atoms and one boron

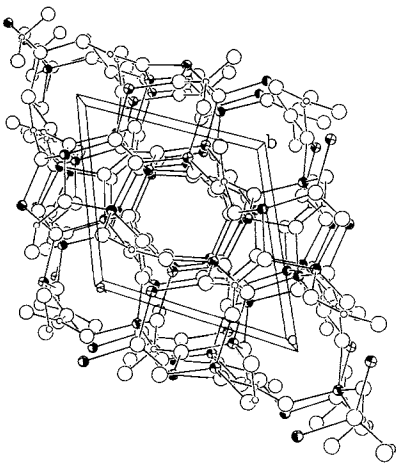

Fig. 2. ORTEP plot of the unit cell of $Zn_4O(BO_3)_2$ viewed down [100], showing the one-dimensional channels. B: small, empty circles, Zn: filled circles; O: large empty circles. Atom radii are arbitrary.

atom for O(1) and O(2) (Fig. 3), and three zinc atoms for O(3) (Table 1). The following average bond lengths [Å] and angles [°] were determined: d(Zn–O) = 1.939(3), d(B–O) = 1.412(4), θ (O–Zn–O) = 109.5(2), and θ (O–B–O) = 120.0(4). The Zn/B/O connectivity in $Zn_4O(BO_3)_2$ results in oxygen-bridged "three-membered" rings (Fig. 3) and "five-membered" rings of nodal (Zn and B) atoms that surround the central cage, although the oxygen atoms in these rings are all three-coordinate as noted above, in contrast to the typical twofold T–O–T′ (T = tetrahedron) connectivity in tetrahedral molecular sieve structures. The connectivity in these fused rings is Zn–B–Zn and Zn–B–Zn–B–Zn, respectively, ignoring oxygen atoms; in other words, each ring contains a Zn–O–Zn linkage, but no B–O–B links. Extending Smith's zeolite-cage nomenclature scheme[18] to this new type of connectivity would result in an 18-nodal-atom cage with the designation $3^6 5^4$ (six three-membered rings and four five-membered rings). These cages are aligned in the crystallographic [111] direction and interlinked, resulting in a three-dimensional microporous network.

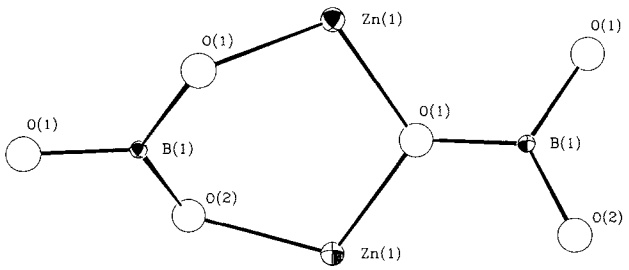

Fig. 3. Detail of the "three-membered" ring in $Zn_4O(BO_3)_2$ built up from tetrahedral ZnO_4 and trigonal-planar BO_3 groups. Selected bond lengths [Å] (standard deviations) in parentheses): Zn(1)-O(1) 1.906(5), Zn(1)-O(1)′ 1.926(5), Zn(1)-O(2) 1.962(5), B(1)-O(1) 1.435(5), B(1)-O(2) 1.367(7).

In summary, we have prepared and characterized a new, neutral-framework zincoborate structure containing a novel network of small channels and cavities. Typically, the product was a powder, but the crystal structure could be elucidated by ab initio methods from laboratory X-ray data, indicating the power of current diffraction software techniques. Further synthetic work is now in progress to determine if other novel, open structures containing tricoordinate

boron atoms as framework species can be prepared. The presence of oxygen-atom vacancies in the framework is also notable, and may facilitate substitution reactions with the Zn/B/O framework itself.

Experimental Procedure

Synthesis: The hydrothermal reaction (sealed teflon pouch, 200 °C, 4 d, pH ca. 8.5) of 3.814 g of borax ($Na_2B_4O_7 \cdot 10H_2O$), 3.440 g of 4 M NaOH solution, 6.43 g of $Zn(NO_3)_2$, and 10 mL of water resulted in a highly crystalline, white powder, which could be indexed "by hand" on a rhombohedral basis with approximate lattice constants of $a = 9.910$ Å and $\alpha = 48.62°$ (hexagonal setting: $a \approx 8.160$ Å, $c \approx 26.156$ Å). The systematic absences of the powder data (rhombic setting: *hhl*, $l = 2n$; *hhh*, $h = 2n$) indicated space groups $R3c$ or $R\bar{3}c$, and no extra lines were left unindexed. The powder was tested for nonlinear optical activity by a powder-second-harmonic-generation (PSHG) test [10] which gave a null response, indicating that the material probably crystallizes in centrosymmetric space group. The space group $R\bar{3}c$ (No. 167) was thus assumed for this material and confirmed by the successful course of the structure refinement. Thermogravimetric analysis indicated no weight loss for this material below 600 °C.

Structure Determination: The crystal structure of $Zn_4O(BO_3)_2$ was solved by ab initio methods from laboratory X-ray powder data [11,12,13]. High-resolution data were collected for a flat-plate sample of $Zn_4O(BO_3)_2$ over 12 h on a Scintag PAD-X automated diffractometer (θ-θ geometry, $16° < 2\theta < 100°$, step-size 0.02°). Optimal estimates of the individual reflection intensities were extracted by a profile-fitting method invented by Pawley [14] and developed by Le Bail [15]. The appropriate "profile" parameters were refined by least-squares fitting, and the intensities themselves (with respect to the $Cu_{K\alpha 1}$ wavelength) were optimized by an iterative procedure [15] using the program GSAS [16]. A total of 186 structure-factor-moduli ($F_{hkl} > 0$) were obtained from the data and corrected for Lorentz, polarization, and multiplicity effects, the maximum possible number of F_{hkl} values observable within the $(\sin\theta)/\lambda$ limit was 230. These F_{hkl} values were used to develop a direct-methods solution (software: SHELXS-86 [17]; 335 triplet-phase-relations, 7 negative-quartet-phase-relations generated) for the crystal structure of $Zn_4O(BO_3)_2$. Careful examination of the direct methods results indicated a plausible tetrahedral fragment (eventually atoms Zn(1) and O(1)), and the model was developed further by placing the two remaining tetrahedral vertices about the center of this fragment and assuming reasonable Zn–O bond distance/angle parameters. These two ZnO_4 vertices (O(2) and O(3)) were both evidently on crystallographic special positions (see Table 1) and were constrained as such. These four atomic positions were used as the starting model for a conventional Rietveld refinement against the X-ray powder data. The Rietveld refinement (program: GSAS) progressed smoothly, and profile and atomic parameters were progressively added to the model as variables in the normal way. A five-parameter pseudo-Voigt function was used to describe the X-ray line-shape and the variation of its width as a function of the scattering angle; a correction for preferred orientation (direction [111]) was allowed to vary during the refinement. At the end of the initial refinement, a difference Fourier synthesis identified one distinct peak at roughly (0.74, 0.75, $\frac{1}{4}$) which was a chemically reasonable site for a boron atom. Bond-length restraints were applied to this B-atom site (d(B–O) = 1.43(2) Å) to assure a stable convergence of the positional parameters of the boron atom. Assuming full occupancy for all five atom sites results in a unit-cell stoichiometry of $Zn_{12}B_6O_{22}$ whose charge does not balance (apparent charge = −2). Because no extra-framework sites were apparent from Fourier maps, the fractional occupancy factors for the oxygen atoms were refined. Those for O(1) and O(3) refined to values near to unity (1.00(2) and 1.08(3), respectively), while that of O(2) refined to a value of 0.84(2). The fractional occupancy of O(2) was then fixed at 0.833, and those for O(1) and O(3) were set to 1.0, giving a charge-neutral unit-cell content of $Zn_{12}B_6O_{21}$ or $Zn_4O(BO_3)_2$. Refining this model resulted in a satisfactory convergence to final agreement values of $R_p = 0.109$ and $R_{wp} = 0.142$, as defined in Table 3. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-56997, the names of the authors, and the journal citation.

Table 3. Crystallographic data for $Zn_4O(BO_3)_2$.

empirical formula	$Zn_4O_7B_2$
M_r	384.37
crystal form	white powder
crystal system	rhombohedral
$a = b = c$ [Å]	9.9115(4)
$\alpha = \beta = \gamma$ [°]	48.602(1)
V [Å^3]	502.61
Z	3
space group	$R\bar{3}c$ (No. 167)
T [°C]	25(1)
$\lambda(Cu_{K\alpha})$ [Å]	1.54178
ρ_{calc} [g cm^{-3}]	3.81
refinement method	X-ray Rietveld refinement
software	GSAS
extinction correction	none applied
absorption correction	none applied
data range	$16 \le 2\theta \le 100°$
number of data	4198 powder data points
parameters (reflections)	31 (191)
R_p [a]	0.109
R_{wp} [b]	0.142

[a] $R_p = \sum|y_o - Cy_c|/\sum|y_o|$. [b] $R_{wp} = [\sum w(y_o - Cy_c)^2/\sum wy_o^2]^{1/2}$; C is a scaling factor.

Synthesis of the Mono(Dewar Benzene) Isomer of [1.1]Metacyclophane**

By *Geerlig W. Wijsman, Daniël S. van Es, Willem H. de Wolf,* and *Friedrich Bickelhaupt**

Small, strained cyclophanes with nonplanar benzene rings are of great interest because of their unusual structure and reactivity. In this respect the question of the extent of aromaticity in such compounds is particulary important.[1–3] In the series of simple metacyclophanes the borderline for stability at room temperature is found between [4]metacyclophane

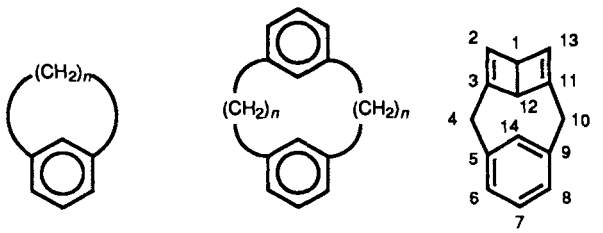
(**1a**), which can only be trapped as a short-lived intermediate,[1,4] and [5]metacyclophane (**1b**).[1,5] In contrast, [2.2]metacyclophane (**2b**)[6,7] is much more stable and was first reported almost one hundred years ago. We were interested in investigating whether [1.1]metacyclophane **2a**, the smallest compound in this series, can be synthesized ; **2a** can be considered a [5]metacyclophane derivative, but it may be more strained than **1b** because of the additional rigidity imparted by the aromatic ring in the bridge. Although we have not yet been successful in synthesizing **2a**, we report here on a crucial step en route: the preparation of the also quite strained mono(Dewar benzene) isomer **3** (systematic name: tetracyclo[9.1.1.1^{5,9}.0^{3,12}]tetradeca-2,5,7,9(14),11(13)-pentaene) and some of its reactions.

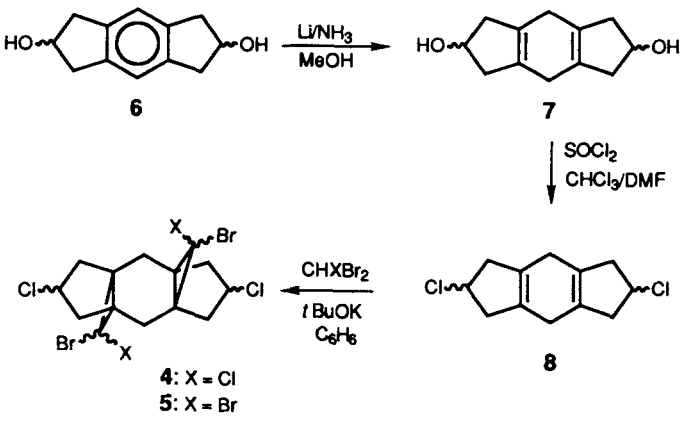


1a: $n = 4$
1b: $n = 5$

2a: $n = 1$
2b: $n = 2$

3

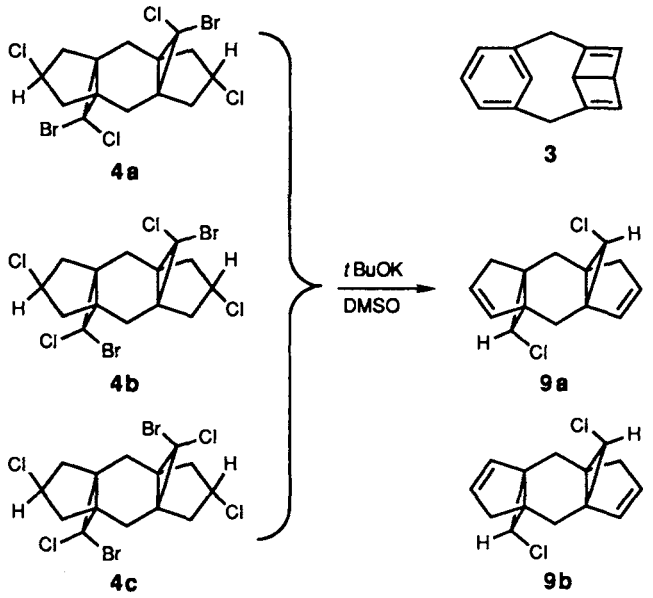
In analogy to the successful syntheses of the [*n*]metacyclophanes **1**,[1,4,5] we attempted to prepare **2a** by the fourfold elimination of HX from bispropellane **4**, which in turn was obtained in three steps: Birch reduction of **6**[8] gave **7**, subsequent conversion provided dichloride **8**, and double addition of bromochlorocarbene yielded **4**.



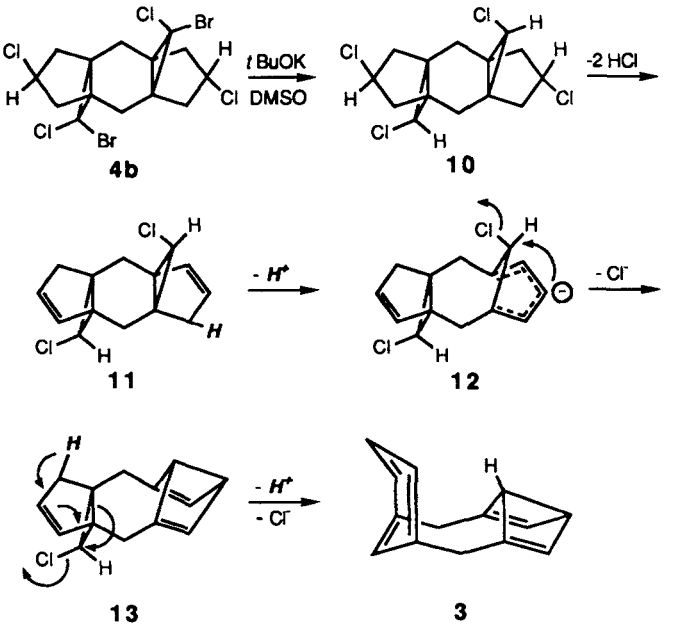
4: X = Cl
5: X = Br

Compounds **4**–**8** are mixtures of stereoisomers. In the analogous reaction of **8** with dibromocarbene to furnish **5**, one of the stereoisomers was isolated in crystalline form; its structure was determined by X-ray crystallography[9] to be that of **5a** (the tetrabromo analogue of **4a**). It was thus possible to assign the structures of the other isomers of **5**, and also of **4**, by comparison of the ^{1}H NMR spectra.

When a solution of the isomeric mixture **4** in DMSO was treated with potassium *tert*-butoxide at room temperature, compounds **9a,b** and **3** were formed in addition to a yellow polymer. Unfortunately, purification of the slightly stable metacyclophane **3** was quite difficult. Various methods of purification were attempted; **3** was finally obtained only 80% pure by column chromatography and recrystallization. It has not yet been possible to remove the remaining **9a,b**. The structure of **3** as a Dewar benzene isomer of the expected **2a** was established by NMR spectroscopy, mass spectrometry, and its chemical transformations.



The ^{1}H NMR signals (400 MHz, [D$_8$]THF) are especially instructive for the structure determination of **3**; the chemical shifts of the signals indicate the presence of a 1,3-disubstituted benzene ring ($\delta = 7.14$ and 6.82, $^3J(H,H) = 7.3$ Hz, A_2B system; $\delta = 7.24$, br. s) with a normal aromatic ring current, a Dewar benzene ($\delta = 5.88$, 3.38, 2.13!), and a benzylic methylene bridge ($\delta = 4.03$, 2.95, $^2J(H,H) = 16.5$ Hz, AB system). The ^{1}H NOE and ^{13}C NMR spectra are also in accord with the proposed structure. The signal of H12 on the Dewar benzene unit ($\delta = 2.13$) is very informative. Its unusual chemical shift can be explained by the strong shielding of the aromatic ring, which proves that the central eight-membered ring occurs in the chair–boat conformation (Scheme 1). This

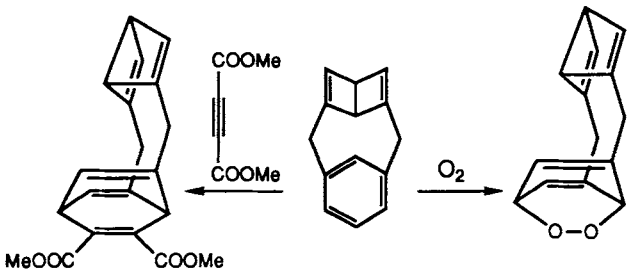


Scheme 1. Postulated reaction sequence for the formation of **3**.

is expected because of the *trans* orientation of the two cyclopropane rings in compound **4**. Interestingly, this conformation plays a minor role in simple [5]metacyclophanes of type **1**, as the crown conformation is usually more stable.[1]

Although the unexpected formation of **3** is not completely understood, the general mechanism can be outlined based on studies of small [*n*]metacyclophanes[1] (Scheme 1). We believe the stereoisomer **4b** to be the most likely precursor for **3** on the basis of the following mechanistic and stereochemical considerations. The reduction of the bromo function in **4b** to give **10** is certainly the initial and fastest step in the reaction sequence;[10] this step must be postulated for the formation of **3** but can also be deduced directly from the structures of **9a,b**. Subsequent double elimination of HCl leads to **11** (or to the regioisomer corresponding to **9b**). Abstraction of an allylic proton and (probably simultaneous) electrocyclic ring opening then provides **12**. Finally, intramolecular S_N2-type substitution with the *anti* chlorine atom as the leaving group generates the Dewar benzene portion of **13**. This sequence has a perfect analogy in the formation of 2,6-tetramethylene(Dewar benzene).[11] In this way the central ring, in **4b** originally a six-membered ring, is expanded into a seven-membered ring in **13**. The conditions are then met for the aromatization of the propellane system of **13** to give **3**, a step known from the formation of [5]metacyclophane (**1b**). The *syn* position of the chlorine atom relative to the five-membered ring is important for the smooth transformation.[1,4]

The high strain energy of **3** is evident from its reactivity. The compound is not stable at room temperature for very long. The strain in **3**, as in **1b**,[1,12] is reduced when the compound serves as a diene in Diels–Alder reactions (Scheme 2). This reaction proceeds very quickly with strong



14 **3** **15**

Scheme 2. Diels–Alder reactions with **3** as the diene.

dienophiles like maleic anhydride and tetracyanoethene; the reaction with dimethyl acetylenedicarboxylate lasted about one day and provided adduct **14**, which was isolated in pure form and characterized by NMR spectroscopy and high-resolution mass spectrometry (HRMS). Compound **3** reacts with the oxygen in air to give endoperoxide **15**. Although the reaction is accelerated by irradiation, it is not certain if sensitization plays a role.

We have tried to aromatize the Dewar benzene portion of **3** thermally and photochemically in order to obtain the parent compound **2a**; these experiments have not been successful so far but have led to polymeric products.

Experimental Procedure

Compounds **7**[13] and **8**[14] were prepared according to known methods.

4: To a cooled (0 °C) solution of **8** (0.45 g, 2.0 mmol) and $CHBr_2Cl$ (2.46 g, 12 mmol) in anhydrous benzene (20 mL) under nitrogen was added *t*BuOK (1.33 g, 12 mmol) over 0.5 h. The reaction mixture was stirred for another 1 h and then poured into a cold water/ether mixture. The resulting precipitate which was removed by filtration was composed primarily of stereoisomers **4a–c**. The organic phase was treated again with $CHBr_2Cl$ and *t*BuOK. A standard workup provided a total of 547 mg **4** (1.14 mmol, 57%), probably a mixture of all ten possible stereoisomers of **4**. **4a–c**: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 4.29 (m, 2H; CHCl), 3.01–2.87 (m, 4H), 2.48–2.24 (m, 4H), 2.22 (s, 4H (**4c**)), 2.18 (AB system, 4H, δ_A = 2.23, δ_B = 2.13; ^2J(H,H) = 14 Hz (**4b**)), 2.15 (s, 4H (**4a**)); HR-MS: $C_{14}H_{14}{}^{79}Br^{81}Br^{35}Cl_3{}^{37}Cl$ ($M^{+\cdot}$) calcd.: *m/z* 483.8167, found: *m/z* 483.816 ± 0.002.

3: To a solution of **4** (173 mg, 0.36 mmol) in anhydrous DMSO (35 mL) at room temperature under nitrogen was added *t*BuOK (3.6 mmol) over 3 h. The reaction mixture was stirred for another 0.5 h and then poured into cold water/pentane. The aqueous phase was extracted with pentane five times. The combined pentane phases were washed with water, dried ($MgSO_4$), concentrated, and chromatographed (Al_2O_3, activity II-III eluting with pentane). **9a,b** could not be removed by chromatography but could be partially removed by multiple recrystallizations from pentane. **3**: ^{1}H NMR (400 MHz, [D_8]THF): δ = 7.24 (br. s, 1H; H 14), 7.14 (t, ^3J(H,H) = 7.3 Hz, 1H; H7), 6.82 (d, ^3J(H,H) = 7.3 Hz, 2H; H6/8), 5.88 (br. s, 2H; H 2/13), 3.49 (AB system: δ_A = 4.03, δ_B = 2.95, ^2J(H,H) = 16.5 Hz, 4H; H4/10), 3.38 (br. s, 1H; H1), 2.13 (br. s, 1H; H12); ^{13}C NMR (50.29 MHz, [D_8]THF): δ = 161.5 (s; C3/11), 149.1 (d, J(C,H) = 155 Hz; C14), 143.3 (s; C5/9), 131.1 (d, J(C,H) = 170 Hz; C2/13), 129.2 (d, J(C,H) = 160 Hz; C7), 125.3 (d, J(C,H) = 161 Hz; C6/8), 54.7 (d, J(C,H) = 152 Hz; C12), 42.4 (d, J(C,H) = 156 Hz; C1), 37.7 (t, J(C,H) = 129 Hz, C4/10); HR-MS: $C_{14}H_{12}$ ($M^{+\cdot}$) calcd.: *m/z* 180.0939, found: *m/z* 180.092 ± 0.001.

Diels–Alder reactions: The reactions were conducted in an NMR tube. A solution of **3** in $CDCl_3$ was treated with a small excess of the dienophile, and the reaction was followed by ^{1}H NMR spectroscopy. Products **14** and **15** could be purified by column chromatography (silica gel or alumina, eluting with pentane/ether). **14**: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 6.59 (ddd, ^3J(H,H) = 5.6 Hz, ^4J(H,H) = ^4J(H,H) = 2 Hz, 2H), 6.49 (d, J(H,H) = 2 Hz; 2H(Dewar benzene)), 4.83 (t, ^3J(H,H) = 5.6 Hz, 1H), 4.73 (t, ^4J(H,H) = 2 Hz, 1H), 3.79 (s, 3H; Me), 3.76 (s, 3H; Me), 3.60 (m, 1H), 3.49 (m, 1H), 3.13 (AB system with a further coupling: δ_A = 3.26 (d), δ_B = 3.00 (br. s), ^2J(H,H) = 15.8 Hz, ^4J(H_A,H) = 2 Hz, 4H); ^{13}C NMR (50.29 MHz, $CDCl_3$): δ = 166.2 (s), 166.0 (s), 156.1 (s), 153.3 (s), 147.5 (s), 145.6 (s), 139.0 (d, J(C,H) = 172 Hz), 136.1 (d, J(C,H) = 175 Hz), 56.3 (d, J(C,H) = 145 Hz), 52.2 (q, J(C,H) = 147 Hz), 52.1 (d, J(C,H) = 147 Hz), 52.0 (q, J(C,H) = 147 Hz), 48.1 (d, J(C,H) = 145 Hz), 43.4 (d, J(C,H) = 161 Hz), 33.0 (t, J(C,H) = 129 Hz); HR-MS: $C_{20}H_{18}O_4$ ($M^{+\cdot}$) calcd.: *m/z* 322.1205, found: *m/z* 322.121 ± 0.001.

15: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 6.62 (ddd, ^3J(H,H) = 5.7 Hz, ^4J(H,H) = ^4J(H,H) = 2 Hz, 2H), 6.48 (d, ^4J(H,H) = 2 Hz; 2H(Dewar benzene)), 5.11 (t, ^3J(H,H) = 5.7 Hz, 1H), 4.95 (br. s, 1H), 3.62 (m, 1H), 3.56 (br. s, 1H), 3.16 (AB system with a further coupling: δ_A = 3.39 (d), δ_B = 2.93 (br. s), ^2J(H,H) = 16.3 Hz, ^4J(H_A,H) = 2 Hz, 4H); ^{13}C NMR (50.29 MHz, $CDCl_3$): δ = 154.6, 151.7, 140.2, 131.5, 79.6, 72.1, 52.1, 43.7, 32.9; HR-MS: $C_{14}H_{12}O_2$ ($M^{+\cdot}$) calcd.: *m/z* 212.0837, found: *m/z* 212.084 ± 0.001.

A Sulfide-Linked Oligonucleotide Analogue with Selective Hybridization Properties**

By *Bin Meng, Stephen H. Kawai, Daguang Wang, George Just,* Paul A. Giannaris,* and *Masad J. Damha**

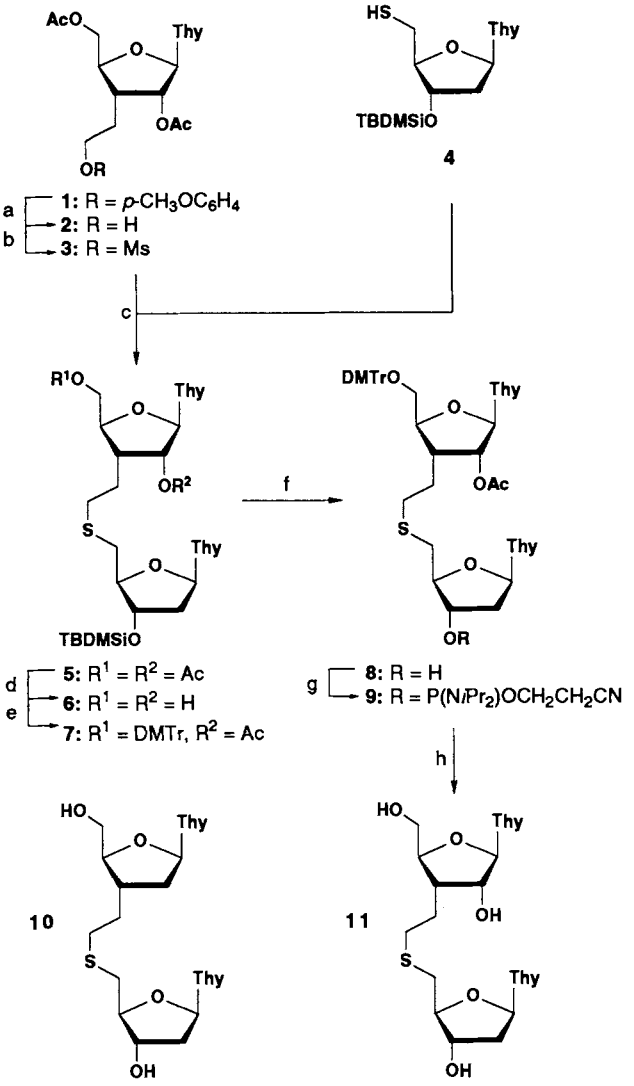
Dedicated to Professor Jean Jacques on the occasion of his 75th birthday

In response to the instability of DNA and RNA oligomers in vivo as well as problems regarding cellular uptake, a great deal of recent work has been devoted to the development of nucleic acid analogues for use as specific inhibitors of gene expression (the antisense strategy).[1] In addition to oligonucleotides bearing modified phosphodiester groups, a number of antisense systems in which the phosphate group is replaced altogether have been described.[2] Apart from evaluating the suitability of antisense systems as potential therapeutics, the study of their DNA and RNA hybridization properties addresses the fundamental question of the role played by the backbone (sugar–phosphate units in natural strands) in the formation and stabilization of nucleic acid helices.

Our research in the antisense field has focused on oligonucleotide analogues in which phosphodiester groups are replaced by dialkyl sulfide linkages.[3] We chose this modification as it is stable and nonhydrolyzable, and because examination of models suggested that binding to complementary oligonucleotide targets would not be disrupted. In work previously carried out in our laboratory, DNA strands incorporating internucleoside dialkyl sulfides were synthesized and shown to possess enhanced stability towards nuclease degradation. These sulfide-containing strands also exhibited cooperative binding to both fully natural DNA and RNA.[4]

Here, we describe the preparation of a mixed ribo–deoxyribo dinucleoside analogue **11** in which the two furanoses are linked through a thioether group, and the successful incorporation of this compound into DNA. In evaluating the effect of this modification on complexation with complementary natural nucleic acids (DNA, RNA), we were surprised by the marked selectivity of the system for RNA.

Phosphoramidite **9** was synthesized from the 3′-deoxy-3′-(2-hydroxyethyl)ribofuranosylthymine derivative **1**[5] as outlined in Scheme 1. The oxidative removal of the *p*-methoxyphenyl group was effected by treatment with ceric ammonium nitrate (CAN), and followed by mesylation of the resulting alcohol **2**, which afforded the 5′-end of the dimer in 74% yield. The coupling of mesylate **3** and thionucleoside **4**[5] was carried out in *N,N*-dimethylformamide (DMF) employing cesium carbonate (84% yield). The solvent was deoxygenated by saturation with nitrogen over 20 min; this was necessitated by the otherwise rapid oxidation of the thiol to the disulfide under basic conditions. The deacetylation of **5** by ammonia cleanly gave diol **6** in 97% yield. The 5′-hydroxyl function was then selectively protected[6] by a dimethoxytrityl (DMTr) group, and immediately following, the 2′-*O*-acetate group required during the subsequent solid-phase synthesis was reintroduced with acetic anhydride to yield **7** (76% yield). The 3′-silyl ether was cleaved with tetra-*n*-butylammonium fluoride (94%), and the resulting alcohol **8** was treated with 2-cyanoethyl-*N,N*-diisopropylchlorophosphoramidite under standard conditions[7] to yield (68%) the appropriately activated dimer **9** (mixture of P-isomers) for incorporation into DNA.



Scheme 1. Synthesis of phosphoramidite **9**. TBDMSi = *tert*-butyldimethylsilyl. a) CAN/H_2O/MeCN, 0 °C, 30 min (76%); b) MsCl/Et_3N/CH_2Cl_2, 1 h (97%); c) Cs_2CO_3/DMF (84%); d) NH_3/MeOH, 0 °C, 11 h (97%); e) DMTrCl/Et_3N/pyridine, 8 h then Ac_2O (62 equiv) (76%); f) nBu_4NF/THF, 1 h (94%); g) $iPr_2NP(Cl)OCH_2CH_2CN$/Et_3N/CH_2Cl_2, 6 h (72%); h) from **8**, OPC: TFA/MeCN/H_2O then NH_4OH/H_2O.

To confirm that the internucleoside sulfide linkages are stable to enzymatic degradation, triol **11** (prepared from **8** by cleavage of the DMTr group with trifluoroacetic acid (TFA) and deacetylation with ammonium hydroxide during purification with an oligonucleotide purification cartridge (OPC)) was subjected to a number of nucleases. Incubation of **11** with SVPDE, nuclease S_1, nuclease P_1, and CSPDE did to result in any modification of the dimer.[8]

The modified DNA dodecamer **12** (Fig. 1), which incorporates three sulfide-linked ribofuranosylthymine-thymidine dimers **11** ($T_S^{OH}T$), was synthesized by the phosphoramidite method[9] by using standard solid-phase techniques.[10] A fifth bottle containing a 0.08 M solution of **9** in acetonitrile was attached to the DNA synthesizer, and the reaction time

for the tetrazole-mediated coupling of **9** to the growing chain was increased to 10 min. To verify that the sulfides incorporated into the strand are not converted to the sulfoxide or sulfone during the oxidation step of the cycle, a sample of the sulfide dimer was stirred in the reagent I_2/pyridine/THF/H_2O for 15 minutes (30 times longer in the synthetic cycle). Thin-layer chromatography of a mixture of sulfoxide and sulfone dimers obtained with buffered Oxone reagent ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$) clearly demonstrated that no oxidation had taken place. The fully natural DNA strands **13** and **14**, as well as RNA dodecamer **15**, were also prepared by standard solid-phase methods.[11]

Fig. 1. Sequences of oligomers **12**–**15** shown in 5′ to 3′ direction. $T_S^{OH}T$ denotes the sulfide-linked dimers.

The results of thermal denaturation studies[12] are summarized in Table 1. The data clearly indicates that the strands containing $T_S^{OH}T$ dimers can discriminate between complementary DNA and RNA over a wide range of salt concentrations. As expected, cooperative binding between unmodified DNA strands **13** and **14**, and between **13** and natural RNA oligomer **15**, was observed with melting temperatures (T_m) of 55 °C and 52 °C (100 mM NaCl), respectively. In the case of hybridization between the sulfide-containing oligomer **12** and RNA **15**, a melting temperature of 34 °C was measured at the same salt concentration. This corresponds to a decrease in T_m of 6.3 K per sulfide-substitution and indicates that, while weakening the complexation to targeted RNA, the modification still allows for good cooperative binding. However, in the case of complexation between modified oligomer **12** and DNA dodecamer **14**, no cooperative transition was observed over a wide range of salt concentrations.

Table 1. Melting temperatures T_m [°C] and hypochromicities (in parentheses) [a].

c (NaCl) [mM]	**13/14**	**13/15**	**12/14**	**12/15**
10	47 (24)		[b]	19 (10)
100	55 (24)	52 (24)	[b]	34 (10)
210	58 (24)		[b]	39 (12)
910	65 (24)		[b]	40 (12)

[a] Thermal denaturation was carried out in phosphate buffer (pH 7.0) at the indicated NaCl concentrations. Curves were obtained by recording the absorbance at 260 nm (average of 30 readings) at 1 min intervals between 5 and 80 °C and at a rate of 0.5 °C min^{-1}. [b] No observable T_m.

This selectivity is also clearly demonstrated by native-gel hybridization. Mixtures of the complementary oligomers **12** and DNA **14**, **12** and RNA **15**, DNA **13** and DNA **14**, and DNA **13** and RNA **15** were incubated in 30% sucrose solutions containing 10 mM magnesium chloride and then applied to separate lanes of a polyacrylamide gel containing no urea. Oligomers **12** through **15** were also applied individually. After electrophoresis (4 °C/18 h/5 mA) the gel showed bands corresponding to duplexes DNA **13**/DNA **14** and DNA **13**/RNA **15**, as well as that formed between **12** and RNA **15**. Moreover, this latter band migrated much more slowly than either **13**/**14** or **13**/**15**, reflecting the lower charge (three fewer phosphate groups) of the complex **12**/**15**. In contrast, the lane containing the mixture of **12** and DNA **14** showed only the two bands corresponding to the unassociated single strands.

This selectivity exhibited by **12** for RNA is quite surprising; only a few oligonucleotide analogues exist that can discriminate between DNA and RNA, and these systems are very different from the natural structures.[13] DNA is known to be much more flexible than RNA, which manifests itself in the fact that double helices of the latter usually form A-type helices whereas duplex DNA is polymorphic.[14] Thus, one would expect that any modified system that binds to RNA should also complex to DNA. Efforts are presently underway to gain an understanding of this selectivity.

Experimental Procedure

5: Cesium carbonate (549 mg, 1.68 mmol) was suspended in dry, deoxygenated DMF (9 mL), and a solution containing **3** (505 mg, 1.17 mmol) and **4** (479 mg, 1.29) in DMF (14 mL) was added under nitrogen. The reaction mixture was stirred for 1 h, the solvent evaporated, and the residue extracted with dichloromethane and washed with aqueous bicarbonate and water. Chromatography of the crude material over silica gel (1:2.5 EtOAc/hexanes) afforded sulfide **5** (84%). – ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.092 (s, 6H; $SiMe_2$), 0.90 (s, 9H, *t*Bu), 1.60–1.80 (m, 2H; ^{5}H1″), 1.92, 1.93 (2s, 6H; 2 × 5-Me), 2.10, 2.15 (2s, 6H; 2 × CO-Me), 2.18–2.26 (m, 2H, ^{3}H2′), 2.41–2.51 (m, 1H; ^{5}H3′), 2.51–2.70 (m, 2H; ^{5}H2″), 2.75 (A of ABX, 1H; ^{3}H5′A), 2.78 (B of ABX, 1H; ^{3}H5′B), 3.94 (q, 1H; ^{5}H4′), 4.10 (dt, 1H; ^{3}H4′), 4.28–4.37 (m, 3H; ^{3}H3′, ^{5}H5′), 5.45 (d, 1H; ^{5}H2′), 5.61 (s, 1H; ^{5}H1′), 6.21 (t, 1H; ^{3}H1′), 7.30, 7.56 (2s, 2H; 2 × H6), 9.01 (br s, 2H; 2 × NH); J(^{5}H1′, ^{5}H2′) = 0 Hz, J(^{3}H1′, ^{3}H2′) = 6.6, J(^{5}H2′, ^{5}H3′) = 6.0, J(^{5}H3′, ^{5}H4′) = 7.5, J(^{3}H3′, ^{3}H4′) = 4.5, J(^{3}H4′, ^{3}H5′A) = 5.7, J(^{3}H4′, ^{3}H5′B) = 4.9, ^2J(^{3}H5′A, ^{3}H5′B) = –13.8; ^{13}C NMR (75.4 MHz, $CDCl_3$) δ = 11.11 (2 × 5-Me), 17.12 (Si-*C*-Me_3), 20.22, 20.32 (2 × CO-*Me*), 24.31 (^{5}C1″), 25.21 (Si-Me_2, Si-C-*Me*$_3$), 30.50 (^{5}C2′), 33.49(^{3}C5′), 39.87 (^{3}C2′), 40.16 (^{5}C3′), 62.88 (^{5}C5′), 73.01 (^{3}C3′), 76.67 (^{5}C2′), 81.69, 84.54, 85.18 (^{3}C1′, 2 × C4′), 91.27 (^{5}C1′), 110.25, 110.70 (2 × C5), 135.35, 135.62 (2 × C6), 149.82, 150.10 (2 × C2), 163.79, 163.87 (2 × C4), 169.21, 169.94 (2 × *C*O-Me); FAB-MS glycerol/NBA (nitrobenzyl alcohol)): *m/z* 725 (MH^+, 7.5%), 599 (MH^+ – ThyH, 52), 473 (MH^+ – 2 ThyH, 12), 399 (33), 341 (57), 295 (17), 213 (100).

8: FAB-MS: *m/z* 871 (MH^+, 59%), 745 (MH^+ – ThyH, 28), 551 (MH^+ – DMTrOH, 87); HRMS (FAB, glycerol): *m/z* calcd. for $C_{45}H_{50}N_4O_{12}S$: 870.31459, found: 870.31421.

9: FAB-MS: *m/z* 1072 (MH^+, 10%), 946 (MH^+ – ThyH, 8), 853 (MH^+ – $iPr_2NP(OH)OCH_2CH_2CN$, 5), 768 (MH^+ – DMTr, 9) 551 (16), 457 (100); ^{31}P NMR (81.0 MHz, $CDCl_3$) δ = 148.94, 149.31.

12–**15**: DNA oligomers were synthesized with an Applied Biosystems DNA/RNA synthesizer (model 381A) employing amidine-protected phosphoramidites and LCAA-CPG (LCAA = long-chain alkyl amine, CPG = controlled pore glass) bearing 3′-terminal deoxyribonucleosides. Oligomers were prepared on a 1.0 μmol scale employing the standard synthesis cycle. In the case of **12**, a 0.08 M solution of **9** was attached to a fifth port on the synthesizer and the coupling time increased to 10 min from the standard 60 s. The coupling efficiency of **9** was routinely >98% as monitored by the release of the DMTr cation. RNA oligomer **15** was prepared by standard means.

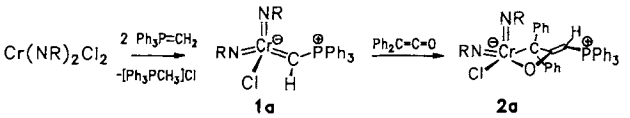
Synthesis of the First Stable 2-Chromaoxetane and its Homologues via α-Phosphonio(methylidene) Complexes of Hexavalent Chromium, Molybdenum, and Tungsten**

By *Jörg Sundermeyer,** *Klaus Weber*, and *Hans Pritzkow*

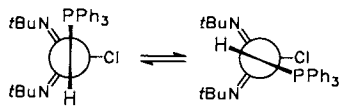
The synthesis of stable organochromium(VI) compounds appeared for a long time to be an inaccessible goal. Only recently have there been promising attempts[1] in this area of research in organometallic chemistry. However, till now neither the synthesis of an alkylidenechromium(VI) complex nor the isolation of 2-chromaoxetanes, that is, of four-membered ring compounds with an oxa-2-metallacyclobutane skeleton have been reported. 2-Metallaoxetanes have been discussed as short-lived intermediates in oxo transfer reactions from reactive oxo complexes such as OsO_4, CrO_2Cl_2, or oxo(porphyrinato) species to olefins.[2] Although these organometallic intermediates have a surprisingly high thermodynamic stability according to quantum mechanical calculations,[3] the synthesis and structural characterization of the electron-deficient metallacycles with a metal center in the highest oxidation state (d^0 electron configuration) remained a particular challenge.[4, 5] These four-membered ring compounds appear to be predestined to decompose into a thermodynamically particularly stable oxo complex and an olefin.[5] We now report on the synthesis and characterization of the first Cr^{VI} complex **1a** containing a formal Cr–C double bond and on the unusual cycloaddition reaction of **1a** and its heavier homologues **1b,c** with diphenyl ketene, which affords the stable compounds **2a–c** containing 2-metallaoxacyclobutane frameworks.

Only recently we proposed higher valent α-phosphonio(methylidene) complexes of molybdenum, tungsten, and rhenium, amongst them also tetrahedral complexes of the type $[M(=NtBu)_2(=CHPPh_3)_2]$ (M = Mo, W), in which four multiple bonds, two each to an anionic carbon and nitrogen atom, are present.[6] Complexes of this type have very reactive (because strongly polar) metal–carbon bonds, which even react spontaneously with thermodynamically stable molecules like CO and CO_2, a reactivity that is typically lacking for the d^0 alkyl- and aryloxo and alkyl- and arylimido complexes of the sixth and seventh group. Surprisingly, $[Cr(=NtBu)_2Cl_2]$,[7] the relatively easily reducible *tert*-butylimido derivative of chromyl chloride, can also be transformed into the hitherto unknown α-phosphonio(methylidene)chromium(VI) complexes through the transylidation reaction with two equivalents of the ylides $R_3P=CH_2$ (R = alkyl, aryl) (see Scheme 1). The example presented here



Scheme 1. Synthesis of **1a** and **2a**. R = *t*Bu.

(**1a**) is isoelectronic to the hitherto unknown alkylidene complexes of formally hexavalent chromium containing the binding unit $[Cr=CHSiR_3]$. Compound **1a** displays significant spectroscopic characteristics of alkylidene complexes; for instance, the NMR signals of the metal-bound α-CH function are shifted downfield ($\delta_C = 200.1$, $\delta_H = 11.84$) relative to the signals of the free, unmetalated phosphorus ylide $Ph_3P=CH_2$ ($\delta_c = -4.2$, $\delta_H = 0.77$).[8] The pronounced Cr–C double bond character is also reflected in the high barrier for rotation about this bond axis, which renders the signals of the *tert*-butylimido groups inequivalent at the low-temperature limit (Scheme 2). The free energy of activation for the hindered rotation was calculated from the coalescence temperature of these signals in the variable-temperature ^1H NMR spectra. The value of $\Delta G^{\ddagger}_{(336K)} = 75\ kJ\,mol^{-1}$ ($17.9\ kcal\,mol^{-1}$) lies within the range of $\Delta G^{\ddagger} = 15$–$18\ kcal\,mol^{-1}$ determined for the alkylidene molybdenum and tungsten complexes of the Schrock type.[9]



Scheme 2. Newman projection of two conformations obtained by rotation about the Cr–C bond.

Compound **1a**, like the derivatives of the heavier homologues **1b** (M = Mo) and **1c** (M = W), can be used as complex-modified C-nucleophiles for selective C–C coupling or C–O cleavage reactions. Phosphorus ylides that are not sub-

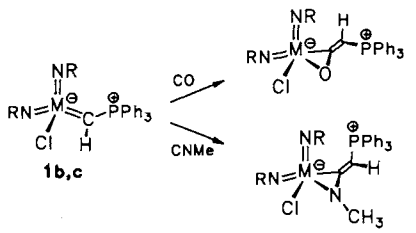
[**] Organometallic Imido Complexes—Higher Valent Derivatives of the d-Metal Acids, Part 7. This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Universitätsbund Würzburg. We thank Prof. Dr. H. Werner for his kind support and the company H. C. Starck, Berlin, for gifts of chemicals. Part 6: J. Sundermeyer, J. Putterlik, H. Pritzkow, *Chem. Ber.* **1993**, *126*, 289-296.

stituted by a metal do not typically undergo such reactions. Thus carbon monoxide and isonitriles insert diastereoselectively to form η^2-acyl or iminoacyl complexes (Scheme 3) that were characterized by crystallography,[10] whereas for lactones a C–O bond in the ring is cleaved.[11]



Scheme 3. Insertion of CO and CNR into **1b** and **1c**.

We present here the result of the reaction with diphenyl ketene as an unusual example of the reactivity of **1a–c**. In all three reactions neither the expected product of the usual [2 + 2] cycloaddition **B** (see Scheme 4) nor the resonance-stabilized enolate complex **C**, conceivably formed by a simple insertion reaction, was isolated. Instead on the evidence of the typical ^{183}W satellites in the ^{13}C NMR spectrum of **2c**, a bond between the CPh_2 unit and the tungsten center can be deduced without doubt. The lack of a typical ν(C=O) stretching band in the IR spectrum of the spectroscopically almost identical products **2** (Table 1) suggested that the common structural element must be an [M-O-C-C] four-membered ring with an exocyclic α-phosphonio(methylidene) unit. This assumption was confirmed by the determination

Table 1. Selected spectroscopic data of the complexes **2**. The NMR spectra of **2a** were recorded in CD_2Cl_2 at 190 K, those of **2b,c** in C_6D_6 at 298 K.

of the single-crystal structure of **2b** (Fig. 1). The metal atom of **2b** lies at the center of a distorted square-pyramidal coordination polyhedron and is part of a four-membered metallacycle that forms one edge of the base. The four-membered ring is folded along the O–C2 vector by 39.6°. Another structural characteristic is the trigonal-planar coordination of the carbocationic center C1 (sum of the angles 359.6°), whose charge is compensated by the + M effects of the O atom and the conjugated carbanionic center C3. The C1–O distance is comparable to the corresponding distance in enols. In contrast to the characteristics of the d^0-2-metallaoxetane [Mo(NAr)(O*t*Bu)$_2$(η^2-(*O*,*C*)OCH(C_6F_5)CH*t*Bu)], a rather unstable complex at 25 °C reported only recently by Schrock et al.,[5] the bond lengths determined here for **2b** indicate a stabilization of the four-membered ring, which is expressed in the resonance form **D** (Scheme 4). Since

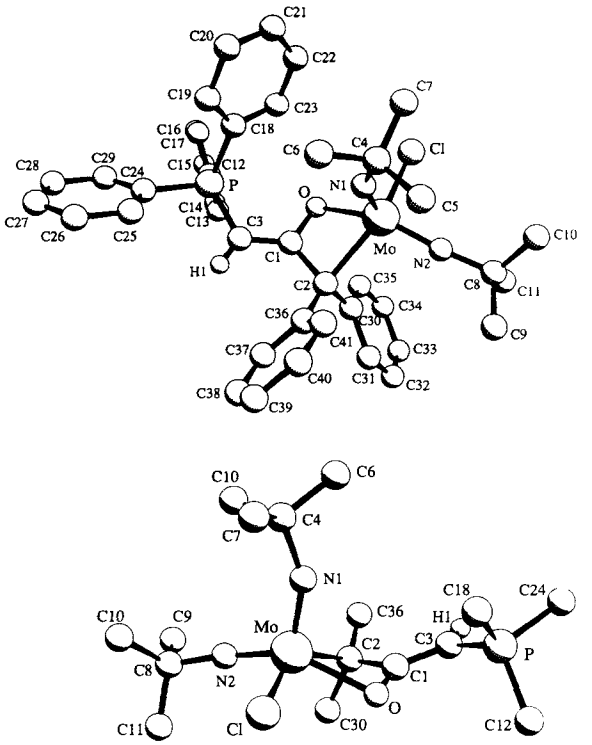

Fig. 1. Schakal representation of the molecular structure of **2b**. For clarity in the view shown at the bottom, only the *ipso* C atoms of the five phenyl groups are shown. 2b does not tend to decompose thermally into $[Ph_3PCH{=}C{=}Ph_2]^+[MoO(NtBu)_2Cl]^-$, it would be an interesting challenge also to attempt the synthesis of 2-metallaoxetane by addition of a polarized [C=C] bond of an allenylphosphonium ion to a polar, nucleophilic [M=O] function.

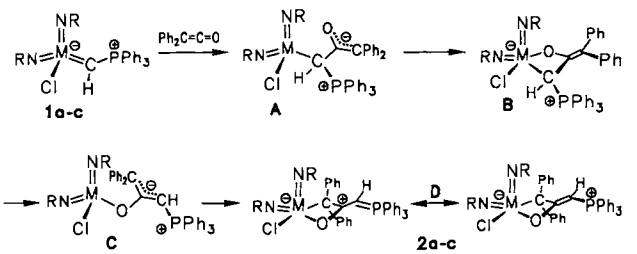

Scheme 4. Plausible mechanism for the formation of **2a–c** and their resonance forms. R = *t*Bu.

The complexes **2** show a stereochemically dynamic behavior in solution. Low-temperature NMR studies on **2a–c** confirm that axial and basal imido functions exchange rapidly. Even at 190 K the equivalence of these ligands observed in the ^{1}H and ^{13}C NMR spectra cannot be lifted.

A plausible mechanism for the formation of **2a–c** seems to be a nucleophilic attack of the α-C atom in **1a–c** on the

ketene, followed by rearrangement of the betain-like oxallyl intermediate **A** to the zwitterionic enolate species **C**, although none of the intermediates could be isolated or detected by spectroscopic methods (Scheme 4). Crucial for the next M–C bond linkage accompanied by reorganization of the 2-metallaoxetane framework is the formation of the exocyclic, planar α-phosphoniomethylene unit. The reactivity pattern presented here is not restricted to reactive ketenes, but is possible with almost all CO_2 derivatives, including the parent compound, the relatively inert CO_2 itself.[10]

Experimental Procedure

1a: A solution of $[Cr(=NtBu)_2Cl_2]$ [7] (1.00 g, 3.8 mmol) in toluene (50 mL) under an inert atmosphere (argon) at −78 °C was treated with $Ph_3P{=}CH_2$ (2.08 g, 7.5 mmol). After slow warming to room temperature (2 h), the deep violet suspension was stirred for a further 2 h and then filtered through a glass frit covered with dried Celite. After washing the precipitated $[Ph_3P{-}CH_3]Cl$ with toluene, the filtrate was concentrated to 10 mL under reduced pressure and layered with *n*-hexane (30 mL). At −30 °C the dark violet, finely crystalline product precipitated. It was washed with *n*-pentane (20 mL), and any remaining solvent was removed under high vacuum ($<10^{-3}$ mbar). Yield: 1.67 g (93%), m.p. 64 °C (decomp.).

2a–c: **1a**, **1b**, or **1c** (1 mmol) was dissolved in THF (20 mL) and treated with diphenyl ketene (190 μL, 1.1 mmol) at −90 °C. After warming to room temperature (1 h) the mixture was stirred for another 60 min and then filtered over a glass frit covered with dried Celite. The filtrate was concentrated to 5 mL under reduced pressure. After layering with *n*-pentane (20 mL), the crystalline products **2a–c** precipitate. Suitable single crystals of **2b** were grown from methylcyclohexane/THF. **2a**: orange crystals, 75%, decomp. >75 °C; **2b**: beige crystals, 90%, decomp. >119 °C; **2c**: light beige crystals, 95%, decomp. >151 °C.

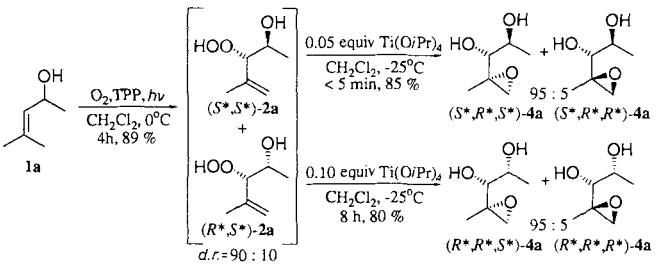
Titanium-Catalyzed Epoxy–Hydroxylation of Allylic Alcohols: A Convenient Diastereoselective Synthesis of Epoxy Diols**

By *Waldemar Adam** und *Bernd Nestler*

The titanium(IV)-catalyzed epoxidation of allylic alcohols by *tert*-butyl hydroperoxide (TBHP) represents a convenient route to synthetically valuable epoxy alcohols.[1] When allylic hydroperoxides are employed as substrates,[2] which are readily accessible through the ene reaction of singlet oxygen with olefins, the olefins are converted into epoxy alcohols without the need of a separate oxygen atom donor. In this direct epoxy–hydroxylation of olefins the allylic hydroperoxide generated in situ serves a double role; namely, it first acts as an oxygen donor, and after oxygen transfer the resulting allylic alcohol functions as an acceptor. We report here that this useful methodology can be extended to the direct epoxy–hydroxylation of the chiral allylic alcohol **1a** (Scheme 1) to afford the highly regio- and diastereoselective epoxy diol **4a**, for which the hydroperoxy homoallylic alcohol **2a**[3] is a key intermediate. The advantage of this epoxy–hydroxylation is that up to four successive chiral centers can



Scheme 1. Stereoselective transformation of the allylic alcohol **1a** into the epoxy diol **4a**. TPP = tetraphenylporphyrin. The asterisks on *R* and *S* indicate that they are relative configurations.

be constructed with predictable configuration, as illustrated for the allylic alcohol **1b** [Eq. (a)].

The fast rate with which the epoxidation proceeds is remarkable, especially since α, β-unsaturated diols are general-

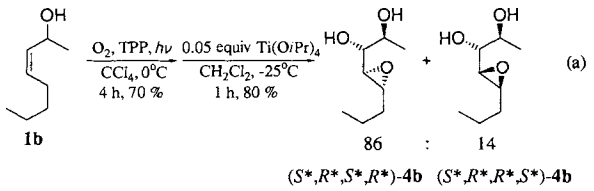
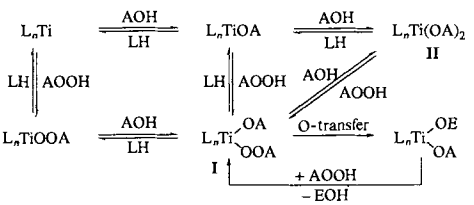
[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347: Selektive Reaktionen Metall-aktivierter Moleküle) and the Fonds der Chemischen Industrie.



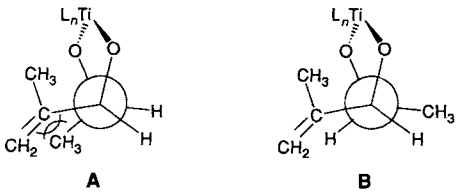
ly poor substrates for titanium metal-assisted epoxidations.[4] For example, when the epoxidation of the allylic diol (*S**,*S**)-**3a** (not shown), derived from the hydroperoxide (*S**,*S**)-**2a**, was attempted with TBHP in the presence of $Ti(OiPr)_4$, even after three days no epoxy diol **4a** was observed although ten times as much catalyst was employed as in the direct transformation of the hydroperoxide (*S**,*S**)-**2a**.

This large difference in reactivity can be rationalized in terms of the proposed mechanism[5] for such metal-catalyzed reactions (Scheme 2). The first steps consist of reversible formation of the complex **I**, in which both the allylic substrate **3** (AOH, oxygen acceptor) and the hydroperoxide **2** (AOOH, oxygen donor) are bound to the titanium by successive ligand exchanges. Irreversible oxygen transfer in this "loaded complex" **I** then yields the coordinated epoxide **4**. A favorable kinetic feature is the fact that the hydroperoxide **2** (AOOH) is converted by oxygen atom transfer directly in the coordination sphere of the titanium to the allylic substrate **3** (AOH). Hence only replacement of epoxy diol **4** (EOH) by ligand exchange with fresh hydroperoxide **2** (AOOH) is necessary to regenerate the loaded complex **I** and thereby complete the catalytic cycle. For the tridentate hydroperoxide **2** such exchange is expected to be fast, but if the epoxidation of diol **3** is performed with TBHP instead of hydroperoxide **2** as oxygen donor, the bidentate TBHP is ineffective in substituting the tridentate epoxy diol **4** and, as expected, the titanium(IV)-catalyzed epoxidation is slower than the direct transformation of hydroperoxide **2**. Moreover, since small amounts of $Ti(OiPr)_4$ are usually employed in such conversions with TBHP, it is reasonable to assume that all coordination sites of the catalyst are occupied by the bidentate diol **3a** (**II** in Scheme 2), and formation of the loaded complex **I** should, therefore, be significantly more difficult.



Scheme 2. Proposed mechanism[5] for metal-catalyzed epoxidations. AOH = vinylic diol **3**, AOOH = hydroperoxide **2**, EOH = epoxy diol **4**.

The substantial rate difference observed in the epoxy–hydroxylation of the diastereomeric hydroperoxy alcohols (*S**,*S**)-**2a** and (*R**,*S**)-**2a** is of mechanistic interest and of use for synthesis. Whereas only minutes sufficed for complete reaction when (*S**,*S**)-**2a** was treated with catalytic amounts of $Ti(OiPr)_4$, the diastereomer (*R**,*S**)-**2a** required hours under comparable conditions (Scheme 1); nonetheless, in both cases the epoxy diols were obtained with high diastereoselectivity (*d.r.* = 95:5). Presumably the allylic alcohols (*S**,*S**)-**3a** and (*R**,*S**)-**3a** are bound with unequal strength at the titanium metal site in the loaded complex **I**. Indeed, this was confirmed through control experiments. After the addition of an equimolar amount of $Ti(OtBu)_4$ to a solution of (*S**,*S**)-**3a**, the signals of the CHO*H* protons in the ^1H NMR spectrum completely vanished. This implies that (*S**,*S**)-**3a** was completely coordinated to the metal. In contrast, under identical conditions only small amounts of (*R**,*S**)-**3a** were bound to titanium, as indicated by the fact that the corresponding CHO*H* resonance signals remained unchanged, that is, they correspond to those in the free diol. These different abilities for coordination of both diastereomers (*S**,*S**)-**3a** and (*R**,*S**)-**3a** apparently arise from unfavorable steric interactions between the isopropenyl and the methyl group, which occur for the (*R**,*S**)-configurated diol (structure **A**) but not for the (*S**,*S**)-configurated diol (structure **B**).



Besides these mechanistic implications, the different reactivity of the diastereomeric hydroperoxides in the titanium(IV)-catalyzed epoxy–hydroxylation is also significant for synthesis. For example, for the kinetic resolution of diastereomeric mixtures of **2a**, the latter are conveniently obtained through the photooxygenation of the chiral allylic alcohol **1a** (Scheme 1). Thus, the allylic alcohol **1a** was transformed diastereoselectively to the epoxy diols (*S**,*R**,*S**)- and (*S**,*R**,*R**)-**4a** (*d.r.* = 95:5) in a one-pot, two-step process simply by adding catalytic amounts of $Ti(OiPr)_4$ to the photooxygenated solution of allylic alcohol **1a** and stopping the reaction after complete consumption of the hydroperoxide (*S**,*S**)-**2a**.

In summary, chiral allylic alcohols can be converted efficiently and diastereoselectivity to epoxy diols by photooxygenation and subsequent titanium(IV)-catalyzed oxygen transfer. In the case of allylic alcohol **1a** as substrate, three successive chiral centers are constructed with predictable configuration, while for substrate **1b** even a total of four chiral centers are fixed. Use of enantiomerically pure allylic alcohols should make optically active epoxy diols accessible, which should in turn serve as useful building blocks in asymmetric synthesis. Significant for mechanistic understanding and preparative applications is the finding that tridentate hydroperoxides are necessary as effective oxygen atom donors in the titanium(IV)-catalyzed epoxidation of bidentate vinylic diols.

Experimental Procedure

To a solution of (*S**,*S**)-**2a** (264 mg, 2.00 mmol) in CH_2Cl_2 (4 mL) was introduced $Ti(OiPr)_4$ (29 μL, 5 mol%) at −25 °C in the presence of molecular sieves (4 Å). After 5 min the reaction mixture was diluted with diethyl ether (4 mL), and water (0.1 mL) was added under vigorous stirring. The mixture was stirred for an additional 30 min, then the solvent was evaporated (18 Torr, 20 °C) and the residue **immediately** purified by column chromatography on silica gel by elution with diethyl ether. This afforded **4a** [(*S**,*R**,*S**):(*S**,*R**,*R**) = 95:5] (224 mg, 85%) as colorless plates, m.p. 71–72 °C.

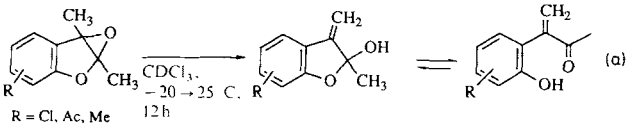
Epoxidation of 2-Methyl-3-phenylbenzofurans with Dimethyldioxirane: A Novel Reversible Valence Isomerization between Labile Benzofuran Epoxides and Quinone Methides, their Rearrangement, Methanolysis, and Cycloaddition Chemistry**

By *Waldemar Adam,* Lazaros Hadjiarapoglou, Karl Peters,* and *Markus Sauter*

2,3-Dimethylbenzofuran epoxides are rather labile compounds[1] which readily rearrange even at about $-20\,^{\circ}C$ by a 1,3-hydrogen migration with the participation of the 3-methyl group to afford mixtures of the hemiacetals and their ring-opened phenols [Eq. (a)]. Other substituents, for example, a 3-phenyl instead of the 3-methyl group, should facilitate the elucidation of the chemistry of these novel benzofuran epoxides. Indeed, epoxidation of the 2-methyl-3-phenylbenzofurans **1** with dimethyldioxirane afforded the expected epoxides **2** or their valence isomeric quinone methides **3** quantitatively, which could be characterized by NMR spectroscopy at $-25\,^{\circ}C$. From the chemical transformations (Scheme 1) it becomes evident that the benzofuran epoxides **2** and the quinone methides **3** coexist through the unprecedented reversible valence isomerization **2** ⇌ **3**.



Reaction of the benzofuran **1a**[2] with dimethyldioxirane (in acetone)[3] at -70 to $-20\,^{\circ}C$ afforded within 4 h quantitatively the hitherto unknown epoxide **2a**. The solvent was removed by distillation at $-25\,^{\circ}C$ to afford **2a** as a red oil. The ^1H NMR [methyl group at $\delta = 1.73$ (s, 3H)] and ^{13}C NMR spectroscopic data (singlets at $\delta = 70.6$ and 96.4) confirm unequivocally the epoxide structure of **2a**. Since the epoxide **2a** itself contains no chromophore to absorb in the visible region, the red color is assigned to the quinone methide **3a**, present in the product mixture by valence isomerization of the epoxide; however, insufficient amounts of **3a** are formed to permit IR and NMR spectroscopic detection. This isomerization is analogous to that of furans to *cis*-enediones, when the former are oxidized with *meta*-chloroperbenzoic acid (MCPBA)[4] or dimethyldioxirane.[5] A related, but irreversible valence isomerization was reported[6] in the rearrangement of 2*H*-chromenes into oxabenzobicyclohexenes.

In solution, the epoxide **2a** is stable at room temperature for at least 24 h, but exposure for more than three days to ambient temperature led to total decomposition into a complex, intractable mixture which consisted of many products. In contrast, heating the epoxide **2a** in the presence of catalytic amounts (ca. 0.1 mol%) of tetraethylammonium bromide in acetone at 40 °C for 8 h yielded benzofuran-2-one **4a** nearly quantitatively.[7]

Reaction of the epoxide **2a** with methanol at 20 °C gave the hemiacetal **5a** (*d.r.* = 50:50) within 30 min, which was isolated in 76% yield after column chromatography as colorless needles (m.p. 102–102.5 °C, Et_2O/petroleum ether).[8] Unlike the corresponding hemiacetals derived from the 3-methyl-substituted benzofuran epoxides,[1, 12] **5a** does not undergo ring opening to give its tautomer **5'a**.

An unexpected reaction of the epoxide **2a** was its cycloaddition with tetracyanoethylene (TCNE) to afford the benzofurofuran **6a** in 96% yield (colorless needles, m.p. 183–184 °C, Et_2O/petroleum ether).[8] The epoxide **2a** reacts with an excess of ethyl vinyl ether at room temperature in two hours to give the adduct **7a**, the product of an inverse Diels–Alder reaction; **7a** was isolated in 86% yield after distillation of the solvent and column chromatography (colorless powder, m.p. 72–73 °C, Et_2O/petroleum ether). Compounds **6a** and **7a** were characterized by X-ray structure analysis (Fig. 1).[9]

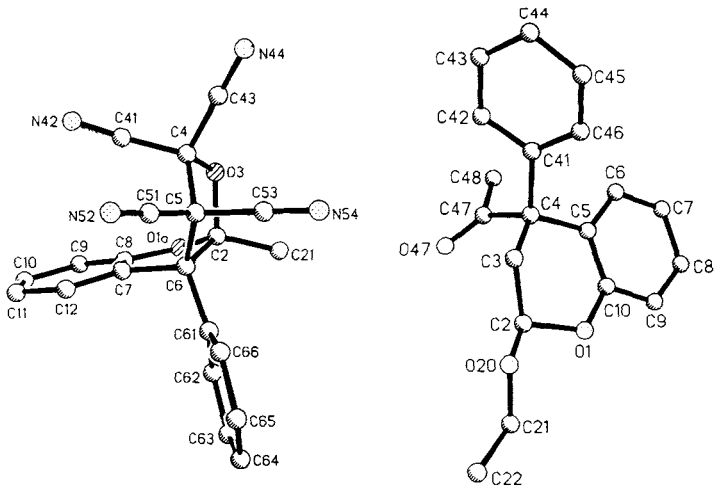


Fig. 1. Crystal structures of the benzofurofuran **6a** (left) and the benzopyran **7a** (right) (ORTEP).

In contrast to **1a**, the reaction of the benzofuran **1b**[10] with dimethyldioxirane did not yield the expected epoxide **2b**, but instead the quinone methide **3b** was obtained quantitatively as a dark red solid. The structure assignment is based on NMR spectroscopic data measured at $-30\,^{\circ}C$. The most characteristic signals in the ^1H NMR spectrum are

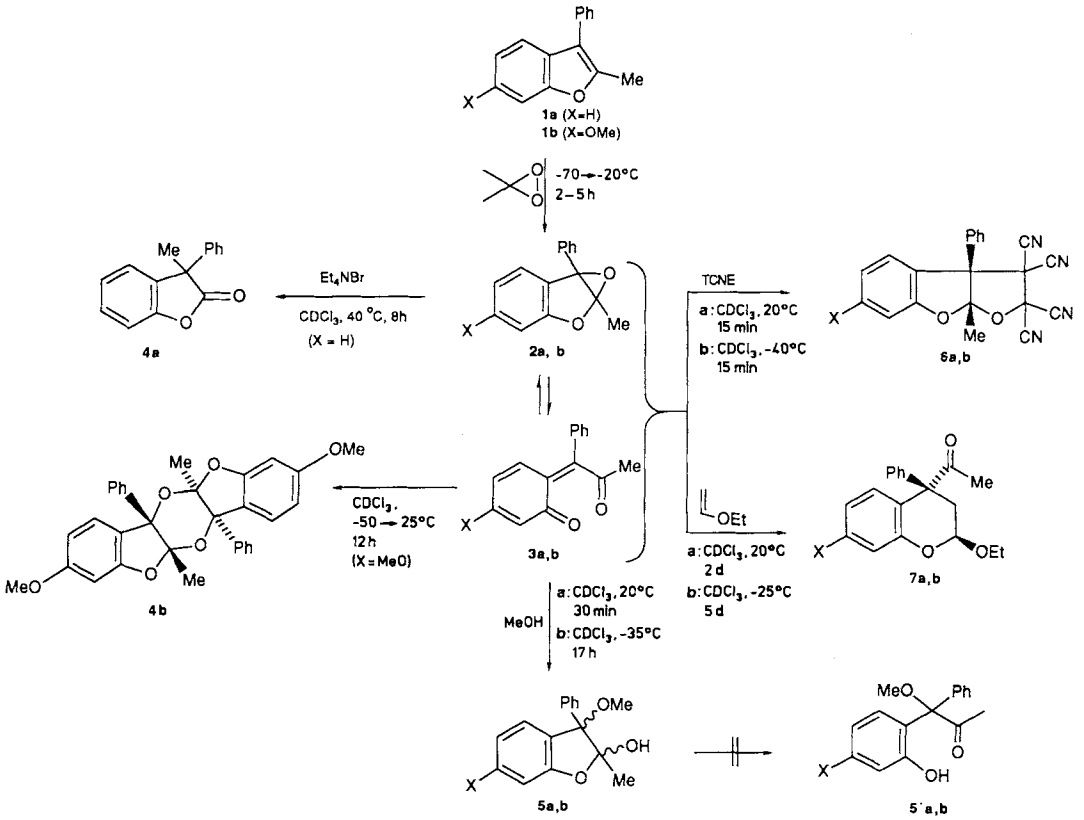

Scheme 1. Rearrangement, methanolysis, and cycloaddition chemistry of the benzofuran epoxide **2** and the quinone methide **3**.

those of the methyl group at $\delta = 2.20$ (s, 3H) and of the olefinic proton 2-H at $\delta = 5.70$ (d, $J = 1.6$ Hz, 1H), and in the ^{13}C NMR spectrum those of the acetyl group at $\delta = 28.0$, of the cyclohexadienone carbonyl atom at $\delta = 185.1$, and of the carbonyl atom of the acetyl group at $\delta = 203.9$. These data are in accord with those of known quinone methides.[11]

Presumably the formation of quinone methide **3b** is facilitated by the +M effect of the 6-methoxy group, which stabilizes the intermediate benzylic cation derived from the cleavage of the bond between the epoxide oxygen and the C-3 atom. That the resulting 1,3 dipole is a reasonable intermediate is supported by the fact that on warming the quinone methide **3b** from −30 to 20 °C over 5–10 h, dimerization to the 1,4-dioxane derivative **4b** (colorless solid, m.p. 276–277 °C) was observed.[8] Compound **4b** exhibits the molecular peak at *m/z* 508 in the mass spectrum, and due to its symmetry (C_i), one set of signals is displayed in the ^1H and ^{13}C NMR spectra. Although not even traces of epoxide **2b** can be observed by NMR spectroscopy at low temperature, it is hard to conceive how the quinone methide **3b** dimerizes into **4b** without passing through the ring-opened 1,3 dipolar structure of epoxide **2b**.

Methanolysis of the quinone methide **3b** led, like the epoxide **2a**, exclusively to attack at the benzylic position to yield the adduct **5b** as a pale yellow oil in 83% yield (*d.r.* = 43:57).[8] Also the reaction between the quinone methide **3b** and TCNE at −40 °C gave the 1,3 dipolar cycloadduct **6b** in 78% yield (colorless needles, m.p. 127–128 °C, Et_2O/petroleum ether).[8] Finally, the reaction of the quinone methide **3b** with ethyl vinyl ether led to the benzopyran **7b**, which is extremely sensitive towards moisture and, therefore, no satisfactory elemental analysis could be obtained; however, the spectroscopic data of the [4 + 2] cycloadduct **7b** are very similar to those of **7a**.

This unusual set of mutual reactions of the benzofuran epoxide **2a** and the quinone methide **3b** (Scheme 1), that is, they both give the epoxide trapping products **5a,b** with methanol, both afford the 1,3 dipolar cycloadducts **6a,b** with TCNE, and both lead to the inverse Diels–Alder adducts **7a,b** with ethyl vinyl ether, speaks for the reversible valence isomerization **2** ⇌ **3**. These results account for the previously reported difficulty in observing labile benzofuran epoxides.[12]

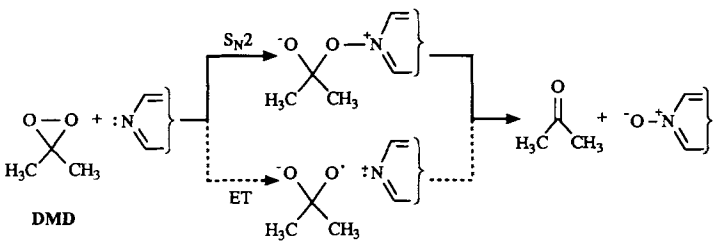
S_N2 Reaction versus Electron Transfer in the Oxygen Transfer by Dimethyldioxirane to Nitrogen Heteroarenes**

By *Waldemar Adam** and *Dieter Golsch*

Dimethyldioxirane (DMD), especially in acetone,[1] has been developed into an effective but mild reagent for the oxidation of π bonds, heteroatoms, and even σ bonds.[2] While most of these oxygen atom transfer reactions appear to take place by direct substitution (S_N2) on the dioxirane peroxide bond by the nucleophile, more complex electron-transfer (ET) activity has been implicated (Scheme 1) particularly for substrates with low oxidation potentials.[3]



Scheme 1.

The purpose of the present mechanistic study was to probe for ET involvement in the heteroatom oxidation of nitrogen heteroarenes by comparing the relative rates and regioselectivities of DMD oxygen transfer with those of CH_3I methylation. The S_N2 behavior of CH_3I is well defined, for which electronic and steric factors play their usual role.[4] For the heteroarenes examined herein, a clear-cut S_N2 rather than ET mechanism applies in the nitrogen lone pair oxidation by DMD.

The results of the comparative reactivities are best appreciated in the log k_{rel}(DMD) versus log k_{rel}(MeI) plot in Figure 1, for which a good straight line ($y = -0.54 + 1.38\,x$) with a correlation coefficient $r = 0.977$ was obtained. For

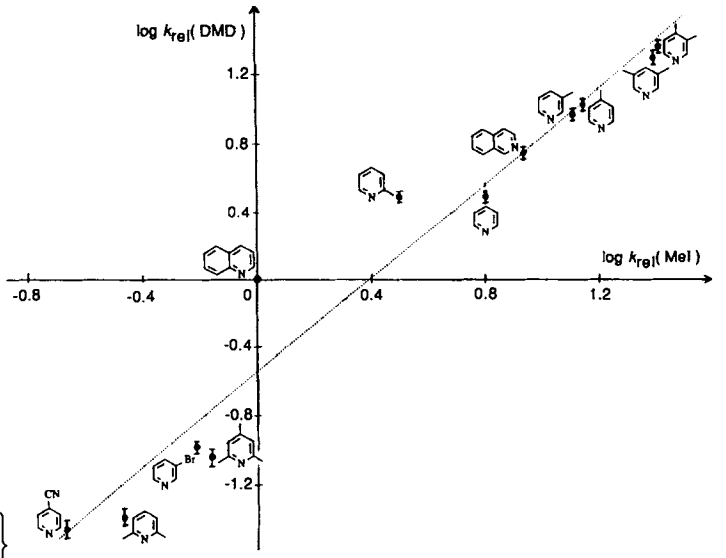


Fig. 1. Plot of log k_{rel}(DMD) versus log k_{rel}(MeI); values are taken from Table 1.

this purpose the acetone solutions of DMD (ca. 0.1 M)[1] were prepared according to our modified procedure,[5] which is more convenient than previous preparations.[1, 6] The relative rate constants k_{rel}(DMD) (Table 1) were determined by competition experiments with quinoline as reference substrate. The constants k_{rel}(MeI) (Table 1) were determined from literature data (they were extrapolated from related data under diverse conditions and normalized relative to quinoline as reference substrate).

Despite the fact that the k_{rel}(MeI) values came from various sources and had to be extrapolated, their correlation with the k_{rel}(DMD) data (Fig. 1) is quite good, especially if one keeps in mind the set of diverse structure types employed in this correlation. This result clearly speaks for a S_N2 mechanism in the oxygen transfer to the nitrogen atom of these heteroarenes.

Table 1. Relative rate constants for oxygen transfer by DMD [k_{rel}(DMD)] and for methylation by CH_3I [k_{rel}(MeI)], pK_a values and ionization potentials [$E_{IP adiab.}$ and E_{IP}(N:)] for heteroarenes and for their *N*-oxides [E_{IP}(NO)] all in eV.

[f] Ionization potential of the corresponding *N*-oxide.

Since a direct correlation exists between nucleophilicity and pK_a of the nitrogen base, the log k_{rel}(DMD) data were plotted against the pK_a values of the heteroarenes (Table 1). This appeared particularly attractive since accurate pK_a data are available under a consistent set of experimental conditions for the aromatic nitrogen bases examined here; how-

ever, such a plot gave a much poorer correlation ($r = 0.398$). In hindsight this is not too surprising because the pK_a values do not reflect the steric factors that result from methyl or benzo substitution in the proximity of the nitrogen heteroatom, which can hinder the oxygen transfer by the dioxirane. By excluding such sterically encumbered substrates (Table 1, entries 2, 3, 5, 7), again an excellent correlation is observed ($y = -2.47 + 0.59\,x$; $r = 0.994$). Therefore, the principal reason why the $\log k_{rel}$(DMD) versus $\log k_{rel}$(MeI) plot for all twelve substrates correlates much better ($r = 0.977$) than that for the $\log k_{rel}$(DMD) versus pK_a plot ($r = 0.398$) is that oxygen transfer by DMD and methylation by CH_3I are subject to similar steric factors. Furthermore, if a straight line is calculated for the $\log k_{rel}$ values of DMD versus those of MeI in the case of the eight sterically unhindered pyridines, the best correlation is obtained ($y = -0.59 + 1.38\,x$; $r = 0.999$).

How good, however, is the correlation of the relative rate constants of DMD [$\log k_{rel}$(DMD)] with the ionization potentials of these heteroarenes? The plot of $\log k_{rel}$(DMD) against the adiabatic ionization potentials E_{IP}(adiab.), that is the energy of the ionization out of the π-electron system of the heteroarene, was unsatisfactory even for the eight sterically unhindered pyridines ($r = 0.830$). All twelve pyridines together again gave a much poorer correlation ($r = -0.399$).

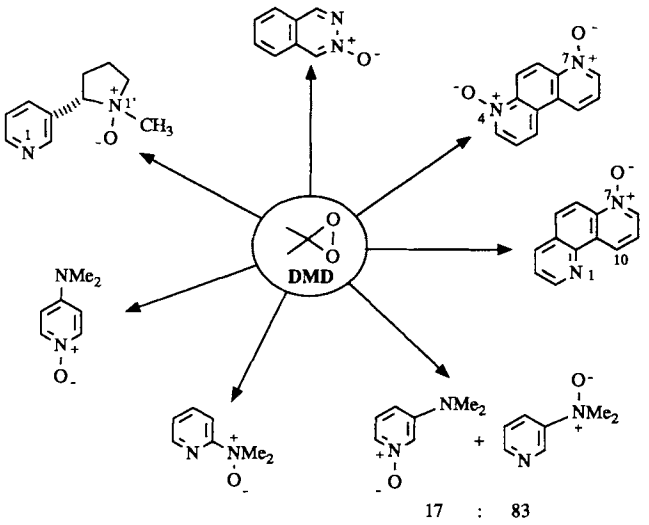
If electron transfer is responsible for the oxidation of the nitrogen heterorenes by DMD, then one should choose ionization potentials which measure the removal of an electron out of the lone pair of the nitrogen atom, [E_{IP}(N:)]. Again, a plot of $\log k_{rel}$(DMD) versus E_{IP}(N:) gave a very bad correlation ($r = -0.213$). Consequently, these reactivity data confirm a S_N2 and not an ET mechanism for the oxidation of nitrogen heteroarenes by dimethyldioxirane. Like methylation by methyl iodide, oxygen transfer by DMD is also subject to electronic *and* steric factors in the heteroarene.

Another criterion for the differentiation of the S_N2 and the ET mechanism is the comparison of the regioselectivities for the DMD oxidation and CH_3I methylation of heteroarenes with several nitrogen sites. An impressive selection of regioselectivities is illustrated in Scheme 2.

Since *N*-oxides have substantially lower ionization potentials (by ca. 1 eV) than the corresponding *N*-heteroarenes (Table 1), when ET would apply, the second oxygen transfer should proceed even more readily than the first. Therefore, one would expect both 1,7- and 4,7-phenanthroline to give the appropriate dioxides with an excess of DMD. Indeed, the 7-monoxide of the 1,7-isomer and the 4,7-dioxide of the 4,7-isomer were obtained.

This is analogous to CH_3I, for which *N*,*N*'-dimethylation of 4,7-phenanthroline takes place readily, while only *N*-monomethylation can be achieved with the 1,7-isomer.[11] The *peri* hydrogen atom at C-10 obstructs the approach of the two electrophiles CH_3I and DMD and therewith prevents S_N2 attack at N-1.

Still more revealing are the results of the DMD oxidations of the three regioisomeric dimethylaminopyridines (Scheme 2). The *para* isomer gives exclusively the corresponding pyridine-*N*-oxide and the *ortho* isomer exclusively the dimethylamino-*N*-oxide. This selectivity is identical to the *N*-methylation by CH_3I.[12] In contrast the *meta* isomer behaves in a more complicated manner; while DMD afforded a 17:83 mixture of the pyridine-*N*-oxide and dimethylamino-*N*-oxide (Scheme 2), *N*-methylation by CH_3I is reported[12] to take place exclusively at the pyridine nitrogen atom, and a peroxy acid oxidizes the dimethylamino nitrogen preferentially.[12] Thus, for the *meta* isomer there exists a substantial differentiation between these three electrophiles, of which DMD displays intermediate behavior between *N*-methylation by CH_3I and *N*-oxidation by RCO_3H. Presumably steric factors are responsible for the control of the preferred S_N2 attack by the electrophile. That also electronic factors may play a role, is reflected in nicotine as substrate (Scheme 2). All three reagents exclusively attack the pyrrolidine nitrogen, as would be expected for the higher nucleophilicity of this aliphatic nitrogen atom.[13]



Scheme 2. Regioselective oxidations of bidentate nitrogen heteroarenes by DMD.

In summary, comparison of the relative rates of the DMD oxidation of nitrogen heteroarenes with those of methylation by methyl iodide reveals that the S_N2 mechanism rather than electron transfer applies for the DMD oxidation. This is particularly evident from the poor correlation between the relative rate constants of oxygen transfer by DMD and the ionization potentials E_{IP}(adiab.) and E_{IP}(N:). Also the regioselectivities of the DMD oxidation of bidentate nitrogen heteroarenes are consistent with S_N2 attack on the peroxide bond of the dioxirane, controlled by the usual steric and electronic factors.

$[(\overset{\frown}{PP})_2RhH]$ and $[(\overset{\frown}{PP})_2Rh][O_2CH]$ Complexes as Models for the Catalytically Active Intermediates in the Rh-Catalyzed Hydrogenation of CO_2 to HCOOH**

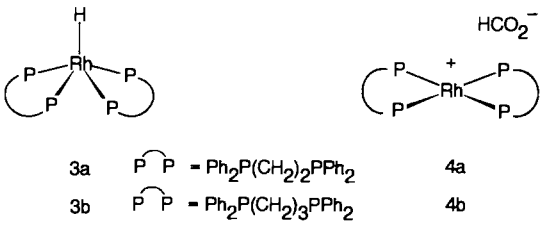
By *Thomas Burgemeister, Fritz Kastner,* and *Walter Leitner**

The hydrogenation of CO_2 to formic acid is an interesting approach to the chemical exploitation of CO_2.[1, 2] We reported recently that up to 1150 moles of formic acid per mole of rhodium may be obtained under the conditions summarized in Scheme 1 by using catalyst **1c**, generated in situ from $[\{Rh(cod)Cl\}_2]$ ($c_{Rh} = 1.35 \times 10^{-3}$ M) and dppb[3] (dppb: Rh = 1.2).[4] At about the same time, Nicholas and Tsai published the results of their investigations on the hydrogenation of CO_2 in THF with the ionic complex $[Rh(PPhMe_2)_3(nbd)][BF_4]$ (**2**) as catalyst.[5] After activation of **2** with hydrogen, 64 moles of formic acid were formed per mole rhodium per day under more drastic conditions (p = 100 atm, T = 40 °C).

$$H_2 + CO_2 \underset{\mathbf{1a\text{–}d}}{\overset{\text{DMSO, NEt}_3}{\rightleftharpoons}} HCO_2H$$

Scheme 1. Rhodium-catalyzed hydrogenation of CO_2 to formic acid. Conditions: p = 40 atm, T = 297 K, and t = 18 h. The catalyst **1** is generated in situ from $[\{Rh(cod)Cl\}_2]$ (**A**) (c(Rh) = 10^{-2} M) and a bidentate phosphane ($\overset{\frown}{PP}$: Rh = 1.2). **1a**: **A** + dppe, 13 mol HCO_2H per mol Rh; **1b**: **A** + dppp, 185; **1c**: **A** + dppb, 210; **1d**: **A** + dippe, 205 mol HCO_2H per mol Rh.

In the course of our efforts to optimize in situ catalysts of type **1**, we established that the catalytic activity was influenced greatly by the steric and electronic properties of the phosphane ligand (see Scheme 1). Approximately the same tendency was observed for the rhodium-catalyzed transfer-hydrogenation with formates.[6] In this communication, we report preliminary investigations with the model complexes **3**[7] and **4** that should contribute to our understanding of these phenomena on a molecular level.



3a $\overset{\frown}{P\ P}$ = $Ph_2P(CH_2)_2PPh_2$ **4a**
3b $\overset{\frown}{P\ P}$ = $Ph_2P(CH_2)_3PPh_2$ **4b**

The conformity of our model complexes with the actual active species in the catalytic cycle is emphasized by the fact that model **3b** may likewise be used as catalyst for the hydrogenation of CO_2 in DMSO. Under the conditions described in Scheme 1, 30 moles of formic acid per mole of **3b** were formed within 16 hours. The large difference in activity between **3b** and **1b** can be attributed to the different ligand-to-metal ratio, because a comparable reduction in activity is observed for the in situ system **1c** upon raising the ligand-to-metal ratio to 2:1 (as in **3b**). The 18e complex **3b** is, of course, far less reactive than a coordinatively unsaturated, hypothetical intermediate [(dppp)RhH]. Depending on the ligand, complexes of type $[(\overset{\frown}{PP})RhH]$ form clusters of formula $[\{(\overset{\frown}{PP})Rh(\mu\text{-}H)\}_x]$, which probably exist in equilibrium with the corresponding monomers under the above catalytic conditions.[8] The supposition that such fragments are the catalytically active intermediates in the hydrogenation of CO_2 in DMSO is supported by the observation that the catalytic activity (200 cycles in 18 hours) of [(dippe)Rh-(η^3-C_4H_7)], which gives rise to $[\{(dippe)Rh(\mu\text{-}H)\}_2]$ under H_2-pressure[8b] is almost identical to that of the in situ catalyst **1d**. On the other hand, not even half as many catalytic cycles as for **1c** were observed for the cationic complex $[(dppb)Rh(nbd)][CF_3SO_3]$ (83 moles of formic acid per mole of rhodium within 18 hours). From the latter observation, it appears improbable that the hydrogenation of CO_2 to formic acid under our reaction conditions proceeds according to the mechanism described by Nicholas et al.[5]

Complex **3b** reacts at room temperature in DMSO, under 1 atm CO_2, to give complex **4b** quantitatively in less than thirty minutes. The reaction is accompanied by a change in the color of the solution from red to yellow, and may be monitored by ^1H NMR spectroscopy, through the disappearance of the hydride ligand signal at $\delta = -10.51$ (dq, J(H,Rh) = 8 Hz, J(H,P) = 19 Hz) and concomitant growth of a signal for the formyl proton at δ = 8.55. A protonation of complex **4b** prior to insertion of CO_2 by residual water in $[D_6]$DMSO[9] is not observed, owing to the low basicity of the dppp ligand. If, upon completion of the transformation of **3b** into **4b**, the carbon dioxide atmosphere is replaced by hydrogen, the solution virtually decolorizes, and a high-field signal ($\delta = -8.66$, dm, $J(H,P_{trans}) = 138$ Hz, J(H,Rh) = 12 Hz $\approx J(H,P_{cis})$) is observed in the ^1H NMR spectrum, characteristic of the cation $[(dppp)_2Rh(H)_2]^+$.[10] The integration of the NMR signals is consistent with the formulation $[Rh(dppp)_2(H)_2][HCO_2]$ **5**. After about 30 minutes, **3b** and **5** can be observed in a ratio of 1:1 in the solution, and

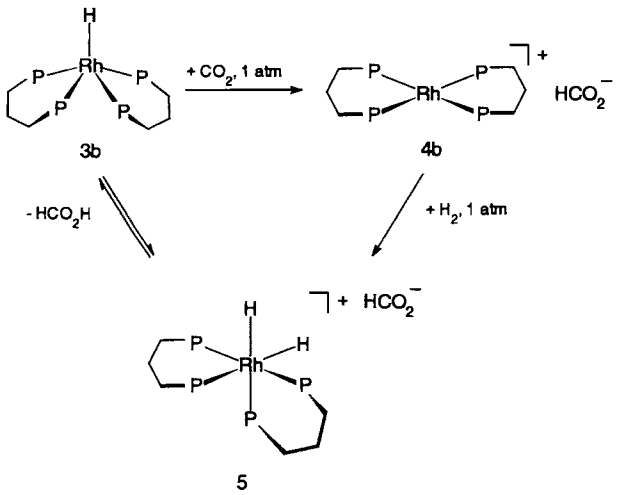
[**] CO_2 Activation, Part 2. This work was supported by the Fonds der Chemischen Industrie (Liebig-Stipendium for W. L.). We thank Degussa AG for a gift of hydrated rhodium(III) chloride. Part 1: [4a]. $\overset{\frown}{PP}$ = bidentate phosphane.

hence every step of the catalytic cycle depicted in Scheme 2 for the hydrogenation of CO_2 to formic acid can be detected by ^1H NMR spectroscopy.



Scheme 2. Intermediates determined by ^1H NMR spectroscopy in the hydrogenation of CO_2 to formic acid, with the complex **4b** as catalyst ([D$_6$]DMSO, 297 K).

The reaction of **3a** with CO_2, carried out in suspension owing to its insolubility in DMSO, produces a yellow solution in which no formate can be detected by ^1H NMR spectroscopy. Complex **4a** is, however, obtained in good yield from the reaction of [(dppe)Rh(acac)] with HCO_2H in THF in the presence of a further equivalent of dppe. The analogous synthesis of **4b** is only successful if performed at $-40\,^\circ C$. While **4a** is also accessible through reaction of [(dppe)$_2$RhCl] with KO_2CH in acetone under reflux, the analogous reaction with [(dppp)$_2$RhCl] gives **3b** in over 80% yield under the same conditions. Here, the intermediate formation of **4b** may be observed by ^1H NMR spectroscopy, and the liberated CO_2 detected through clouding of an aqueous $Ba(OH)_2$ solution.

It is apparent from the NMR data that the complexes **4** undergo complete dissociation in [D$_6$]DMSO. This distinguishes them from previously characterized formatorhodium complexes,[5, 11] as well as from the related complexes [(iPr$_3$P)$_2$Rh(O$_2$CCR$_3$)],[12] in which the carboxylate group is coordinated to the metal through at least one of the two oxygen atoms, even in solution.

The influence of the chelate ring size on the propensity of the formate group towards C–H activation that is apparent from the above described reactivities of **4a** and **4b** reflects the different catalytic activities of in situ systems **1a** and **1b**. This influence can be quantified according to the rate of $^{13}CO_2/^{12}CO_2$ exchange ([D$_6$]DMSO, $T = 297$ K, 1 atm $^{13}CO_2$), because the characteristic signal of the HCO_2^- group in the ^1H NMR spectrum ($\delta = 8.55$) is split into a doublet (J(H,C) = 172 Hz) upon incorporation of $^{13}CO_2$. The half-life for the incorporation of $^{13}CO_2$ into **4a** is thus determined to be 7.5 hours, in contrast to a mere 8 minutes for **4b**.

This tendency is also observed for H/D exchange in the formyl position. Under an atmosphere of D_2, incorporation of deuterium is already quantitative for **4b** after 15 minutes, but is only 25% complete after 64 hours for **4a**. From the data available it is not possible to decide whether the poor catalytic activity of the dppe complex arises from relatively slow H_2 cleavage[10] or from low reactivity towards CO_2.

In contrast to the related nickel complex [(cy$_3$P)$_2$Ni(H)(O$_2$CH)],[13] H/D exchange is *faster* than CO_2 exchange for **4b**. One possible explanation is that CO_2 remains in the coordination sphere of the rhodium center directly after decarboxylation,[14] and thus not every C–H bond cleavage leads to CO_2 exchange. It is also conceivable that the activation of the formyl group is strongly accelerated following oxidative addition of H_2 or D_2 to **4b**.

The results described herein provide the first unambiguous experimental proof that CO_2 is inserted into the M–H bond of a neutral rhodium complex.[11, 15, 16] This reaction has been shown by quantum mechanical calculations to be a potential elementary step in the rhodium-catalyzed hydrogenation of CO_2,[17] and has already been established experimentally for other metals.[18] The most important consequence of this study is, however, the fact that starting from complexes of type **3**, every step of the catalytic cycle for the rhodium-catalyzed hydrogenation of CO_2 to formic acid can be monitored by ^1H NMR spectroscopy, and that the influence of the ligands on the reactivity of the resulting intermediates **4** relates directly to their influence on the catalytic activity of the corresponding in situ systems. Thus, we have an efficient model at our disposal, in which the influence of steric and electronic properties of a phosphane ligand on the catalytic activity of a metal center may be studied systematically. In this way, we hope to be somewhat closer to an understanding of those effects vital for rational catalyst design.

Experimental Procedure

All manipulations were performed under exclusion of atmospheric oxygen. The complexes and ligands used were prepared according to known procedures. High-pressure experiments were accomplished as described elsewhere [4a]. NMR studies were carried out on a Bruker AC250 spectrometer.

4a: To a solution of [(nbd)Rh(acac)] (180 mg, 0.61 mmol) in THF (20 mL) was added dppe (492 mg, 1.23 mmol), and the mixture heated to boiling. A yellow solid separated within 30 min. After cooling to room temperature, dry formic acid (30 µL, 0.79 mmol) was added, and the mixture stirred for 30 min. The color of the precipitate faded slightly. To complete the precipitation, pentane (20 mL) was added. Following filtration, washing with pentane, and thorough drying under high vacuum, **4a** was obtained (490 mg, 85%) in analytically pure form. ^1H NMR ([D$_6$]DMSO, 250 MHz): $\delta = 8.55$ (s, 1H, HCO_2^-), 7.38 (m, 8H, *para*-H), 7.24 (m, 32H, *meta*, *ortho*-H), 2.20 (br.m, 8H, P-CH$_2$-); $^{31}P\{^1H\}$ NMR ([D$_6$]DMSO, 101 MHz): $\delta = 58.8$ (d, J(Rh,P) = 133 Hz).

4b: Preparation was as described for **4a**, but with the addition of formic acid and workup at $-40\,^\circ C$. ^1H NMR ([D$_6$]DMSO, 250 MHz): $\delta = 8.55$ (s, 1H, HCO_2^-), 7.18 (m, 40H, Ph), 2.39 (br.m, 8H, P-CH$_2$-), 1.81 (br.m, 4H, -CH$_2$-); $^{31}P\{^1H\}$ NMR ([D$_6$]DMSO, 101 MHz): $\delta = 9.1$ (d, J(Rh,P) = 133 Hz); $^{13}C\{^1H\}$ NMR ([D$_6$]DMSO, 63 MHz): $\delta = 164.7$ (s; gated decoupling: d, J(H,C) = 171.7 Hz, HCO_2^-).

[15] The formation of **4a** from the reaction of **3a** with CO_2 in CH_3CN is postulated on the basis of ^{31}P NMR data [16a]. Under these conditions, we obtained a yellow powder whose ^1H NMR and IR spectra are not identical to those of **4a**, but which nonetheless allowed the formation of a carbonato or hydrogencarbonato complex to be inferred. The ^{31}P NMR spectra of these compounds and of **4a** show, upon complete dissociation, only the signal of $[(dppe)_2Rh]^+$ and are therefore identical.

Can Single-Chain Perfluoroalkylated Amphiphiles Alone Form Vesicles and Other Organized Supramolecular Systems?**

By *Marie-Pierre Krafft, Françoise Giulieri,* and *J. G. Riess**

The formation of bilayers and vesicles usually requires bicaudal (double chain) amphiphiles, which can be either natural or synthetic.[1, 2] On the other hand, single-chain amphiphiles at concentrations higher than the critical micellar concentration tend normally to aggregate into micelles which may be spherical, cylindrical, or plate-shaped.[3] In the latter case lamellar mesophases can form but only at very high concentrations (> 50 % w/v).

When dilute dispersions are considered, the formation of bilayers and vesicles from single-chain amphiphiles (i.e. amphotropic behavior) requires an element of order to promote the alignment of the molecules in bilayers and to maintain molecular packing.[3] Such order can be brought about through steric interactions. Rigid amphiphiles have thus been reported to form vesicles when they possess a rodlike segment inserted between the polar head and the hydrophobic chain (typically biphenyl, azobenzene, or diphenylazomethine moieties).[4] Rigid coamphiphiles like cholesterol are also used to obtain stable vesicles.[5] Order can also be brought about by intermolecular associations, including those resulting from electrostatic forces (pairing of oppositely charged amphiphiles),[6] hydrogen bonding,[7] or polymerization.[8]

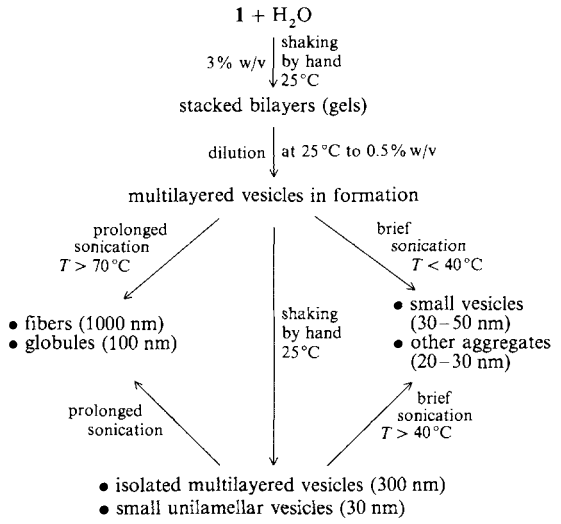
[**] This work was supported by the Centre National de la Recherche Scientifique. The authors are grateful to the Centre Commun de Microscopie Appliquée (CCMA, Prof. G. Nicaise, S. Pagnotta, J. P. Laugier) of the Université de Nice-Sophia Antipolis for assistance.

We investigated whether lamellar phases, vesicles, and, more generally speaking, organized supramolecular systems could be obtained from a single pure monocaudal nonrigid amphiphile by reinforcing the *hydrophobic interactions* in the surfactant film through the use of a highly perfluorinated tail, without recourse to classical steric effects or intermolecular associations.

For this purpose we prepared a linear "perfluoroalkylated" amphiphile (F-alkyl-PC) **1** phosphocholine derivative[9] and its hydrocarbon analogue **2**, and examined their dispersions in water with a view to assessing the effect of the fluorinated chain on supramolecular organization.

$C_8F_{17}C_2H_4OP(O)_2^-OC_2H_4N^+(CH_3)_3$ **1**
$C_{10}H_{21}OP(O)_2^-OC_2H_4N^+(CH_3)_3$ **2**

We report here that in contrast to its hydrocarbon analogue, F-alkyl-PC **1** forms stable organized supramolecular systems even in very dilute aqueous dispersions, without the need of secondary additives (Scheme 1). Depending on the conditions of preparation, various organized systems, significantly different in morphology, including stacked bilayers, vesicles, globules, and long fibers are observed.



Scheme 1. Organized supramolecular systems formed by **1**.

Dispersions of F-alkyl-PC have been prepared by hydrating the thin-layered compound with distilled water for 15 min at room temperature, followed by gentle shaking by hand. Depending on the concentration, clear to slightly turbid gels with viscoelastic properties were obtained. These gels display a consistency ranging from gelatin-like (1–3 % w/v) to glass-like (> 6 % w/v). They remain stable at room temperature for over 12 months without any sedimentation, crystallization, or phase separation. The gels can even be heat-sterilized (121 °C, 15 min, 15 Nm^{-2}) without apparent modification.

Investigation of such gels (3 % w/v) by transmission electron microscopy (TEM)[10] shows that they consist uniformly of stacked bilayers (Fig. 1). The lamellar structure of these assemblies is supported by optical polarization microscopy which visualizes the characteristic defects of the bilayers called "maltese crosses" and "oily strikes".[11] The lamellar structure is further supported by proton-decoupled ^{19}F NMR spectroscopy which shows a significant decrease of the linewidth of all resonance signals when temperature increases (e.g. from ca. $\Delta\nu_{1/2} = 400$ Hz at 10 °C to ca. 70 Hz at 70 °C

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1993 0570-0833/93/0505-0741 $ 10.00+.25/0

for the CF_3CF_2 resonance signal), indicating a mesophase transition. Complete melting of the F-alkyl chain occurs in the liquid phase over an unusually large temperature range (30–60 °C), in line with our previous observations on liposomes of glycerophosphocholines with two perfluorinated alkyl groups.[12]

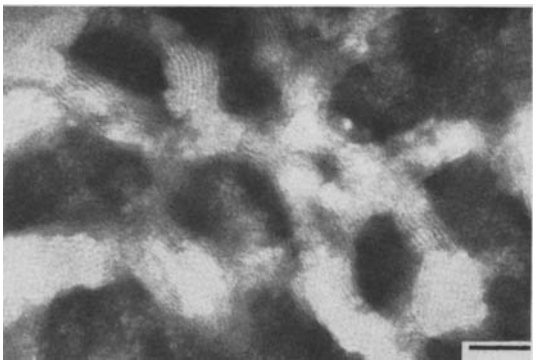


Fig. 1. TEM (negative staining) of a dispersion (3% w/v, shaken by hand at room temperature) of **1**. The length of the bar corresponds to 50 nm.

When the gels are diluted with water to a final concentration of 0.5% w/v, then gently shaken by hand for 1 min at room temperature, the constitution of multilayered vesicles "in formation" is observed. This is comparable to what occurs during the formation of liposomes from a coarse dispersion of phospholipids. When this dispersion is shaken by hand for a longer period, *isolated* multilayered vesicles are obtained, as shown by TEM micrographs (Fig. 2). Their sizes were evaluated by laser light scattering spectroscopy (LLSS), which showed large aggregates (300 nm, 40%) in addition to smaller aggregates (30 nm, 60%). The latter may consist either of micelles or of small vesicles and are not visible with TEM.

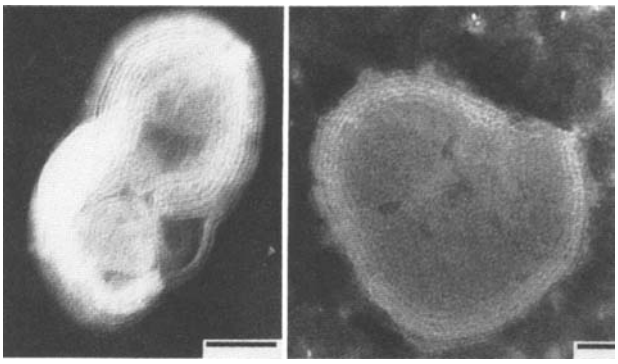

Fig. 2. TEM of isolated multilayered vesicles in a dilute dispersion (0.5% w/v) of **1** after gentle shaking by hand at room temperature. The length of each bar corresponds to 50 nm.

Brief sonication of the multilayered vesicle-containing dispersions at 40 °C or below (Scheme 1) (sonifier: Branson B30, titanium probe, 4 min, dial 5, pulse 50) led to the formation of small bilayered vesicles, which could be observed by TEM. Long aggregates were also present on the micrographs, and we suspect these to be fragments of lamellae, precursors of the vesicles.[13] LLSS measurements did not allow the distinction between the small vesicles and the long aggregates, and indicated only the presence of small particles of about 30 nm in diameter. After one month at room temperature, no significant evolution of sizes was detected by LLSS.

When the multilamellar vesicle-containing dispersions (0.5% w/v) are sonicated at a temperature at which the F-alkyl chain is completely fluid (i.e. above 70 °C when no further decrease of the linewidth of the ^{19}F NMR resonance signals is observed), two populations of aggregates of distinct morphologies are formed: globules and fibers. Their sizes have been evaluated on electron micrographs to be about 100 nm in diameter for the globules and about 1000 nm in length for the fibers. Since repulsion forces between bilayers usually increase with temperature,[14] we can suppose that at 70 °C bilayers dissociate to form inversed-phase microdomains stabilized by hydrophobic interactions. The globules may thus consist of closely packed assemblies of inverse micelles stabilized in water by a monolayer belt.[15] The fibers may be a one-dimensional extension of the spherical inverted structure.

Preliminary stability studies show that the fibers slowly grow, within a few weeks at room temperature, into a superstructure consisting of assembled fibers. This superstructure (several μm long) can be observed by contrast-phase optical microscopy. It is noteworthy that for the assemblies with perfluorinated alkyl chains reported here no crystallization was observed, even after a month, while limited lifetime is usual for fibrous aggregates.[16]

The strong tendency towards aggregation evidenced for the single-chain F-alkylated phosphocholine is in sharp contrast with the behavior of its hydrocarbon analogue **2** whose dispersions remain fluid, like water, even at concentrations up to 30% w/v. No evidence of liquid crystal formation has been detected in such solutions by polarization microscopy. In addition no aggregates have been imaged by TEM. LLSS measurements only showed the presence of micelle-sized aggregates (3–5 nm). The line width of the NCH_3 resonance signal in the ^1H NMR spectra (3 Hz) is also consistent with the formation of isolated micelles. Under the same conditions a far less well-resolved spectrum is obtained for the F-alkylated amphiphile **1**, with a NCH_3 line width of about 10 Hz. These results show that the dispersions of **2** only consist of fluid micelles, even when its concentration is increased to 30% w/v.

The formation of organized systems—multilayered and unilamellar vesicles, globules and fibers—by an F-alkylated phosphocholine, when compared to the inability of its hydrocarbon analogue to form anything more organized than micelles, establishes that a single F-alkyl chain can be sufficient to induce the alignment of amphiphilic molecules in bilayers. One major component of this driving force is likely to arise from the strongly hydrophobic interactions of the F-alkyl chains, endowing the molecule with a *strong* amphotropic (lyotropic + thermotropic) behavior. It also means that the tendency toward organization because of such hydrophobic effects overcomes the low intermolecular interactions between F-alkylated chains.

The geometry of the amphiphile may also contribute to the development of supramolecular aggregation properties.[17] Conically shaped surfactants (typically single-chain ones) tend to form micelles more easily, whereas cylindrically shaped ones prefer to assemble in bilayers. The bulkiness of the F-alkylated chain can therefore also be one of the factors which confers to the amphiphile the cylindral shape propitious to the formation of bilayers and vesicles.

Much attention has been focused on the influence of entropy on interactions in both natural and synthetic membranes; there is, however, a scarcity of suitable model mem-

branes; which may have hindered the understanding of the aggregation behavior. The single-chain systems reported here and the unique aggregation properties induced by perfluorinated chains may help provide insight into interactions between amphiphilic surfaces.

Investigations of the Structure and Kinetics of Intermediates in Proton-Induced Alkylidyne–Isocyanide Ligand Coupling Reactions**

By *Cecilia M. Bastos, Nancy Daubenspeck,* and *Andreas Mayr**

Dedicated to Professor Herbert D. Kaesz on the occasion of his 60th birthday

Proton-induced alkylidyne–isocyanide coupling reactions[1, 2] belong to a class of coupling reactions whose general features are well understood.[3] However, mechanistic details of this type of transformation are much less well defined. The immediate coupling precursors are assumed to be N-protonated alkylidyne isocyanide metal complexes,[1, 2] but it was also found that the preferred site of protonation in these complexes is the alkylidyne carbon atom.[2] This paper is concerned with the structural effects of protonation of alkylidyne isocyanide complexes and with the mechanism of the methanol-catalyzed transformation of $C_{(alkylidyne)}$-protonated alkylidyne isocyanide metal complexes into aminoacetylene metal complexes.

The cationic alkylidene complexes **2a–e** precipitate when complexes **1a–c**[4] are protonated in ether with trifluoromethanesulfonic acid or tetrafluoroboric acid [Eq. (a)]. The

protonation of the alkylidyne carbon are clearly visible in the superimposition of the two structures (Fig. 3). The protonated alkylidyne ligand in **2b** is shifted from the coordination site, which it would occupy in an ideal octahedral coordination polyhedron, apparently to optimize the agostic interaction between the metal center and the formed C–H bond.[7] The plane of the alkylidene ligand is oriented roughly diagonally to the coordination axes of the adjacent ligands, such that the C15–H30 bond is oriented towards the isocyanide

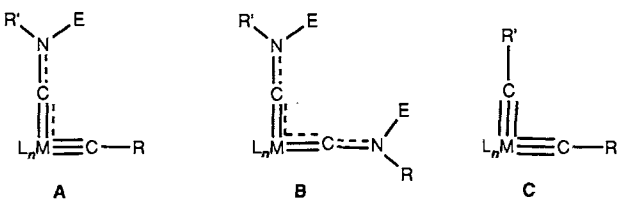
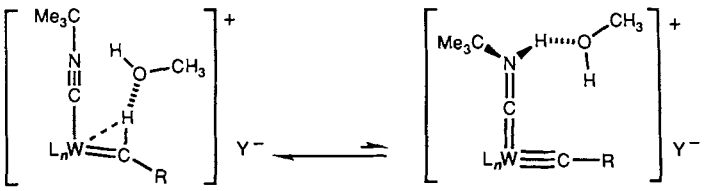
complex **2a** on the concentration of methanol follows saturation kinetics.[8] These results imply the reversible formation of an adduct between **2a** and methanol. To probe the mechanism of this reaction further, the dependency of the reaction rate on several variables was tested: a) The rate shows little dependence on the nature of the coordinated halide ligand X. b) The reaction is significantly slower when the substituent (R) on the alkylidene carbon atom is changed from a phenyl group to a methyl group. c) The rate depends very strongly on the nature of the counterion Y^-, increasing with the nucleophilicity of Y^-.

Proton-induced alkylidyne–isocyanide coupling reactions have previously been proposed to proceed via N-protonated alkylidyne isocyanide metal complexes, that is alkylidyne (aminomethylidyne)metal complexes of type **A**, as the immediate coupling precursors.[1, 2] In the related coupling of two isocyanide ligands,[9, 10] bis(aminomethylidyne)metal complexes **B** are firmly established as intermediates. Filippou et al. synthesized stable complexes of type **B** by sequential addition of electrophiles (alkylation) to two isocyanide ligands and demonstrated that the coupling of the two aminomethylidyne ligands is induced by the addition of nucleophiles.[11] If we accept the assumption that the protonation of the isocyanide ligands also in reaction (b) brings about the activation of the coupling reaction, then the mechanism must involve a reversible step in which a proton in the alkylidene–methanol adduct is transferred to the isocyanide ligand. We propose that methanol acts as the proton transfer agent.



Scheme 1. Postulated proton transfer mechanism.

A possible mechanism for the proton transfer is shown in Scheme 1.[12] The C15–N1 distance of 4.12 Å found in the structure of **2a** even suggests that a C···H···O···H···N hydrogen-bonded arrangement of alkylidene ligand, methanol, and isocyanide ligand may participate in the proton transfer step. The slower rate of reaction of the methyl-substituted complex **2e**, compared to that of **2a**, would be explained by a lower equilibrium concentration of **5** for **2e**, due to an increased basicity of the alkylidene carbon atom in **2e**. The strong dependency of the rates of the nucleophilicity of the anions Y^- indicates that the actual coupling step is induced by nucleophilic attack of Y^- at intermediate **5**.[13] The alternative to this step would be spontaneous coupling of the alkylidyne and aminomethylidyne ligands in **5** and trapping of the formed aminoacetylene complexes by Y^-. In this case a much smaller anion dependency would be anticipated.[14]



4 **5**

The results, therefore, support the assumption of discrete alkylidyne(aminomethylidyne)metal complexes **A** as intermediates in proton-induced alkylidyne–isocyanide coupling reactions. In the formal coupling of two alkylidyne ligands[15] discrete bis(alkylidyne) complexes **C** were not postulated as intermediates, since such species would be expected to be very unstable.[16, 17] The observation of alkylidene–isocyanide coupling in complexes **2** in the presence of the "non-nucleophilic" ions $CF_3SO_3^-$ and BF_4^- shows clearly how strongly the alkylidyne (aminomethylidyne) intermediates **A** are activated for coupling. Recently Lippard et al. reported evidence for similar intermediates in the silyl halide–induced coupling of siloxymethylidyne and carbonyl ligands.[18]

Experimental Procedure

All kinetics experiments were performed under argon and under rigorously anhydrous conditions. The reaction vessel was immersed in a constant temperature bath at 20.0 ± 0.1 °C. The reactions were monitored by IR spectroscopy, by measuring the absorbance of the carbonyl band of the alkylidene complexes **2**.

2a: Complex **1a** (0.107 g, 0.19 mmol) was dissolved in ether (5 mL), the solution was cooled to −78 °C, and CF_3SO_3H (20 mL, 0.226 mmol, 1.2 equiv) was added. A yellow precipitate formed almost quantitatively upon warming to 0 °C. The mixture was centrifuged, the supernatant decanted, and the product was washed with ether (2 × 5 mL) and dried under vacuum. The complexes **2b–e** were obtained in an analogous way with the appropriate acid.

Spectroscopic data: The IR spectra were measured in CD_2Cl_2, the NMR spectra in CD_2Cl_2. The first $\tilde{\nu}$ values given in the IR data refer to $\nu(CNCMe_3)$, the second to $\nu(CO)$. The ^1H NMR data give the δ value for the C(*H*)R proton, the ^{13}C NMR data for the corresponding *C*(H)R carbon atom.

2a: IR: $\tilde{\nu}$[cm^{-1}] = 2189, 1993; ^1H NMR (−30 °C): $\delta = -3.2$; ^{13}C NMR (−30 °C): $\delta = 230.8$ (J(C,H) = 67 Hz). **2b**: IR: $\tilde{\nu}$[cm^{-1}] = 2189, 1993; ^1H NMR ($CDCl_3$): $\delta = -2.57$; ^{13}C NMR ($CDCl_3$): $\delta = 230.4$ (J(C,H) = 72 Hz). **2c**: IR: $\tilde{\nu}$[cm^{-1}] = 2186, 1987. **2d**: IR: $\tilde{\nu}$[cm^{-1}] = 2188, 1987; ^1H NMR (−30 °C, $CDCl_3$): $\delta = -3.01$; ^{13}C NMR: $\delta = 230.2$ (J(C,H) = 77 Hz). **2e**: IR: $\tilde{\nu}$[cm^{-1}] = 2185, 1992; ^1H NMR: $\delta = -2.53$; ^{13}C NMR: $\delta = 241.7$ (J(C,H) = 73 Hz).

3: An aliquot of one of the complexes **2a,c–e** (0.075–0.15 mmol) was dissolved in CH_2Cl_2 (1 mL). Then methanol (8 μL, 1.97×10^{-1} mmol) was added. Aliquots were taken at regular time intervals, and the IR spectra were recorded at room temperature. In a series of experiments with complex **2a** the methanol concentration was varied from 6.9×10^{-2} to 9.8×10^{-1} M. In two sets of experiments equivalent amounts of NEt_4Cl (**2f**) and $NEt_4(4\text{-}CH_3C_6H_4SO_3)$ (**2g**) were added to **2e** before methanol addition. The kinetics for **2b** were not measured.

Spectroscopic data: The IR data refer to ν(CO), the ^{13}C NMR data to $\delta(RCCNHCMe_3)$. IR: $\tilde{\nu}$[cm^{-1}] = 1947 (**3a**, **3b**), 1946 (**3c**), 1939, 1917(**3d**), 1924 (**3e**), 1931 (**3f**); ^{13}C NMR: $\delta = 209.1$, 206.8 (**3a**, **3b**), 210, 209, 203, 201 (two isomers of **3c**), 212.5, 210.5 (**3d**), 206, 200 (**3e**), 207.5, 206.5 (**3f**).

[12] Deprotonation of the alkylidene ligand, presumably the slowest step in any mechanism for the equilibration of species such as **4** and **5**, is very rapid. The rate of H–D exchange between **2b** and CH_3OD is too fast to be measured by conventional spectroscopic methods.
[13] An increase of the concentration of Y^-, $Y = CF_3SO_3$ ($NEt_4CF_3SO_3$), led to a decrease of the reaction rate of **2a**. It is assumed that adduct formation between methanol and added $NEt_4CF_3SO_3$ reduces the effective concentration of methanol.

Transition-Metal-Substituted Volatile Alanes, Gallanes, and Indanes: Synthesis and Structure**

By *Roland A. Fischer,* Joachim Behm, Thomas Priermeier,* and *Wolfgang Scherer*

Transition-metal-substituted alanes, gallanes, and indanes have so far attracted little attention. Their instability and tendency to disproportionate prevent their isolation in a pure form and make their chemistry appear fruitless.[1] These particular compounds, however, possibly possess a high industrial potential: they might be suitable as single-source precursors for the chemical vapor deposition of bimetallic thin films such as β-CoGa.[2, 3] We have now begun the systematic development of this type of compound with the aim of achieving volatility and defined pyrolysis to yield the pure metal phase by structural modification of the molecular precursor.[4]

The synthesis of stable complexes with a metal ratio of 1:1 is not easy. From the syntheses of **1**–**12** (Scheme 1, Table 1) it is seen that tetracarbonylcobaltate does *not* react with $[(CH_3)_3SiCH_2]_2InCl$ to give the expected CoIn complex, an analogue of the stable CoGa compound **5**,[4] but rather it reacts with the elimination of trialkylindium to give **13** (Fig. 1).[5] The remarkable feature of the structure of **13** is

$[\{(CO)_4Co\}_2In(CH_2SiMe_3)(thf)]$ **13**

the distorted tetrahedral environment of the indium atom. The sum of the angles (354°) about the In atom, which involve Co1, Co2, and C2, indicates an almost planar environment. If alkyl groups such as *tert*-butyl or methyl are found at the indium atom, an undesired symmetrization occurs, giving compounds of the type $[\{L(CO)_nM\}_3In]$.

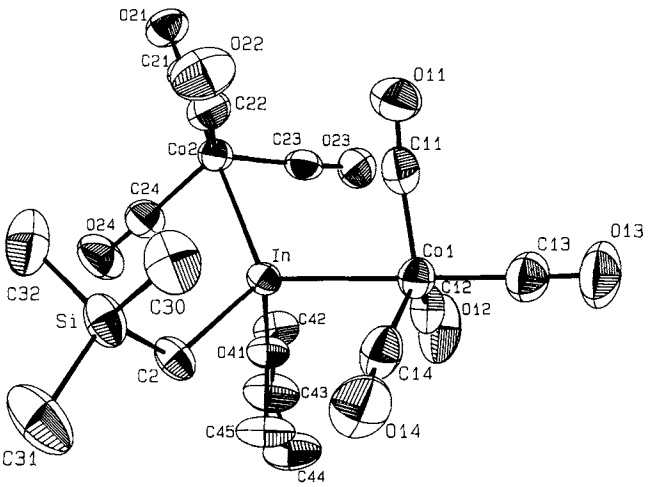

Fig. 1. Crystal structure of **13** (ORTEP). Selected bond lengths [pm] and angles [°]: In-Co1 263.83(4), In-Co2 263.03(4), In-O41 233.9(2), In-C2 216.8(3); Co1-In-Co2 117.17(1), Co1-In-O41 104.67(5), Co1-In-C2 118.30(8), Co2-In-O41 97.31(4), Co2-In-C2 118.63(8), O41-In-C2 92.42(8). The In atom lies 34.7 pm above the plane Co1, Co2, O41.

The only dialkylindium complexes known to date to be resistant to exchange are *cis*-$[L_2PtInR_2]$ (L_2 = $Cy_2P(CH_2)_2PCy_2$, Cy = *cyclo*-C_6H_{11}; R = CH_2SiMe_3)[6] and *fac*-$[(Me_3P)_3(Et)(H)IrInEt_2]$,[7] however, these are *not* volatile. The FeIn complex **1** (Fig. 2[5]) and its Mn, Co, and Ni analogues **2**–**4** (Scheme 1) owe their combination of stability *and* volatility to two chelating 3-dimethylaminopropyl groups which shield the In center. With the very long In–N3 and In–N4 distances, which vary by approximately 10 pm, and a clearly nonlinear N-In-N arrangement (angle N3-In-N4 = 155.4(2)°), the trigonal-bipyramidal environment of the In atom in **1** is unusually strongly deformed. If the Fe complex fragment is replaced by an electronegative bromide substituent, the resulting structure has identical In–N distances, approximately 10 and 20 pm shorter than those in **1**, and a linear N-In-N arrangement.[8] EHMO calculations on similar systems[9] indicate that the reason for these differences may be an electron transfer from the d-block metal into σ^*(In–N) orbitals. Photolysis of **1** in daylight leads to **14**. The In–N bond of the alkylindium complex fragment

$[(\mu\text{-CO})(\mu\text{-InR})\{(Cp(CO)Fe_2\}_2]$ **14**, R = $(CH_2)_3NMe_2$

($In[(CH_2)_3NMe_2]$ isolobal with CH_2) in the Fe_2In complex **14** no longer participates in the electron system of the d-

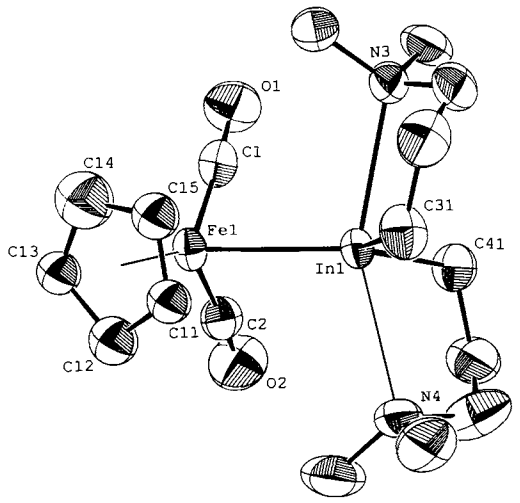

Fig. 2. Crystal structure of 1 (ORTEP). Selected bond lengths [pm] and angles [°]: Fe-In 263-93(8), Fe-Cl 173.3(7), Fe-C2 175.7(7), In-N3 264.3(5), In-N4 272.6(5), In-C31 220.7(6), In-C41 219.5(6), C1-Fe-In 84.4(2), C2-Fe-In 85.9(2), C1-Fe-C2 89.2(3), Fe-In-N3 101.7(8), Fe-In-N4 102.9(2), Fe-In-C31 123.6(2), Fe-In-C41 117.4(2), N3-In-N4 155.4(2), C31-In-C41 119.0(3), Fe-Cp 175.1.

block metals on symmetry grounds and is shortened to 239.2(6) pm.[5] Similarly, the σ(Co–Ga) bonds also react sensitively to variation of the substituents. The shortest Co–Ga distance known so far is found in **8** (237.8 pm) (Fig. 3).[5]

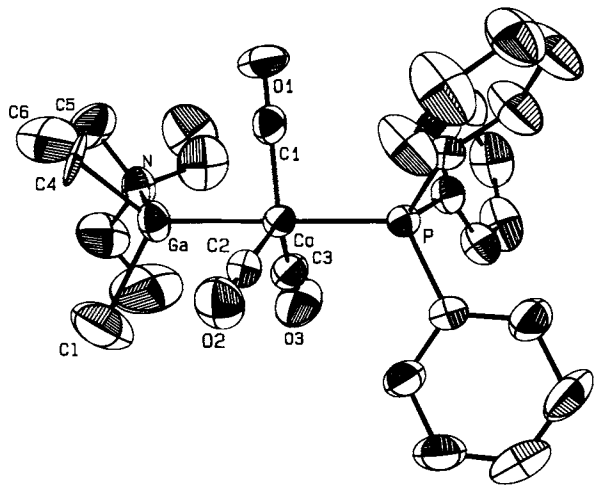

Fig. 3. Crystal structure of **8** (ORTEP). Selected bond lengths [pm] and angles [°]: Co-Ga 237.78(4), Ga-C1 217.6(1), Ga-N 217.2(3), Ga-C4 201.8(2), Co-P 220.02(8); Ga-Co-P 175.56(3), Ga-Co-C1 84.39(8), Ga-Co-C2 83.50(8), Ga-Co-C3 83.65(9), Co-Ga-C1 114.50(3), Co-Ga-N 116.93(6), Co-Ga-C4 120.20(7).

The exchange of the chlorine substituent in **8** for a methyl group (**8**-Me) extends the Co–Ga bond length to 249.7(3) pm.[5] The upper limit for σ(Co–Ga) distances seems to be about 260 pm.[4]

Intramolecular adduct formation or the use of sterically demanding groups are proven means for the preparation of organometallic compounds of Group 13 elements with unusual properties.[6, 8] Thus, the existence of the H_2Ga complexes **6** and **7** is particularly surprising, especially when one considers how little success has been achieved despite the intensive search for analogous compounds with H_2B units.[10] In the ^{1}H NMR spectra of **6** and **7** one broad Ga–H resonance signal is found at δ = **5**–**6**, which has the appropriate intensity ratio to that of the donor ligand NMe_3. The $2A_1 + E$ (splitting) pattern characteristic for $LM(CO)_4$ complexes with C_s symmetry for **6** is, as expected, shifted to higher wavenumbers by approximately 10 cm^{-1}, in comparison with the analogous alkyl compound **5**.[4] Compounds **6** and **7** start to decompose at about 80 °C in a sealed NMR tube, which leads to the liberation of the donor ligand, Ga deposition, H_2 evolution, and the formation of [E(M-$(CO)_n)_3$]. An attack at the carbonyl ligands does not occur! Correspondingly, the otherwise typical L_nM-Co-Al coordination is, in the Fe, Co, and Ni complexes **10**, **11**, and **12**, obviously suppressed in favor of hitherto unknown aluminum d-block metal bonds. Since single crystals suitable for X-ray structure analysis have not yet been obtained, the proposal for the structure is based on the complete agreement of the spectroscopic data of **10**–**12** with those of the formally analogous Ga complexes **8** and **9**. The chiral environment of the Al center and the occurrence of a chelate structure are manifested in the magnetic nonequivalence of all the ring protons of the metallacycle, the methylene protons of the neopentyl group, and the two methyl groups at the N atom. In the ^{13}C NMR spectrum of the FeAl complex **10** two sharp resonance signals for the diastereotopic carbonyl groups occur at δ = 219.5 and δ = 219.2; these have the same intensity. The existence of an $L(CO)_3$Co-Al unit is confirmed for **11**, for example, also by the $A_1 + E$ pattern in the IR spectrum, which is analogous to that of the structurally characterized complex **9**; from −90 to +150 °C the CO ligands in **11** are equivalent. The ^{31}P NMR resonance signal of **11** lies within the expected range (δ = 9.0), likewise the ^{27}Al NMR resonance signals for the complexes **10**–**12** at δ = 200(±15). Even the replacement of the bromine substituent in BrH_2AlNMe_3 by strong organometallic nucleophiles is possible without CO attack, and leads, by the elimination of the alkali metal bromide, to a product soluble in toluene, which we are investigating at present. Based on the complexes **1**–**12** the unexploited chemistry of the highly reactive d-block metal–Group 13 metal bond can now be developed.[11]

Experiments confirming the unexpected all-round suitability of *undecomposed volatile* complexes—depending on their structure at −10 to +100 °C and 10^{-1} to 10^{-3} mbar—for the chemical vapor deposition of intermetallic films such as β-CoGa and ε-NiIn, are described in the following communication.[3]

Experimental Procedure

1: Under argon (using a U-shaped tube fitted with a frit [4]) Na[Cp-$(CO)_2$Fe]·0.5 THF (2.35 g, 10 mmol) and $BrIn\{(CH_2)_3NMe_2\}_2$ (3.67 g, 10 mmol) [8] were mixed together in THF at −10 to + 25 °C. After the mixture had been stirred for 30 min the solvent was removed under vacuum. The product was extracted with *n*-pentane and crystallized at −78 °C (yellow crystals, 3.95 g, 85% yield). **2**–**13** were accessible in an analogous way.

Selected physical data: **6**: colorless needles (*n*-pentane), m.p. −15 °C (decomp > 40 °C, sublimation at −10 °C, 10^{-3} Torr). ^{1}H NMR (399.78 MHz, [D$_8$]toluene, 25 °C, TMS): δ = 1.92 (s, 9 H, NCH_3), 5.36 (s, br, 2 H, GaH); ^{13}C NMR (100.5 MHz, [D$_8$]toluene, 25 °C, TMS): δ = 49.5 (q, NCH_3), 205.1 (s, CoCO). IR [12]: $\tilde{\nu}$[cm^{-1}] = 2074 st, 2006 st, 1978 sst, 1964 sst (ν(CO)). Correct C, H, N analysis. **11**: white microcrystalline powder (*n*-pentane), m.p. 35 °C (sublimation at 60 °C, 10^{-3} Torr). δ = 0.66 (d, 1H, ^1J(H,H) = 14.1 Hz, $AlCH_2$), 0.68–0.76 (ABCD, 1H, $AlCH_2CH_2$), 0.79–0.88 (ABCD, 1H, $AlCH_2CH_2$), 0.95 (d, 1H, ^1J(H,H) = 14.1 Hz, $AlCH_2C$), 1.09 (d, 9H, ^2J(P,H) = 8.5 Hz, PCH_3), 1.29 (s, 9H, CCH_3), 1.64–16.8 (ABCD, 1H, $AlCH_2CH_2$), 1.79–1.83 (ABCD, 1H, $AlCH_2CH_2$), 2.06 (s, 3H, NCH_3), 2.06–2.10 (ABCD, 1H, NCH_2CH_2), 2.27 (s, 3H, NCH_3), 2.35–2.40 (ABCD, 1H, NCH_2CH_2); ^{13}C{^{1}H} NMR (100.5 MHz, C_6D_6, 25 °C, TMS): δ = 11.4 (br, $AlCH_2CH_2$), 22.5 ($AlCH_2CH_2$), 32.2 ($AlCH_2C$), 34.8 (CCH_3), 34.9 (br, $AlCH_2C$), 47.5 (NCH_3), 47.7 (NCH_3), 65.0 (NCH_2), 205.8 (d, ^1J(P,C) = 8 Hz, CoCO); ^{27}Al{^{1}H} NMR (104.14 MHz, [D$_8$]toluene, 25 °C, $Al(NO_3)_3/H_2O$ ext.) δ = 198 ($\nu_{1/2}$ = 4340 Hz); ^{31}P{^{1}H} NMR (161.9 MHz, [D$_8$]toluene,

$-80\,^{\circ}C$, 85% H_3PO_4 ext.): $\delta = 9.0$. IR (*n*-pentane): $\tilde{\nu}[cm^{-1}] = 1922$ sst, 1903 sst (ν(CO)). EI-MS (70 eV): m/z 403 (M^+, 3%). Correct elemental analysis.

[11] **1**–**12** undergo complex insertion reactions (insertion of, for example, chalcogens (S, Se, Te) and pnictogens (P, As) into the d-block metal–Group 13 metal bond) and show a very promising photochemistry (cf. the transformation of **1** into **14**).

[12] The localization of the $\nu(GaH_2)$ vibration in the IR spectra of **6** and **7** is still not clear due to the overlapping carbonyl bands. Deuteration experiments are in progress.

β-CoGa and ε-NiIn Films from Organometallic Single-Source Precursors: Ligand-Control of the Film Composition**

By *Roland Fischer*,* *Wolfgang Scherer*, and *Matthias Kleine*

Thin-film heterostructures such as CoGa on GaAs produced by molecular beam epitaxy are currently the subject of intensive study.[1] These materials could become essential as new Ohmic contacts or Schottky barriers. For example, they could serve as Gate metallizations for metal semiconductor field-effect transistors (MESFETs) for the construction of ultralarge-scale integrated circuits (ULSIs).[2] Starting from *two* separate precursors, the chemical gas-phase epitaxy of β-CoGa on GaAs(100) has been achieved.[3] The deposition of such bimetallic materials from single-source precursors is particularly advantageous when all the factors essential for the layering process are incorporated into the molecular structure of the precursor and thus, only pressure and temperature remain as regulating parameters.[4] The transition-metal-substituted alanes, gallanes, and indanes **1**–**6** (Fig. 1),[5] about whose suitability for chemical vapor deposition of intermetallic films we report here, come close to this property profile.

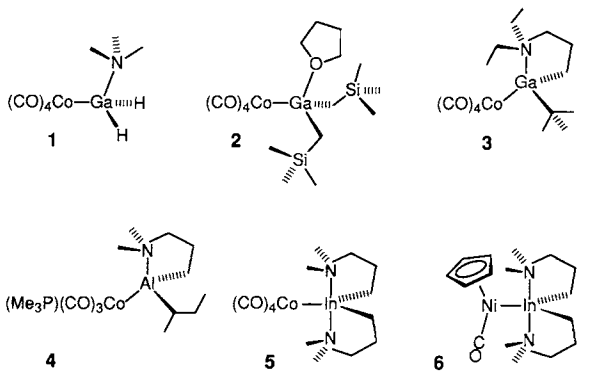

Fig. 1. Volatile transition-metal-substituted alanes, gallanes, and indanes [5].

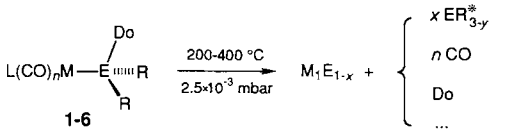
The vapor pressure of the CoIn system **5**, which is 0.020(5) mbar (tensiometric[6]) at 20 °C is exemplary for this group of compounds. For the chemical vapor deposition (CVD) a horizontal hot-walled reactor was used. Complexes **1**–**6** were sublimed at 2.5×10^{-3} mbar from a thermostated reservoir directly into the reaction zone preheated to 200–400 (±10) °C,[7] and pyrolyzed there. Carrier gases were not used. Volatile by-products were collected in a cold trap (−196 °C). The analysis of the highly adhesive, metallic, polycrystalline films[8] (Table 1) deposited on various substrates (growth rate ca. $1\,\mu m\,h^{-1}$), and of the gaseous by-products[9] showed that the degradation of the precursors occurs according to Scheme 1.



Scheme 1. Degradation reactions of the precursors **1**–**6** to give intermetallic phases. (L = CO, Cp, PMe_3; $n = 1$–3; M = Co, Ni; E = Al, Ga, In; $0 \geq x \geq 1$; R* = alkyl, then $y = 0$; R* = Cp, then $y = 2$; "..." denotes cleaved, volatile organic ligands or ligand fragments [9]).

The 1:1 metal ratio of the precursors is *not* necessarily reproduced in the films. Thus, from the degradation of **2** approximately half of the gallium is found as $Ga(CH_2SiMe_3)_3$ (which is stable to pyrolysis) in the cold trap. The discharge of the Group 13 metal proved to be a general effect. For a given substrate temperature this process is controlled by the ligands at both metal centers, as shown, for example, by the comparison of **2** and **3**.[10] Since **1**–**6** sublime without decomposition, and the pressure in the system is low, we assume surface reactions are the explanation for this occurrence. According to mass spectrometric findings[11] the lowest energy and probably favored first steps in the degradation of the molecule are the cleavage of the donor ligand at the Group 13 metal and the breaking of the intermetallic bond. Thereafter, competition between ligand fragmentation and ligand reorganization plays a role. The latter may, in certain cases, lead to thermally stable organometallic compounds of Group 13 elements, which then desorb. Thus, it is understandable that the deposition of CoGa from a 1:1 mixture of $GaEt_3$ and $[Cp(CO)_2Co]$ at 250–300 °C and 1010 mbar (laminar flow reactor) afforded cobalt-rich, metastable α-Co_xGa_{1-x} films ($x \geq 0.41$). Only a tenfold excess of the gallium precursor compensates for its inefficient pyrolysis and leads—mass transport limited—to β-CoGa films.[3] However, the vacuum degradation of single-source precursors to yield a thin film is controlled kinetically[12] and offers the interesting possibility of adjusting the composition of the film through regulation of the temperature alone. If the formation of thermally stable organometallic compounds of Group 13 elements during the growth of the film is negligible, the limiting value M/E = 1 is already reached at very low temperatures. This is particularly the case for **1** and **5**.[10] Thus, the instability of gallane prevents a discharge of gallium for **1**, in sharp contrast to the related complex $[(CO)_5MnSiH_3]$, in which the silane is a potentially stable leaving group.[13] However, not only the substituents at the Group 13 metal are involved in the degradation process, the ligands at the d-block metal are also important. Whereas **5** affords Co_1In_1 films exclusively, the closely related NiIn precursor **6** gives, depending on the substrate temperature, films with a NiIn ratio of 2.9 to 1.1. The determining factor for this is the extent of Cp transfer to the In atom, leading to the formation of [CpIn], which leaves the reaction chamber. The ligand control of the composition of the film is an aspect that in future should be considered when CVD experiments are carried out. This is particularly true when, during heterogeneous pyrolysis, a part of the ligand sphere takes part in reorganization processes, and is bound *unfragmented* in the form of stable, volatile by-products.[14]

The suitability of CO ligands for CVD precursors is disputed. There is the danger of CO dissociation and thus, of the contamination of the film with C and O. We found, however, that the films were surprisingly low in impurities (Table 1, Fig. 2). Typical values are 1–4 atom% C and ≤1 atom% O (N, P could not be detected). The best conductivities (about 100 $\mu\Omega$cm) are close to the literature values.[15] The residual C content seems to stem from hydrocarbon ligands, since high C contents appear together with high H contents (EA[8]), whereas contaminations with O are only influenced by the leak velocity and the manipulation of the samples. The degradation of the precursors in the plasma-enhanced CVD experiment is remarkably less selective, leading to considerably higher $(CH)_x$ portions in the bimetallic films.[16]

The identity of the phases of the films corresponds to the binary phase diagram of the respective combination of metals. β-CoGa, for example, consists of 34.4% Ga to 57.8% Ga at 25 °C.[17] All CoGa films obtained proved to be single-phase β-CoGa with a dominant [110] reflection.[18] In the Co/In system only $CoIn_2$ and $CoIn_3$ are stable.[19] CoIn films deposited from **5** show reflections which are attributed to these phases.[18] The phase diagrams of other interesting alloys such as Co/Al, Ni/Ga, and Ni/In are more complex, and the homogeneity regions are narrower. Thus, it is very difficult to obtain single-phase films. We have achieved this for the first time with NiIn films deposited from **6** at 350 °C. The complete indexed X-ray diffractogram[18] (Fig. 3) contains only reflections of the hexagonal ε-NiIn phase,[20] a potential epitactic contact metal for GaAs and InP.[2] These results are encouraging for the further development of single-source precursors for bimetallic films.

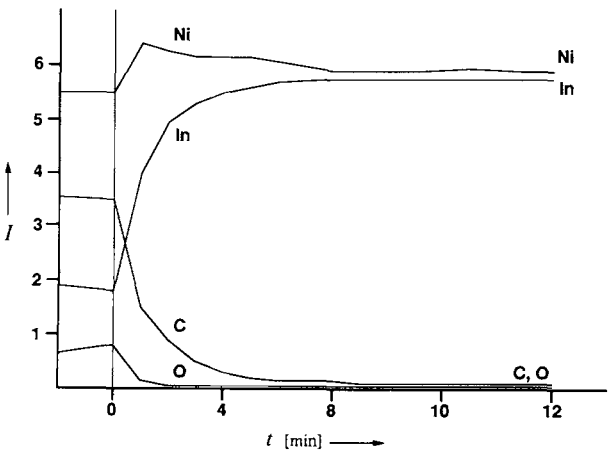

Fig. 2. Depth profile (Auger electron spectroscopy) of a film deposited on GaAs(100) $Ni_{0.52}In_{0.48}$ (see Table 1, last entry) from **6** at 350 °C. The signal intensity I (peak to peak ratio in arbitrary units) is plotted against the sputter time t (argon ions) for the Auger lines: Ni, LMM at 848 eV; In, MNN at 404 eV; C, KLL at 272 eV, and O, KLL at 504 eV.

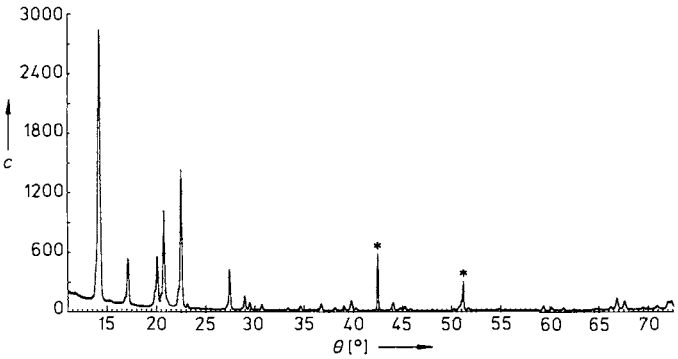

Fig. 3. X-ray powder diffractogram [18] of the $Ni_{0.52}In_{0.48}$ film from Figure 2 in the range 11° ≤ θ ≤ 73° (abscissa). The most intense reflection [*hkl*], θ value (relative intensity %): [101], 14.22° (100); [110], 17.09° (7); [111], 20.05° (6); [002], 20.74° (11); [201], 22.49° (18); [112], 27.39° (5). The reflections marked with * stem from the GaAs substrate. c = counting rate.

Experimental Procedure

The precursor reservoir of the reactor fueled with substrates and conditioned 24 h at ≤ 5×10^{-6} Torr and 250 °C was filled with substance (0.5–1.0 g) under argon at 25 °C. After the reservoir had been cooled to −30 °C, the deposition zone was warmed up to the desired substrate temperature under continuous

vacuum. After the vacuum had stabilized the reservoir temperature was regulated slowly up to a system pressure of about 2.5×10^{-3} mbar and deposition was carried out for about 5–6 h.

[7] A temperature range of 300 ± 50 °C is of interest for commercial applications [1–3].

[8] The films deposited on borosilicate glass, quartz, Si(100), GaAs(100), InP(100), KBr disks, and stainless steel were characterized by: Auger electron spectroscopy (AES; Perkin–Elmer Phi 595, initial irradiation 3 keV, intensity 0.20 μA), scanning electron microscopy (SEM), energy-dispersive X-ray spectroscopy (EDX), X-ray powder diffractometry [18], classical combustion analysis according to Pregl (EA; yield of ca. 20–50 mg film by dissolving the KBr substrates in water or by quenching of the reaction reaction tube) as well as by atomic absorption spectroscopy (AAS) after the dissolution of the film in HNO_3. Quantitative AES and EDX data were calibrated against AAS and EA values and against standard samples ($Co_{0.50}Ga_{0.50}$). A significant variation of the composition over the layered surface (ca. 3.5 cm^2) and layer thickness (0.2 μm to ca. 6–7 μm) was not present (AES, EDX).

[9] The trapped volatile by-products were fractionated under high vacuum, isolated, and characterized (^1H, ^{13}C NMR; IR; GC/IR/MS; AAS). The percentage of Group 13 metal discharged was determined quantitatively (AAS) by acidic hydrolysis. The liberation of CO was confirmed by GC/IR. The spectrum of the organic by-products, depending on the precursors, is dominated by olefins such as isobutene, 3-dimethylaminopropene (and isomers thereof), or cyclopentadiene. The donor ligands trimethylamine and tetrahydrofuran from **1** or **2** are deposited without fragmentation. The trimethylsilylmethyl groups in **2** afford a mixture consisting mainly of tetramethylsilane, trimethylsilane, 1,2-bis(trimethylsilyl)ethane, and ethyltrimethylsilane.

[10] If halide groups are present at the Group 13 metal, as in the complex $[(CO)_4CoGaCl_2(thf)]$, the composition of the films is constant only above 500 °C [3,15].

Models for the Photosynthetic Reaction Center—Synthesis and Structure of Porphyrin Dimers with *cis*- and *trans*-Ethene and Skewed Hydroxymethylene Bridges**

By *Mathias O. Senge, Kevin R. Gerzevske, M. Graça H. Vicente, Timothy P. Forsyth,* and *Kevin M. Smith**

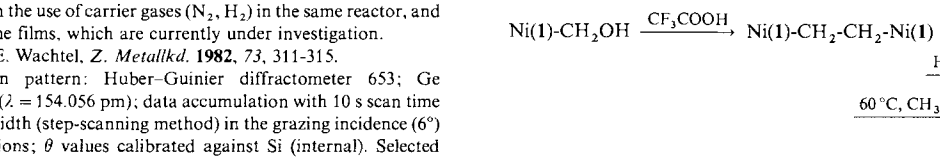
Dedicated to Professor Emanuel Vogel on the occasion of his 65th birthday

Covalently linked porphyrin dimers are of continuing interest as biomimetic models of the photosynthetic reaction center.[1] They serve as models for studying charge separation, exciton transfer, and other spectroscopic characteristics of the "special pair" in the bacterial reaction center.[2] To facilitate such studies the geometry of the subunits in a dimer must be known, and preferably the relative arrangement of the subunits should be varied to study effects of interplanar separation and spatial arrangement, for example, on the photophysical parameters. Herein we report the preparation and structural characterization of three bisporphyrins with different macrocycle arrangements: cofacial, extended linear, and skewed "gable-type" macrocycle orientations.

Of special interest are cofacial (face-to-face) porphyrin dimers which have considerable overlap of the π-electron systems and thus mimic the situation in vivo more closely than linear arrays. Although a number of such compounds has been prepared, their synthesis is laborious and plagued with low yields.[3–5] In general such compounds can be prepared only by linking two porphyrins with two or more bridging units ("strapping")[4] or by using rigid bridging units such as biphenylenediyl, anthracenediyl,[5] or 1,2-phenylene[6] which force the subunits into a cofacial arrangement. Tetrapyrroles linked by flexible bridging units such as CH_2-CH_2 invariably lead to the formation of dimers with extended structures.[7]

Recently it was shown that the titanium-induced reductive coupling (McMurry reaction)[8] of 5-formylporphyrins **2**, which are easily derived from octaethylporphyrin (OEP) **1**, provides convenient access to CH=CH bridged bisporphyrins.[9] For thermodynamic reasons this reaction should lead to the *trans* isomer **4**. However, spectroscopic data indicate[9] that when the Ni formylporphyrin **2b** is used, a mixture of *cis* and *trans* isomers results.

The coupling of **2b** proceeds in about 50% yield to give the ethene-bridged bis(porphyrinato)nickel(II) complex. After 1 h reaction time several signals for the *meso* protons were observed in the ^1H NMR spectrum (Fig. 1b), and UV/VIS spectroscopy indicated the presence of two compounds. Two of the NMR signals for the *meso* protons were identical with those obtained for **4b**, which was prepared by the reaction sequence shown in Scheme 1.[10]



Scheme 1. Synthesis of **4b**. acac = acetylacetonate.

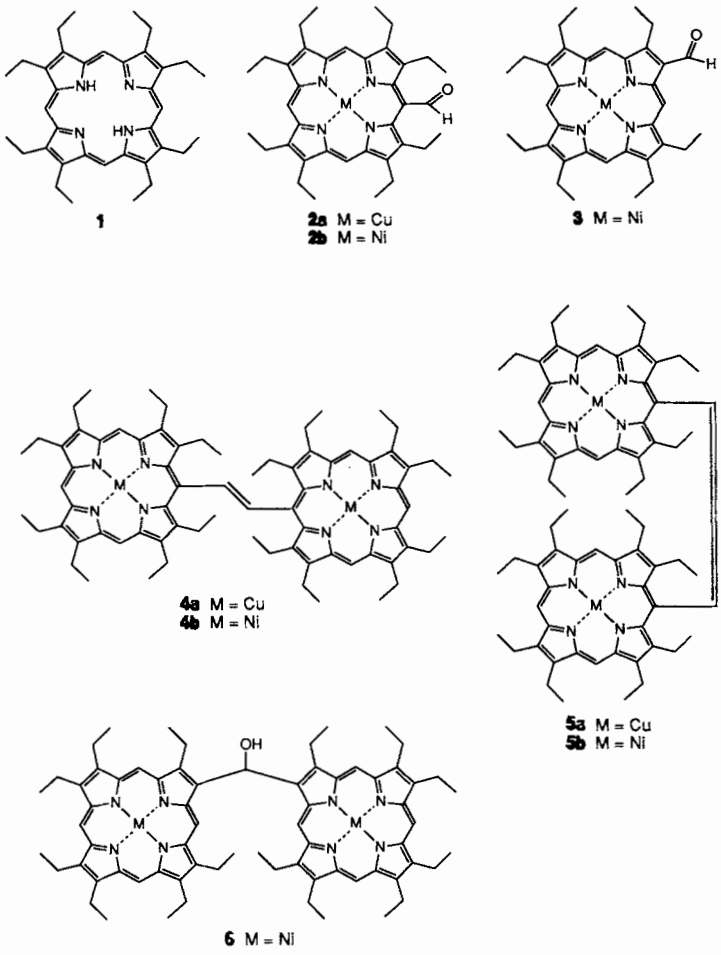
[**] This work was supported by the National Science Foundation (CHE-90-01381) and the Deutsche Forschungsgemeinschaft (Se543/1-1). We thank Prof. G. V. Ponomarev (Moscow) for stimulating discussions.



A variable-temperature NMR study in $[D_2]$1,1,2,2-tetrachloroethane showed broadening and subsequent disappearance of two of the signals for the *meso* protons above 120 °C.

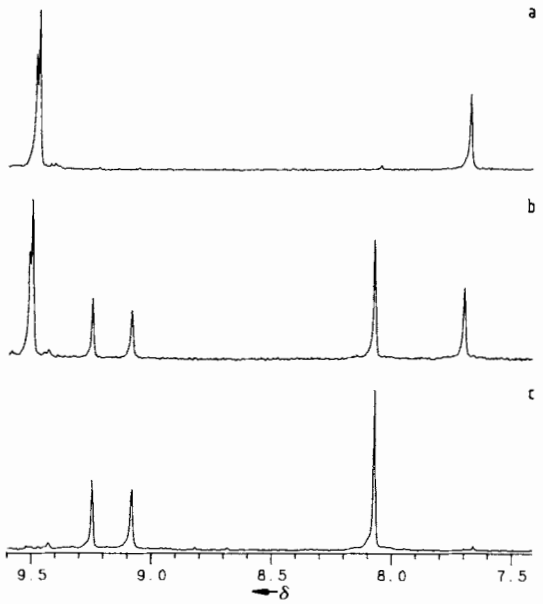


Fig. 1. ^{1}H NMR spectra of the Ni^{II} porphyrin dimers in $[D_2]$1,1,2,2-tetrachloroethane; region for the *meso* protons. a) Spectrum of **4b**, identical with the one obtained after heating the sample from spectrum b) for 1 h at 120 °C; b) spectrum of the product mixture from the coupling of **2b** after 1 h reaction time; c) spectrum of **5b**. For assignments of the signals see ref. [12].

The remaining NMR signals (Fig. 1a) were identical with those obtained for the *trans* isomer prepared according to the method of Ponomarev and Shul'ya.[10]

The results of the NMR studies can thus be interpreted as indicating the conversion of the *cis* compound **5b** into the *trans* compound **4b**. This process is irreversible, possibly because of the slightly acidic solvent used which led to acid-catalyzed formation of the thermodynamically more stable *trans* isomer. Likewise, heating **5b** in $[D_2]$1,1,2,2-tetrachloroethane at 120 °C for roughly 12 h resulted in complete conversion to **4b**. A similar conversion was observed after prolonged irradiation. However, treatment with acid at room temperature led to no changes. A variable-temperature NMR study of the pure *trans* dimer **4b** showed only broadening of the peaks arising from the *meso* protons.

After evaporation of the NMR sample containing **4b**, brown crystals were obtained from CH_2Cl_2/CH_3OH. Preliminary X-ray data show clearly the *trans* configuration of the bridging CH=CH unit and an extended linear array of the porphyrins with coplanar orientation of the macrocycle planes.[11] The structure closely resembles that obtained for a CH_2-CH_2 bridged Ni^{II}(OEP) dimer.[7a] This allowed a correct assignment of the NMR and UV/VIS data of the *trans* compound **4b**.[12] The situation was much simpler for the related copper(II) compounds. Coupling of **2a** led to formation of the dimer in about 70% yield. After column

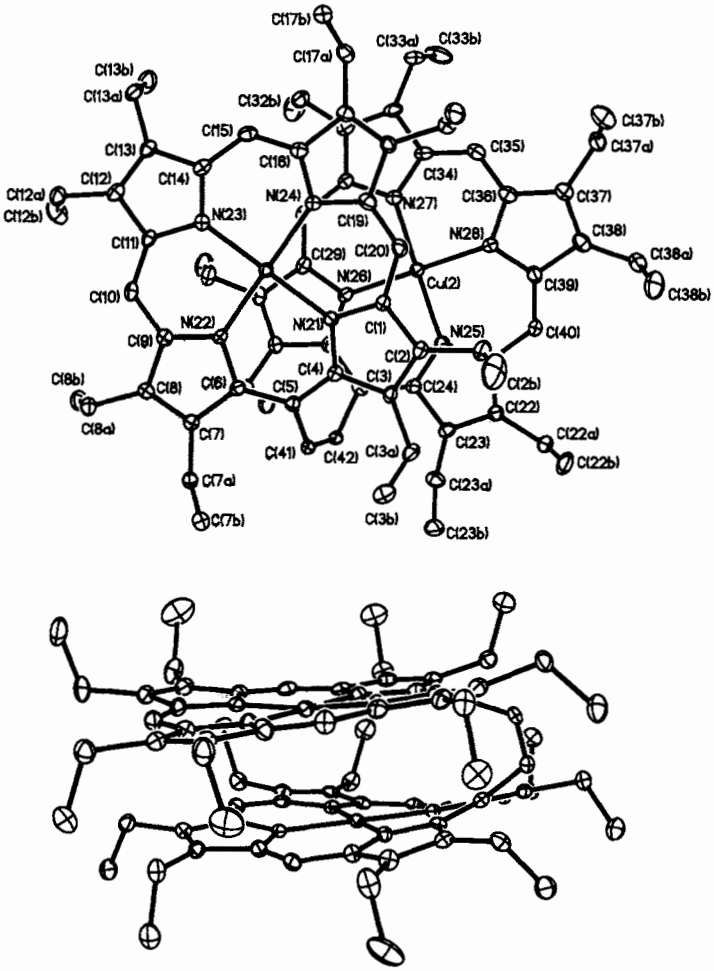

Fig. 2. The crystal structure of **5a**. Ellipsoids are drawn at the 40% occupancy level. Top: Top view; bottom: side view. Selected bond lengths [Å] and angles [°]: C(5)-C(41) 1.489(7), C(41)-C(42) 1.327(7), C(42)-C(25) 1.489(6), C(5)-C(41)-C(42) 121.9(4), C(25)-C(42)-C(41) 123.8(4).

chromatography and crystallization from CH_2Cl_2/CH_3OH, a single compound (**5a**) was obtained which displayed sharp UV/VIS absorption maxima at 393 and 568 nm. The crystal structure analysis[13, 14] (Fig. 2) indicate the predominant formation of the *cis* ethene-bridged bisporphyrin **5a**. Thus this type of system is readily accessible.

The *trans* dimer **4a** is insoluble in most organic solvents and was thus easily separated from the *cis* dimer **5a** during chromatography; **4a** remained on top of the column used for purification, while **5a** was cleanly eluted. By analogy the formation of both isomers in the dimerization of **2b** leads to two sets of signals for the *meso* protons. The unexpected formation of a *cis* bisporphyrin from **2b** and its predominant formation from **2a** appear to indicate strong π–π stacking of the two halves of the dimer prior to final formation of the alkene bond.

The strong overlap of the π-electron systems deduced from the crystal structure indicates that porphyrin–porphyrin aggregation plays a significant role in stabilizing the cofacial macrocycle arrangement. The two macrocycles are almost parallel; the angle between the two planes of the four nitrogen atoms is 1.9°. If the bridging double bond alone were to influence the geometry of the dimer, an arrangement with larger angles between the planes would have been expected. The short mean separation of the two planes by 3.36 Å can thus be explained only by aggregation forces that bring the two macrocycles into the observed cofacial conformation. This value is close to those reported for other cofacial dimers, for example, 3.43 Å in a 1,2-phenylene-bridged[6b] and 3.45 Å in a biphenylenediyl-bridged bisporphyrin,[5a] and 3.52 Å in "Cu_2-hexyldiporphyrin-7".[4a] The Cu–Cu separation in **4a** is 4.63 Å, which, together with a slip angle of 43.9°, leads to a lateral shift of the metal centers by 3.21 Å. These quantities have been used by Scheidt and Lee[15] to classify the degree of porphyrin aggregation. On this basis, the present dimer falls into the middle range of this type of interaction. The geometry of the bisporphyrin with its lateral displacement of the two macrocycles resembles closely the arrangement predicted by Abraham et al.[16] on the basis of NMR studies for the aggregation of metalloporphyrins in solution. The displacement of the macrocycles clearly results from electrostatic interactions between the metal centers and the aromatic ring system. The signals of the *meso* protons of the *cis* dimer **5b** are shifted upfield up to $\Delta\delta = 1.5$. This indicates a shielding effect in the stacked porphyrin array in solution similar to that observed in the crystal structure. The UV/VIS spectra show generally a blueshifted Soret band for the *cis* dimer (393 nm) compared to that of the *trans* dimer (414 nm) indicating excitonic interaction. Similar results were obtained for a 1,2-phenylene-bridged dimer by Osuka et al.[6b] No changes were observed in NMR spectra recorded below −80 °C. This indicates that the two halves of the bisporphyrins oscillate against each other and that only an averaged structure is observed on the NMR timescale.

The use of the McMurry reaction also allows a further variation in the geometry of the dimers obtained. If instead of a *meso*-formyl-substituted a β-formyl-substituted porphyrin (**3**) is used, the reaction proceeds not by formation of a connecting HC=CH unit but rather by loss of one of the formyl groups and formation of a hydroxymethylene-bridged dimer **6**. The crystal structure analysis of **6** (Fig. 3) shows that this type of dimer has a skewed arrangement of the two porphyrin rings.[14, 17] The two planes through the nitrogen atoms of the porphyrins form an angle of 77.3°. The macrocycle conformation in the two subunits is quite different. While the *meso* carbon atoms in the macrocycle with Ni(1) show an average deviation from planarity of 0.35 Å,

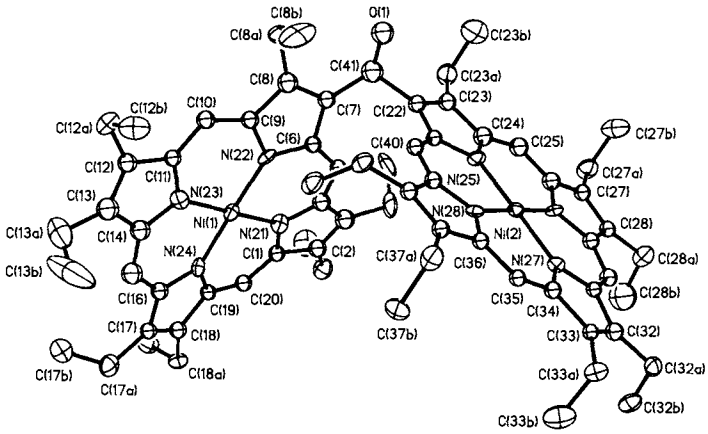

Fig. 3. The crystal structure of **6**. Ellipsoids are drawn at the 40% occupancy level. Selected bond lengths [Å] and angles [°]: C(7)-C(41) 1.54(2), C(22)-C(41) 1.55(2), C(41)-O(1) 1.32(2), C(7)-C(41)-C(22) 113(1), C(7)-C(41)-O(1) 116(1), C(22)-C(41)-O(1) 110(1).

those of the ring with Ni(2) show deviations of only 0.1 Å. A similar situation prevails in the crystal structure of **5a**: in one ring the *meso* carbon atoms are displaced on average by 0.05 Å, while in the other displacements of 0.36 Å are observed. These results might have implications for influencing the conformational flexibility[18] in tightly packed porphyrin arrays.

A simple variation of the position of the formyl group in the starting material thus allows the formation of two dimer types with very distinct geometric features. In addition, when the starting complex **2** has the appropriate metal ion, cofacial bisporphyrins **5** with *cis* double bonds can be prepared, which can be easily converted to the *trans* compounds **4**. This makes possible further studies on the dependence of photophysical parameters and catalytic properties on the relative geometrical arrangement of the porphyrin subunits.

[11] Crystal structure analyses of the *trans* dimers proved to be very difficult. Due to the insolubility of **4a** and **4c** no crystals were obtained for the Cu

and Zn complexes; likewise we have not yet been able to grow crystals of **4d**. Brown cubes of **4b** were obtained from $CHCl_3/CH_3OH$. $C_{74}H_{88}N_8Ni_2 \cdot 2CHCl_3$, triclinic, space group $P\bar{1}$, $a = 10.286(1)$, $b = 12.812(2)$, $c = 14.775(2)$ Å, $\alpha = 104.64(1)$, $\beta = 108.46(1)$, $\gamma = 95.66(1)°$, $V = 1752.8(7)$ Å^3; data collection at 126 K with $Cu_{K\alpha}$ radiation. The structure solution revealed all atoms including two $CHCl_3$ molecules of solvation and clearly showed the *trans* configuration of the connecting double bond. However, refinement below $R = 0.19$ was not possible due to systematic twinning problems.

[12] Characterization of the Ni^{II} *cis* and *trans* dimers: **4b**: m.p. > 300 °C; UV/VIS (CH_2Cl_2): λ_{max}[nm](ε) = 414 (1.599×10^5), 488 (30400), 530 (20740), 566 (22760). ^1H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 9.50$ (s, 2H, *meso*), 9.48 (s, 4H, *meso*), 7.66 (s, 2H, CH=CH), 3.88 (m, 16H, CH_2), 3.76 (q, 8H, CH_2), 3.37 (m, br, 8H, CH_2), 1.83, 1.82 (t, 12H each, CH_3), 1.75 (t, 12H, CH_3), 1.02 (t, 12H, CH_3). **5b**: m.p. > 300 °C; UV/VIS (CH_2Cl_2): λ_{max}[nm](ε) = 393 (1.682×10^5), 435 (12190), 568 (14650). ^1H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 9.30$, 9.05 (s, 2H each, *meso* and CH=CH), 8.06 (s, 4H, *meso*), 4.03, 3.84, 3.75, 3.57, 3.47, 2.89 (m, 4H each, CH_2), 2.60 (s, 8H, CH_2), 1.83 (m, 12H, CH_3), 1.43–1.53 (m, 24H, CH_3), 0.67 (t, 12H, CH_3). The *cis* and *trans* isomers can easily be separated based on solubility properties.

[13] Crystal structure data of **5a** (crystallized from CH_2Cl_2/CH_3OH): $C_{74}H_{88}N_8Cu_2$, $M_r = 1216.6$, monoclinic, space group $P2_1/n$, $a = 19.208(7)$, $b = 14.672(5)$, $c = 24.170(7)$ Å, $\beta = 111.15(3)°$, $V = 6352(4)$ Å^3, $Z = 4$; $\rho_{calcd} = 1.271$ Mg m^{-3}; $\mu(Mo_{K\alpha}) = 0.718$ mm^{-1}. Data collection on a Siemens R3m/V diffractometer at 130 K with $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å) and a graphite monochromator; crystal size: $0.52 \times 0.32 \times 0.21$ mm. Patterson synthesis, refinement by least-squares on $|F|$, all atoms refined with anisotropic thermal parameters, H atoms incorporated using a riding model, $R = 0.056$, $wR = 0.064$, $S = 1.22$; 8040 reflections observed with $F > 5.0\,\sigma(F)$, $2\theta_{max} = 55°$ [14].

[14] Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-57206, the name of the authors, and the journal citation.

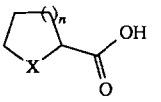
Separation of Diastereomers by Distillation—A New Procedure for the Synthesis of Optically Active Heterocyclic Carboxylic Acids

By *Elke Fritz-Langhals**

In the conventional preparation of optically active carboxylic acids by resolution, the racemic carboxylic acids are treated with an optically active amine, and the resulting diastereomeric salts are separated by fractional crystallization. This standard method has also been used for the isolation of the optically active heterocyclic carboxylic acids **1a–d**. The resolution of 2-tetrahydrofurancarboxylic acid **1a** (X = O, $n = 1$), for example, has been performed with brucine, cinchonidine,[1] quinine,[2] and the optically active amines 4-bromo- and 4-chloro-1-phenylethylamine,[3] which are not commercially available. The yields are moderate or low, however, especially when products of high optical purity are required. Moreover, since the isolation of the second enantiomer from the mother liquor presents considerable difficulties, a second optically active amine is necessary. The resolutions of analogous heterocyclic carboxylic acids such as 2-tetrahydrothiophenecarboxylic acid **1b** (X = S, $n = 1$)[2, 4] and 2-tetrahydropyrancarboxylic acid **1c** (X = O, $n = 2$)[2] suffer from similar complications.



1a: X = O, $n = 1$; **1b**: X = S, $n = 1$
1c: X = O, $n = 2$; **1d**: X = S, $n = 2$

The disadvantages of classical resolution prevent the preparation of larger amounts of optically pure compounds and restrict the possibility of applications of optically active heterocyclic carboxylic acids in pharmaceuticals such as Terazosin, a vasodilator,[6] and as building blocks for liquid crystals.[7] The isolation of *both* enantiomers in *one* step would be particularly desirable. We wondered if instead of the differences in solubilities of diastereomeric compounds, the differences in boiling points could be used for simple preparative separations. For this purpose we linked the previously mentioned racemic heterocyclic carboxylic acids with various optically active amino acid esters with an amide bond. The resulting diastereomeric carboxylic acid amides **2** (Table 1) displayed unusually large differences in boiling points of up to 7 K, thus allowing separation by distillation.

[a] GC retention time on Carbowax 20M, 25 m quartz capillary, heated from 70–230 °C at a rate of 8 °C min^{-1}. [b] Boiling point [°C] at a pressure of ca. 0.01 Torr. [c] Type of column: PC: packed column 5 cm in diameter packed with 4 mm glass spirals, reflux ratio ca. 5:1 to 10:1; SBC: spinning-band column, reflux ratio ca. 20:1. Length *l* in m. [d] Diastereomeric excess obtained in preparative separation; the absolute configuation (in parentheses) was assigned after hydrolysis of the optically enriched diastereomer by comparison with the literature values for the optical rotations. [e] Refers to one diastereomer. [f] Pressure ca. 0.05 Torr.

For example, the acid chloride derivative **3a** of racemic 2-tetrahydrofurancarboxylic acid **1a** was treated with (*S*)-valine methyl ester (*ee* > 99 %[8]) to provide the diastereomeric amides **2a** (X = O, $n = 1$, R = $CH(CH_3)_2$, R′ = CH_3) (Scheme 1), and these were separated by distillation through a 1 m packed column (Table 1). Acidic hydrolysis of the two fractions "(*R,S*)" and "(*S,S*)" gave the two enantiomers of **1a** without racemization. (*S*)-Valine may also be recovered

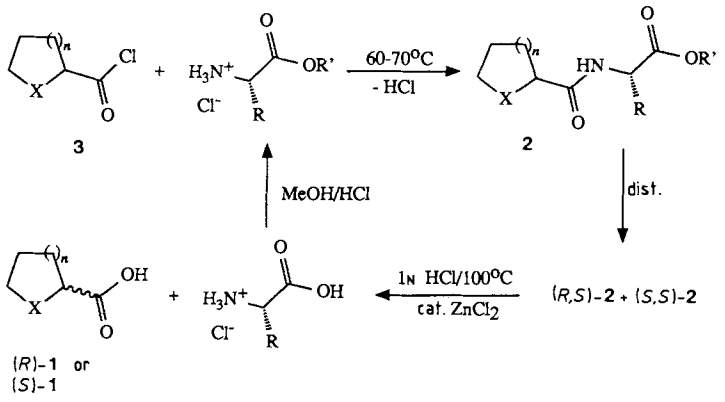
Zentrale Forschung der Wacker-Chemie GmbH
Zielstattstrasse 20, D-W-8000 München 70 (FRG)

without significant loss of optical purity (*ee* > 96.6%). This simple separation providing both enantiomers in high yield and optical purity can be performed in the laboratory easily with amounts between 0.5 and 1 kg per run.



Scheme 1.

As shown in Table 1, the methyl and ethyl esters of (*S*)-alanine and (*S*)-leucine can be used instead of (*S*)-valine derivatives. Besides the heterocyclic carboxylic acids **1a–c** previously known in optically active form, the two enantiomers of 2-tetrahydrothiopyrancarboxylic acid **1d** (X = S, $n = 2$) could be isolated by this procedure. Of course, the optical purity achieved by the separation of diastereomers can be improved by increasing the reflux ratio and the number of theoretical plates. The effort required for the distillation can be estimated from the difference in the GC retention times.

In contrast to the amides described here, the diastereomeric esters prepared from heterocyclic carboxylic acids and various optically active alcohols[9] have minimal boiling point differences (< 1 K). This illustrates that in analogy to resolution by fractional crystallization, various derivatives must be tested to determine whether they are suitable for separation by distillation. In contrast to the traditional method, however, simple GC analysis of the product mixture gives a quick and reliable assessment of the separation, as the difference in the retention times reflects the difference in boiling points.

Experimental Procedure

Heterocyclic carboxylic acid amides **2**: To a stirred suspension of 0.98 mol (*S*)-amino acid ester hydrochloride[10] in 350 mL toluene heated at 50–70 °C was added dropwise 0.89 mol heterocyclic carboxylic acid chloride **3** (obtained from carboxylic acids **1a**, **1b**[4a], **1c**[11], or **1d**[12] by reaction with thionyl chloride). The reaction mixture was stirred and heated at this temperature until the evolution of HCl had ceased (ca. 20 h). The reaction mixture was washed with water and distilled. Representative yields: **2a** 94%, **2a″** 87%, **2b** 79%, **2c** 80%, **2d** 73% (R = $CH(CH_3)_2$, R′ = CH_3). The diastereomeric pairs were separated by distillation, see Table 1.

(*R*)-**1a**: A mixture of 100 g (0.437 mol) (*R,S*)-**2a** (diastereomer ratio (*R,S*):(*S,S*) = 98.7:1.3) and 3 g (22 mmol) $ZnCl_2$ in 400 mL 1 M HCl was heated at 100 °C for 4 d. The reaction mixture was concentrated to dryness and the residue extracted with methyl *tert*-butyl ether (MTBE). The filtered MTBE extract was distilled giving 36 g (78%) (*R*)-**1a** with b.p. 83 °C/0.3 Torr (ref.[10] b.p. 97–100 °C/1.05 Torr); $[\alpha]_D^{27} = +33.3$ ($c = 1.23$, $CHCl_3$; ref.[1]: −30.1 ($c = 1.21$, $CHCl_3$) for the (*S*) enantiomer), $[\alpha]_D^{23} = +33.5$, $[\alpha]_D^{27} = +35.1$ ($c = 1.07$, $CHCl_3$; ref.[1]: +30.4 ($c = 1.01$, $CHCl_3$)). For the determination of enantiomer ratio the product was reduced with $LiAlH_4$ to give the tetrahydrofurfurylalcohol which was then analyzed by gas chromatography[13]. The ratio found was *R*:*S* = 98.7:1.3. The residue filtered off the MTBE phase consisting of (*S*)-valine hydrochloride was dried in vacuo and weighed (43 g, 70% recovery). For the determination of the optical purity of the recovered valine a portion was treated with methanol/HCl and trifluoroacetic anhydride and then analyzed by gas chromatography (Chiral-XE-60-S-Val). The enantiomer ratio found was *S*:*R* = 98.3:1.7.

An Ab Initio MO Study on Stabilizing Interactions in Dinuclear Zr/Al Complexes with a Planar Tetracoordinate Carbon Center**

By *Rolf Gleiter,* Isabella Hyla-Kryspin, Shuqiang Niu,* and *Gerhard Erker*

In their seminal work, Hoffmann et al. considered the possibility of stabilizing planar methane.[1] They concluded that the distortion of tetrahedral methane to the square-planar CH_4 isomer leaves only six electrons available to form four C–H bonds and a doubly occupied 2p orbital at the carbon center (Scheme 1). This high-energy structure can be stabilized by σ-donor and π-acceptor substituents X. These thoughts were substantiated by Schleyer et al. by ab initio calculations.[2] Only a few structures have been determined so far in which a carbon atom is surrounded by four substituents in a single plane.[3]

[**] This research was supported by the Volkswagen-Stiftung, the Deutsche Forschungsgemeinschaft (SFB 247), the Fonds der Chemischen Industrie, and BASF AG.

Prompted by the experimental work of Erker et al.[4] on zirconocene complexes such as **1** we present here a theoretical model based on ethylene. Bending a $=CH_2$ unit of ethylene into a T-shape (Fig. 1) stabilizes the C–C σ orbital but destabilizes two C–H σ orbitals (denoted as P^+ and P^-).

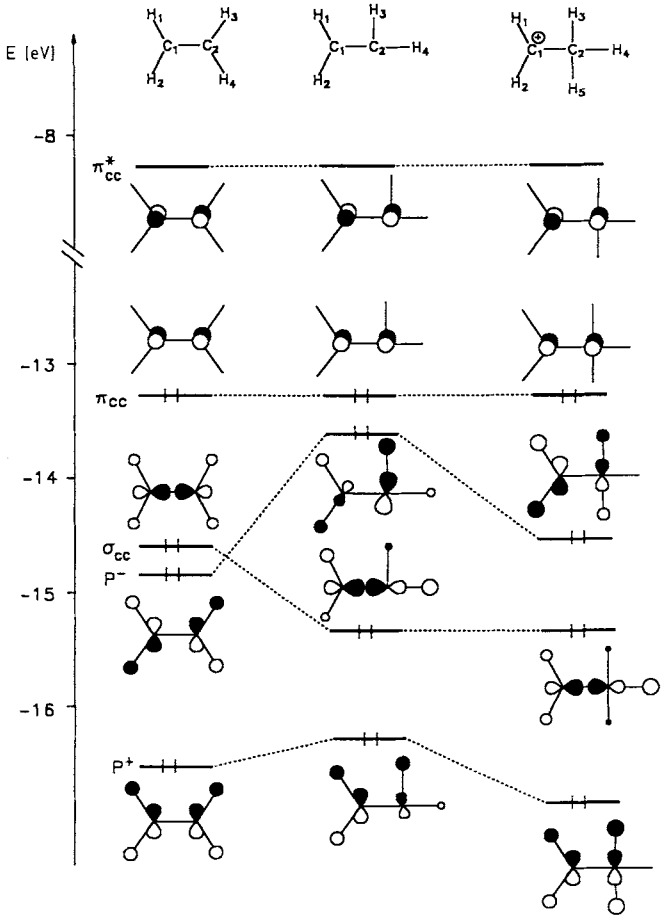

Fig. 1. Correlation diagram for the protonation of distorted T-shaped ethylene.

As a result this distorted ethylene is about 2 eV higher in energy than the normal structure. When a suitable σ-acceptor orbital is offered (e.g. the 1s orbital of a proton, Fig. 1) the highest occupied σ MO may be stabilized considerably. Further stabilization may be achieved by introducing an additional π-acceptor substituent. A group that fulfills both conditions is a d^0 zirconocene fragment, as it provides both σ- and π-accepting energy levels.[5]

Our previous investigations on the nature of agostic interactions of alkenyl moieties bound to a Cp_2ZrX (**2**) or a Cp_2Zr^+ (**3**) fragment, respectively, have shown that in the case of **2** a specific combination of steric and electronic effects must be met[6] for an agostic interaction, whereas in the case of **3** electronic factors dominate.[7]

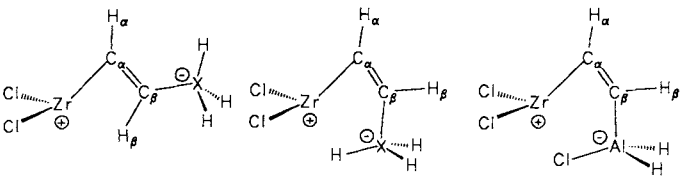
3

To test our qualitative arguments presented for a distorted ethylene molecule as a model for constructing complexes containing planar tetracoordinate carbon and to probe the acceptor and donor capabilities of a $ZrCp_2$ moiety we have carried out model calculations on the neutral dimetallic complexes **4**–**8**.



4: X=Al
5: X=B

6: X=Al
7: X=B

8

The calculations were carried out with the Gaussian 86 program[8] using STO-3G basis sets for all atoms (**4**–**7**)[9] and a split valence basis set for Zr[10] in the case of **8**. In addition we also carried out Extended Hückel (EH) calculations[11] on these systems using standard parameters for all atoms.[12] In our model calculations we replaced the Cp groups of the real molecules by chloro ligands which has been shown in other studies to provide a good theoretical substitute for the actual bent metallocene system.[13]

Fig. 2. Geometrical parameters and total energies [Hartree] for **4**–**8**.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1993 0570-0833/93/0505-0755 $ 10.00+.25/0

The fully optimized geometries of **4**–**8** are shown in Figure 2. The "inside" structures **6** and **7** were found to be more stable than the "outside" congeners **4** and **5** by 91 and 68 kcal mol^{-1}, respectively. The geometrical parameters calculated for **6**–**8** are remarkably close to those reported from X-ray investigations on **1**.[4]

The geometry optimization under the constraint that both olefinic carbon atoms maintain normal sp^2 hybridization but leaving all other parameters relaxed, leads to the "standard structures" **6a**–**8a**. As an example, we have depicted the constrained structure of **8a** at the bottom of Figure 2. The standard structures are 46.4 (**6a**), 47.5 (**7a**), and 34.0 (**8a**) kcal mol^{-1} less stable than **6**–**8**. In order to find out why the geometries of structures **6**–**8** are preferred, we calculated the differences in the overlap populations ΔOP and the differences in the electron densities Δq of **6**–**8** and **6a**–**8a** (Table 1). An analysis of the data shows that the structures

Table 1. Differences in the overlap populations (ΔOP) and in the electron densities (Δq) of fully optimized (**6**–**8**) and standard structures (**6a**–**8a**).

	ΔOP			
Structure	Zr-C_β	C_β-H_β	C_β-Al/B	Zr-Al/B
6–**6a**	0.2129	−0.0002	−0.1549	0.0585
7–**7a**	0.1332	−0.0023	−0.1235	0.0901
8–**8a**	0.1981	0.0022	−0.1459	0.0597

	Δq* [a]				
Structure	Zr	C_α	C_β	H_β	Al/B
6–**6a**	+0.17	−0.10	+0.03	−0.04	−0.01
7–**7a**	+0.10	−0.07	+0.10	−0.05	−0.10
8–**8a**	+0.49	−0.06	+0.04	−0.01	−0.15

[a] Positive sign of Δq means an increase in the electron density

with the square-planar carbon atom (**6**–**8**) are stabilized by a strong Zr–C_β bonding interaction and to lesser extent by Zr–Al/B interactions. This can be visualized by comparison of the contour plots of the HOMO-1 of **8** and the HOMO of its congener **8a** (Fig. 3). The MO plots are based on EH calculations on **8** with application of experimental X-ray structure data, and on **8a** with sp^2-hybridized C_α and C_β.[14] It is evident that there is a strong σ-bonding interaction between the 4d orbital at Zr and the 2p orbital at C_β in **8**. This interaction is absent in **8a**. Our analysis shows furthermore that any direct $\pi(C_\beta)$–d_π(Zr) interaction is negligible, although some Zr–C_α π interaction may be present.[3, 4]

To conclude we can say that the planar tetracoordinate geometry at the C_β center of **1** is based on electronic effects. It is not stabilized by additional (C_β–Zr) delocalization of the olefinic π electrons or the good donor properties of *both cis* metal substituents. The major factors contributing to its stabilization are the "in-plane" σ-acceptor property of the Zr center which stabilizes the high-lying P$^-$ MO of the distorted ethylene, and the good donor properties of C_α, Al, and R″.

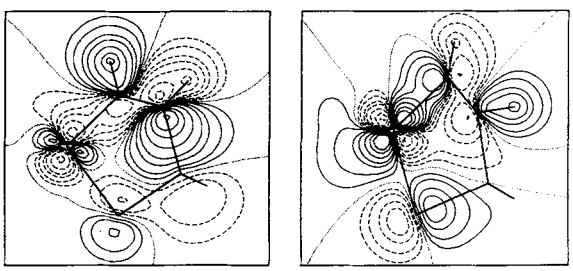

Fig. 3. Contour plots of the HOMO of **8a** (standard structure, left), and the HOMO-1 of **8** (planar structure, right). The values of the contour lines are ± 0.01, ± 0.02, ± 0.04, ± 0.06, ± 0.10, ± 0.22, ± 0.30.

Phosphinidenetantalum(v) Complexes of the Type [(N_3N)Ta=PR] as Phospha-Wittig Reagents (R = Ph, Cy, *t*Bu; $N_3N = (Me_3SiNCH_2CH_2)_3N$)**

By *Christopher C. Cummins, Richard R. Schrock,** and *William M. Davis*

We wish to report that terminal phosphinidene complexes of the type [(N_3N)Ta=PR] (R = Ph, *c*-C_6H_{11}(Cy), *t*Bu; $N_3N = (Me_3SiNCH_2CH_2)_3N$) are readily prepared and, furthermore, that these complexes react smoothly with aldehydes to generate phosphaalkenes. Phosphaalkenes[1, 2] stabilized either by conjugation[3] or by sterically demanding substitu-

[+] X-ray structure analysis.

[**] This work was supported by the National Science Foundation (Grant CHE 91 22827). C.C.C. thanks the National Science Foundation for a Predoctoral Fellowship. — The term phosphinidene complex is used here instead of that recommended by IUPAC, λ^3-phosphanediyl complex.

ents[4] have previously been prepared by silicon migration[3] or dehydrohalogenation;[4] Mathey et al. have developed a phospha-Wittig reaction that produces phosphaalkenes stabilized by $M(CO)_5$ (M = Cr, W) complexation.[5] The utilization of terminal phosphinidene complexes as phospha-Wittig reagents has not been described previously, perhaps in part because complexes containing the required M=PR linkage are extremely rare;[6] known examples[7-10] employ quite bulky substituents (e.g. the "supermesityl" (2,4,6-$tBu_3C_6H_2$) group) at phosphorus. Transient phosphinidene complexes of low-valent transition metals have been generated,[11] but these are electrophilic at phosphorus, much in the same manner as Fischer carbenes are electrophilic at carbon; we sought a nucleophilic phosphinidene complex.[12] Recently we reported the synthesis of a series of trigonal-monopyramidal complexes in which the presence of an empty coordination site is sustained by a ligand of the N_3N type,[13, 14] and we reasoned that the pocket formed by the three "upright" R_3Si substituents would be effective at stabilizing a nucleophilic phosphinidene unit.

Addition of $TaCl_5$ and $Li_3(N_3N)$[14] powders to ether at $-78\,^{\circ}C$ resulted in formation of $[(N_3N)TaCl_2]$ (**1**), a yellow crystalline solid, which was isolated in 32% yield by crystallization from ether after removal of LiCl [Eq. (1), see Table 1

$$Li_3(N_3N) + TaCl_5 \xrightarrow[-3\,LiCl]{Et_2O,\ -78\ to\ 25\,^{\circ}C} \underset{\mathbf{1}}{[(N_3N)TaCl_2]} \qquad (1)$$

for NMR data for the new compounds]. The molecule is apparently fluxional[15] since the three arms of the N_3N ligand are equivalent on the NMR timescale. Treatment of dichloride **1** with two equivalents of LiPHR[16] afforded the corresponding phosphinidene complexes **2** in good yield [Eq. (2)]. At present there is no evidence to indicate whether

$$\underset{\mathbf{1}}{[(N_3N)TaCl_2]} + 2\,LiPHR \xrightarrow[-2\,LiCl,\ -H_2PR]{Et_2O,\ -40\ to\ 25\,^{\circ}C} [(N_3N)Ta{=}PR] \qquad (2)$$

2a, R = Ph
2b, R = Cy
2c, R = *t*Bu

the TaP multiple bond is formed by dehydrohalogenation, with the second equivalent of phosphide acting as the base, or alternatively by α-proton abstraction from a bis(phosphide) complex;[17] when one equivalent of LiPHPh was slowly added to a solution of **1**, a mixture of **2a** and unreacted **1** was obtained.

The NMR spectra (^1H, ^{13}C, and ^{31}P; Table 1) of phosphinidene complexes **2** support the proposed formulation as follows: 1) the presence of one phosphorus atom per tantalum center is indicated by doublet splitting (J_{CP}) of two of the carbon resonances attributed to the N_3N ligand; 2) the phosphinidene ^{31}P signal is observed at low field, as expected;[18] 3) the ^{31}P signal for each phosphinidene complex is somewhat broad (**2a**, $\Delta\nu_{1/2} = 105$ Hz; **2b**, 140 Hz; **2c**, 205 Hz), consistent with local threefold symmetry at tantalum and consequent quadrupolar broadening by ^{181}Ta[19] (> 99% natural abundance[20]); 4) the three arms of the N_3N ligand are equivalent on the ^{13}C and ^1H NMR timescales.

A single-crystal X-ray diffraction study[21] of **2b** confirmed the proposed structure of phosphinidene complexes **2** (Fig. 1).

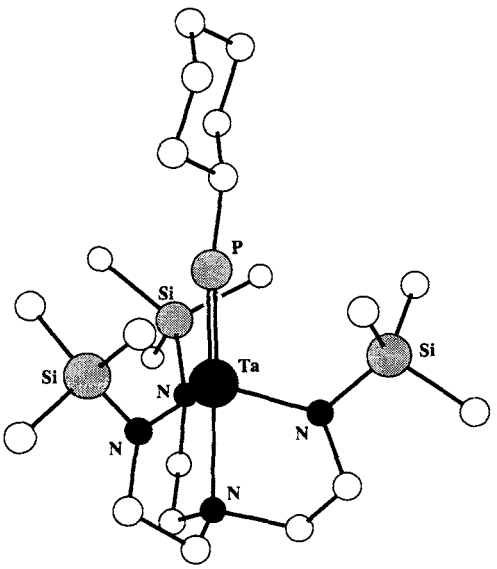

Fig. 1. Crystal structure of **2b**.

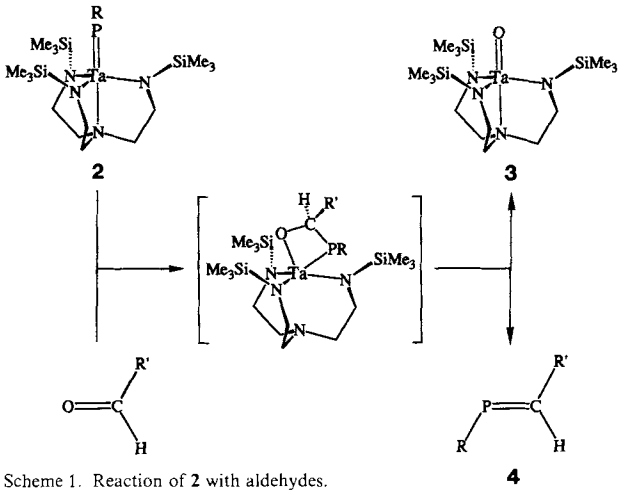
Multiple bonding between Ta and P is indicated by the short TaP distance of 2.145(7) Å (the sum of covalent radii for Ta and P is 2.44 Å[22]); this is expected, as symmetry considerations permit formation of a pseudo-triple bond for the approximately linear phosphinidene unit. Inspection of the structure suggests that stabilization of the reactive Ta=P linkage is a result of its location within the pocket afforded by the surrounding $SiMe_3$ substituents. These groups shield the Ta=P bond, but Ta is still accessible through the three clefts between the arms of the N_3N ligand, and access to P is also possible because of its relatively small organic sub-

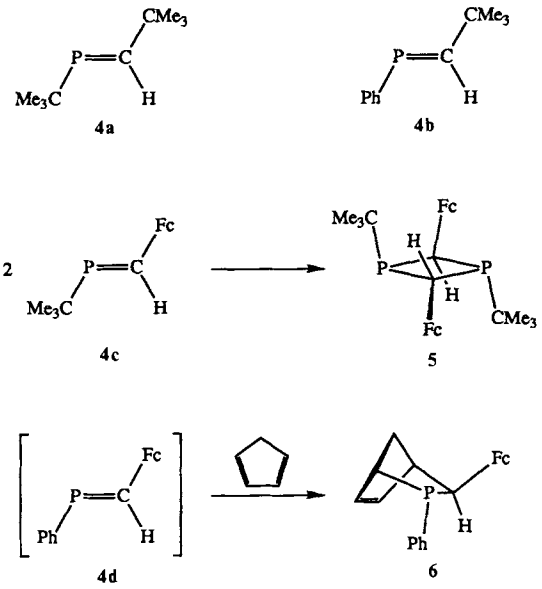
stituent. This combination of structural features results in stable phosphinidene complexes (**2a** was heated in C_6D_6 solution for 12 h at 100 °C with no observable decomposition) that react readily with appropriate small substrates.

Aldehydes react smoothly with **2** to provide the stable oxotantalum complex[23–25] **3** and the corresponding phosphaalkene **4** (Scheme 1). Formation of the phosphaalkene in this manner is reminiscent of the olefination of carbonyl compounds as mediated by high-valent tantalum alkylidene complexes.[26] The reaction is likely to proceed via a four-membered metallacycle,[27] and it would be interesting to know what role the amine donor plays in either the formation or destruction of this postulated metallacycle.[28] Simple phosphaalkenes are stable when substituted with bulky groups, whereas with smaller substituents they are prone to dimerize or oligomerize;[1, 2] the following set of experiments illustrates that phosphinidene complexes **2** are capable of producing, in a synthetically useful manner, both stable and reactive phosphaalkenes.



Scheme 1. Reaction of **2** with aldehydes.

The reaction between pivalaldehyde and [(N_3N)Ta=P*t*Bu] (**2c**) was relatively slow (complete after 7 h at 95 °C; 0.05 mol L^{-1} of each reagent) but proceeded smoothly to provide phosphaalkene **4a** (Scheme 2) and **3**; **4a** was previously prepared by a two-step synthesis requiring 11 weeks.[29] Phosphaalkenes such as **4a** are readily identified by their characteristic low-field ^{31}P and ^{13}C chemical shifts and diagnostic $^1J_{CP}$ coupling[1, 2] (Table 1); the $^2J_{PH}$ coupling can be useful in distinguishing the *E* (depicted) and the *Z* isomers.[30, 31] In the reaction between [(N_3N)Ta=PPh] (**2a**) and pivalaldehyde (25 °C; 0.05 mol L^{-1} of each reagent) the new phosphaalkene **4b** (Scheme 2) was produced quantitatively (according to ^1H NMR) in less than 5 minutes. After [(N_3N)Ta=O] (**3**) was removed by filtration through alumina, **4b** was isolated in pure form as a nonvolatile oil. When [(N_3N)Ta=P*t*Bu] (**2c**) was treated with ferrocenealdehyde (FcCHO)[32], the resulting red color indicated formation of phosphaalkene **4c**, which is stable for short periods at 25 °C but ultimately dimerizes to 1,3-diphosphetane **5** (Scheme 2).[33] Yellow-orange **5** was obtained in pure form by filtration of an ethereal solution through alumina; it formed as a single diastereomer. The reaction of **2a** with FcCHO resulted in the rapid generation of [(N_3N)Ta=O] (**3**), but phosphaalkene **4d** (Scheme 2) was too unstable to be observed at 25 °C. However, **4d** was trapped efficiently in the presence of cyclopentadiene (20 equiv) as Diels–Alder adduct **6**;[34] the adduct was an approximately 1:1 mixture of two diastereomers, the result of two possible modes of addition of the *E* phosphaalkene **4d** to cyclopentadiene. One diastereomer of **6** (Scheme 2) was isolated in pure form by filtration through alumina and subsequent crystallization from pentane at −40 °C.



Scheme 2. Phosphorus-containing products.

With the ready isolation of cycloadducts such as **6**, it becomes clear that [(N_3N)Ta=PR] complexes could be useful for the one-pot synthesis of many phosphaalkenes or molecules derived from phosphaalkenes, by sequential phospha-Wittig and cycloaddition reactions. The phospha-Wittig reaction with [(N_3N)Ta=PR] (**2**) contrasts with (and is complementary to) the related reaction decribed by Mathey[5] in that the phosphaalkene products are *not* complexed to a low-valent transition metal, but are produced in the free state, with attendent differences in stability and reactivity. It is also significant that complexes **2** are the first stable phosphinidene complexes of a d^0 transition metal.[35] By comparing the bond energies of the C=O (173 kcal mol^{-1})[36] and P=C (approximately 110 kcal mol^{-1})[37–38] linkages, it may be estimated that the Ta=O bond energy is at least 63 kcal mol^{-1} greater than the Ta=P bond energy, consistent with the well-known[24] oxophilicity of tantalum. Mathey has noted[5] that the diagonal relationship between carbon and phosphorus leads to a strong similarity in the chemistry of these elements. We intend to investigate whether tantalum phosphinidene complexes catalyze metathesis reactions of phosphaalkenes, by analogy with olefin metathesis.[39]

Experimental Procedure

General: Satisfactory elemental analyses (C, H, N) were obtained for complexes **1**, **2a**, **2c**, **3**, and **6**. All operations were performed with inert-atmosphere techniques and appropriately dried and degassed solvents. Unless otherwise stated, procedures were carried out at 25 °C.

1: $TaCl_5$ powder (6.246 g, 17.437 mmol) and Li_3(N_3N) powder (6.636 g, 17.437 mmol) were added to 300 mL of ether that was stirred at −78 °C under Ar. The reaction mixture was allowed to warm to 25 °C over 5 h and subsequently stirred for 19 h. LiCl was removed by filtration through a bed of celite, and the reaction mixture was concentrated to ca. 20 mL and chilled to −40 °C for 12 h. The yellow crystalline product was then collected by filtration, washed with 5 mL of cold ether, and dried in vacuo (3.425 g, 5.600 mmol, 32%).

2a: A pale yellow solution of LiPHPh (1.260 g, 10.860 mmol, 2.1 equiv) in 250 mL of ether was chilled to −40 °C, and **1** (3.163 g, 5.172 mmol) was added with stirring; the color changed to deep burgundy and then to yellow-gold over a period of 10 min. The reaction mixture was stirred overnight at 25 °C, at which point LiCl was removed by filtration through a bed of celite. The solvents were removed in vacuo, and the yellow residue was washed with 100 mL of pentane, collected by filtration, and dried in vacuo to yield **2a** (2.920 g, 4.501 mmol, 87%) as a yellow powder. **2a** may be obtained readily in crystalline form by chilling a concentrated ether solution to −40 °C. **2b** and **2c** were prepared similarly, except that they are more soluble than **2a** in pentane, and therefore were crystallized from pentane at −40 °C.

4b: A stirred solution of **2a** (1.274 g, 1.964 mmol) in 15 mL of dichloromethane was treated with pivalaldehyde (254 mg, 2.946 mmol). After 3 h the solvent was removed in vacuo, the residue was extracted with 10 mL of ether, and the extract was filtered through a 1.5 cm plug of basic alumina in a 30 mL sintered glass frit. The plug was then washed with 50 mL of additional ether. The ether was removed from the filtrate in vacuo to give **4b** as a nonvolatile oil (291 mg, 1.633 mmol, 83%) that was > 95% pure by NMR (^{1}H, ^{13}C, and ^{31}P).

Bromine Azide—Determination of the Molecular Structure by Electron Diffraction in the Gas Phase**

By *Magdolna Hargittai,* Inis C. Tornieporth-Oetting,* Thomas M. Klapötke,* Maria Kolonits,* and *István Hargittai**

The experimental determination of the molecular structure of halogen azides XN_3 (X = F, Cl, Br, I) is particularly hindered, since all XN_3 compounds are explosive substances.[1–4] Nevertheless many azides have been structurally characterized: HN_3[5] and FN_3[6] by microwave (MW) spectroscopy, F_3CN_3 by a combined analysis of electron diffraction (ED) and MW spectroscopy[7] ClN_3 by MW spectroscopy,[8] IN_3 by X-ray crystallography of single crystals,[9] and H_3CN_3 by ED.[10] Recently quantum mechanical ab initio calculations have increased knowledge on the structures of halogen azides. For example ab initio calculations were carried out at a high level for HN_3,[11] FN_3,[7, 11] ClN_3,[11] BrN_3,[11] IN_3,[9, 11] and $I_2N_3^+$.[12] Prior to this work there were no reports of structural data for BrN_3 and IN_3 determined by gas-phase experiments. Since, on the basis of available structural information for halogen azides, the structure parameters for BrN_3 could be predicted with high accuracy, the experimental determination of the molecular structure was an interesting challenge.

The crucial problem was to produce the bromine azide vapor and direct it into the electron diffraction apparatus safely. Finally, BrN_3 was synthesized according to Equation (a) (see Experimental Procedure).

$$Br_2 + NaN_3 \text{ (excess)} \xrightarrow{1\,h,\ 20\,^\circ C} BrN_3 + NaBr \qquad (a)$$

The electron diffraction intensities from experiments for the two camera distances used are shown in Figure 1. The radial distribution obtained from the 50 cm camera distance is shown in Figure 2.

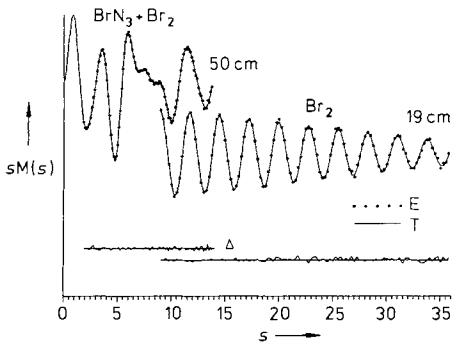

Fig. 1. Electron diffraction intensities from the molecular beam of the gaseous product from the reaction of bromine and sodium azide. Conditions: 60 kV electrons, sample container at −78 °C, nozzle at room temperature. The data, which were determined with a camera distance of 50 cm, were best approximated by a model of 73% BrN_3 and 27% Br_2. The data, which were determined with a camera distance of 19 cm, could be approximated by bromine alone. $M(s)$ = molecular intensity, $s = (4\pi/\lambda)\sin(\theta/2)$ in $Å^{-1}$.

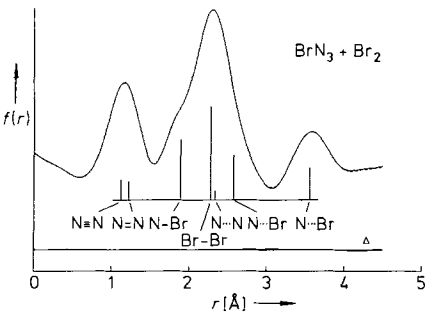

Fig. 2. Radial distribution $f(r)$ obtained from the electron diffraction intensities of the data from the experiment with a camera distance of 50 cm (cf. Fig. 1). The heights of vertical bars are roughly proportional to the relative weights of the contributions of internuclear distances r to electron scattering.

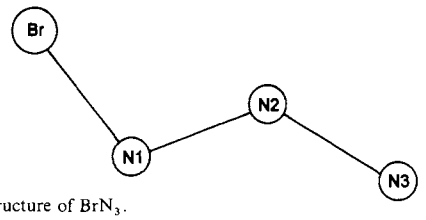
The experiment with a camera distance of 50 cm was carried out with sufficient BrN_3 to elucidate its structure with the assumption of some of the parameters. The two N–N bond lengths could not be refined independently from one another so their difference was constrained from the MP2 MO calculations.[11] The mean amplitudes of vibration were calculated by a normal coordinate analysis. The results of the structural analysis are summarized in Table 1. Although the structure parameters obtained experimentally generally agree with those of the HF MO calculation, the distances determined from the MP2 calculation seem to be too large. This effect is not unexpected, because the equilibrium bond length (the result of the computation, r_e) should always be smaller than the experimentally determined thermal average bond length (r_g).[13] The calculated difference of the two N–N bond lengths is probably much better determined than the individual bond lengths. The BrN_3 molecule has a *trans*

Table 1. Bond lengths r_g [Å] and bond angles [°] of BrN_3 determined by electron diffraction (ED) [a, b] and ab initio calculations for comparison [11].

	ED	HF/6-31G(d,p) [c]	MP2/6-31G(d,p) [d]
$(N\text{-}N)_{mean}$	1.180 ± 0.003	1.171	1.211
ΔN-N	0.102 [e]	0.146	0.102
N2-N3	1.129 ± 0.022	1.098	1.160
N1-N2	1.231 ± 0.022	1.244	1.262
Br-N	1.899 ± 0.006	1.896	1.923
N-N-N	170.7 ± 2.4	174.2	171.4
Br-N-N	109.7 ± 1.1	109.1	108.5

[a] The azide content of the sample was found to be 73 ± 1%, the Br–Br distance in Br_2 was determined to be $r_g(Br\text{–}Br) = 2.284 \pm 0.005$ Å. [b] Estimated total errors [23], indicated as error limits, include $\sqrt{2}$ times the least-squares standard deviation, a systematic error of 0.2%, and an uncertainty introduced by a change of 0.044 Å (the difference between the HF and MP2 all electron calculations, see ref. [11]) in the assumed ΔN-N value. [c] All electron HF MO calculation [11]. [d] All electron MP2 MO calculation [11]. [e] Assumed from the MP2 calculation [11].

configuration for which the Br–N bond lengths and the mean N–N bond lengths, as well as the Br-N-N and the N-N-N bond angles are determined with relatively high precision (Scheme 1). These structure parameters are consistent with those of other halogen azides. Quite recently the structure of the isoelectronic BrNCO was determined by MW spectroscopy.[14] This contains a NCO chain, which is slightly bent away (ca. 8°) from the Br atom (cf. BrN_3, 9°). In BrNCO the Br–N distance was found to be 1.862 Å, just slightly shorter than that in BrN_3 (1.899 Å). The angle at the bromine-carrying nitrogen atom, however, in BrNCO is significantly larger than the corresponding Br-N-N angle in BrN_3 (117.99 vs. 109.7°).



Scheme 1. Molecular structure of BrN_3.

Although halogen azides can be handled more readily in solution, preparations for the pure compounds have been described.[15–18] In a separate experiment we synthesized BrN_3 on a preparative scale in order to grow single crystals of BrN_3.[19] However, this has so far been unsuccessful, which is mainly due to the fact that BrN_3 always explodes during the liquid/solid phase transition.

Experimental Procedure

At −196 °C bromine (0.25 g, 1.56 mmol) was placed in a glass tube (diameter 4 mm) and sodium azide (0.13 g, 2.00 mmol) was layered over it. The glass tube was then warmed to −10 °C and placed into the container of the nozzle system of the electron diffraction apparatus. A modification of a previously described nozzle system built for very volatile substances was used [20]. The flow of vapor was regulated by a needle valve. The sample container was first recooled to −196 °C and evacuated. The sample was then warmed to 0 °C and allowed to react for 1 h at room temperature with the needle valve closed. In the most successful experiment (50 cm camera distance) the valve was gradually opened during electron diffraction.

Setting the nozzle system to the 19 cm camera distance, we experienced that only bromine escaped from the reaction mixture. In another experiment the sample was allowed to warm to 0 °C with the needle valve left open. After 20 minutes the electron diffraction patterns were recorded and they proved to originate predominantly from bromine.

Caution: Bromine azide is explosive[21] and very sensitive to phase transitions and pressure changes! In one experiment the NaN_3 was compacted on the

frozen Br_2 to make it more difficult for bromine to escape. This sample exploded and the (PTFE) container was blown apart. When the surface of the cold trap was cleaned there was also a small explosion.

Phosphane (PH_3) in the Biosphere**

By *Günter Gassmann** and *Dietmar Glindemann*

Synthetic phosphane (PH_3) is an industrial product and used in the form of metal phosphides as insecticides and as dopant gas in electronic chip manufacture.[1] Mineral phosphides are only known from meteorites in the form of schreibersite.[2] Biogenic phosphane has been detected and described a few times since the beginning of this century.[3] These early reports of biogenic phosphane formation in Nature have been questioned until recently.[4] In 1988, Hungarian scientists succeeded in detecting biogenic phosphane in sewage sludge[5] and they predicted its ubiquitous occurrence in the hydrosphere. This prediction was confirmed recently, when phosphane was detected in harbor sludge and marine sediments.[6] In these cases phosphane occurred together with methane, confirming reports from as early as 1929.[7] This points to an obligatory correlation between methanogenesis and the reduction of phosphate to phosphane in Nature. The global production of biogenic methane is estimated to be 500 million metric tons per year,[8] of which 100 million metric tons originate from bovine rumens. If methanogenesis and the reduction of phosphate to phosphane are correlated as indicated above, measurable amounts of phosphane must be expected in the biosphere.

To test the hypothesis that CH_4 and PH_3 production occurs together, we searched for phosphane in various sources including the feces of cattle. In the fresh pats from grazing cattle we detected phosphane in nanogram quantities. Phosphane was also found in the content of rumen, gut, and manure of freshly slaughtered cattle. Interestingly, the phosphane concentration increases along the course of digestion, with highest values in the excretion products (Table 1, entries 1–4).

Table 1. PH_3 in the digestive tract of cattle, and in the feces and manure of cattle and swine.

Entry	Origin	PH_3 [ng kg^{-1}]
1	rumen (of cattle)	2.9 ± 0.1
2	gut (of cattle)	5.1 ± 1.1
3	cow pat	9.0 ± 0.1
4	cattle manure	13.9 ± 5.4
5	colon (of swine)	103.0 ± 4.5
6	manure (of swine)	964.1 ± 11.7

If measurable amounts of phosphane are present in the intestinal tract of a herbivore, higher concentrations should be expected in the gut content of an omnivore, even if less methane will be formed. The higher phosphate contents of the food could yield larger amounts of phosphane. Our results on the feces of pigs are listed in Table 1 (entries 5 and 6). Humans consume phosphate-rich food like meat, sausage, cheese spread, and soft drinks. Consequently, we expected to find phosphane in their feces. We examined the feces of a baby (milk diet), of an eight-month-old weaned toddler (mixed diet), of an adult vegetarian, and of a married couple (identical mixed diet), and found the phosphane quantities given in Table 2.

Table 2. PH_3 content of the feces of man.

Entry	Origin	PH_3 [ng kg^{-1}]
1	baby (4.5 months old; milk diet)	not detectable
2	toddler (8.5 months old; mixed diet)	162.1 ± 11.7
3	vegetarian	12.7 ± 1.7
4	married couple (husband; mixed diet)	81.0 ± 17.3
5	married couple (wife; mixed diet)	81.2 ± 16.4

Due to their phosphate-rich food omnivores are expected to show a high phosphane production. Thus, we examined two species of predatory fish, plaice and cod. In cod we found an age-dependent phenomenon. While immature cod showed no phosphane in their guts, mature cod had detectable phosphane concentrations in their intestinal tracts (Table 3;

Notkestrasse 31, D-W-2000 Hamburg 52 (FRG)

[**] This work was supported in part by the Bundesministerium für Forschung und Technologie. – According to the IUPAC rules for nomenclature both phosphine and phosphane is permitted for PH_3; however, the second name is recommended. See *Nomenclature of Inorganic Chemistry* (Ed.: G. J. Leigh), Blackwell Scientific Publ., Oxford, **1990**.

Table 3. PH_3 in the intestinal tract of fish.

Entry	Origin	PH_3
1	cod (immature)	not detectable($n = 23$)
2a	cod (mature)	5.4 ± 0.2 pg/individual
2b	cod (mature)	69.1 ± 4.6 pg/individual[12]
3	plaice	138.0 ± 45.0 fg/individual($n = 46$)

entries 1, 2a, b). In contrast, phosphane is generally present in plaice at much lower concentrations (Table 3; entry 3).

Although our study is only based on a few examples, the results strongly suggest that biogenic phosphane is formed in the biosphere wherever methanogenic conditions prevail. In order to confirm the biogenic origin of phosphane, "fecult" experiments were carried out with two different phosphane-free culture media. Inoculants were 250 mg human feces with a phosphane content of 3 pg. Inoculated media and blanks (500 cm^3) were incubated anaerobically at 36 °C for 6 and 14 days, respectively. As shown in Table 4 and Figure 1, the phosphane and diphosphane contents rise 8500- and 31 000-fold, respectively. This experiment convincingly demonstrates the existence of a biological system which produces phosphane and diphosphane.

Table 4. Formation of PH_3 and P_2H_4 in an anaerobic mixed bacterial culture.

Entry	Origin	PH_3	P_2H_4

4	blank B	0.0	0.0
5	"fecult" medium B (6 days)	51.2 ± 14.4	0.6 ± 0.1
6	"fecult" medium B (14 days)	0.0	24.0 ± 5.2

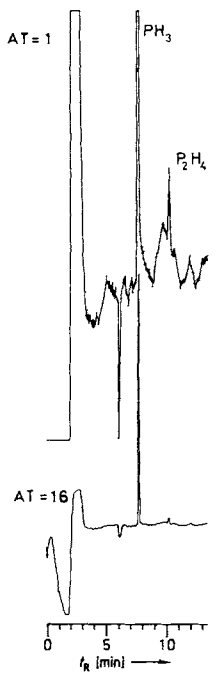

Fig. 1. Gas chromatogram of a gas sample (10 cm^3 from 1150 cm^3) of "fecult" medium A (6 days; 50 cm^3 from 500 cm^3) with phosphorus-selective thermionic detection. Separation (retention time $t_R = 7.60$ min and 10.17 min, respectively) and determination of 55.2 pg PH_3 (peak height 4342 mm at attenuation (AT) = 1) and 398 fg P_2H_4 (peak height 32 mm at AT = 1). Analytical column (0.35 mm internal diameter): 5 m CPWax-57CB + 10 m Poraplot-Q + 50 m CPWax-57CB. Helium as carrier gas at 100 kPa; oven temperature 40 °C isothermal. The detection limit of phosphane is 70 fg (Hewlett-Packard 5890 II-NPD).

The confirmation of phosphane production in the biosphere sheds new light on various issues. The ignition of methane by the autoignition of diphosphane provides the basis for a biogenic ignition mechanism, which Wolfe[9] claimed as an explanation for the legendary fire-breathing dragon (if it ever existed). Likewise it offers a plausible explanation for the phenomenon of lights over swampy grounds or cemeteries (ignis fatuus or will-o'-the-wisp; cf.[2]).

For the first time, it is now possible to evaluate the participation of phosphane in the global biogeochemical cycle of phosphorus. Devai et al.[5] showed that biogenic phosphane accompanies the methane production in a sewage sludge digester (Imhoff Tank). In this system the ratio of phosphane to methane is 0.0035 vol%. The extrapolation of this value based on a global biogenic methane production of 500 million tons, reveals the potential for the formation of 40 000 metric tons of biogenic phosphane per year.

A very important aspect of phosphane formation in the biosphere is the toxicity of phosphane. It is genotoxic to human lymphocytes in concentrations of a few nanograms per liter culture medium.[10] The biogenesis of phosphane in the human intestinal tract may be the factor which is responsible for the increased risk of cancer in carnivores and omnivores in comparison with vegetarians.[11] The involvement of phosphane biogenesis for human cancer epidemiology deserves to be investigated more closely[13].

Experimental Procedure

Sampling of feces (15–150 g) was carried out in the field (Table 1; entry 3), at farms around Hamburg (Table 1; entries 4, 6), in the slaughter house in Hamburg (Table 1; entries 1, 2, 5), in the Pediatric Hospital in Hamburg-Altona (Table 2; entries 1, 2). Other samples were taken from members of this institute (Table 2; entries 3–5). Fish were caught by the German research vessel "HEINCKE" (Table 3; entries 1–3). The phosphane content was determined in the laboratory or aboard the research vessel within one hour of sampling. Because of a shortage of mature cod specimens, only two single measurements are given in Table 3. Because of the difficulty in determining the exact weight of the intestinal tract of fish on board ship, the phosphane content was related to the individual. Experiments with living vertebrates were not carried out.

The "fecult" experiments were performed in 500 cm^3 glass bottles equipped with rubber caps. The sterile, anaerobic culture medium for "fecult" A contained (per dm^3) 5 g bactopeptone, 2.5 g bacto yeast extract, 5 g D-(+)-glucose, 10 g KH_2PO_4, 0.4 g $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$, 1 g $CaSO_4 \cdot 2H_2O$, and 2 g $MgSO_4 \cdot 7H_2O$. "Fecult" B corresponds to medium A, but bactopeptone was replaced by 200 cm^3 meat extract from 50 g fresh beef. 250 mg human feces with a known phosphane content (3 pg) was used as inoculum. Anaerobicity was controlled by the addition of resazurine. The culture bottles were pressurized with nitrogen to 100 kPa. Aliquots of the liquid phase (50 cm^3) were withdrawn with a gas-tight syringe after 6 and 14 days, and digested under alkaline conditions as reported elsewere [6]. The phosphane content was determined immediately after digestion.

[12] This species of cod displays an abnormal growth, as large as a fist, on its kidney in addition to its relatively high intestinal phosphane content. This phenomenon is not rare in mature cod. A possible connection between the phosphane content and the abnormal growth will be investigated in more detail during future expeditions.
[13] Phosphane is a relatively stable compound. The half-life period (5–28 h) depends on the concentration of $OH^{\bullet}$ radicals in ambient air. The amphoteric chemical properties of phosphane imply an unchanged exhalation of phosphane in cases of poisoning by metal phosphides. Oxidized derivatives such as hypophosphite, phosphite, and phosphate are urinal excretion products (cf. [1]).

$[Cp^*TaS_3\{Rh(cod)\}_2]$ and $[Cp^*TaS_3\{RuH(PPh_3)_2\}_2]$: A New Class of Heterometallic TaM_2 Clusters

By *Kazuyuki Tatsumi,* Hiroyuki Kawaguchi, Yoshihisa Inoue, Akira Nakamura, Roger E. Cramer,** and *James A. Golen*

We recently reported the synthesis of the trisulfidotantalum complexes **1**.[1] An important feature of these molecules is that the lithium cations are bound directly to the sulfido

$[\{Cp^*TaS_3Li_2(thf)_2\}_2]$ **1a**

$[\{Cp^*TaS_3Li_2(dme)\}_2]$ **1b**

$[Cp^*TaS_3Li_2(tmeda)_2]$ **1c**

$[\{Cp^*TaS_3Li_3Cl(tmeda)\}_2(\mu\text{-tmeda})]$ **1d**

$Cp^* = C_5Me_5$, dme = 1,2-dimethoxyethane, tmeda = *N,N,N',N'*-tetramethylethylenediamine

ligands. Thiometalates such as $[MoS_4]^{2-}$, $[WS_4]^{2-}$, $[VS_4]^{3-}$, and $[ReS_4]^-$ are known to react with various metal halides to give a multitude of heterometallic clusters,[2–6] often comprised of linear arrays of metal atoms. We hoped that complexes **1** would serve as starting materials for the synthesis of rare organotantalum clusters.[6b] In fact, complexes **1** were found to react smoothly with $[\{RhCl(cod)\}_2]$ (cod = 1,5-cyclooctadiene) and $[RuH(Cl)(PPh_3)_3]$ to give the trinuclear clusters **2** and **3**. These reactions and the structures of the resulting clusters are described here.

$[Cp^*TaS_3\{Rh(cod)\}_2]$ **2**

$[Cp^*TaS_3\{RuH(PPh_3)_2\}_2]$ **3**

Treatment of **1a** with two equivalents of $[RhCl(cod)]_2$ in THF at 50 °C yielded a dark brown solution, from which we isolated **2** as yellow-brown crystals. Analogously, the reaction of **1a** with four equivalents of $[RuH(Cl)(PPh_3)_3]$ in THF (2 h, 50 °C) afforded cluster **3** as reddish-brown crystals. Use of **1b–1d** instead of **1a** in the above reactions also gave clusters **2** and **3**. The $TaRh_2$ cluster **2** is freely soluble in nonpolar organic solvents, while crystals of **3** are only slightly soluble in hexane and benzene. Both compounds are somewhat air- and moisture-sensitive and also diamagnetic. These clusters were fully characterized by NMR, IR, and Raman spectroscopy, elemental analysis, and X-ray structure analysis.

The molecular structure of **2**[7] shown in Figure 1 consists of a Cp^*TaS_3 half-sandwich unit and two Rh(cod) complex fragments, and has virtual but not crystallographically imposed mirror symmetry. The central Cp^*TaS_3 unit assumes

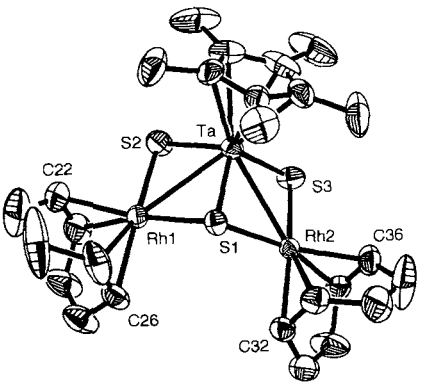

Fig. 1. Molecular structure of **2** (thermal ellipsoids at the 50% level). Selected distances [Å] and angles [°]: Ta-Rh1, 2.982(1); Ta-Rh2, 2.953(1); Ta-S1, 2.307(1); Ta-S2, 2.279(1); Ta-S3, 2.274(1); Rh1-S1, 2.364(1); Rh1-S2, 2.347(2); Rh2-S1, 2.366(1); Rh2-S3, 2.354(1); Rh1-Ta-Rh2, 84.4(1); S1-Rh1-S2, 98.4(1); S1-Rh2-S3, 98.5(1); Ta-S1-Rh1, 79.3(1); Ta-S2-Rh1, 80.3(1); Ta-S1-Rh2, 78.4(1); Ta-S3-Rh2, 79.3(1).

a slightly distorted three-legged piano stool structure, in which the S_3 plane is parallel (179.7°) to the plane of the Cp* ring. Each Rh atom is bound to two sulfido ligands and S1 bridges the Rh atoms. The Ta, S1, S2, and Rh1 atoms are coplanar (maximum deviation, 0.005 Å), as are Ta, S1, S3, and Rh2 (maximum deviation, 0.087 Å). The two double bonds in the cod ligand are perpendicular to the corresponding RhS_2Ta plane. The mean Ta–Rh distance of 2.968 Å suggests a dative bond between d^8 Rh and d^0 Ta, a conclusion which is supported by the expansion of the S-M-S angles and concomitant contraction of the M-S-M angles within the M_2S_2 quadrilaterals. There is no direct bonding between the Rh atoms (3.983(1) Å). The S2-Ta-S3 angle (106.4(1)°) is slightly larger than the S1-Ta-S2 (102.1(1)°) and S1-Ta-S3 (102.6(1)°) angles. Compared to the other Ta–S bonds the Ta–S1 bond is 0.03 Å longer as a result of binding two Rh centers; the Rh–S1 distances are also increased (0.012 Å, 0.017 Å).

In the temperature-dependent ^1H NMR spectra of **2** in $[D_8]$toluene the olefinic protons of the η^4-cod ligands give rise to three peaks $\delta = 5.63$, 5.44, and 5.23 at −90 °C with the intensity ratio of 1:2:1. The intensity of the central peak must be due to an accidental overlap of two resonances (or

the chemical shifts of the two signals are so close that they are not resolved even at −90 °C). As the temperature is raised, the two outside peaks broaden and merge with the central peak above the coalescence temperature of approximately −60 °C. This broad signal then becomes increasingly sharp up to 30 °C ($\delta = 5.24$).[8] We think that the η^4-cod ligands rotate around the Ta–Rh bond axes in solution. The solid-state NMR spectrum shows the four olefinic protons to be nonequivalent. The analysis of the variable-temperature ^{1}H NMR spectra will be reported in detail elsewhere.[9]

In the molecular structure of **3**[10] (Fig. 2) the two $Ru(H)(PPh_3)_2$ complex fragments are unsymmetrically coordinated to the Cp^*TaS_3 unit. Three sulfido ligands link

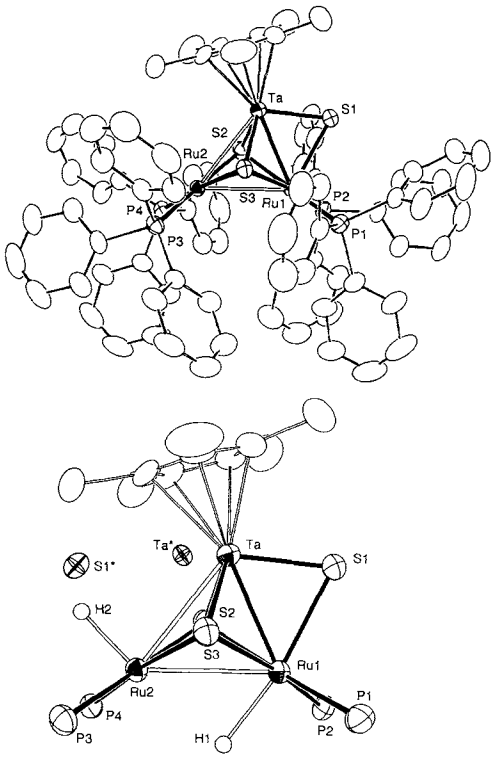

Fig. 2. Molecular structure of **3** (thermal ellipsoids at the 50% level). The entire molecule (top) and its main frame with hydride positions (bottom) are shown. The molecule is disordered with the occupancy factors of 0.9 and 0.1; Ta* and S1* belong to the minor configuration. Selected distances [Å] and angles [°]: Ta-S1, 2.258(4); Ta-S2, 2.333(3); Ta-S3, 2.301(2); Ru1-S1, 2.521(4); Ru1-S2, 2.498(4); Ru1-S3, 2.455(3); Ru1-P1, 2.343(4); Ru1-P2, 2.349(3); Ru2-S2, 2.403(3); Ru2-S3, 2.385(3); Ru2-P3, 2.301(2); Ru2-P4, 2.299(3); Ru1-H1, 1.93(3); Ru2-H2, 1.70(3); S1-Ta-S2, 96.5(1); S2-Ta-S3, 92.4(1); S1-Ta-S3, 99.1(1); Ta-S1-Ru1, 68.7(1); Ta-S2-Ru1, 68.0(1); Ta-S3-Ru1, 69.2(1); Ta-S2-Ru2, 82.4(1); Ta-S3-Ru2, 83.5(1); S2-Ru1-S3, 84.9(1); P1-Ru1-P2, 98.8(1); S2-Ru2-S3, 88.6(1); P3-Ru2-P4, 97.5(1); Ru1-S2-Ru2, 75.6(1); Ru1-S3-Ru2, 76.7(1).

Ru1 to the Ta atom, while two sulfido ligands bridge Ru2 and Ta. As a consequence, the Ta–Ru1 distance is short (2.703(4) Å) and the Ta–Ru2 distance is very long (3.119(5) Å), in contrast to the equilateral $TaRh_2$ triangle in **2**. The Ta–S bonds of two μ_3-sulfur atoms S2 and S3 are elongated by 0.075 and 0.043 Å relative to the Ta–S1 bond. Conversely, the Ru1–S1 bond is somewhat longer than the Ru1–S2(S3) bonds. The Ru-bound phosphane ligands are situated *trans* to the μ_3-sulfido ligands. Although determination of the positions of hydrogen atoms from X-ray data alone is difficult, we nonticed a distinct peak on the Fourier map in each Ru coordination sphere, which could be assigned to terminal hydrido ligands. The corresponding structure is shown at the bottom of Figure 2; the Ru2–H1 (2.40 Å) and Ta–H2 (3.33 Å) distances are too long to invoke bonding interactions. When these hydrido ligands are included, the coordination geometry at Ru1 is distorted octahedral, whereas the geometry at Ru2 is square-pyramidal. The difference in coordination number results in longer Ru1–S (mean, 2.491 Å) and Ru1–P (mean, 2.346 Å) bonds relative to the corresponding Ru2–S (mean, 2.394 Å) and Ru2–P (mean, 2.300 Å) bonds. The Ru1–Ru2 (3.004(5) Å) and Ta–Ru2 distances are long. However, expansion of the S-M-S angles and contraction of the M-S-M angles within each M_2S_2 quadrilateral suggests that weak metal–metal bonding is present. It is interesting that the coordinatively unsaturated Ru2 center does not strongly interact with either the Ta or Ru1 atom.

The $^{31}P\{^1H\}$ NMR spectrum of **3** in [D$_8$]THF shows two singlets at $\delta = 43.7$ and 49.8. In the hydrido region two triplets of equal intensity were detected at $\delta = -15.0$ ($J_{PH} = 13.0$ Hz) and −24.6 ($J_{PH} = 35.5$ Hz).[11] These observations provide evidence for the *cis* (or facial) disposition of a hydrido and two phosphane ligands at each of two chemically different Ru centers, and prove that neither of the hydrido ligands bridge two Ru atoms. The NMR results are entirely consistent with the solid-state structure shown in Figure 2; this configuration was found by NMR to be rigid up to 60 °C.

The synthesis of these $TaRh_2$ and $TaRu_2$ clusters demonstrates that the $Cp^*TaS_3Li_2$ unit in complexes **1** can serve as a convenient precursor for organoheteronuclear clusters. There are two important aspects in this cluster formation: 1) the reactions proceed smoothly under mild conditions so that the labile ligands such as cod and H remain bound and are incorporated into the clusters; 2) the two metal centers, each coordinated to such a ligand, are in close proximity, and we may expect the two metal centers to cooperate for substrate activation.

Experimental Procedure

All operations and manipulations were carried out under an argon atmosphere, and the solvents were dried before use.

2: A solution of $[\{RhCl(cod)\}_2]$ (0.14 g, 0.28 mmol) in THF was added to a solution of **1a** (0.21 g, 0.14 mmol). The resulting reddish-brown solution was warmed to 50 °C and stirred for 2 h. After removal of the solvent in vacuo, the residue was extracted with benzene (10 mL), which upon evaporation left a dark-brown solid of **2** in nearly quantitative yield. Recrystallization from hexane gave yellow-brown crystals suitable for X-ray diffraction (45% yield). Satisfactory C,H,S-analysis. Raman (crystals): $\tilde{\nu}[cm^{-1}] = 432$(m), 315(m); ^{1}H NMR (100 MHz, C_6D_6): $\delta = 2.01$ (s(br), 16H, cod(methylene)), 2.19 (s, 15H, Cp*), 5.39 (s(br), 8H, cod(olefin)).

3: A solution of **1a** (0.11 g, 0.096 mmol) in THF (10 mL) was added to a slurry of $[RuH(Cl)(PPh_3)_3]$ (0.36 g, 0.40 mmol) in THF. The resulting suspension was warmed to 50 °C with stirring for 2 h, whereupon a clear reddish-brown solution was obtained. The solvent was removed and the residue extracted with benzene (20 mL). Recrystallization from THF/hexane gave reddish-brown crystals of **3** in 44% yield. Satisfactory C,H-analysis. Raman (crystals): $\tilde{\nu}[cm^{-1}] = 446$(w); ^{1}H NMR (400 MHz, [D$_8$]THF): $\delta = 7.0-7.3$ (m, 60H, PPh_3), 2.01 (s, 15H, Cp*), −15.0 (t, $J_{PH} = 13.0$ Hz, 1H, Ru-*H*), −24.6 (t, $J_{PH} = 35.5$ Hz, 1H, Ru-*H*); $^{31}P\{^1H\}$ NMR (21.35 MHz, [D$_8$]THF, 95% H_3PO_4 external standard): $\delta = 49.8$ (s, 2P), 43.7 (s, 2P).

[7] Crystal structure analysis of **2** [10]: single crystal with dimensions $0.2 \times 0.4 \times 0.6$ mm^3, monoclinic space group $C2/c$, $a = 33.29(1)$, $b = 12.047(2)$, $c = 13.711(3)$ Å, $\beta = 90.50(2)°$, $V = 5498(2)$ Å^3, $Z = 8$, $\rho_{calcd} = 2.016$ Mg m^{-3}. Data collection with a Nicolet R3m/V diffractometer; $Mo_{K\alpha}$ radiation, 2θ scans, $2\theta = 4-60°$, 8842 measured reflections, 8055 independent, 7469 observed ($F_o > 1.0\,\sigma F_o$), empirical absorption correction based on azimuthal scans. Solution and refinement with the Nicolet SHELXTL PLUS package (direct methods); all non-hydrogen atoms were refined anisotropically and hydrogen atoms were put at calculated positions with a fixed isotropic U value; full matrix, refined parameters 283, $R = 0.0347$ and $R_w = 0.0474$, GOF = 0.96, maximum residual electron density 0.90 and -0.75 eÅ^3.

[8] The full width at half-height ($v_{1/2}$) of the olefinic proton resonance at 30 °C is 8 Hz, and the coupling with the Rh nuclei was not detected. The corresponding resonance for $[\{Rh(cod)Cl\}_2]$ in C_6D_6 at room temperature comes at $\delta = 4.40$ with $v_{1/2} = 10$ Hz (100 MHz).

[9] K. Tatsumi, H. Kawaguchi, K. Tani, R. E. Cramer, J. W. Gilje, T. T. Bopp, unpublished.

[10] Crystal structure analysis of **3**: single crystal with dimensions $0.2 \times 0.2 \times 0.3$ mm^3, triclinic space group $P\bar{1}$, $a = 12.84(1)$, $b = 14.21(2)$, $c = 21.620(9)$ Å, $\alpha = 81.5(1)$, $\beta = 74.5(1)$, $\gamma = 75.2(1)°$, $V = 3663(2)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.565$ Mg m^{-3}. Data collection with a Rigaku AFC5R diffractometer; $Mo_{K\alpha}$ radiation, ω-2θ scan, $2\theta = 4-50.1°$, 13157 measured reflections, 13098 independent, 9953 observed ($I > 3.0\,\sigma I$), empirical absorption correction based on azimuthal scans. Solution and refinement with the TEXSAN package of Molecular Structure Corporation (direct methods); all non-hydrogen atoms except for the THF solvent molecule were refined anisotropically and hydrogen atoms were put at calculated positions; full matrix, refined parameters 1064, $R = 0.0331$ and $R_w = 0.0424$, GOF = 1.63, maximum residual electron density 1.05 and -0.82 eÅ^3. The molecule is disordered with major and minor occupancies of 0.9 and 0.1. In the minor configuration (see Fig. 2 bottom), S1* bridges Ta* and Ru2 instead of Ta and Ru1; the Ta*–Ru2 distance is 2.619(4) Å while the Ta*-Ru1 distance is longer at 3.206(5) Å. Due to its low occupancy, we were only able to locate two atoms, Ta* and S1*, of the minor configuration. This structure was solved twice with different crystals, once in Osaka and once in Honolulu. The Osaka results, which are slightly more accurate, are those reported here. Very similar disorder was found in both crystals. Further details of the structure analysis for **2** and **3** may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-57031, the names of the authors, and the journal citation.

[11] The resonance of the hydrido ligand in $[RuH(Cl)(PPh_3)_3]$ appears at $\delta = -17.75$ with $J_{PH} = 26$ Hz in CD_2Cl_2. P. S. Allman, B. R. McGarvey, G. Wilkinson, *J. Chem. Soc. (A)*, **1968**, 3143.

BOOKS

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Book Reviews

Molecular Dynamics Simulation. Elementary Methods. By *J. M. Haile*. Wiley, Chichester, 1992. XI, 489 pp., hardcover £ 47.50.—ISBN 0-471-81966-2

This book by J. M. Haile gives the information that is promised by the title. After an introductory chapter on the philosophy of computer simulation, it introduces classical dynamics and the fundamental principles of computer simulation of dynamics in Chapter 2. The next topic is simulation of systems consisting of hard spheres (Chapter 3). Simulation techniques for systems with continuous potential energy functions are treated in the next two chapters: finite-difference methods and soft-sphere systems. The last two chapters discuss methods for determining static properties (Chapter 6) and dynamic properties (Chapter 7) of a simulated system. There are 13 appendices containing background material, examples of computer programs, and other useful information. The book also contains a bibliography of books and articles on the subject.

The book is a useful addition to the literature on computer simulation of atomic and molecular systems. It gives a thorough and practical explanation of the basics of molecular dynamics simulation. Since each chapter contains a separate list of references, the interested reader has easy access to more advanced literature. Each chapter also contains a number of exercises which offer the opportunity to obtain insight by practical work. The book reads easily and illustrates the theory with graphs and results from simulations where possible. Moreover, it treats a number of topics, such as reliability of trajectories and results, propagation of errors, equilibration, and sampling problems, that are often only briefly mentioned in other texts on the subject.

To those who are seriously interested in dynamic computer simulation techniques I can recommend reading this neat and well-written book.

Superelectrophiles**

By George A. Olah*

In memory of Hans Meerwein

Electrophiles that are capable of further interaction (coordination, solvation) with strong Brønsted or Lewis acids can be activated in this way. The resulting enhancement of their reactivity is great compared to that of their parent compounds under conventional conditions and indicates superelectrophile formation (i.e., electrophiles with doubly electrodeficient (dipositive) nature whose reactivity substantially exceeds that of their parent electrophiles). As representative examples the protolytic or electrophilic activation of the following electrophiles in superacidic and related strongly electrophilic media is discussed: oxonium, carboxonium, sulfonium, selenonium, and telluronium ions; acyl cations; protonated CO, CO_2, COS, and carbonic and thiocarbonic acids; heteroatom-substituted carbocations (and some of their boron analogs); halonium ions; azonium (including nitronium) and carbazonium ions. Emphasis is placed on both experimental chemical investigations and theoretical treatment of the involved systems. As prototypes for protolytically activated onium ions, the protohydronium dication (diprotonated water) and its sulfur analogue, the protosulfonium dication, are of particular significance. The protoacetyl and protoformyl dication (diprotonated carbon monoxide), diprotonated carbonic acid and carbon dioxide, diprotonated hydrogen cyanide and nitriles, as well as the protonitronium dication —among others—and their emerging chemistry are discussed as examples of superelectrophiles.

1. Introduction and General Concepts

Electrophiles are reagents that take up electrons in their reactions and thus are electron acceptors; that is, they are electron-deficient compounds.[1, 2] The statement attributed to Rundle that "there are no electron-deficient compounds, only theory-deficient chemists" may have reflected the view of the 1950s, but since that time much has happened to improve our understanding. The proton is the ultimate electrophile, having no electron at all. In the condensed state, however, no "naked" proton can exist, and it is always solvated (associated). Trivalent carbocations are similarly highly electron-deficient electrophiles, although they tend to compensate partially for their electron deficiency by either intra- or intermolecular interactions. The better stabilized the species (e.g. a carboxonium ions or acyl cation) the less electron-deficient it is.

Over the course of 35 years my research group has studied and continues to investigate long-lived electrophilic intermediates. These include carbocations,[3] acyl cations, carboxonium ions, several onium ions[4] including oxonium, sulfonium, halonium,[5] nitronium, and azonium ions, as well as other electron-deficient species. Our studies generally uti-

lized superacidic media like the essential low-nucleophilicity environments,[6] since long-lived, highly electron-deficient (i.e., acidic) species in the condensed state can only exist in such environments. Our studies resulted in what is now generally referred to as *superacidic, stable-ion chemistry* and the chemistry of stable carbocations.[3, 6] Thousands of publications from around the world have contributed and are continuing to contribute to this very active field.

During our studies on superacidic systems we made observations which indicated that superacids, besides being highly ionizing, low-nucleophilicity media, in some instances were also capable of additional unexpected activation of electrophiles by further protolytic (or electrophilic) interaction (coordination, solvation). In 1975 we first reported[7] that in superacidic media the acetyl cation (CH_3CO^+) and nitronium ion (NO_2^+) display highly enhanced reactivity indicative of their protolytic (protosolvated) activation[*] through the dications, $CH_3\overset{+}{C}=\overset{+}{O}H$ and NO_2H^{2+}. Later we found similar indications for the protoformyl dication ($HCOH^{2+}$, diprotonated CO). In 1986 we described studies relating to the protohydronium dication (H_4O^{2+})[8] and subsequently the tetrahydridosulfonium dication, H_4S^{2+}[9]. In 1989 we published a brief review on protonated (protosolvated) onium ions (onium dications).[10] The overall concept and significance of these studies, however, has as yet aroused relatively little response or even interest in the broader chemical community. This is probably because our studies were considered of highly specialized nature involved generally in somewhat exotic superacidic systems. Not unlike most chemists' attitude towards mass spectrometric, gas-phase ion chemistry, superacidic chemistry is still frequently viewed as a field where surprising (even "magic") observations can be made, which do not necessarily relate to "real" chemistry.

Electrophilic solvation (or protosolvation) of electrophiles such as onium, carboxonium, and related ions involves their further interaction with Lewis or Brønsted superacids. Such interaction of these ions with superacid systems can in the limiting case lead to extremely reactive de facto dications, although electrophilic assistance by the strong acids through polarized donor–acceptor interactions should have similar effect. Electrophilic activation can play a significant role in Friedel–Crafts and superacid-catalyzed reactions, as well as in solid-acid-catalyzed systems and even in enzymatic reactions. This review centers on this emerging field and calls attention to the general significance of protolytic/electrophilic activation and the role of superelectrophiles, that is, electrophiles of doubly electron-deficient (dipositive) nature whose reactivity greatly exceeds that of their parent compounds in aprotic or conventional acidic media. The definition is arbitrary, as is that of superacids, but describes the remarkably enhanced reactivity of activated, dipositive electrophiles.

As already emphasized, in the condensed state the ultimate electrophile, the proton, cannot exist in its "free" form, but will interact with any electron donor present in its environment. We shall nevertheless use "H^+" as a shorthand depiction throughout this review for simplicity. Furthermore, in the condensed state cations must be balanced by appropriate anions (counter- or gegenions). Again for simplicity we shall not reflect on the effect of counterions (ion pairing, dissociation, etc.). None of these limitations exist, of course, in the gas phase. For example in mass spectrometric and related studies, free ions (including H^+) and their reactions can be readily investigated. The differences between gaseous molecule–ion reactions and condensed-state chemistry are well recognized. The present discussion will primarily emphasize the behavior of electrophiles in the condensed state, and the ways they can be activated. Only occasional comparison with gas-phase behavior of electron-deficient ions will be made. This will be the case particularly when considering the results of theoretical, quantum mechanical calculations, which are increasingly used as a powerful tool in chemistry. These calculations usually still relate only to idealized gas-phase conditions. Whereas such calculations give much insight into the nature of reactive electrophilic intermediates and their reactions, by necessity they neglect ion–pair interactions, clustering, solvation, etc., although recently efforts have been made to include solvent effects (for example, in Pople's GAUSSIAN 92 program).

An impressive and ever expanding number of new gas-phase techniques, including mass spectrometric methods under relatively high pressure,[11] allows experimental study of interactions between ions and neutral molecules that include some association (clustering). Ion–molecule equilibria that were studied in the gas phase include those of $H_3O^+(H_2O)_n$ and $CH_5^+(CH_4)_n$, in which twenty or more neutral molecules

[*] In protosolvation the interaction between the heteroatom and the second proton is not as strong as in protonation, but is sufficient to form a superelectrophile.

Georg Olah was born in 1927 and educated in Budapest, Hungary. He moved in 1957 first to Canada and then to the USA with the Dow Chemical Company. Since 1977 he has been Director of the Loker Hydrocarbon Research Institute and Distinguished Professor of Organic Chemistry at the University of Southern California, Los Angeles. He is a member of the US National Academy of Sciences, a Foreign Member of the Italian Academia dei Lincei, and an Honorary Member of the Hungarian Academy of Sciences. He received Honorary Doctorates from the University of Durham (England), the University of Munich, and his alma mater, the Technical University of Budapest. He is the recipient of many awards including the American Chemical Society Awards in Petroleum Chemistry, Creative Work in Synthetic Organic Chemistry, and the Roger Adams Award. His research interests are in the area of synthetic and mechanistic organic chemistry, reactive intermediates (carbocations), superacids, and hydrocarbon chemistry. He has published close to 1000 scientific papers, holds 100 patents, and authored or co-authored 15 monographs.

associate with the ionic center. In a way these conditions are similar to solvation, though, of course, the number of associated molecules is very limited.

Acid–base interactions are at the heart of our understanding of chemistry. The concept of acidity and basicity and its broader application in electrophile–nucleophile interactions represents the core of what is considered heterolytic (ionic) chemistry. These concepts are too well known to be repeated here. It should be pointed out, however, that for too long the assumed fundamental differences between gas-phase and condensed-state chemistry hindered our understanding of the underlying general concepts and their logical application to develop new insights into related chemistry.

The concepts of acidity were originally developed in solution chemistry and are primarily still related to aqueous systems. "Strong" mineral acids are H_2SO_4, HCl, HNO_3, etc. These acids span only a relatively limited range of acidities. It has generally been assumed that gas-phase studies on the "free" proton and its reactions has little to offer to our understanding of condensed-phase chemistry.

Since the early sixties the development of superacids opened up new vistas in condensed-state chemistry and helped to narrow, but not to eliminate, the gap between gas-phase and condensed-state chemistry.[6]

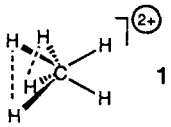
Superacids were arbitrarily defined as acids stronger than 100% sulfuric acid (in case of Brønsted acids, by Gillespie[6b]) or $AlCl_3$ (in case of Lewis acids, by us[6a]). The logarithmic Hammett acidity (H_0) scale was extended from -12 for 100% H_2SO_4, to -25 in the case of some "magic acids" (fluoroantimonic or related acid systems). As in the condensed state the proton is always solvated; in a superacid system based, for instance, on HF, HSO_3F, etc. protonated cations (in the examples, H_2F^+ and $H_2SO_3F^+$) are present in conjunction with their counterions. Indeed significant differences (including steric and chemical) were observed for different protocations under nonexchanging conditions. In superacidic systems, the anions are generally associated through fluorine bridges to form oligomeric anions. This helps to delocalize the negative charge and thus to enhance the proton donor ability of the systems. This also takes place in solid, polymeric superacids, such as Nafion-H.

Superacids and their electrophilic chemistry was comprehensively reviewed,[6] and readers are referred to these reviews.

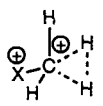
Protonation (protosolvation) or the related Lewis acid complexation (alkylation) of electrophiles capable of undergoing further interaction results in doubly electron-deficient, dicationic superelectrophiles that are substantially different from the large spectrum of dications formed by conventional depletion of electrons from neutral molecules (or atoms).

Carbodications are of increasing significance both in solution and in gas-phase chemistry. Their structural properties have been addressed in recent reviews.[12, 13] These reviews focus on organic dications that are observable under superacidic, stable-ion conditions or detectable in the gas phase by charge-stripping mass spectrometry. They also illustrate that the rigorous bonding topology that applies to carbodications is quite different from the building-block methodology that is used for neutral molecules.[14]

Besides protonation/alkylation of nonbonded electron pairs of onium ions, carboxonium ions, and the like (see later sections) it is also possible to form geminal onium dications (**1**) by protonating/alkylating covalent bonds in these ions or in certain carbocations. Typcial examples include diprotonated methane,[15] and diprotonated hetero-substituted methanes (**2**).[16]



1



2, X=NH_3, OH_2, HN_2 etc.

The former has two three-center two-electron (3c–2e) bonds to attach the six hydrogens to the carbon atom of methane. The latter includes the protonation of a nonbonded electron pair on the heteroatom as well as a 3c–2e bond.

To appreciate the viability of doubly charged species it is instructive to recall that as far back as 1933 Pauling predicted kinetic stability for the dicationic dimer of helium.[17a] He_2^{2+} is isoelectronic with the hydrogen molecule. Coulomb explosion studies and theoretical calculations support this prediction.[17b] A activation barrier of 33.2 kcal mol^{-1} has been calculated for its exothermic (by 200 kcal mol^{-1}) dissociation. Possibly even more impressive is that the He^+–He^+ bond distance of 0.741 Å is 0.037 Å shorter than the H–H bond in hydrogen. This establishes that the bonding interaction in the dication is strong enough to counter the substantial electrostatic charge–charge repulsion.

2. Oxonium Dications

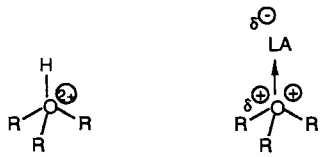
To assess the scope of electrophilic or protolytic activation we first address the extent to which further alkylation or protonation of heteroatoms in onium ions is possible. In these cases the heteroatom's nonbonded electron pairs bind the proton (as in the protonation of ammonia). The question then arises whether heteroatoms with several lone pairs can undergo second protonation despite strong charge–charge repulsion.

2.1. Alkyloxonium Dications

Alkyloxonium ions are formally derived from the parent hydronium ion H_3O^+ by substituting one, two, or all three hydrogen atoms with alkyl groups (i.e., ROH_2^+, R_2OH^+, R_3O^+). These are referred to as primary, secondary, or tertiary oxonium ions; those containing hydrogen atoms are termed acidic oxonium ions.

Alkyl cations observed as long-lived stable species in superacidic media[18] are extremely powerful alkylating agents. Alkyloxonium ions are significantly stabilized by alkyl substituents.[14] Meerwein salts, such as the trimethyl and triethyl oxonium ions R_3O^+ with various counterions such as SbF_6^-, BF_4^-, $SbCl_6^-$ and PF_6^-, are excellent alkylating agents for nucleophiles containing heteroatoms but are not capable of C-alkylating aromatic or aliphatic compounds. In conjunction with strong protic acids, such as FSO_3H, CF_3SO_3H, or FSO_3H:SbF_5 (Magic Acid), however, they were found to alkylate aromatics readily. For example, ben-

zene and toluene have been methylated and ethylated with trimethyl- and triethyloxonium salts in the presence of Magic Acid.[19] The methylation of toluene gave an isomer distribution (60% *ortho*-, 11% *meta*-, and 21% *para*-xylene) typical of an aromatic substitution reaction with a reactive electrophilic reagent. The protolytic activation of trialkyloxonium ions points to a protonation (protosolvation) of the nonbonded electron pair of the oxygen atom, which enhances the electrophilicity of the alkyl groups (see Scheme 1). Lewis acid complexation has a similar effect.

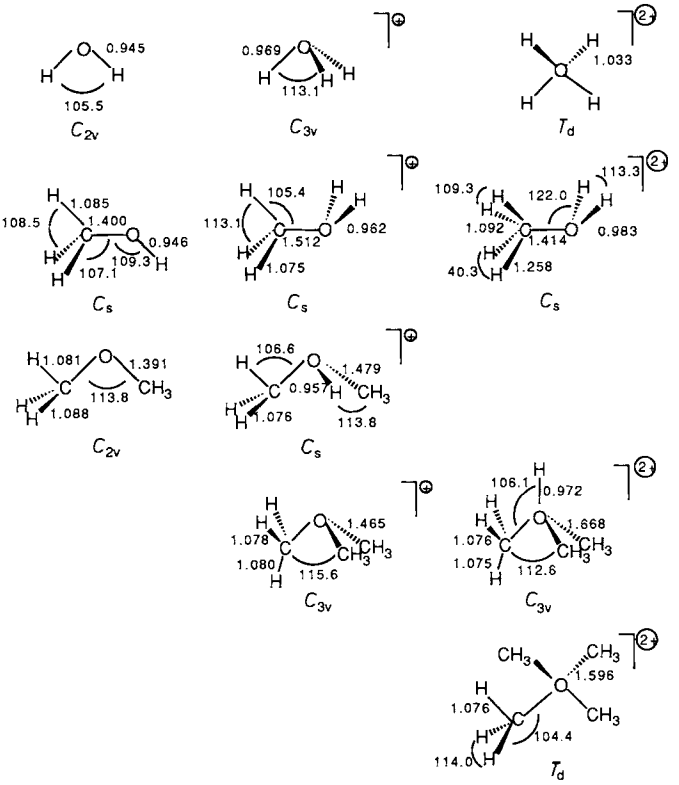


Scheme 1. Activation of oxonium ions by protonation or by Lewis acids (LA).

Theoretical calculations were carried out to determine the energies of water, methanol, dimethyl ether, and the trimethyloxonium ions, as well as of their mono- and diprotonated forms and the related proton affinities (see Table 1).[20a]

The diprotonated acidic methyloxonium ions $MeOH_3^{2+}$ and $Me_2OH_2^{2+}$ are thermodynamically unstable and dissociate to the monoprotonated ions and a proton, but the kinetic barriers to deprotonation are significant. In the case of H_4O^{2+} this amounts to about 39 kcal mol^{-1}. These data relate to isolated molecules in the gas phase; in superacidic solutions clustering of the dipositive ions with their precursors could aid the stabilization by greatly facilitating delocalization of excess charge.

The optimized structures for mono- and diprotonated (methylated) oxonium ions for all species for which potential energy minima were found (intermediates) are depicted in Scheme 2.



Scheme 2. HF/6-31G* optimized structures of H_2O, MeOH, Me_2O, and Me_3O^+, as well as of the most stable isomers of their mono- and diprotonated or methylated derivatives (bond lengths in Å, angles in degrees).

Table 1. Absolute energies E [Hartree] [a] with zero-point energies [kcal mol^{-1}] [20b] in parentheses [b], proton affinities PA [kcal mol^{-1}] [a] in the gas phase [20c, d], and enthalpies from isodesmic equations [kcal mol^{-1}] [20e] [a] (determined with the G2 method) for the protonatable and protonated molecules and ions discussed in this review.

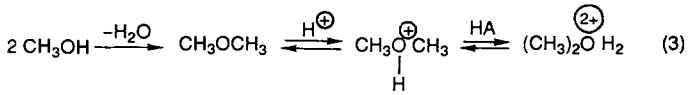
Acid-catalyzed alkylation of aromatics with alcohols is widely used. Whereas tertiary (and secondary) alcohols react with relative ease by a carbocationic mechanism, alkylation with primary alcohols is generally achieved only in case of more reactive aromatics, and even then under forcing conditions.

Monoprotonation of methanol under superacidic, stable-ion conditions gives the methyloxonium ion as a stable, well-defined oxonium ion [Eq. (1)].

(1)

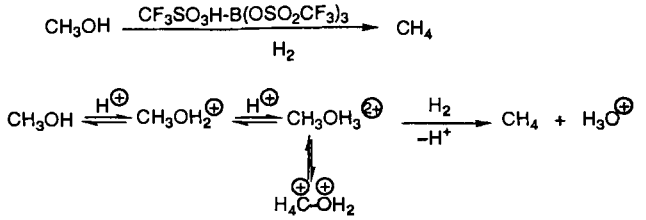
The methyloxonium ion reacts with nucleophiles by proton transfer or displacement analogous to nucleophilic S_N2 substitutions to yield methylated products. It is significant that in superacidic media, or with solid superacids, methylation of aromatics is greatly facilitated.[21] This might reflect activation through further protonation (protosolvation) of the nonbonded electron pair of the oxygen atom, as shown in Equation (2). Alternatively, methanol, which readily undergoes intermolecular dehydration under acidic conditions to give dimethyl ether, then forms dimethyloxonium ion $(CH_3)_2OH^+$ and, on further protonation, a superelectrophilic methylating agent [Eq. (3)].

(2)



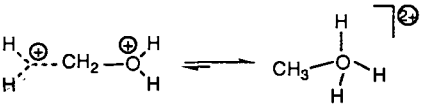
(3)

The methyloxonium ion $MeOH_2^+$ in superacidic media also readily undergoes ionic hydrogenation to give methane.[22] As cleavage to the methyl cation (CH_3^+) is improbable for energetic reasons, the reaction is best interpreted as proceeding through a superelectrophilic protonated methyloxonium dication (Scheme 3).



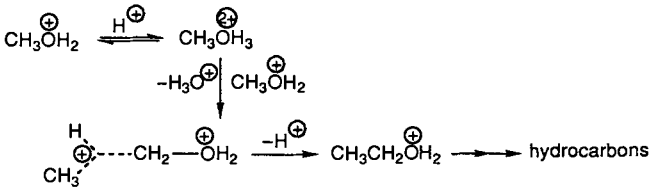
Scheme 3. Ionic reduction of methanol to yield methane in superacids and a plausible pathway for this reaction.

As shown by the theoretical calculations, diprotonation of methanol in the gas phase gives preferentially the O,C-protonated dication $^+CH_4OH_2^+$. In solution, however, contribution from the O,O-protonated form is possible [Eq. (4)].



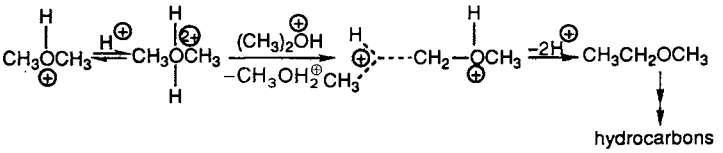
(4)

When methanol (or dimethyl ether) reacts with superacids (either HF–SbF_5, FSO_3H–SbF_5 or TaF_5, NbF_5, etc.) under forcing conditions (100–300 °C), self-condensation occurs. When reacting methanol (or trimethyl phosphate) with phosphorus pentoxide or polyphosphoric acid, at 190 °C, Pearson detected C_3–C_9 alkanes as well as toluene and C_8–C_{10} aromatics.[23] He suggested electrophilic methylation of methanol, but this is expected only on oxygen and would give dimethyl ether. In superacids methanol is completely protonated; there is no evidence for any deprotonation equilibrium. It is possible that under these conditions it is the methyloxonium ion $CH_3OH_2^+$ which undergoes methylation at a C-H bond (Scheme 4). The active methylating agent is considered to be a superelectrophilic methylating agent formed in the system.



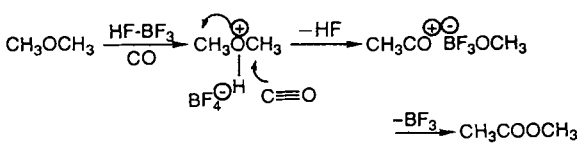
Scheme 4. Probable mechanism for the self-condensation of methanol in superacids.

Once the first C–C coupling is achieved, protonated ethanol will readily yield the observed hydrocarbon products (by further alkylation or through dehydration to ethylene, which is known to react further by acid-catalyzed electrophilic chemistry). Dimethyl ether can react in a similar way to methanol (Scheme 5).



Scheme 5. Mechanism for the self-condensation of dimethyl ether in superacids.

Similar activation is possible in the carbonylation of dimethyl ether (or methanol) to methyl acetate [Eq. (5)] in superacidic (HF–BF_3) solution.[24] The methyloxonium ion does not normally react with CO, unless activated by superacids to yield a superelectrophilic dication.



(5)

2.2. Protohydronium Dication (Diprotonated Water)

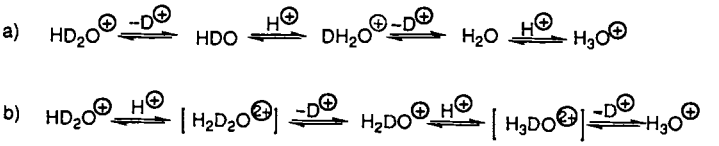
In understanding the chemistry of protonated (protosolvated) alkyloxonium ions, the parent tetrahydridooxonium dication H_4O^{2+} (protohydronium dication, diprotonated water) is of fundamental significance.

The existence of protonated water, H_3O^+ (hydronium ion), was first postulated in 1907.[25] Its preeminent role in acid-catalyzed reactions in aqueous media was first realized in the acid–base theory of Brønsted and Lowry.[26] Direct evidence for the hydronium ion in solution and in the solid state came mainly from IR,[27] Raman,[28] and neutron diffraction studies.[29] The gaseous ion was observed in mass spectrometric studies.[30] In superacid solution the hydronium ion was shown to be extremely stable by ^1H and ^{17}O NMR spectroscopy.[6, 31–33] In fact, Christe has isolated hydronium ion salts with a variety of counterions such as SbF_6^-, AsF_6^-, and BF_4^-.[34] All of the available experimental and high-level ab initio theoretical data support a tetrahedral geometry for the hydronium ion (Scheme 6).[33, 35, 36]

Scheme 6. Structures of H_3O^+ and H_4O^{2+}.

Gold et al. prepared long-lived isotopic hydronium ions such as H_3O^+, H_2DO^+, and HD_2O^+ in HSO_3F:SbF_5–D_2O/SO_2ClF solutions and characterized them by ^1H and ^2H NMR spectroscopy without exchange.[31a, c]

Subsequently, we demonstrated that in even stronger superacidic media (HF/DF–SbF_5 with increasing amounts of SbF_5) hydrogen/deuterium exchange of isotopic hydronium ions including $D_2H^{17}O^+$ and $DH_2^{17}O^+$ with superacids can be monitored by ^{17}O NMR spectroscopy.[37a] The acidity of the FSO_3H–SbF_5 (1:1) system (H_0) is about -21, whereas H_0 for the 1:1 mixture of HF and SbF_5 is estimated at -25. Two mechanisms are possible for the observed H/D exchange (Scheme 7): a) deprotonation–protonation equilibria involving the neutral molecules and the monocations or b) protonation–deprotonation equilibria involving monocations exchanging H and D through OH_4^{2+} dications. Because H/D exchange occurs only at the highest acidities (i.e., with HF/DF–SbF_5 but not with HSO_3F/DSO_3F–SbF_5) and no deprotonation to form water is feasible in these systems, the results suggest that isotopic exchange takes place via isotopomeric H_4O^{2+}. Under extremely strongly acidic conditions the remaining nonbonded electron pair of the oxygen atom of H_3O^+ apparently also undergoes a protolytic interaction.



Scheme 7. Two possible mechanisms for H/D exchange for water in superacids.

To evaluate the structure and stability of the H_4O^{2+} dication, ab initio calculations have been carried out.[37] The H_4O^{2+} dication is isoelectronic with H_4N^+, CH_4, and BH_4^-, all known to have tetrahedral geometries. At the HF/6-31G* level, the structure with T_d symmetry corresponds to an energy minimum but not the planar D_{4h} form (Table 2). Apparently the double positive charge can be adequately accommodated in the tetrahedral structure to prevent spontaneous fragmentation. It should be recalled that in H_3O^+ the oxygen is negatively charged, the positive charge being essentially on the hydrogen atoms.

Thermodynamically H_4O^{2+} is unstable towards deprotonation to H_3O^+ by 59.8 kcal mol^{-1} (HF/6-31G*) (see Table 2), although it has significant kinetic stability (deprotonation barrier 39.4 kcal mol^{-1}). These energies remain nearly the same when valence electron correlation interactions are included in the calculation: the deprotonation energy for H_4O^{2+} becomes -52.9 kcal mol^{-1}, the activation barrier 43.9 kcal mol^{-1} (MP4SDTQ/6-31G**//HF/6-31G*). The planar H_4O^{2+} structure is 94.6 kcal mol^{-1} less stable than the tetrahedral. The heat of formation of H_4O^{2+} is estimated as 557 kcal mol^{-1} from $\Delta H_f^0(H_3O^+) =$ 139 kcal mol^{-1} and $\Delta H_f^0(H^+) = 365.2$ kcal mol^{-1}, the calculated heat of deprotonation.

More recently calculations[20a] using the GAUSSIAN-2 method made the deprotonation favorable by -61.9 kcal mol^{-1} and lowered the activation energy slightly to 38.2 kcal mol^{-1}. The proton affinity calculated for 298 K at the same level is 60.4 kcal mol^{-1}. These data support the previous studies and conclusions reached for an associative mechanism of the H/D exchange of H_3O^+ in superacidic media.

Although the activation energy for the deprotonation of H_4O^{2+} is substantial, it may be affected by tunneling. Within a range of 5 kcal mol^{-1} below the classical barrier (considered to be the maximum deprotonation barrier of H_4O^{2+},

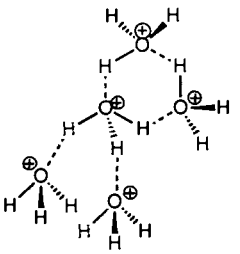
namely the "bare" Born-Oppenheimer barrier + zero-point energy for the transition state), the reaction rate was calculated to change sharply from 10^9 to 10^3. Similarly, the calculated H/D isotope effect (through a dissociative mechanism, that is, cleavage into H^+/D^+ and H_3O^+) only becomes substantial directly below the classical threshold. Since, in general, any tunneling effect for the deprotonation is small, it was concluded that the kinetic stability of H_4O^{2+} is indeed significant.

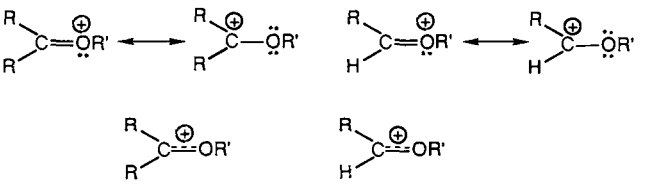
Despite this kinetic stability of H_4O^{2+}, calculations show that the protonation of H_3O^+ is thermodynamically unfavorable; however, it must be recognized that the calculational data referred to dilute gas-phase conditions and thus do not fully relate to condensed-state conditions. Solvation or clustering effects may have a major influence. In particular in small dications, solvation tends to diminish the effect of charge-charge repulsion, and thus could bring H_4O^{2+} into a thermodynamically more accessible region. Superacid solutions of H_3O^+ could be highly structured. Thus, the H_4O^{2+} protons might be shared by more than one H_3O^+ in a dynamic fashion (Scheme 8).



Scheme 8. Possible stabilization of H_4O^{2+} by H_3O^+ ions in superacids.

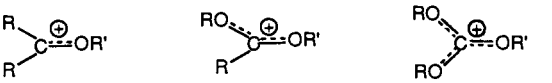
3. Carboxonium Dications (Diprotonated/Alkylated Carbonyl Compounds)

Carboxonium ions were first studied by Meerwein. They are highly stabilized compared to alkyl cations.[17] Their behavior reflects both their oxonium and carbenium ion nature, though the former predominates (Scheme 9). This de-



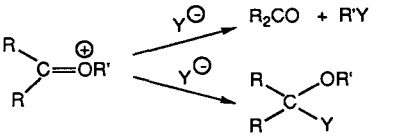
Scheme 9. Top: Resonance structures of protonated/alkylated ketones and aldehydes. Bottom: Formulation as delocalized carbenium ions. R' = H, alkyl, aryl.

piction of delocalized carboxonium ions is fully warranted by their physical (spectroscopic) properties and chemical behavior. Carboxonium ions, according to Perst's classification,[14a,b] can be acidic or neutral and regarded as carbenium ions in which the carbocationic center bears hydroxy or alkoxy (aryloxy) substituents (Scheme 9). Depending on the number of oxygen atoms attached to the carbocationic center the carboxonium ions are primary, secondary, and tertiary (Scheme 10).



Scheme 10. Primary, secondary, and tertiary carboxonium ions. R' = H, alkyl.

Carboxonium ions are ambident electrophiles and can react either by transferring the ligand attached to oxygen (H, alkyl, or aryl group) to a nucleophile Y^- or by addition of the nucleophile to the carbocationic center (Scheme 11).



Scheme 11. Carboxonium ions as ambident electrophiles.

The carbocationic nature of carboxonium ions is limited by strong delocalization resulting from contributions of the oxonium forms. This restricts the reactions at the carbocationic center to those with efficient nucleophiles.

Acidic carboxonium ions tend to be efficient proton transfer agents. Nucleophilic attack at the carbocationic center has been observed only rarely (see below), and results primarily in rearrangement reactions in strong acid solutions. However, the carbocationic reactivity of carboxonium ions can greatly be enhanced by their protosolvation (protonation) in superacidic solutions.

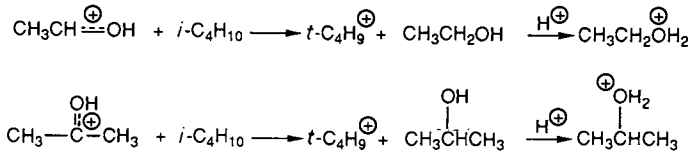
Trivalent carbocations (carbenium ions) have long been recognized as efficient hydride abstractors that generate, for example, related carbocations from tertiary isoalkanes [Eq. (6)]. In contrast, carboxonium ions, being weaker electrophiles, show no hydride abstracting ability with isoalkanes when they react in aprotic solvents (SO_2 or SO_2ClF).

(6)

Brouwer and Kiffen,[38] however, observed that both protonated acetaldehyde and acetone readily reacted in 9:1 mixtures of HF and SbF_5 or HF and BF_3 with isobutane to give the *tert*-butyl cation. (The proposed reaction mechanisms are shown in Scheme 12).

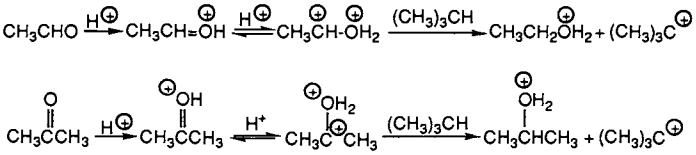
Brouwer and Kiffin stated that "The hydride transfer from an alkane molecule to a hydroxycarbonium ion to form an alkylcarbenium ion and an alcohol molecule is thermodynamically a very unfavorable reaction. The equilibrium of this reaction as such would lie completely to the side of the starting compounds. It is the high degree of the protonation of the alcohol that renders the hydride transfer thermodynamically possible."

It is now apparent, based on the low carbocationic reactivity of the methylcarboxonium ($CH_3CH{=}\overset{+}{=}OH$) and dimethylcarboxonium ($(CH_3)_2C{=}\overset{+}{=}OH$) ions and thermodynamic considerations, that the observed hydride transfer re-



Scheme 12. Initially proposed mechanism for the hydride abstraction from isobutane by acetaldehyde or acetone in superacids.

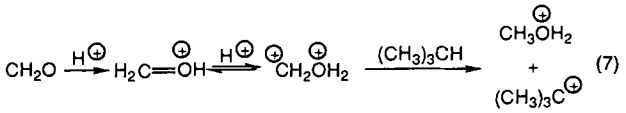
actions in solutions containing an excess of superacid were indeed induced by superelectrophilic diprotonated acetaldehyde or acetone, respectively, and not by the monoprotonated species (Scheme 13).



Scheme 13. More likely mechanism for the hydride abstraction of Scheme 12, involving dications.

The reactions with diprotonated superelectrophiles are thermodynamically favored, and protonated alcohols are formed directly in the hydride transfer reaction (not by subsequent protonation of neutral alcohols). The diprotonated carbonyl compounds act as extremely reactive superelectrophiles.

Protonated formaldehyde reacts similarly [Eq. (7)]. We observed[39] that when monomeric formaldehyde was treated with a 3:1 mixture of HF and SbF_5 or HSO_3F and SbF_5 (containing some HF) in SO_2ClF solution at -78 to $-40\,^{\circ}C$, protonated fluoromethanol $FCH_2OH_2^+$ was obtained. It was suggested at the time that the reaction proceed-

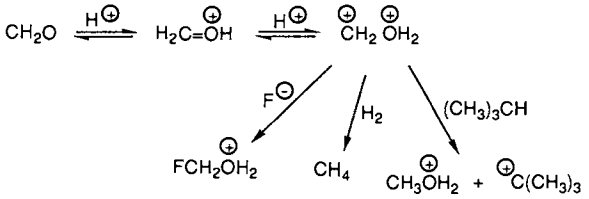


(7)

ed with formation of fluoromethanol, which was subsequently protonated [Eq. (8)]. Analogously, the reaction with HCl gave protonated chloromethanol $ClCH_2OH_2^+$.[40]

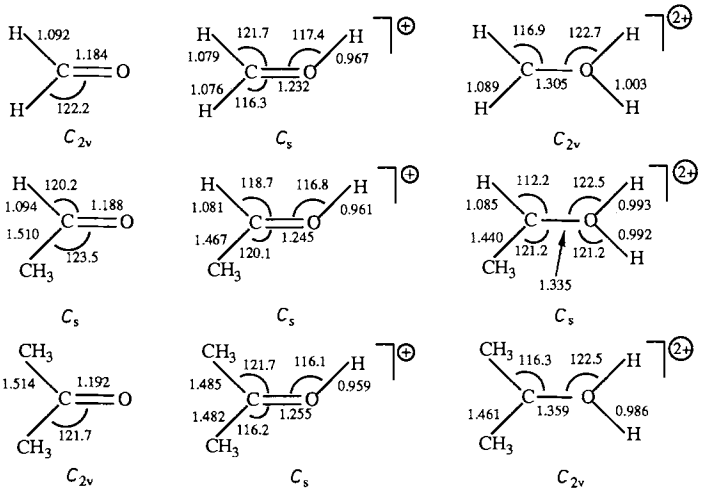
(8)

It now seems possible that the process involves the more reactive superelectrophilic diprotonated (protosolvated) formaldehyde on reaction with F^- at the carbon, which has greatly enhanced carbocationic properties. This would give the stable protonated fluoromethanol directly. Furthermore, formaldehyde is readily reduced to the methyloxonium ion (and subsequently to methane) under ionic hydrogenation conditions even at room temperature,[22] while monoprotonated formaldehyde is considered to have too weak a carbocationic nature to be able to account for the reactions (Scheme 14).



Scheme 14. Reactions with formaldehyde in superacidic media.

The diprotonation of the carbonyl compounds, formaldehyde, acetaldehyde, and acetone, was also studied by MO theoretical calculations (see Table 1).[20] Diprotonation is increasingly favored along the series from formaldehyde through acetaldehyde to acetone. The optimized structures of the neutral and mono- and diprotonated species are shown in Scheme 15.



Scheme 15. Optimized structures (HF/6-31G*) of neutral and mono- and diprotonated formaldehyde, acetaldehyde, and acetone.

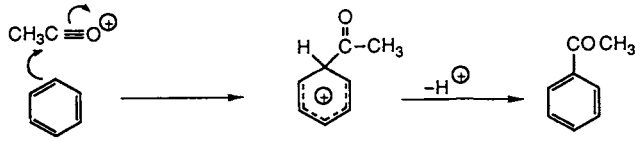
Krivdin, Facelli, et al.[41] recently also carried out a theoretical study of the protonation of acetone and calculated NMR chemical shifts and coupling constants for the mono- and diprotonated species. Experimentally no diprotonated acetone could be observed (by NMR). This is, however, not unexpected, as its equilibrium concentration should be very low and fast exchange with the monoprotonated form difficult to freeze out.

4. Protonated (Lewis Acid Complexed) Acyl Dications

Acyl cations are relatively weak electrophiles. This is easily understood, since their structure is predominantly that of a linear carboxonium ion (Scheme 16).[42] In their reactions with suitable nucleophiles, such as π-arenes or heteroatom donor nucleophiles, the readily polarizable linear acylium ions undergo displacement of a π-electron pair to oxygen,

Scheme 16. Resonance structures of acyl cations. The predominant structure is on the right.

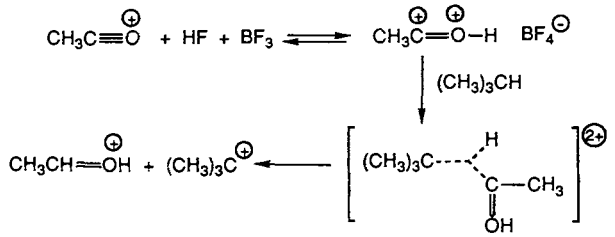
bending the ion. The empty p orbital that develops as a result on the carbocationic center enables the reaction to proceed. As example, the acetylation of benzene is depicted in Scheme 17.



Scheme 17. Acetylation of benzene as an example of the nucleophilic attack of an acyl cation on an arene.

The lack of reactivity of acyl cations such as the acetyl cation with deactivated arenes or weakly electron-donating, saturated hydrocarbons is therefore not unexpected. However, under strongly acidic conditions such reactions including superelectrophilic activation of the acetyl cation are greatly enhanced. For instance, Friedel–Crafts type acetylation of benzene and chlorobenzene with acetyl hexafluoroantimonate ($CH_3CO^+SbF_6^-$) is enhanced when using superacidic CF_3SO_3H as solvent instead of the relatively weak CF_3CO_2H. Shudo[43] found that short reaction times (15–30 min) gave high (78–81%) yields in CF_3SO_3H, whereas even 10 to 50 times longer reaction times gave only less than 1–8% yield in CF_3CO_2H.

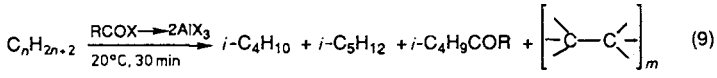
Brouwer and Kiffen[44a] have reported the hydride transfer from isobutane to the acetyl cation generated from acetic acid in excess HF–BF_3. We,[44b] on the other hand, showed that such a reaction does not occur with isolated acetylium salts in aprotic solvents such as SO_2, SO_2ClF, AsF_3, and CH_2Cl_2. Further, the hydride abstraction from isobutane by the acetyl cation is endothermic by 8.5 kcal mol^{-1} (in the gas phase). In all probability, therefore, the reaction proceeds by protonation (protosolvation) of the acetyl cation by the superacidic HF–BF_3 system (Scheme 18).



Scheme 18. Probable mechanism of the hydride transfer between CH_3CO^+ and $(CH_3)_3CH$ in HF–BF_3.

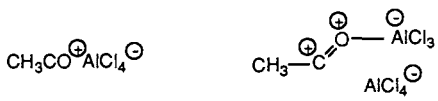
The superelectrophilic protoacetyl dication has not been observed by NMR spectroscopy. In the IR spectrum of the acetyl cation in superacids, however, a shift in the carbonyl stretching frequency is observed. Theoretical calculations have shown that the structure CH_3COH^{2+} corresponds to the global minimum. This agrees with charge-stripping mass spectrometric studies in which the $C_2H_4O^{2+}$ dication has been observed.[45] Interestingly, the isomer protonated at the C-H bond, $^+CH_4{-}C^+{=}O$, is only 24.6 kcal mol^{-1} less stable than the O-protonated acetyl cation. The isoelectronic analogue of $C_2H_4O^{2+}$ is diprotonated diazomethane ($CH_4N_2^{2+}$), which has also been studied theoretically.

Apart from Brønsted acid activation, the acetyl cation (and other acyl ions) can also be activated by Lewis acids. While the 1:1 CH_3COX–AlX_3 Friedel–Crafts complex is inactive for the isomerization of alkanes, a complex with a two equivalents of AlX_3 was found by Vol'pin et al.[46,47] to be extremely reactive in the isomerization of saturated hydrocarbons and other electrophilic reactions [Eq. (9)].



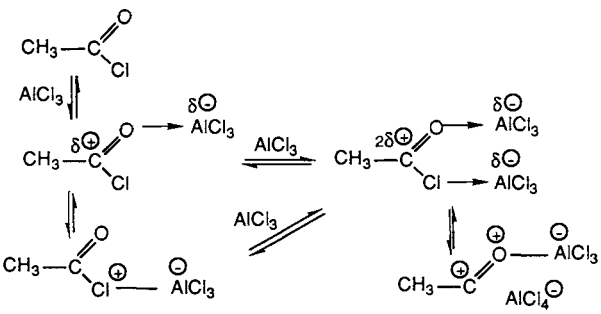
(9)

Vol'pin calls the $CH_3COCl \cdot 2AlCl_3$ complex an aprotic superacid. The results indicate that the acetyl cation is highly activated by further O-complexation with a second molecule of AlX_3 (the equivalent of protonation or protosolvation) (Scheme 19).



Scheme 19. Left: the Friedel–Crafts complex; right: the aprotic superacid complex.

Alternatively, the ionization of acetyl chloride with excess $AlCl_3$ can involve bidentate interaction (Scheme 20).

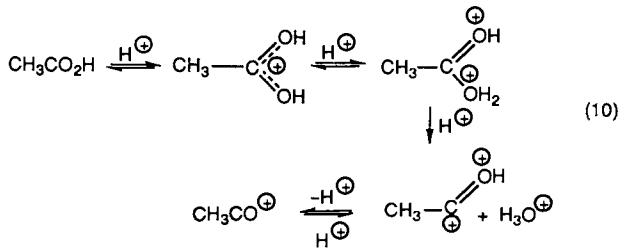


Scheme 20. Activation of acetyl chloride by bidentate coordination to $AlCl_3$.

5. Diprotonated Carboxylic Acids

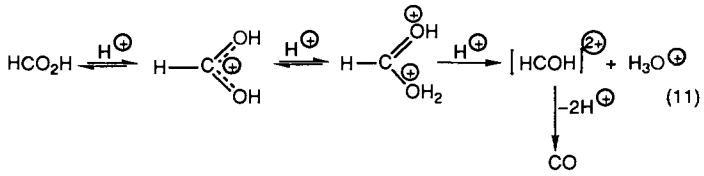
Acetic acid (and other carboxylic acids) become protonated in superacids to form stable, observable (by NMR) carboxonium ions. Cleavage to related acyl cations is observed by raising the temperature of the solutions. In an excess of the superacid a diprotonation equilibrium can play a role in the ionization process [Eq. (10)].[42]

Protonation of formic acid in superacids leads, after the formation of the parent carboxonium ion at low temperature, to the generation of CO; the formyl cation is not ob-



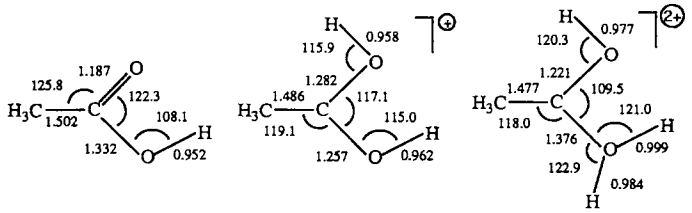
(10)

served by NMR (see Section 7). A diprotonation equilibrium may be again involved [Eq. (11)].



(11)

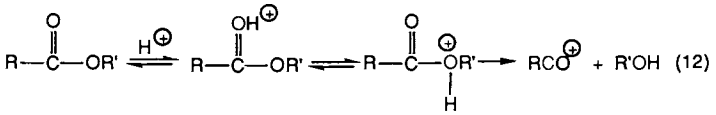
The protonation and diprotonation of formic and acetic acid was also studied theoretically (see Table 1).[40] In Scheme 21 the optimized structures of neutral and protonated and diprotonated acetic acid are compared.



Scheme 21. Calculated structures of neutral and mono- and diprotonated acetic acid that correspond to minima on the potential energy surface.

6. Diprotonated Esters

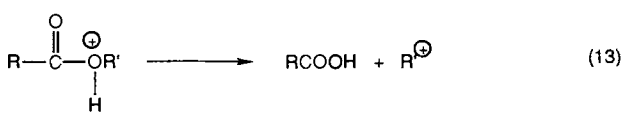
The acid-catalyzed hydrolysis of esters [Eq. (12)] is assumed to involve an equilibrium between intermediates protonated at the carbonyl and the ether oxygen atom. The



(12)

latter leads to cleavage of the acyl–oxygen bond. When R′ is capable of forming a sufficiently stabilized carbocation, the alkyl–oxygen bond is ruptured [Eq. (13)].

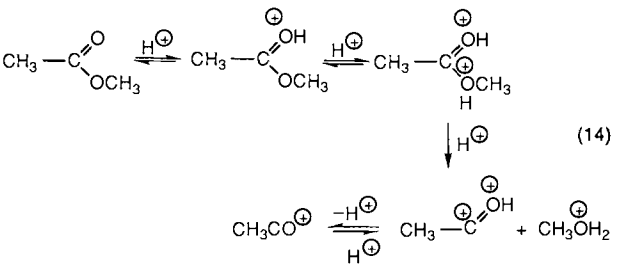
Whereas esters protonated at the carbonyl oxygen atom have been observed and studied under stable-ion conditions,[6] the isomeric acyloxonium ions were proposed to be



(13)

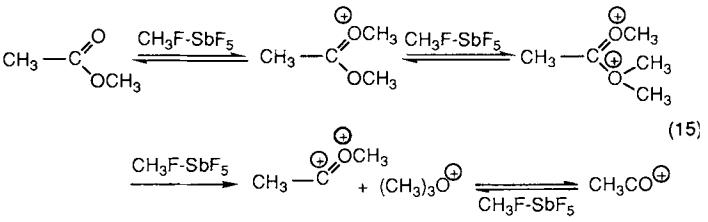
intermediates, however, without structural (spectroscopic) evidence. In the presence of nucleophiles they were assumed to react rapidly to yield their cleavage products.

In superacidic solution where esters are completely protonated, their protolysis can be considered to involve diprotonation, as shown in case of methyl acetate. In superacids the carbonyl-protonated ester does not show any deprotonation equilibrium, but there can be an equilibrium with the diprotonated form [Eq. (14)]. Similar behavior is indicated in the



(14)

methylation with the powerful methyl fluoride–antimony pentafluoride complex [Eq. (15)].

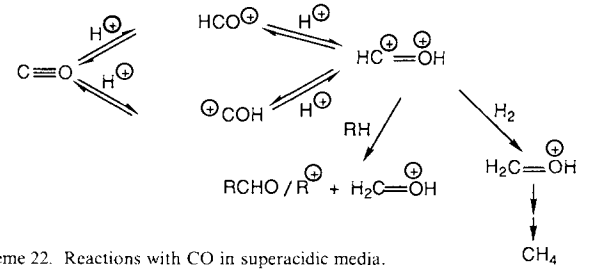


(15)

7. Diprotonated Carbon Monoxide (Protoformyl Dication)

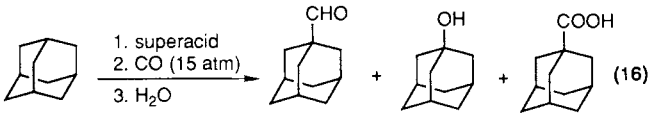
C-Protonation of carbon monoxide leads to the formyl cation (HCO^+). O-Protonation leading to the isoformyl cation (^+COH) is energetically less favored. The formyl and isoformyl cations are stable in the gas phase, and the latter was also detected in interstellar space.[48] Neither ion has been observed in superacidic solutions by NMR where most other acyl cations are stable and readily studied.[42]

The failure to observe the static formyl cation by ^1H NMR in superacid solutions, even at low temperatures, is now recognized to be due to fast intermolecular exchange resulting from a second protonation from the protoformyl dication (diprotonated carbon monoxide).[49] ^{13}C NMR studies do show an exchanging formyl cation system.



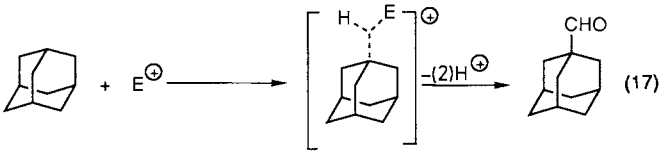
Scheme 22. Reactions with CO in superacidic media.

The existence of diprotonated carbon monoxide can also explain the observed high reactivity of carbon monoxide in superacidic media (Scheme 22). With saturated hydrocarbons both carbonylation and formylation was observed. Adamantane, for example, reacts under pressure of CO to yield 1-adamantane-carboxaldehyde along with the 1-carboxylic acid and 1-alcohol [Eq. (16)].[50] The latter two products are the expected Koch–Haaf products produced through the bridgehead 1-adamantyl cation (formed by hydride abstraction).



(16)

The yield of 1-adamantanecarboxaldehyde increased from 9.1 to 14.5 to 21% along the series CF_3SO_3H, CF_3SO_3H–$B(OSO_2CF_3)_3$, and CF_3SO_3H–SbF_5. The increase in yield with increasing acidity supports direct formylation of the adamantane C-H bond by the formyl cation or more probably by its more reactive protosolvated dicationic form [Eq. (17), where $E^+ = HCO^+$ or $HCOH^{2+}$]. As with the



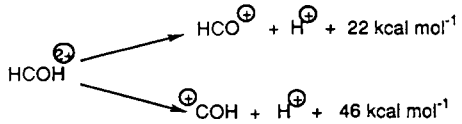
(17)

acetyl cation (see Section 4), the linear formyl monocation itself would not be reactive enough to attack C-H σ bonds. An alternative pathway for the formation of 1-adamantanecarboxaldehyde could be hydride abstraction from excess adamantane by the 1-adamantanoyl cation (or its protosolvated form) formed in the Koch reaction. This was ruled out by labeling studies with 1,3,5,7-tetradeuterioadamantane, which showed no significant deuterium incorporation into the CHO group.[50]

The suggested de facto formylating agent is either the protosolvated formyl cation or the protoformyl dication present in equilibrium in the superacidic system. Protosolvation of the formyl cation can render it highly reactive. In fact in the aromatic formylation[51] of toluene (T) and benzene (B) with CO in the strongly superacidic HF–SbF_5 medium at −95 °C gave a low k_T/k_B rate ratio of 1.6 and increased proportion of *ortho* substitution. On the other hand, with less acidic HF–BF_3 the k_T/k_B ratio at 0 °C was 860; the *para*-substituted product was predominant. In the former case the de facto formylating species must be highly activated[52] because it does not significantly discriminate between toluene and benzene.

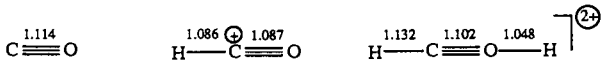
The formylation of arenes such as benzene and toluene with HCOF and excess BF_3 showed a substrate selectivity of $k_T/k_B = 36$ and also gave increased *ortho* substitution.[51] Complexation of the formyl cation to a Lewis acid ($H\text{-}\overset{+}{C}{=}O \rightarrow BF_3$) can explain the data. When the formyl cation forms a complex with excess Lewis acid, it is more reactive than the parent cation or the 1:1 HCOF · BF_3 complex, similar to Vol'pin's RCOCl · $2AlCl_3$ systems.[46, 47]

Protonation of carbon monoxide to either the formyl or isoformyl cation is exothermic. The formyl cation was calculated to be more stable than the isoformyl ion by 38 kcal mol^{-1}. The calculated rearrangement barrier of 36 kcal mol^{-1} (MP3/6-31G**)[53, 54] suggests that the isoformyl cation, once formed, should be a relatively long-lived species. There are also significant kinetic barriers to deprotonation (Scheme 23).



Scheme 23. Reaction energies for the deprotonation of the formyl dication.

Theoretical calculations at the MP2/6-31G*//HF/6-31G* level gave the values shown in Table 1 for the energies for mono- and diprotonated CO and the corresponding proton affinities and isodesmic enthalpies. The optimized structures (calculated at the HF/6-31G* level) are shown in Scheme 24.



Scheme 24. Optimized structures of neutral and mono- and diprotonated CO, each with $C_{\infty v}$ symmetry.

Theoretical calculations support the kinetic stability of the protoformyl dication,[53] which has also been observed by mass spectrometry.[55] The dication with its very short C–O bond distance of 1.102 Å has a deprotonation barrier of more than 20 kcal mol^{-1}.

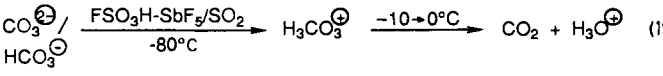
8. Protonated and Diprotonated Carbonic Acid and Carbon Dioxide

Carbonic acid has specific importance in nature. The equilibria of carbon dioxide and water [combined in Eq. (18)] and their significance are well recognized. Although carbon-

(18)

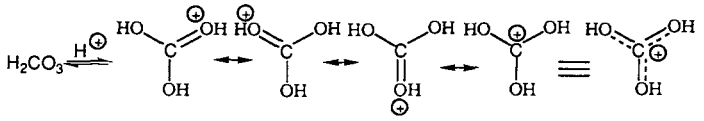
ates are among the most abundant minerals on earth, carbonic acid is difficult to observe spectroscopically in its free form. Only an NMR spectrum of its ether complex $H_2CO_3 \cdot Et_2O$ has been reported.[56]

Protonated carbonic acid in superacidic media is remarkably stable.[57] It can be obtained by simply dissolving carbonates or hydrogen carbonates in FSO_3H–SbF_5 (or other superacids). The solutions decompose only at around 0 °C to give hydronium ions and carbon dioxide [Eq. (19)]. The SbF_6^- salt of $H_3CO_3^+$ can even be isolated.



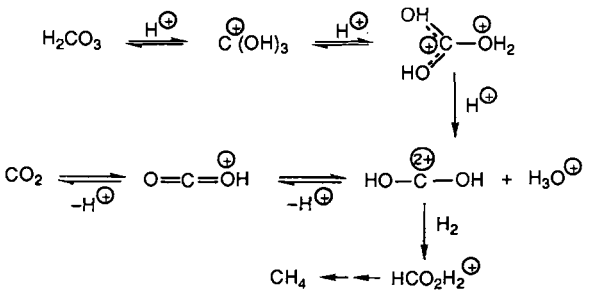
(19)

The close analogy between protonated carbonic acid and the guanidinium ion explains its stability. Both are highly resonance stabilized (Scheme 25).



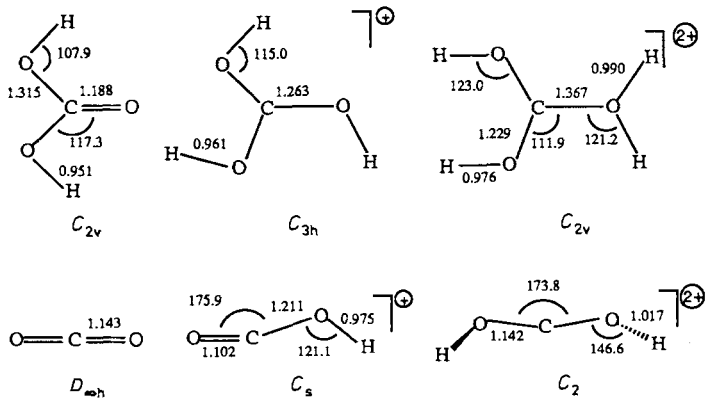
Scheme 25. Resonance structures for protonated carbonic acid.

The guanidinium ion undergoes further protonation in superacid solution, and the dication was observed in such media by NMR spectroscopy. Protonated carbonic acid can also readily undergo a second protonation to $H_4CO_3^{2+}$.[58] Theoretical calculations reveal the similarity between diprotonated guanidine and diprotonated carbonic acid, but due to more rapid proton exchange (Scheme 26), $H_4CO_3^{2+}$ has not yet been observed as a static dication by NMR spectroscopy.



Scheme 26. Equilibria of protonated and diprotonated carbonic acid and their reactions.

The observation that carbonic acid in superacidic media can act as a carboxylating agent[57] under certain circumstances and readily undergoes ionic reduction to methane is significant, as it points to the intermediacy of protonated (diprotonated) carbon dioxide (Scheme 26). The protolytic cleavage of carbonic acid, which leads to carbon dioxide, also implicates protonated and diprotonated CO_2, that is, $O{=}C{=}OH^+$ and $HO{=}C{=}OH^{2+}$, respectively. Koch and Schwarz were the first to study $CO_2H_2^{2+}$ by ab initio molecular studies.[59]

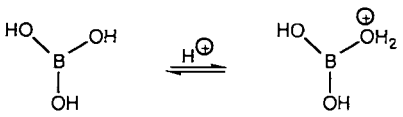


Scheme 27. Optimized structures of carbonic acid and carbon dioxide in neutral and mono- and diprotonated form.

Our calculations of the energies of mono- and diprotonated carbonic acid and carbon dioxide as well as their proton affinities are shown in Table 1. Optimized structures calculated at the HF/6-31G* level are depicted in Scheme 27. Protonation and diprotonation of carbon dioxide bends the molecule somewhat and thus results in the formation of reactive carboxylating agents.

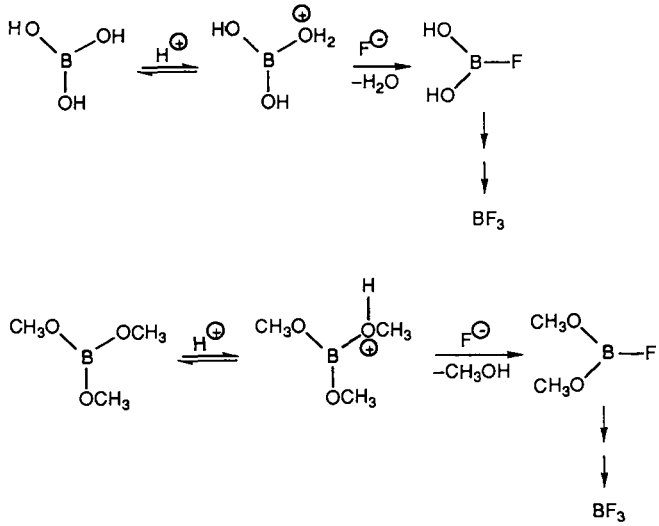
Protonated and diprotonated carbonic acid and carbon dioxide may also have implications in biological carboxylation processes. Although behavior in highly acidic solvent systems cannot be extrapolated to in vivo conditions, related multidentate interactions at enzymatic sites are possible.

The boron analogue of diprotonated carbonic acid is protonated boric acid [Eq. (20)], which Attina, Cacace, and Ricci studied in the gas phase.[60]



(20)

In solution chemistry the facile reaction of boric acid[61] or trimethyl borate[59] with HF or fluorosulfuric acid containing HF to give boron trifluoride is indicative of a pathway via protonated boric acid (or trimethyl borate). Though boric acid is only a weak Lewis acid, its reactivity toward nucleophiles such as F^- is greatly enhanced by protonation (Scheme 28).



Scheme 28. Enhancement of the nucleophilicity of boric acid and trimethylborate by protonation.

9. Sulfonium, Selenonium, and Telluronium Dications

Similarly to oxonium ions, sulfonium ions also undergo protonation (protosolvation) in superacids to produce sulfur-based superelectrophiles [Eq. (21)]. The parent sulfoni-

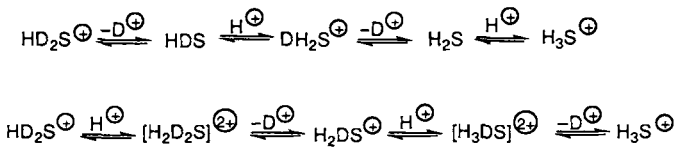
(21)

um ion is the trihydridosulfonium ion (H_3S^+), that is, protonated H_2S. The ion has been characterized in the superacidic medium FSO_3H–SbF_5/SO_2 at low temperature by ^1H NMR spectroscopy.[62] It is also well known in the gas phase and was studied by mass spectrometric techniques. Christe[63] has isolated $H_3S^+SbF_6^-$ as a white crystalline solid at low temperatures. It reacts with water to liberate H_2S. The pyramidal nature of the sulfonium ion **3** was substantiated by vibrational spectroscopy.[63]

3 **4**

Similarly to the hydronium ion,[37] the hydrogen atoms of the sulfonium ion also exchange with deuterium in superacids. The H^+/D^+ exchange of H_3S^+ and its isotopomers has been followed by ^1H NMR spectroscopy.[64] Compared to the FSO_3H/SO_2 system, the H^+/D^+ exchange rate is considerably enhanced in the more acidic 4:1 mixtures of FSO_3H and SbF_5/SO_2 and further enhanced in the even more acidic 1:1 mixtures of FSO_3H and SbF_5/SO_2.

Again, two mechanisms are possible for this hydrogen–deuterium exchange in superacids (Scheme 29): a deprotonation/deuteration equilibrium in which hydrogen sulfide is reprotonated/redeuterated by the acid system and a protonation/deuteration of the isotopomeric sulfonium ions to their dications (for example, **4**) and subsequent dedeuteration/deprotonation.



Scheme 29. Possible mechanisms for H/D exchange of H_2S in superacids.

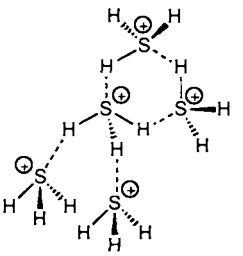
The observed isotopic exchange does not per se permit unequivocal differentiation between the two mechanisms. However, the increased exchange rate observed with increase in the acid strength of the Magic Acid system (from 4:1 to 1:1) supports the mechanism involving H_4S^{2+}. The H_0 value of the 1:1 system is -21.5, that of the 4:1 system about -18. The alternative mechanism would be expected to show the opposite influence because dissociation of H_3S^+ would be facilitated by decreasing acidity. Furthermore, H_3S^+ shows no indication of any deprotonation equilibrium in superacid solution (according to NMR studies).

To probe the structure and stability of H_4S^{2+}, ab *initio* theoretical calculations were carried out with Pople's GAUSSIAN programs. The isoelectronic first-row species, BH_4^-, CH_4, NH_4^+,[65] the discussed H_4O^{2+} cation, along with the second-row species AlH_4^-, SiH_4, and PH_4^+,[66] and the isoelectronic H_4S^{2+} cation[67] are all expected to be tetrahedral. Indeed, at the HF/6-31G* level of theory the structure of diprotonated hydrogen sulfide having T_d symmetry corresponds to a minimum on the potential energy surface.

Although H_4S^{2+} is thermodynamically unstable toward deprotonation by 59.2 kcal mol^{-1}, it has significant kinetic stability because the activation energy is calculated to be 25.2 kcal mol^{-1}. The heat of formation is estimated to be 584 kcal mol^{-1}. The S–H bond distance in the tetrahedral structure is 1.396 Å. H_4S^{2+} should be obtained more readily by protonation of H_3S^+ than H_4O^{2+} by protonation of H_3O^+ [Eq. (22)]. The larger size of the sulfur atom may help

(22)

to accommodate the additional charge better. Again it must be pointed out that these calculational data refer to isolated gas-phase conditions under which protonation of H_3S^+ is not thermodynamically favored. Association (clustering) may also play an important role in the condensed phase and could give a very structured dication-like species with C_{3v} symmetry in superacidic solution (Scheme 30).



Scheme 30. Possible stabilization of H_4S^{2+} ions by H_3S^+ ions in superacids.

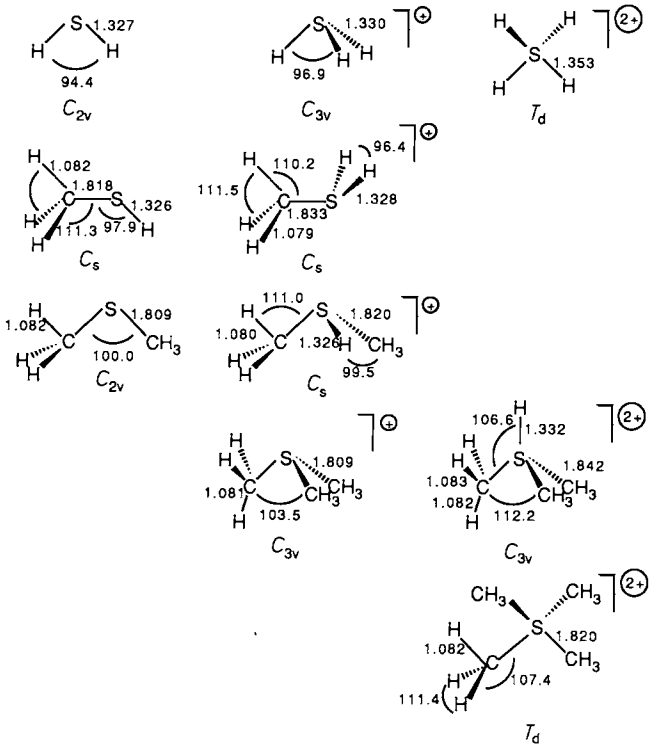
Calculations have also been carried out on the planar SH_4^{2+} dication. This D_{4h} structure is less stable than its T_d isomer by 245 kcal mol^{-1}. This energy difference is surprisingly larger than its counterpart for H_4O^{2+} (94.6 kcal mol^{-1}). Despite its high thermodynamic instability, planar H_4S^{2+} represents a local minimum on the potential energy surface.[68] Surprisingly, the S–H bond distances in planar H_4S^{2+} (1.379 Å) are 0.017 Å shorter than in the tetrahedral isomer.

Whereas tetrahedral H_4S^{2+} may be viewed as diprotonated H_2S, planar H_4S^{2+} represents dioxidized sulfurane (H_4S).

Trialkylsulfonium ions are, at best, weak alkylating agents. They do not alkylate aromatic hydrocarbons. Laali et al., however, found[69] that similar to their oxonium analogues in the presence of superacids trialkylsulfonium ions are greatly activated and alkylate arenes with ease [Eq. (23)]. Protic activation of the sulfonium ions via their dications is indicated.

(23)

Theoretical calculations on the series of methylsulfonium ions and dications were carried out[20a] to determine their energies and their related proton affinities (Table 1). Diprotonated sulfanes are shown to be considerably more stable than their oxo analogues. The optimized structures for all species located at minima are depicted in Scheme 31.



Scheme 31. HF/6-31g* optimized structures of the most stable isomers of neutral sulfur-containing bases and their mono- and diprotonated and mono- and dialkylated ions.

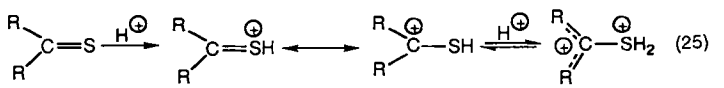
Radom[68] reported a theoretical study of the tetrahydridoselenonium dication, SeH_4^{2+}. No experimental studies are, however, thus far available.

Laali et al. have studied[69] the superacid-catalyzed alkylation of arenes with trialkylselenonium and telluronium ions. In analogy to previously discussed alkylations with trialkyloxonium and sulfonium ions (see Section 3 and above), they concluded that further protonation to the related onium dications activates them, allowing alkylation of arenes to occur [Eq. (24), X = Se, Te].

(24)

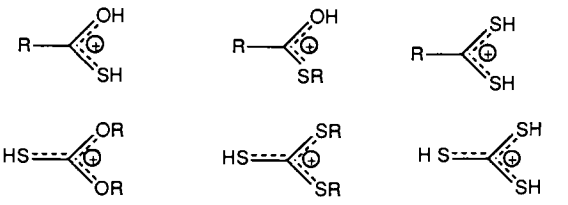
10. Diprotonated/Dialkylated Thiocarbonyl Compounds, Thiocarboxylic Acids, Thiocarbonic Acid, and Carbonyl Sulfide

Thioketones are protonated in superacids and were studied by ^{13}C NMR spectroscopy.[70] Further protonation by excess superacid as formulated in Equation (25) is indicated by their enhanced activity in electrophilic reactions.



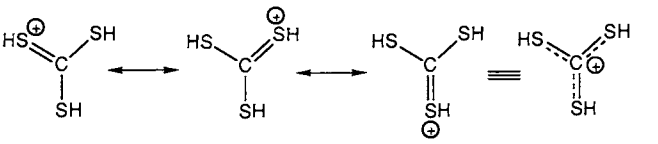
(25)

Thiocarboxylic acids like their oxygen analogues form stable protonated ions in superacidic media[71] (Scheme 32).



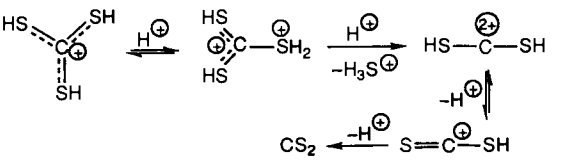
Scheme 32. Resonance-stabilized monoprotonated thiocarboxylic and thiocarbonic acids and their esters.

Thiocarbonates are also readily protonated in superacid to protonated thiocarbonic acid (**5**),[72] which is also formed through the cleavage of dialkylthiocarbonates. There is an



5

indication that diprotonated thiocarbonic acid present in a preequilibrium with its monocation is eventually cleaved at somewhat elevated temperatures to give carbon disulfide [Eq. (26)]. The protolytic cleavage proceeds consecutively through di- and monoprotonated carbon disulfide.



(26)

Protonation of carbon disulfide and carbonyl sulfide in superacids is accompanied by ready oxidation. However, COS was methylated by the CH_3F–SbF_5 complex and found to be a very reactive electrophilic thiocarboxylating agent for arenes[73] [Eq. (27)].

(27)

11. Protonated/Alkylated Dialkylhalonium Dications

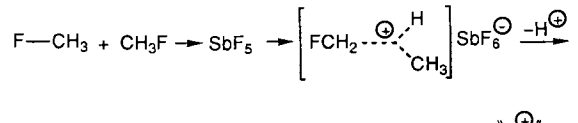
In the presence of acid catalysts haloalkanes become alkylating agents. In 1877 Friedel and Crafts discovered the catalytic effect of anhydrous aluminium trichloride in alkylation reactions (Friedel–Crafts reaction).[74] The mechanism of the reaction is today understood to involve coordination of a nonbonded electron pair in the halogen atom of R–X:, giving either a polarized donor–acceptor complex or an alkylcarbenium ion pair (depending on the nature of the alkyl halide, the Lewis acid, and the reaction medium) [Eq. (28)].

(28)

Use of an excess of a powerful Lewis acid halide such as SbF_5 in low nuleophilicity solvent systems (SO_2, SO_2ClF, etc.) provides stable alkyl cations as persistent, long-lived species.[75, 76] In contrast, when an excess of the haloalkane is used, self-alkylation leads to the formation of dialkylhalonium ions, which have even been isolated as stable salts [Eq. (29), X = Cl, Br, I].

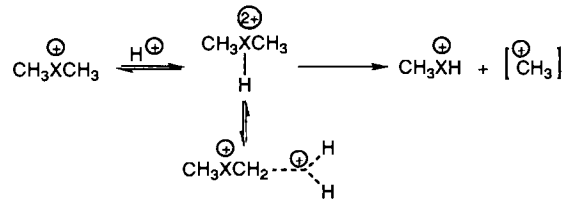
(29)

Fluoroalkanes do not give dialkylfluoronium ions, because of the high electronegativity of fluorine. Instead a C–H (or C–C) bond is alkylated. Fluoromethane, for example, undergoes alkylative self-condensation according to Equation (30).[77]



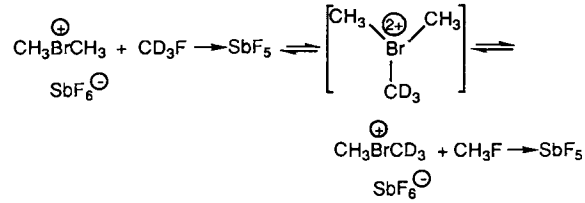
(30)

Halomethanes represent a rather special case. As the "bare" methyl cation is energetically extremely unfavorable, no persistent methyl cation has been observed in superacidic media. Instead polarized donor–acceptor complexes or dimethylhalonium ions are formed. Dimethylhalonium ions in superacidic media show extremely enhanced reactivity. This behavior is apparently caused by protolytic (electrophilic) activation involving the nonbonded electron pair of the halogen atom (Scheme 33).



Scheme 33. Possible explanation for the strong enhancement of the reactivity of methylations with halomethanes in superacids.

When the dimethylbromonium ion reacts with the isotopomeric CD_3F–SbF_5 complex, methyl interchange is observed, which indicates that an intermediate superelectrophile $(CH_3)_3Br^{2+}$ is formed by further methylation on the bromine atom [Eq. (31)].[59]



(31)

12. Protonated or Lewis Acid Complexed Halocarbenium Dications and Their Analogues

Not only onium and carboxonium ions, but also certain heteroatom-substituted carbocations are protolytically activated in superacids.

Trivalent alkyl cations (trialkylcarbenium ions) R_3C^+ with a sextet of electrons at the carbocationic carbon are strong Lewis acids and powerful electrophiles. The formal electron deficiency at the carbocationic centers is, however, decreased by interaction with attached electron donor ligands. These can be not only π-donors (such as arenes, vinyl groups, etc. acting through conjugative interactions) or n-donors (such as halogen, oxygen, nitrogen, or sulfur atoms acting through n–p back donation), but also σ-donors (such as alkyl or cycloalkyl groups acting through hyperconjugative C–H or C–C bond delocalization). Only in the case of the methyl cation CH_3^+ are such stabilizing interactions absent. CH_3^+ is thus the ultimate electrophilic alkyl cation, which explains why in the condensed state it is not observed in its "free" form (at least with such spectroscopic methods as NMR or IR). Most other alkyl cations can be observed as stable, long-lived species in superacidic media, although primary or secondary alkyl cations readily rearrange to their more stable tertiary (or secondary) isomeric ions. The reader is referred to reviews about stable carbocations for further information.[3, 6, 78]

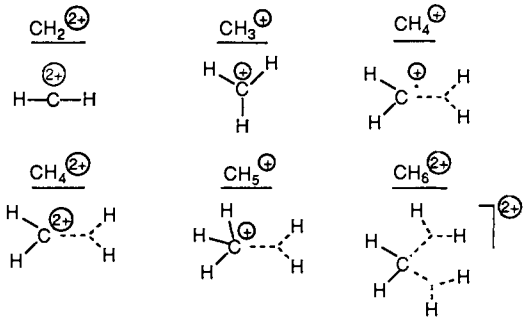
In 1972 I suggested[79] that carbocations can be divided into two limiting categories: trivalent carbocations, of which CH_3^+ is the parent ion, and five (or higher) coordinate ions, of which the methonium ion CH_5^+ may be considered the parent. The former are frequently called classical ions and the latter nonclassical.

The protonation of methane to form CH_5^+ was studied theoretically and experimentally, including by ESCA spectroscopy.[80] The diprotonation of methane to form CH_6^{2+} has also been studied.[81] Schmidbaur et al. were able to isolate a pentakis(triphenylphosphanaurio)methonium salt analogous to CH_5^+ [Eq. (32), HMPA = hexamethylphosphoric triamide] and determined its crystal structure.[82a] A salt related to CH_6^{2+} (**1**) has also been obtained.[82b]

(32)

The CH_4^+ radical cation is the parent molecular ion in mass spectrometry studies of methane. Our theoretical calculations first revealed its planar structure.[83a] Stahl, Schwarz, Vogel et al.[83b] studied the gas-phase CH_4^+, CH_4^{2+}, and CH_5^{2+} ions by experimental and ab initio molecular orbital investigations. The planar CH_4^{2+} dication was also investigated theoretically by Radom.[83c]

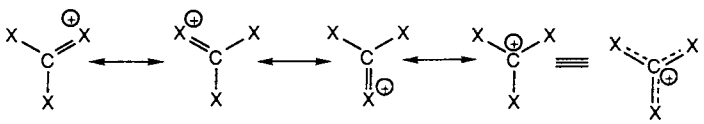
It is informative to recall the parent C_1 carbocations CH_2^{2+}, CH_3^+, CH_4^+, CH_4^{2+}, CH_5^+, CH_6^{2+} and their preferred structures (Scheme 34). CH_5^+ and CH_6^{2+} are accessible by protonating and diprotonating methane. Loss of H_2 from CH_6^{2+} gives CH_4^{2+}, and the radical ion CH_4^+ is generated by electron loss from methane. The CH_2^{2+} dication was investigated in the gas phase and theoretically.[84] Formation of its substituted analogues is indicated in superacid systems.



Scheme 34. The most stable structures of C_1 carbocations.

Whereas, as mentioned before, the free methyl cation CH_3^+ is not observable in solution chemistry, its alkyl- or halogen-substituted analogues, such as $(CH_3)_2CH^+$, $(CH_3)_3C^+$, $(CH_3)_2CX^+$, $CH_3CX_2^+$, and CX_3^+ (X = Cl, Br, I), have been prepared and studied as stable ions in superacidic media. If the neighboring groups can be affected by further protolytic (or electrophilic) interaction, the electron deficiency of the carbocationic center becomes more pronounced, which results in enhanced superelectrophilic reactivity.

Trihalomethyl cations CX_3^+ (X = Cl, Br, I), characterized by NMR spectroscopy in superacidic media,[85,86] are substantially resonance-stabilized by back-donation from the nonbonded electron pairs of the halogen atoms (Scheme 35).



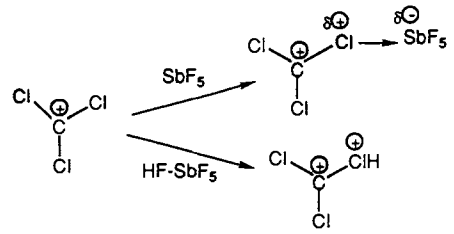
Scheme 35. Resonance structures of the trihalomethyl cation.

The significant delocalization deduced from their ^{13}C NMR spectra results in their being only moderately active electrophiles. The chemical shift for CCl_3^+ is $\delta = 236$, deshielded by 159 ppm from $HCCl_3$, whereas $C^+(CH_3)_3$ is deshielded by some 320 ppm from $HC(CH_3)_3$.

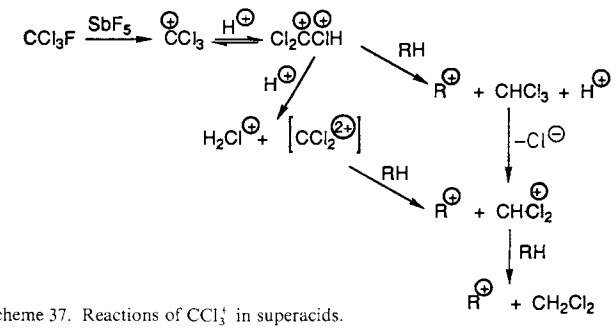
Bach et al. found that $CCl_4/AlCl_3$ is an extremely reactive hydride abstracting and ionic chlorinating system for adamantane.[87a] Use of the CCl_4/HF–SbF_5 system (and in related superacids) greatly enhances the reactivity of hydride abstraction from hydrocarbons to form carbocations as shown by Sunko et al.[87b] Sommer et al. reported similar activation in the carbonylation of propane.[87c] A similar reactivity was also observed for dichloromethane (or dibromomethane) and chloroform.[87e]

As CCl_3^+ is only a weak electrophile according to ^{13}C NMR results for the stable ion, these results are difficult to interpret on the basis of initial formation of CCl_3^+ alone. In order to explain the unexpected reactivity it is suggested that the CCl_3^+ ion formed by ionization of CCl_4 with $AlCl_3$ or SbF_5 can further coordinate with excess Lewis acids (or the related conjugate protic acids), forming a superelectrophile (Scheme 36).

Cleavage of the Cl_2CClH^{2+} dication can even give the incipient CCl_2^{2+} dication, an even more reactive superelectrophile. This dication would promote extremely facile intermolecular hydride transfer giving the $HCCl_2^+$ ion, which itself could then react further (Scheme 37).



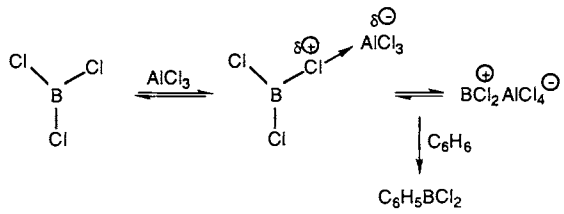
Scheme 36. Proposed activation of CCl_3^+ by Lewis acids or superacids.



Scheme 37. Reactions of CCl_3^+ in superacids.

Chloroform and dichloromethane (or its fluorine exchange product, CH_2F_2) were observed as by-products of the reactions. It is possible, however, that protolytic ionization of chloroform, formed in the first hydride transfer reaction can account for CH_2Cl_2 formation.

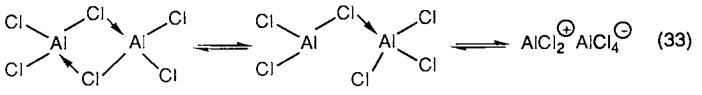
The boron analogue for CCl_2^{2+} is BCl_2^+. Ionization (or donor–acceptor complexation) of BCl_3 with strong Lewis acids produces a superelectrophilic analogue. This is involved in the Friedel–Crafts reaction of BCl_3 with arenes (Scheme 38).[88]



Scheme 38. Friedel-Crafts borylation of arenes.

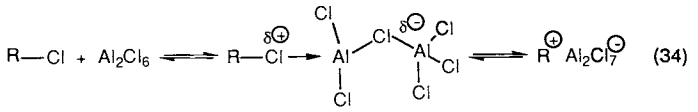
The aluminum analogue, anhydrous aluminum trichloride, is the most widely used Friedel–Crafts catalyst.[89a] Its activity is generally assigned to the Lewis acidity of its monomeric form, although it has long been recognized that it is dimeric up to 440 °C except in strongly coordinating solvents.[89a] This doubly halogen-bridged dimer is, however, catalytically inactive, because both aluminum atoms are four coordinate. As the dissociation energy for the reaction $Al_2Cl_6 \rightleftharpoons 2\,AlCl_3$ is 29 ± 1 kcal mol^{-1}, it is more reasonable to postulate that dimeric Al_2Cl_6 undergoes less energetic opening of only one of the chlorine bridges at a time [Eq. (33)].

The resulting monobridged Al_2Cl_6 contains a tricoordinate electron-deficient aluminum atom. In the limiting case it ionizes to $AlCl_2^+AlCl_4^-$. Al_2Cl_6 may consequently act as a



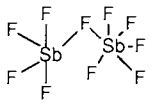
(33)

strong Lewis acid and readily coordinates with haloalkanes or other suitable electron donor reagents [Eq. (34)].



(34)

Superacidic antimony pentafluoride (and related Lewis acid fluorides) are known to be associated, but as in **6**, only through monofluorine bridges.[89a]



6

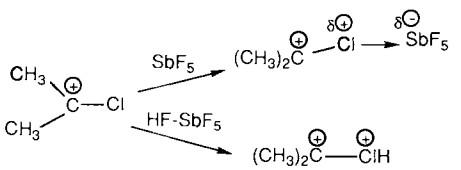
Mukaiyama found[89b] that highly efficient catalytic Friedel-Crafts acylation reactions and Beckmann rearrangements can be carried out with $GaCl_3$–$AgClO_4$ and $SbCl_5$–$AgClO_4$, which are assumed to give ionic $GaCl_2^+ClO_4^-$ and $SbCl_4^+ClO_4^-$. Highly polarized donor–acceptor complexes would, however, be similarly active.

In the hydroboration reaction of olefins with diborane, the $B_2H_6 \rightleftharpoons 2BH_3$ equilibrium is assumed. It is again possible that opening of just one of the hydrogen bridges, according to Equation (35) can account for the electrophilic reactivity of diborane in some cases. This is particularly valid

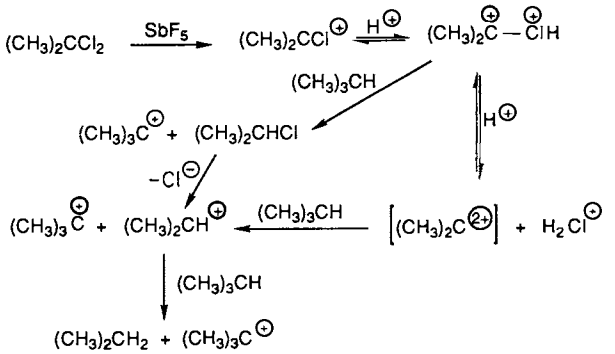
(35)

in the absence of ether (or other complexing agents). Hurd's early work showed that not only ethylene, but benzene and even methane react with diborane at elevated temperatures and without side reactions with solvents to give boronated by-products.[90a] Silanes were later also shown to react with diborane.[90b]

When $(CH_3)_2CCl_2$ is ionized in SbF_5-containing superacids[86] $(CH_3)_2CCl^+$ is formed. This system converts alkanes extremely efficiently. The ion is thus probably activated by superelectrophilic solvation or even by incipient superelectrophilic $(CH_3)_2C^{2+}$ dication formation (Scheme 39). The reaction sequence of Scheme 40 is accordingly proposed for the reaction with isobutane.

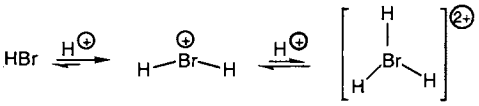


Scheme 39. Activation of $(CH_3)_2CCl^+$ by Lewis acids or superacids.



Scheme 40. Proposed reaction sequence for the superacid-catalyzed reaction of $(CH_3)_2CCl_2$ with isobutane.

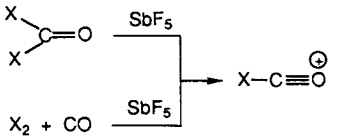
Sommer et al. observed that Br^- or Br_2 added to superacid HF–SbF_5 solutions greatly accelerated the carbonylation of alkanes such as propane.[87d] They proposed the formation of a "Br^+" ion (called a "superelectrophile"), which abstracted a hydride ion from propane prior to carbonylation. However, there is no evidence for monoatomic Br^+ in solution. As we and Houk showed,[91] even if it existed, its triplet form would be preferred over the singlet, and it would give unselective carbonylation of propane, in contradiction of the experimental findings. It is more probable that further protolytic activation of H_2Br^+ or Br_2^+H (as well as Br_3^+) explains the increased reactivity towards hydrocarbons. Reports, notably by Gold et al.[92a] and Kramer,[92b] called attention to the high acidity of liquid HBr in solvents such as SO_2ClF.[92c] Further protolytic equilibrium [Eq. (36)] is possible in excess superacid and would explain some of the unexpected results.



(36)

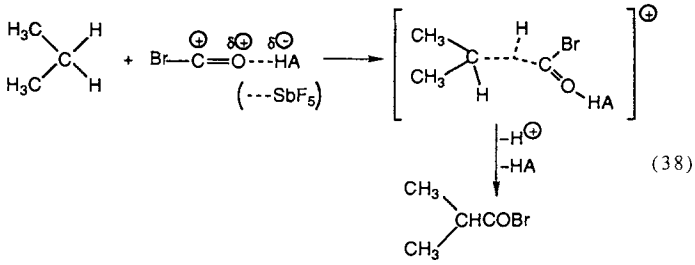
As discussed by Lowry and Richardson,[93] the *leveling effect* means that "no acid stronger than the conjugate acid of the solvent can exist in appreciable concentration in that solvent". Thus in aqueous solution no acid stronger than H_3O^+ can exist, in HSO_3F none stronger than $H_2SO_3F^+$, in HBr none stronger than H_2Br^+, etc. However, in excess superacids in which "bases" are completely monoprotonated, equilibria with their diprotonated "bases", i.e. H_4O^{2+}, $H_3SO_3F^{2+}$, H_3Br^{2+}, are possible.

In an alternative pathway for Sommer's bromine-assisted carbonylation of propane in superacids[87c,d] the bromocarbonyl cation forms as intermediate. Halocarbonyl cations (XCO^+, X = Cl, Br, I) have recently been prepared under stable-ion conditions as long-lived species at low temperatures [Eq. (37)] and were characterized by ^{13}C NMR spectroscopy.[87e] The bromocarbonyl cation itself, however,



(37)

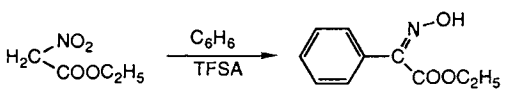
may not be reactive enough to influence the reaction. Further activation by coordination with protic or Lewis superacids can convert it into a superelectrophile that is highly reactive and that reacts selectively with the C–H bond of propane to yield the 2-carbonylated product [Eq. (38)].



(38)

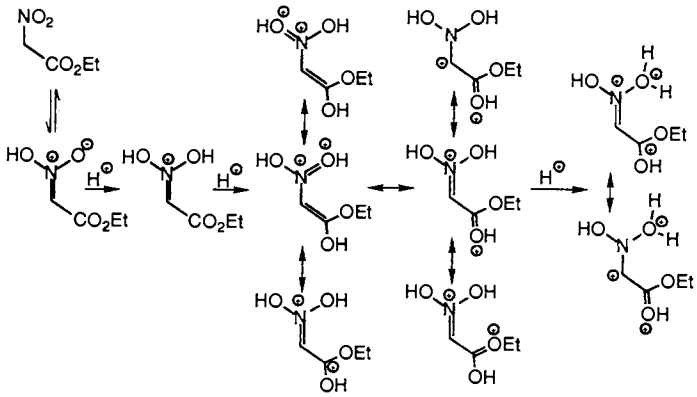
13. Dicationic Nitrogen-Containing Systems

Substituted nitromethanes react with benzene in superacidic trifluoromethanesulfonic acid (TFSA) to give the corresponding oximes in high yields [Eq. (39)].[94a] In this



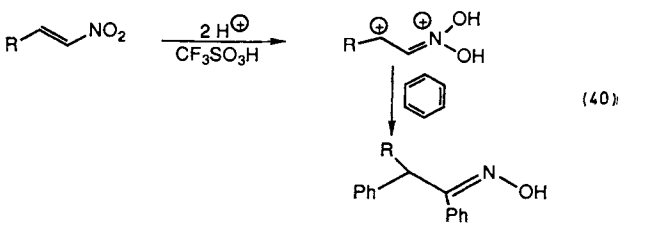
(39)

reaction, O,O-diprotonation of the nitro group was invoked by Shudo to explain the remarkable reactivity (Scheme 41).



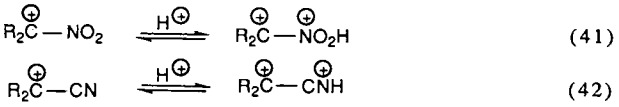
Scheme 41. Multiple protonation of ethyl nitroacetate and important resonance structures for the cations.

α,β-Unsaturated nitroolefins also react with benzene in TFSA. Dicationic O,O-diprotonated nitroolefins were suggested as reaction intermediates [Eq. (40)].[94b] Shudo et al. have exploited these reactions to carry out highly interesting organic transformations.[95, 96]



(40)

Other heteroatom-substituted carbocations[97] are also activated by superacids. α-Nitro and α-cyanocarbenium ions, $R_2C^+NO_2$ or R_2C^+CN, are thought to undergo O- or N-protonation, respectively, which greatly enhances the electrophilicity of the carbocationic centers [Eq. (41) and (42)].



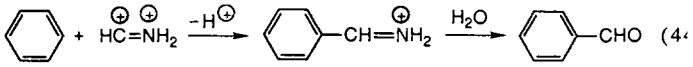
(41)

(42)

The acid-catalyzed reaction of hydrogen cyanide and nitriles with aromatic hydrocarbons (Gattermann and Houben-Hoesch reactions, respectively) are well known. The generally accepted mechanism includes N-protonation of HCN or the nitriles to form the corresponding nitrilium ions. Meerwein first studied protonated nitriles as BF_4^- salts,[14b] and we were able to protonate HCN in superacids [Eq. (43), R = H, alkyl].[6, 14b] The resonance-stabilized nitrilium ions show only limited iminocarbenium ion nature and accordingly are only mildly electrophilic agents.

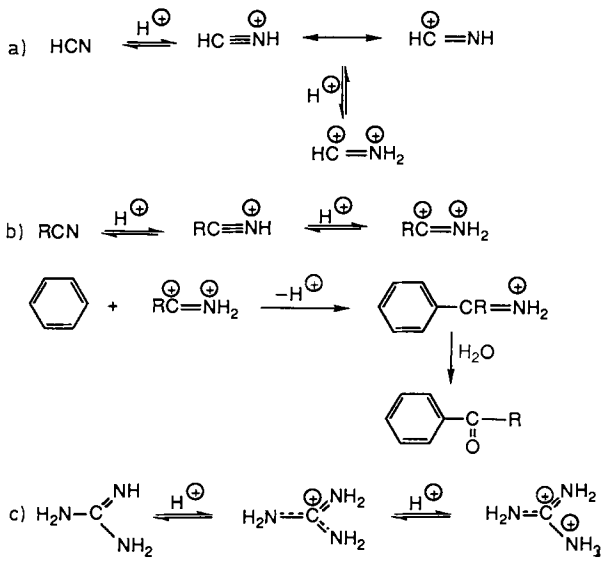
(43)

In order to explain the experimentally observed high reactivity of HCN and alkyl nitriles under superacidic conditions, Shudo reported[98] results of studies that indicate that in the Gattermann reactions, diprotonated HCN is involved as the de facto reagent. Accordingly, the mechanism of the Gattermann reaction in superacids can be depicted as in Equation (44).



(44)

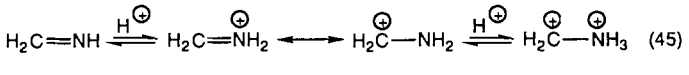
N,N-diprotonated HCN was first suggested by Schwarz's studies (Scheme 42a).[99] For the Houben–Hoesch reaction



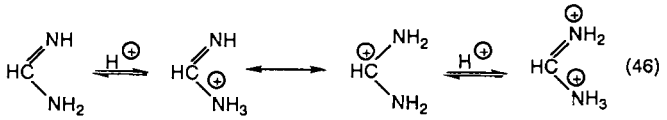
Scheme 42. Protonation/deprotonation equilibria for a) HCN, b) RCN, and c) guanidine. Under b) a mechanism for the Houben-Hoesch reaction is also proposed.

in superacids Shudo similarly suggested that N,N-diprotonated nitriles are the de facto reagents (Scheme 42b).

Guanidine was also found to undergo diprotonation in superacids (Scheme 42c); the dication was observed (by NMR spectroscopy) as a stable species.[100] Diprotonated guanidine and its derivatives are similar to the diprotonated carbonic acids discussed in Section 8. Theoretical calculations indicate that methanimine, too, can give a stable diprotonated intermediate [Eq. (45)].[59] Formamidine can similarly undergo diprotonation [Eq. (46)].

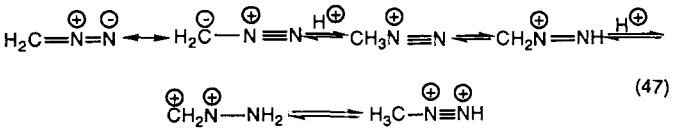


(45)



(46)

The protonation of diazomethane was shown experimentally to take place either on nitrogen or carbon.[101] Presumably in superacids interconversion goes through a diprotonated form [Eq. (47)] and not through a deprotonation–reprotonation reaction (for which there is no evidence).



(47)

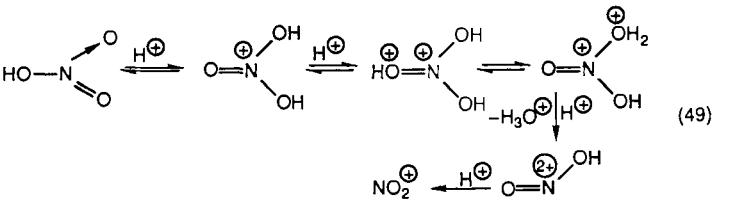
The protonation of hydrazoic acid was shown in our investigations to give the aminodiazonium ion, $H_2NN_2^+$.[102] Subsequent cleavage liberates N_2 probably assisted by protosolvation.

14. Diprotonated Nitric Acid and the Protonitronium Dication

Protonation of nitric and nitrous acid is of substantial interest because of subsequent cleavage to the nitronium and nitrosonium ion.[103] The pioneering studies go back to Hantzsch and Ingold, who made the now generally accepted proposal that the initial protonation of nitric acid yields the nitracidium ion,[103] that is, nitric acid protonated at the hydroxy group [Eq. (48)].

(48)

The ready cleavage of the nitracidium ion to the nitronium ion involves practically no barrier. This is considered to be a consequence of its structure, which can be described as a nitronium ion solvated by water. More recent theoretical calculations, however, indicate that the stable form of protonated nitric acid is that of the dihydroxynitrosonium ion. Its cleavage to the nitronium ion in excess of superacid could thus proceed by diprotonation [Eq. (49)].[104]



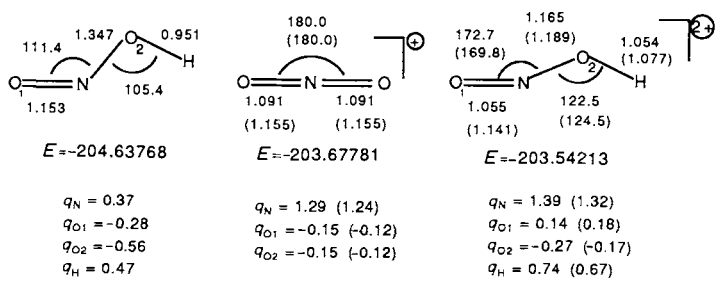
(49)

Nitronium salts such as $NO_2^+BF_4^-$ were introduced by us as highly reactive nitrating agents. They are generally used in aprotic solvents, for instance nitromethane, sulfolane (= *S,S*-dioxotetrahydrothiophene), or dichloromethane.[103] A large variety of arenes can be nitrated with excellent yields.

Highly deactivated arenes such as *meta*-dinitrobenzene are, however, not nitrated under these conditions. In contrast in superacidic FSO_3H solution, nitronium salts nitrate *meta*-dinitrobenzene to form 1,3,5-trinitrobenzene in 70% yield.[105] Similarly, $NO_2^+BF_4^-$ does not nitrate deactivated nitrofluorobenzenes in sulfolane solution, but in superacidic TFSA efficient nitration takes place.[106] Whereas nitronium salts show no reactivity towards methane in aprotic media, the reaction takes place, albeit in low yield, in FSO_3H to give nitromethane.[107] These data indicate that the nitronium ion is activated by the superacidic media. To explain the highly increased reactivity of the nitronium ion, it has been proposed[107, 110] that the linear nitronium ion, despite being a positively charged species, can undergo protonation (protosolvation) to the protonitronium dication (NO_2H^{2+}), an extremely reactive superelectrophile. The linear nitronium ion $O{=}N^+{=}O$ has neither a vacant atomic orbital on nitrogen nor a low-lying molecular orbital. Its electrophilic potential is mainly due to its polarizability when interacting with π-donor aromatic nucleophiles. In contrast to a reactive arene, a strongly deactivated arene is too weak an electron donor to bring about such polarization. A "reactive" nitronium ion should be bent and have a developing p orbital on nitrogen. The driving force for the formation of such a reactive nitronium ion is the ability of the nonbonded electron pairs on the oxygen atoms to coordinate with the strong protic acid in the nitrating system.

Simonetta's lower level calculation[108] on the assumed protonitronium dication did not locate a minimum. Recent high-level ab initio calculations, however, show that NO_2H^{2+} is an energy minimum (Scheme 43).[104]

The protonitronium dication, an analogue of nitrous acid, is characterized by quite short N–O1 (1.055 Å) and N–O2



Scheme 43. Geometries (bond lengths in Å, bond angles in degrees), energies (in Hartrees), and partial charges q calculated by ab initio methods for nitrous acid, the nitronium ion, and the protonitronium dication (at the 6-31G*//6-31G* level and in parentheses at the MP2/6-31G**//MP2/6-31G** level).

(1.165 Å) bonds. The shorter N–O1 bond distance is caused by the strong interaction of (formally) doubly occupied p_y and p_z orbitals of the oxygen atom with the empty orbitals of the nitrogen atom, thereby generating incipient triple-bond character in the N–O1 bond, whereas the shorter N–O2 bond is due to the interaction of an empty p_y orbital of nitrogen with an occupied p_y orbital of the hydroxyl oxygen, causing the double-bond character of N–O2 bond. This interaction is also reflected in the O-N-O bond angle (170°) of NO_2H^{2+} which is much larger than that in HNO_2 (111°). In other words lone-pair–bond-pair repulsion in HNO_2 makes the O-N-O angle closer to the tetrahedral angle.

Although the protonitronium dication is substantially more energetic than the nitronium ion, the deprotonation barrier was calculated to be 17 kcal mol^{-1}. It should be mentioned again that calculated results refer to the gas phase, while in superacidic solvents dications can be stabilized through delocalization of excess charge by solvation or clustering. Instead of complete dication formation, however, protosolvation can also account for activation.[109]

15. Bidentate and Multidentate Activation of Electrophiles over Solid Superacids and Relevance to Catalytic and Enzymatic Systems

The discussion of superelectrophiles has centered on the activation of electrophiles in superacidic solution. However, superacidic systems are not limited to solution chemistry. Solid superacids, possessing both Brønsted and Lewis acid sites, are increasing in significance. They range from supported or intercalated systems, to highly acidic perfluorinated resinsulfonic acids (such as Nafion-H and its analogues), to certain zeolites (such as H-ZSM-5). A more detailed discussion of these systems is beyond the scope of this paper, and reviews are available.[6] One of the major difficulties in characterizing solid acids is the accurate determination of their acidity. The most frequently used methods are based on kinetic rather than thermodynamic measurements. These can give data on catalytic activity of the solid acids, but not necessarily on their thermodynamic acidities. Also the extrapolation of results of measurements based on assumed analogies with solution equilibria studies is questionable, for instance in the determination of H_0 and related acidity functions.[110] Spectroscopic studies, frequently based on surface acid–base interactions, calorimetric measurements, and recently solid-state NMR methods including ^{1}H MAS NMR studies of zeolites have started to change the picture.[111]

Solid acids such as Nafion-H or HZSM-5 possess superacidic properties. In order to explain how these acidic solids can sometimes display remarkable activity, for example in allowing the catalytic transformations of extremely low nucleophilicity alkanes (even methane), a reappraisal of the activity at the acid sites of such solid acids is expedient.

Nafion-H is known to contain acidic SO_3H groups clustered together (Fig. 1). H-ZSM-5, which also displays superacidic activity, was found by Haag et al.[112] to isomerize and alkylate alkanes readily (H_2 was formed as the protolytic by-product in stoichiometric amounts). In the zeolite, active Brønsted and Lewis acid sites are again in close proximity (approximately 2.5 Å) (Scheme 44).

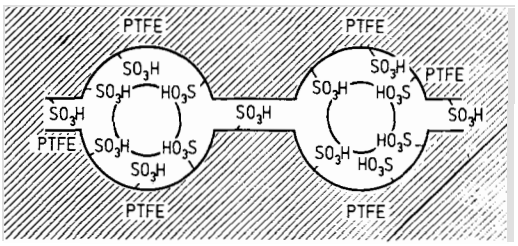


Fig. 1. Sketch of a perfluorinated resinsulfonic acid similar to Nafion-H, showing clustering of SO_3H groups; PTFE = poly(tetrafluoroethylene).

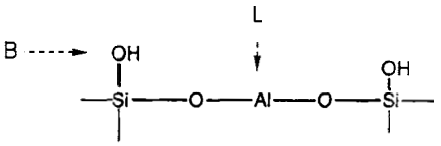


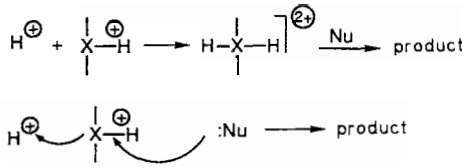
Scheme 44. Brønsted (B) and Lewis acid sites (L) in zeolites

It is not unreasonable to suggest that in these (and other) solid superacid catalyst systems, bi- or multidentate interaction forming highly reactive intermediates is possible. This amounts to the solid-state equivalent of protosolvation (protonation) discussed previously for solution systems.

Nature is able to perform its own transformations in ways which chemists have only started to understand. At enzymatic sites many significant transformations take place which are acid catalyzed (in a generalized sense electron-deficient metal-ion-catalyzed processes can also be included). Because the unique geometry at enzymatic sites frequently makes bi- and multidentate interactions possible, the principles discussed throughout this paper may also help improve our understanding of some enzymatic processes.

16. Conclusions and Significance

The discussion throughout this article has emphasized the increasing body of experimental observations and related theoretical calculations which show that a variety of electrophiles capable of further interaction (coordination) with Brønsted or Lewis superacids can be greatly activated by them. Examples are onium and carboxonium ions, acyl cations, halonium, azonium, carbazonium ions, and even certain substituted carbocations and the like. This activation produces *superelectrophiles*, that is, electrophiles of doubly electron-deficient (dipositive) nature whose reactivity (Scheme 45, top) significantly exceeds that of their parent monocations under conventional reaction conditions. Superelectrophiles are highly reactive intermediates. They are the de facto *reactive intermediates* of many electrophilic reactions in superacidic systems (including those involving solid

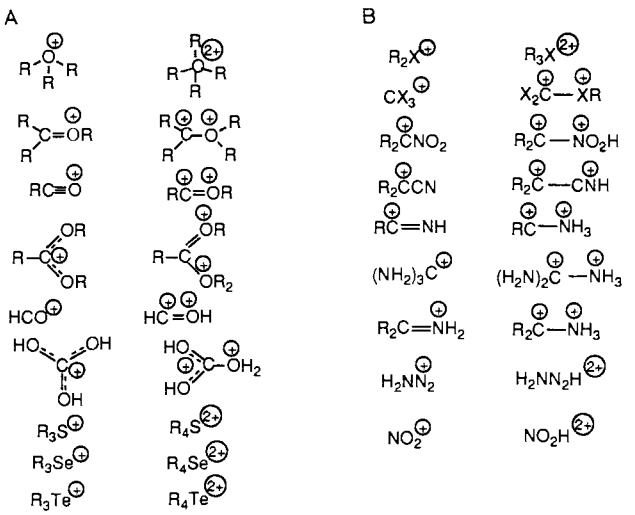


Scheme 45. Activation by superacids. Top: formation of a dication; bottom: electrophilic assistance.

superacids) and should be differentiated from energetically low-lying, much *more stable intermediates*, which frequently are observable and even isolable but not necessarily reactive without further activation.

It should be recognized, however, that some of the observed superelectrophilic reactions may also proceed with only "electrophilic assistance" by the superacids without forming distinct dipositive intermediates (Scheme 45, bottom). This may be the case in reactions with suitable nucleophiles, such as π-donor arenes and olefines or substrates containing n-donor heteroatoms, but not necessarily with weak σ-donor alkanes or highly deactivated π systems. Protosolvolytic (electrophilic) activation of electrophiles referred to throughout this article should be considered in this context.

Examples of superelectrophiles studied so far and their parent monocations are listed in Scheme 46.



Scheme 46. Examples of superelectrophiles and the electrophiles from which they are derived. A: R = H, alkyl, Lewis acid. B: X = Cl, Br, I; R = H, alkyl. In each group the parent electrophiles are in the left column.

I am grateful to all my collaborators listed in the references who contributed so much to the development of the chemistry discussed in this review. Particularly, I would like to acknowledge the contribution of Professor G. K. S. Prakash to our joint efforts over the years in the chemistry of superacidic and stable-ion systems. Financial support of our work was provided by the National Science Foundation, the National Institutes of Health, the Office of Naval Research, and the Loker Hydrocarbon Research Institute.

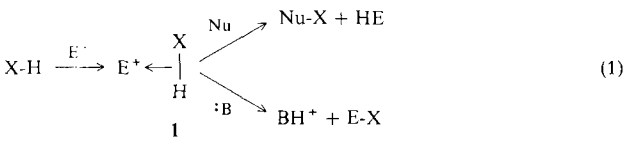
Transition Metal Complexation of σ Bonds

By Robert H. Crabtree*

The first σ complexes were found in the 1960s and 1970s, but they did not attract more than passing attention. Only now are we beginning to recognize their key role in the chemical reactions of σ bonds, and this has encouraged more detailed study. In contrast with the more familiar π-donor complexes such as M–(CH_2=CH_2) and complexes like M–NH_3, in which the lone pair of electrons on the N atom is bound to the metal atom, in a σ complex an X–H group binds to the transition metal atom; the X–H σ-bonding electron pair acts as a 2e donor to give an (X-H)-M type complex. Dihydrogen complexes (X = H) are one important group of σ complexes. C-H-M complexes (X = R_3C) with an agostic C-H-M interaction have not only been found in the ground state but also implicated in the transition states of many important organometallic transformations such as Ziegler–Natta catalysis and sigma bond metathesis. The importance of X–H bond activation will encourage continued growth in this field.

1. Introduction

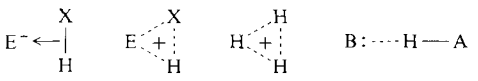
An electrophile E^+ can react with an X–H bond to give a σ complex **1**, in which the X–H bond acts as a 2e donor. **1a** and **1b** show two common ways of representing **1**. Coordination to E^+ alters the chemical properties of the X–H bond and can activate it either for nucleophilic attack at X or deprotonation [Eq. (1)]. In many cases adduct **1** is not



(1)

1

stable enough to be isolable in the condensed phase. For example, the gas-phase species H_3^+ (**2**, H–H = 0.88 Å),[1] the adduct of H_2 and a proton, is too strong an acid to exist in solution.



1a **1b** **2** **3**

The X–H bond is always coordinated side-on to E^+, as in **1**, in sharp contrast to the linear structure **3** (HA = acid, B = base).

Since **1** is a two-electron system, only the Ψ_1 molecular orbital, which bonds over all three centers, is filled (Fig. 1a). This three center, two-electron (3c-2e) bond therefore leads to a closed structure. In contrast, **3** is a four-electron system, and so Ψ_2 must be filled. As this molecular orbital has an antibonding interaction on one side of the triangle, formation of a linear structure is preferred. Sometimes steric effects or the conformation of the molecule prevent a 3c-2e bond from adopting its preferred geometry, and an "open" or canted side-on arrangement is adopted.

Main group elements often form bridged hydrides (e.g. B_2H_6) and alkyl complexes (e.g. $(LiMe)_4$), and even in carbon chemistry, several isolable cations with 3c-2e bonds are now known.[2] The prospects for isolating main group dihydrogen complexes have been examined theoretically.[3]

If the electrophile is a transition metal ion then the HX(σ) → M bond is much the same as in H_3^+ (Fig. 1b); however, the d_π electrons on the metal can now strengthen the M–(HX) interaction by backbonding into the HX σ* orbital (Fig. 1c). Modest backbonding accounts for the sta-

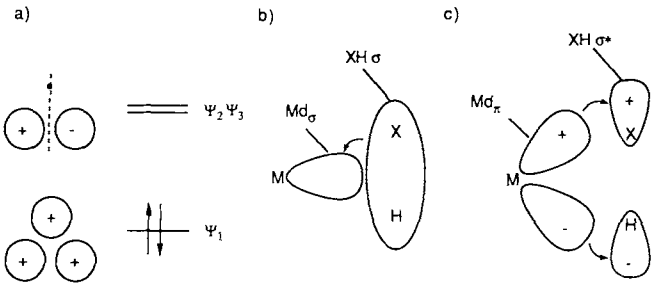


Fig. 1. The bonding picture for a σ complex. a) In H_3^+ only the totally symmetric orbital Ψ_1, which bonds over all three centers, is occupied. Occupation of Ψ_2 would lead to the opening of one edge of the triangle (nodal plane marked as a dotted line). b) In an M-(H-X) complex the electrons of the X–H σ bond are donated to an empty metal d_σ orbital. This resembles the totally symmetric Ψ_1 orbital in H_3^+ and is analogous to the binding of the lone pair on NH_3 to a metal atom. c) Electron density from the M(d_π) orbital is donated to the XH σ* orbital (back-donation). This resembles $M(d_\pi) \rightarrow CO(\pi^*)$ back-donation and is unique to a transition metal σ complexes. An isolable complex must have some backbonding, but strong back-donation leads to cleavage of the X–H bond by oxidative addition to give an X-M-H complex.

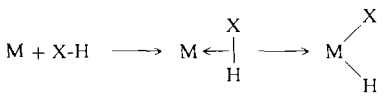
bility of many σ complexes, but strong backbonding can lead to X–H bond scission in the process known as oxidative addition to give compounds of the type X-M-H as shown in Equation (2).



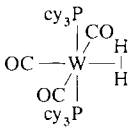
(2)

In complexes with weak backbonding, the length of X–H bond is similar to that in free X–H. The acidity and electrophilicity of XH can be strongly enhanced, however, because σ bonding reduces the electron density in the X–H unit. Stronger back-donation can lead to σ complexes with elongated X–H bonds and reduced electrophilicity of the X–H group.

[*] Prof. Dr. R. H. Crabtree
Yale Chemistry Department
New Haven, CT 06511-8118 (USA)

The strength of the M–(HX) interaction is also affected by the energy of the X–H σ and σ* orbitals. The more basic X–H systems (e.g., Si–H compounds) have higher lying σ orbitals which lead to enhanced M–(HX) σ bonding. Weaker X–H bonds such as M–H bonds will have lower energy σ* orbitals, leading to enhanced π back-donation. As expected from this analysis, M-H-M and Si-H-M complexes are almost always strongly bound, and the X–H bond is substantially stretched relative to the free state.

Perhaps one of the most striking examples of a σ complex is the dihydrogen complex **4**[4] (cy = cyclohexyl) synthesized by Kubas et al., which was one of the most significant recent



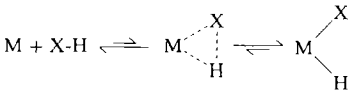
4

discoveries in inorganic chemistry. The formation of **4** was proved by NMR spectroscopy and neutron diffraction methods; its slow reversible equilibration [Eq. (3)] with complex **5**, the product of oxidative addition, was studied by NMR spectroscopy.

$$\underset{\mathbf{4}}{[W(H{-}H)(CO)_3(Pcy_3)_2]} \rightleftharpoons \underset{\mathbf{5}}{[W(H)_2(CO)_3(Pcy_3)_2]} \qquad (3)$$

If complex **4** is regarded as being derived from $(CO)_3(Pcy_3)_2W + H{-}H$, then it must be considered a σ complex. This is appropriate because the H–H distance in **4** (0.82 Å by neutron diffraction) is little changed from its value in free H_2 (0.74 Å). Since the H–H bonds in most H_2 complexes are not stretched, it is not surprising that the activation energy for loss of H_2 (more generally XH) is not usually large. Facile loss of XH can be important in applications to catalysis, for example, because the resulting coordinatively unsaturated intermediates may be very reactive.

We can also look at σ complexes as being derived from the classical adduct $[L_nM(X)(H)]$ in which an attractive interaction between X and H causes these two ligands to approach one another. This description is more appropriate for "stretched" σ complexes in which the X–H distance is substantially longer than in the free XH molecule. Such stretched complexes with H_2 ligands are known but are most common with Si–H ligands. Eisenstein et al.[5] have shown how hydrido ligands even in classical dihydrides of type $[L_nMH_2]$ have a mutually attractive interaction not present in CH_4.[5b] Attractive interactions between ligands are likely to facilitate reactions such as reductive elimination and insertion, reactions in which two ligands must approach each other to reach the transition state. Factors that stabilize a complex like **6** should also stabilize the transition state for oxidative addition and reductive elimination [Eq. (4)] and lower the activation energy. This helps explain the special facility of these reactions in transition metal complexes.



(4)

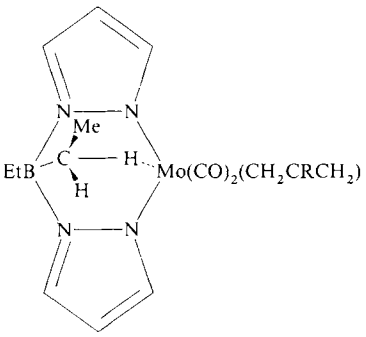
6

Some other transition metal σ complexes, for example, with B–H, Si–H, and C–H bonds, were known before 1970. As early as 1960, Nöth and Hartwimmer[6] prepared the Ti^{III} complex $[Cp_2Ti(H_2BH_2)]$ and proposed an M-H-B bridged structure based on IR data. Kaesz, Dahl, et al. were the first to prove B-H-M bridging crystallographically in $[Mn_3(CO)_{10}(H)(B_2H_6)]$, which has one Mn-H-Mn and six B-H-Mn bridges.[7]

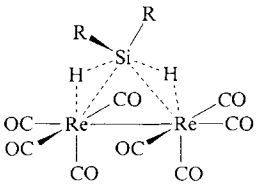
While boranes commonly have B-H-B bridges, analogous structures are not found in silanes and alkanes; the first C-H-M and Si-H-M systems thus were particularly noteworthy. Ibers et al.[8] drew attention to a close CH···M contact of 2.6 Å in $[RuCl_2(PPh_3)_3]$ but preferred not to infer any special attractive interaction; similar effects were seen in other compounds.[9] In 1968, Trofimenko[10] proposed a CH···M interaction in **7** (R = H) based on the high-field signal in the C-*H* NMR spectrum ($\delta = -2.4$) and evidence in the IR spectrum of a weak C–H bond (ν(CH) = 2664, 2704 cm^{-1}). Cotton et al.[11a] confirmed the C-H-Mo bridge in **7** (R = Ph) by X-ray crystallography and proposed the now-standard 3c–2e bonding model. The fluxionality of complex **7** was studied by NMR spectroscopy and an estimated activation energy of 17–20 kcal mol^{-1} was associated with the M–HC binding energy.[11b] A complex analogous to **7** with a B-H-M bridge was also prepared.[11c] In related work Perutz, Poliakoff, Turner, et al. presented strong evidence from IR spectroscopy for the binding of CH_4 to $M(CO)_5$ (M = Cr, Mo, W) in a methane matrix.[12]

The first silane σ complex (**8**) was formed from R_2SiH_2 and $[Re_2(CO)_{10}]$. When R is methyl, the coupling constant J(R,Si-*H*) in the ^1H NMR spectrum is reduced from 4.2 Hz in the free silane to 1.5 Hz in the complex.[13a] The first mononuclear silane σ complex was mentioned at an Ameri-

Robert H. Crabtree, born in London in 1948, was an undergraduate at Oxford with Dr. M. L. H. Green and a graduate student at Sussex University with Prof. J. Chatt. He then spent four years at the CNRS Natural Products Lab at Gif with Dr. H. Felkin. He has been at Yale since 1977 and since 1985 as Full Professor. He won the Organometallic Chemistry prizes of the Royal Society of Chemistry (1990) and the American Chemistry Society (1993) and is the author of an organometallic chemistry text.



7



8

can Chemical Society meeting and reported in 1970 only as a news item in *Chemical & Engineering News*.[13b] One reason that the field did not develop significantly at that time may have been the misconception that such relatively weak M–(XH) interactions as found in **7** would not have usefully large effects on the reactivity of the X–H bond.

Starting in the early 1980s, the activity in the area of C–H activation led to renewed interest in compounds with C-H-M bridges. In their 1983 review, Brookhart and Green[14] directed attention to C-H-M systems, which they named agostic. During the same period, Schubert et al.[15] carefully defined the chemistry and structure of a homologous series of Si-H-M systems which they also examined with neutron diffraction.

With the identification of σ complexes the three-part structure of modern coordination chemistry is complete. The field started with Werner's studies of complexes with lone pair donors such as NH_3. The recognition of π-donor complexes in the 1950s led to the development of organometallic chemistry. The recent developments in the studies of σ complexes have been encouraged by the current interest in σ-bond activation.

2. Dihydrogen Complexes

In spite of their relatively recent discovery, dihydrogen complexes are prototypes of σ complexes. Reviews by Kubas,[4b] myself,[16] and especially by Jessop and Morris[17] report work from over 300 papers. Dihydrogen or (η^2-H_2) complexes are sometimes called nonclassical as opposed to classical hydrido complexes, which have terminal M–H bonds only. The strength of M→(H_2) backbonding largely determines if [$L_nM(H)_2$] or [$L_nM(H_2)$] is formed (Fig. 1). Morris proposed that in the IR spectrum of [$L_nM(N_2)$] a $\nu(N_2)$ band in the range 2060–2160 or 2180 cm^{-1} indicates that the L_nM complex fragment has a π-basic character appropriate for forming [$L_nM(H_2)$].

It is not always easy to differentiate between $M(H)_2$ and M(η^2-H_2) complexes. Neutron diffraction studies are difficult and only five structures have been published. Determining the position of an H_2 ligand may or may not be possible in X-ray structure analyses. Spectroscopic methods are therefore of key importance in characterization. Kubas[18] identified the absorption at 2800 cm^{-1} in the IR spectrum of **4** as the "$\nu(H_2)$" stretch; for free H_2, $\nu(H_2)$ is observed at 4000 cm^{-1} (Raman). Unfortunately, Raman studies on H_2 complexes have not been successful because the complexes decomposed under laser irradiation even when exceptional precautions were taken.[19] The coupling constant ^1J(H,D) of 32 Hz in the ^{1}H NMR of the HD analogue of **4** was a most convincing piece of spectroscopic evidence, since the coupling constant for free HD is 43 Hz, and for the classical H-M-D complexes <1 Hz. The neutron diffraction study of **4** gave a separation r(H–H) of 0.82 Å, but librational motion of the H_2 ligand may make this value too short. The distance r(H–H) of 0.86 Å determined by solid-state NMR is probably more accurate.[20]

Before 1984, many undetected H_2 complexes had certainly been made. In most cases, protonation of a metal hydride gives an H_2 complex, at least as an intermediate. This complex often loses H_2 and undergoes further reactions to form a stable compound. In 1971, Aresta et al.[21] reported the synthesis of "[$FeH_4(PR_3)_3$]"; they were obviously puzzled by an unexpected IR band at 2380–2400 cm^{-1} which disappeared on loss of H_2 and formation of [$FeH_2L(PR_3)_3$] (L = N_2 or vacancy). We were able to reassign the complex as [$FeH_2(H_2)(PR_3)_3$] in 1986 on the basis of T_1 measurements (NMR spectroscopy);[22] this result was later confirmed by neutron diffraction experiments [r(H–H) = 0.82(1) Å].[23]

The T_1 method we proposed for identifying (η^2-H_2) complexes[24] is often useful. Two protons that are close together (<1 Å) relax very rapidly primarily by the dipole–dipole (DD) mechanism. Thus T_1 for the spin of the H_2 ligand in the ^{1}H NMR spectrum can be very short. T_1 is a function not only of structure of the complex but is also dependent on the magnetic field strength of the spectrometer and on molecular motion (temperature and solvent). We found that the complicating factor of molecular motion in solution could be removed by studying the temperature dependence of T_1. Unless the moment of inertia of the molecule is too small (e.g., $[ReH_9]^{2-}$), a minimum T_1 value, denoted T_1(min) can be found at a readily accessible temperature, usually between −80 and 20 °C. Since T_1(min) scales with spectrometer field, the field used must be cited. Although T_1 values determined at arbitrary temperatures cannot be compared with each other, T_1(min) values may be compared even for compounds with different moments of inertia.

The interpretation of the resulting T_1(min) value went through several improvements with time. We argued that in a dihydrogen complex the relaxation of the spins of the closely spaced pair of H_2 protons should be dominated by DD relaxation. We showed[25] that the calculated contribution to DD relaxation from all possible pairs of H ligands in a structurally characterized series of complexes was in reasonable agreement with experiment. Morris et al.[26a] pointed out that if the H_2 ligand is rapidly spinning, the rate of relaxation should fall to 25% of the static value. The assumption of a freely rotating H_2 ligand resulted in substantially better agreement. Since much of the activation energy for M–(H_2) rotation must be due to backbonding in the M–(H_2) bond, which must be small for an η^2-H_2 ligand, fast rotation is consistent with the bonding scheme of Figure 1. Eckert et al. measured the activation energy for the rotation of the H_2 ligand in [$MH(H_2)\{P(CH_2CH_2PPh_2)_3\}$]$BPh_4$ by inelastic neutron scattering.[26b] This is indeed small but higher for M = Fe (1.82 kcal mol^{-1}) than for M = Ru (1.36 kcal mol^{-1}), as previously proposed by Morris on the basis of the T_1 values and the higher lability of the Ru com-

plex, even though Ru is normally considered to be more π-basic.[26c]

The T_1(min) value for $[ReH_7(PPh_3)_2]$ is lower than for most classical hydrides but higher than for most nonclassical species, which led us to propose[22] that this and related species "might...constitute an intermediate group". This seemed to be contradicted by the neutron diffraction structure of $[ReH_7(dppe)]$ (dppe = $Ph_2PCH_2CH_2PPh_2$) determined by Howard et al.,[27] which showed it to be a classical heptahydride. Since the T_1 value for the dppe complex is 13% less than that predicted from the structure (assuming only H–H dipole–dipole relaxation), additional contributions to spin relaxation had to be present. Cotton et al.[28a] suggested several possibilities. Halpern et al.,[28b] Bakhumutov et al.,[28c] and our own group[29a] attributed the additional contribution to spin relaxation to metal–hydrogen DD relaxation. It is now clear that for Re, Nb, V, Mn, Co, and Ta, the M–H DD contribution, easily calculated assuming normal M–H distances, must be subtracted from the observed T_1(min) value to make the data comparable with those from hydrido complexes of other metals. Once corrected in this way, a short T_1(min) value (<40 ms at 250 MHz) denotes a nonclassical structure and a long T_1(min) (>100 ms) a classical structure; for intermediate values a distinction cannot be made, however.[29b]

The story took an unexpected turn when Howard, Koetzle, et al.[30] found that in **9** one H_2 unit has an unprecedented r(H–H) of 1.357 Å (neutron diffraction, Fig. 2). This distance was much longer than those in the previously reported H_2 complexes and supported the existence of an intermediate group between classical hydrides and "normal" H_2 complexes—stretched H_2 complexes. There was some initial question as to whether **9** really is an H_2 complex, but there is good evidence that it is. Complex **9** does not adopt the tricapped trigonal-prismatic structure found for all known classical nine-coordinate polyhydrido complexes (including $[ReH_7(dppe)]$), but has the dodecahedral coordination expected for an eight-coordinate complex (the midpoint of the stretched H_2 ligand is considered one of the coordination positions). Molecular mechanics calculations[31] show that the smallest separation between nonbonded hydrogen atoms in strained organic structures is 1.7 Å. Finally, the T_1 value of **9** is best interpreted if the H_2 ligand is assumed to be rapidly rotating about the M–(H_2) axis, as expected for H_2 complexes but not classical hydrides. Morris et al.[17] suggested a r(H–H) range of 1.1–1.6 Å as appropriate for stretched H_2 complexes. $[ReH_7L_2]$ complexes analogous to **9** may be borderline cases as was emphasized by the HF-SCF theoretical studies of Hay et al. on the complex with L = PH_3, which suggested that the classical form is only 2–4 kcal mol^{-1} more stable than the nonclassical one. PH_3 is a better donor ligand than PAr_3 (Ar = aryl) and should therefore stabilize the classical form.[32]

$[ReH_7\{P(p\text{-}C_6H_4CH_3)_3\}_2]$ **9**

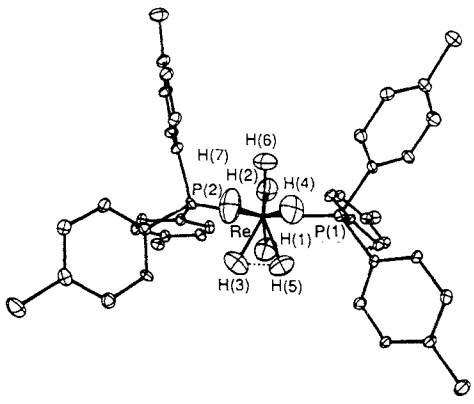


Fig. 2. The structure of the first stretched H_2 complex **9** (obtained by neutron diffraction). The H3–H5 distance in the H_2 ligand is 1.357 Å. The view is approximately aligned along the pseudo-S_4 axis of the dodecahedron. The unlabeled atoms are the carbon atoms of the tolyl groups (from ref. [30]).

One reason that the stretched H_2 ligand in **9** was so unexpected is that the previously known hydrides with structures on the borderline between classical and nonclassical (**4**/**5**, **10**/**11**, **12**/**13**)[33] have two tautomers in solution, one classical, the other nonclassical but with a normal (i.e. unstretched) H–H distance. As the activation energies are sufficiently large, 16 kcal mol^{-1} for reaction (3), 11.2 kcal mol^{-1} for reaction (5), and 11.6 kcal mol^{-1} for reaction (6), the two forms can be distinguished by NMR spectroscopy at low temperature. It has generally been thought that the activation barrier is due to cleavage of the H_2 bond. Now it seems far more likely that the energy barrier arises from the rearrangement of the heavy ligands, and that the hydrido ligands in the classical forms are not *cis* to each another but as shown in Equation (5) for **10** → **11**. This picture is also consistent with the absence of a kinetic isotope effect for reaction (3)[34a] and Morokuma's RHF study[34b] of the oxidative addition of H_2 to the $Pt(PH_3)_2$ complex fragment. The H–H distance in the transition state was calculated to be only 0.77 Å, but the P-Pt-P angle decreases from 180° to 130°.

$[ReH_4(CO)L_3]^+ \rightleftharpoons [ReH_2(H_2)(CO)L_3]^+$ (6)

12 **13**

If there were little or no change in the positions of the heavy ligands, the equilibration of classical and nonclassical forms might be very fast on the NMR timescale, which could complicate physical studies and characterization. In this case, the coupling constants J(H,D) and J(H,P) should be temperature- and perhaps solvent-dependent. Such behavior was found for *trans*-$[Os(H_2)H(depe)_2]^+$ (depe = $Et_2PCH_2CH_2PEt_2$) which may therefore be a candidate for fast equilibration.[35a]

An interesting illustration of the importance of the positions of the heavy atoms is the solid-state chemistry of a complex synthesized by Bianchini et al. Crystalline $[Co(PP_3)(N_2)]^+$ undergoes reversible substitution of the N_2 ligand for H_2, but two different isomers of the product can be formed, classical or nonclassical, depending on the coun-

terion. X-ray studies of the BPh_4^- salt show that formation of the classical dihydride requires considerable rearrangement of the geometry around Co. This rearrangement is presumably favored by packing effects in this salt. In contrast, when PF_6^- is used as the counterion, the nonclassical H_2 complex is formed. In solution the H_2 complex is always formed, whatever the counterion.[36]

Several other stretched H_2 complexes are now known (Table 1). Their properties are intermediate between those of H_2 complexes with normal H–H separations and classical hydrides. For example, $[ReH_5(H_2)L_2]$ ($L = P(p\text{-tolyl})_3$) loses H_2 when warmed to 60 °C, while the classical hydride $[ReH_7L_2]$ (L_2 = dppe) survives intact to >120 °C. H_2 complexes with normal H–H separations tend to lose H_2 at much lower temperatures; however, there are as yet no unstretched H_2 complexes in the $[ReH_7L_2]$ series for a direct comparison. Unlike normal H_2 complexes whose pK_a would be expected to be no higher than 15, the stretched H_2 complex $[ReH_7(PPh_3)_2]$ requires a very strong base such as *n*BuLi for deprotonation.[32]

Table 1. Selected structural and NMR data for some stretched dihydrogen complexes.

Complex	H-H [Å]	Method [a]	^1J(H,D)	Ref.
$[Re(H_2)H_5\{P(p\text{-}MeC_6H_4)_3\}_2]$	1.357	nd	–	[30]
	1.35	T_1	–	[37b]
$[Re(H_2)H_5\{P(p\text{-}CF_3C_6H_4)_3\}_2]$	1.24	T_1	–	[37b]
$[Re(H_2)H_5\{P(p\text{-}MeOC_6H_4)_3\}_2]$	1.42	T_1	–	[37b]
$[Os(en)_2(H_2)(OAc)]^+$	1.34	nd	1.6	[38a]

$[Os(en)_2(H_2)(Cl)]^+$	–	–	7.2	[38a]
$[Os(en)_2(H_2)(MeCN)]^{2+}$	–	–	17.9	[38a]
$Ni(H_2)$	1.41	[b]	–	[38b]

[a] Method used to determine the H–H distance. nd = neutron diffraction, T_1 (NMR spectroscopy). [b] Theoretical value determined by CMD-CI calculations.

Unstretched H_2 complexes do not show a very large change in T_1(min) or ^1J(H,D) when the electronic properties of the metal center are altered by changing the ligands. We found that the exchange of $L = PMe_2Ph$ for $P(OCH_2)_3CEt$ or CO in $[RuH(H_2)L(triphos)]^+$ (triphos = $PhP(CH_2CH_2PPh_2)_2$) had only a small effect on these parameters.[37a] Stretched H_2 complexes are much more sensitive to electronic effects. The T_1(min) values for a series of $[Re(H_2)H_5\{P(p\text{-}XC_6H_4)_3\}_2]$ complexes vary with the electron donor/acceptor properties of X in a way that suggests that the strongest donor group, OMe, leads to a lengthening of $r(H\cdots H)$ to 1.42 Å and the strongest acceptor group, CF_3, causes a shortening to 1.24 Å.[37b]

A remarkable series of stretched H_2 complexes was prepared recently by Taube et al.[38a] In the complex ions $[Os(en)_2(H_2)(X)]^{n+}$ the coupling constant ^1J(H,D) varies greatly: the complex with X = OAc, $n = 1$ [r(H–H) = 1.34 Å by neutron diffraction] has a ^1J(H,D) value of 1.6 Hz; the complex with X = MeCN, $n = 2$, a value of 17.9 Hz. This J(H,D) value of 1.6 Hz is much less than that found for normal H_2 complexes (12–34 Hz), but the acetonitrile complex has a coupling constant within the normal range. We now need to know how the chemical and physical properties of the H_2 ligand vary with r(H–H).

A useful review of theoretical work has been published by Burdett, Eisenstein, et al.[39] Theoretical studies by Siegbahn et al. suggest that the binding energy in $[Ni(H_2)]$, with an $H\cdots H$ distance of 1.41 Å, is as much as 9.5 kcal mol^{-1} with respect to Ni and H_2. Figure 3 shows how the $H\cdots H$ bond energy for two free H atoms changes with distance according to Kolos and Wolniewicz.[38c,d] A surprisingly large proportion of the H–H bond energy is retained at long distances (e.g. about 50% at 1.35 Å).

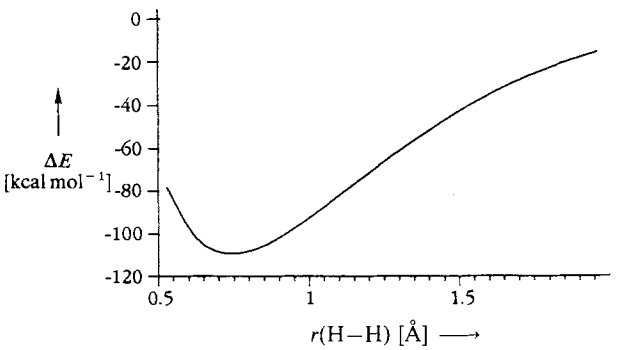

Fig. 3. The potential energy curve for two isolated H atoms according to the calculations of Kolos and Wolniewicz (from ref. [38c,d]).

Strong $H\cdots H$ interactions are probably involved in quantum exchange coupling. Heinekey et al.[40a] were very surprised to find that in the ^1H NMR spectrum of $[Cp^*IrH_3]^+$ the hydride resonances showed very temperature-dependent second-order signals. Attempts to analyze these in the usual way provided apparent H,H′ coupling constants that were unusually large and extremely temperature dependent. For example, for the Ir complex with $L = AsPh_3$, J_{app} changed from 376 Hz at 176 K to 570 Hz at 189 K. A neutron diffraction study showed that all the $H\cdots H$ distances are >1.67(1) Å and are therefore essentially nonbonding.[40b] Heinekey, Zilm, et al.[40b] and Weitekamp et al.[40c] suggested that the exchange effect is due to abnormal motion of the MH_3 unit which brings the H and H′ atoms unusually close together. Rotational tunneling of an H_2 complex has also been considered as possibly responsible for the exchange effects.[40d] The observation that the effect is quenched in the deuterated complex $[Cp^*LIr(D)(H)(D)]^+$ is consistent with quantum mechanical exchange effects being responsible, because the H and D nuclei are not identical particles. The effects can be very large. For example, for the complex with L = CO, J_{app} can approach 20000 Hz.[40e] The required close approach of the H and H′ atoms may be favored if a complex of the type $[Cp^*IrLH(H_2)]^+$ is not too far removed in energy from the ground state. Eisenstein et al. found another type of attractive interaction in $[FeH_2(H_2)(PEt_2Ph)_3]$ between the terminal Fe–H bond and the H_2 ligand in the same molecule. The major contribution to the interaction was attributed to the electron donation of the M–H(σ) to the H–H(σ^*) molecular orbital and was thought to be responsible for the conformation of the H_2 ligand and to contribute to the activation energy for the rotation of the H_2 ligand.[23]

An H_2 ligand probably bridges the two metalloporphyrin groups in the isolable complex [L(OEP)Ru(H_2)Ru(OEP)L] (L = *tert*-butyl-5-phenylimidazole, OEP = octaethylpor-

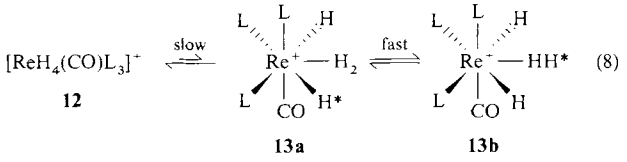
phyrin; $J(H,D) = 15$ Hz).[41] A species of this sort may be involved in reaction (7) in which two monohydrido complexes eliminate H_2.

$$2[(thf)(OEP)Ru\text{-}H] + 2THF \longrightarrow 2[(thf)_2(OEP)Ru] + H_2 \quad (7)$$

Polyhydrides are a rich source of dihydrogen complexes; Lin and Hall[42a] reported calculations at the MP2 level on a number of these compounds. They found that the nonclassical form is favored for $[MH_6L_2]^+$, $[MH_7L_2]$, and $[RuH_6L_2]$, while the classical form is favored for $[WH_4L_4]$, $[ReH_5L_3]$, $[ReH_4L_4]^+$, $[MoH_4L_4]$, and $[OsH_5L_3]$ (L = PH_3; M = Rh, Ir). The heptahydrides are as yet unknown, but would be interesting synthetic targets. Calculations on cyclopentadienylpolyhydrido complexes[42b] showed that the strongly donating Cp ligand favors formation of classical hydrides. Only for the unknown complex $[CpRh(CO)H_3]^+$ (related to Heinekey's system mentioned above) was an H_2 complex the most stable tautomer. Trispyrazolylborate, as a poorer donor ligand, may be more suitable for forming nonclassical structures such as $[\{HB(3,5\text{-}Me_2pz)_3\}Rh(H_2)H_2]$ (Me_2pz = dimethylpyrazolyl) (T_1 (min) = 42 ms at 400 MHz) prepared by von Philipsborn, Venanzi, et al.[43]

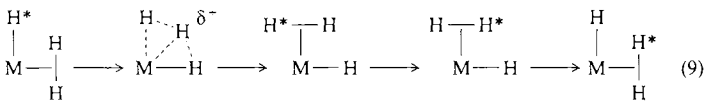
Burdett et al.[44] suggested that polyhydrido complexes best described as containing H_3 or H_n ligands may exist, but none has yet been found. Distinguishing securely between a ground state H_3 complex and its possible tautomeric forms, such as $MH(H_2)$ and MH_3, is difficult. As early as 1961, Lipscomb et al.[45a] suggested that the three *endo* hydrogen atoms in $[B_{11}H_{14}]^-$ might be arranged in the form of an equilateral triangle with short H–H distances. The X-ray structure analysis,[45b] NMR spectroscopic studies in solution and in the solid state, and theoretical studies[46] all suggest that the H ··· H distances are all entirely nonbonding (r(H–H) > 1.7 Å) and that the structural units with the *endo* H atoms consist of two BHB bridges and one terminal BH unit.

We obtained evidence for an H_3 complex in a simple "reaction" of a nonclassical polyhydride, the fluxional proton exchange between $M(H_2)$ and the M–H positions.[33c] The very fluxional classical hydride **12** (L = PMe_2Ph) is in slow equilibrium with the nonclassical tautomer **13** [Eq. (8)]. We



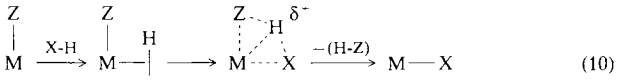
12 **13a** **13b** (8)

found that site exchange between the terminal hydrides and the H_2 ligand in **13** (**13a** → **13b**) has a significantly (1.7 kcal mol^{-1}) larger energy barrier than that for conversion between the two tautomers **12** and **13**. Thus the exchange in **13** does not proceed via the classical isomer **12**: if hydrogen exchange is not dissociative with respect to the H_2 ligand, it must be associative. After excluding other associative pathways, we were left with a mechanism in which one terminal hydride approaches the H_2 ligand, and the resulting transition state or intermediate with an H_3 ligand leads to exchange [Eq. (9)]. Since we were not able to observe



(9)

decoalescence of the signals of the classical isomer by low-temperature ^{1}H NMR spectroscopy, we assume that the barrier to site exchange is also lower than that for interchange of the two tautomers. If this is true, the most likely exchange path for the classical isomer is one in which the terminal hydrido ligands do not associate to form an H_2 ligand. Theoretical work[47] for the related complex $[Fe(H_2)H(PH_3)_4]^+$ supports the idea of an open, allyl-like η^3-H_3 complex as a transition state for fluxional exchange in **13**. Although H_3^+ itself is cyclic, at least one bond of the three-membered ring is cleaved upon binding to a metal atom as a result of back-donation. A plausible interpretation[24] of a transition state with an open H_3 unit is the transfer of a protonic H atom of an H_2 complex to the hydridic H atom of a terminal M–H group. This fluxional process is also the simplest example of a sigma bond metathesis reaction [Eq. (10)] for which the four-center transition state shown has been widely accepted. The chemistry of Equation (8) suggests that the σ complex of Equation (10) (M = Re) is a likely precursor to this transition state.

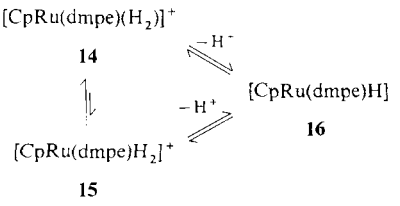


(10)

A very simple reaction of H_2 complexes is loss of H_2. This generates a two-electron vacancy at the metal center which allows a ligand such as the substrate for a catalytic reaction to bind. The complexes $[MH_4L_3]$ (M = Fe, Ru, Os; L = tertiary phosphane) all have the same stoichiometry, but the Fe and Ru complexes are very much more labile and more catalytically active for a variety of reactions, including alkane activation. Our T_1 data suggested that the Fe and Ru complexes have H_2 ligands, while the Os complex is a classical hydride;[22] this proposal was supported by neutron diffraction studies on the Fe and Os complexes.[23] Some H_2 complexes are so labile that a substantial pressure of H_2 is required for their preparation in significant quantities. A good example is the Cr analogue of **4**, which has been studied by IR and NMR spectroscopic methods under 60 atm H_2 pressure. When the magnetization corresponding to the $Cr(H_2)$ resonance was inverted, the recovery of the original magnetization follows a biexponential curve. The faster process reflects the short T_1 (min) of 10 ms, the slower is a result of slow exchange with free H_2 in solution; the activation energy for loss of H_2 extracted from the data is 12.7 (±1) kcal mol^{-1}.[48] A catalyst for alkyne hydrogenation is formed from $[RuH(H_2)\{PhP(CH_2CH_2PPh_3)_3\}]^+$ after initial loss of H_2.[49]

Heterolytic cleavage of the coordinated H_2 ligand to give a metal hydride and a proton is an important reaction for H_2 complexes. The H_2 ligand in $[IrH(H_2)(bq)(PPh_3)_2]^+$ (bq = 7,8-benzoquinolinato) is kinetically more acidic than the Ir–H group, although they must have the same pK_a.[44] Heinekey et al. described an interesting equilibrium in which

14 and **15** only slowly interconvert.[50a] The equilibrium [Eq. (11)] lies on the side of **14**, which has a pK_a of 17.5 in



(11)

acetonitrile. In a case like this, thermodynamics requires that the less abundant compound be the most acidic, because the two tautomers share the same conjugate base. Although the dihydrogen complex is the weaker acid thermodynamically, it alone is capable of protonating the conjugate base **16** at a significant rate (according to saturation transfer in NMR spectroscopic studies).[49] The same data also imply that the terminal hydrido ligand of **16**, rather than the metal center, is the kinetically preferred site for protonation. Similarly, $[CpRu(H_2)(PPh_3)_2]^+$ is formed on protonation of the neutral hydride, but the complex irreversibly rearranges to the classical isomer on warming.[50a]

Morris et al. looked at the effect of the R group on the position of the tautomeric equilibrium and the pK_a in $[CpRuH_2(R_2PCH_2CH_2PR_2)]^+$. The change from R = *p*-$C_6H_4CF_3$ to R = Me causes the pK_a to increase from 4.5 to 10. This is a substantial shift and correlates well with the oxidation potential of $[CpRuH(R_2PCH_2CH_2PR_2)]$, which becomes easier to oxidize, and the position of tautomeric equilibrium, which moves to favor the classical isomer.[35b] Attack of D^+ on the metal atom in $[Cp_2WH_2]$ would be expected to give the classical complex $[Cp_2WH_2D]^+$. The deuterido ligand should be positioned between the two hydrido ligands, because this is the position of the M lone pair. The distribution of the isotopic label found in the product led Parkin and Bercaw to invoke protonation at M–H to give a rapidly spinning HD complex as intermediate, followed by irreversible oxidative addition of the η^2-HD ligand.[50b]

Heinekey et al.[51] and Morris et al.[52] both showed that the thermodynamic acidity of free H_2 (pK_a ca. 35)[53] can be dramatically enhanced when bound as a σ complex; the pK_a values of H_2 σ complexes are in the range of roughly 10 to −2 (water scale).[54] The acidity enhancement is comparable[55] to that produced by forming the radical cation $XH^{\cdot+}$ and greatly exceeds the acidity enhancement caused by binding XH to a metal through a lone pair on X. For example, when H_2O is bound to a divalent metal cation in the usual way through a lone pair on the O atom the acidity is typically enhanced by only about 6 pK units. Morris[56] showed how the acidity of $[L_nM(H_2)]$ complexes can be estimated from the π-donor ability of the L_nM complex fragment, which is in turn estimated from Lever's[57] electrochemical parameters for the L_nM group.

We have seen that as M–H_2 binding gets stronger, as in the stretched H_2 complexes, the acidity of H_2 complexes tends to decrease. For d^0 complexes, in contrast, higher acidity is expected because back-donation is absent, but the strength of M–H_2 binding will be small for the same reason. No d^0 dihydrogen complexes have been isolated to date; however, a labile complex between Cp_2^*Eu and H_2 has been inferred from its ^1H NMR spectrum.[58] This leads to the apparent paradox that the activation of the ligand is large when the binding is weak and vice versa.

Hydrogenolysis of d^0 alkyl complexes is usually rapid, as in the sigma bond metathesis reaction (12) (R = alkyl). Al-

$$[Cp_2ZrRCl] + H_2 \longrightarrow [Cp_2ZrHCl] + RH \quad (12)$$

though oxidative addition cannot occur in a d^0 system, an allowed alternative is the formation of an H_2 complex. The acidity of the bound H_2 ligand should be sufficient to allow protonation of the alkyl group, which is strongly basic. A mechanism with an H_2 complex as an intermediate would explain the inverse isotope effect k_{H_2}/k_{D_2} of 0.85 in the hydrogenolysis of the alkyl ligand in $[Cp_2^*Zr(CH_2tBu)Cl]$,[59] if a preequilibrium involving H_2 or D_2 coordination favored D_2, as can be the case in H_2 complexes.[60]

The metal centers in most H_2 complexes are d^6 and have octahedral coordination, but d^8, d^4, and d^2 complexes such as $[Co(H_2)P(CH_2CH_2PPh_2)_3]^+$,[61a] $[ReH_2(H_2)(CO)(PMe_2Ph)_3]^+$, and $[Re(H_2)H_5(PAr_3)_2]$ are known. In a d^0 polyhydrido complex the metal center has no lone pairs, and so the M–H bond must be protonated. At −80 °C, we find that the classical hydride $[WH_6(L_3)]$ (L_3 = PhP-$(CH_2CH_2PPh_2)_2$, T_1(min) at 250 MHz = 103 ms) is protonated reversibly in solution to give "$[WH_7(L_3)]^+$", which only loses H_2 on heating to −20 °C. The product, $[WH_{7-2x}(H_2)_x(L_3)]^+$ has a short T_1(min) value of 21 ms [Eq. (13)]. If $x = 0$ the permitted oxidation state for W would

$$[WH_6(L_3)] + H^+ \longrightarrow [WH_{(7-2x)}(H_2)_x(L_3)]^+ \quad (13)$$

be exceeded, and $x = 1$ is unlikely because a d^0 system cannot backbond and so would not be expected to give a stable H_2 complex. Thus the most reasonable formulations have $x = 2$ or 3.[62]

Direct protonation of an M–H unit was also evident for the d^6 complex [Cp*FeH(dppe)] examined by Lapinte et al. At −80 °C protonation gives the dihydrogen complex (T_1(min) at 300 MHz = 7 ms), but at −40 °C this complex irreversibly rearranges to the classical tautomer (T_1(min) at 300 MHz = 175 ms) [Eq. (14)].[63]

$$[Cp^*FeH(dppe)] \xrightarrow{H^+,\ -80\ ^\circ C} [Cp^*Fe(H_2)(dppe)]^+ \xrightarrow{-40\ ^\circ C} [Cp^*Fe(H)_2(dppe)]^+ \quad (14)$$

A reaction involving net heterolysis of dihydrogen is D_2/H^+ isotope exchange [Eq. (15)]. This seems to be very effi-

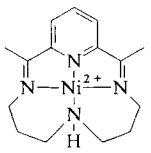
$$D_2 + ROH \rightleftharpoons HD + ROD \quad (15)$$

cient when the complex has an M–(H_2) arrangement as in $[Ru(H_2)(OEP)(thf)]$,[64] or a *cis*-$MH(H_2)$ arrangement as in $[IrH(H_2)(bq)(PPh_3)_2]^+$;[65] the classical hydrides studied were inactive. In the Ru complex, the metal center appears to increase the acidity of the H_2 ligand sufficiently so that it can directly exchange with the protons in solution. The mechanism proposed for the reaction of the Ir complex is shown in Equation (16). The role of the H_2 ligand seems simply to be to dissociate to allow D_2 access to the metal center. Once D_2

$$MH(H_2) \xrightarrow{D_2} MH(D_2) \longrightarrow MD(HD) \xrightarrow[-HD]{ROH}$$
$$MD(ROH) \longrightarrow MH(ROD) \xrightarrow{D_2} MH(D_2) + ROD \quad (16)$$

is coordinated, fluxional exchange leads to deuteration of the terminal site. Subsequent binding of the protic solvent then leads to exchange between the deuterido ligand and the bound solvent. Sterically less demanding solvents like MeOH are found to bind more strongly and to show reduced catalytic activity relative to sterically demanding solvents like *tert*-BuOH; the former probably tend to prevent the D_2 from binding to the metal by direct competition for the site at the metal.

Reversible electrochemical one-election oxidation is shown by $[Os(H_2)(NH_3)_5]^{2+}$[66a] and $[Re(H_2)Cl(PMe_2Ph)_4]$,[66b] but these complexes decompose on oxidation. The reduction of protons to H_2 has been studied in connection with the nickel-containing enzyme, hydrogenase.[67a] Electrochemical reduction of a number of Ni^{II} precursors such as **17** in protic medium leads to the evolution of H_2.[67b] Because the reaction is first order in nickel, the two



17

electron-transfer steps and the two protonation steps seem to occur on a single metal center. A $Ni^{II}(H_2)$ complex seems the most plausible immediate precursor from which H_2 is lost in this reaction [Eq. (17)].[67b] If this is the case in hydrogenase, as has been suggested,[67c] σ complexes may have biological significance.

$$Ni\text{-}L \xrightarrow{e^-} (Ni\text{-}L)^- \xrightarrow{H^+} H\text{-}Ni\text{-}L \xrightarrow{e^-,H^+} (H_2)\text{-}Ni\text{-}L \xrightarrow{-H_2} Ni\text{-}L \quad (17)$$

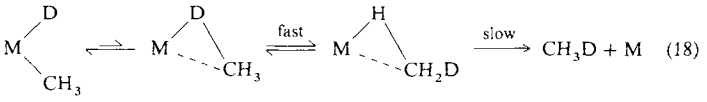
3. Alkane Complexes and Agostic C-H-M Systems

In its σ complexes the C–H bond is more weakly bound than is H_2 in H_2 complexes, perhaps because the C–H bond is slightly less basic and much more hindered than the H–H bond in dihydrogen ligands. There are many isolable H_2 complexes but for the moment no analogues for coordinated methane or other alkanes. For C-H-M complexes to be isolable the C–H bond must be part of a ligand L that is already strongly bound to the metal center, in which case, the chelate effect favors the binding.

The first evidence for alkane complexes[12] came from low-temperature studies of photochemically generated $M(CO)_5$ complex fragments (M = Cr, Mo, W) in an alkane or alkane/rare gas matrix. In early work, H_2 complexes were identified in studies on very similar complex fragments in H_2 matrices.[68]

Alkane complexes also appear to be intermediates in certain reactions. Moore, Bergman, et al.[69a] identified $[CpRh(CO)(H\text{–}CH_2tBu)]$ as an intermediate in the gas-phase photolysis of $[CpRh(CO)_2]$ in the presence of CMe_4. The energy of the Rh–alkane bond is at least 5 kcal mol^{-1}, and the subsequent reaction to give $[CpRh(CO)(H)(CH_2tBu)]$ has an activation energy of approximately 4.5 kcal mol^{-1} at $-100\,^{\circ}C$. In other studies,[69b] short-lived alkane and related complexes with M–alkane bond energies in the range of 7–11 kcal mol^{-1} have been detected. In complexes with coordinated CH_3F, however, an M–F bond seems more likely than a (C-H)-M bond.

Bergman et al.,[69c] Norton et al.,[70] and Heinekey et al.[71] all reported on complexes (**18**–**20**) in which isotope exchange between α-C–H and M–H sites in an alkyl hydride is faster than reductive elimination of alkane [Eq. (18)].

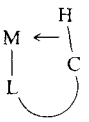


$$\xrightarrow{\text{slow}} CH_3D + M \quad (18)$$

18–**20** (M = Cp*Ir(PMe_3), **18**; Cp_2W, **19**; Cp_2Re^+, **20**)

Bergman first proposed that an alkane σ complex is involved. Complexes **18** and **20**[69c, 71] show an inverse kinetic isotope effect (k_H/k_D = 0.5 (Ir), 0.8 (Re)) for reductive elimination, which is also consistent with a preequilibrium involving an alkane σ complex before loss of alkane. The alkane complex is sufficiently long lived so the metal atom can coordinate interchangeably to different C–H bonds and reversibly undergo oxidative addition. A smiliar isotope exchange in $[Ir(PPh_3)_2D(CH_2CHDtBu)(solvent)_2]^+$,[72] could proceed by the same pathway; however, in this case an alternative mechanism involving rapid α-elimination via a carbene intermediate [IrHD(=CHCHD*t*Bu)] is possible because of the coordinative lability of the ligated solvent molecule.

Agostic complexes of type **21** are often recognized in X-ray studies. Although the hydrogen atom is not always well located, its position can sometimes be inferred from the po-



21

sitions of the heavy atoms. Neutron diffraction studies show that the C–H bond is not greatly elongated (bound, 1.13–1.19 Å; unbound, 1.1 Å) by the interaction. In early work on complexes with weak agostic interactions, it was not clear whether the C–H bond just happened to be close to the metal atom or whether there was a genuine attraction. Complex **7** was the first to show a very short separation and therefore an unambiguously attractive interaction. We compared[73a] a series of structures of C-H-M complexes to determine the kinetic pathway for {C–H} + M → {C-M-H} by the method of Bürgi and Dunitz.[73b] The C–H bond approaches the metal atom end-on, resulting in a strong M–H interaction; the C–H bond then rotates bringing the carbon atom close to the metal center (Fig. 4). In all cases the C-H-M unit is bent with canted side-on coordination of C–H as expected from the bonding scheme of Figure 1. The transition state suggested in our work[73a] resembles that found in RHF calculations by Morokuma et al.[74a] for addition of CH_4 to [RhCl-

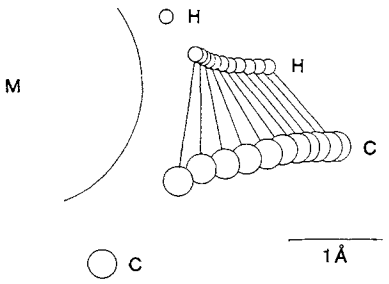


Fig. 4. A kinetic pathway for the reaction M + C–H → C-M-H as deduced from a series of structures of agostic complexes (from ref. [73]).

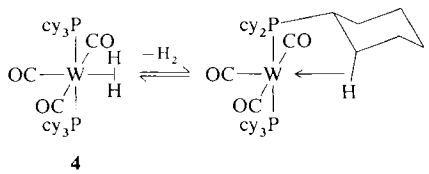
$(PH_3)_3$]. A methane complex was also identified as an intermediate in the heterolytic C–H activation of CH_4 with $L_nTi{=}NH$ to give $[L_nTi(Me)NH_2]$.[74b] As might be expected, a metal center capable of binding H_2 as a σ complex can often bind other X–H groups [Eq. (19)].

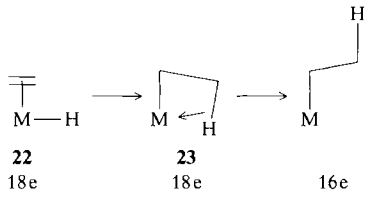


4 (19)

Apart from crystallography, NMR spectroscopy is most useful for detecting C-H-M bridges. In the complex the $^{13}C,H$ coupling constant $^1J(^{13}C,H)$ is reduced by up to 50% relative to the uncomplexed ligand (free, ca. 125 Hz, bound 60–120 Hz), just as $^1J(H,D)$ is reduced by about the same amount in unstretched H_2 complexes (free, 43 Hz, bound 22–33 Hz). The signal of the agostic H atom normally appears upfield from tetramethylsilane, and in this respect resembles a metal-bound rather than a C-bound H atom. Unfortunately, interpretation of the NMR spectrum is often complicated by dynamic processes. For example, an agostic CH_3 group will normally rotate so rapidly that each proton is in the bridging site for one-third of the time. From the value of the resulting averaged $^1J(C,H)$ coupling constant an agostic methyl group cannot be securely distinguished from an unbound methyl group; the upfield shift of the agostic CH_3 group is also reduced by two-thirds.

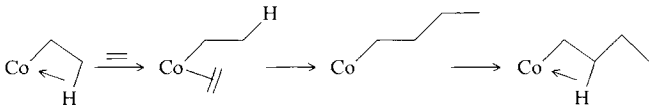
Shapley et al.[75a] showed that Isotopic Perturbation of Resonance (IPR) in NMR spectroscopy[75b] is very useful in such a case. The methyl group is partially deuterated and the isotope shifts for CH_2D and CHD_2 are measured. The different zero-point energies of the two C–H(D) bonds lead to a substantial enrichment of H atoms in the bridging site. Assuming that bridging and terminal ligands have a significant chemical shift difference $\Delta\delta$, as is usually the case, the averaged resonance for the isotopomers will show a temperature-dependent shift relative to the CH_3 signal. Since any process, such as oxidative addition, that causes the symmetry of the CH_3 to be lowered will in general also lead to an IPR effect, interpretation requires care. IR studies show the expected shift of the C–H band to lower energy upon complexation, consistent with bond weakening. The typical frequency range observed for alkane σ complexes is $\nu(C{-}H) = 2250{-}2800\ cm^{-1}$.

Agostic complexes can be on the mechanistic pathway in organometallic reactions such as alkene insertion [Eq. (20)]



22 18e **23** 18e 16e (20)

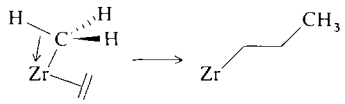
or CO insertion.[76a] Morokuma et al.[74c] found a β-agostic transition state for alkene insertion in $[Rh(CO)_2(PH_3)(C_2H_4)H]$, for example. Sometimes an alkene hydrido complex like **22** is the ground state of the system, sometimes the agostic alkyl complex **23** is, as in the case of $[Cp^*Co(C_2H_4)(CH_2CH_2{-}H)]^+$.[76b] Brookhart et al. proposed that a metal center at which **22** and **23** readily interconvert should also be suitable for the much rarer alkene insertion into metal–alkyl bond, a reaction which proceeds readily in the closely related species $[Cp^*Co\{P(OMe)_3\}(CH_2CH_2{-}H)]^+$, which is an alkene polymerization catalyst [Eq. (21)].[77] An α-agostic alkyl complex was proposed[14]



(21)

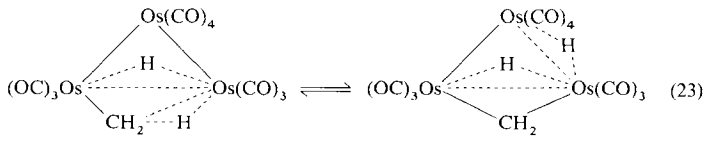
[Co = $Cp^*Co\{P(OMe)_3\}$]

as being the intermediate that undergoes insertion in Ziegler–Natta alkene polymerization catalysts. If so, the agostic binding may rotate the methyl group towards the alkene and so prepare it for insertion [Eq. (22)]. Direct evi-



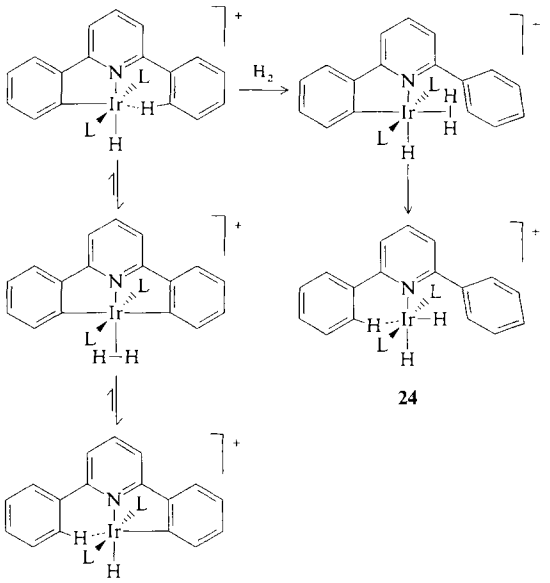
(22)

dence for this has now been obtained by Brintzinger et al.[78a] and by Bercaw et al.[78b] in an experiment originally conceived by Grubbs et al.[78c] in which the stereochemistry of the insertion is different if C–H or C–D is involved in the agostic binding. If an isotope effect is found, agostic transition states are indicated. α-Agostic alkyl complexes such as $[Cl_2(Me_3P)_2(C_2H_4)Ta\{CH(\eta{-}H)tBu\}]$ are now well known.[78d] Canty[79a] found that loss of ethane from $[Pd(bpy)Me_3I]$ (bpy = bipyridine) requires loss of I^- and proposed that formation of an agostic bond helps the methyl group rotate and start bond formation with the adjacent methyl group. GVB calculations by Low and Goddard[79b] on ethane loss from MMe_2 (M = Pd, Pt) also implicate a methyl group rotation in the transition states, the structures of which resemble those of known, stable agostic complexes. Shapley et al. identified an agostic Os_3 complex **21** that was in equilibrium with its tautomer **22** [Eq. (23)].[75]



(23)

Albéniz et al.[80] found the set of equilibrating tautomers in Equation (24), which shows that the coordinated σ bond tends to form *trans* to a ligand with a strong trans effect, in this case the aryl group. The activation energy for exchange



(24)

24

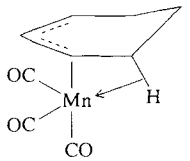
was only 12.3 kcal mol^{-1}. The H_2 complex depicted is a possible intermediate.[80] In the presence of excess H_2, the C–H group was displaced and a conventional H_2 complex was formed. With longer reaction times, this complex undergoes hydrogenolysis to give **24**, perhaps by the pathway of Equation (24).

Gladysz et al. invoked agostic intermediates to account for the migration of the metal atom from one enantioface to the other in a variety of alkene complexes of the type $[Cp(NO)(PR_3)Re(alkene)]^+$.[81] Since the metal atom does not dissociate and the alkene ligand does not undergo stereochemical or isotope scrambling, the metal must bind to a C–H bond as it passes across the alkene plane.

As for H_2 complexes, the d^6 configuration is the most common for agostic M-(C-H) complexes. d^0 Complexes show short M···C contacts as are found in a number of crystal structures of complexes of f-block elements. $[Cp''_2Yb]$ and $[Cp''_2Eu]$ ($Cp'' = (1,3\text{-}Me_3Si)_2C_5H_3$) are rare examples from the lanthanide group.[82] In the Eu complex the Eu···C separation is 3.09 Å, whereas the normal Eu–C bond length is 2.7 Å. Actinide complexes more commonly show agostic M-(C-H) bonds. In $[Cp^*_2Th(CH_2tBu)_2]$ one α-CH bond on each neopentyl ligand is bent back towards the metal forming Th-C-H angles of 84.4° and 87.1° (determined by neutron diffraction).[83a] Many other examples are known, but in some cases the complexes may not be truly agostic; instead alkyl groups may be semibridging leading to structures reminiscent of that of $[Me_2Al(\mu\text{-}Me)_2AlMe_2]$, in which the C–H bonds are thought not to be involved in coordination. Here, the 3c-2e bond involves the two Al and the C atom only.[83b] Examples of d^0 transition metal complexes include the α- and β-agostic $[Ti(\eta^2\text{-}CH_3)(dmpe)Cl_3]$ and $[Ti(\eta^3\text{-}CH_2CH\text{–}H)(dmpe)Cl_3]$,[84a] and the α-agostic alkylidene complex $[Cp_2ClTa{=}C\text{–}H(tBu)]$.[84b]

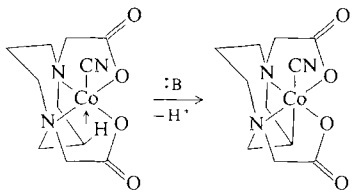
Weak C–H···M attractions were identified by Albinati, Pregosin, et al.[85] in a number of late transition metal complexes. The H···M distances are in the range 2.3–2.5 Å. In the ^1H NMR spectra of these complexes the resonances are not shifted upfield and the $^1J(C,H)$ values are not reduced as in complexes with normal agostic interactions. Since the square-planar coordination geometry of the d^8 metal is almost undistorted by the approach of the C–H bond perpendicular to this plane, these complexes must represent a very early stage of C–H···M bridge formation.

By analogy with H_2 complexes the C–H bond becomes more acidic on binding. For example, the pK_a (water scale) of the agostic CH group in **25** is 14.[55,86]



25

Reaction (25) is especially interesting since deprotonation gives a metal alkyl complex. In the starting complex a C–H bond on a remote, unactivated portion of an alkyl chain is



(25)

sufficiently acidified to be deprotonated by methoxide ion.[87] The degree of C-*H*-M acidification is probably comparable to that for the $M(H_2)$ case.

The selectivity order for alkane reactions is usually tertiary > secondary > primary, because both the tertiary radical (homolytic cleavage) and the tertiary carbonium ion (heterolytic cleavage) are more stable than the corresponding secondary or primary species. If a σ complex were involved in the alkane reaction, we might expect more facile deprotonation relative to the free alkane, but the order of selectivity would not be tertiary > secondary > primary. Deprotonation of the agostic complex **21** is certainly more facile than deprotonation of an alkane. If the C atom involved in the agostic bond is tertiary, then the required side-on coordination and formation of the σ complex is strongly disfavored as a result of steric effects. Even for simple complexes of type M–R very few examples are known with tertiary R groups.

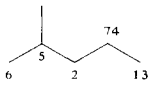
Shilov et al. carried out ground-breaking studies on Pt^{II} catalyzed H/D exchange in alkanes [Eq. (26)] which proceed

$$C_6H_{12} \xrightarrow{PtCl_4^{2-},\ D^+} C_6H_{12-x}D_x \qquad (26)$$

by heterolytic C–H activation and are not selective for tertiary sites. Several examples of the proposed alkylplatinum intermediates were isolated.[89] An alkane complex would be an attractive intermediate for this heterolysis, but none has been directly detected.

The selectivity in reactions of alkanes with cobalt(III) acetate also deviates from the normal order tertiary > secondary > primary.[90] **26** shows the selectivity pattern (% at-

tack at each position shown) for oxidation of 2-methylpentane. Here we have a very electrophilic metal ion which is at



26

the same time a powerful 1e oxidizing agent. The large kinetic isotope effect observed indicates that C–H bond breaking is important in the transition state. The data was interpreted in terms of an outer sphere, 1e oxidation of the alkane in a preequilibrium process, followed by rate-determining deprotonation of the $RH^{\bullet+}$ radical cation. The mechanistic work in this area was carried out long before σ complexes or proton-coupled electron transfer (PCET, shown in Eq. (27),

$$C\text{–}H + B \rightarrow C^{\bullet} + BH^{+} + e^{-} \quad (27)$$

B = base, C–H = bond in RH)[91] were recognized. PCET can take place when a substrate RH cannot lose an electron directly, but concerted deprotonation and oxidation is favorable. Alkanes are very difficult either to deprotonate or to oxidize, but as we discussed in more detail elsewhere,[92] PCET in an alkane complex is consistent with the kinetic data and is chemically reasonable. PCET should be considered whenever alkane oxidation occurs with an abnormal selectivity pattern.

4. B-H-M and Al-H-M Complexes

Since B-H-B bridges are already known in neutral boranes, it is no surprise that B-H-M complexes are also very stable and have been known for a long time. BH_4^- forms many such complexes, for example, $[Ti(HBH_3)_2(H_2BH_2)(PMe_3)_2]$, $[Cp_2Zr(H_2BH_2)_2]$, and $[Hf(H_3BH)_4]$; AlH_4^- behaves similarly.[14b, 93]

As methane complexes have not been characterized by crystallography, some idea of the structure of M-H–CH_3 complexes can be gained from M-H–BH_3^-, although the strength of the BH_4–M interaction is much greater. In $[FeH(dppe)_2(\eta^2\text{-H–}BH_3)]$ the B-H-M bond angle is surprisingly large (162°).[94]

5. Si-H-M and Sn-H-M Complexes

A substantial series of σ complexes of silanes are known, many of which were carefully characterized by Schubert et al.[95] using neutron diffraction. In general, their structures more closely resemble those of oxidative addition products than those of σ complexes with an unstretched Si–H bond. This is also evident in the ^1H NMR spectrum: the percentage reduction in $^1J(Si,H)$ is much greater than for $M(H_2)$ or C-H-M complexes. In $[(MeCp)Mn(HSiPh_3)(CO)_2]$, for example, the coupling constant $^1J(Si,H)$ is 65 Hz compared to approximately 200 Hz for free $HSiPh_3$.[96] The greater basicity of the Si–H bond relative to H–H and C–H bonds probably makes the Si–H unit a better σ donor. Since the Si–H bond is weaker than H–H and C–H bonds, the Si–H σ* orbital is more accessible and the Si–H unit is therefore a better π acceptor. Si···H distances in the range 1.7–1.85 Å are common (Si–H bond 1.48 Å, sum of the van der Waals radii 3.1 Å). These silane adducts with stretched Si–H bonds are not particularly reactive and do not lose silane or undergo nucleophilic attack at the silicon atom.

If a change in the ligands or silane substituents causes a buildup of negative charge on the metal atom or of positive charge on the Si atom, the increased back-donation to the Si–H σ* orbital causes the extent of oxidative addition to increase. Like stretched H_2 complexes, these silane complexes are very sensitive to electronic effects. The best indicators of the extent of oxidative addition are noted by Schubert et al.:[97] the coupling constant $J(Si,H)$, which decreases with advancing oxidative addition, the Mn–Si distance, which increases, and the $\Delta H^{\neq}$ value for dissociation of silane, which decreases. Table 2 shows some of the NMR and structural data for the Mn complexes $[(C_5H_4Me)Mn(CO)L(HSiR_3)]$. The ease of dissociative loss of silane in $[(C_5H_4Me)Mn(CO)_2(H\text{–}SiR_3)]$ follows the order $SiCl_3 \ll SiPh_3 < SiHEt_2$, as expected on the premise that the complex with the least stretched Si–H bond should lose silane most easily.[95]

Table 2. Data for $[(MeC_5H_4)Mn(CO)L(H\text{–}SiR_3)]$ reflecting the extent to which oxidative addition of silane has advanced (from ref. [95]).

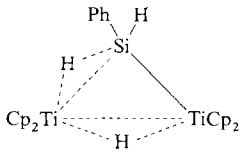
L	R_3	r(Mn-Si) [Å]	J(Si-H) [a] [Hz]	J(Si-Mn-H) [b] [Hz]
CO	HPh_2	2.364(2)	205.2	63.5
CN(*t*Bu)	HPh_2	–	194.1	57.5
$P(OPh)_3$	HPh_2	–	199	45
$P(p\text{-}ClC_6H_4)_3$	HPh_2	–	196	46.5
PPh_3	HPh_2	–	191	43
$P(p\text{-}MeC_6H_4)_3$	HPh_2	–	191	44.5
PMe_3	HPh_2	2.327(1)	188	38
CO	Cl_3	2.254(1)	–	54.8
PMe_3	Cl_3	–	–	20 [c]

[a] Coupling constant of the uncomplexed Si–H bond. [b] Coupling constant of the complexed Si–H bond. [c] Oxidative addition in this complex must be very advanced or even complete.

The crystal structures of the same series of Mn complexes suggest that the main change as the oxidative addition proceeds is a decrease in r(Mn–Si) rather than a change in r(Mn–H) or r(Si–H). This led Schubert to propose a reaction trajectory for oxidative addition in which the H atom of the Si–H unit approaches the metal center, and the Si–H unit then pivots so as to bring the Si atom up to the metal. This agrees with the trajectory we postulated later for the interaction of a C–H bond with a metal atom,[73] and with theoretical work.[98a] EH calculations carried out by Saillard, Schubert, et al.[98b] on $[CpMn(CO)_2(H\text{–}SiH_3)]$ are consistent with the bonding scheme in Figure 1. The Si–H overlap integral falls from 0.74 in the free Si–H bond to only 0.24 for Mn-Si-H, consistent with their being stretched σ complexes. The Si–H distances in the complexes in Table 2 are roughly 20% greater than Si–H distances in free sp^3-Si–H bonds; in comparison, the H–H bond in **4** is only 11% longer and typical agostic C–H bonds are <10% longer. Yang determined the energy of the coordination of an Si–H unit to the $CpMn(CO)_2$ complex fragment by photoacoustic calorimetry. Electron-donating R groups on silicon destabilize the adduct as do bulky SiR_3 groups, although the steric effect is

first evident at a cone angle of 135°.[99] In contrast, the binding energy of silanes to the $Cr(CO)_5$ complex fragment is strengthened by the presence of electron-releasing groups on Si. One explanation is that since the Cr fragment is predominantly a σ acid and not a π base, the basicity of the Si–H group is the controlling factor.[100] Thus, it is probable that the complexes $[(R_3Si–H)Cr(CO)_5]$ are unstretched.

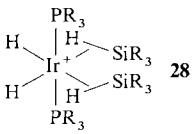
Several di- and polynuclear silane σ complexes are known, of which **27** is of particular interest. As d^1 centers the Ti



27

atoms are not very effective at backbonding, and the Si–H distances in **27** are only 7% longer than in the free silane, although the coupling constant J(Si,H) does show a substantial decrease on binding (from 148 Hz to 58 Hz for the terminal Si–H bond). The original tetrahedral geometry at the Si atom is also largely retained as opposed to the more distorted geometry at the Si atom in $[CpMn(CO)_2(H–SiR_3)]$. These observations indicate that **27** is an unstretched σ complex, rare for a silane.

The reactions of complexes **28** suggest that these are unstretched silane complexes. The silane is very easily dis-

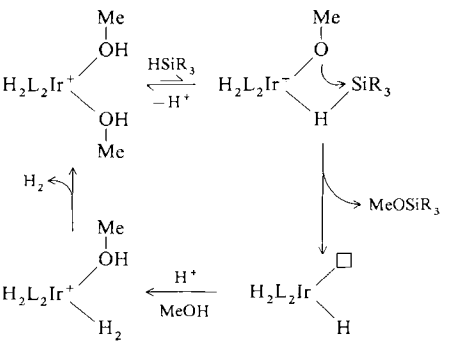


28

placed, consistent with a small extent of oxidative addition in **28**. The silane is also extremely sensitive to nucleophiles; **28** is the most efficient catalyst known for silane alcoholysis [Eq. (28)]. Mechanistic studies were consistent with the

$$R_3SiH + R'OH \longrightarrow R_3SiOR' + H_2 \qquad (28)$$

sequence shown in Scheme 1. Although the pathways via the silane σ complex and the oxidative addition product are kinetically indistinguishable, the spectroscopic data for **28** is much more consistent with a bis(silane)iridium(III) complex, at least for the resting state.[101] The electrophilicity induced



Scheme 1. The proposed mechanism of silane alcoholysis catalyzed by $[IrH_2(PPh_3)_2(H–SiR_3)_2]^+$ (from ref. [101]). □ = vacancy.

in the X–Y bond by binding to the metal atom and forming a σ complex is evident in this catalytic system as a large enhancement in the susceptibility of the system to nucleophilic attack at Si, rather than as an enhancement of proton acidity, no doubt because a free Si–H bond has a positive partial change on the silicon atom and a partial negative charge on the H atom.

Alternative formulations for **28** (L = PR_3) such as $[Ir(H)(SiR_3)(H–SiR_3)(H_2)L_2]^+$ and $[Ir(SiR_3)_2(H_2)_2L_2]^+$ could be ruled out from the long T_1(min) values. For a related Os complex, however, the T_1(min) value of 17 ms at 200 MHz indicates that the dihydrogensilyl tautomer $[Os(H_2)SiR_3(CO)L_2]$ dominates.[102a] The factors that govern this type of equilibrium are not yet understood. A clear-cut example of an unstretched silane complex $[\{(C_6H_{11})PSiH(mesityl)\}_3Cr(CO)_3]$ (J(Si,H) = 136 Hz, r(Si–H) = 1.52(4) Å, r(Cr–Si) = 2.616(1) Å, r(Cr–H) = 1.75(5) Å) has now been reported.[102b]

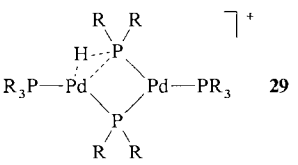
We were surprised to find that in contrast with other seven-coordinate complexes, $[ReH_2(SiPh_3)(CO)(PMe_2Ph)_3]$ is not fluxional by ^1H NMR spectroscopy.[103] An X-ray study showed a distorted geometry for the heavy atoms. Later we were able to crystallize $[ReH_6(SiPh_3)(PPh_3)_2]$, a complex first obtained by Ephritikhine, and show by X-ray and neutron diffraction that four H···Si distances are short (2.12–2.45 Å), although not as short as in $[CpMn(CO)_2(H–SiR_3)]$.[104] The presence of attractive interligand interactions was confirmed in theoretical work of Lin and Hall, which also showed that the P···H distances were rather shorter than normal (2.56 Å).[105] These interligand interactions may be responsible for the unusual fluxional properties of $[ReH_2(SiPh_3)(CO)(PMe_2Ph)_3]$.

Si-H-M intermediates have been proposed as the immediate precursors to the four-center transition state in sigma bond metathesis reactions.[106]

Schubert et al.[107] showed how Sn–H bonds behave as donors in σ complexes. For example, $[(C_5H_4Me)Mn(HSnPh_3)(CO)_2]$ has a Sn···H distance of 2.16 Å and $^1J(^{119}SnH)$ is 270 Hz; in comparison the values for the uncomplexed Sn–H bond are 1.6 Å and 1500–1800 Hz. This suggests that Sn–H bond in σ complexes tends to be even more stretched than the Si–H bond in the analogous complexes.

6. P-H-M and S-H-M Complexes

A σ complex with an agostic P–H bond **29** was reported by Pregosin, Albinati, et al.[108] as the protonation product of the corresponding neutral bis(μ-phosphanido) complex.



29

Four distinct signals for the R_2P groups are seen in the NMR spectrum, and instead of the normal J(P,H) values for terminal P–H bonds of 322–324 Hz, the μ-H atom has a J(P,H)

value of 151 Hz. NOE data suggest an r(P–H) of 1.9 Å. Since the location of the H atom is not easy to determine, it is quite possible that similar complexes lie unrecognized in the literature.

$[(PhS)Fe(CO)_3(PEt_3)]^-$ is protonated at $-80\,^\circ C$ to give as the kinetic adduct a complex assigned as $[(\eta^2\text{-PhS–H})Fe(CO)_3(PEt_3)]$, a σ complex with an S–H bond. It irreversibly converts to the classical hydrido complex $[PhSFeH(CO)_3(PEt_3)]$ on warming.[109]

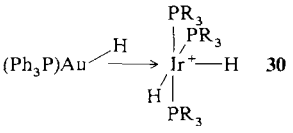
7. M-H-M and M-H-M′ Complexes

M-H-M complexes have been known for a long time, are of great importance in structural chemistry, and can be considered σ complexes of an M–H bond. The bridging hydride ligand does not seem to be particularly reactive, and as befits a σ complex, the M-H-M unit is always bent.[110] Venanzi et al.[111] exploited the synthetic consequences of the σ-bond concept by synthesizing a series of new M-H-M complexes from the reaction of various metal hydrides (18e) with coordinatively unsaturated metal complex fragments (16e) [Eq. (29)]. M-H-M complexes are usually stretched in the

$$[L_nM-H] + [M'L'_n] \longrightarrow [L_nM-H-M'L'_n] \qquad (29)$$

sense that the distance from M to the bridging H atom is usually substantially longer than to a terminal H atom. Possible exceptions are complexes with a weakly π-basic M′ atom such as Cu^+, but no neutron diffraction structures are available on any of these complexes yet.

The extension of reaction (29) to cases in which M′ is Cu^+, Ag^+, and $Au(PPh_3)^+$ produced some interesting heterobimetallic hydrido clusters.[112] A number of complexes are known in which Au-H-M bridges are present, for example, **30**.[113] The structure of **30** (R = Ph) is shown on the left side



30

of Figure 5; the P–Au and H–Ir vectors point to the center of the Au-H-Ir triangle, as befits a 3c-2e bond. The Au–H1/H2 bonds are fluxional and can be rationalized by the transfer of $(AuPPh_3)^+$ between the two Ir–H sites, in close analogy to the η^3-H_3 intermediate suggested for fluxional H atoms in M(H)(H_2) complexes. $[MeC(CH_2PPh_2)_3MH_3]$ (M = Rh, Ir) reacts with one and two $AuPPh_3^+$ groups to give MAu and MAu_2 hydrido complexes, respectively.[114] These are part of a series extending from the analogous H_2 complexes such as $[(H_2)IrH_2(PR_3)_3]^+$[115a] to the M-H-M complexes like $[(dppe)Rh(\mu\text{-}H)_2IrH_2(PR_3)_2]$ reported by Venanzi, Albinati, et al.[111] The structure of an interesting Au_4 complex with H bridges is shown in Figure 5 left.[116]

Both Caulton et al.[115b] and Venanzi et al.[114b] looked at the reactions of polyhydrides with Ag^+ and Cu^+ ions (M'^+). The structures of the products tend to contain M'_3 triangles or M'_6 octahedra (Fig. 6). Cu···Cu distances in

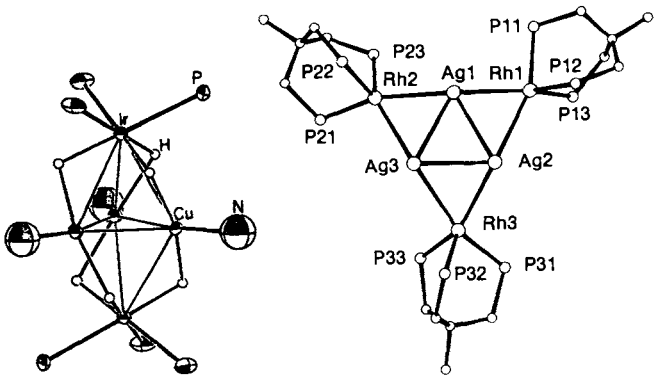


Fig. 6. The X-ray crystal structures of $[\{(MeCN)Cu\}_3\{(\mu\text{-}H)_3Ir(PMe_2Ph)_3\}_2]^{3+}$ (left) and $[Ag_3\{(\mu\text{-}H)_3Rh(PPh_2CH_2)_3CMe\}_3]^{3+}$ (right) cations. The hydrido ligands were not located in the Ag_3Rh_3 structure (from refs. [114b, 115b]).

$[\{(MeCN)Cu\}_3\{(\mu\text{-}H)_3Ir(PMe_2Ph)_3\}_2]$ are typically 2.6 Å and can clearly be interpreted as bonding. The interactions in some of these complexes are more complicated than simple σ complexation, and direct M′–M′ bonds are also possible.[117] $[H_{24}Cu_6Re_4(PPh_3)_8]^{2+}$ is an unusual hydride-rich cluster but the locations of the H atoms are as yet not known.[115c] Although the terminal $(AuPPh_3)^+$ complex fragment can formally replace H^+ in many hydrido complexes, replacing a μ-H ligand by the gold complex fragment does not always lead to a similar structure; an example where the structure is retained upon substitution is shown in **31** and **32**.[118] The Au_3 complex **33** would be isolobal with

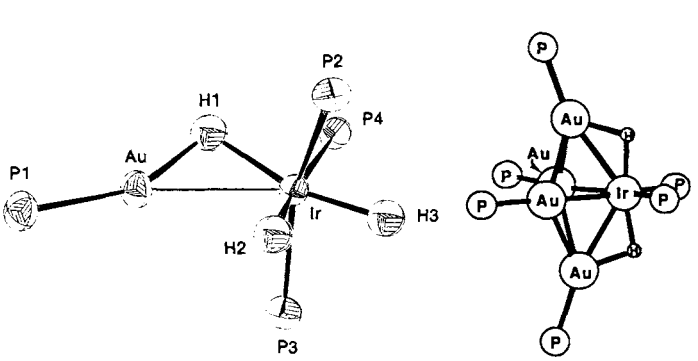

Fig. 5. Left: The X-ray crystal structure of $[(PPh_3)Au(\mu\text{-}H)IrH_2(PPh_3)_3]^+$. Note how the P1–Au and H3–Ir vectors point to the center of the Ir-Au-H^1 triangle (from ref. [113]). 31 **32**

33

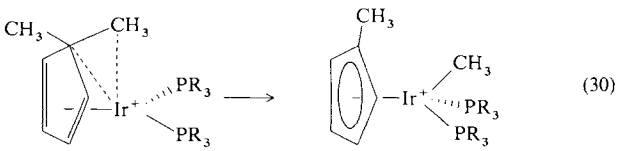
an as yet unknown trihydrogen analogue.[119] Albinati, Venanzi, et al. proposed that the bonding is not simply of the

σ type but that direct $M(d_\pi) \rightarrow Au(p)$ interactions may also contribute.[120]

8. Can X–Y σ Complexes Exist if X ≠ H, Y ≠ H?

For strong complexation in X–Y σ complexes, one of the two atoms X or Y must be a H atom. If X or Y has a lone pair or the ligand has an X–H bond, then these will bind preferentially to the metal atom. In $[IrH_2(PPh_3)_2(IMe)_2]^+$ the MeI ligand can bind to the Ir atom without the C–I bond breaking.[121] Crystallographic studies show, however, that the I atom binds to the Ir center through its lone pair. Since the C–I σ bond is not involved, these are not σ complexes. An enhancement of the electrophilicity of the MeI ligand is certainly observed, but it is much more modest than in σ complexes; only a strong nucleophile like an enamine can attack MeI, but not a weak one like MeOH. A main group compound like $Me_2Al(\mu\text{-}Me)_2AlMe_2$, is a σ complex of an Al–C bond, but similar bridges are not seen in transition metals.

In a few complexes the X–Y bond of the ligand (X,Y ≠ H) is very close to the metal atom. For example, **34**[122] has short nonbonded Ir···C distances of 2.80 and 3.39 Å. On heating, the complex rearranges by the Green–Eilbracht[123] reaction, which corresponds to the oxidative addition of a C–C bond, to give **35** [Eq. (30)]. Unlike the analogous reactions of C-H-M complexes in which the activation energy is low, heating at 150 °C is required for the rearrangement of **34**.



(30)

34 **35**

Another remarkable class of clusters of the type $[M\{Au(PPh_3)\}_n]$, including $[Pt\{Au(PPh_3)\}_8]^{2+}$ (**36**), was reported by Steggerda.[124] In these complexes the Au···Au distances of 2.8–3.15 Å are very short (2.67 Å in Au metal). In the isolobal polyhydrido complexes a pair of H ligands interacts, but here all the Au atoms, not just a pair, interact because they are essentially close packed around the Pt atom. It is still not clear if complexes like **34** and **36** can be described as σ complexes. Pignolet et al. recently reported that **36** catalyzes very rapid (one turnover per second for the solid) isotope exchange in H_2/D_2 mixtures and has proposed that $M(H_2)$ and M-H-Au complexes are reactive intermediates.[125]

9. Complexes with Three-Center, Four-Electron X-H-M Bridges

Some complexes with X-H-M bridges are not σ complexes, as shown by Brammer et al.[126] These bridges resemble conventional hydrogen bonds and are considered 3c-4e interactions. Their distinguishing characteristics are: 1) the X-H-M group is linear and not bent; 2) on complex formation the signal of the bridging hydrogen atom moves to low field in the ^1H NMR spectrum rather than high field; 3) the bridge can form even if the metal atom has an 18e configuration, in contrast to a σ complex. The open or linear geometry as in H_3^- (**37**) is characteristic of a 3c-4e interaction, while the

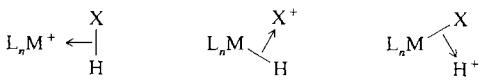
$[H{-}H{-}H]^-$ **37**

closed, triangular, or side-on arrangement is characteristic of a σ interaction as in H_3^+ (**2**).[127]

The X-H-M bridge is essentially a hydrogen bond, since X is usually an electronegative atom (N atom), an electronegative group, or a carbon-bearing electronegative substituent. A careful neutron diffraction study of $[Et_3NH][(Co(CO)_4)]$ at 15 K shows that the Co···H distance is 2.613 Å, close to but somewhat less than the sum of the van der Waals radii (ca. 3 Å), and just within the range of M···H distances (1.8–2.8 Å) found in agostic systems. The N–H distance in this complex is 1.054 Å, somewhat longer than the average distance (1.033 Å by neutron diffraction) in free R_3NH^+ ions; the N–H···Co angle is 180°. The $[Co(CO)_4]^-$ ion has a distorted tetrahedral symmetry; three OC-Co-CO angles open up by about 6° to give an approximately C_{3v} arrangement. The ^1H NMR signal of the bridging proton is at $\delta = 8.31$ in C_6D_6, a chemical shift very different from those of agostic complexes. Other similar examples but with a smaller M···H separations are known, for example, in $[Pt\text{-}Br(C_{10}H_6NMe_2)(C_{10}H_6NMe_2)]$ $r(Pt\cdots H) = 2.11$ Å.[128]

10. Characteristics of σ Complexes

Structures **38**–**40** are three possible representations of $[L_nM(HX)]$ complexes. Their relative importance is likely to depend on the electronegativity of L_nM, X, and H. Normally, the L_nM fragment will be the most electropositive and **38** will be dominant. Structure **40** gives the H atom its enhanced acidity, but its significance decreases when the L_nM complex fragment is a better donor (and therefore more electropositive) or when the X atom becomes more electropositive (as in SiHM complexes). Structure **39** ($X = SiR_3$) gives unstretched Si-H-M complexes their enhanced sensitivity to nucleophilic attack at the Si atom with the M–H unit as leaving group.



38 **39** **40**

All σ complexes have a closed or bent structure appropriate for a 3c-2e bond. For the XY group to bind, the metal must be coordinatively unsaturated in order to be able to accept the electron pair of the XY σ bond. So far, one of the two atoms, X or Y, has to be a H atom. This allows the close approach of the X–H bond to the metal atom and back-donation into the XH σ* orbital. Two extreme structures can be distinguished: unstretched σ bond complexes in which the X–Y bond is weakened only a little relative to free XY, and stretched σ complexes in which the structure more closely resembles the product of the oxidative addition of the XY

ligand to the metal atom with some attractive interaction between the X and Y atoms. Depending on the XY unit, the unstretched (e.g. XY = H_2, CH) or the stretched (e.g., XY = SiH, SnH) σ complexes are more common. In the unstretched σ complexes, the electrophilic character of the XY unit is greatly enhanced. In $M(H_2)$ and C-H-M complexes, this is reflected by the enhanced acidity of the H atom. In SiH complexes, the result is enhanced sensitivity to nucleophilic attack at the Si atom. In these ways, σ complexation provides a powerful method for X–Y bond activation.

11. Conclusion

Although σ complexation is a widespread phenomenon, this area of research is still at an early stage of development. Patterns are now emerging as different classes of σ complexes are compared. Although the M–(XY) binding energies are often low, σ binding can have a large effect on the chemistry of the X–Y bond. σ Complexes are often intermediates or transition states in reactions such as oxidative addition and alkene insertion, and the added stabilization contributes to lowering the activation energy for the reactions. σ Complexation also provides a way to stabilize what would otherwise be coordinatively unsaturated species. σ Complexes are intermediates in reactions in which the enhanced electrophilicity of the X–Y bond induced by binding activates the bond for nucleophilic attack. σ Complexation allows a metal to activate a σ bond without oxidative addition by sigma bond metathesis. For a metal with a d^2 or higher configuration this merely provides an alternative pathway to oxidative addition, but for d^0 systems, oxidative addition is not possible. Our understanding of the role of σ complexation in chemistry is still in a primitive state.

I would like to thank Professors M. L. H. Green, O. Eisenstein, J. W. Faller, J. H. Prestegard, R. H. Morris, D. M. Heinekey, M. Saunders, and K. W. Zilm for helpful discussions. I thank the Centre National de la Recherche Scientifique for financing a visit to the Laboratoire de Chimie Théorique at Orsay, where this review was written, the National Science Foundation for funding our research in this area, and my successive co-workers, Maryellen Lavin, Douglas Hamilton, Ana Albéniz, Xiao-Liang Luo, and Demetrius Michos, who have contributed most of the ideas in our work.

Solid-State Chemistry with Nonmetal Nitrides

By Wolfgang Schnick*

Among the nonmetal nitrides, the polymeric binary compounds BN and Si_3N_4 are of particular interest for the development of materials for high-performance applications. The outstanding features of both substances are their thermal, mechanical, and chemical stability, coupled with their low density. Because of their extremely low reactivity, boron and silicon nitride are hardly ever used as starting materials for the preparation of ternary nitrides, but are used primarily in the manufacture of crucibles or other vessels or as insulation materials. The chemistry of ternary and higher nonmetal nitrides that contain electropositive elements and are thus analogous with the oxo compounds such as borates, silicates, phosphates, or sulfates was neglected for many years. Starting from the recent successful preparation of pure P_3N_5, a further binary nonmetal nitride which shows similarities with Si_3N_4 with regard to both its structure and properties, this review deals systematically with the solid-state chemistry of ternary and higher phosphorus(v) nitrides and the relationship between the various types of structure found in this class of substance and the resulting properties and possible applications. From the point of view of preparative solid-state chemistry the syntheses, structures, and properties of the binary nonmetal nitrides BN, Si_3N_4, and P_3N_5 will be compared and contrasted. The chemistry of the phosphorus(v) nitrides leads us to expect that other nonmetals such as boron, silicon, sulfur, and carbon will also participate in a rich nitride chemistry, as initial reports indeed indicate.

1. Introduction

Nitrogen, the main component of the atmosphere, is omnipresent. The lightest element in the fifth main group plays an important role in chemical compounds, in particular in the oxidation states v and III (NO_3^- and NO_2^-, respectively) as well as −III (NH_3, $-NH_2$, −NH−, and $\gtrless$N−). The oxidation state of nitrogen in the nitrides is also −III; only a few hundred nitrides have so far been characterized, although for example the neighboring element oxygen has been shown to form more than ten thousand oxides. In spite of this relatively small number, the nitrides include some extremely useful compounds: silicon nitride, Si_3N_4, has become an important nonoxidic material, whose applications range from ceramic turbochargers to integrated semiconductor modules.[1, 2] Because of its unusually high thermal conductivity ($285\,Wm^{-1}K^{-1}$[3]), aluminum nitride is predestined for use as a substrate material in semiconductor manufacture. Boron nitride is used as a high-temperature crucible material, as a lubricant (hexagonal (*h*)-BN), and in the abrasives sector (cubic (*c*)-BN). In recent years *h*-BN has also become increasingly important in the manufacture of composite materials.

The extreme stability of the substances, which are used as high-performance ceramics, is due in part to the strengths of the bonds joining the constituent elements; a second important factor is the presence of highly crosslinked structures in the solid state. When the electronegativity difference is only small, heteronuclear bonds with a high degree of covalent character are formed. The high chemical, thermal, and mechanical stability of nitridic materials such as silicon nitride or boron nitride results from the interplay of these two factors: extremely strong bonds between the elements and the presence of highly crosslinked covalent structures.

Besides these two criteria, the extremely high bond energy of N_2 (941 $kJmol^{-1}$) as a possible decomposition product of the nitrogen compounds is also of importance when discussing the thermal stability of nitridic materials. Compared with the corresponding oxides, the thermal dissociation of many nitrides with evolution of N_2 (for the oxides O_2, bond energy: 499 $kJmol^{-1}$) occurs at much lower temperatures. Thus, the elimination of N_2 from Si_3N_4 occurs at atmospheric pressure at about 1900 °C, while SiO_2 can be heated to over 2000 °C without any noticeable decomposition. Aluminum nitride decomposes above about 1800 °C, while the extrapolated boiling point of Al_2O_3 is about 3000 °C.

The affinity of most elements for oxygen is larger than that for nitrogen, thus the bond energies for element–oxygen bonds are generally higher than those of the corresponding element–nitrogen bonds (single bond energies: Si–O = 444, Si–N = 335; P–O = 407, P–N = 290 $kJmol^{-1}$[4]). Similarly the bond enthalpies of the oxides are significantly higher than those of the corresponding nitrides ($\Delta H_f^0(SiO_2) = -911$, $^1/_3[\Delta H_f^0(Si_3N_4)] = -248$; $^1/_2[\Delta H_f^0(B_2O_3)] = -637$, $\Delta H_f^0(BN) = -254$; $^1/_2[\Delta H_f^0(Al_2O_3)] = -838$, $\Delta H_f^0(AlN) = -318\,kJmol^{-1}$[5]), although a quantitative comparison is difficult because of their differing compositions.

The formation of oxides is thus an important side reaction in the syntheses of nitrides. Thus, the preparation of nitrides in a pure state requires the complete exclusion of oxygen and water. This precondition has certainly previously played an important role in hindering a detailed investigation of nitrides.

Among the theoretically possible binary main group element nitrides with nitrogen in the oxidation state −III and the electropositive elements in the maximum oxidation state corresponding to their group number, many are either nonexistent or have until now not been obtained in a pure

[*] Prof. Dr. W. Schnick

Telefax: Int. code (921)55-2535

and well-defined form because of their low stability (Fig. 1). Li_3N exhibits an unusually high tendency for formation; the reaction between lithium metal and molecular nitrogen starts at room temperature and atmospheric pressure without any additional activation. In contrast, there is no reliable evidence for the existence and stability of analogous compounds of the heavier alkali metals. Apparently in the nitrides M_3N (M = Na, K, Rb, Cs) the high formal charge of the nitride ion (N^{3-}) and the unfavorable molar ratio of cations to anions (3:1) make it impossible to form a stable ionic structure in which the electrostatic, coordinative, and lattice-energetic requirements of a stable solid material are fulfilled. For the alkaline earth metals, binary nitrides with the composition M_3N_2 are, however, known for all the elements.

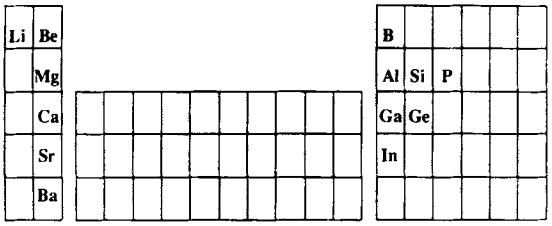

Fig. 1. Binary nitrides are only known for a fraction of the main group elements in the maximum oxidation state corresponding to their group numbers.

In contrast to the ionic structures of the nitrides of lithium and the alkaline earth metals, the decreasing electronegativities from the third group onwards lead to the formation of compounds with more covalent character (e.g. BN, AlN, Si_3N_4). As the group number increases, the heavier homologues in their highest oxidation state show a clearly decreasing tendency to form stable binary nitrides: In the third main group TlN is "missing", while in the neighboring group tin and lead form no stable nitrogen compounds with the expected stoichiometry M_3N_4.[6] This trend continues up to the sixth main group; here no compounds with the composition $M^{VI}N_2$ (M = S, Se, Te) are known. In some cases the instability of the element–nitrogen bond appears to be responsible for the nonexistence of the corresponding binary nitrides. Thus stable molecular compounds of antimony(v) and nitrogen are only formed when the basicity of the nitrogen atoms is decreased by electron-withdrawing groups or by mesomeric effects,[7] a requirement which is hardly realizable in the speculative compound Sb_3N_5. In the case of other main group elements (e.g. carbon and sulfur) the reasons for the hitherto nonexistence of corresponding binary nitrides (C_3N_4 and SN_2) appear to be more complex or to be due to preparative problems.

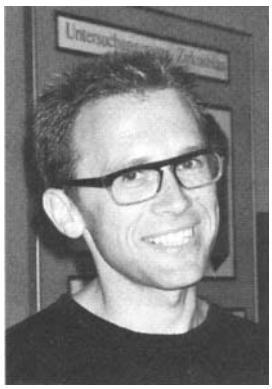
The binary nonmetal nitrides BN, Si_3N_4, and P_3N_5 will be main subjects of the following discussion. These are the only nonmetal nitrides so far studied in detail in which the electropositive elements have the maximum possible oxidation state corresponding to their group number. The syntheses, structure, and properties of BN and Si_3N_4 were described many years ago. However, both compounds had been studied because of their application in the area of high-performance materials. Because of preparative difficulties, pure phosphorus(v) nitride has only recently been obtained. Although P_3N_5 is thermodynamically appreciably less stable than BN or Si_3N_4, it has still been possible to develop a multifaceted solid-state chemistry of the phosphorus(v) nitrides. This success has provided the impetus for a further systematic search for new ternary and higher nonmetal nitrides.

2. The Binary Nonmetal Nitrides BN, Si_3N_4, and P_3N_5

Binary nitrides form the basis for the syntheses of ternary or higher nonmetal nitrides containing electropositive elements. Innumerable methods for the preparation of these compounds are known; however, only a limited number of these procedures which afford pure, well-defined products can be readily carried out under laboratory conditions. Such methods must be applied when the binary nitrides are to be used in the syntheses of new compounds.

2.1. Boron Nitride BN

Within the family of known ceramic materials boron nitride has the lowest density ($\varrho = 2.27\ g\,cm^{-3}$). It is colorless in the pure state and sublimes at about 2330 °C under a nitrogen pressure of one atmosphere.[8] Its decomposition



Wolfgang Schnick, born in 1957 in Hannover, studied chemistry at the Universität Hannover and received his doctorate there in 1986, having worked with Martin Jansen on alkali metal ozonides. After a postdoctoral year with Albrecht Rabenau at the Max-Planck-Institut für Festkörperforschung in Stuttgart he moved to the Universität Bonn. His habilitation in the field of inorganic chemistry was completed at the beginning of 1992. His particular interest within the area of preparative solid-state chemistry lies with the nitrides; his work is mainly concerned with their preparation and characterization, and the determination of the relationship between structures and properties. A further main area of interest involves the preparation of new types of compounds which can potentially be used as ceramic materials, ionic conductors, pigments, and catalysts. In 1989 Wolfgang Schnick was awarded the Benningsen–Foerder Prize of Nordrhein-Westfalen and in 1992 he received a Heisenberg scholarship from the Deutsche Forschungsgemeinschaft. In addition, he obtained a "Dozentenstipendium" from the Fonds der Chemischen Industrie and the Academy Prize of the Göttinger Akademie der Wissenschaften. Since 1993 he has been a Professor of Inorganic Chemistry at the Universität Bayreuth.

vapor pressure (N_2) is 1.6 Pa at 1900 °C and 573 Pa at 2300 °C,[8] while under a high nitrogen pressure (50 MPa) boron nitride melts at about 3300 °C.[9] Its thermodynamic data are also known.[8, 10] Boron nitride is isoelectronic with elemental carbon and, like the latter, occurs in several modifications. Hexagonal boron nitride (*h*-BN, α-BN) is the most stable form under normal conditions. It is analogous to graphite in that it contains planar layers of condensed six-membered $[B_3N_3]$ rings (d(B–N) = 145 pm). In contrast to carbon (staggered stacking) these layers are stacked directly above each other, so that the boron atoms of one layer are in direct contact with the nitrogen atoms of the neighboring layers (d(B···N) = 333 pm). Under normal conditions the cubic (*c*-BN, β-BN) and hexagonal (γ-BN) forms of boron nitride with zinc blende- and wurtzite-type structures, respectively, are metastable.[8]

Many procedures for the preparation of boron nitride have been suggested.[10] Exceptionally pure products are obtained from the reactions of boron trichloride BCl_3 with NH_3 or N_2/H_2 at temperatures below 1300 °C, or by microwave discharge.[10, 11] Oxygen-free boron nitride can also be prepared from the reaction of $K[BH_4]$ with NH_4Cl at temperatures up to 1050 °C.[10] A number of industrial methods for the synthesis of boron nitride are also known, although they do not always afford pure products. These include the reactions of oxygen-containing boron compounds such as B_2O_3 or $B(OH)_3$ with nitriding compounds such as urea, biuret ($NH(CONH_2)_2$), dicyandiamide, or melamine and the carbothermal reduction of B_2O_3 with carbon and nitrogen at 1800 to 1900 °C.[10] The reaction of alkaline earth metal cyanamides ($CaCN_2$, $SrCN_2$, $BaCN_2$) with boric acid $B(OH)_3$ leads to mixtures of *h*-BN and the corresponding borates and cyanides.[10, 12] The direct nitridation of elemental boron can also be carried out at temperatures above 1200 °C; however, this process is of neither industrial nor preparative importance.[10, 11] Chemical vapor deposition (CVD) of boron nitride has been attempted starting from a large number of volatile, molecular boron compounds, which are particularly suitable for the formation of amorphous or crystalline thin films or fine powders.[8] Several boron-containing polymers have also been used as precursors for BN.[13] Under typical laboratory conditions most processes afford *h*-BN, which is either amorphous or has a strongly disordered crystalline structure; these can, however, be converted to a regular crystalline state by suitable thermal aftertreatment.[8, 10] The conversion of hexagonal (α-BN) to cubic (β-BN) boron nitride at high pressures and temperatures is favored when Li_3BN_2 or Mg_3BN_3 are used.[14]

2.2. Silicon Nitride Si_3N_4

Silicon nitride is at present the most important nitridic material in the area of high-performance applications[15] because of its great hardness (Vickers hardness = 1400–1700 MNm^{-2}), its high mechanical strength (up to about 1300 °C), and its low density ($\varrho = 3.2\ g cm^{-3}$). Pure Si_3N_4 decomposes above about 1900 °C. Crystalline silicon nitride exists in two polymorphous modifications (α-Si_3N_4, β-Si_3N_4); in both cases the structures consist of topologically similar three-dimensional networks composed of corner-sharing SiN_4 tetrahedra (d(Si–N) ≈ 174 pm (mean value))[16] (Fig. 2). The two modifications differ only slightly in their lattice energies (difference ≈ 1.3 %[17]); the heat of conversion has been estimated to be about 30 $kJ mol^{-1}$.[17] Because of this small difference in stability the two phases can coexist. The proportion of the α-modification increases as the temperature at which the Si_3N_4 is prepared decreases. The reconstructive phase transition (above 1650 °C) only takes place in the direction α-Si_3N_4 → β-Si_3N_4; the reverse reaction appears to be kinetically hindered.

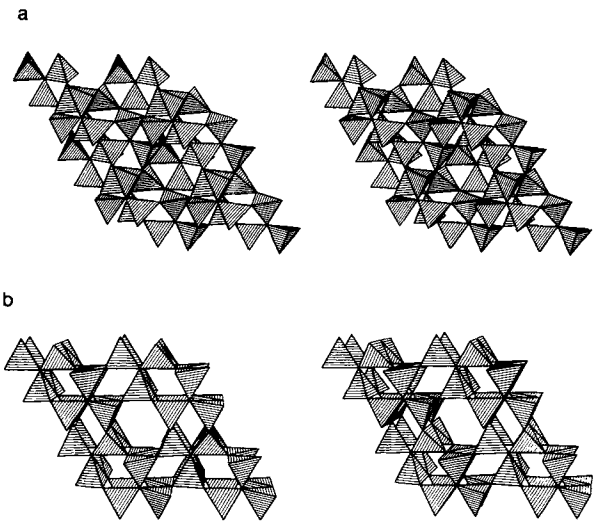


Fig. 2. Crystal structures of α-Si_3N_4 (a) and β-Si_3N_4 (b) (stereoscopic representation looking along [001]). The SiN_4 tetrahedra are shown as closed polyhedra.

Three methods for the preparation of pure silicon nitride are of particular importance and are also used industrially: the direct nitridation of elemental silicon,[15, 18–21] the carbothermal reduction of silicon dioxide under a nitrogen or ammonia atmosphere,[15, 22–26] and the ammonolyses of $SiCl_4$ or SiH_4.[15, 27–31] The ammonolysis reactions are particularly suitable for preparative purposes; they lead initially to amorphous and relatively undefined silicon diimide $Si(NH)_2$, which is converted at temperatures above about 900 °C to amorphous Si_3N_4 and above about 1300 °C to α-Si_3N_4.[15, 27–29, 32]

2.3. Phosphorus(v) Nitride P_3N_5

In contrast to the well-studied nitrides BN and Si_3N_4, very little reliable information on the synthesis, structure, and properties of P_3N_5 was available for a long time. Thus, phosphorus(v) nitride is only mentioned in passing in Allcock's monograph on phosphorus–nitrogen compounds,[33] while it takes up only a few lines in Corbridge's thousand-page book on phosphorus compounds.[34]

In principle it should be possible to prepare P_3N_5 by methods analogous to those used for BN and Si_3N_4. However, neither the direct nitridation of elemental phosphorus in low-pressure plasma[35] nor the simple ammonolysis of molecular phosphorus compounds such as PCl_5, P_4S_{10}, $(PNCl_2)_3$, $(PN(NH_2)_2)_3$, or $SP(NH_2)_3$[36–42] lead to the formation of pure, crystalline, and well-defined phosphorus(v)

nitride. Such attempts lead in fact to amorphous products that in some cases still contain chlorine, sulfur, or hydrogen; these generally have a very large surface area and cannot be characterized further. The main problem in the synthesis of pure crystalline P_3N_5 is that this nitride is much less thermally stable than BN or Si_3N_4; thus, decomposition with evolution of nitrogen occurs above about 850 °C [Eq. (1)].

$$2\,P_3N_5 \longrightarrow 6\,PN + 2\,N_2 \longrightarrow 3\,P_2 + 5\,N_2 \quad (1)$$

Brown undefined amorphous phosphorus(III) nitride is formed in this reaction; thus, in contrast to the situation for boron or silicon nitride it is not possible to remove impurities (such as H, Cl or S) simply by raising the temperature and thereby obtaining monophasic P_3N_5. The preparation of pure crystalline P_3N_5 starting from molecular phosphorus compounds is thus a tightrope walk between incipient thermal decomposition and sufficient activation of the P–N bonds (cleavage and reformation) for the construction of an ordered crystalline solid via amorphous polyphosphazene intermediates.[43] Since thermal activation alone is insufficient, the necessary P–N bond breaking and formation must be supported by chemical means.

The ammonolysis of PCl_5 or $(PNCl_2)_3$ using NH_4Cl rather than NH_3 at temperatures below 800 °C indeed leads to the formation of colorless, microcrystalline compact P_3N_5 that is hydrogen- and chlorine-free [Eqs. (2), (3)]. It seems likely that the HCl present, which in pure form decomposes P_3N_5 at higher temperatures with the formation of volatile products, leads to the reversible and reconstructive formation of crystalline P_3N_5.[43]

$$(PNCl_2)_3 + 2\,NH_4Cl \xrightarrow{780\,^\circ C,\ 2d} P_3N_5 + 8\,HCl \quad (2)$$

$$3\,PCl_5 + 5\,NH_4Cl \xrightarrow{780\,^\circ C,\ 2d} P_3N_5 + 20\,HCl \quad (3)$$

According to IR, EXAFS, ED, HRTEM, and ^{15}N and ^{31}P solid-state MAS NMR spectroscopic studies,[*] phosphorus(v) nitride P_3N_5 has a three-dimensional network, consisting of corner-sharing PN_4 tetrahedra (d(P–N) = 160 pm).[43] The solid, formulated as ${}^3_\infty[P^{[4]}_3N^{[3]}_2N^{[2]}_3]$, contains two types of nitrogen atom in a molar ratio of 2:3, which are linked to three and two phosphorus atoms, respectively.[43] Because of a stacking disorder in P_3N_5 demonstrated by HRTEM,[43] it has so far not been possible to carry out a complete single-crystal X-ray structural analysis. However, recently, completely ordered single crystals of P_3N_5 have been obtained.[43]

3. Ternary and Higher Phosphorus(v) Nitrides

The combination of the two elements phosphorus and nitrogen is isosteric with a corresponding combination of silicon and oxygen. This fact stimulated the systematic study of the siloxanes (typical building block: $-R_2Si-O-SiR_2-$)[44,45] in analogy to the isosteric phosphazenes (typical building block: $-R_2P=N-PR_2=$). Wide-ranging systematic investigations of the chemistry of molecular P–N compounds have led to the discovery of a very large number of well-characterized monomeric, oligomeric, and polymeric phosphazenes; these can contain diverse substituents R (such as F, Cl, Br, NH_2, NR_2, CF_3, N_3, NCS, NCO). It has proved possible not only to synthesize chain-like and cyclic phosphazenes of widely varying molecular size but also to cross-link such units to give polymeric materials with exactly tailored properties.[33,34,46] In contrast to the phosphazenes, the siloxanes are, however, much less readily accessible; thus, the systematic investigation of this class of compounds has taken place only relatively recently.[44,45]

The situation is completely opposite in the case of the corresponding Si–O and P–N solid-state compounds. While a large group of preparatively readily accessible Si–O compounds (silicates, silicon dioxide)[47] is known which also includes a number of naturally occurring species (e.g. quartz, pyroxene, amphibole, kaolinite, pyrophillite, mica, feldspar), there were only a few indications of the possible existence of analogous P–N compounds.[48,49] The analogy between silicon oxides (silicates) and phosphorus(v) nitrides is, however, not so close as the isostericity between molecular siloxanes and phosphazenes discussed previously, in which in each case a molar ratio of Si:O = P:N = 1:1 is involved. The consideration of typical silicate building blocks and the corresponding phosphorus–nitrogen isosteres shows the formal charge to be different in each case: SiO_4^{4-}/PN_4^{7-}, $Si_3O_9^{6-}/P_3N_9^{12-}$, SiO_2/PN_2^-. When these charges are compensated in ternary compounds by cations of electropositive elements (e.g. alkali metals or alkaline earth metals), we can expect that mainly covalent P–N substructures as well as contacts between nitrogen and the cations with clearly ionic character will be formed. Thus, in spite of their differing overall composition the phosphorus(v) nitrides should contain P–N substructures which have isosteric analogues within the silicate family.

For a long time it proved impossible to prepare phosphorus(v) nitrides in a pure crystalline form, and no reliable information existed on the structure and properties of particular compounds. The greatest problem was that pure P_3N_5 was not available as a starting material for the preparation of such compounds. Thus, the development of a route to well-defined phosphorus(v) nitride (see Section 2.3) was a basic precondition for the systematic study of ternary and higher phosphorus(v) nitrides containing electropositive elements.

3.1. Alkali Metal and Alkaline Earth Metal Phosphorus(v) Nitrides

Ternary phosphorus(v) nitrides derived from metals should be accessible from the corresponding binary nitrides. The analogy with oxo chemistry suggests that a reaction between an "acidic" nonmetal nitride (P_3N_5) and a "basic" metal nitride should be successful. For various reasons the quasibinary Li_3N/P_3N_5 system appeared to be particularly suitable for the systematic study of the ternary phosphorus(v) nitrides: Among the alkali metals only lithium forms a binary nitride with the composition M_3N (M = Li, Na, K,

[*] EXAFS = extended X-ray absorption fine structure, ED = electron diffraction, HRTEM = high-resolution transmission electron microscopy, MAS = magic angle spinning.

Rb, Cs). Lithium nitride is readily available from its constituent elements;[50] in addition its thermodynamic stability is sufficient to permit reactions with phosphorus(v) nitride to be carried out in the temperature range 600–850 °C.

The quasibinary Li_3N/P_3N_5 system has so far afforded four lithium phosphorus(v) nitrides, which have been prepared in a pure form and characterized both structurally and with respect to their properties: Li_7PN_4,[51] $Li_{12}P_3N_9$,[52, 53] $Li_{10}P_4N_{10}$,[54] and $LiPN_2$[55] can in each case be prepared in solid-state reactions between stoichiometric amounts of the binary nitrides Li_3N and P_3N_5 [Eqs. (4)–(7)]. A crucial factor

$$7\,Li_3N + P_3N_5 \xrightarrow[\text{W crucible, } N_2 \text{ atm.}]{620\,^\circ C,\ 4d} 3\,Li_7PN_4 \quad (4)$$

$$4\,Li_3N + P_3N_5 \xrightarrow[\text{W crucible, } N_2 \text{ atm.}]{750\,^\circ C,\ 5d} Li_{12}P_3N_9 \quad (5)$$

$$10\,Li_3N + 4\,P_3N_5 \xrightarrow[\text{W crucible, } N_2 \text{ atm.}]{720\,^\circ C,\ 5d} 3\,Li_{10}P_4N_{10} \quad (6)$$

$$Li_3N + P_3N_5 \xrightarrow[\text{W crucible, } N_2 \text{ atm.}]{800\,^\circ C,\ 4d} 3\,LiPN_2 \quad (7)$$

in these reactions is the choice of the crucible material, since at the temperatures used lithium nitride reacts with all the standard materials. Pure tungsten metal is particularly suitable for the crucibles for these reactions, since under the reaction conditions used the interior of the crucible is passivated by a layer of tungsten nitride, which, when all the experimental parameters (temperature, reaction time, particle size of the Li_3N used) are optimized, prevents a further attack on the crucible to give Li_6WN_4.

Besides reactions between the binary nitrides, it is also possible to react the lithium phosphorus(v) nitrides themselves with Li_3N or P_3N_5 to obtain the corresponding ternary phases [Eqs. (8)–(11)].

$$2\,Li_3N + LiPN_2 \xrightarrow[\text{W crucible, } N_2 \text{ atm.}]{620\,^\circ C,\ 14d} Li_7PN_4 \quad (8)$$

$$2\,Li_3N + 4\,LiPN_2 \xrightarrow[\text{W crucible, } N_2 \text{ atm.}]{700\,^\circ C,\ 5d} Li_{10}P_4N_{10} \quad (9)$$

$$6\,P_3N_5 + 10\,Li_7PN_4 \xrightarrow[\text{W crucible, } N_2 \text{ atm.}]{630\,^\circ C,\ 10d} 7\,Li_{10}P_4N_{10} \quad (10)$$

$$3\,Li_3N + 3\,LiPN_2 \xrightarrow[\text{W crucible, } N_2 \text{ atm.}]{770\,^\circ C,\ 5d} Li_{12}P_3N_9 \quad (11)$$

The lithium phosphorus(v) nitrides are obtained from these syntheses as colorless powders or transparent single crystals. The sensitivity of the compounds towards hydrolysis increases with increasing lithium content and their thermal stability decreases. While $LiPN_2$ is stable up to about 900 °C and is hardly affected by moist air or water, Li_7PN_4 decomposes above 650 °C and is hydrolyzed by water in a violent reaction. The two other ternary compounds $Li_{12}P_3N_9$ and $Li_{10}P_4N_{10}$ take up an intermediate position in both respects, decomposing above about 780 °C and being somewhat sensitive towards hydrolysis.

All the lithium phosphorus(v) nitrides referred to have an ionic structure consisting of Li^+ ions and complex P–N anions. The common structural features are the PN_4 tetrahedra, which can be linked in different ways through common vertices: Li_7PN_4 contains "isolated" $[PN_4]^{7-}$ ions (mean P–N bond length = 171 pm), which are isoelectronic with orthosilicate $[SiO_4]^{4-}$ and orthophosphate $[PO_4]^{3-}$ building blocks. In the cubic unit cell of Li_7PN_4, the complex anions are arranged in a manner analogous to the β-tungsten type (A15) (Fig. 3), while the Li^+ ions are tetrahedrally coordinated by the nitrogen atoms of the PN_4 tetrahedra. The crystal structure of Li_7PN_4 can be considered as an anti-fluorite type. Thus, the nitrogen atoms adopt a distorted cubic close packing, in which Li^+ ions and phosphorus atoms occupy all the tetrahedral holes in an ordered manner.[51]

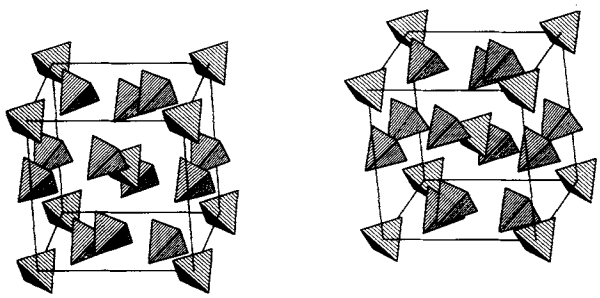

Fig. 3. Unit cell of Li_7PN_4 (stereoscopic representation). The PN_4 tetrahedra are shown as closed polyhedra; for the sake of clarity the Li^+ ions are not shown [51].

At the quasibinary Li_3N/P_3N_5 intersection, $LiPN_2$ is found as the compound with the lowest lithium content. PN_4 tetrahedra are again the characteristic building blocks of the P–N substructure. However, because of the molar ratio P:N = 1:2 they are not isolated but form a three-dimensional infinitely linked network $^3_\infty[PN_{4/2}^-]$, which is topologically equivalent to and isoelectronic with β-cristobalite (SiO_2) (d(P–N) = 164.5(7) pm, $\sphericalangle$ P-N-P = 123.6(8)°[55]). Compared with the C9 type (the idealized β-cristobalite structure), $LiPN_2$ is clearly distorted; all the PN_4 tetrahedra are rotated by an angle $\varphi = 34.2°$ about their axes of inversion. According to O'Keeffe and Hyde,[56] a distortion of this type starting from a filled variant of the C9 type ($\varphi = 0°$) leads, by a continuous transformation, to the chalcopyrite type ($\varphi = 45°$), a superstructural variant of zinc blende. Thus, the crystal structure of $LiPN_2$ (Fig. 4) can also be explained on the basis of the concept of sphere packing: Li^+ ions and phosphorus atoms systematically occupy half of the tetrahedral holes in a distorted cubic closest packing of nitrogen atoms in an ordered manner. The Li^+ ions and phosphorus

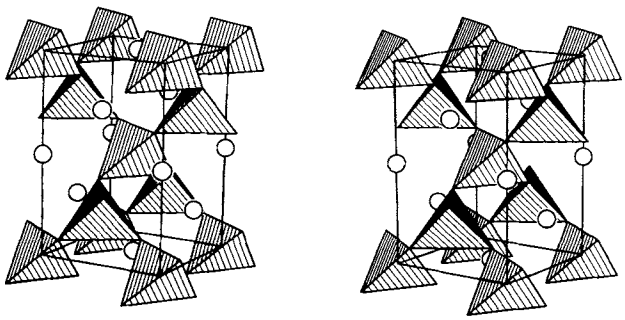

Fig. 4. Crystal structure of $LiPN_2$ (stereoscopic representation). The PN_4 tetrahedra, which are condensed at all their vertices, are shown as closed polyhedra, the Li^+ ions as open circles [55].

atoms in $LiPN_2$ and Li_7PN_4 appear not to be influenced by the significantly different bonding situations of P and N on the one hand or of Li and N (mainly covalent and ionic, respectively), on the other; thus, it is surprising to find such extreme structural similarities.

Within the quasibinary Li_3N/P_3N_5 system, Li_7PN_4 and $LiPN_2$ are the two ternary compounds with the highest and lowest lithium content, respectively. Their anionic P–N substructures $[PN_4]^{7-}$ and $^3_\infty[PN_{4/2}^-]$ are isosteric analogues of orthosilicate and silicon dioxide, respectively; these two Si–O compounds have the lowest and highest degree of condensation of SiO_4 tetrahedra, respectively. In analogy with the large family of silicate structures, it appeared appropriate to search for phosphorus(v) nitrides with an intermediate degree of condensation of corner-sharing PN_4 tetrahedra, which are perhaps similar to the chain or layer silicates.

Two further ternary compounds within the Li_3N/P_3N_5 system, Li_4PN_3 and $Li_5P_2N_5$, have both been prepared in a pure state and structurally characterized. In comparison with Li_7PN_4 and $LiPN_2$, both of these lithium phosphorus(v) nitrides have an intermediate lithium content. We thus expected to find an intermediate degree of condensation of the corner-sharing PN_4 tetrahedra. In fact Li_4PN_3, in analogy to the cyclotrisilicate $[Si_3O_9]^{6-}$, contains complex anions with three corner-sharing PN_4 tetrahedra,[52, 53] and thus the formula for this lithium phosphorus(v) nitride is $3(Li_4PN_3) = Li_{12}P_3N_9$. The cyclic anions exist in a chair conformation (Fig. 5).

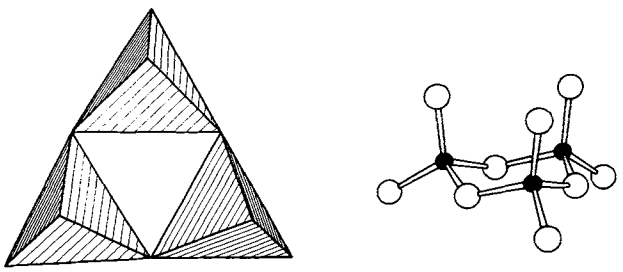

Fig. 5. Cyclotrisilicate-like $[P_3N_9]^{12-}$ ions (chair form) in $Li_{12}P_3N_9$ [52,53].

Since the molar ratio of phosphorus to nitrogen in $Li_5P_2N_5$ is 2:5, the analogy with the silicates leads us to expect either layer-type arrangements (silicate example: $Ba[Si_2O_5]$)[57] or double rings (example: $[Ni(H_2N(CH_2)_2NH_2)_3]_3[Si_6O_{15}] \cdot 26H_2O$[58]) consisting of corner-sharing PN_4 tetrahedra. In fact this lithium phosphorus(v) nitride contains complex $[P_4N_{10}]^{10-}$ ions, which are thus the first nitrido analogue of molecular phosphorus(v) oxide P_4O_{10} (Fig. 6).[54] As in molecular P_4O_{10}, and in agreement with the assumption of higher double bond or polar bond character, the bonds to the terminal atoms are clearly shorter than those to the bridging atoms (P_4O_{10}: $d(P–O_{term}) = 141–151$, $d(P–O_{br}) = 153–160$ pm;[59] $[P_4N_{10}]^{10-}$: $d(P–N_{term}) = 158$, $d(P–N_{br}) = 168$ pm[54]).

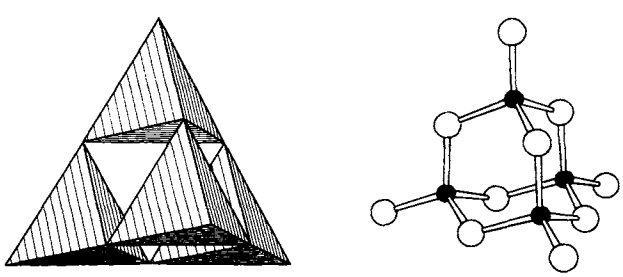

Fig. 6. Structure of the $[P_4N_{10}]^{10-}$ ion in $Li_{10}P_4N_{10}$. The complex anion has T_d symmetry in the solid and a regular tetrahedral structure [54].

There is a close relationship between the $[P_4N_{10}]^{10-}$ cage and the cagelike double rings in the silicates.[58] Thus both the $[P_4N_{10}]^{10-}$ ions and the $[Si_6O_{15}]^{6-}$ double rings are composed of "dreier"[*] rings. An $[Si_4O_{10}]^{4-}$ building unit isosteric with the $[P_4N_{10}]^{10-}$ ion, which represents the smallest possible cage built up of corner-sharing SiO_4 tetrahedra, has so far not been observed.

In the solid state, the complex anions in $2(Li_5P_2N_5) = Li_{10}P_4N_{10}$ have ideal T_d symmetry; the ten nitrogen atoms form an almost undistorted section from cubic closest packing. In comparison with the situation in molecular phosphorus(v) oxide, a much more favorable packing of the complex building units is attained in the solid state; molecular P_4O_{10}, like urotropine, has a distorted body-centered structure (with respect to the center of gravity of the molecule),[60] while the packing of the $[P_4N_{10}]^{10-}$ units is derived from the cubic face-centered zinc blende-type structure.[54] In the solid the neighboring $[P_4N_{10}]^{10-}$ ions, which themselves have an almost completely regular tetrahedral structure, are arranged in a manner such that they face each other with their triangular surfaces parallel and rotated by 60° (Fig. 7).

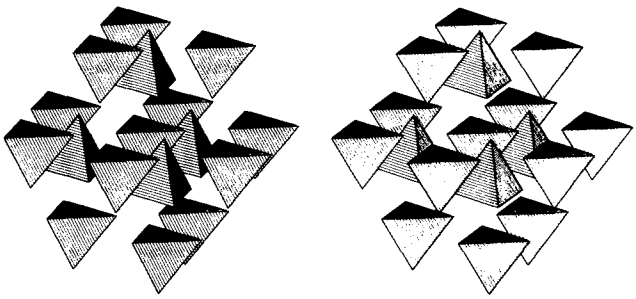

Fig. 7. Packing of the $[P_4N_{10}]^{10-}$ ions in the solid state (stereoscopic representation).

The extension of this packing principle to a three-dimensional infinite solid leads to the formation of "free" layers, which extend in all directions in space because of the cubic symmetry of the crystal (Fig. 7): The lithium ions occupy these layers. Because of the topology of the complex anions in $Li_{10}P_4N_{10}$, the packing described for the solid does not permit the relatively high number of cations ($Li^+:[P_4N_{10}]^{10-} = 10:1$) to be coordinated in a uniform manner by the nitrogen atoms. The Li^+ ions are coordinated either in a trigonal planar manner, tetrahedrally, or with a distorted octahedral nitrogen environment; the molar ratio of these arrangements is 6:1:2. The remaining ten per cent of the lithium ions are distributed with disorder on a site with

[*] The term "dreier" ring was coined by Liebau [47] and is derived from the German word drei, which means three; however, a dreier ring is not a three-membered ring, but a six-membered ring comprising *three* tetrahedral centers and *three* electronegative atoms (cf. Figs. 5 and 6). Similar terms exist for rings comprising four, five, and six tetrahedral centers (and the corresponding number of electronegative atoms), namely "vierer", "fünfer", and "sechser" rings, respectively.

higher multiplicity. Lattice-energy and point-potential calculations[61] confirm that in the highly symmetric packing of the complex anions in $Li_{10}P_4N_{10}$ only a proportion of the cations can be accommodated in positions with deep potential wells (tetrahedrally and octahedrally coordinated Li^+ ions). Only flat potential wells are available for the remaining cations, these leading in part to intrinsic disorder.

In all these lithium phosphorus(v) nitrides the Li–N contact distances determined $d(Li–N) = 192–224$ pm) are approximately equal to the sum of the ionic radii and increase as expected with the increasing coordination number of the cations. When the electronegativity differences $\Delta\chi$ between lithium and nitrogen ($\Delta\chi = 2.0$) and between phosphorus and nitrogen ($\Delta\chi = 1.0$) are taken into account, a simple Pauling-type estimate[62] leads us to expect P–N substructures with predominantly covalent bond character (78% covalent). The interactions between lithium and nitrogen should in contrast be predominantly (63%) ionic. A systematic study of the lithium–phosphorus(v) nitrides is also of interest because the covalent and polarizable P–N substructures in these compounds, in combination with their ionic Li–N contacts, should lead to a considerable mobility of the Li^+ ions in the solid state, so that they could form a new class of ionic conductors. Impedance-spectroscopic measurements on $LiPN_2$ and Li_7PN_4[63] (Fig. 8) confirm this prediction. The solid state Li^+ ion conductivities determined are,

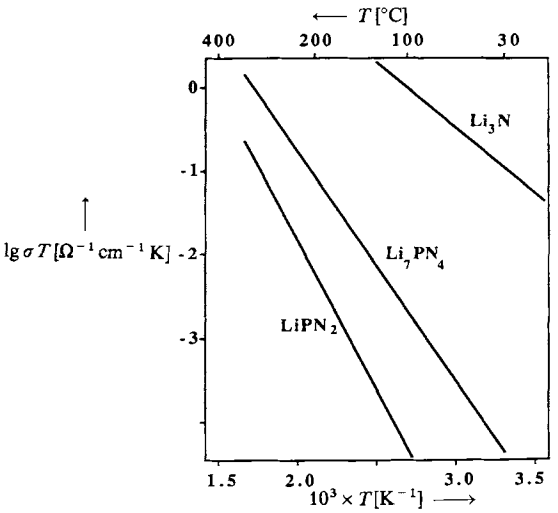

Fig. 8. Temperature dependence of the Li^+ ion conductivities in Li_3N, $LiPN_2$, and Li_7PN_4 [63].

however, lower than the extremely high conductivities of binary Li_3N,[50] which arise on the one hand from an appreciable doping with hydrogen according to the formula $Li_{3-x}H_xN$, and on the other from the unusual crystal structure of lithium nitride. Li_7PN_4 has a higher conductivity and a lower activation energy than $LiPN_2$ (Table 1). This difference between the two lithium phosphorus(v) nitrides can be understood on the basis of the crystal structures, the coordination of the Li^+ ions, and the number of charge carriers available in the solid state: In both Li_7PN_4 and $LiPN_2$ all cations are coordinated tetrahedrally by nitrogen, the observed contact distances Li–N being identical on average

Table 1. Specific Li^+ ion conductivities and activation energies of Li_3N, Li_7PN_4, and $LiPN_2$.

	σ_{400K} [$\Omega^{-1}cm^{-1}$]	E_a [kJ mol^{-1}]	Ref.
Li_3N	4.0×10^{-3}	24	[50]
Li_7PN_4	1.7×10^{-5}	47	[51, 63]
$LiPN_2$	6.9×10^{-7}	59	[55, 63]

(Li_7PN_4: 209 pm; $LiPN_2$: 209 pm).[51, 55] The number of charge carriers available for ionic conductivity is, however, much higher in Li_7PN_4. Thus, Li_7PN_4, because of its composition, contains much more lithium; in addition the anti-fluorite crystal structure (identical with a defect CsCl type) has a large number of interstitial sites which are available for ionic conduction. $LiPN_2$, in contrast, has a closely packed structure (chalcopyrite type, identical to a zinc blende modification). In this case no interstitial sites of comparable geometry are available. A diffusion of the Li^+ ions in the solid state is thus considerably hindered in $LiPN_2$, which results in a higher activation energy and a conductivity lower than that of Li_7PN_4.[63]

$Li_{10}P_4N_{10}$ contains structural features which lead us to expect a high mobility of the Li^+ ions in the solid: the symmetrical packing of the $[P_4N_{10}]^{10-}$ ions leads to the formation of free layers which permeate the solid in all directions. The intrinsic disorder of the cations in this compound, the fact that the Li^+ ions most probably occupy broad, shallow potential wells, and the coordination modes of a fraction of the Li^+ ions which are particularly favorable for ionic conduction (trigonal planar) are all factors which would favor a high Li^+ ionic conductivity in the solid.[53, 54]

The lithium phosphorus(v) nitrides discussed above contain either discrete complex P–N anions (Li_7PN_4, $Li_{12}P_3N_9$, $Li_{10}P_4N_{10}$) or a three-dimensional network of PN_4 tetrahedra($LiPN_2$). In the silicate family, the cyclosilicates are less stable than the corresponding chainlike compounds. Hard cations (e.g. Li^+, Mg^{2+}) increase this effect, while soft cations (e.g. Ca^{2+}, K^+) stabilize the rings.[47] The replacement of the monovalent Li^+ ions by bivalent alkaline earth metal ions while the P:N ratio is kept at 1:3 leads, in contrast to the observations made for the silicates, to a surprising result: A solid-state reaction between the corresponding amounts of the binary nitrides Ca_3N_2 and P_3N_5 [Eq. (12)] affords a ternary alkaline earth phosphorus(v) nitride of the composition Ca_2PN_3.

$$2\,Ca_3N_2 + P_3N_5 \xrightarrow[\text{W crucible, } N_2 \text{ atm.}]{800\,^\circ C,\ 4d} 3\,Ca_2PN_3 \qquad (12)$$

While "dreier" rings are present in $Li_{12}(PN_3)_3 = Li_{12}P_3N_9$, the alkaline earth phosphorus(v) nitride contains infinite chains $^1_\infty[PN_2N^{4-}_{2/2}]$ of corner-sharing PN_4 tetrahedra (Fig. 9).[64] The "zweier" chain found here has an extreme stretching factor $f_s = 1.0$, as found, for example, in the chain silicate $CaMn[Si_2O_6]$.[47, 65] As well as the calcium compound, a magnesium phosphorus(v) nitride Mg_2PN_3 is also known[66] whose crystal structure is an ordered wurtzite variant. More recent studies[67] indicate that this phosphorus(v) nitride also contains infinite "zweier" chains made up of corner-sharing PN_4 tetrahedra.

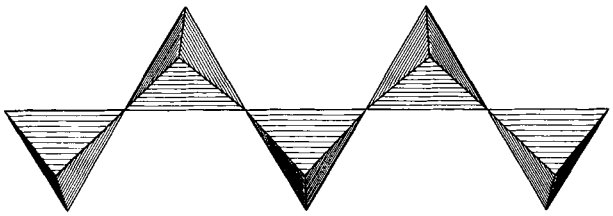

Fig. 9. Infinite "zweier" chains of corner-sharing PN_4 tetrahedra in Ca_2PN_3 [64].

3.2. Phosphorus(v) Nitride Imides and P–N Sodalites

The first intermediate in the ammonolysis of phosphorus pentachloride could in principle be the corresponding pentaamide $P(NH_2)_5$. In fact, however, condensation reactions occur when only a fraction of the chlorine atoms have been replaced by NH_2 groups; these lead to the formation of oligocyclo- and polyphosphazenes.[68] Product formation is influenced both by the reaction temperature and the ratio of NH_3 to PCl_5, so that either chlorine-rich compounds, such as $[NPClNH_2]_x$, or completely substituted compounds, such as $[NP(NH_2)_2]_x$, are obtained. It was postulated that the final product of substitution and condensation reactions in the ammonolysis of PCl_5 was a polymeric compound $^3_\infty[PN_{2/2}(NH_2)_{2/2}] \triangleq HPN_2$.[69–71] However, it is in fact found that the reaction of phosphorus pentachloride and ammonia leads to a vast number of different oligomeric and polymeric phosphazenes; thus, a homogeneous reaction product HPN_2 is not formed. The compound HPN_2 can, however, be obtained in a pure crystalline form from the heterogeneous ammonolysis of pure phosphorus(v) nitride under pressure [Eq. (13)]. A particularly useful procedure[72] involves the in situ preparation of the ammonia required, starting from the corresponding amounts of ammonium chloride and magnesium nitride [Eq. (14)].

$$P_3N_5 + NH_3 \xrightarrow{580\ °C,\ 14d} 3\ HPN_2 \quad (13)$$

$$Mg_3N_2 + 6\ NH_4Cl \xrightarrow{400\ °C} 8\ NH_3 + 3\ MgCl_2 \quad (14)$$

Like $LiPN_2$, phosphorus(v) nitride imide HPN_2 has a network structure $^3_\infty[PN^-_{4/2}]$ consisting of PN_4 tetrahedra linked through all four vertices by corner-sharing. This structure can be derived from the isosteric β-cristobalite-type (d(P–N) = 160 pm, $\sphericalangle$ P-N-P = 130°[72]); the hydrogen atoms are covalently bonded to one half of the nitrogen atoms of the P–N skeleton.[72]

A second phosphorus(v) nitride imide, HP_4N_7,[73] can be obtained by reacting the required amounts of P_3N_5 and ammonium chloride in sealed quartz ampoules [Eq. (15)].

$$4\ P_3N_5 + NH_4Cl \xrightarrow{820\ °C,\ 14d} 3\ HP_4N_7 + HCl \quad (15)$$

Equation (16) shows that the removal of one molecule of ammonia from four formula units of HPN_2 leads mathematically to the formation of HP_4N_7. It is unfortunately not possible to carry out this reaction preparatively, since the thermal decomposition of HPN_2 cannot be halted at the stage of HP_4N_7.

$$4\ HPN_2 \xrightarrow[-NH_3]{} HP_4N_7 \quad (16)$$

There appears to be a close structural relationship between the two phosphorus(v) nitride imides. Thus, HP_4N_7 can be regarded as a shear structure variant of HPN_2. As shown above, the structure of HP_4N_7 results from the elimination of one nitrogen atom (as NH_3) from four formula units of HPN_2; two of the remaining nitrogen atoms of the P–N skeleton then saturate the valences at the phosphorus atom. With respect to the β-cristobalite-like P–N substructure $^3_\infty[P^{[4]}N^{[2]}_{4/2}{}^-]$ in HPN_2, a fraction (two sevenths) of the nitrogen atoms in HP_4N_7 must form three P–N bonds according to the formula $^3_\infty[P^{[4]}_4N^{[2]}_5N^{[3]}_2{}^-]$.[73]

The ternary phosphorus(v) nitrides so far discussed that incorporate electropositive elements (hydrogen, alkali metals, or alkaline earth metals) mainly contain P–N structural elements with isosteric analogues in the silicate family. It thus seemed appropriate to treat Si–O compounds of particular interest, such as framework silicates and zeolites, as structural models for the preparation of new phosphorus(v) nitrides.

The importance of zeolites as catalysts, molecular sieves, adsorbents, and ion exchangers has increased considerably in recent years. The properties that render them so useful are based particularly on the characteristic topology of their tetrahedral skeletal structures, which have the general composition TO_2 (T = Si, Al).[74] By exchanging aluminum or silicon for other elements such as B, P, Ga, Ge, As, Sb, Ti, Zr, Hf, Fe, Cr, it proved possible to tailor the catalytic properties of zeolites in a manner favorable for certain applications.[74, 75] Substitution in the anion substructure of the framework, for example by replacing oxygen by other electronegative elements, has, in contrast, been almost completely neglected. It appeared to us that the preparation of nitrido zeolites should be particularly interesting in view of the possibility of obtaining desirable material properties (stability) and modifying the chemical properties of the zeolites (basicity).

The synthesis of a zeolite-like framework structure $^3_\infty[PN^-_{4/2}]$ is possible[76] when, for the in situ preparation of ammonia in the high-pressure ammonolysis of P_3N_5, Zn_3N_2 rather than Mg_3N_2 is treated with ammonium chloride [Eq. (17)]. The reaction then proceeds quantitatively to afford $Zn_5H_4[P_{12}N_{24}]Cl_2$ [Eq. (18)]. Analogously to HPN_2, a

$$Zn_3N_2 + 6\ NH_4Cl \xrightarrow{400\ °C} 8\ NH_3 + 3\ ZnCl_2 \quad (17)$$

$$4\ P_3N_5 + 4\ NH_3 + ZnCl_2 \xrightarrow{640\ °C} Zn_5H_4[P_{12}N_{24}]Cl_2 + 8\ HCl \quad (18)$$

phosphorus(v) nitride is formed, with a molar ratio P:N = 1:2, while at the same time zinc and chlorine are incorporated into the solid through gaseous $ZnCl_2$, which is volatile under the experimental conditions. A complete exchange of the hydrogen atoms in the product obtained is possible in a subsequent reaction with additional $ZnCl_2$ in which HCl is liberated [Eq. (19)].

$$Zn_5H_4[P_{12}N_{24}]Cl_2 + 2\ ZnCl_2 \xrightarrow{700\ °C,\ 3d} Zn_7[P_{12}N_{24}]Cl_2 + 4\ HCl \quad (19)$$

In $Zn_7[P_{12}N_{24}]Cl_2$ phosphorus and nitrogen form a sodalite-like three-dimensional network $^3_\infty[PN_{4/2}^-]$ of PN_4 tetrahedra which are linked through all four vertices by corner-sharing. (d(P–N) = 163.7 pm, ∢ P-N-P = 126°; Fig. 10).

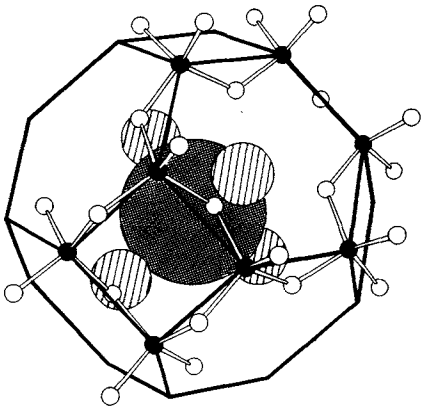

Fig. 10. Section of the crystal structure of $Zn_7[P_{12}N_{24}]Cl_2$. The zeolite-like β-cage made up of condensed $[P_4N_4]$ and $[P_6N_6]$ rings is shown. P: black, N: white, Cl: gray, Zn: striped. The size of Zn^{2+} and Cl^- corresponds to their respective ionic radii [76].

While in HPN_2 and $LiPN_2$, as in β-cristobalite, only three-dimensionally bonded $[P_6N_6]$ rings are found, the sodalite-like skeleton also contains $[P_4N_4]$ rings. The two types of rings together form truncated octahedra (β cages), which are typical building units of sodalites and zeolites. Situated at the center of each β-cage is a chloride ion, in a tetrahedral environment of Zn^{2+} ions. Besides the Zn–Cl contact (260 pm), the metal cations have contact with three nitrogen atoms of the P–N skeleton (d(Zn–N) = 196 pm). According to the formula $Zn_7[P_{12}N_{24}]Cl_2$, there is a statistical defect occupancy (occupancy factor 7/8) at the Zn position. A fraction of the Zn^{2+} ions can be replaced by two protons each, which in turn are covalently bonded to nitrogen atoms of the P–N skeleton. The P–N sodalite has a phase width of $Zn_{(7-x)}H_{2x}[P_{12}N_{24}]Cl_2$ ($0 \le x \le 2$). By starting from a material with a lower metal content $Zn_6H_2[P_{12}N_{24}]Cl_2$, it is possible to prepare a chlorine-free phosphorus(v) nitride $Zn(PN_2)_2$ by elimination of HCl [Eq. (20)]; the structure of the product is highly distorted and it is no longer crystalline.[73, 77] It is, however, probable that this compound possesses a three-dimensional network structure of corner-sharing PN_4 tetrahedra containing $[P_4N_4]$ and $[P_6N_6]$ rings.[73, 77]

$$Zn_6H_2[P_{12}N_{24}]Cl_2 \xrightarrow{800\ °C,\ 3d} 6\ Zn(PN_2)_2 + 2\ HCl \qquad (20)$$

The synthetic method described previously is not suitable for the preparation of modified P–N sodalites containing other metal cations, (e.g. alkaline earth metals, transition metals, lanthanides). On the one hand, it requires that the corresponding binary metal nitride M_3N_2 be both existent and stable, while on the other, the metal chloride MCl_2 formed in the reaction with NH_4Cl must have a certain minimum volatility.

P–N Sodalites $M_5H_4[P_{12}N_{24}]Cl_2$ (M = Zn, Co, Ni) can also be obtained remarkably easily by reacting corresponding amounts of the metal chloride MCl_2, hexachlorocyclotriphosphazene $(PNCl_2)_3$, and ammonium chloride [Eq. (21)]. This reaction is carried out in sealed ampoules,

$$5\ MCl_2 + 4\ (PNCl_2)_3 + 12\ NH_4Cl \xrightarrow{700\ °C,\ 2d} M_5H_4[P_{12}N_{24}]Cl_2 + 44\ HCl \qquad (21)$$

and the batch size is limited by the amount of HCl formed. An alternative procedure involves the use of a molecular phosphorus component in which the chlorine atoms are completely replaced by amino groups $[\{PN(NH_2)_2\}_3]$ [Eq. (22)]; in this case the product is the hydrogen-free P–N sodalite $M_7[P_{12}N_{24}]Cl_2$.[77]

$$7\ MCl_2 + 4\ (PN(NH_2)_2)_3 \xrightarrow{700\ °C,\ 2d} M_7[P_{12}N_{24}]Cl_2 + 12\ NH_4Cl \qquad (22)$$

A particularly elegant method for the preparation of P–N sodalites modified in various ways is the simple reaction between phosphorus(v) nitride imide HPN_2 and the corresponding metal halide MX_2 [Eq. (23)], which affords compounds with a large number of different metal cations and halide ions (e.g. M = Mg, Cr, Mn, Fe, Co, Ni, Cu, Zn, Pb; X = Cl, Br).[73, 77]

$$5\ MX_2 + 12\ HPN_2 \xrightarrow{700\ °C,\ 2d} M_5H_4[P_{12}N_{24}]X_2 + 8\ HX \qquad (23)$$

By using the methods described above it has been possible to obtain a wide variety of P–N sodalites. As well as divalent cations such as Mg^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Pb^{2+}, trivalent cations such as Cr^{3+}, Fe^{3+}, and even monovalent cations such as Cu^+ can be incorporated. In all cases phase widths are observed in which a fraction of the metal ions can be replaced by the corresponding number of hydrogen atoms, which are then covalently bonded to nitrogen atoms of the P–N skeleton.[73, 77]

The P–N sodalites exhibit remarkable properties: They are thermally stable up to about 800 °C (in a nonoxidizing atmosphere) and are inert towards all common solvents as well as hot acids and alkalis. Of particular interest is the fact that, depending on the metal cation present, some P–N sodalites are intensely colored (blue (Co, Ni), brown (Fe), dark green (Cr)), which suggests that they may find a use as pigments.

3.3. Silicon Phosphorus(v) Nitride $SiPN_3$

With respect to the development of new high-performance phosphorus(v) nitride ceramic materials it appears attractive to look at purely covalent ternary compounds containing both phosphorus and a second electropositive element, the latter being able to form a stable nitride which is a known ceramic material (BN, AlN, Si_3N_4). Earlier attempts to prepare ternary nitrides in the system Si–P–N or B–P–N starting from the binary nitrides were unsuccessful because of the low self-diffusion coefficient of these substances and the fact that the binary nitrides do not melt congruently.

Silicon phosphorus(v) nitride $SiPN_3$ is, however, available from the molecular precursor **D** in which the required structural element ≡Si–N=P≡ is already preformed (Scheme 1).

Compound **D** can be obtained in a three-step synthesis starting from bis(trimethylsilyl) azane ("hexamethyldisilazane") **A** and proceeding via the intermediates **B** and **C**. Low temperature ammonolysis of **D**, followed by removal of the ammonium chloride formed and pyrolysis in a stream of ammonia, leads to $SiPN_3$.[78]

$$(CH_3)_3Si{-}NH{-}Si(CH_3)_3 \xrightarrow{SiCl_4} Cl_3Si{-}NH{-}Si(CH_3)_3 \xrightarrow{Cl_2,\ -40\,^\circ C}$$

A **B**

$$Cl_3Si{-}N(Cl){-}Si(CH_3)_3 \xrightarrow{PCl_5} Cl_3Si{-}N{=}PCl_3 \xrightarrow[2.)\ NH_3,\ 800\,^\circ C]{1.)\ NH_3,\ -70\,^\circ C} SiPN_3$$

C **D**

Scheme 1.

Silicon phosphorus(v) nitride has a three-dimensional network structure of corner-sharing alternating PN_4 and SiN_4 tetrahedra. Analogous to the isosteric compounds Si_2N_2O[79] and Si_2N_2NH,[80] the crystal structure of $SiPN_3$ is derived from a defect wurtzite modification. It contains two-dimensional infinitely linked layers of condensed six-membered $[Si_3N_3]$ rings in a boat form; half of the silicon atoms in the rings are replaced by phosphorus atoms. The $^2_\infty[(Si/P)_3N_3]$ layers, which are arranged parallel to each other in the crystal, are linked through bridging nitrogen atoms which saturate the remaining free valences at phosphorus and silicon (Fig. 11).[78] $SiPN_3$ decomposes above about

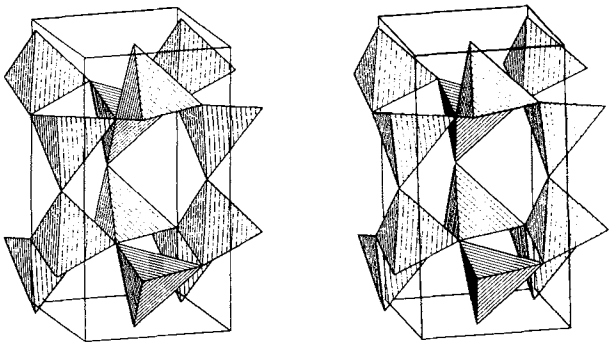

Fig. 11. Crystal structure of $SiPN_3$ (stereoscopic representation). The SiN_4 and PN_4 tetrahedra are shown as closed polyhedra [78].

1000 °C to give Si_3N_4 and gaseous phosphorus (P_4), which acts as an oxygen scavenger. After 3 h at 1400 °C the decomposition product is pure α-Si_3N_4, which acts as a nucleus for crystallization. Calcination of commercially available amorphous Si_3N_4 by the addition of small amounts of $SiPN_3$ gives pure crystalline Si_3N_4 with a low oxygen content and a high content of α-Si_3N_4, which is preferred for sintering processes.[78]

4. Ternary Boron Nitrides

Very few ternary boron nitrides have so far been prepared. The dimorphic lithium boron nitride Li_3BN_2[81-83] and the analogous sodium compound Na_3BN_2[84] have been studied in detail and structurally characterized. Magnesium boron nitride Mg_3BN_3[85] is also known; like Li_3BN_2 it has a catalytic effect on the conversion of hexagonal (*h*-BN) to cubic boron nitride (*c*-BN) under high-temperature/high-pressure conditions.[14] A more complex cerium boron nitride $Ce_{15}B_8N_{25}$ has also been described.[86] Besides Na_3BN_2, these ternary compounds are obtained by reacting the corresponding binary nitrides at temperatures between 800 °C (α-Li_3BN_2) and 1480 °C ($Ce_{15}B_8N_{25}$). Since binary sodium nitride as a starting material for the preparation of Na_3BN_2 does not exist, a procedure for the preparation of this compound had to be devised in which Na_3N is a formal intermediate. The reaction of a mixture of elemental sodium and sodium azide has proved suitable [Eq. (24)]. Under the reaction conditions the otherwise unstable alkali metal nitride appears to react instantaneously to give the required product.[84]

$$2\,Na + NaN_3 + BN \xrightarrow[1000\,^\circ C,\ 15\ min]{\text{Belt apparatus, } 4\,GPa} Na_3BN_2 + N_2 \quad (24)$$

The ternary boron nitrides so far characterized contain only "isolated" B–N anions rather than condensed structural units. Thus, Li_3BN_2 and Na_3BN_2 are constructed of alkali metal cations and linear, symmetrical units NBN^{3-}. The complex anion has 16 valence electrons and is thus isoelectronic with CO_2, NCO^-, CNO^-, N_2O, N_3^-, CN_2^{2-}, C_3^{4-}[87,88] and CBN^{4-}.[89] The relatively short B–N bond length (134 pm[82-84]) can be explained on the basis of either a considerable degree of double bond character or a polar bond; this result is in agreement with spectroscopic studies.[81] The two dimorphic modifications of Li_3BN_2 differ in particular in a reorientation of the linear $[BN_2]^{3-}$ ions; all the Li^+ ions in β-Li_3BN_2 (isostructural with Na_3BN_2) are almost tetrahedrally coordinated by nitrogen atoms, while in α-Li_3BN_2 they are in part linearly coordinated.[82,83]

Unexpectedly, Mg_3BN_3 also contains linear $[BN_2]^{3-}$ ions, the structure in fact is $[(Mg^{2+})_3(BN_2^{3-})(N^{3-})]$; the "isolated" N^{3-} ions have no direct contact with boron atoms.[85] A trigonal planar anion $[BN_3]^{6-}$ (d(B–N) = 146 pm), isoelectronic with orthoborate $[BO_3]^{3-}$, was found in $Ce_{15}B_8N_{25}$; again "isolated" N^{3-} ions are also present, which are octahedrally surrounded by cerium atoms.[86] The remarkably short Ce–Ce distances (d(Ce–Ce) $\geq$ 363 pm) indicate the presence of metal-metal bonds as well as the presence of a mixed-valency compound according to $[(Ce^{4+})_6(Ce^{3+})_9(BN_3^{6-})_8(N^{3-})]$.[86]

5. Ternary Silicon Nitrides

In spite of many attempts it has so far been possible to prepare only a few ternary silicon nitrides containing electropositive elements in a pure form and to characterize them both structurally and with respect to their properties. The isotypic compounds $MSiN_2$ (M = Be, Mg, Mn, Zn) with the same valence electron concentration (VEC) of 4[90] can be considered as ternary substitution variants of aluminum nitride (AlN).[91-97] Their preparation in pure form is possible by solid-state reactions of the corresponding binary nitrides [Eq. (25)] or, in the case of the manganese com-

pound, by reacting Si_3N_4 with elemental manganese in an ammonia atmosphere [Eq. (26)].[94]

$$Mg_3N_2 + Si_3N_4 \xrightarrow[N_2]{1200\,^\circ C} 3\,MgSiN_2 \quad (25)$$

$$3\,Mn + Si_3N_4 + 2\,NH_3 \xrightarrow{1050\,^\circ C} 3\,MnSiN_2 + 3\,H_2 \quad (26)$$

In the solid state these compounds contain three-dimensional infinite network structures with SiN_4 tetrahedra linked through all four vertices by corner-sharing, which forms condensed $[Si_6N_6]$ twelve-membered rings (d(Si–N) = 174–180 pm, $\sphericalangle$ Si-N-Si = 122° in $MgSiN_2$[96]). Together with the metal cations these lead to a wurtzite-like structure.

$LiSi_2N_3$[98] and the structurally very similar silicon nitride imide Si_2N_2NH[80] have defect wurtzite structures. The lithium compound can be obtained by reacting stoichiometric amounts of the binary nitrides (100 h, 1000 °C). Crystalline silicon nitride imide[80] is obtained from silicon and ammonia under ammonothermal conditions by using potassium amide as a mineralizer [Eq. (27)].

$$2\,Si + 3\,NH_3 \xrightarrow[6\,kbar\,NH_3]{550/600\,^\circ C,\ 120\,h} Si_2N_2NH + 4\,H_2 \quad (27)$$

Analogous to Si_2N_2O and $SiPN_3$ (see Section 3.3), $LiSi_2N_3$ and Si_2N_2NH consist of two-dimensional infinite, parallel layers of condensed $[Si_6N_6]$ twelve-membered rings in a boat form, which are linked together by bridging nitrogen atoms (d(Si–N) = 171–176 pm). In Si_2N_2NH the hydrogen atoms are covalently bonded to the bridging nitrogen atoms, while in $LiSi_2N_3$ the Li^+ ions occupy free tetrahedral sites in the defect wurtzite structure. Silicon nitride imide (like silicon diimide $Si(NH_2)_2$, which has so far only been obtained in an undefined amorphous form) is an intermediate in the industrial preparation of Si_3N_4 from the ammonolysis of silicon tetrachloride. It decomposes above about 1050 °C with elimination of ammonia to give Si_3N_4.[80]

Lanthanum silicon nitride $LaSi_3N_5$ is obtained by reacting the binary nitrides under pressure (1830 °C, 270 bar N_2);[99] the reaction of Si_3N_4 with La_2O_3 (2000 °C, 50 bar N_2) also affords the compound as single crystals.[100] As for all ternary silicon nitrides which have so far been characterized, $LaSi_3N_5$ has a three-dimensional network structure with SiN_4 tetrahedra linked through all four vertices by corner-sharing. The solid contains "dreier", "vierer", "fünfer", and "sechser" (six-, eight-, ten-, and twelve-membered) rings with alternating silicon and nitrogen atoms. According to the molar ratio Si:N = 3:5, two-fifths of the nitrogen atoms are bonded to three silicon atoms (d(Si–N) = 173–181 pm), while the remainder (three-fifths) have only two silicon atoms as directly bonded neighbors (d(Si–N) = 162–173 pm). Lanthanum is coordinated by a total of nine nitrogen atoms of the Si–N substructure (d(La–N) = 244–312 pm).[100]

Besides the compounds mentioned above, the existence of further ternary silicon nitrides such as Li_2SiN_2, Li_5SiN_3, and Li_8SiN_4 has been postulated, although it has so far not been possible to obtain exact structural data for these compounds or to determine their composition unequivocally.[101–104] Studies of the quasibinary Li_3N/Si_3N_4 system have also produced some evidence for the existence of ternary lithium silicon nitrides with ionic conducting properties in the solid state.[105] A number of different phases was also identified in the Be_3N_2/Si_3N_4 system.[106, 107]

A number of germanium compounds isotypic with the corresponding silicon nitrides mentioned above are also known.[49, 93, 94, 97, 101, 103, 108]

6. Special Cases: Carbon and Sulfur

In agreement with the quantification of the Van-Arkel-Ketelaar triangle as described by Allen,[109, 110] the nonmetals carbon, sulfur, or selenium (which are more electronegative than boron, silicon, or phosphorus) form binary nitrides which exhibit a clear preference for molecular structures. These binary nitrogen compounds in low oxidation states are often discrete molecules with homonuclear bonds (e.g. $(CN)_2$, S_4N_4, S_4N_2, S_5N_6[111]), though some polymeric compounds are also known (e.g. $(CN)_x$ and $(SN)_x$). Carbon and sulfur in the maximum oxidation state corresponding to their group number (IV and VI, respectively) have so far not provided any indication of the existence of the binary nitrides C_3N_4 and SN_2, respectively. Although ab initio calculations indicate that a hypothetical binary carbon nitride with a β-Si_3N_4-like structure should have an unusual mechanical stability,[112, 113] no compound of the composition C_3N_4 has until now been prepared in a pure defined form.[114–116]

The cyanamides can, however, formally be considered as ternary carbon(IV) nitrides ($M^I_2CN_2$, M = Li, Na, K, Ag, Tl; $M^{II}CN_2$, M^{II} = Ca, Sr, Ba, Zn, Pb) which contain the linear anion CN_2^{2-} with 16 valence electrons.[117–120] Lithium cyanamide can be prepared from lithium carbide and lithium nitride in molten lithium [Eq. (28)], though the separation of the product from lithium metal is preparatively difficult.[117, 118] Pure Li_2CN_2 can be obtained easily on a preparative scale from the reaction between lithium nitride and melamine in a molar ratio of 1:2 [Eq. (29)].[121]

$$Li_2C_2 + 4\,Li_3N \xrightarrow[Li\ melt]{530\,^\circ C,\ 150\,h} 2\,Li_2CN_2 + 10\,Li \quad (28)$$

$$(NCNH_2)_3 + 2\,Li_3N \xrightarrow{650\,^\circ C} 3\,Li_2CN_2 + 2\,NH_3 \quad (29)$$

Alkali metal hydrogen cyanamides ($NaHCN_2$, $Na_4H_2(CN_2)_3$[122, 123]) and crystalline cyanamide (H_2CN_2[124, 125]) have been prepared and structurally characterized. The reaction of dicyandiamide with cesium carbonate leads to cesium dicyanamide $Cs[(CN)_2N]$, which in the solid state contains the bent pentaatomic anion $N{\equiv}C{-}\ddot{N}{-}C{\equiv}N^-$.[126]

In the case of sulfur(VI) no ternary or higher nitrides have so far been obtained. The only compound worthy of mention here is the sulfur(IV) compound K_2SN_2, which in the solid state contains the bent anion SN_2^{2-} isosteric with SO_2.[127] Exact structural data are, however, not yet available for this compound.

7. Outlook and Future Prospects

Numerous new publications, not only in the area of nonmetal nitrides, make it clear that nitride chemistry is still only in its infancy[128] and that many fascinating results can be expected. As shown by the results of systematic studies on the phosphorus nitrides, nonmetal nitrides have the potential for the development of novel solids with interesting properties; these can be either related to the technically, industrially, and economically important sulfates, phosphates, and silicates, or may be completely novel. In contrast to oxygen, nitrogen affords an extension of the structural scope, since covalent bonds can be formed not only to two, but also to three or even four neighboring atoms.[129] The synthesis of nitrido zeolites according to the structural model provided by the zeolites appears particularly attractive with respect to desirable material properties and the modification of known compounds. However, the extended structural possibilities offered by nitrogen lead us to expect that completely new types of structures should also be possible.

Regardless of the possible applications of such compounds as ceramic materials, ionic conductors, catalysts, or pigments, the systematic exploration of new nonmetal nitrides will close a large gap in the chemistry of the main group elements.

My grateful thanks are due to my co-workers Ute Berger, Verena Schultz-Coulon, Jan Lücke, and Martin Volkmann for their tenacity, their inspiration, and their enthusiasm during our pleasant and fruitful cooperation in the area of the phosphorus nitrides. I should like to thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen for their generous financial support. I am particularly indebted to Monika Schmitt for her understanding, her support, and for many stimulating suggestions.

Molecular Machines: How Motion and Other Functions of Living Organisms Can Result from Reversible Chemical Changes

By Dan W. Urry*

Certain model proteins dramatically fold and become more ordered on raising the temperature. When the temperature is raised to drive folding and assembly, these model proteins can lift weights and perform work; they can produce motion. The temperature of warm-blooded animals, however, is kept constant. Therefore, motion cannot result from a change in temperature. In this case, a free energy change, caused, for example, by an increase in the concentration of a chemical, can lower the temperature at which the protein folding and assembly transition occurs from above to below physiological temperature. Raising the concentration of a chemical isothermally has indeed been shown to result in motion and the efficient performance of work. These model proteins and the mechanism they reveal provide insight into the molecular basis for diverse biological functions; they are models for the molecular machines that comprise the living organism, and they provide a new class of materials for both medical and nonmedical applications.

1. Introduction

A molecular machine, commonly an assembly of polymeric molecules, is a structural fabrication that can convert energy from one form or location to another. Living organisms represent the synergistic integration of functionally diverse molecular machines made of a single class of polymers, the proteins.

The living organism is capable many types of energy conversions, specifically free energy transductions, which are responsible for its existence. The functions of living organisms involve Gibbs free energy changes caused, for instance, by changes in mechanical force and/or length, changes in temperature and/or the extent of order, changes in pressure and/or volume, changes in chemical potential and/or numbers of a chemical species, changes in the oxidative state and/or numbers of electrons of chemical moieties, or by changes due to the absorption of light or other electromagnetic radiation. When free energy in one of the above forms is available to the correct protein construct (i.e., a specific molecular machine), the free energy can be converted or transduced by the appropriate protein into any one of the other forms.

While the molecular machines of living organisms are functionally diverse, a common molecular mechanism could be responsible for the many paired free energy transductions required for life.[1] The purpose of this review is to elucidate such a mechanism and to impart a sense of understanding of the underlying molecular processes.

Perhaps because in the words of Albert Szent-Gyorgyi,[2] "Motion has always been looked upon as the index of life," our elucidation of the molecular process can begin by considering how motion can occur. But we also start with motion, because it can be the direct result of the folding and assembly or the unfolding and disassembly of protein constructs, and because the underlying mechanism for diverse free energy transductions can be seen most directly in a simple, visual assay in which this reversible folding and assembly of specific model proteins results in motion. These model proteins can be referred to as elastic protein-based polymers, as they derive from repeating sequences found in the mammalian elastic protein, elastin.

The repeating sequences and designed modifications thereof are polymerized into high molecular weight polymers; hence the name elastic protein-based polymers or simply elastomeric polypeptides. Most fundamental is that these repeating sequences fold and/or self-assemble into more highly ordered structures when the temperature is raised in water. This increase in order of the polypeptide with increase in temperature is referred to as an inverse temperature transition, and the temperature at which the folding occurs is indicated as T_t. It is in learning the rules whereby these molecules fold and assemble on raising the temperature (and thereby in learning how to control the temperature T_t for the folding transition) that insight into diverse free energy transductions can be gained.

Significantly, *in warm-blooded animals temperature is not raised to achieve the transition for folding and assembly; rather the temperature at which the folding and assembly occur is lowered from above to below physiological temperatures.* This is referred to as the ΔT_t mechanism. In this way, the free energy input required to lower the transition temperature becomes the free energy of contraction for useful mechanical work. When the free energy input involves a change in the concentration of a chemical and the folding results in a contraction, this is called chemomechanical transduction; it is chemically elicited motion. The efficiency of this mechanism, which utilizes shifting the temperature of inverse temperature transitions to achieve chemomechanical transduction, appears to be an order of magnitude more efficient than mechanisms involving charge–charge interactions or protein denaturation (see Section 7). Furthermore, all of the six free energy changes noted above have now been shown to employ the ΔT_t mechanism to drive folding and assembly. Thus a common mechanism could underlie the diverse molecular machines of living organisms.

With a rationale for the design of model proteins and a practicable mechanism, both considered in some detail below, it becomes possible to mimic biological processes, and this area of biomimetics provides many challenges for applications both medical and nonmedical ranging from tissue reconstruction to robotics.

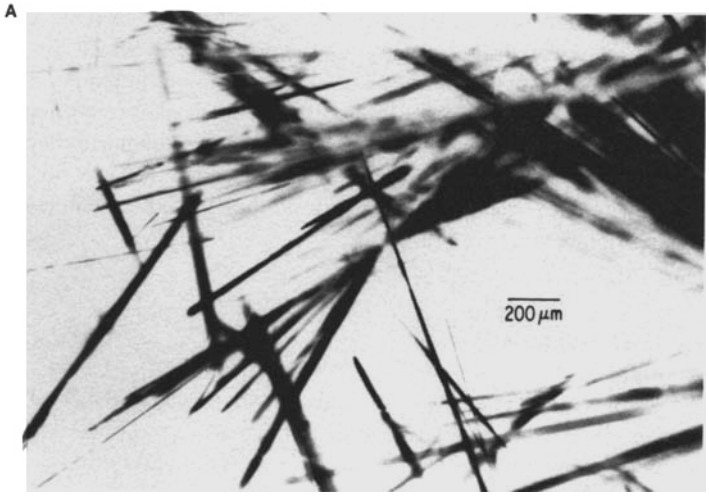
2. Model Proteins that Increase Order on Increasing the Temperature

2.1. Polypeptides that Crystallize from Water on Raising the Temperature

A polypeptide with a correct balance of apolar (hydrophobic) and polar moieties can be soluble in water at low temperature and yet, on raising the temperature, it can separate out. Such a polypeptide is *cyclo*(Val-Ala-Pro-Gly-Val-Gly)$_2$, that is, a cyclic analogue of the repeating hexapeptide of elastin, (VAPGVG)$_n$. In fact, *cyclo*(VAPGVG)$_2$ crystallizes on raising the temperature and dissolves on lowering the temperature (see Fig. 1).[3] Because a crystal is the epitome of order, molecules that go from a random distribution in solution to a discretely ordered crystal are molecules that increase order on raising the temperature.

2.2. Polypeptides that Self-Assemble into Fibers on Raising the Temperature

Removing the essentially neutral alanine residue (being neither apolar nor polar) from the hexapeptide (VAPGVG), gives the pentapeptide (VPGVG). This is the most prominent repeating sequence in elastin, occurring more than eleven times in a single sequence, that is, (VPGVG)$_{11}$.[4-6] High



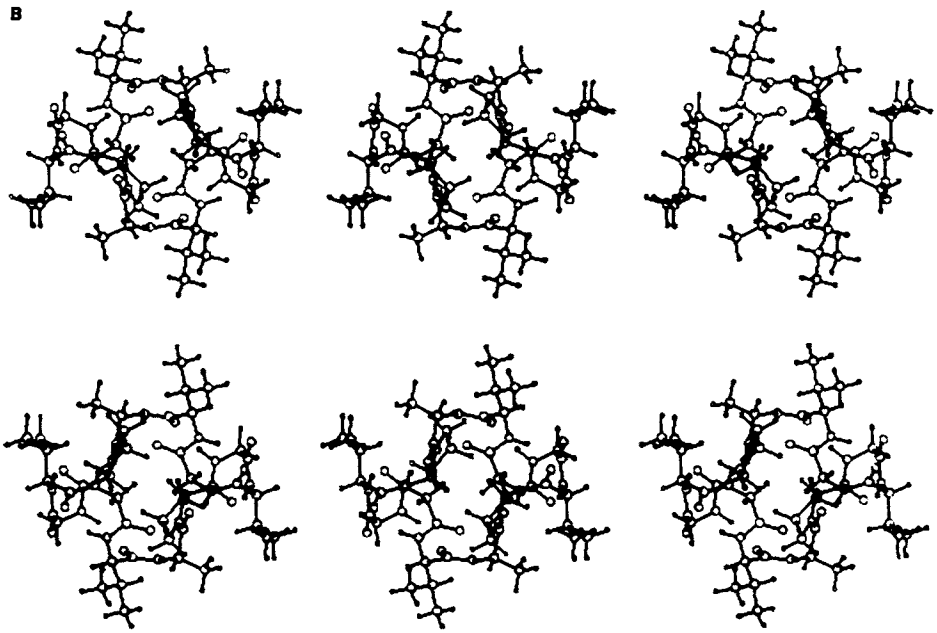


Fig. 1. A) Crystals of *cyclo*(VAPGVG)$_2$, which form on raising the temperature and dissolve on lowering the temperature (from reference [3]). B) Working model of the structure of *cyclo*(VAPGVG) based on NMR data and molecular mechanics and dynamics calculations. Top: view of one side; bottom: view of the other side (from reference [14]). In each row are stereo-pairs: the right-hand pair are for cross-eye viewing and the left-hand pair for wall-eye viewing. The structure is characterized by internal hydrogen bonds and externally directed aliphatic side chains.

Dan W. Urry, born in 1935, obtained his B.A. in medical biology at the University of Utah, Salt Lake City, and graduated with a Ph.D. in Physical Chemistry under H. Eyring in 1964. After a postdoctorate fellowship at Harvard University, he worked at the University of California in Berkeley, and the University of Chicago before moving to the University of Alabama at Birmingham, where since 1970 he has been Director of the Laboratory of Molecular Biophysics and Professor of Biochemistry and, in addition since 1979, Professor of Physiology and Biophysics. The honors conferred upon him include the Wright A. Gardner Award 1991 and the selection as Scientist of the Year 1988 by the Research and Development Magazine. He is member of the editorial boards of several journals and has published over 400 papers. His main research interests are protein structure and function, structures and applications of protein-based polymers, biomolecular materials, the channel mechanism of ion transport, and the ΔT_t mechanism of energy conversion.

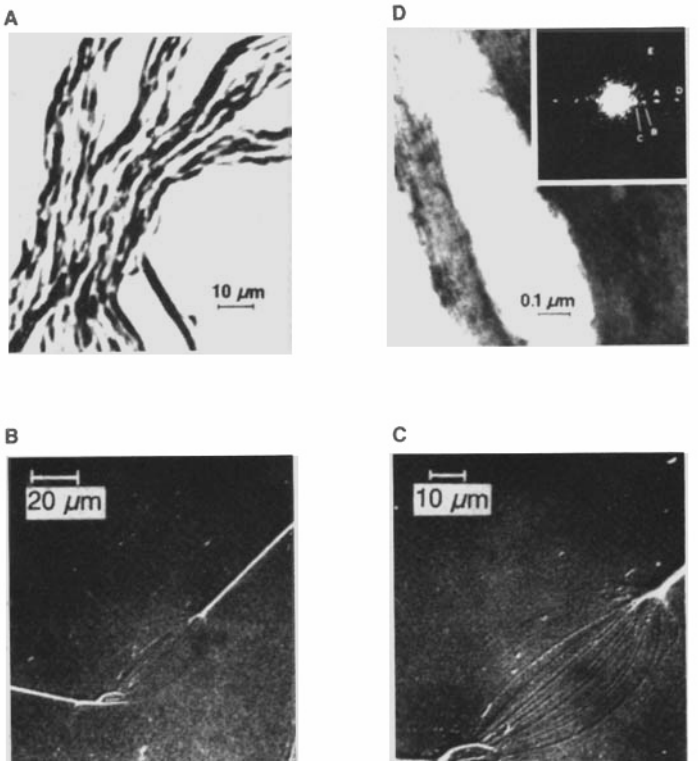

Fig. 2. Self-assembly of poly[f_x(VPGVG),f_x(VPGXG)] into anisotropic fibers (X = Glu, Lys; $0.1 \leq f_x \leq 0.2$). A water-soluble carbodiimide was used to cross-link the Glu and Lys side chains during initial aggregation [10]. A) Light micrograph (without staining and using only the form birefringence for contrast) showing the formation of fibers several microns in diameter (from reference [9]). B) and C) Scanning electron micrographs after aluminum coating of a single fiber (two to three microns in diameter) that splays out into many parallel fibrils and coalesces back into the same sized fiber (from reference [10]). D) Transmission electron micrograph of negatively stained fibrils, showing that they comprise filaments about 5 nm in diameter aligned parallel to one another (from reference [11]). Inset: optical diffraction of negatively stained nascent aggregates of poly(VPGVG), showing a dominant meridional reflection near 5 nm and diagonal reflection indicative of an underlying helical structure (from reference [87]).

molecular weight protein-based polymers of this repeat, poly(VPGVG), are also soluble in water below 25 °C. On raising the temperature above 25 °C, they aggregate and undergo a phase transition to a viscoelastic state that is about 50% peptide and 50% water by weight.[7] If the nascent aggregates are caught on a carbon-coated grid and negatively stained, transmission electron microscopy shows them to comprise 5 nm wide filaments with a supercoiled or twisted substructure.[8] Under conditions where chemical cross-linking can occur, this protein-based polymer can be seen, by light microscopy, to have self-assembled into several micron diameter fibers (Fig. 2A).[9] By scanning electron microscopy the fibers are seen to be made up of parallel aligned fibrils (Fig. 2B and C), and by transmission electron microscopy and negative staining the fibrils are seen to arise from the association of 5 nm diameter filaments (Fig. 2D).[7, 10, 11] This protein-based polymer self-assembles into anisotropic fibers on raising the temperature.

2.3. Basis for the Inverse Temperature Behavior

The cyclopentadecapeptide, *cyclo*(VPGVG)$_3$, has a conformation that is nearly identical to that of poly(VPGVG);[12] it also aggregates on raising the temperature, and its crystal structure is about one-fourth water by weight; the water forms hydrophilic channels within the stacks of cyclopentadecapeptides but no water is present between molecules (Fig. 3).[13] Also, its crystal structure exhibits six hydrophobic rods. The hydrophobic rods are formed by apolar side chains, and they run parallel to each stack of molecules such that the intermolecular interactions are dominated by contacts between hydrophobic side chains. The molecular structure of *cyclo*(VAPGVG)$_2$ thus also appears to be one where the more polar peptide moieties are buried and the more apolar (hydrophobic) side chains are at the exterior for hydrophobic contacts when forming the crystal on raising the temperature (see Fig. 1B).[14]

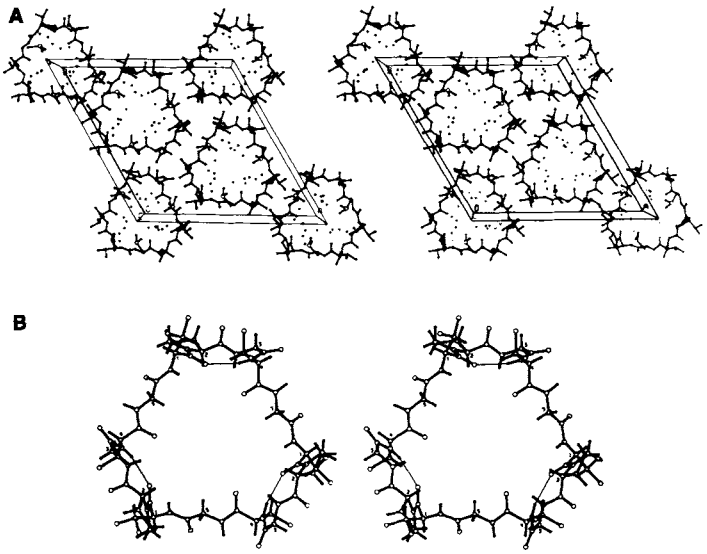

Fig. 3. *Cyclo*(VPGVG)$_3$: A) Stereo-pair view (cross-eye) of the crystal structure showing that intermolecular contacts are dominated by association of hydrophobic side chains and that the substantial amount of water in this aggregated state is within the threefold symmetric stacks of molecules. B) Molecular structure in stereo-pair view (cross-eye) showing the β-turns on end and suspended segments connecting the β-turns (from reference [13]). This has been shown to be the same conformation with only slight torsional angle changes in the backbone as the helical poly(VPGVG); that is, it corresponds to the cyclic conformation of the linear poly(VPGVG) [12].

These molecules are characterized in their aggregated or crystalline states by hydrophobic association. Before aggregation the hydrophobic side chains are surrounded by water, and the water molecules abutting apolar moieties have been shown in the crystal structure of alkane gas hydrates and in the crystal structure of the protein crambin to be arranged as pentagons. In the methane gas hydrate, twelve such pentagons enclose a methane molecule, that is, a pentagonal dodecahedran (Fig. 4A).[15] In crambin, pentagons of water are seen adjacent to the aliphatic side chain of leucine (Fig. 4C).[16]

Hydrophobic hydration, which is most explicitly exemplified in the pentagonal arrays of water molecules, is a favorable exothermic process; the enthalpy of hydration, ΔH(hydration), is negative. Solubility in water is limited, however, because of the limiting Gibbs free energy of solvation given by the expression, ΔG(hydration) = ΔH(hydration) $- T\Delta S$(hydration). In this case the entropy of hydra-

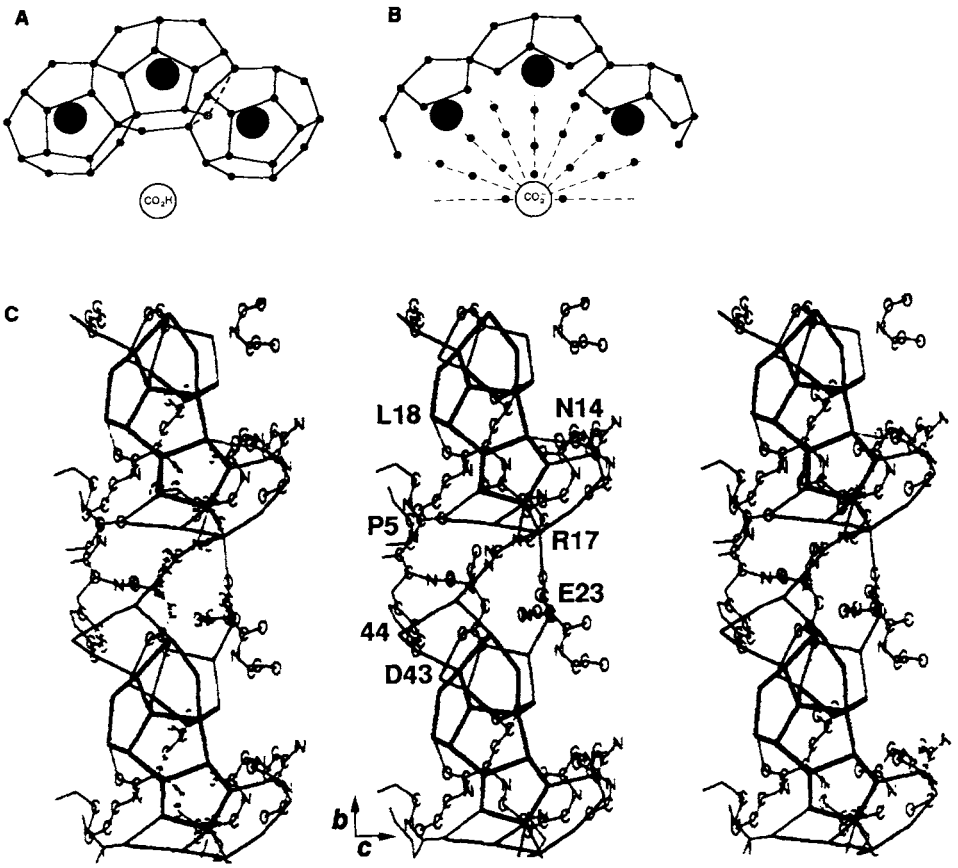

Fig. 4. Examples of the pentagonal arrangement of water molecules associated with hydrophobic residues. A) Crystal structure of alkane gas hydrates surrounded by water molecules arranged into pentagons. About twelve pentagons surround the alkane. (From reference [15].) These are the more ordered water molecules surrounding hydrophobic moieties that become less ordered bulk water when the hydrophobic moieties associate. B) A carboxylate group destructuring the pentagonal arrays as it forms its own hydration shells. ●: hydrophobic moieties; ○: polar (e.g., ionizable) groups; • oxygen atom of a water molecule. C) Stereo-pairs of a section of the crystal structure of crambin showing the pentagonal arrangements of water molecules, for example, adjacent to the leucine-18 (L18) side chain (from reference [16]).

tion, ΔS(hydration), is negative due to the increase in order of the water.[17-19] Accordingly, on raising the temperature of these protein-based polymers in water, the more ordered water surrounding the hydrophobic moieties becomes less ordered bulk water; this positive entropy change is larger in magnitude than the negative entropy change that arises because the polypeptide part of the system becomes more ordered. It is the unique structuring and destructuring of water molecules relative to hydrophobic hydration and dehydration that is responsible for these polypeptides exhibiting increased order on increasing the temperature, and it is all in keeping with the second law of thermodynamics.

With regard to energy conversion, the perturbations that interfere with or assist the water structuring around hydrophobic moieties such as the carboxyl and carboxylate of Figure 4A and B become the free energy changes that drive polypeptide folding or unfolding.

3. Motion (Contraction) Due to Thermally Driven Folding

Numerous physical studies indicate[20,21] that poly(VPGVG) folds into a dynamic helical structure by optimizing intramolecular hydrophobic contacts. The folded state, a β-spiral also known as state II, is given in Figure 5A along with an extended structure, state I, in Figure 5B.[22]

These deductions at the molecular level can be tested on a macroscopic scale. By γ-irradiation cross-linking of poly(VPGVG) in state II, an elastomeric matrix is formed. The matrix is designated as X^{20}-poly(VPGVG), signifying that a 20 Mrad dose of cobalt-60 radiation was used.

This matrix swells in water below 20 °C, and it contracts to less than one-half its extended length on raising the temperature to 40 °C.[1] This is a macroscopic counterpart of the thermally driven folding of poly(VPGVG). On attaching a weight at 20 °C, the elastic matrix stretches; on raising the temperature to 40 °C, it contracts and lifts the weight (Fig. 6). This is thermally driven contraction; it is the conversion of thermal energy into useful mechanical work or thermomechanical transduction (that is, thermal energy⇌mechanical work). The elastic cross-linked matrix is a heat-driven molecular machine.

In general, the proteins of living organisms do not function as heat-driven molecular machines. Most commonly they function as chemically driven molecular machines. How then might this mechanism become more relevant to biological function? The answer lies in determining the chemical means whereby the temperature of the folding and assembly transition can be changed or controlled. For example, if the temperature of the folding transition is above physiological temperature, then the model protein will be unfolded at 37 °C. But if by a chemical means, the temperature T_t of the folding transition can be lowered to below 37 °C, then the model protein should be folded at physiological temperature. By the process of chemically changing or controlling the temperature at which the folding transition occurs, it becomes possible to have a chemically driven molecular machine. In what follows, the means of chemically and otherwise changing the temperature of the folding transition are reviewed.

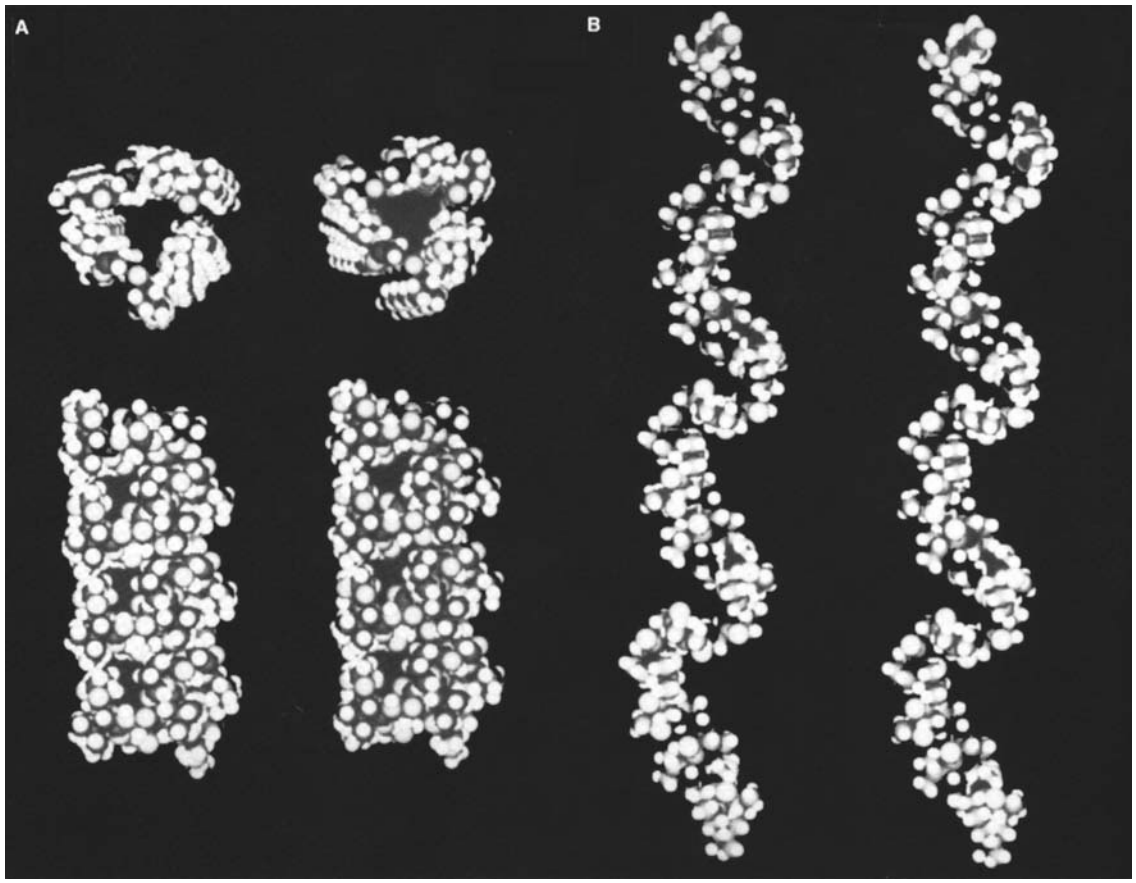

Fig. 5. Stereo-pairs (cross-eye views) of the molecular structure of poly(VPGVG). A) The β-spiral structure has approximately three pentamers per turn. Contacts between the turns of the β-spiral involve the Val-$^1\gamma$-CH_3 group of repeat i with the Pro-β-CH_2 group of repeat $(i + 3)$. The view along the spiral axis (top) shows the space for water inside the spiral, as within the stacks of *cyclo*$(VPGVG)_3$ molecules represented in Figure 3A. The side view (bottom) depicts the linear helical conformation that corresponds to the conformation of the cylic isomer in Figure 3. B) An extended state in which the interturn hydrophobic contacts have been disrupted and where the hydrophobic moieties would be surrounded by more highly ordered water as in Figure 4 (from reference [22]).

4. Deliberate Change in the Temperature T_t at which Folding Occurs

The chemical parameters that can change the value of T_t may be grouped as intrinsic and extrinsic. Intrinsic to the class of model proteins of 50000 Da molecular weight or greater are 1) the concentration of polypentapeptide itself, 2) changes in the amino acid composition within the polypentapeptide, 3) changes in the degree of ionization of functional side chains controlled by changes in pH, 4) the phosphorylation of side chains such as serine by enzymes called kinases, 5) the oxidation or reduction of a prosthetic group attached to the model protein either electrically, chemically, or enzymatically, and 6) photochemical reactions of attached chromophores. With awareness of the concentration effect and of certain conformational restrictions, the effect of changing the amino acid composition on the value of T_t can be determined. The result is a hydrophobicity scale based for the first time directly on the hydrophobic folding and assembly process of interest. The extrinsic chemical parameters are the effects 1) of salts and 2) of organic solutes. There are already examples for each of the above intrinsic and extrinsic variables including, most recently, that of photochemical reactions. Another extrinsic variable, pressure, has also been found to change the value of T_t. It may also be noted that there is a dependence on chain length that becomes significant at lower molecular weights where shorter chain lengths result in higher values of T_t.

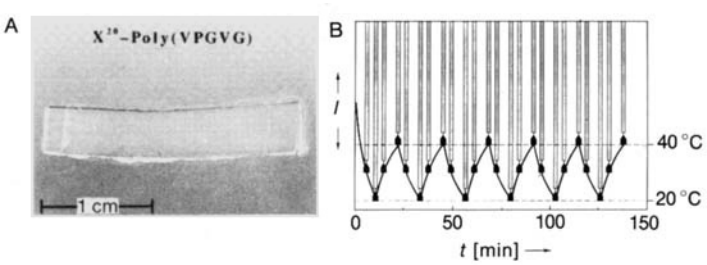

Fig. 6. A) Elastomeric strip of X^{20}-poly(VPGVG). B) A series of thermally driven contraction/relaxation cycles of lifting and lowering a weight. The contraction is the visible macroscopic result of hydrophobic folding and assembly as the temperature is raised. (From reference [35].)

4.1. Intrinsic Chemical Changes

The chemical equivalent of raising the temperature in molecular systems that exhibit inverse temperature transitions is chemically lowering the transition temperature T_t at which the folding occurs.

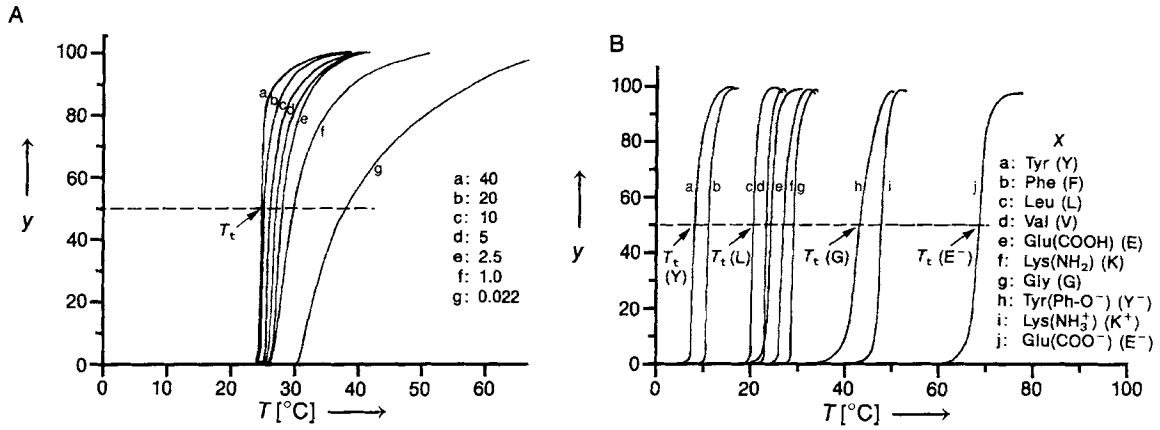

Fig. 7. TPτ profiles for aggregation of poly[f_v(VPGVG),f_x(VPGXG)]. Turbidity (y[%]) is monitored at 300 nm. A) Concentration dependence of T_t for $f_v = 1$, that is, for poly(VPGVG). The concentrations for a–g are given in mg mL^{-1} (from reference [7]). B) Composition dependence of TPτ for $f_x = 0.2$ (from reference [1]). The change in T_t with composition is the basis for a new hydrophobicity scale (see Fig. 8 and Table 1).

4.1.1. *Effect of Concentration*

When the concentration of poly(VPGVG) is increased, the temperature of the inverse temperature transition decreases till a high concentration limit is reached at about 40 mg mL^{-1}.[7] In Figure 7A are given a series of temperature profiles for turbidity formation (TPτ curves) in which the temperature for the onset of turbidity decreases and the steepness of the curve increases as the concentration is increased to the high concentration limit. For this high-concentration limit the temperature T_t of the inverse temperature transition is the temperature at which 50% of the normalized turbidity is obtained. Accordingly, this is the concentration that was used for comparing polypentapeptides of different compositions, and this effect should be kept in mind when examining each of the other means of changing the value of T_t.

4.1.2. *Effect of Composition*

The general formula for the polypentapeptide can be written as poly[f_v(VPGVG),f_x(VPGXG)] where f_v and f_x are mole fractions ($f_x + f_v = 1$), and X is any of the naturally occurring amino acid residues or chemical modifications thereof. A series of TPτ curves are given in Figure 7B for $f_x = 0.2$.[1] Again T_t is defined as the temperature for half-maximal turbidity. As may be seen by plotting f_x versus T_t for all of the naturally occurring amino acid residues (Fig. 8),[23] residues more hydrophobic than Val (Ile(I), Phe(F), etc.) lower the temperature of the transition, whereas less hydrophobic residues like Ala(A), Gly(G) and polar residues like Asp(COO$^-$)(D$^-$) or Lys(NH$_3^+$)(K$^+$) raise the temperature of the transition (i.e., raise the value of T_t). The plots are essentially linear. Therefore, on extrapolating the linear plots to $f_x = 1$, values of T_t are obtained that give an index of relative hydrophobicity. These values are given in Table 1.[23]

4.1.3. *Effect of Changing the Degree of Ionization by Changing the pH*

A very effective means of raising the value of T_t is to increase the degree of ionization α of an amino acid residue such as Asp(COO$^-$), Lys(NH$_3^+$), or Glu(COO$^-$). The most potent in this respect is the Glu (E) residue (see Table 1 and Figs. 7B and 8). With $f_x = 0.2$ the transition temperature in water is too high to measure (greater than 80 °C). On addi-

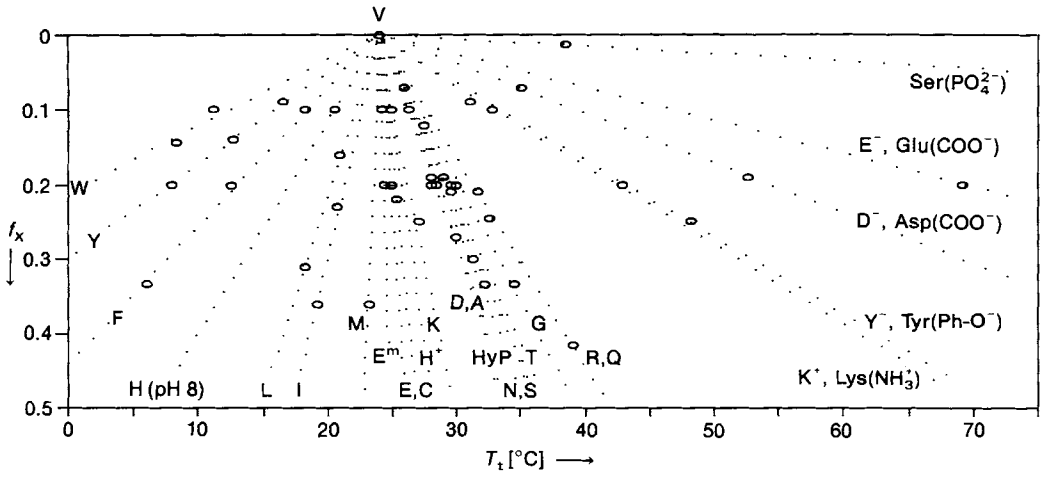

Fig. 8. Plots of T_t for poly-[f_v(VPGVG),f_x(VPGXG)] in phosphate-buffered saline as a function of f_x, at small f_x. At such low X content the plots are essentially linear, and the relative values can be compared for a reference composition (see Table 1). (From reference [23].)

Table 1. Temperature of the inverse temperature transition, T_t for poly[f_x(VPGVG),f_x(VPGXG).

Amino acid X	T_t [°C]	Correlation coefficient
Lys(NMeN, red.) [a]	−130	1.000
Trp (W)	−90	0.993
Tyr (Y)	−55	0.999
Phe (F)	−30	0.999
His (pH 8) (H)	−10	1.000
Pro (P)	(−8)	[b]
Leu (L)	5	0.999
Ile (I)	10	0.999
Met (M)	20	0.996
Val (V)	24	[c]
Glu($COOCH_3$) (E^m)	25	1.000
Glu(COOH) (E)	30	1.000
Cys (C)	30	1.000
His (pH 4) (H^+)	30	1.000
Lys(NH_3) (K)	35	0.936
Asp(COOH) (D)	45	0.994
Ala (A)	45	0.997
HyP	50	0.998
Asn (N)	50	0.997
Ser (S)	50	0.997
Thr (T)	50	0.999
Gly (G)	55	0.999
Arg (R)	60	1.000
Gln (Q)	60	0.999
$Lys(NH_3^+)$ (K^+)	120	0.999
Tyr(Ph-O) (Y)	120	0.996
Lys(NMeN, ox.) [a]	120	1.000
Asp(COO) (D)	170	0.999
Glu(COO) (E)	250	1.000
Ser(PO_4^{2-})	1000	1.000

[a] NMeN represents *N*-methylnicotinamide pendant on a lysyl side chain, i.e., *N*-methylnicotinate attached by amide linkage to the ε-NH_2 of lysine. The reduced state is *N*-methyl-1,6-dihydronicotinamide residue. [b] Calculated. [c] Serves as reference substance.

tion of 0.15 N NaCl the value of T_t for $\alpha = 1$ (i.e., Glu(COO^-) is 69 °C, which is shifted from 24 °C for $\alpha = 0$, that is, Glu(COOH). For the extrapolated reference state of $f_x = 1$, the value for Glu(COO^-) is 250 °C and for Glu(COOH) is 30 °C (see also Fig. 18).

4.1.4. *Effect of Phosphorylation of a Serine Side Chain*

The most potent means (on a per mole pentamer basis) yet found for changing the value of T_t is phosphorylation.[124] It is some four times more potent than the Glu(COO^-) perturbation. For the extrapolated reference state of $f_x = 1$, the value for Ser(PO_4^{2-}) is greater than 1000 °C. While electrostatic interactions have in the past been given as the explanation for the prominent use in biology of phosphorylation/dephosphorylation in changing protein structure to achieve function, the present mechanism provides a more potent explanation in aqueous systems. This will be discussed in Section 8.1.1.

4.1.5. *Effect of Electrochemical or Chemical Reduction of a Prosthetic Group*

Reduction of a chemical moiety could be expected to change the value of T_t for the protein-based polymer to which it is bound. Recent results have demonstrated that the electrochemical reduction of *N*-methylnicotinamide (NMeN), pendant on a lysine side chain, very significantly lowers the value of T_t for the polymer. For poly[0.73(GVGVP),0.27(GK(NMeN)GVP)] T_t was 48 °C and on partial reduction became 31 °C (Fig. 9A). When extrapolated to $f_x = 1$, the oxidized state would give 120 °C for T_t, and with the assumption of complete reduction, the electrochemically reduced state expected to yield the 6-hydroxy-*N*-methyl-1,4,5,6-tetrahydronicotinamide would give 37 °C for T_t. If conversion in the experiment were not complete, the value of T_t would be lower. The present best estimate places the value below 0 °C. The UV absorption spectra corresponding to the TPτ curve of Figure 9A are given in Figure 9B (Urry, Hayes, Gowda, and Harris, unpublished results).

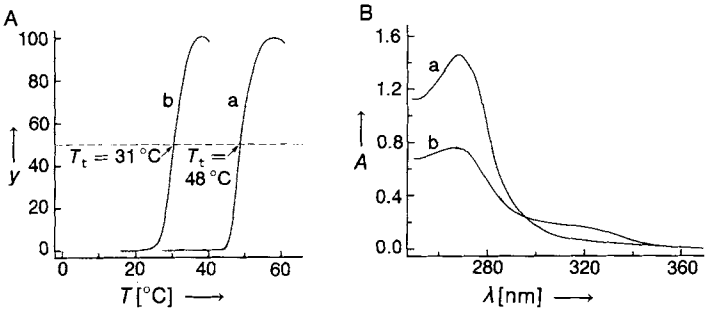

Fig. 9. A) Dependence of T_t on redox state of the *N*-methylnicotinamide residue in poly[0.73(GVGVP),0.27(GK(NMeN)GVP)]. At a concentration of 10 mg mL^{-1}, T_t is 48 °C when oxidized (a), and 31 °C when reduced at −1.8 V for 30 min in a carbonate/KCl buffer system at pH 9. B) Absorption spectra corresponding to the curves in A, after the samples were diluted by 50% with buffer.

Chemical reduction with dithionite has been found to reduce T_t from 49 °C to 9 °C for an estimated 60% reduction based on the absorption spectra for *N*-methyl-1,6-dihydronicotinamide. Extrapolating to $f_x = 1$ gives for the oxidized state the same T_t value as in the electrochemical experiment of 120 °C and for the reduced state a value of −130 °C. The ΔT_t of 250 °C for this NMeN redox couple is slightly larger than the ΔT_t of 220 °C for the Glu(COOH)/Glu(COO^-) chemical couple.[125]

4.1.6. *Effect of Photochemical Reactions*

It was also anticipated, and has now been confirmed, that photochemical reactions would change the hydrophobicity or polarity of a photoreactive side chain or chromophore attached to an amino acid side chain. As the photoproducts can be quite varied, some reactions could be expected that would raise the value of T_t whereas others might decrease it. This will be an interesting feature to pursue. In the results obtained to date (K. Heimbach, T. Parker, and D. W. Urry, unpublished data) photochemical reaction of a spiropyran attached by ester linkage to a Glu residue causes a decrease in the value of T_t, and photochemical reaction of an attached cinnamic acid moiety causes a dark reversible increase in T_t.

4.2. Extrinsic Chemical Changes

Many extrinsic chemical perturbations of salts and organic solutes have now been identified that change the temperature of the inverse temperature transition. In both categories some raise the value of T_t while others lower it.

4.2.1. Effects of Adding Salts

The first demonstrated salt effect was that of sodium chloride, which lowers the value of T_t 14 °C N^{-1} (i.e., gram equivalent per liter).[26] NaBr is less effective in lowering T_t whereas NaI and NaSCN cause small increases. The salts with the most potent effect on a normality basis are those with multivalent anions such as the carbonates, sulfates, and phosphates. A number of these salt effects are shown in Figure 10A. All have the potential of being used for chemically driven folding or, as in the case of the few that raise T_t, for chemically driven unfolding.

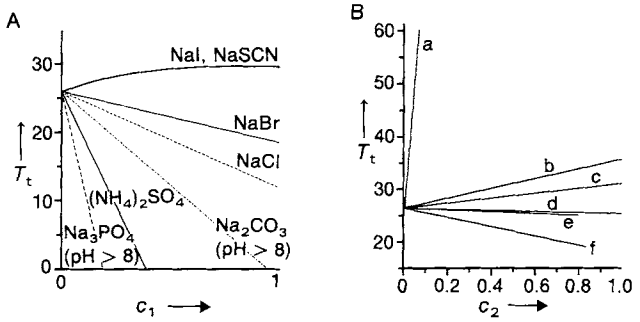

Fig. 10. Influence of salts (A, adapted from reference [35]) and organic solutes (B, unpublished data) on T_t for poly(VPGVG). c_1 = salt concentration in N. c_2 = concentration of organic solute in M. a: sodium dodecyl sulfate; b: guanidinium chloride; c: urea; d: ethylene glycol; e: glycerol; f: trifluoroethanol.

4.2.2. Effects of Organic Solutes

As seen in Figure 10B, the effects of organic solutes appear to be more variable than those of salts, and a few are even biphasic. Organic solutes in order of decreasing potency for raising T_t are sodium dodecylsulfate (600 °C mol^{-1} at 0.1 M), guanidine hydrochloride (12 °C mol^{-1} at 0.3 M), urea (5.5 °C mol^{-1} at 0.3 M), and Triton X-100, which is biphasic (22 °C mol^{-1} at 0.3 M). Organic solutes that lower T_t are ethylene glycol, trifluoroethanol (−11 °C mol^{-1} at 0.4 M), trifluoracetic acid, and glycerol (−2.2 °C mol^{-1} at 0.4 M). Dimethyl sulfoxide and ethylene glycol (at very low concentrations) are biphasic, which increases the value of T_t at lower concentrations and progressively lowers the value of T_t at higher concentrations.

4.3. Another Extrinsic Change: Pressure

Increases in pressure will also raise the value of T_t [27] and will do so most effectively if aromatic residues such as Phe(F), Tyr(Y), and Trp(W) are present (Fig. 11). The effect occurs because the volume occupied per water molecule is less when the water molecules are more ordered around aromatic moieties than in bulk water. This means that application of pressure could be used to drive unfolding, and the release of pressure could bring about folding.

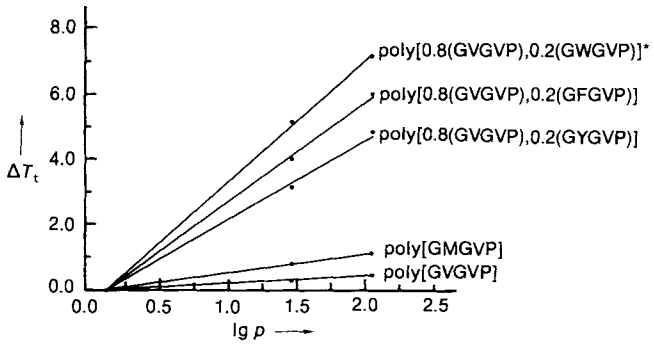

Fig. 11. The effect of pressure on T_t. The data is plotted according to the Clausius–Clapeyron equation. The change in transition temperature ΔT_t is plotted versus lg p (p in atm); the slope is thus $p\Delta V/\Delta S$. By using differential scanning calorimetry data to evaluate $\Delta S(=\Delta H/T)$, the volume changes can be calculated. (From reference [27].)

4.5. A Unifying Basis for Diverse Energy Conversions: The ΔT_t Mechanism

The ΔT_t mechanism is currently under investigation to determine just how ubiquitous it is. Many intrinsic and extrinsic chemical changes have now been shown to change the temperature at which the inverse temperature transition (the temperature of the hydrophobic folding and assembly transition) occurs. These are the initial, necessary demonstrations of feasibility in properly designed elastic protein-based polymers before conditions can be developed for working with a viscoelastic phase that has been made into a suitable cross-linked elastic matrix. Several chemical energy inputs and pressurization energy can result in contraction of the elastic materials with the performance of useful mechanical work, and it can be argued that an even more diverse set of energy conversions will be possible. This discussion and the categorization of the energy conversions will be introduced by a brief review of the development of the ΔT_t mechanism.

It was first observed that polypeptides or model proteins with the correct balance of apolar (hydrophobic) and polar moieties became more ordered on raising the temperature. This process was called an inverse temperature transition. For some of the polypeptides the inverse temperature transition was seen to be a reversible phase transition with the formation of a more dense, polypeptide-rich, viscoelastic phase on raising the temperature. When the viscoelastic phase was cross-linked, elastic matrices were formed which, on raising the temperature past the inverse temperature transition, would contract and in doing so could lift weights that were a thousand times the dry weight of the matrix. These matrices could thus perform useful mechanical work on raising the temperature. Such elastic matrices may be called zero-order molecular machines of the inverse temperature transition (T_t) type.

Next, having demonstrated that varying the composition of the protein-based polymer systematically altered the transition temperature, it was anticipated that changing the de-

gree of ionization of a functional side chain in the polypeptide (an intrinsic chemical change) would change the temperature at which the inverse temperature transition occurred, because this varies the composition without synthesis of a new polymer. It was further anticipated that the cross-linked viscoelastic phase of such a polypeptide would exhibit an isothermal pH-driven contraction capable of doing useful mechanical work. This was observed.[28] In general, such an elastic matrix (in which chemical energy or any other energy source could change the temperature of the inverse temperature transition and thereby cause contraction enabling useful mechanical work to be performed) will be called a first-order molecular machine of the T_t type. The work performed is the direct result of hydrophobic folding and assembly. The energy conversions now directly demonstrated to be feasible, indirectly argued as occurring, or proposed as possible by the ΔT_t mechanism are summarized in Figure 12. The T_t-type

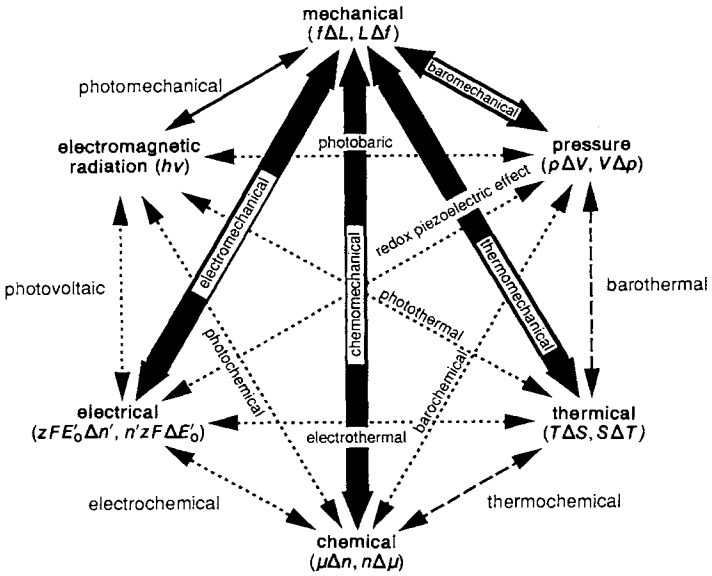

Fig. 12. Demonstrated and putative energy conversions with molecular machines of the T_t type. The bold arrows indicate the energy conversions that have been observed with the elastic protein-based matrices. Photomechanical energy conversion is inferred from photoreduction of nicotinamide [90] and, for example, from photoisomerism of a cinnamic acid chromophore attached to a side chain. To our knowledge these arrows include all energy conversions that can occur in the living organism, and all appear possible by T_t-type molecular machines.

first-order energy conversions are those with arrows directly terminating at the mechanical apex. Those already demonstrated are depicted as broad arrows; the one for which the shift in T_t has been demonstrated in a suitably designed polypeptide prior to cross-linking is indicated by the solid line; those for which there is indirect data are indicated by the dashed arrows; and those which are as yet hypothetical are given as the dotted arrows.

The arrows indicating energy conversions not ending at the mechanical apex will be considered second-order energy conversions of the T_t type. Though they utilize the hydrophobic folding and assembly capacity of the elastic matrix, mechanical work is not one of the pair of energies being interconverted.

5.1. First-Order Molecular Machines of the T_t Type

5.1.1. Conversion of Chemical Energy into Mechanical Work

The capacity chemically to change the temperature T_t at which the folding and assembly transition occurs implies that conversion of chemical energy into mechanical work can occur isothermally, that is, under the homoiothermic conditions of warm-blooded animals.

5.1.1.1. Proton-Driven Contraction

This ΔT_t mechanism was first demonstrated for chemomechanical transduction. The demonstration utilized the γ-irradiation cross-linked matrix, X^{20}-poly[0.8(VPGVG),0.2-(VPGEG)], shown above Figure 13A. First, however, the conditions under which thermally driven contraction occur were examined. At low pH (2.2), this matrix in phosphate-buffered saline (0.15 N NaCl, 0.01 M phosphate) begins to contract as the temperature is raised above 20 °C. This thermally driven contraction is complete by 40 °C. At a higher pH (4.5), thermally driven contraction does not begin until near 45 °C. By the ΔT_t mechanism, it should be possible to maintain the temperature at 37 °C and lower the pH to drive contraction. This does occur, as seen in Figure 13A. Raising the concentration of protons converts the Glu(COO^-) residue to Glu(COOH), and the matrix at 37 °C contracts picking up a weight.[28] The cross-linked Glu-containing matrix converts chemical energy into mechanical work; it is a chemically driven molecular machine, that is, chemical energy ↔ mechanical work.

5.1.1.2. Salt-Driven Contraction

As shown in Figure 10A, addition of NaCl lowers the value of T_t for poly(VPGVG) by 14 °C N^{-1}. Even the change from pure water to 0.15 N NaCl at 25 °C results in quite significant contractions.[29] Figure 13B shows a series of salt-driven contractions and relaxations of the X^{20}-poly(VPGVG) elastic matrix shown. Accordingly, an extrinsic chemical change can be used to drive contraction and to perform useful mechanical work. Any salt capable of changing the value of T_t may be expected to drive contraction, including those shown in Figure 10A.

When the protein-based polymer contains a charged moiety such as a Glu(COO^-) residue, the sensitivity of T_t to salt concentration is an order of magnitude greater in the low concentration range (Luan and Urry, unpublished data). When the polymer concentration is 40 mg mL^{-1}, this increased effect is observed between 0 and 0.2 N. Above this concentration of salt, the coefficient is again near 15 °C N^{-1}. The effect arises presumably from the weak ion-pairing of the salt's sodium cation with the carboxylate anion of the protein-based polymer. In this case a smaller chemical energy change could be expected to perform a given amount of chemical work. The comparison of the efficiency of the charge–charge repulsion mechanism and the ΔT_t mechanism is discussed in the following without considering this increased sensitivity.

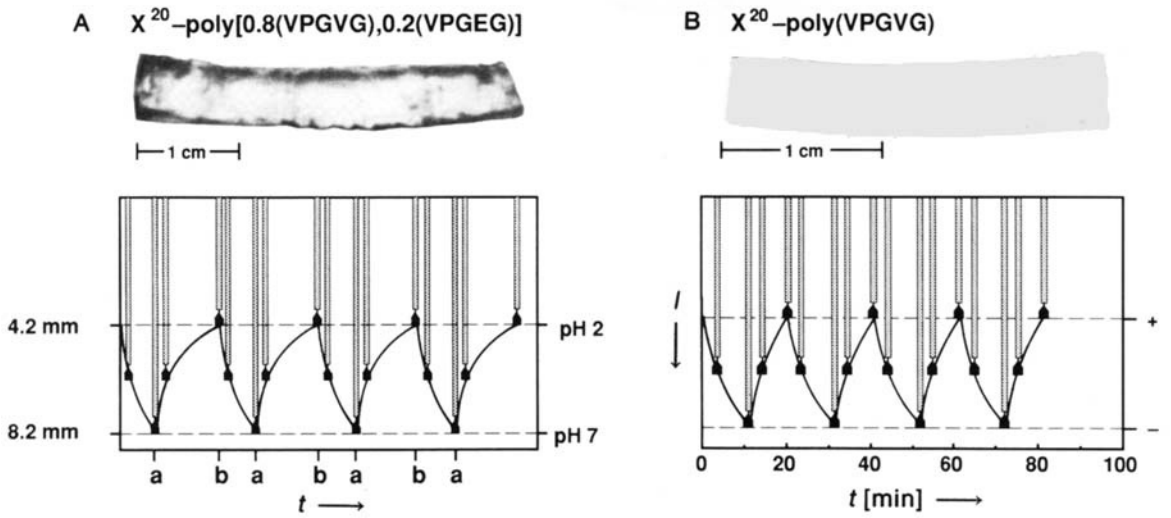

Fig. 13. A) A strip of cross-linked, Glu-containing elastic matrix, here X^{20}-poly[0.8(VPGVG),0.2(VPGEG)] as proton-driven molecular machine. At low pH the length of the strip of elastic matrix with a weight attached was 4.2 mm; on raising the pH the strip extended lowering the weight (b, neutralization); when the pH was lowered (by addition of acid at a) the strip contracted lifting the weight. This proton-driven molecular machine can be operated through many cycles. (From reference [35].) B) A strip of cross-linked poly(VPGVG) as salt-driven molecular machine. The strip is extended in the absence of salt. Addition of salt causes a contraction, and the the weight is lifted. This cycle can be repeated for days without any loss in the extent of contraction. Run in reverse, that is, providing the mechanical energy of stretching, this molecular machine could be used for desalination. (From reference [35].) + : salt present. – : no salt present.

5.1.1.3. Reduction-Driven Contraction

With a 20 Mrad cross-linked *N*-methylnicotinamide containing elastic matrix, X^{20}-poly[0.73(GVGVP),0.27(GK-(NMeN)GVP)], partial reduction by dithionite has now been observed to lower the temperature range over which thermally driven contraction occurs. Accordingly, at a temperature of 40 °C the matrix contracts when dithionite is added and picks up a weight. Thus, contraction driven by chemical reduction has now been observed.[30] Since reduction may also be carried out electrochemically this may be termed electromechanical transduction as indicated in Figures 12 and 14.

5.1.2. Conversion of Pressurization Energy into Mechanical Work

In Section 4.3, pressure was noted as another variable, extrinsic to the polypeptide, that could change the value of T_t, particularly in protein-based polymers containing aromatic residues. From the increase in T_t as the pressure was increased and the experimental heat divided by the transition temperature, it was calculated that a water molecule in bulk water occupies a greater volume than a water molecule in the solvent sphere surrounding the most hydrophobic moieties (the aromatic moieties such as those of the Phe(F), Tyr(Y) and Trp(W) residues).[27] At the appropriate temperature and at elevated pressure the elastic matrix suspending a weight will be extended, and the aromatic moieties will be surrounded by the more ordered, denser water. On releasing the pressure, the more ordered water molecules convert to bulk water as the model protein hydrophobically folds, thereby contracting and performing the mechanical work of lifting the weight. This baromechanical transduction has now been observed.[31] At the appropriate temperature, the properly designed elastic matrix is a pressure-responsive molecular machine.

In this example of a molecular machine capable of free energy transduction, the interconverting Gibbs free energies are the products of the intensive variable of mechanical force and the extensive variable of distance the weight is moved against the force of gravity and of the intensive variable of pressure and the extensive variable of change in volume.

5.2. Second-Order Molecular Machines of the T_t type

As an example of a T_t-type second-order energy conversion, consider a swollen matrix of unfolded polypeptides containing both an oxidized component of a redox couple, for example *N*-methylnicotinamide, and the charged moiety of a chemical couple, for example (COO^-), in which the composition of the protein-based polymer is such that T_t is just above the operating temperature. Under these circumstances, either lowering the pH to convert the COO^- into COOH or reduction of the nicotinamide, the oxidized prosthetic group (redox couple), would lead to hydrophobic folding and assembly. If the oxidized prosthetic group were reduced, then the resulting folding would be expected to shift the pK_a of the carboxyl moiety, and under the proper conditions the chemical result would be an uptake of protons (a decrease in proton chemical potential). If, on the other hand, the pH were lowered and the carboxylate anion were protonated, the electrochemical potential of the oxidized prosthetic group would be expected to shift in favor of reduction and the electrical result could be the uptake of electrons. Either of these scenarios could be designated as electrochemical transduction as the arrow connecting the electrical and chemical apices in Figure 12 indicates. Both would utilize the hydrophobic folding, but the energy produced or the work performed would not be mechanical in nature. The elastic

matrix so designed to achieve electrochemical transduction would be in our designation a second-order molecular machine of the T_t type.

Equivalent scenarios could be described for other T_t-type second-order energy conversions such as photochemical, photovoltaic, thermochemical, that is, for any of the pairwise energy conversions not including the mechanical apex of Figure 12.

There are, therefore, many energy conversions that may be considered to arise from the basic ΔT_t mechanism. Future studies will be directed toward designing protein-based polymers, and the suitable experimental apparatus and conditions for each, with which to demonstrate these energy conversions. To our knowledge these include all of the energy conversions which occur in living organisms. The effectiveness and efficiency of the ΔT_t mechanism for each interesting energy conversion will need to be established. By the process of natural selection living organisms probably would evolve to utilize the most efficient mechanism for energy conversion that is available to its composition.

A summary of the ΔT_t mechanism of free energy transduction is given in Figure 14 for zero-order and first-order molecular machines of the T_t types.

6. Physical Basis for ΔT_t-Type Energy Conversions

The physical basis for the ΔT_t mechanism of energy conversion resides in changing hydration within the system. For the conversion of chemical energy into mechanical work by means of intrinsic chemical changes, the basis is the competition for hydration between hydrophobic and more polar moieties (for example, between Val side chains and the carboxylate anion) that are both part of the same amphiphilic polymer with constraints on the distance between them. As this distance can be changed only by changes in the folded state of the polymer, control can be exercised over the folding/unfolding process.

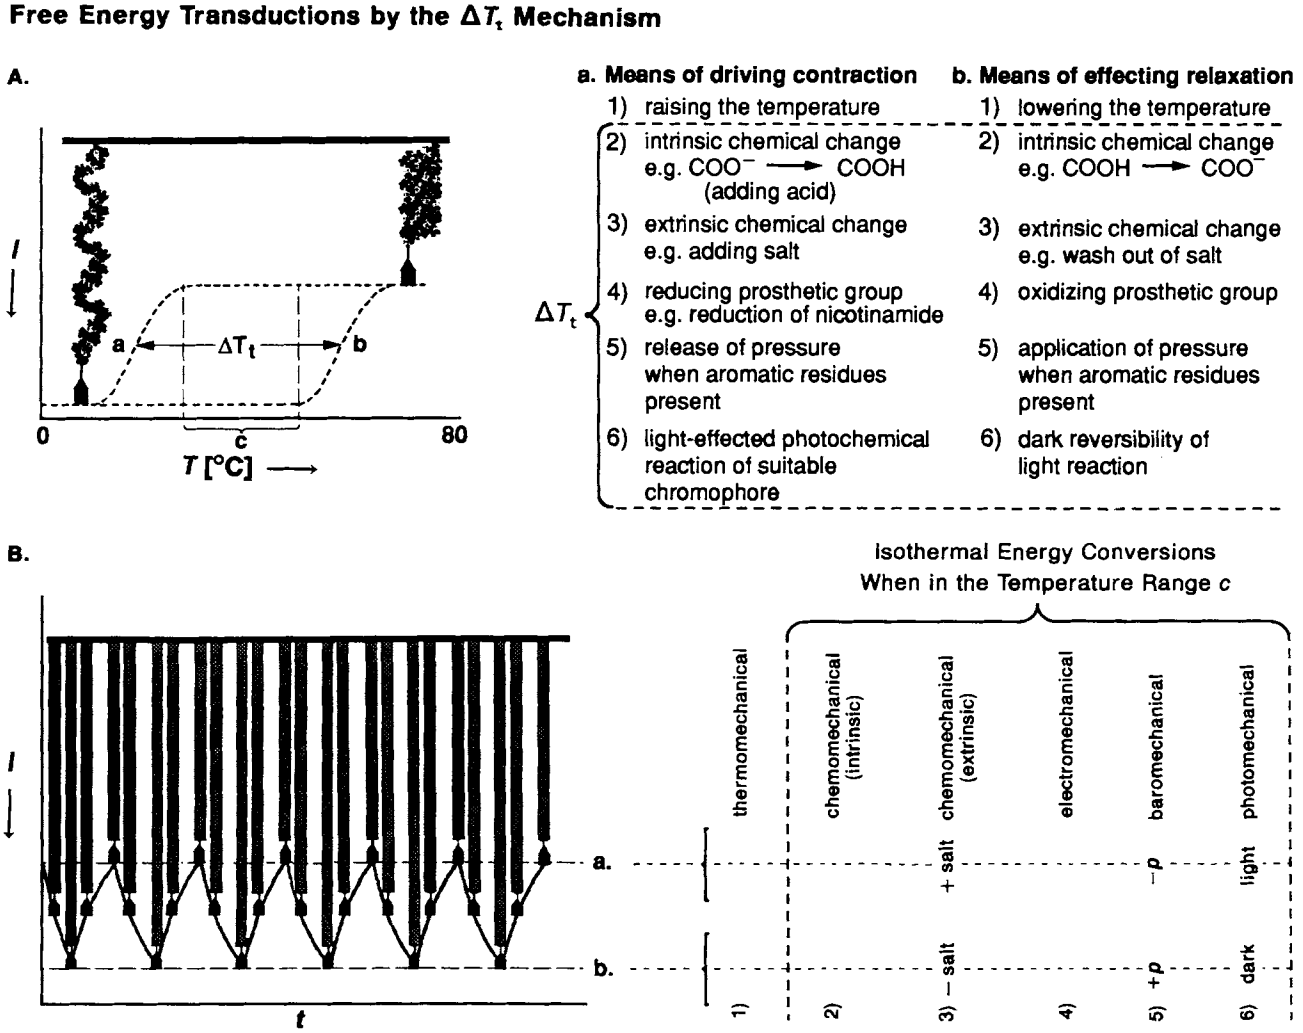

Fig. 14. Summary and present state of the development of the ΔT_t mechanism. A) Left: Schematic illustration of the β-spiral of poly(VPGVG) in extended (unfolded) state at low temperature and contracted (folded) state at elevated temperature. The temperature range over which the transition occurs is designated as ΔT_t; the temperature range over which maximal contraction can be achieved is indicated by c. Right: the list of conditions that can influence T_t. B) Left: Schematic illustration of an elastic protein-based model reversibly undergoing contraction and relaxation when in the temperature range c. Right: The energy conversions of items 1)–6) of A that achieve contraction, and the conditions required for them. The photochemical reaction can either raise or lower the value of T_t; both have been observed.

6.1. When Hydrophobic Hydration Dominates in Amphiphilic Polymers

When hydrophobic hydration dominates in amphiphilic polymers such as proteins, in our view the prevalence of the more ordered water structure surrounding the hydrophobic species results in an inadequate water structure for the hydration of charged species. The free energy of hydration of the charged species is less favorable (higher), and ionization is less probable. This is seen experimentally as a hydrophobicity-induced increase in the pK_a.

The protein-based polymer poly[0.8(VPGVG),0.2-(VPGEG)] in water at 37 °C has a pK_a of 4.6; the more hydrophobic poly[0.8(IPGVG),0.2(IPGEG)] under the same conditions has a pK_a of 6.0.[32] With correct design of primary structure even greater shifts can be seen.

Deliberate changes in the nanometer range can result in extraordinary pK_a shifts. Schematic representations of the β-spirals of the poly(GVGVP) and pentapeptides that differ from poly(GVGVP) by the introduction of Glu(E) and Phe(F) residues are given in Figure 15. In the polypeptide in

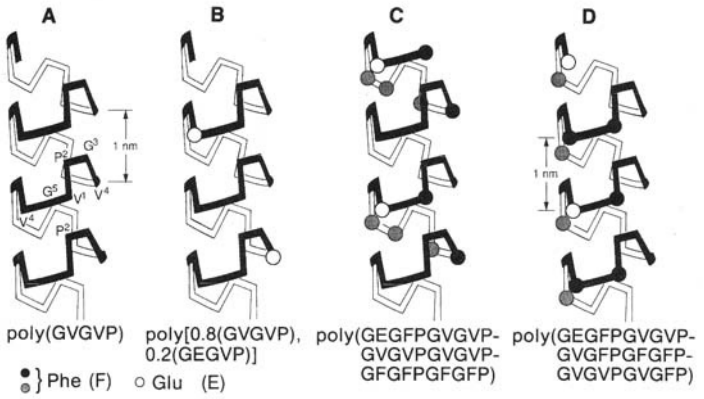

Fig. 15. Schematic representations of the β-spiral structure of polypeptides. A) Poly(GVGVP). B) Random incorporation of Glu(E) residues in 20% of the poly(GVGVP) pentamers. C) The polytricosapeptide, poly(GEGFPGVGVPGVGVPGVGVPGFGFPGFGFP), in which the Phe(F) residues are in a fixed relationship to the Glu(E) residue. D) The polytricosapeptide, poly(GEGFPGVGVPGVGFPGFGFPGVGVPGVGFP), in which the particular folding of the β-spiral with three pentamers per turn provides an optimal arrangement of the Phe residues around the Glu residue. (From reference [33].)

Figure 15D, the Phe(F) residues are optimally arranged around the Glu(E) residue. Figure 16 depicts the acid–base titration curves for the polymers in Figure 15 (I, IV, and V) as well as those of two other polymers (II and III) consisting of the same pentamers as those in Figure 15C and D, respectively, but the pentamers are randomized.[33] Thus, the Phe(F) residues are optimally placed for the β-spiral structure in polymer V, which results in a remarkable pK_a for Glu(E) at 20 °C in water of 8.1, a shift from a pK_a value of 4.3 for polymer I under these conditions. It is the proximity of the aromatic (phenyl) side chains surrounded by the more ordered water molecules that make hydration of the COO^- moiety in polymer V so unfavorable.

An estimate of the repulsive Gibbs free energy of hydration can be obtained from the chemical potential μ of the protons required to maintain the Glu side chain at 50% ionization. As $\mu = RT\ln a$ where a is activity, $\mu = RT\ln[H^+]$, since at the low proton concentrations, activity is equivalent to concentration. Rewriting with the logarithm to the base 10 (lg) gives $\mu = 2.3\,RT\lg[H^+]$, but as $pH = -\lg[H^+]$, the chemical potential becomes $\mu = -2.3\,RT\,pH$. The change in proton chemical potential $\Delta\mu$ required to maintain the Glu side chain at 50% ionization (that is, at its pK_a), is simply $\Delta\mu = -2.3\,RT\Delta pK_a$. Since $R = 1.987\ cal\,mol^{-1}\,K^{-1}$, RT at 20 °C (293 K) is 582 $cal\,mol^{-1}$, a ΔpK_a of −3.8 (4.3−8.1) requires a $\Delta\mu$ of 5 $kcal\,mol^{-1}$.

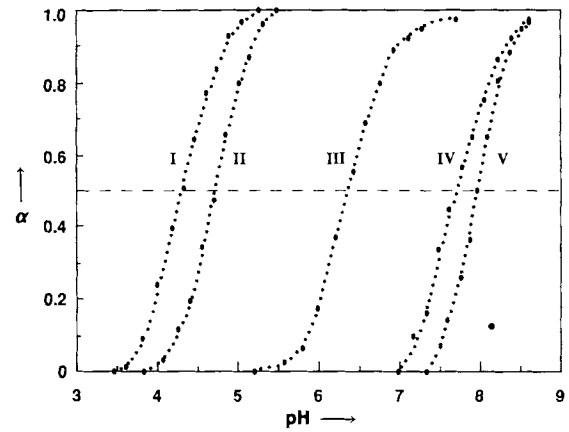

Fig. 16. Structure-dependent pK_a shifts induced by hydrophobicity, demonstrated by the resolved acid–base titration curves for polymers B–D of Figure 15 (I, IV, and V, respectively), as well as for an isomer each of IV and V (II and III, respectively), which were synthesized by direct polymerization of the pentamers and not by the polymerization of the tricosamers. (From reference [33].) α = degree of ionization.

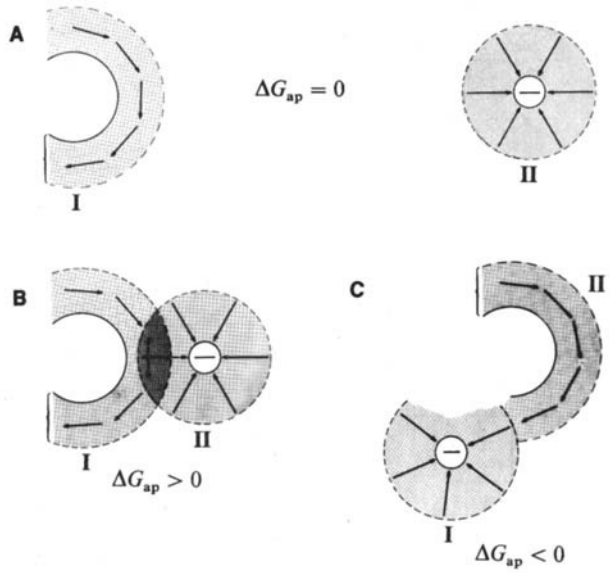

Fig. 17. Relationship between the distance from charged species to hydrophobic moiety and ΔG_{ap} for hydration-mediated apolar–polar interactions. The water molecules are represented as dipole moment vectors. The water vector is tangential to the surface of the hydrophobic moiety (I), whereas it points directly at the negatively charged moiety (II). A) When the hydrophobic and polar species are far apart, there is no interaction. Each receives its full free energy of hydration. B) When the hydration shells overlap, there is a loss of free energy of hydration and ΔG_{ap} is positive. This can give rise to the hydrophobicity-induced pK_a shifts when the apolar moieties dominate. As the charged species form, there is a destructuring of the hydrophobic hydration sphere. C) For special orientations of apolar and polar moieties in which water molecules can simultaneously serve both hydration spheres, ΔG_{ap} is negative. This can be seen in the crystal structure of crambin (Fig. 4C). (From reference [34].)

This is the hydration-mediated apolar–polar repulsive free energy, ΔG_{ap}, which drives unfolding on ionization of the carboxyl group. An attempt to depict ΔG_{ap} is shown in Figure 17.[34] With the aspartic acid residue Asp(D) in place of the glutamic acid residue Glu(E) in polymers I(A) and V(D) of Figures 15 and 16, the pK_a values are 3.9 and 10.1, respectively, giving a ΔG_{ap} of 8.3 kcal mol^{-1}. This is the largest pK_a shift yet observed in a designed model protein (Urry, Gowda, Perry, Parker, Jing, Harris, unpublished results).

6.2. When Ionic Hydration Dominates in Amphiphilic Polymers

In our view, in this case the more ordered water molecules surrounding the hydrophobic moieties are substantially disrupted by the orientation of water molecules to hydrate the proximal charged moieties. With loss of the more structured water surrounding the hydrophobic moieties, there is no longer the Gibbs free energy as driving force for the inverse temperature transition, that is, for the hydrophobic folding. Therefore, the polymer unfolds.

Recall that the hydration of hydrophobic moieties is exothermic (ΔH(hydration) is negative). Since the hydrophobic hydration is structured (that is, the less ordered bulk water becomes the more ordered water of hydrophobic hydration), ΔS(hydration) is negative. Because $-T\Delta S$(hydration) is therefore positive and of a magnitude similar to the negative ΔH(hydration), solubility is limited. In the polymer, solubility reflects the presence of the unfolded state and insolubility of the hydrophobic-containing species the presence of the folded state. Folding and unfolding of the polymer arises when the relative magnitudes of the two terms are changed. When the charged species is present, there would be less of the structured water surrounding the hydrophobic moiety; ΔS(hydration) for the transition would be smaller, and a higher temperature T would be required before $-T\Delta S$(hydration) dominates. Therefore, T_t would increase with increase in numbers of charged species.

That the temperature of the transition increases with increased degree of ionization α is clearly shown in Figure 18.[35] Corresponding with increase in degree of ionization and increase in T_t, the heat required to destructure the more structured water around hydrophobic moieties is seen to decrease (Fig. 19).[36] When there are less than two COO^- moieties per hundred residues, the endothermic heat required to drive the transition is reduced almost to one-fourth. In our interpretation, the hydration of the two COO^- moieties formed in a hundred residues effectively destroyed some three-fourths of the more ordered structure of the water that had surrounded the hydrophobic moieties.

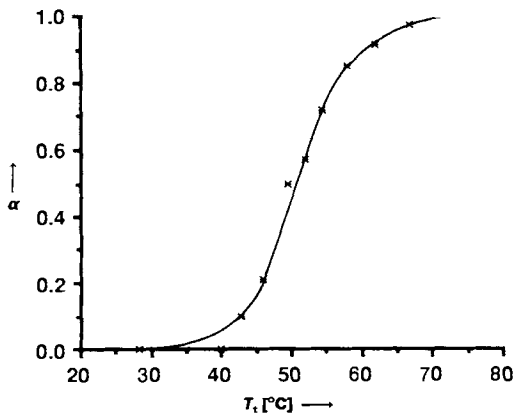

Fig. 18. Dependence of T_t on degree of ionization α for poly[0.8(VPGVG),0.2(VPGEG)] in 0.15 N NaCl. The acid–base titration was carried out at 37 °C. (From reference [35].)

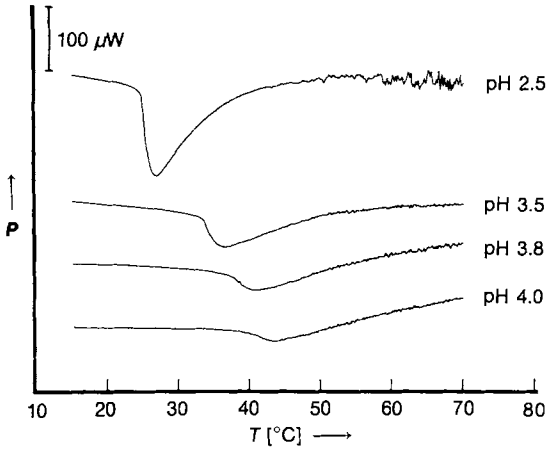

Fig. 19. Differential scanning calorimetry scans of poly[0.8(VPGVG), 0.2(VPGEG)] in water at several pH values. At pH 2.5 when essentially all Glu residues are present as COOH, the endothermic heat required to destructure the waters of hydrophobic hydration is 0.97 kcal per mol^{-1} pentamer. As the pH is raised producing more COO^- moieties, the temperature of the transition increases, consistent with the data in Figure 18, and importantly, the endothermic heat of the transition decreases. By the time there are less than 2 COO^- groups per 100 residues (pH 4.0), the heat required to destructure the waters of hydrophobic hydration is reduced to 0.27 kcal per mol^{-1} pentamer (from reference [36]). P = heat flow; a negative peak represents an endothermic process, a positive peak an exothermic process.

The T_t hydrophobicity scale of Table 1 shows that there is essential continuity from the most hydrophobic residues, Trp(W), to the most polar moiety, PO_4^{2-}. Charged species provide more extreme examples of the competition for hydration. Qualitatively, however, the same argument can be applied whenever an intrinsic chemical change to a more polar moiety results in an increase in the value of T_t.

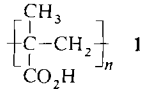
7. Relative Efficiencies for Converting Chemical Energy into Mechanical Work (Motion)

Much is known about muscle contraction in terms of the sliding filament model in which actin filaments slide past myosin rods,[37] and a third elastic filament, titin, is probably important in the assembly process.[38] Nonetheless, there is considerable controversy about the source of force development. The prevalent swinging cross-bridge theory is being challenged by proposed length changes and force development in the myosin rods in one school[39] and in the actin filament in another.[40] Also, the calculation of efficiency requires more than merely the consideration of the ATP consumed at the filaments; the ATP equivalents required to achieve the important calcium ion concentration changes must also be considered.

It is possible to compare efficiencies of model systems. The charge–charge repulsion mechanism, represented by polymethacrylic acid, and the salt-dependent collapse of the collagen structure can be compared with phenomena observed with protein-based polymers. A measure of efficiency η can be the mechanical work achieved, which is the product of the force f and the displacement ΔL, divided by the chemical energy $\Delta\mu \cdot \Delta n$ expended in performing the work, where $\Delta\mu$ is the change in chemical potential discussed above and Δn is the change in number of moles for the intrinsic change. For example, Δn can be the number of moles of carboxylate groups (COO^-) changed to acid groups (COOH). The expression for efficiency therefore can be written as Equation (a).

$$\eta = \frac{f\Delta L}{\Delta\mu\Delta n} \qquad \text{(a)}$$

Fortunately, polymethacrylic acid (**1**) utilizes the same ($COOH/COO^-$) chemical couple as the protein-based polymer, poly[0.8(VPGVG),0.2(VPGEG)]. Also, the cross-linked matrices of both can contract to about one-half their extended length and can lift weights that are a thousand times greater than their dry weight. The numerators $f\Delta L$ are thus similar in magnitude.[41–43] Where the difference occurs is in the chemical energy required to achieve that work.



1

For polymethacrylic acid, extension due to charge–charge repulsion is achieved when 50 to 60% of the carboxyl groups are converted to COO^-, and the collapse of the extended state to achieve contraction is complete by 0 to 10% ionization.[41–43] Thus some 40 carboxylate groups must be protonated per 200 backbone atoms for complete contraction. For X^{20}-poly[0.8(VPGVG),0.2(VPGEG)], only 4 carboxylates per 300 backbone atoms need to be protonated for complete contraction. Thus, the Δn is more than ten times larger for the polymethacrylic acid system. Also, the change in the chemical potential $\Delta\mu$ of protons required to achieve any particular degree of ionization is greater for the charge–charge repulsion case (polymethacrylic acid) as shown in Figure 20.[1] The change in proton chemical potential to go from 50–60% to 0–10% ionization is some 2 pH units for polymethacrylic acid because of the negative cooperativity of the titration curve.[1,42] For the protein-based polymer, the titration curve exhibits positive cooperativity, and the change of only a fraction of a pH unit achieves the required change in degree of ionization. This comparison is summarized in Scheme 2. The conversion of chemical energy into mechanical work is thus over ten times more efficient for the ΔT_t mechanism than for the charge–charge repulsion mechanism.

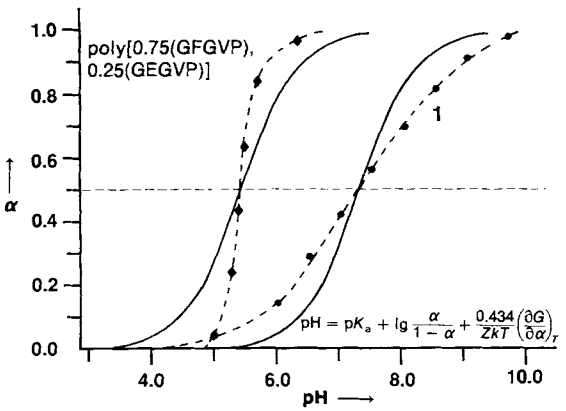


Fig. 20. Acid–base titration curves for poly[0.75(GFGVP),0.25(GEGVP)], which is steeper than the reference curve (solid line), and of polymethacrylic acid (**1**), which is less steep than the reference curve. The reference curves are calculated from the first two terms of the equation (bottom right). Whether the curve is steeper than the reference curve depends on the sign of $(\partial G/\partial\alpha)_T$, which is positive for apolar–polar repulsion and negative for the charge–charge repulsion. (From reference [1].)

η_{cc} = efficiency of charge–charge repulsion mechanism (as exemplified by polymethacrylic acid)
w: $\Delta L \approx 0.5$; $f \approx 1000 \times$ dry weight
Δn: > 40 ($COO^- \rightarrow COOH$) per 200 backbone atoms
$\Delta\mu$: ($\Delta\alpha \approx 0.6 \rightarrow \Delta pH \approx 2.0$) ≈ 2.8 kcal mol^{-1}

η_{ap} = efficency of apolar–polar repulsion free energy mechanism (as exemplified by X^{20}-poly[4(VPGVG),(VPGEG)])
w: $\Delta L \approx 0.5$; $f \approx 1000 \times$ dry weight
Δn: < 4 ($COO^- \rightarrow COOH$) per 300 backbone atoms
$\Delta\mu$: ($\Delta\alpha \approx 0.8 \rightarrow \Delta pH \approx 0.7$) ≈ 0.94 kcal mol^{-1}

Result: $\frac{\eta_{ap}}{\eta_{cc}} > 10$

Scheme 1. Comparison of the efficiency of chemomechanical transductions. For the definition of η see Equation (a) and the explanatory text.

It may be noted that just as polymethacrylic acid can be used as a model for charge–charge interaction, polymers such as poly(*N*-isopropylacrylamide) have been found to display inverse temperature transitions referred to as lower critical solution temperatures (LCST). For an extensive review, see Schild.[44] Related properties were observed because of the proper balance of apolar and polar moieties, but a ΔT_t-type of mechanism was not recognized, perhaps because of the more limited control of composition.

Complete salt-driven contraction can readily be achieved in X^{20}-poly(VPGVG) on going from 0 to 1 N NaCl, and even a change from 0 to 0.15 N NaCl can drive very effective contractions.[28] For contraction in collagen, special salts are required, such as LiBr and NaSCN, and urea. These solutes lower the temperature at which denaturation occurs. For LiBr, the best characterized case, the low concentration limit was 0 to 0.3 N, and the high concentration limit was 11.25 N.[45] Again, the change in chemical potential required to drive contraction was over an order of magnitude greater in the collagen model.

8. The ΔT_t Mechanism and Insight into Diverse Biological Penetralia

In the foregoing sections, the effect of changing proton concentrations and the equivalent of changing the p*K*a of a protonatable functional moiety provided ready illustrations of the ΔT_t mechanism. That proton gradients are a fundamental commodity in living organisms is well appreciated.

For example, in the Stryer encyclopedic biochemistry text it is emphasized that "...proton gradients are a central interconvertible currency of free energy in biological systems".[46a] In fact, Stryer shows that proton gradients are equivalent to each of the free energy apices of Figure 12 except the one involving pressure.[46b]

8.1. The ΔT_t Mechanism in Protein Folding and Assembly

In the ΔT_t mechanism decreasing proton concentration, for example, increases the number of polar COO^- groups, which in our interpretation destructures the more ordered water surrounding hydrophobic moieties, thereby removing the driving force for hydrophobic folding. Here an equivalence is drawn between the polar COO^- group and the even more polar phosphate group, PO_4^{2-}. As the phosphate group is several times more polar on the T_t-hydrophobicity scale (see Table 1), it is reasonable in the thylakoid membrane of chloroplasts that "...about three protons flow through the CF_1–CF_0 complex per ATP synthesized..."[47] ATP is adenosine triphosphate, the most generally recognized energy currency in living organisms, which is commonly used to phosphorylate proteins to activate them. ADP, adenosine diphosphate, is formed in the process.

8.1.1. Effect of Phosphorylation on an Elementary Depiction of Protein Folding

To depict the ΔT_t mechanism in protein folding, a clam-shaped globular protein is considered that can be in either of two states, open or closed (Fig. 21A). The conditions are such that the temperature for the inverse temperature transition T_t is below the working temperature. Therefore, the equilibrium lies on the side of the hydrophobically folded, closed state. When opened, the hydrophobic moieties become surrounded by more highly ordered water molecules; this is unfavorable as the system is above the transition temperature. On phosphorylation of the hydroxyl group near the cleft, the tendency of the negative phosphate group for hydration is so strong that it prevents the formation of the more ordered water around the sufficiently proximal hydrophobic moieties. The temperature for the hydrophobic transition is raised above the working temperature, and the equilibrium is now shifted to the open state.

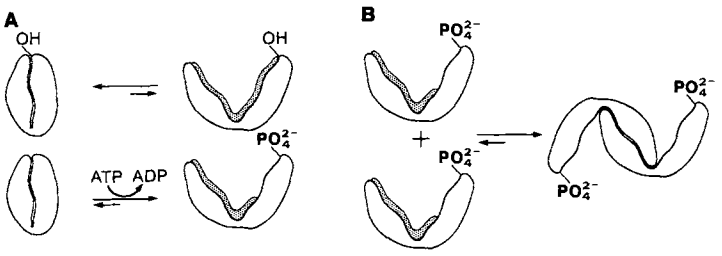

Fig. 21. A) Phosphorylation-driven unfolding illustrated for a hypothetical clam-shaped globular protein. Before phosphorylation the equilibrium lies on the left-hand side; after phosphorylation with ATP it lies on the right-hand side at the same temperature. For details see text. B) Phosphorylation-driven dimerization; for details see Section 8.1.3. The dotted region represents areas of hydrophobic hydration in A and B. (From reference [1].)

The effect of phosphorylation on T_t has been demonstrated with the elastic protein-based polymer, poly[30(IPGVG),(RGYSLG)],[24] where RGYSLG is a cyclic AMP-dependent protein kinase site from the enzyme, lysozyme.[48,49] In the buffer system for the kinase, T_t of the test polymer is 18 °C as shown in Figure 22. On introduction of the protein

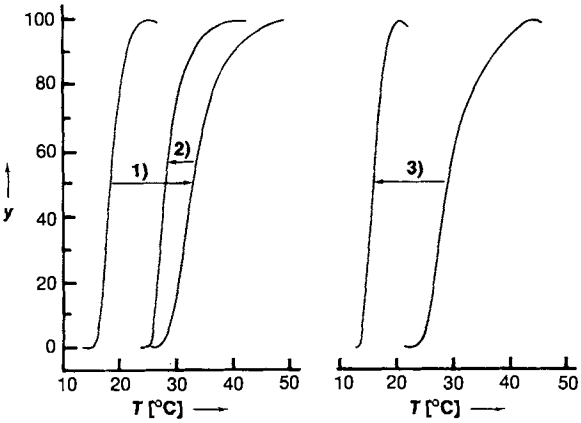

Fig. 22. Effect of protein kinase phosphorylation of the serine unit in RGYSLG on the temperature of the inverse temperature transition T_t in poly[30(IPGVG),(RGYSLG)]. 1) Protein kinase phosphorylation; 2) protonation, pH 7.3 → 2.0; 3) dephosphorylation by phosphatase (from reference [24]). y = % turbidity.

kinase and ATP, about 50% of the Ser residue of RGYSLG becomes phosphorylated, and the temperature of the hydrophobic folding and assembly transition is raised to 32 °C.[24] Thus at an intermediate temperature of 25 °C, one phosphate in three hundred residues would cause the unfolding of the elastic protein-based polymer. The formation of four COO^- moieties per hundred residues raised the transition temperature by 40 °C in poly[0.8(IPGVG),0.2(IPGEG)].[50] In terms of the hydrophobicity scale of Table 1, some four COO^- groups are equivalent to one phosphate group, and this is consistent with a ratio of three to four protons per phosphorylation, as in the case of the thylakoid membrane of chloroplasts.[43]

8.1.2. Heat-Shock Proteins, Chaperonins, and Biology's Modulation of Hydrophobic Folding

When *E. coli* bacteria are subjected to an abrupt increase in temperature, their response is to produce a set of proteins called heat-shock proteins (hsp). Consistent with the stabilization of hydrophobic folding on an increase in temperature, the hsp are uniquely involved in facilitating the transportation and folding of proteins in which hydrophobic associations are paramount. In terms of inverse temperature transitions and the ΔT_t mechanism, an increase in temperature would increase hydrophobic folding and could shift folding equilibria such that proteins could become trapped in nonfunctional, hydrophobically interacted states. This has brought to light a set of homologous proteins, called chaperonins,[51] from other organisms that function to assist protein folding by ATP modulation of hydrophobic association.

A complex process of modulating hydrophobic associations is the transport of proteins encoded in the cell nucleus

through the lipid bilayer of the outer mitochondrial membrane and the insertion of the properly folded state into the lipid layer of the inner mitochondrial membrane.[52, 53] The 70 kDa chaperonins, which provide that function, are released upon ATP hydrolysis. Presumably, phosphorylation disrupted the hydrophobic association. That phosphorylation indeed modulates the hydrophobic associations is more apparent in a series of chaperonin-assisted protein systems in which hydrophobic folding is directly implicated.

In the denaturation and refolding of protein or in the folding of a protein after its synthesis, the functional protein is understood to be the thermodynamically favored state of the protein.[54] Proteins, however, can become trapped in metastable states. Metastable hydrophobic associations with transition temperatures well below physiological temperatures could occur, and in our view the role of chaperonins is to tend these more hydrophobic domains of proteins until the appropriate circumstances are at hand when the more hydrophobic domains may form proper associations. The studies of Landry and Gierasch suggest that chaperonin 60 binds to the hydrophobic aspects of an α-helix from the enzyme rhodanese.[55] Studying T4-lysozyme interaction with chaperonin 70, Matsumura et al. [56] conclude that the preference is for interaction with aliphatic residues; the propensity for interaction is proportional to the likelihood of the residue being buried in the hydrophobic interior of the protein.

There is evidence that the associations of chaperonins with difficult-to-fold proteins is dominantly hydrophobic in nature, as well as good evidence that association is controlled by ATP hydrolysis, for example by phosphorylation. In a review Lorimer[51] states that "...The formation of native Rubisco (dimeric ribulose biphosphate carboxylase) from the binary chaperonin 60–Rubisco complex requires the presence of chaperonin 10 and MgATP.[57, 58] The hydrolysis of ATP appears necessary because nonhydrolyzable analogs do not support the reaction..." and later "...Of particular interest is the striking similarity between the structures of muscle actin (375 residues) and the ATPase fragment (386 residues) of chaperone 70.[59] This has prompted the intriguing idea that both proteins may share a similar mechanism for coupling the hydrolysis of ATP to the association–dissociation of protein–protein complexes". And finally Lorimer concludes in the abstract of the review, "Although this permits the mechanism of ATP hydrolysis to be understood at the atomic level, the manner in which this is coupled to folding, assembly, or release of the target protein remains obscure". The present review should remove that obscurity. ATP hydrolysis, for example phosphorylation, influences folding and assembly by removing of the thermodynamic driving force for hydrophobic association as depicted in Figure 21A.

The protein constructs can be such that phosphorylation disrupts or promotes hydrophobic folding and assembly, as shown in Section 8.1.3.

8.1.3. Elementary Depictions of Protein Assembly

The most obvious depiction of the effect of phosphorylation on hydrophobic assembly, the assembly/disassembly of a filament, is shown in Figure 23. The protein subunits, which do not have multiple conformations available, are capped on each end with hydrophobic surfaces that can be disrupted by phosphorylation. When the protein can exist in

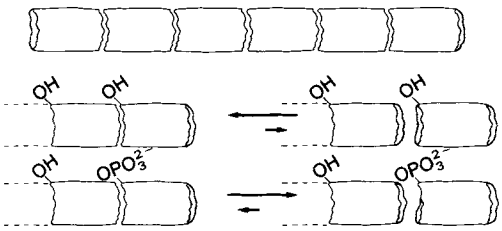

Fig. 23. Representation of the modulation of filament assembly by globular proteins capable of only a single conformation. Top: The ends of the globular proteins are hydrophobic; assembly (center) would therefore be the result of an inverse temperature transition. Phosphorylation is shown to shift the equilibrium away from filament formation, that is, phosphorylation leads to dissociation (bottom). This is the most elementary case. Often conformational changes occur such that phosphorylation can also lead to association as shown in Figure 24. (From reference [88].) The shaded areas represent a shell of clathrate water.

two states, open or closed, as shown in Figure 21A, additional possibilities exist. Even in the phosphorylated state there is still hydrophobic surface that is covered with more ordered water of hydrophobic hydration. As shown in Figure 21B, when the residual functional hydrophobic surfaces of the open state are complementary, phosphorylation can drive hydrophobic dimerization. With more complex structures having different conformational states available and more complex surfaces, filament formation, for example, could be driven by phosphorylation. Thus, as in microtubule growth and shortening,[60–62] the binding of GTP, an analog of ATP, could cause an unfolding and exposure of hydrophobic surfaces favoring tubule growth, whereas the conversion to the less polar GDP with but two phosphates could result in the formation of more stable dimers which would dissociate and cause a shortening of the tubule.

8.2. A Prototypic Sliding Filament Model of a T_t-type Molecular Machine

Instead of the hydrophobic folding depicted in Figure 5, a pair of filaments each with a hydrophobic surface could be responsible for the shortening process of contraction. This is equivalent to the straightening of the clam-shaped globular protein of Figure 21 to form a rod or filament as shown in Figure 24. Under conditions for optimizing hydrophobic overlap of two such rods, the structure on the upper right would be obtained. Due to hydrophobic hydration shown at the upper left, efforts to slide one rod or filament past the other would meet a resistance. The equilibrium would lie on

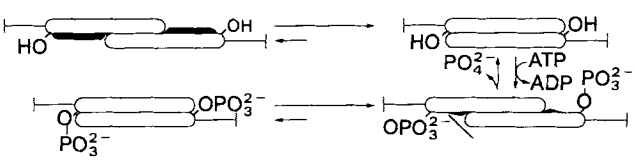

Fig. 24. Phosphorylation-driven extension in a prototypic sliding filament model. See text for discussion. (From reference [1].)

the side of maximal overlap, the contracted state. If the two filaments were phosphorylated as indicated in the lower part of Figure 24, sliding could occur with formation of an extended or relaxed state. Each filament could comprise different proteins, and even multiple proteins; cross-bridges could occur with complex hydrophobic interactions between filaments. However, the basis for interaction between filaments could be the ATP modulation of hydrophobic association, as crudely depicted in Figure 24. It would be a first-order molecular machine of the T_t type.

8.3. First-Order Molecular Machines of the T_t Type: Stretched Extracellular Matrix Causing Intracellular Chemical Response

The elastic protein-based polymeric matrix X^{20}-poly[0.8(VPGVG),0.2(VPGEG)], provides a direct demonstration that stretching of the elastic matrix can result in a chemical response. As shown in Figure 25, when this matrix is not under tension, the pK_a was determined by acid–base titration to be 3.99.[63] On application of the small force of 1 g to stretch the matrix, the pK_a increased to 4.84. At an intermediate pH of 4.5, the effect of stretching would be to take up protons as the chemically induced response of stretching.

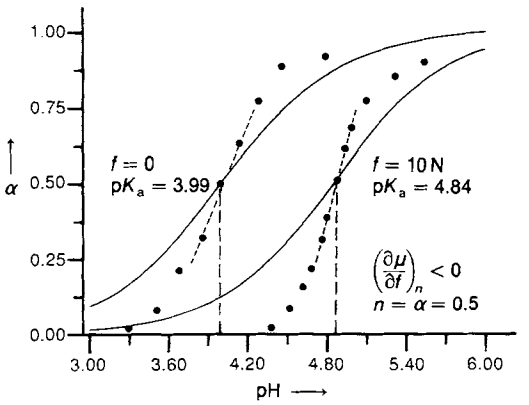

Fig. 25. Stretch-induced pK_a shift in X^{20}-poly[0.8(VPGVG),0.2(VPGEG)]. The solid curves are the reference curves as in Figure 20. The effect of an increase in force f is a decrease in the chemical potential μ of the protons required to maintain the elastic matrix at 50% ionization. Thus $(\partial\mu/\partial f)n$ is negative; the sign is exactly the opposite of that for the charge–charge repulsion mechanism, as seen in Figure 20. This defines the new mechanism. Of particular importance is the fact that the effect of the stretching (i.e. the increase in mechanical force) can be a chemical response. See the text for further details. Another feature to note in the data is that both before and after stretching the curves are steeper than the curve calculated from the first two terms of the equation in Figure 20. This positive cooperativity is due to the apolar–polar repulsive free energy of hydration. (From reference [63].)

As shown in Figures 15 and 16, with the appropriate design of the protein-based polymer the initial pK_a could be as high as 8 and stretching would raise the pK_a further. If, for example, the pK_a were 7 and the matrix were stretched to give a pK_a of 8, at physiological pH the effect would be the uptake of protons. By changing the functional group to that of a Lys residue, the direction of the shift would be reversed and the effect would be the release of protons. Thus the design of the stretchable matrix can determine the response that occurs in this mechanochemical transduction.

The increase in pK_a of a $COOH/COO^-$ chemical couple that occurs on stretching results, in our view, from the stretching of the hydrophobically folded matrix, which causes exposure of hydrophobic groups. Around these an ordered structure of water forms. Though there is more water in the matrix, it is unsuited for hydration of the polar COO^- moiety, and the free energy of this species increases as evidenced by the increase in pK_a. Similarly, the free energy of a peptide bearing a bound phosphate group could be expected to increase on stretching; accordingly, dephosphorylation would be a more likely response. It should even be possible to drive phosphorylation of another species by this increase in free energy of the phosphate. As a test of this, stretching of the X^{20}-poly[30(IPGVG),(RGYS(PO_4^{2-})LG)] matrix should drive the protein kinase reaction backwards and achieve phosphorylation of ADP. This test of the ΔT_t mechanism will be attempted once technical difficulties are overcome.

A clear picture is now emerging that in living cells tensional forces (stretching of the extracellular matrix to which the cells are attached) can signal intracellular chemical responses.[64] This is thought to involve receptors in the cell membrane, called integrins, which bind at specific attachment sites to proteins in the extracellular matrix. One such cell attachment sequence is the celebrated GRGDSP sequence of fibronectin, where RGD is the key sequence[65–69] to which fibroblasts and other cells attach. A related sequence in the protein laminin is a preferred site for endothelial cell attachment, which utilizes the vitronectin receptor as opposed to the fibronectin receptor.[70]

The attachment of a cell to a stretchable matrix is illustrated in Figure 26. The specific matrix is represented as X^{20}-poly[20(GVGVP),(GRGDSP)] to which cells have been shown to attach, spread, and grow to confluence.[71] In the natural tissue the attachment would be to proteins in the extracellular matrix where stretching can occur to the extent characteristic of the tissue. As depicted in Figure 26 a cell is attached to its matrix by means of two integrins within the cell membrane. Between the two attachment sites are cytoskeletal (muscle-like) fibers that contract relative to the

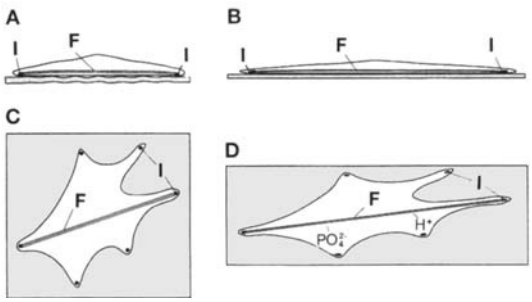

Fig. 26. Effect of stretching of a cell attached to an elastic substrate. A) Cross-section of a cell attached to the elastic matrix X^{20}-poly[20(GVGVP),(GRGDSP)] (shaded) as substrate by means of integrins (I), which bind to its cell attachment sites GRGDSP. Cytoskeletal fibers (F) contract between integrins and cause some buckling of the substrate. B) Cross-section of the elastic matrix when stretched. C) Top view of A. D) Top view of B. The tension in the cell is due to the stretching of the elastic matrix to which it is attached. The physical result is that the cytoskeletal fibers become stretched, and the integrins possibly also become deformed. For further details see text.

matrix causing some buckling. When the matrix is stretched, the cytoskeletal fibers are stretched, and the integrin itself could be deformed (shown by conversion from a spherical to an ellipsoidal shape). Since, as seen in Figure 25, stretching of X^{20}-poly[4(VPGVG),(VPGEG)] causes a chemical response, so too could stretching of the cellular components. Ingber states in his review[64] that "...mechanical stimuli can alter many cell functions, including ion transport, release of chemical second messengers, protein syntheses, secretion, and even expression of specific genes". In this way a cell can respond appropriately to maintain or remodel a tissue to meet the demands placed on it by the physical role that it must fill. Much earlier Glagov et al. showed that vascular wall cells (e.g., smooth muscle cells), when attached to purified internal elastic lamina of aorta and stimulated by subjection to cyclic stretching, produce the macromolecular components required of a vascular extracellular matrix.[72-74]

The stimulus for a cell to function in a manner appropriate to the tissue in which it resides could be provided by a first-order molecular machine of the T_t type. A tensional force could give rise to increased exposure of hydrophobic surfaces to effect a change in proton concentration with all of its possible ramifications.[46] As noted above, it could effect a more direct transferral of a phosphate moiety to activate a number of possible responses, or it could effect a release of Ca^{2+}, etc.

8.4. Second-Order Molecular Machines of the T_t Type: Oxidation of Food as Cells' Energy Source

Chemical energy arises from changes in chemical potential, that is, from concentration changes or concentration gradients. When thinking of chemical energy in food, one means the oxidation of the food giving rise to carbon dioxide, water, and energy, commonly viewed in terms of heat. But the oxidation of food results in the reduction of certain prosthetic groups, which in giving up their electrons to oxygen generate a concentration gradient of protons. This gradient in turn results in the formation of ATP, a more flexible, equivalent energy currency in living organisms (see Stryer[46a] for a general reference). This is called oxidative phosphorylation, and it involves the electron transport chain, a series of proteins with prosthetic groups that can be reduced and oxidized.

In Section 5.2 was given an example of a second-order molecular machine of the T_t type in which either the reduction of a nicotinamide moiety would result in proton uptake, or the protonation of a carboxylate group in an uptake of electrons. In the electron transport chain, the oxidation of a reduced nicotinamide or of a reduced flavine residue gives rise to proton release on one side of a cell membrane to produce a proton concentration gradient. In the second-order molecular machine of the T_t type of the proper design, oxidation of a reduced nicotinamide residue could result in the release of a proton. If that were done in the appropriate circumstance, as in the inner membrane of a mitochondrion, and the release were between the inner and outer membrane, this could generate a proton concentration gradient capable of production of ATP by phosphorylation of ADP. Again, the nature of the competition between polar and apolar moieties for hydration in macromolecules capable of inverse temperature transitions could explain another important free energy conversion of living organisms.

8.5. Medical Relevance to Elastin Fiber Formation and Pathology

Elastin is perhaps most noteworthy for its capacity to provide tissues with their required elasticity without contributing greatly to pathological and associated disease states. This is particularly true in view of the findings that it has a low turnover in the body. The half-life for elastin, as determined by three independent methods, is of the order of 70 years or more![75, 76] This implies a remarkable durability particularly in the aortic arch and thoracic aorta, where in that period of time the elastic fibers will have undergone some 2 billion demanding stretch/relaxation cycles.

There is indeed failure, however, from chronic processes such as a very slow pathological calcification but also sometimes from catastrophic occurrences, as in the dissecting aortic aneurysm. In the lung, which is chronically exposed to oxidizing and other toxic atmospheres, elastic fiber destruction can be severe resulting in pulmonary emphysema, which is responsible for more than 100000 deaths per year in the U.S. alone.

8.5.1. A New Perspective on Pulmonary Emphysema

Pulmonary emphysema is usually described as a biochemical process without a significant biophysical component. The biochemical process is characterized by decreased antiprotease activity allowing for proteolytic digestion and fragmentation of elastin fibers in the lung. In the genetic anomaly of deficiencies in α_1-antiproteases, pulmonary emphysema is the focal disease process, and it is generally thought that the primary process results from unchecked proteolytic digestion of elastin; but why does the primary disability occur in the lungs and not in the arteries where the demand for elastic function is so stringent?

On the basis of the ΔT_t mechanism, the primary insult can be the oxidation of the hydrophobically folded and assembled elastin fibers and the toxic reactions that result in more polar moieties, which lead to an increase in the value of T_t above physiological temperature and the unfolding of the protein. It would then be the partially unfolded protein that is susceptible to proteolytic digestion; otherwise, why would the lung be the tissue most notably affected by the genetic defect and why would this happen in a protein otherwise remarkable for its resistance to proteolytic degradation as evidenced by its long half-life for turnover even under demanding circumstances? That oxidants cause elastin fiber unfolding has been demonstrated in an experiment with an O_2^--generating system and hydrogen peroxide.[77] These oxidants can be released by a human macrophage attacking an airborne particulate in the lung and as a consequence also damage the elastic fibers by oxidation.

8.5.2. Absence of Elastin Fibers in Scar Tissue

In the wound repair response, the activity of prolyl hydroxylase is markedly elevated in order to hydroxylate the

prolyl residues of nascent collagen as required for the formation of a strong connective tissue. The same enzyme hydroxylates the prolyl residues of nascent elastin, but this raises its T_t above physiological temperatures, and elastin fibers do not form. This explains the paucity of elastin fibers in scar tissue.[77]

9. Biomimetics and Applications of Elastic Protein-Based Polymers

What has, in fact, been described while demonstrating the ΔT_t mechanism of free energy transduction is a new class of biomaterials. From the knowledge developed while detailing the T_t-based hydrophobicity scale and the numerous means of controlling the value of T_t, the new class of biomaterials can be designed for an extraordinarily diverse set of applications, both medical and nonmedical. At present there are twenty U.S. patents and patents pending, and additional patent coverage is being sought in Europe and the Far East. To date, only the earlier patents have been cited in the literature, and thus the new developments of this laboratory constitute the state of the art.

The medical applications under development include the use of the elastomeric matrices as a barrier for the prevention of adhesions following surgery and other trauma, the development of cell attachment matrices aimed at tissue reconstruction, and drug delivery using all the means of controlling T_t. The latter implies converting many free energies to useful mechanical work for releasing drugs as well as for controlling rates of their degradation. In nonmedical applications the concept of drug delivery can be extended to controlled pesticide release; in the general area of robotics the materials can simultaneously be sensor and actuator, utilizing the many forms of free energy transduction which can each be designed for diverse conditions—where chemomechanical transduction could occur, high efficiency, high sensitivity, and enzymatic specificity are anticipated. Also, the elastic matrix, being predominantly entropic in nature, is extraordinarily durable. As with the natural elastic fiber, which is a predominantly entropic elastomer having a half-life in the body of some seventy years,[75, 76] it has the potential to sustain billions of stretch–relaxation cycles.

9.1. Medical Applications

For use in the body a material must be biocompatible. For poly(GVGVP) and its cross-linked elastic matrix, X^{20}-poly(GVGVP), this has been determined. The series of recommended biological tests that have been utilized (the results are given in parentheses) include 1) the test for the Ames mutagenicity (nonmutagenic), 2) the cytotoxicity–agarose overlay (nontoxic), the tests for 3) acute systemic toxicity (nontoxic), and 4) intracutaneous toxicity (nontoxic), 5) muscle implantation (favorable), the tests for 6) acute intraperitoneal toxicity (nontoxic), 7) systemic antigenicity (nonantigenic), 8) dermal sensitization—the Magnusson and Kligman maximization method (nonsensitizing), and 9) pyrogenicity (nonpyrogenic), 10) Lee–White clotting study (normal clotting time), and 11) the in vitro hemolysis test (nonhemolytic). "Thus, this new elastomeric polypeptide biomaterial...exhibits an extraordinary biocompatibility".[78]

This degree of biocompatibility takes on added significance in view of the complications that have arisen with the use of silicon and polyurethane (for example, approval for use in breast implants has recently been withdrawn, etc.) and in view of the sensitization and allergenic responses to implants made of treated natural protein.

9.1.1. Prevention of Post-Surgical Adhesions

In the United States and Europe in the 60 million operations per year a potential postoperative complication is the formation of adhesions. The outcome of many of these could be improved with a material that would prevent or reduce the incidence of unwanted adhesions. The elastic protein-based polymers (in this context referred to as bioelastic materials) are being tested for efficacy in preventing adhesions in three different animal models: in the rat as a contaminated peritoneal model, in the rabbit eye in connection with strabismus and retinal surgical procedures, and in the calf for the use of the total artificial heart as a bridge to heart transplantation.

The studies are most advanced in the contaminated peritoneal model.[79] In 29 control animals adhesions formed, whereas with use of X^{20}-poly(GVGVP) sterilized with ethylene oxide gas, 80% of 29 animals showed insignificant adhesions (59% no adhesions, and 21% grade 1 adhesions). An example of a grade 1 adhesion is shown in Figure 27 in which the small sheet of X^{20}-poly(GVGVP) is seen against the abdominal wall, and a small band of adhesion is seen to have grown around the optically transparent matrix and attached to a loop of bowel.[80] No fibrous capsule had encased the bioelastic material as is usual for a foreign material; there is no inflammation of the abdominal wall where contact has been maintained for two weeks; and the adhesion is weak and can be detached with a light pull.[79]

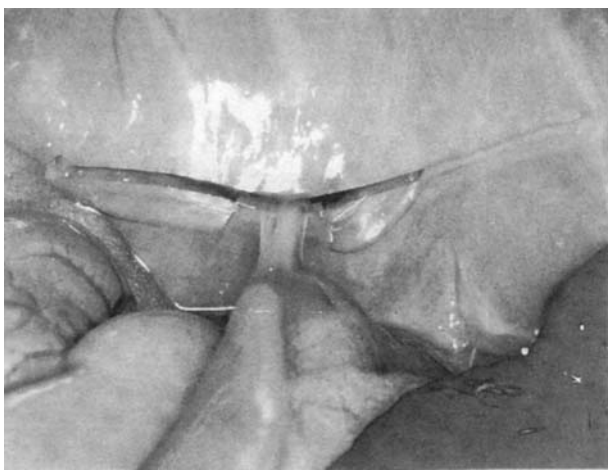

Fig. 27. View of the abdomen in which a sheet of X^{20}-poly(GVGVP) around which a strip of adhesion has grown lies against the abdominal wall. See text for discussion. (From reference [80].)

9.1.2. Cell Attachment Matrices and Tissue Reconstruction

While the simple matrix, X^{20}-poly(GVGVP), provides very poor support for cell attachment, inclusion of the cell attachment sequence, GRGDSP, as noted in Section 8.3, results in a matrix in which the cells can not only attach but can also spread and grow to confluence.[71,81] Shown in Figure 28 on the bioelastic matrix, X^{20}-poly[n(GVGVP), (GRGDSP)] (*n* ranges from 20 to 100), are low-density platings of bovine aortic endothelial cells (A) and *ligamentum nuchae* fibroblasts (B) that have grown to confluence at three days (C and D, respectively).

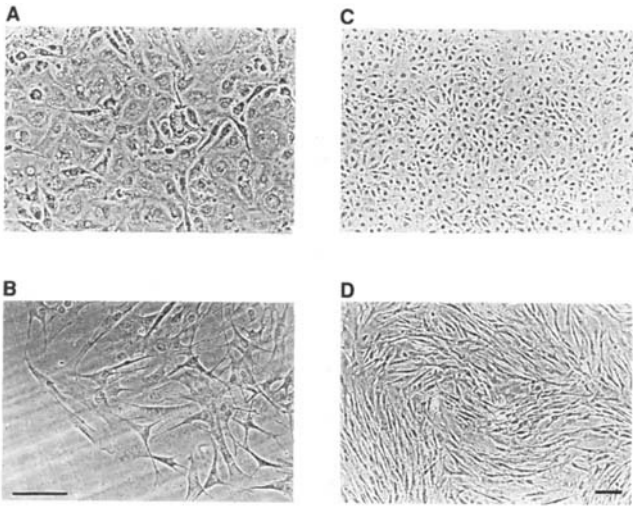

Fig. 28. Cell growth on the elastic matrices, X^{20}-poly[*n*(GVGVP),(GRGDSP)] (*n* is in the range of 20 to 100). A and C: bovine aortic endothelial cells: B and D *ligamentum nuchae* fibroblasts. In A and B the cells were plated at high density. In C and D they were plated at low density (1×10^4 cells per mL) and then allowed to grow to confluence over a period of three days. The cells are seen to adhere, spread, and grow to confluence. (From reference [71].) The bars in B and D represent 100 μm.

Recall the discussion in Section 6.1 in relation to Figure 26 in which a stretched extracellular matrix causes intracellular responses, and cells so stimulated produce the requisite macromolecules to sustain the applied forces. Based on this concept, the approach with the bioelastic materials is to design a biocompatible cell attachment matrix that can serve as a temporary functional scaffolding while being remodeled into a natural tissue appropriate for sustaining the stresses of its tissue site of function.

9.1.3. Drug Delivery

The opportunity of controlling T_t in bioelastic matrices offers the challenge of utilizing a most effective means to achieve a particular drug-delivery regimen.[82,83] Chemical clocks can be introduced with designed half-lives, which would initiate a contraction or a swelling to effect drug release. For example, depending on the sequence in which it is found, the carboxamide of asparagine, Asn(N), in phosphate-buffered saline will hydrolytically cleave to form aspartic acid, Asp(D).[84] At physiological pH, this conversion of a carboxamide to a carboxylate anion could then effect the change in T_t just as effectively as raising the pH.

One use of carboxamide ($CONH_2$) breakdown to carboxylate (COO^-) is illustrated in Figure 29 where the rate of drug release from a doped, homogenous slab depends on the half-life of the asparagine (Asn(N)) or glutamine (Gln(Q)) carboxamide.[82] Sequences containing the N or Q residues can be chosen so that the half-lives range from days to decades.[84] Additionally, linkages that have different rates of hydrolytic cleavage can be placed in the backbone of the protein-based polymer. In a series of recently synthesized protein-based polymers, half-lives ranging from days to tens of days have been obtained under conditions in which the half-life of the control, poly(GVGVP) or X^{20}-poly(GVGVP), appears to be in the range of many years.[83]

Given the many means of achieving the useful mechanical work of drug delivery depicted in Figure 12 (i.e., the set of arrows ending at the mechanical apex), an optimal means of delivery can probably be found for every situation. The delivery vehicle could be designed to release drugs in response to the chemical abnormality of the diseased tissue to be treated. And the delivery vehicle would degrade into amino acids and a sensor, which itself could be an amino acid or a natural prosthetic group.

The capacity to sense the altered chemistry of the diseased state and to respond with drug delivery has been called the diagnostic–therapeutic pair. In the case of specially designed elastic protein-based polymers, bioelastic materials, the first-order molecular machine could function by using the chem-

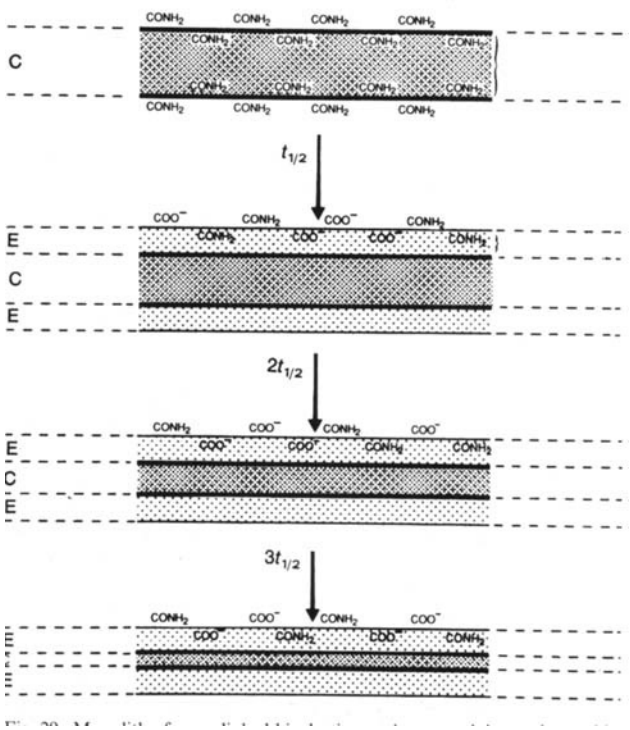

Fig. 29. Monolith of cross-linked bioelastic matrices containing carboxamide moieties from asparagine and glutamine residues (C). At the aqueous interface the $CONH_2$ groups hydrolytically cleave to yield carboxylates, which increases the T_t of the surface layer and causes its volume to swell to 10 times its original size (E). This allows, for example, for diffusional release of drug that had previously been doped in the slab. The rate at which the surface layer swells and the drug is released depends on the half-life $t_{1/2}$ of the Asn or Glu carboxamide; this can be controlled by the sequence in which it is placed. (From reference [89].)

ical energy provided by the difference in the chemical concentration of a substance in the diseased state to trigger the mechanical response that releases the drug. Since a change in the redox state can be used to drive a contraction or a swelling (see Section 5.1.1.3), such a system, if coupled to a redox enzyme such as glucose oxidase or glucose reductase, could utilize changed glucose concentrations to bring about release of the therapeutic agent. This approaches the ultimate objective of drug delivery, which by Pitt and Schindler's definition is "...to develop delivery systems which respond to the biochemical need for the drug, comparable to the way the human body exercises control over releases and distribution of its own endogenous biological agents".[85]

9.2. Nonmedical Applications

9.2.1. Biomimetics

Biomimetics may be considered the technique of mimicking or utilizing biological materials and processes. The purpose could be to obtain a substance with the *strength* of spider drag-line silk, or the *durability* of the biological elastomer, or the *toughness* of a composite ceramic represented by a seashell, or the special aqueous *adhesiveness* of the mussel protein glue. It could be used to design prosthetic materials as *temporary functional scaffoldings* for tissue reconstruction, as discussed in Section 9.1.2 for a medical application. Or it could be employed to obtain molecular machines with the *miniaturization* of the flagellar rotary motor, with the *efficiency* for energy conversion as in chemomechanical transduction (Section 7), with the *specificity* introduced by enzymes, with *reliability* to undergo many cycles of use, with the *sensitivity* of a channel function elicited by the stimulus of a chemical, light, a pressure change, etc., or with a *uniqueness* to utilize new sources of energy.

9.2.2. Reversible Mechanochemical Engines

In the McGraw-Hill *Concise Encyclopedia of Science and Technology*,[86] an engine is defined as "a machine designed for the conversion of energy into useful mechanical motion". When useful mechanical motion or work is performed by a first-order molecular machine of the T_t type, the machine is a reversible molecular engine. When the source of energy is chemical, the first-order molecular machine can be a reversible mechanochemical engine. These mechanochemical engines can use any of the intrinsic or extrinsic chemical concentration changes noted in Sections 4.1 and 4.2 to perform useful mechanical work. At one extreme, an engine could use the chemical concentration differences between fresh (river) water and sea water to drive a turbine. At another extreme, it could use specific enzyme sites to assay for specific enzyme activities. On the other hand, since the ΔT_t mechanism is reversible, mechanical work could be the energy input for chemical separations (e.g., desalination). These reversible mechanochemical engines are as diverse as the chemical energy inputs that can change the temperature T_t of the inverse temperature transition.

9.2.3. Transducers

A transducer is defined by Webster's *International Dictionary* as "a device actuated by power from one system and supplying power in the same or any other form to a second system...." The units of power are energy per unit time. Thus, the molecular machines of the T_t type, capable of the energy conversions depicted in Figure 12, could be called molecular transducers of the T_t type. The processes themselves have regularly been referred to as free energy transductions.

When the device operates on the principle of the elastomeric bands of Figure 13, it would be a low-power transducer because of the relatively long time to half contraction (on the order of minutes), but as with an elastomeric band the energy stress could be supplied over a period of time at fixed length, and then the snap-back of an elastomeric band on removal of the tension can be seen with response times of a fraction of a second. Also, with improvement in fabrication, the time constant of the elastomeric band construct could be shortened. Higher power molecular transducers of the T_t type require different concepts, such as the sliding filament design of Figure 24. This design would not be dependent on the slower folding and unfolding required for the transition from one structural state to another in Figure 5. The response time in striated muscle, a sliding filament device, is on the scale of fractions of a second. A similar time constant would be applicable to the flagellar rotary motor of bacteria.

As in the integration of the diagnostic–therapeutic pair into a single device to be used in drug delivery, here the integration of sensor and actuator into a single device is envisaged for applications in robotics.

9.2.4. Superabsorbents

The elastomeric sheets or viscoelastic materials normally consist of about 50% water by weight in their contracted or coacervate state, and they can be lyophilized to form dry paper-like or even Styrofoam-like states. When swollen, however, they can contain more than 90% water by weight. Accordingly, the materials are potential superabsorbents which could be triggered by any of the means for controlling the transition summarized in Figure 12; that is, these superabsorbent devices present an unusual control over the transition to the superabsorbent state.

Having discussed esoteric, perhaps even heady, devices this review can end at the opposite extreme with a more down-to-earth application, that of a biodegradable diaper. Consider the properties it could have: a capacity to absorb liquids ten times its own weight, a thermal control element where liquid would be drawn from warmer to cooler temperatures, a pressure response which could convert water to more dense states rather than squeeze it out as in a sponge, and a capacity to decompose within a selected period of time and in minutes with only mild chemical treatment.

10. Summary and Outlook

10.1. Summary

A series of model proteins has been studied which exhibits an increase in intramolecular and intermolecular order on increasing the temperature. This phenomenon is called an inverse temperature transition and the temperature at which it occurs is designated as T_t. The increase in order within the protein arises because the more ordered water molecules surrounding the hydrophobic moieties become less ordered bulk water as folding and assembly occurs, which is characterized by intra- and intermolecular contacts involving hydrophobic moieties. On cross-linking, elastomeric matrices are formed in which the inverse temperature transition is seen as a contraction capable of doing the useful mechanical work of lifting a weight against the gravitational force.

By carefully changing the amino acid composition of the model protein, the temperature T_t can be changed in a regular manner allowing a hydrophobicity scale to be developed for all of the natural amino acids. It is then seen that there are many ways of changing the value of T_t. Chemical changes in the model protein, such as changing the degree of ionization of a side chain, phosphorylating and dephosphorylating a serine side chain, or reducing an attached redox moiety (e.g., a nicotinamide) dramatically change the value of T_t, as do adding salts or organic solutes to the medium. Changing the pressure also changes the value of T_t.

Next, it is appreciated that lowering T_t from above to below a working temperature is equivalent to raising the temperature from below to above T_t. Thus, for the cross-linked matrices, all means of lowering the value of T_t become means for isothermally driving contraction and the performance of useful work. This means that the elastic matrices have become molecular machines capable of converting one form of free energy into another. With the inclusion of photochemical reactions, which has just been demonstrated, there are six forms of free energy that could be interconverted by the ΔT_t mechanism. The intensive variables for these free energies are mechanical force, temperature, pressure, chemical potential, electrochemical potential, and electromagnetic radiation. To our knowledge, these include all the free energy conversions of living organisms. Proteins that can carry out these energy conversions could be considered molecular machines. A device that operates by thermally driven contraction (folding) on raising the temperature is called a zero-order molecular machine of the T_t type. The other energy conversions resulting in contraction are called first-order molecular machines of the T_t type. Those energy conversions not involving mechanical force are called second-order molecular machines of the T_t type. While these conversions utilize the hydrophobic folding transition, mechanical force, the direct result of folding, is not one of the intensive variables involved. Thus, the ΔT_t mechanism is a unifying basis for diverse energy conversions.

The physical basis for the ΔT_t-type energy conversions is described as arising out of the competition of apolar (hydrophobic) and polar moieties for waters of hydration in polymers in which there are constraints on the distances between the moieties. An analysis is presented which shows that the ΔT_t mechanism for conversion of chemical energy into mechanical work is an order of magnitude more efficient than the charge–charge repulsion mechanism in aqueous systems.

It is then anticipated that, under the pressure of natural selection, living organisms would have evolved to utilize the most efficient mechanism available to its composition. Accordingly, this mechanism provides new insight into many not so readily explained biological processes. The correlation between the central role of phosphorylation in protein mechanisms and phosphorylation as the most dramatic chemical perturbation for changing the value of T_t is considered more than coincidental.

Finally, the potential medical applications of the new biomaterials that these elastic protein-based model proteins represent are considered. Discussions of applications include the prevention of postsurgical adhesions, tissue reconstruction, and drug delivery. And the potential of these materials as reversible mechanochemical engines and transducers is discussed briefly.

10.2. Outlook

The outlook challenges both basic research and applied research. There is the challenge to demonstrate each of the energy transductions of Figure 12 by designing the appropriate protein-based polymer and the requisite apparatus with which to study the energy conversion. There is the need to quantitate the apolar–polar free energies of repulsion for ionization of each relevant amino acid residue, to evaluate the effects of naturation/denaturation and purification, as well as of solutes on the hydrophobic folding and assembly process, to quantitate hydrophobic domain size and intensity for independence of hydrophobic domain folding and assembly, and to quantitate hydrophobicity-enhanced charge–charge interactions. There is also the need to study protein structure and function with the foregoing perspective. Specific questions might be: does phosphorylation (or ionization) of amino acid residues with shifted pK_a values disrupt hydrophobic associations?

The emergence of a new material is naturally associated with the search for applications. When the material appears capable of performing the many free energy transductions involving all of the intensive variables of mechanical force, temperature, pressure, chemical potential, electrochemical potential, and electromagnetic radiation, the number of opportunities increase. When the basic material is biocompatible and appears to function on the same principles as proteins, the number of potential medical applications alone becomes extraordinarily large. When the basic material is essentially ignored by the body but can be modified by introducing cell attachment sites, specific enzyme sites, natural chemical clocks, enzyme prosthetic groups, etc., to fill specifically defined functional roles, the opportunities seem limited only by the resources with which to pursue them. This capacity to start with an innocuous elastic protein-based polymer capable of exhibiting an inverse temperature transition and then to design-in any of many possible functions or combinations of functions provides exciting challenges for the future. In all of this there is the pleasure of turning concepts into molecular machines of practical value.

I wish to acknowledge the many members of the Laboratory of Molecular Biophysics, past and present, who have contributed so extensively to the work reviewed here. This research was supported in part by contract N00014-89-J-1970 from the Department of the Navy, Office of Naval Research, and by grant HL-29578 from the National Institutes of Health.

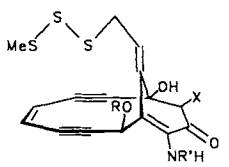
Conjugated Enediynes—An Old Topic in a Different Light

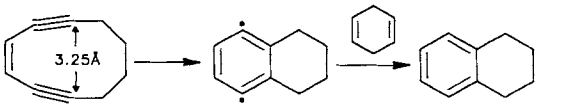
By *Rolf Gleiter** and *Detlef Kratz*

If *Angewandte Chemie* had published "Highlights" twenty years ago, the topic of this article would certainly have been addressed then. The most recent reports from the research groups led by Nicolaou,[1] Diederich, [2] Vollhardt,[3] and Myers[4] prove that the chemistry of conjugated enediynes continues to flourish. What is more remarkable, however, is the difference in the goals of the investigations of enediynes then and now. Twenty years ago the syntheses of new $4n$ and $(4n + 2)$ π-electron systems and tetrahedranes were the main points under consideration; today's motivation for examining these compounds comes from natural products chemistry and from interest in new modifications of carbon.

Biologically Active Anticancer Antibiotics: Nicolaou et al. were not only the first to complete the synthesis of the anticancer antibiotic calicheamycin γ_1,[1a, d] indeed a preparative masterpiece, they also contributed to the understanding of the mode of action of the aglycon (**1**) responsible for the DNA cleavage.[1b, c] The incorporation of the enediyne unit in the ten-membered ring of the aglycon enhances the reactivity of the already labile planar 6 π-electron system; after activation by attack of a nucleophile, the triple bonds are even closer together and ring closure to give a 1,4-diradical (Bergman cyclization)[5] is induced. For the systematic study of the mechanism of DNA cleavage cyclodeca-3-ene-1,5-diyne (**2**) was prepared as the most strained member of a series of monocyclic conjugated enediynes; because of the short transannular distance between the triple bonds (d = 3.25 Å in **1**), its cyclization via the 1,4-diradical **3** to give tetralin (**4**) proceeds even at 50 °C. By determining the structures of a number of model compounds Nicolaou et al. were able to predict whether an enediyne would undergo Bergman cyclization at room temperature, and thus be a potential anticancer drug. The transannular separation of the triple bonds serves as the decisive parameter; in compounds in which $d < 3.2$–3.31 Å, spontaneous Bergman cyclizations can be expected.

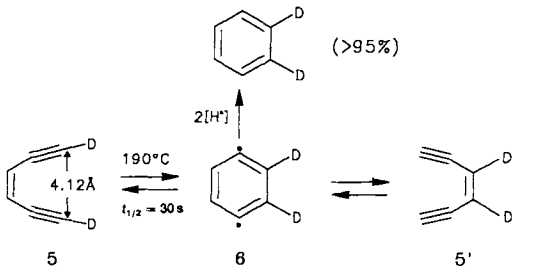


1

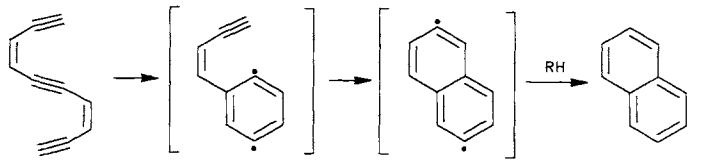


2 3 4 (55%)

Kinetics and Mechanism: First evidence that cyclization of conjugated enediynes proceeds via 1,4-didehydrobenzene intermediates like **6** was reported by Bergman et al. about twenty years ago[5] in an elegant study of the dideuterated parent compound, *cis*-hexa-3-ene-1,5-diyne (**5**). Recently, the same research group examined an expanded system, (*Z*,*Z*)-deca-3,7-diene-1,5,9-triyne (**7**), and proved that the analogous double cycloaromatization gives rise to 2,6-didehydronaphthalene (**9**),[6] which is isolated as naphthalene (**10**) after H abstraction from the solvent. The cyclizations of both **5** and **7** are first-order reactions. The rearrangement of **5** to give deuterated benzene proceeds almost quantitatively at 190 °C in dilute solution and has an activation energy of 32 kcal mol^{-1}. In contrast, the reaction of **7** (at 190 °C) provides naphthalene in only 10% yield.



5 6 5'



7 8 9 10 (10?

New Aromatic and Antiaromatic π Systems: A logical connection can be made here to the recently published work of Myers and Finney,[4] in which the extremely unstable 1,2,6,7-tetradehydro[10]annulene (**19**), which can be handled only at temperatures below −40 °C, also rearranges to give naphthalene as the stable, final product. The synthesis of the new [10]annulene is outlined in Scheme 1. Key steps include the Pd-catalyzed Heck coupling of **11** and **12** to give **13**, the chain extension by means of a Wittig reaction to furnish **16**, and the Cr^{II}-catalyzed ring closure to provide **18**. This last reaction proceeds in 40% yield, which is quite remarkable for a ring closure forming a ten-membered cycle.

The cyclization of the aromatic ten-membered ring compound **19** does not proceed by cisoid ring formation analogous to the reactions of **5** and **7** but by "diagonal" reaction to give the diradical 1,5-didehydronaphthalene (**20**),

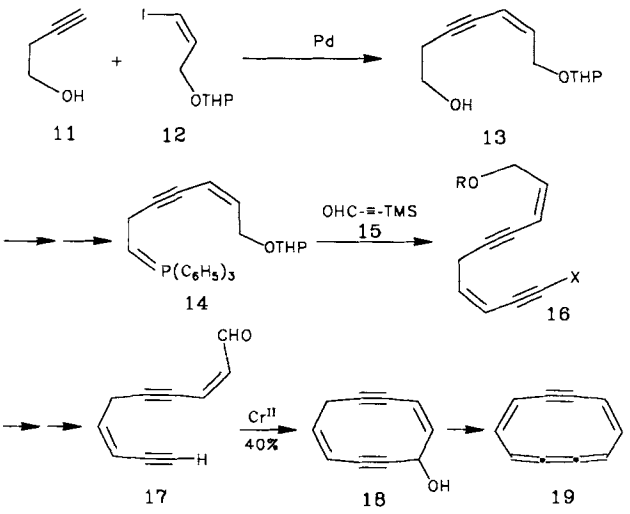
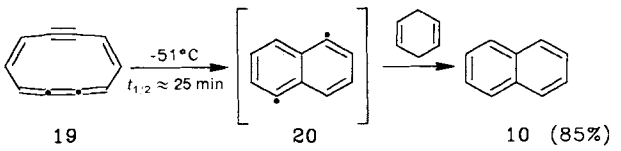
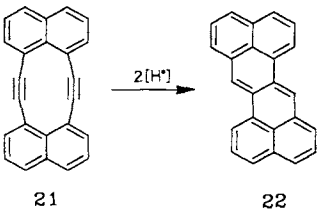


Scheme 1. THP = tetrahydropyran.

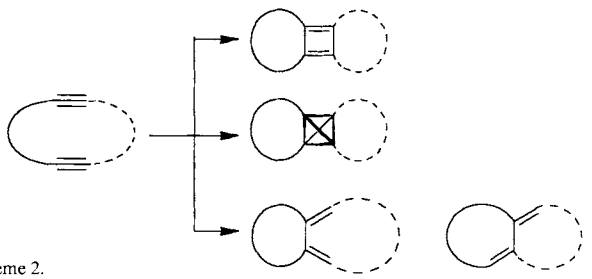
which reacts further by hydrogen abstraction to afford naphthalene. Considering that the "reactants" (alkyne and cumulene units) in **19** are held apart by approximately 3 Å by the allylic bridge, it is not so surprising that **19** undergoes the fastest diradical cycloaromatization reaction observed to date with an activation energy of only 16.4 kcal mol^{-1}.



Interestingly, the activation energy for the formation of the diradical from the cumulene subunit in neocarcinostatin is close to that for **19**. This lends further support for the proposed mechanism of DNA cleavage by neocarcinostatin via an *anti*-configurated diradical. This type of ring formation corresponds to the analogous reaction of the nonisolable diyne **21** which can be trapped as the polycondensed aromatic compound zethrene (**22**)[7a, b] in what can be considered to be the "diagonal" version of the Bergman cyclization.

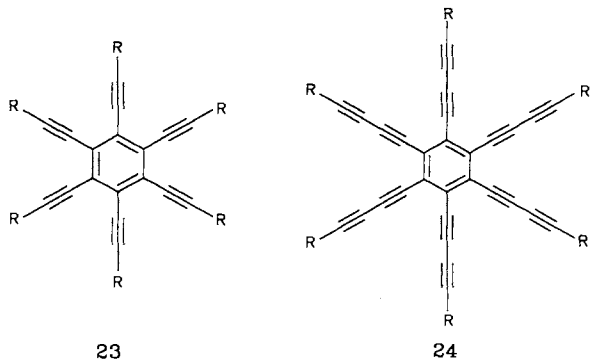


Orientation-Dependent Reactions of Triple Bonds: At this point we digress to briefly review some of the original studies of conjugated diynes and enediynes and pay tribute to the "Highlights" of 25 years ago. As early as 1956 Cram et al. reported attempts at cyclizing two parallel triple bonds to give a cyclobutadiene derivative.[8] Compounds with other connectivities of triple bonds as a function of orientation (yielding tetrahedrane or leading to linear *cis*- or *trans*-butadiene structures, see Scheme 2) were examined later by E. Müller et al., H. Staab et al., and H. W. Whitlock et al.[9–11] Progress in this field was achieved especially when the two C≡C bonds were attached to a rigid framework or built into a cycle, which fixed the bonds not only sterically but also held them closer together. The reactivity was increased as a result. In addition to these studies we should mention the work of Sondheimer et al.[12] and Eglinton, Raphael, et al.[13] which focused primarily on the relation between the aromaticity/antiaromaticity of these compounds and the number of π electrons in the cycle.



Scheme 2.

New Acyclic π Systems and [*n*]Phenylenes: Vollhardt et al. have extended the series of open-chain diyne compounds originally studied with the syntheses of persubstituted arenes with alkynyl substituents, for example, hexaethynylbenzene (**23**)[14] and more recently hexabutyldiynylbenzene (**24**).[3]

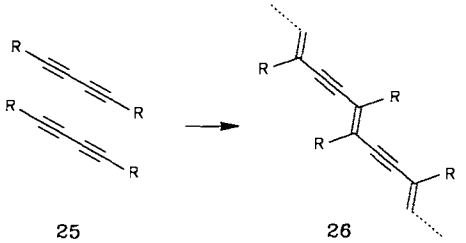


Scheme 3. **23**: $\lambda_{max} = 335$ nm; R = H, $SiMe_3$. **24**: $\lambda_{max} = 375$ nm; R = $Si(iPr)_3$.

The syntheses of these and related compounds is based on the multiple Heck couplings of the appropriate terminal alkyne with hexabromo- or hexaiodobenzene. There is no unequivocal evidence for delocalization of the electrons in the "in-plane" π orbitals of the six triple bonds similar to the apparent conjugation of the electrons in the benzene rings π MOs and those of the substituents. However, the redshift ($\Delta\lambda_{max} = 50$ nm) of all UV bands of the 54 π electron system of **24** relative to those arising from the 30 π electron system in **23** is striking. Arenes with *o*-ethynyl substituents may undergo multiple, simultaneous cyclization induced by transition metals to give polycycles such as [3]phenylene.[14b] It remains to be seen whether reaction of **24** will lead to the

synthesis of [6]phenylene (antikekulene), as Vollhardt has predicted. In contrast to the previously mentioned ring closures of enediynes via diradicals, reactions providing the [*n*]phenylenes, catalyzed by transition metal complexes such as $[CpCo(CO)_2]$, are typical trimerization reactions of triple bonds.

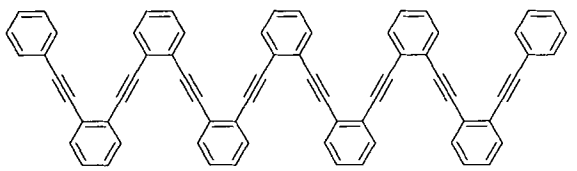
Diacetylenes and Poly(enediyne)s: For polymer chemists on the lookout for new materials, polymeric enediyne compounds continue to be of interest. The synthesis of these compounds relies on the solid-state intramolecular 1,4-addition of diacetylenes **25** to give poly(diacetylene)s **26**.[15a] The



25 26

conjugated backbone of double and triple bonds in these compounds allows the extended delocalization of the π electrons, and as a result these compounds have interesting optical properties and absorb visible light.[15b,c] To better understand the spectroscopic properties of these one-dimensional poly(enediyne)s, the *cis*- and *trans*-linked oligomers **27** and **28** were prepared;[16,17] due to the improved solubility rela-

27 (λ_{max} = 454 nm)

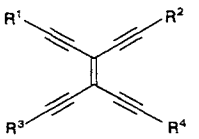


28 (λ_{max} = 388 nm)

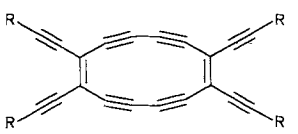
tive to that of the polymers, these compounds could be characterized. The Pd-catalyzed Heck reaction of haloarenes and terminal alkynes was systematically applied, and because of the high yields of the individual reaction steps, sufficient amounts of the new oligomers were obtained. Compounds **27** and **28** each contain eight triple bonds, but whereas **28** has 70 conjugated π electrons and is only slightly colored (λ_{max} = 388 nm), the *trans*-substituted oligomer **27** has only 30 conjugated π electrons and is yellow (λ_{max} = 454 nm). This observation can be explained by the greater capacity of double bonds (compared to the π bonds of benzene) to contribute to delocalization. The two oligomers have similar thermal properties; investigations with DSC (differential scanning calorimetry) show that a strongly exothermic reaction takes place at higher temperatures (**27**: 204 °C; **28**: 286 °C), which produces black solids. Compounds **27** and **28** could serve as potential precursors for one- and two-dimensional graphite-like band structures; *inter*molecular reaction of **27** and domino-like *intra*molecular cyclization of **28** could lead to polyacenes or the previously mentioned [*n*]phenylenes, respectively. In this context, the all-*Z* isomer of **27** (**7** is a partial structure) would be a worthwhile target.

Graphite-like Structures: The extrapolation of the one-dimensional enediyne chains into two- and three-dimensional networks leads to the theoretically interesting graphite-related compounds proposed by Hoffmann, Kertesz, et al.[18] Recent work by Diederich et al. has brought the realization of these fascinating modifications of carbon one step closer.[19] Rational variations in the synthesis allowed the preparation of the silyl-protected derivatives (**29b–d**) of the cross-conjugated enediyne compound tetraethynylethylene (**29a**).[19c] The unprotected $C_{10}H_4$ compound could serve as a precursor for polymeric *peri*-naphthalene or naphthalene, though in this case double Bergman cyclization would be required, yielding 1,4,5,8-tetradehydronaphthalene, which would then undergo fourfold H abstraction to give **10**. The highly reactive cross-conjugated hydrocarbon **29a** polymerizes upon isolation. This feature is also common to compounds **2**, **5**, **7**, and **19**, and these compounds can only be obtained in dilute solution at low temperatures. Because of the high C/H ratio in the monomers one may assume that the resulting black polymers, which have not yet been characterized, have properties similar to those of graphite.

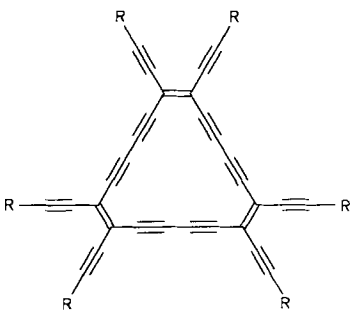
Diederich's goal is to systematically construct mono- and polycyclic units of the target carbon modification from the partially protected enediynes **29b–d**. Oxidative Hay coupling of the unprotected triple bonds leads to the cyclic derivatives of [12]annulene and [18]annulene, **30** and **31**,[2] respectively, or to open-chain compounds such as **32**,[19b] depending on the substrate employed. The extent of conjugation in **32** can be estimated by comparison of its UV/Vis spectrum (λ_{max} = 432 nm) with that of linear **27** (λ_{max} = 454 nm). As expected, the absorptions of the cyclic compounds are shift-



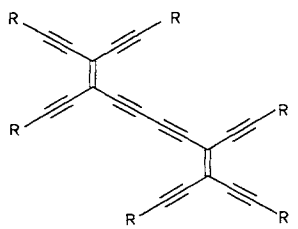
29a-d



30 (λ_{max} = 680 nm)



31 (λ_{max} = 480 nm)



32 (λ_{max} = 432 nm)

Scheme 4. **29a**: $R^1 = R^2 = R^3 = R^4 = H$. **29b**: $R^1 = R^2 = Si(iPr)_3$, $R^3 = R^4 = H$. **29c**: $R^1 = R^3 = Si(iPr)_3$, $R^2 = R^4 = H$. **29d**: $R^1 = R^2 = R^3 = Si(iPr)_3$, $R^4 = H$.

ed to longer wavelengths as was already observed for the corresponding unsubstituted annulenes.[12] It is hoped that unusual modifications of carbon can be constructed from these intermediates after deprotection and renewed coupling of their terminal triple bonds. We hope that the synthesis of further intriguing enediynes will be reported in the near future.

Light from Silicon—Renaissance of Siloxene and Polysilane?**

By *Christian Zybill** and *Vesselinka Petrova-Koch**

In crystalline silicon c-Si radiative recombination processes are only possible in limited amounts (quantum yields of ca. 10^{-4}%) as a result of the indirect band gap(s) $E_{g,\,ind.}$. Since, because $E_{g,\,ind.} = 1.11$ eV, the luminesence[1] does not lie in the visible spectral region, this semiconductor, otherwise so frequently used in microelectronics, is not suitable for optoelectronic applications. A solution is offered by the qualitative alteration of the Si band structure during the transfer to nanocrystalline structural units in the "quantum size regime" (i.e the range in which the size of the particles influences the physical and chemical properties) or by use of luminescent silicon molecular compounds.

The luminescence described here of porous silicon is caused essentially by emission from quantized states in the crystallite interior as well as from energetically low-lying states on the crystallite surface.

Since 1990, the scientific interest on the subject of "light from silicon" has increased exponentially. The reason for this was the observation[2a] of a red to green photoluminescence from nanoporous silicon, which is even visible to the naked eye at room temperature and has a quantum yield of several percent. This is comparable with the luminescence from GaAs, the most frequently used material for optoelectronic applications at present.

Thus, the luminescence–quantum yield of porous silicon is five orders of magnitude greater than that of c-Si. (Fig. 1, the scale of the intensity of the photoluminescence extends over six orders of magnitude). Furthermore, it was shown[2b–d] that the luminescence from the band (ca. 0.3 eV wide) can also be excited electrically; however, the quantum yields of the electroluminescence (10^{-3}%) are still relatively low. Thus, this result can be considered as a first step in the direction of optoelectronic building blocks based on silicon.

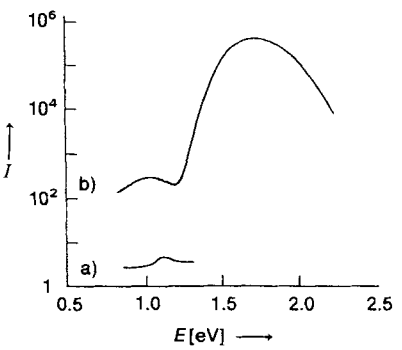

Fig. 1 The photoluminescence spectrum of porous silicon at 300 K (b) compared with that of c-Si (a) [12c]. The intensity I of the luminescence ($I = h\nu = \hbar\omega$ [eV]) extends over six orders of magnitude (Excitation: $\hbar\omega_L = 2.6$ eV = 500 mN cm^{-2}).

[**] We wish to thank Prof. Dr. H. Schmidbaur, Prof. Dr. S. Vepřek, and Prof. Dr. F. Koch for valuable suggestions. Dr. E. Hartmann and Dipl.-Phys. M. Enachescu provided us with a 3D STM image of porous silicon.

Porous silicon is generally prepared by anodic etching of c-Si wafers in HF.[3] Investigations with transmission electron microscopy (TEM)[4a] and X-ray diffraction[4b] show that a self-organized nanostructure is thus formed (for a growth model see [5]). In the case of luminous porous silicon, it could be established empirically that crystallites with diameters of less than 50 Å are present. The form of these aggregates is, however, at present still under debate; quantum wires[2a] as well as so-called quantum dots and a quantum sponge have been proposed.[4a] It is, however, clear that these samples have an extremely large inner surface of several hundred m^2 per cm^3. This means that every tenth to hundredth(!) silicon atom is a surface atom. The inner surface is, after the preparation, initially passivated with hydrogen (SiH_x), which can be removed by thermal aftertreatment,[2d] UV irradiation,[6a] the use of electron beams,[6b] or by air oxidation (formation of a SiO_2 surface as dielectric matrix).

A fundamental electronic property of this new silicon modification discovered by Lehmann and Gösele (Fig. 2) is the blue shift of the UV absorption edge by several hundred meV[5, 6c] in comparison to that of c-Si. This effect is greater than that observed, for example, for amorphous silicon a-Si:H. The blue shift of the absorption edge[6c, 9] can only be a result of quantum size effects on the energy states in the crystallite interior. By effective mass and tight binding calculations of the state density of porous silicon this effect can be confirmed quantitatively.[7]

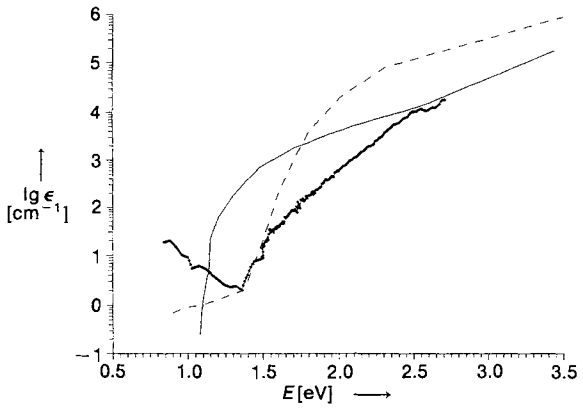

Fig. 2. The absorption edge of porous silicon (···) compared with that of c-Si (—) and that of a-Si:H (- -) according to [6c]. ε = absorption coefficient.

The most interesting electronic property of porous silicon is its photoluminescence. The mechanism of the photoluminescence is very complex, and separate experimental results appear at first to be contradictory. In the initial phase of the investigations this fact has led to the assumption of up to 13 hypotheses, which, however, can be based on three theoretical models. The first group includes models that ascribe the luminescence to recombination processes from quantum states in the interior of quantum wires[2a] or quantum dots.[2c] The second approach is completely different and is based on the assumption that luminescent molecules such as polysilanes[8a] or siloxenes are found on the inner surface of porous silicon.[8b] Besides these two extreme points of view, more recently several hypotheses were proposed and summarized to give a third model.[6c] This considered, above all, discrete, energetically low-lying states on the crystallite surface (surface states) together with quantized states in the crystallite interior. As a result of new important experimental findings this third polycausal approach has become more and more likely.

The following experimental results speak against the second approach, namely that silicon-containing molecular compounds are present on the surface of porous silicon:

- An important counterargument is that the luminescence quantum yield of porous silicon and that of thermally oxidized (O_2) porous silicon (transformation of the hydrogenated SiH_x surface into an oxidized SiO_2 surface) are almost identical.[9a] As is generally known, a surface film from SiO_2 shows, however, no red luminescence.[9b] A convincing counterargument is also that nanocrystalline Si layers[9c] deposited by CVD and thermally oxidized with O_2 as well as Si crystallites dispersed in ethylene glycol and oxidized show similar luminescence behavior.[9d]
- On resonance excitation satellite bands are observed within the luminescence band, which confirm a moment-conserving phonon participation in the optical transitions.[9e] These results are clearly in accord with the occurrence of recombination processes from energy states in the crystallite interior, but do not mean that siloxenes or polysilanes do not participate in luminescence processes.

Now let us consider the proof for energy states on the crystallite surface (model 3). Discrete surface states of lower energy can play an important role in recombination processes, and a series of experimental results can only be understood by the occurrence of such surface states:

- Raman spectroscopic studies on porous silicon show the Si–Si vibrational modes typical for small crystallites at 510–520 cm^{-1}. Furthermore, a broadened Si–Si vibrational band shifted to 480 cm^{-1} is observed by IR spectroscopy (which is more sensitive to the surface), which can be explained by reconstruction of the Si–Si bonds on the crystallite surface. This surface reconstruction similarly leads to a broadening of the Si–H vibrational band in porous silicon in comparison with that of an ideal Si–H vibrational mode.[9f]
- On the crystallite surfaces considerable quantities of "dangling bonds" (very stable Si radicals) can be detected by ESR,[10a] ODMR (optical detection of magnetic resonance), and SDPC (spin-dependent photo-conduction) measurements.[10b] This also agrees with a significant absorption below 1.11 eV in the spectrum of porous silicon, which can only be explained by the existence of deep crystal defects in the band gap. The concentration of Si radicals (dangling bonds), determined by ESR measurements, for samples with optimal luminescence is 10^{16} cm^{-3}; a value which in turn is higher than that for amorphous a-Si:H. The spin density of porous silicon is increased up to 10^{19} cm^{-3} by degradation processes; the luminescence yield of these samples is inversely proportional to the spin density.
- Furthermore, the UV absorption edge of porous silicon changes significantly on saturation of the samples with H_2 (reaction of the radicals with the formation of Si–H bonds). The crystallite size remains unchanged. This is in agreement with the existence of discrete states on the crystallite surface, as discussed in reference [6c].

- Also "tight binding" calculations (which only consider the interactions with the nearest neighbors) confirm the occurrence of surface states (in the form of a reconstruction of the crystallite surface), which lie energetically lower than the quantum states of the crystallites.[11]
- In addition, a red shift of the luminescence is observed on low-temperature oxidation (with constant crystallite size) or on aftertreatment of porous silicon, for example with propanol.[12a]
- Finally, there is a great similarity between the time-resolved photoluminescent behavior of porous silicon and that of a-Si:H.[9b] In amorphous silicon radiative recombination occurs—as proven—through so-called flat localized states ("Urbach tail").

A more exact analysis of the time-, temperature-, and wavelength-dependence of the luminescence behavior of porous silicon shows that several mechanisms are active.

Apart from the above-mentioned luminescence band, porous silicon shows two further bands (Fig. 3). The band 2

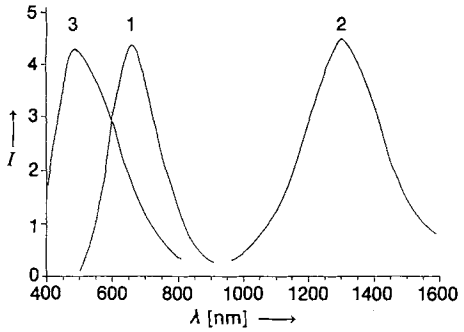

Fig. 3. Schematic representation of the three luminescence bands of porous silicon observed so far: 1: the red bands with slow decay times [2a,9e], 2: the IR band, which was first observed at 4.2 K [12b], and 3: the green-blue band [9e,12d] with rapid decay times.

lies in the region 0.8–1.2 eV [12b, c] and was already observed in 1984 in photoluminescence investigations at 4.2 K, which in the meantime has been almost forgotten. Furthermore, by photoluminescence spectroscopy with different retardation times an additional luminescence band 3 at 2.3–2.5 eV was observed.[12d, e] A special property of this band in the blue region is its extremely rapid decay time (10 ns or less in contrast to a few μs for the luminesence of band 1). It could be shown that also the rapid decay of the luminescence of the band 3 is intrinsic for porous silicon.[12e] Model approaches[6c, 13] provide preliminary explanations for the rapid luminescence (in the range of ns). However, for a better understanding of the three luminescence processes, especially of the latter two mentioned, still many investigations are necessary. All three observed luminescence channels can be of practical significance.

Silicon-containing molecular compounds—siloxenes and polysilanes: What are siloxenes? A siloxene is a layered polymer of $Si_6H_3(OH)_3$. Characteristic for siloxene is probably the partial retention of Si–Si bonds in Si_6 rings, which are saturated by hydrogen substituents and linked together.

Siloxene is prepared by a topochemical hydrolysis reaction from $CaSi_2$, which in all probability also has a layered structure of Si_6 rings. Siloxene samples were described about 130 years ago by Wöhler,[14a] and later by Hönigschmidt[14b] and Kautsky.[14c, d] The structural model with Si_6 rings, proposed by Kautsky and Hengge, was further refined by Weiss et al., who carried out X-ray structural investigations; however, the model has still not been completely proven since to date no suitable single crystals have been obtained.[14e]

A detailed investigation of the photoluminescence properties of siloxenes is mainly the result of work by Hengge.[14f, g] Renewed, intensive investigations and quantum mechanical calculations[15] on siloxenes have been in progress for about two years. The most important experimental result obtained is the observation of a luminescence quantum yield in the percent range, which is comparable to that of porous silicon,[16] and it is this behavior that has led to the renaissance of siloxene research.

Generally, the prepared siloxene samples are polycrystalline and undergo slow hydrolytic decomposition in the air. For siloxene samples that were annealed at temperatures of up to 400 °C, however, luminescence intensity (for shift of the peak position) remains almost unchanged.[12a]

These results show that despite structural rearrangements the luminescence is retained. The cause of the luminescence of siloxenes as well as the structure of these compounds (do in fact only Si_6 rings occur or are there also larger silicon clusters present?) are by no means completely explained. The question must be posed whether the luminescence from siloxenes cannot also be ascribed to a nanostructure comparable to porous silicon.

Indeed, based on preliminary investigations by SAXS (small angle X-ray scattering), in siloxene structural domains of the size of 15–20 Å can be proven.[17] These contradictory results certainly require further intensive reseach, including a possible examination of the structure of the radiative samples.

Furthermore, polysilanes are of interest as an additional class of molecular model compounds. For example, from the pioneering work by West on cyclohexasilanes, it is known that these form relatively stable radical anions and cations ($g = 2.0044$, dodecamethylcyclohexasilane, UV spectrum: $\lambda_{max} = 248$ nm, $\varepsilon_0 = 5400$, $\lambda_{max} = 256$ nm (sh), $\varepsilon_0 = 1100$), in which, according to results from ESR spectroscopy, the SOMO (semi-occupied molecular orbital) is delocalized over the whole Si_6 skeleton.[18] According to investigations by Miller, Michl et al. polysilanes also show luminescence already at 293 K, albeit at 340 and 450 nm (excitation wavelength = 390 nm) with some astonishingly high quantum yields up to 70% and with a lifetime in the 0.1 ns range for the shortwave band. The mechanism of the luminescence of long-chain polysilanes has been studied in detail.[19]

Considering the complex set of questions that still need to be answered, there is a significant overlap of molecular chemistry and solid-state physical problems, which can only be resolved by intensive cooperative work of chemists and physicists in this area.

Although the single models in future may require some modification, one thing is certain: Both porous silicon and nanocrystalline silicon in dielectric matrix, as well as silicon-containing molecular compounds such as siloxene and polysilane luminesce with similar quantum yields to GaAs!

The specific applications for which these materials are suitable will be shown by future developments.

Models for Peptide Receptors

By *Hans-Jörg Schneider**

The development of selective host compounds for reversible binding of peptides is one of the most interesting fields in biomimetic chemistry. The topic is of importance for the understanding of molecular recognition mechanisms including those in proteins, for analytical methods, which incorporate sensor technology, and for the preparation of stereochemically pure peptides. The efficient preparation of peptides with a completely or partially "nonnatural" configuration[1] is a particularly attractive research area in medicinal chemistry because of the enormous diversity of biological activity of many oligopeptides. The therapeutically important stability of peptides against proteases, which often degrade the peptides, administered, for instance, as antibiotics, before they reach their target, can be significantly improved by the introduction of D-amino acids instead of L-amino acids.

In view of this importance and of the early success of the "chiral resolution machine" of Cram et al.,[2] which uses crown ethers containing bisnaphthyl units to separate amino acids, it is somewhat surprising that the selective complexation of peptides by organic host compounds has not yet been attempted on a very broad scale. The major noncovalent interactions for peptides have been analyzed by D. H. Williams et al. for the example of natural host vanomycin (**1**),[3] which binds the carboxylate terminus of Ala-Ala sequences of a peptidoglycan precursor compound (highlighted in boldface superimposed on the structural formula of **1**). A model limited predominantly to the carboxylate binding niche of this antibiotic was obtained by Hamilton et al.[4] in the form of compound **2**; the NMR spectrum of this model compound shows that a proton is transferred from bound

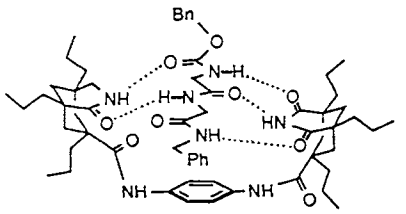
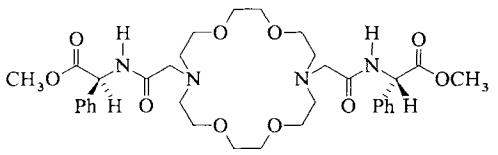
carboxylic acids (e.g., the cyanoacetic acid superimposed on the structural formula of **2**) to its dimethylamino terminus.

Rebek et al. have developed systems like **3** from Kemp's acid and diaminonaphthalenes or *para*-phenylenediamine as spacer between the converging diimidelactam units. The energy difference for the binding of enantiomers of rigid diketopiperazines in systems with 2,6-dimethylnaphthalene as spacer can be up to 2.5 kcal mol^{-1},[5a] but for more flexible peptides (e.g., with *para*-phenylenamine as spacer) this reduces to about 0.5 kcal mol^{-1}.[5b] The association constants in chloroform are maximally $K = 4700\,\text{M}^{-1}$; in general they are smaller for imides than for amides.[5c] For normal amide groupings, the analysis of a large number of supramolecular associations in chloroform as solvent yields—in the absence of additional effects—a common binding energy of (1.2 + 0.2) kcal mol^{-1} or $K \cong 10\,\text{M}^{-1}$ for each hydrogen bond formed.[6]



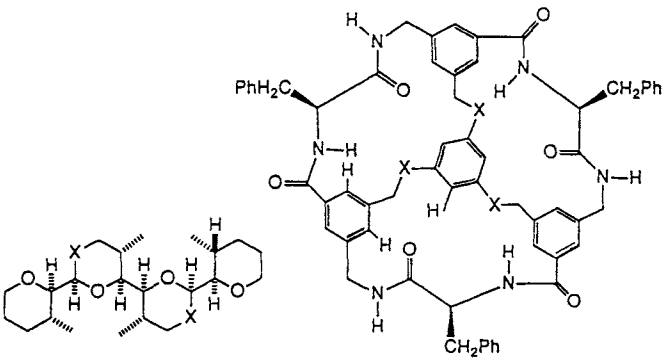
3

Crown ethers bearing amino acids as substituents were also used for the binding of peptides. Thus, according to Žinič et al.[7], the "lariate" ether **4** serves as "symporter" for the simultaneous binding of a potassium ion and a dipeptide carboxylate: for transport, enantiomer ratios sym_l/sym_d of 1.6 (for amino acid derivatives) are achieved. NMR measurements also show anisochronism, but binding constants for the associates have not yet been determined.



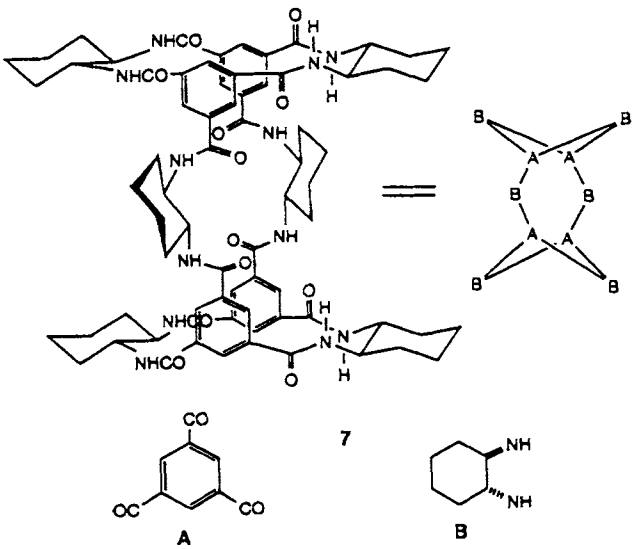
4

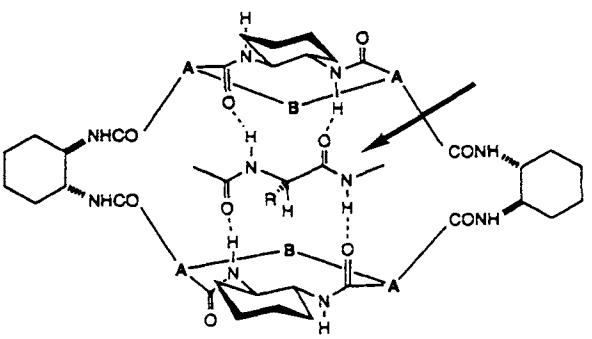
C. Still et al.[8] of Columbia University, New York, have been most intensely involved with the development of macrocyclic host compounds for the enantioselective complexation of peptides. Whereas the mono- and semicyclic receptors employed earlier, like **5** (X = SO_2),[8a] still show only relatively modest preferences of up to 80% *ee* between peptidic ammonium ions, not only because of their high conformational flexibility, $\Delta\Delta G$ values of over 3 kcal mol^{-1} have already been accomplished with the basketlike tricyclic model **6** (X = S).[8b] The host **6** binds Boc-protected peptides with the small NHMe end groups close to its phenyl rings. The L isomer is consistently preferentially bound; at the same time the host discriminates between side chains of Ala, Val, and Leu, for instance.



5 **6**

Most recently Still et al. have made a further breakthrough with the polycyclic receptor **7**,[8c] which not only displays similar enantioselectivities also for N-acylated and Boc-protected peptides, but also can be synthesized surprisingly easily: The condensation of Boc-protected (*R*,*R*)-1,2-diaminocyclohexane (H_2B) with pentafluorophenyl esters of trimesic acid ($A(OH)_3$) (Scheme 1) gives a 39% yield of the desired cyclooligomer **7**; even the treatment of the commercially available free diamine H_2B with trimesic acid trichloride ACl_3 affords in one step a yield of 13% that is still very acceptable when compared with many macrocyclizations! The bonding energies show a preference for L configurations,





Scheme 1. Top: Structural formula and schematic representation of **7**; bottom: **7** with peptide guest (arrow).

which increases with the size of the side chain, for example, from 1.9 for Gly through 3.5 for Ala to 5.0 for Val (in each case in kcal mol^{-1} for the relevant *N*-acyl-NHMe-dipeptide in chloroform). One explanation for this could be that the side chain contributes significantly to the binding through van der Waals forces with the host's phenyl rings—on this subject, see the analyses of the binding of **1** by Williams et al.[3c]—or that the solvent molecule (chloroform) no longer finds space in the cavity next to, for example, the small glycine residue. The geometries of the complex were consistent with the results of force field simulations, and supported experimentally by the upfield shifts $\Delta\delta$ of the protons that are in contact with the host's phenyl rings, which are induced by the ring current (e.g., $\Delta\delta = 2.5$ for the valine methyl proton).

The possible applications of host compounds that are easy to synthesize, capable of immobilization, and able to separate peptides with over 99% *ee* are apparent. In what direction should future research go? Extension to larger peptides is desirable—although the system **7** binds even tripeptides very efficiently, the application of synthetic large-cavity complexes will probably reach a limit set by preparative considerations. The differentiation of the peptide termini, that is the direction of the sequence, might be achieved by the introduction of terminal anionic and/or cationic groups into the receptor. For preparative applications, receptors that can also be used on a larger scale for the separation of diastereomers would be welcomed. More difficult is the development of compounds that also function in aqueous medium. The rational design of new synthetic peptide receptors and antibiotics from them, as well as the efforts to understand biological systems will necessitate the increased application of physical and calculational methods. Finally the implementation of signalling functions—in the simplest case chromophoric elements—is a crucial step to turn the promising systems into actual receptors in the biological sense and to make them applicable for sensor technology.

Tantalum(v) Phosphinidene Complexes as Phospha-Wittig Reagents**

By *Philip P. Power**

The report by Schrock et al.[1] describing the synthesis of tantalum phosphinidene complexes and their behavior as phospha-Wittig (or phosphinidene transfer) reagents will undoubtedly have a major impact in several areas of inorganic and organometallic chemistry. The title compounds, which have the formula **1**, R = Ph, *cyclo*-C_6H_{11}(Cy), or *t*Bu, are the first stable examples of electron-rich (or nucleophilic) phosphinidene complexes. In this manner, they are analogous to the Schrock-type carbenes,[2] and distinct from the transient phosphinidene complexes of low-valent transition metals.[3] The latter species contain an electrophilic phosphorus center and are thus analogous to the Fischer carbene complexes, which contain an electrophilic carbon center.[4] Stable phosphinidene transition metal complexes were originally reported by Lappert et al. in 1987,[5,6] but these and subsequent reports[7,8] employed large groups such as 2,4,6-*t*Bu$_3$C$_6$H$_2$ at the phosphorus center to ensure stability. In contrast, the new tantalum phosphinidene complexes **1** are stable with much smaller substituents at phosphorus such as Ph, Cy, and *t*Bu. In these tantalum complexes the stability has been ascribed to the use of the amido N_3N ligand. This trinegative, tetradentate amido ligand has enabled the isolation of some remarkable trigonal monopyramidal metal complexes with empty apical coordination sites.[9] When bound to tantalum, the ligand forms a protective pocket owing to the "upright" orientation of the three R_3Si substituents, yet, the ligand also permits access to the tantalum atom through the clefts between the arms of N_3N ligand. In addition, access to the phosphorus atom is possible owing to the relatively small organic substituents. Furthermore, the thermal stability of the complexes is such that

Davis, CA 95616 (USA)
Telefax: Int. code + (916)752-8995

[**] The term phosphinidene is used here instead of the less common IUPAC term λ^3-phosphandiyl.

1, R = Ph can be heated for 12 h at 100 °C without observable decomposition.

The synthesis of the new complexes can be summarized by Equations (1) and (2). Phosphine elimination reactions similar to that in Equation (2) have been observed in silicon–phosphorus[10] and boron–phosphorus compounds.[11]

$$Li_3(N_3N) + TaCl_5 \xrightarrow[-3\,LiCl]{Et_2O,\ -78 \rightarrow -25\,^\circ C} [(N_3N)TaCl_2] \quad (1)$$

$$[(N_3N)TaCl_2] + 2\,LiPHR \xrightarrow[-2\,LiCl,\ -H_2PR]{Et_2O,\ -40 \rightarrow -25\,^\circ C} \underset{\mathbf{1}}{[(N_3N)Ta{=}PR]} \quad (2)$$

The structure of one of the new complexes, **1**, R=Cy (see Fig. 1), displays an almost linear Ta-P-C moiety and a short Ta–P distance of 2.145(7) Å. The ^{31}P NMR spectra of the complexes display low field signals between $\delta = 175.1$ and $\delta = 227.3$.

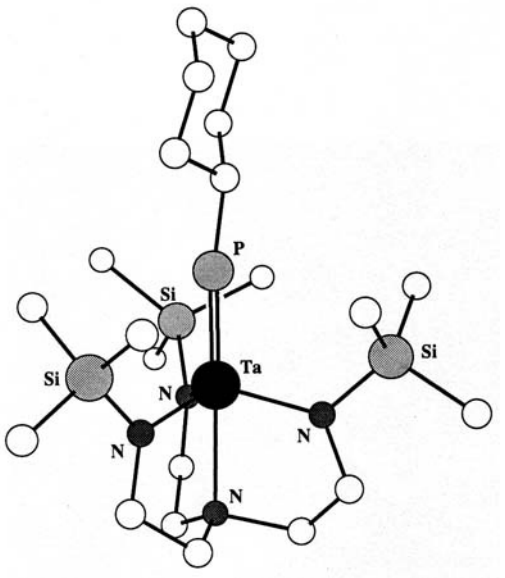

Fig. 1. Crystal structure of **1**, R = Cy.

The most remarkable characteristic of the new compounds concerns their reaction with various aldehydes [Eq. (3)] to give phosphaalkenes—a class of compounds first

$$[(N_3N)Ta{=}PR] + O{=}C\begin{matrix}R'\\H\end{matrix} \longrightarrow [(N_3N)Ta{=}O] + \begin{matrix}R'\\P{=}C\\R\quad H\end{matrix} \quad (3)$$

prepared by Becker in 1976.[12] This transformation, which proceeds under mild conditions, is analogous to the corresponding well-known reaction between tantalum alkylidene complexes and aldehydes to give alkenes.[13] It may proceed by a similar mechanism through a four-membered metallacycle.

The reaction is also quite notable in many other respects. For instance, it represents a new and general synthetic route to phosphaalkenes bearing a wide variety of phosphorus substituents. In addition, it is the first example of a transition metal reagent that metathesizes a heavier main group moiety under mild conditions. The close relationship between the reactions of tantalum alkylidene and tantalum phosphinidene complexes is yet another example of the so-called diagonal relationship between the chemistry of carbon and phosphorus.

It is probable that this new class of compounds can be extended to include the analogous arsinidene and stibinidene complexes, which when reacted with aldehydes could lead to a variety of arsa- and stibaalkenes, respectively. The alkylidene–phosphinidene relationship suggests that it may eventually be possible to obtain complexes with terminal phosphido M≡P ligands, either with tantalum or with the neighboring elements tungsten or molybdenum as the metal center.[14] Metathesis reactions[15] between these complexes and alkynes may give phosphaalkynes in an analogous manner.

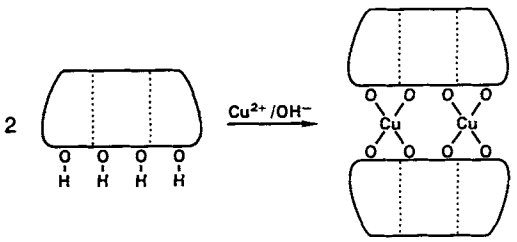
Multinuclear Sandwich-type Complexes of Deprotonated β-Cyclodextrin and Copper(II) Ions**

By *Ralf Fuchs, Norbert Habermann,* and *Peter Klüfers**

In cyclodextrin chemistry "complexes" are usually host–guest complexes formed from the inclusion of a nonpolar molecule in the hydrophobic interior of a cyclodextrin torus[1] or several tori.[2] In contrast, metal complexes with cyclodextrins or with other carbohydrates as ligands are not well known.[3] The only metal complexes with large stability constants described so far are derivatives in which the cyclodextrin torus serves as a framework for attaching complexing functional groups.[4] But cyclodextrins themselves should also be capable of forming complexes, since simple polyols and monosaccharides form stable metal complexes in aqueous alkaline solution, in which they exist as multiply deprotonated polyolato ligands. Under these conditions copper(II) ions and diols form homoleptic bis{diolato(2−)}-cuprates in which the copper center has square-planar coordination.[5] We report here on our efforts at constructing multinuclear sandwich-type complexes from cyclodextrins in which two cyclodextrin tori are joined by copper(II) ions to form a double torus according to the strategy outlined in Scheme 1.



Scheme 1. Formation of multinuclear sandwich-type complexes from cyclodextrins and Cu^{2+}.

Aqueous alkaline solutions with copper(II) ions and cyclodextrins (at the time only poorly characterized) were described in 1927 by Messmer and later by Japanese authors.[6] Matsui et al.[6b] reported that a solution of β-cyclodextrin treated with an excess of NaOH takes up two mol equivalents of copper(II) hydroxide. When we used LiOH as the alkali metal hydroxide we could precipitate blue crystals with varying water content from similar solutions by adding ethanol. As described in the Experimental Procedure at the end of this communication, rhombic crystals of a water-rich form of compound **1** were obtained (**1a**, $x \approx 40$; water

$Li_{11}[Cu_4(\beta\text{-cdH}_{11.5})_2] \cdot x\,H_2O$ **1** β-cdH$_{21}$ = β-cyclodextrin

content determined by analysis). The blue crystals were examined by X-ray crystallography with an area detector.[7] The result of the structure analysis is seen in the figures: Figure 1 shows a homoleptic tetranuclear complex, in which two cyclodextrin tori line up such that their O2–O3 edges face each other and four copper ions are bound to oxygen atoms in distorted square-planar coordination geometry. In

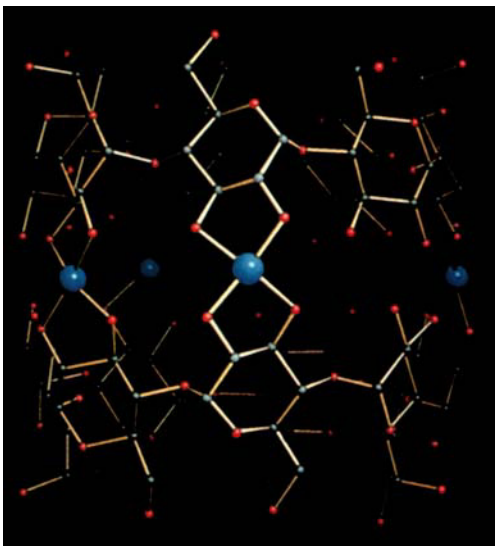


Fig. 1. Side view of the structure of the double torus in **1a**; blue: copper, red: oxygen, gray: carbon.

the double torus copper-bound anhydroglucose residues alternate with copper-free monomer units. As a result of the uneven number of ring members this alternation is not possible throughout the whole complex, but rather Cu-a and Cu-g are directly next to each other. In Figure 2 the double torus between these two copper atoms is cut open, unrolled, and shown from the outer side.

The depiction emphasizes a special feature of the complex not found in the complexes of simpler polyolates, namely, intramolecular hydrogen bonds. These can be inferred from the extent that the cyclodextrin rings were deprotonated: in the crystal structure of **1a** eleven lithium ions were localized per Cu_4 complex, which implies that each cyclodextrin ligand is deprotonated at least 9.5 times. The diolate groups bound to copper are doubly deprotonated according to findings on simple polyols. Thus the degree of deprotonation of each anhydroglucose unit not bound to copper is 1/2. Based on these values and the O–O distances in **1a**, a regular

[**] Polyol-Metal Complexes, Part 4. This research was supported by the Bundesministerium für Forschung und Technologie (grant no. 0319368A), Akzo AG, Wuppertal, and Wacker-Chemie, Munich (donation of cyclodextrin). – Part 3: [5a].

arrangement of nine isolated hydrogen bonds of type $O^- \cdots H-O$ can be deduced; these are represented in Figure 2 by dashed lines.

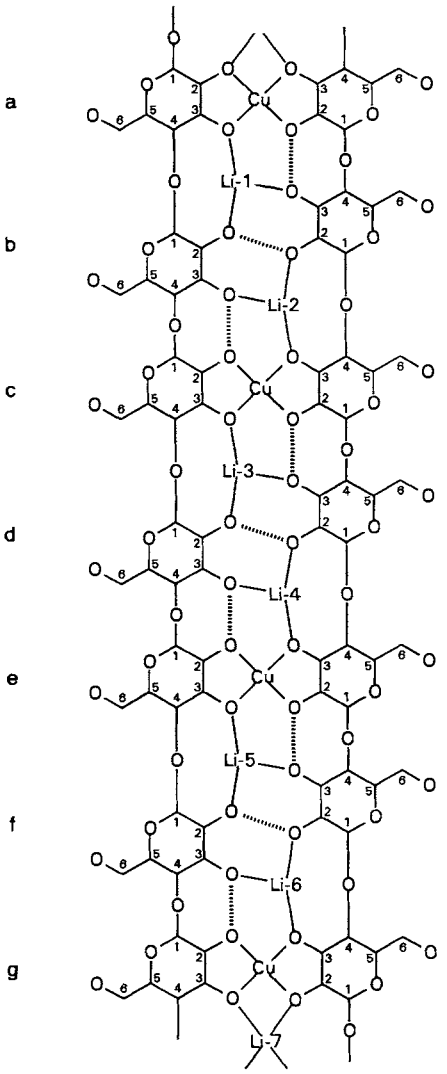

Fig. 2. Topology of the double torus and atomic labeling. All atoms except Li are labeled according to the formula A-*nm* (A = element symbol, *n* = position in the anhydroglucose ring, *m* = monomer unit (a–g in the left, a′–g′ in the right anhydroglucose strand)). O···O distances [pm] in $O^- \cdots H-O$ bonds in **1a**/**1b** (σ = 2 pm): O2a′-O3b′ 261/263, O2b-O2b′ 250/259, O3b-O2c 256/260, O2c′-O3d′ 256/261, O2d-O2d′ 247/254, O3d-O2e 257/267, O2e′-O3f′ 258/257, O2f-O2f′ 262/246, O3f-O2g 258/256.

When simple polyols and monosaccharides are treated with sufficient amounts of the alkali metal hydroxide and copper(II) salt, almost all of the polyol is converted into the deprotonated ligand. Thus it is not immediately evident why only four and not seven copper atoms are incorporated into our complex. We assume that the reason is the formation of intramolecular hydrogen bonds, which are possible for oligosaccharides like β-cyclodextrin but not for simple polyols or monosaccharides. The acidity of the nine protons in the hydrogen bonds is decreased, and deprotonation to give diolate(2−) ligands is apparently not possible under the given conditions.

Seven of the eleven lithium ions are found within the double torus of the tetracuprate complex ion. One of these lithium ions bridges the adjacent anhydroglucose pairs a and g, which are coordinated to copper ions; the other six lithium ions are each bound to three cyclodextrin O atoms in a regular pattern (Figs. 2 and 3). Seven water molecules are mounted in the polar middle of the cavity, which is hydrophobic up to the openings, forming a heptagon and completing the tetrahedral coordination environment of the lithium ions.

Other water molecules are bound to the water heptagon in **1a**. Figure 3 shows six positions, some not fully occupied, of these water molecules in the interior of the double torus; these water molecules have contact with water molecules on the exterior near the openings of the double torus.

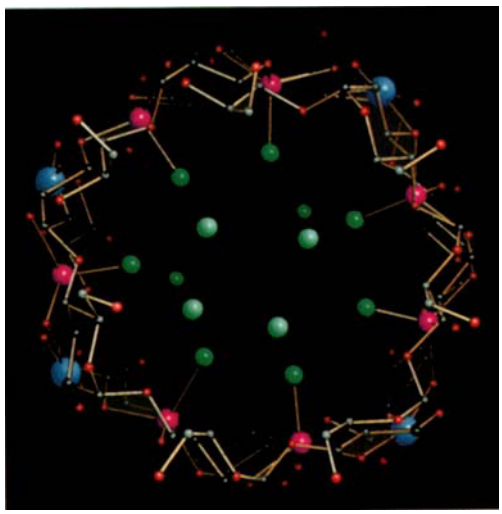

Fig. 3. View of the structure of the double torus in **1a** from the top; colors as in Fig. 1, violet: lithium, green: water.

A portion of the water of crystallization can be easily removed from **1a**. Upon warming to 70 °C (atmospheric pressure) the compound gives up two-thirds of its water content. A crystal of **1** containing less water (**1b**, $x \approx 25$; water content determined only by X-ray crystallography), which we obtained from a solution with a higher concentration of electrolytes, gives an idea of the dehydration process. Complex **1b** forms crystals with the same symmetry as and with cell parameters similar to those of crystals of **1a**. The structure analysis[7] shows the same $[Li_7(H_2O)_7Cu_4(\beta\text{-}cdH_{11.5})_2]^{4-}$ core as in **1a**; however, here the canals of water heptagons are empty, and no water molecules are found between the double tori. The apparently more tightly bound water molecules that form hydrogen bonds to most of the alkoxy O atoms and bring the coordination numbers of the latter to 4 are unaffected. In Figure 4 the double torus is somewhat compressed as a result of the dehydration but is essentially unchanged (see legend to Fig. 2). The packing of the double tori in the crystal resembles stacks of coins and facilitates the diffusion of the water molecules. The packing in **1b** is more dense; in **1a** the tori are surrounded by more water molecules and the stacking axis is tilted.

The metal-bridged cyclodextrin double torus described here could lead to new applications of cyclodextrins as enzyme models and as catalysts in their own right. A hydrophobic tube is found in both simple cyclodextrins and in **1**, although in **1** it is more functionalized. The hydrophobic cavity of the double torus is roughly 1.5 nm long and divided into two halves by a polar region in the middle. The polar region is formed from basic alkoxy units, which bind Lewis acidic centers of various strengths and hardnesses (Li^+,

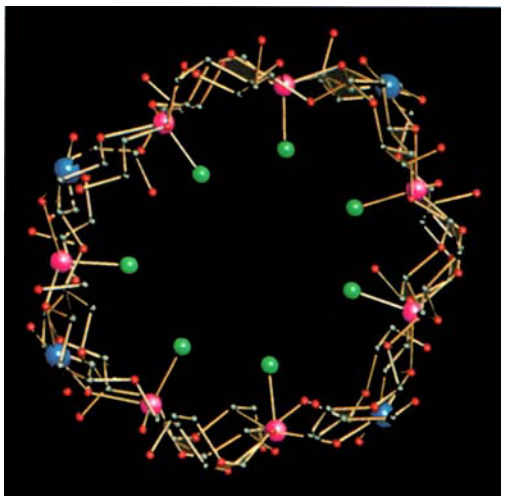

Fig. 4. View of the structure of the double torus in **1a**; colors as in Fig. 3.

Cu^{2+}); in addition, Cu^{2+} is a redox-active transition metal, and water is bound in precisely this region.

There is evidence that these units also exist in solution. Preliminary investigations of solvent equilibria indicate that simple polyols and monosaccharide derivatives form complexes with large stability constants in alkaline solution. At pH values above 11 even ethylenediamine is displaced from copper by diolate(2−) ligands; in amine-free solutions diolatocopper compounds form at pH ≈ 7.[8] We do not yet know, however, to what extent alkali metal cations associate with large, highly charged anions as in **1**.

Experimental Procedure

A solution of $Cu(OH)_2$ (0.97 g, 10 mmol), β-cyclodextrin (cyclomaltoheptaose; 5.68 g, 5 mmol), 8 mL H_2O, and 8 mL 5M LiOH (40 mmol LiOH) was sealed under N_2 and in the dark, and ethanol vapors were allowed to diffuse into the solution. Blue crystals formed within a few weeks; m.p. 205 °C (decomp after gradual dehydration). The crystal of **1a** examined by X-ray crystallography originated from this sort of sample; the elemental analysis indicates 3.6 instead of 4 Cu atoms and 13.2 instead of 11 Li atoms; in other words, **1a** is in a mixture with other complexes.

The Self-Assembly of Catenated Cyclodextrins**

By *Dominique Armspach, Peter R. Ashton, Christopher P. Moore, Neil Spencer, J. Fraser Stoddart*, Trevor J. Wear,* and *David J. Williams*

Supramolecular chemistry[1] has paved the way for self-assembly processes[2] to be developed[3] for the construction of large, ordered, molecular and polymolecular arrays. Catenanes, rotaxanes, and knot compounds[4, 5] have been identified[3, 6] as prototypes for the development of a new synthetic methodology that will be necessary to attain nanometer-scale structures easily and efficiently. Following on from a reliance on covalent bonds[4] to direct the formation of mechanically interlocked molecular systems, the use of metal ion templates has produced[5] a wealth of novel catenanes, rotaxanes, and knots. The application of π-π stacking and edge-to-face interactions involving aromatic rings,[3, 6] along with hydrogen bonding,[7] to construct catenanes and rotaxanes has extended the potential of self-assembly as a synthetic paradigm into the field of organic chemistry. Concurrently with this activity on wholly synthetic systems, the cyclodextrins (CDs) have attracted a lot of attention[8] as building blocks in self-assembling rotaxanes[9] and polyrotaxanes,[10] usually in aqueous media but also quite recently[11] in organic solvents with chemically modified CDs. In 1958, Lüttringhaus, Cramer, Prinzbach, and Henglein[12] attempted to harness the weak noncovalent bonding forces that exist in water between α-CD and a series of substrates containing a hydroquinol ring etherified with, for example, two $(CH_2)_9CH_2SH$ groups in order to obtain, after oxidation, an α-CD catenated by macrocyclic disulfides. Although the experiment failed, it is important in the history of catenated compounds, because it was the first

[**] This work was supported by the Science and Engineering Research Council and by Kodak Limited. We also thank Dr. Andrew Quick of the University of London Computing Centre for preparing the computer-aided ball-and-stick and space-filling representations of the [2]catenanes. These diagrams were produced with the Convex AVS Visualization Software.

reported attempt to synthesize such compounds. Now 35 years on, we have succeeded finally in catenating cyclodextrins. Here, we report the synthesis from *pure*[13] heptakis(2,6-di-*O*-methyl)-β-cyclodextrin (DM-β-CD, Fig. 1) of two [2]catenanes and two [3]catenanes as a mixture of isomers, the characterization of these novel compounds by FAB-MS and NMR spectroscopy, and the X-ray crystal structure of one of the [2]catenanes.

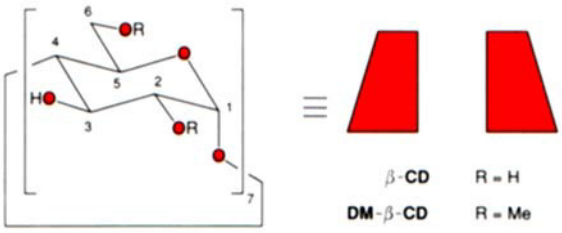

Fig. 1. Structural formula and schematic representation of β-CD and DM-β-CD.

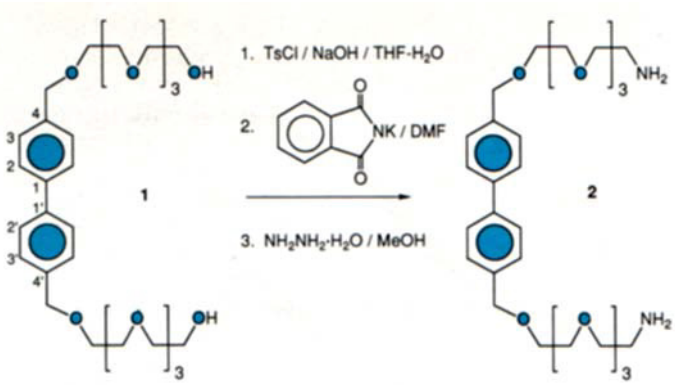
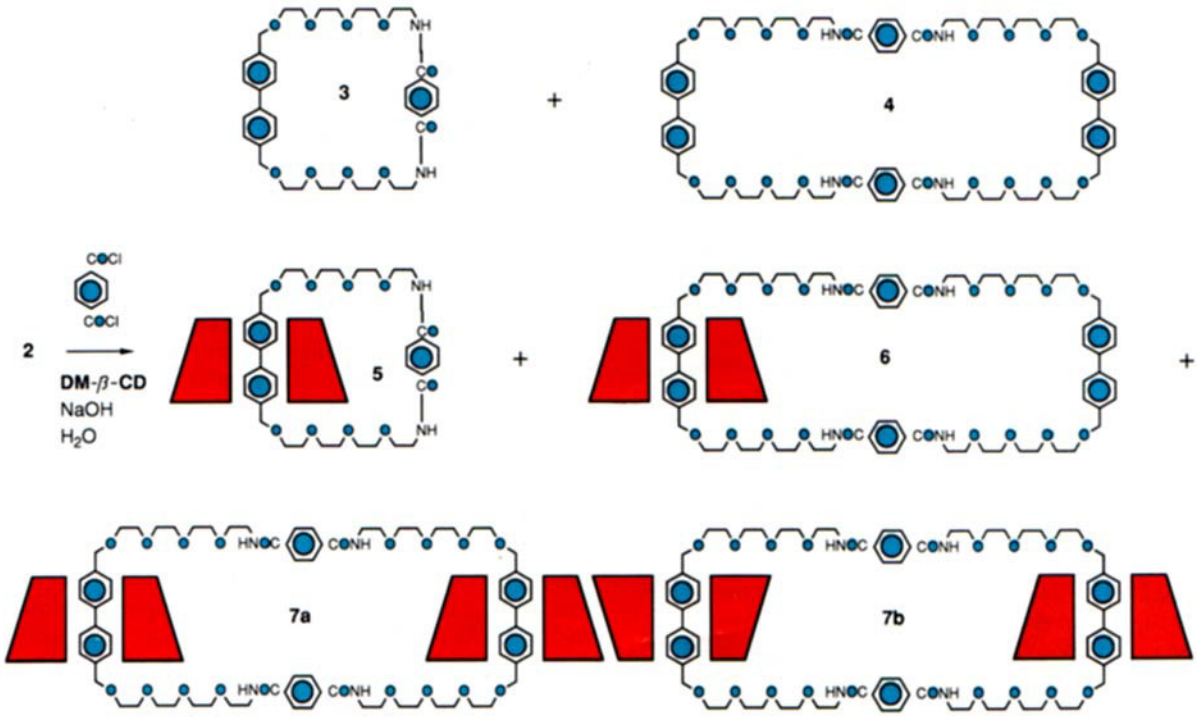
Since we anticipated difficulties in the isolation of catenated CDs, we focussed our attention initially upon one of the methylated CD derivatives[13] that are known to exhibit good solubilities in organic solvents as well as in water. We chose DM-β-CD (Fig. 1), whose torus-shaped cavity is extended and more rigid than that of the parent β-CD, in order to enhance the binding of aromatic ring-containing substrates[14] through their hydrophobic interactions with DM-β-CD in aqueous solution. Since the diol **1**, based on a bitolyl unit (Scheme 1), forms a strong complex (see below) in aqueous solution with DM-β-CD, we investigated the reaction of the more nucleophilic diamine **2** (derived from **1**) under Schotten-Baumann[15] reaction conditions with terephthaloyl chloride (see Scheme 2). In this manner, we satisfied, as far as possible, the interrelated requirements of the substrate,[16] the reaction, and the media for efficient macrocyclization to afford catenated DM-β-CD derivatives in aqueous solution.



Scheme 1.

The binding properties of the diol **1** and the diamine **2** with both β-CD and DM-β-CD in D_2O were investigated by ^{1}H NMR spectroscopy at room temperature. Upfield chemical shift changes in the CDs,[17] particularly for H3 and H5, were accompanied by an upfield chemical shift change[17] for H2 and H2′ in the substrates. The 1:1 stoichiometries of the β-CD · **1** complex (deduced by probing H3 in β-CD and H2 and H2′ in **1**) and of the DM-β-CD · **2** complex (deduced by probing[18] OMe6 in DM-β-CD and H2 and H2′ in **2**) were confirmed[19] by the method of continuous variations (Job's plots). Through ^{1}H NMR spectroscopy it was also possible to obtain association constants (K_a) for the 1:1 complexes β-CD · **1** and DM-β-CD · **1** in D_2O. The K_a values[20] of $8900 \pm 500\ kg\,mol^{-1}$ and $41\,000 \pm 3000\ kg\,mol^{-1}$, respectively, augured well for our attempts to catenate CDs with synthetic macrocycles containing bitolyl units.

The diol **1** was converted into the diamine **2** by the Gabriel procedure (Scheme 1). The water-soluble inclusion complex, which is formed when equimolar amounts of DM-β-CD and



Scheme 2.

2 are dissolved in a large volume of 0.01 N NaOH solution, was treated with 1.1 equivalents of terephthaloyl chloride under sonication at 5 °C (Scheme 2). In addition to isolating the macrocycles **3** (12%, formed by intramolecular ring closure of a straight-chain intermediate) and **4** (3.5%, formed by intermolecular ring closure), the related two [2]catenanes **5** (3.0%) and **6** (0.8%), and the isomeric [3]catenanes **7a** and **7b** (1.1%, as an equimolar mixture) were characterized[21] following chromatography of the $CHCl_3$ extracts of the reaction mixture on silica gel. The relative yields of **3** and **4**, and of **5** and **6** indicate that, somewhat disappointingly, the macrocyclizations leading to catenane formation are inhibited[22] by the bound DM-β-CD component(s).

The solubility characteristics of these catenated CDs are quite unusual and distinctive. With the exception[23] of **6**, they are soluble in hydroxylic (e.g., H_2O and MeOH), halogenated (e.g., CH_2Cl_2 and $CHCl_3$), and aromatic hydrocarbon (e.g., C_6H_6 and MePh) solvents.

The positive ion FAB-MS of **5** and **6** are characteristic of [2]catenanes[24]: in addition to peaks for the molecular ions—often including bound sodium—fragmentation peaks are also observed for the component macrocyclic rings. For **5**, peaks are observed for $[M + Na]^+$, $[M + Na - \mathbf{3}]^+$, and $[M - \text{DM-}\beta\text{-D}]^+$, and for **6** for $[M + Na]^+$, $[M]^+$, $[M - \text{DM-}\beta\text{-CD}]^+$, and $[M + Na - \mathbf{4}]^+$. In the case of the [3]catenanes **7a** and **7b**, the presence of the derived [2]catenane **6**, after loss of one DM-β-CD ring is evident in the positive ion FAB-MS. Thus, peaks are observed for $[M + Na]^+$, $[M + Na - \text{DM-}\beta\text{-CD}]^+$, $[M - 2\,\text{DM-}\beta\text{-CD}]^+$, and $[M + Na - \mathbf{6}]^+$.

The ^{13}C NMR spectra of **5** and **6**, recorded in $CDCl_3$, show that the DM-β-CD component in both [2]catenanes retains its C_7 symmetry, that is, the expected eight signals are observed, in keeping with rapidly pirouetting synthetic macrocycles around the CD torus. However, the original C_{2v} symmetry of **3** and D_{2h} symmetry of **4** are lowered to local symmetries that are C_1 and C_2, respectively, under the influence of the chiral DM-β-CD rings that are rapidly circumrotating in both **5** and **6**. The outcome is a doubling in the number of ^{13}C NMR signals from 16 to 32 on going from **3** to **5** and from **4** to **6**. For example, the signals observed for the bitolyl methylene carbon atoms at $\delta = 72.9$ in both **3** and **4** are replaced by signals at $\delta = 72.5$ and 72.9 in **5** and at $\delta = 72.8$ and 72.9 in **6**. Also, in the ^{13}C NMR spectrum of **5**, the amide carbonyl carbon atoms give rise to two signals at $\delta = 167.0$ and 168.0, whereas they resonate as one signal at $\delta = 166.5$ in the ^{13}C NMR spectrum of **3**. The consequences of catenane formation upon the local symmetries of the synthetically derived ring components are also reflected in the ^1H NMR spectra of **5** and **6**. Most strikingly, the ^1H NMR spectrum of **5** in C_6D_6 solution (Fig. 2) reveals the imposed heterotopic character upon sets of aromatic protons within both the bitolyl and terephthaloyl units, as well as upon the bitolyl methylene groups within which each pair of protons display their expected diastereotopicities. These various topic relationships give rise to three AA′BB′ systems for the 12 aromatic protons and two AB systems for the four bitolyl methylene protons. The ^1H NMR spectrum of **5** was recorded at −60 °C in CD_2Cl_2 solution. Since no temperature dependence was observed, the synthetic macrocyclic component must either be located firmly in one position with respect to the DM-β-CD component, or it must still be circumrotating rapidly on the ^1H NMR time scale.[25] We suspect the latter circumstance prevails, since no temperature dependence was observed in the ^1H NMR spectrum of **6** when it was recorded at −60 °C in CD_2Cl_2 solution. This [2]catenane is perfectly constructed for a degenerate process

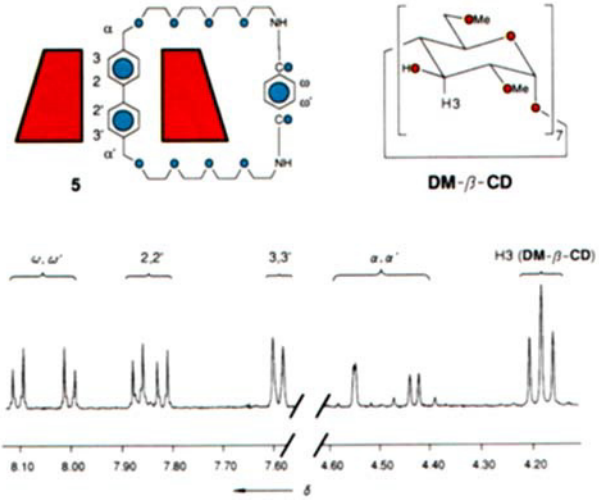


Fig. 2. A section of the ^1H NMR spectrum of the [2]catenane **5** recorded in C_6D_6 solution.

of exchange of the DM-β-CD ring to occur between the equivalent bitolyl units in the synthetic macrocyclic component. Yet it continues to display local C_2 symmetry down to −60 °C in CD_2Cl_2 solution where precipitation of **6** occurs, causing signals to broaden in the ^1H NMR spectrum. Both the ^1H and ^{13}C NMR spectra of **7**, recorded in $CDCl_3$, reveal the presence of two isomers, the head-to-head/tail-to-tail **7a** and head-to-tail/head-to-tail **7b**. In **7a**, the synthetic macrocyclic component has averaged D_2 symmetry (i.e., it behaves like **4**), whereas in **7b**, it has averaged C_2 symmetry (i.e., it behaves like **6**). The spectra are in accordance with these two symmetry types.[26] In addition, the presence of two sets of equal intensity signals for the DM-β-CD protons in the ^1H NMR spectrum of **7a**/**b** confirms the presence of an equimolar mixture of orientational isomers. Their separation is under investigation.[26]

After extensive trials with a wide range of different solvent systems, we obtained small, but well-formed, single crystals of the [2]catenane **5** suitable for X-ray crystallography.[27, 28] The crystal structure of **5** (Fig. 3) reveals that in the solid state the bitolyl unit of the macrocyclic bislactam component is positioned inside the DM-β-CD torus, and the planar bislactam residue lies against the outside. The phenylene rings in the bitolyl unit are nonplanar; the upper ring has a well-defined orientation, whilst the lower one is disordered and adopts two orientations, twisted by about 40° in either one or other direction with respect to the upper ring. As a consequence, the lower polyether strand adopts several different conformations, and that illustrated in Figure 3 represents one of many that can be fitted to the diffuse tube of electron density that appears in this region of the structure. The axis of the bitolyl unit is not inserted perpendicularly through the DM-β-CD torus, but is inclined by about 63° to the plane defined by the seven glycosidic oxygen atoms. Surprisingly, there is no hydrogen bonding between the polyether oxygen atoms and the hydroxyl groups on the upper rim of the cyclodextrin. Indeed, those oxygen atoms that lie over the upper rim of the DM-β-CD torus are directed *away* from the hydroxyl groups. The partial weight included H_2O molecules[*] lie within hydrogen-bonding distance of one of the amide nitrogen atoms. Apart from small perturbations in the orientations of the methoxyl groups on the upper and lower rims of the DM-β-CD component, the gross C_7 geometry of the cyclodextrin is retained.

[*] That is, not all the potential sites for water of crystallization are occupied in different molecules of the crystal.

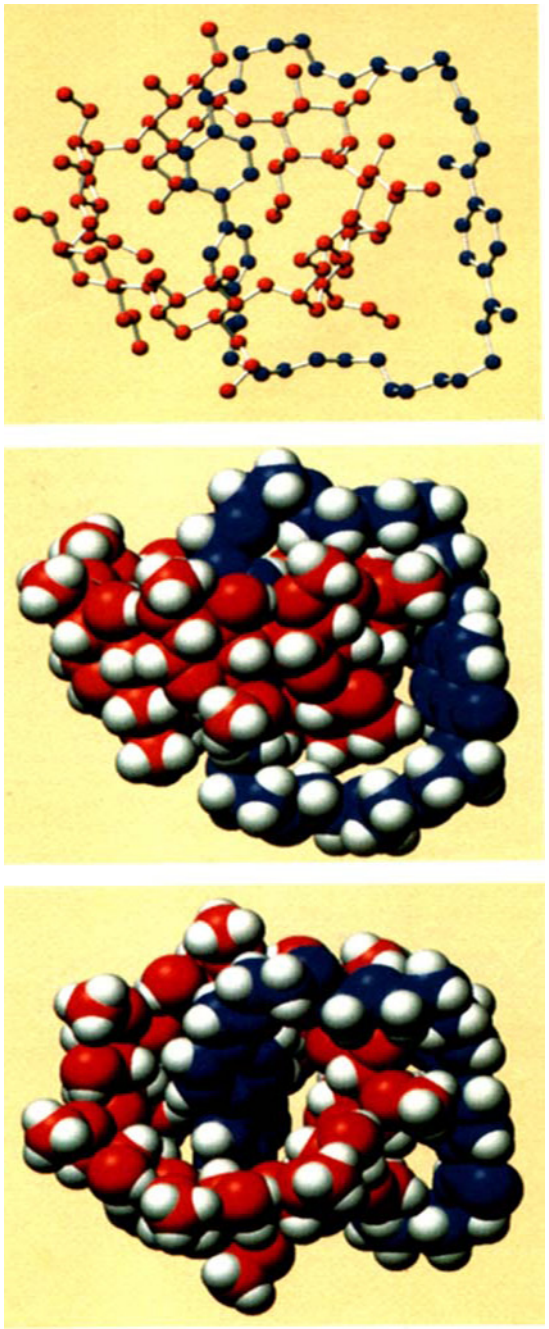

Fig. 3. Top: Structure of **5** in the crystal with the DM-β-CD component depicted in red and the macrocyclic bislactam component (**3**) in blue. Space-filling representations of the [2]catenane viewed from the side of the CD torus (center) and from above (bottom).

We can now anticipate the catenation of β-CD,[29] as well as the lower (α-CD) and higher (γ-CD) homologues—and their chemically modified derivatives—as a prelude to constructing compounds that function as molecular devices, which are soluble in water, in addition to a wide range of organic solvents.

Experimental Procedure

1: Reaction of 4,4′-bis(bromomethyl)biphenyl [30] (10.0 g, 0.029 mol) with the monosodium salt of tetraethyleneglycol—prepared in situ from tetraethylene glycol (160 mL, 1.10 mol) and sodium (2.7 g, 0.117 mol)—for 18 h at 60 °C gave the diol **1** as a colorless oil (12.5 g, 76%) after chromatography on SiO_2($CHCl_3$:MeOH 92:8); positive ion FAB-MS: *m/z* 567, 589, and 605 for $[M + H]^+$, $[M + Na]^+$, and $[M + K]^+$, respectively. ^1H NMR ($CDCl_3$): $\delta = 2.84$ (s; 2H), 3.57 (t, $J = 5.5$ Hz; 4H), 3.61–3.72 (m; 28H), 4.59 (s; 4H), 7.39 (d, $J = 8$ Hz; 4H), 7.54 (d, $J = 8$ Hz; 4H); ^{13}C NMR ($CDCl_3$): $\delta = 61.7$, 69.5, 70.3, 70.6 (× 2), 70.7 (× 2), 72.6, 73.0, 127.1, 128.3, 137.3, 140.3.

2: When the diol **1** (10.0 g, 17.6 mmol) was treated with *p*-toluene sulfonyl chloride (7.6 g, 40 mmol) and NaOH (2.0 g, 50 mmol) in 30 mL of THF-H_2O (2:1) for 4 h at 0 °C, the pure ditosylate (14.5 g) was obtained without further purification in 94% yield. Positive ion FAB-MS: *m/z* = 874 and 897 for $[M]^+$ and $[M + Na]^+$, respectively; ^1H NMR ($CDCl_3$): $\delta = 2.43$ (s; 6H), 3.57–3.72 (m; 28H), 4.16 (t, $J = 5.5$ Hz; 4H), 4.60 (s; 4H), 7.33 (d, $J = 8$ Hz; 4H), 7.41 (d, $J = 8$ Hz; 4H), 7.56 (d, $J = 8$ Hz; 4H), 7.79 (d, $J = 8$ Hz; 4H); ^{13}C NMR ($CDCl_3$): $\delta = 21.6$, 68.7, 69.2, 69.5, 70.5, 70.6 (× 3), 70.7, 73.0, 127.1, 128.0, 128.3, 129.8, 134.0, 137.3, 140.3, 144.8.

Reaction of the ditosylate (140 g, 16 mmol) with potassium phthalimide (6.9 g, 37.2 mmol) in DMF (100 mL) for 7 h at 90 °C afforded the pure diphthalimide as a colorless oil (12.1 g, 92%). Positive-ion FAB-MS: *m/z* 824 and 847 for $[M]^+$ and $[M + Na]^+$, respectively; ^1H NMR ($CDCl_3$): $\delta = 3.58$–3.69 (m; 24H), 3.73 (t, $J = 5.5$ Hz; 4H), 3.90 (t, $J = 5.5$ Hz; 4H), 4.59 (s; 4H), 7.40 (d, $J = 8$ Hz; 4H), 7.55 (d, $J = 8$ Hz; 4H), 7.70 (m; 4H), 7.83 (m; 4H); ^{13}C NMR ($CDCl_3$): $\delta = 37.3$, 67.9, 69.5, 70.1, 70.6 (× 2), 70.7 (× 2), 73.0, 123.2, 127.1, 128.2, 132.2, 133.9, 137.4, 140.2, 168.2.

Treatment of the diphthalimide (12.0 g, 14.5 mmol) with hydrazine hydrate (3.7 mL) in MeOH (250 mL) under reflux for 1 h gave the diamine **2** as a slightly yellowish oil (6.1 g, 75%) after chromatography on SiO_2 ($CHCl_3$:MeOH:NH_4OH 49:9:1). Positive ion FAB-MS *m/z* 565 and 587 for $[M + H]^+$ and $[M + Na]^+$, respectively; ^1H NMR ($CDCl_3$): $\delta = 2.80$ (bs; 4H), 3.52 (t, $J = 5.5$ Hz; 4H), 3.62–3.72 (m; 28H), 4.61 (s; 4H), 7.43 (d, $J = 8$ Hz; 4H), 7.58 (d, $J = 8$ Hz; 4H); ^{13}C NMR ($CDCl_3$): δ ($CDCl_3$) = 41.7, 69.6, 70.3, 70.6 (× 2), 70.7 (× 2), 73.0, 73.3, 127.1, 128.3, 137.3, 140.3.

3, **4**, **5**, **6**, **7a**/**b**: A solution of the diamine **2** (1.0 g, 1.8 mmol), *pure* [13] DM-β-CD (2.5 g, 1.9 mmol) and sodium hydroxide (200 mg, 5.0 mmol) in H_2O (500 mL) was sonicated for 2 h at room temperature. Powdered terephthatholyl chloride (405 mg, 2.0 mmol) was added whilst maintaining the temperature of the reaction below 5 °C. The suspension was sonicated for a further 2 h at room temperature. The reaction mixture was extracted with $CHCl_3$ (3 × 100 mL) and the combined organic layers were washed with 1 N sodium hydroxide solution and H_2O, and then dried ($MgSO_4$). Removal of the solvent in vacuo gave a colorless solid, which was purified by chromatography on SiO_2($CHCl_3$:MeOH 92:8) to afford four fractions. They were characterized as follows: Fraction 1, DM-β-CD; Fraction 2, the macrocyclic **3** (150 mg, 12%, m.p. 134–135 °C); positive ion FAB-MS: *m/z* 695 and 717 for $[M + H]^+$ and $[M + Na]^+$, respectively; ^1H NMR ($CDCl_3$): $\delta = 3.58$–3.72 (m; 32H), 4.55 (s; 4H), 7.24 (bt; 2H), 7.35 (d, $J = 8$ Hz; 4H), 7.41 (d, $J = 8$ Hz; 4H), 7.70 (s; 4H); ^{13}C NMR ($CDCl_3$): $\delta = 40.0$, 69.4, 69.8, 70.2, 70.5, 70.6, 70.7 (× 2), 72.9, 126.9, 127.2, 128.3, 136.8, 137.2, 140.0, 166.5; Fraction 3, which was purified further by preparative TLC on SiO_2 (CH_2Cl_2:MeOH 91:9) to afford (a) the macrocyclic **4** (45 mg, 3.5%, m.p. 148–149 °C); positive ion FAB-MS: *m/z* 1390 and 1412 for $[M + H]^+$ and $[M + Na]^+$, respectively; ^1H NMR ($CDCl_3$): $\delta = 3.56$–3.68 (m; 64H), 4.52 (s; 8H), 7.31 (bs; 4H), 7.34 (d, $J = 8$ Hz; 8H), 7.48 (d, $J = 8$ Hz, 8H), 7.84 (s; 8H); ^{13}C NMR ($CDCl_3$) $\delta = 39.9$, 69.4, 69.8, 70.2, 70.5 (× 2), 70.6 (× 2), 72.9, 127.0, 127.3, 128.3, 137.1, 137.2, 140.2, 166.7; (b) the catenane **5** (105 mg, 3%, m.p. 175–176 °C); positive ion FAB-MS: *m/z* 2049, 1353, and 695 for $[M + Na]^+$, $[M - 3 + Na]^+$, and $[M - DM\text{-}\beta\text{-}CD]^+$, respectively; ^1H NMR (C_6H_6): $\delta = 3.02$ (dd, $J = 3.5$; 10 Hz, 7H), 3.20–3.85 (m; 53H), 3.37 (s; 21H), 3.44 (s; 21H), 3.89 (ddd, $J = 2$, 4.5, 10 Hz; 7H), 4.18 (t, $J = 10$ Hz; 7H), 4.41, 4.45 (AB system, $J_{AB} = 13$ Hz; 2H), 4.54, 4.55 (AB system, $J_{AB} = 13$ Hz; 2H), 4.81 (d, $J = 3.5$ Hz; 7H), 5.30 (s; 7H), 7.46 (bt; 1H), 7.59 (d, $J = 8$ Hz; 4H), 7.82 (d, $J = 8$ Hz; 2H), 7.86 (bt; 1H), 7.87 (d, $J = 8$ Hz; 2H), 8.00 (d, $J = 8$ Hz, 2H), 8.11 (d, $J = 8$ Hz; 2H); ^{13}C NMR ($CDCl_3$): $\delta = 59.0$, 60.3, 70.4, 70.7, 73.3, 81.9, 83.3, 101.2 for the DM-β-CD component and 40.1, 40.3, 72.5, 72.9, 126.0, 126.4, 127.5, 127.7, 127.9, 128.0, 137.1, 137.5, 138.6 (× 2), 138.9, 140.1, 167.0, 168.0 for component **3**, excluding the 14 OCH_2 signals which overlap in the region 69.8–70.6; Fraction 4 was purified further by preparative TLC on SiO_2(CH_2Cl_2:MeOH 9:1) to afford (a) the catenane **6** (20 mg, 0.8%) as an amorphous solid; positive ion FAB-MS: *m/z* 2743, 2721, 1389, and 1353 for $[M + Na]^+$, $[M]^+$, $[M - DM\text{-}\beta\text{-}CD]^+$, and $[M + Na - \mathbf{4}]^+$, respectively; ^1H NMR ($CDCl_3$): $\delta = 3.23$ (dd, $J = 3.5$, 10 Hz; 7H), 3.30 (s; 21H), 3.59 (s; 21H), 3.29–3.74 (m; 92H), 3.89 (t, $J = 10$ Hz; 7H), 4.57 (s; 4H), 4.61 (s; 4H), 4.92 (d, $J = 3.5$ Hz; 7H), 5.06 (s; 7H), 7.16 (bt; 2H), 7.32 (bt; 2H), 7.38 (d, $J = 8$ Hz, 4H), 7.39 (d, $J = 8$ Hz; 4H), 7.52 (d, $J = 8$ Hz; 4H), 7.53 (d, $J = 8$ Hz; 4H), 7.83–7.93 (m; 8H); ^{13}C NMR ($CDCl_3$): $\delta = 58.9$, 60.3, 70.3, 70.6, 73.3, 82.1, 83.4, 101.2 for the DM-β-CD component and 39.9 (× 2), 72.8, 72.9, 126.7, 126.8, 127.3, 127.4, 128.0, 128.1, 137.0, 137.2, 137.4, 137.8, 139.8, 140.2, 166.6 (× 2) for component **4**, excluding the 14 OCH_2 signals which overlap in the region 69.6–70.7; (b) and the orientationally isomeric **7a** and **7b** as an equimolar mixture (39 mg, 1.1%); positive ion FAB-MS: *m/z* 4072, 2742, 1389, and 1353 for $[M + Na]^+$, $[M + Na - DM\text{-}\beta\text{-}CD]^+$, $[M - 2\,DM\text{-}\beta\text{-}CD]^+$, and $[M + Na - \mathbf{6}]^+$, respectively. Both ^1H and ^{13}C NMR spectroscopic data were consistent with the presence of approximately equal amounts of **7a** and **7b** in Fraction 4 (b). At present, attempts are being made to separate the isomers and characterize them fully [26]. Single crystals of

5, suitable for X-ray structural analysis [27, 28] have been grown by vapor diffusion of iPr_2O into an ethanolic solution of the [2]catenane.

[14] Preliminary ^{1}H NMR spectroscopic studies in D_2O established that compounds carrying two 2-[2-(2-hydroxyethoxy)ethoxy] groups with the substitution pattern of α,α' on *p*-xylene, 1,4 on benzene, and 1,5 and 2,6 on naphthalene did not form complexes with either β-CD or DM-β-CD. Although 4,4′-bis[2-[2-[2-(2-hydroxyethoxy)ethoxy]ethoxy]ethoxy]biphenyl does form a complex with β-CD and DM-β-CD, the corresponding diamine does not form catenated compounds with DM-β-CD under the same conditions as those described in Scheme 2 for the diamine **2** based on a bitolyl unit.

[15] J. F. King, R. Rathore, J. Y. L. Lam, Z. R. Guo, D. F. Klassen, *J. Am. Chem. Soc.* **1992**, *114*, 3028.

[16] The bitolyl and bislactam units in the macrocycles **3** and **4** confer a certain amount of rigidity which we believe is ultimately essential for the self-assembly of the catenated DM-β-CDs, **5**, **6**, and **7a**/**b**.

[17] When the 1:1 complexes β-CD · **1** and DM-β-CD · **1** are formed in D_2O at concentrations of 1.3×10^{-2} M, the $\Delta\delta$ values experienced by H3 (in both β-CD and DM-β-CD) and by H2 and H2′ (in **1**) are −0.17 and −0.20, respectively; that is, in this case the chemical shift changes are coincidentally the same for each complex.

[18] This experiment was carried out in 0.1 N NaOD/D_2O solution in order to maintain a constant pD of 13, at which **2** exists entirely as the diamine and DM-β-CD entirely as the heptaol. The Job's plot could not be obtained for β-CD and **2** under these conditions, since β-CD is partially deprotonated in 0.1 N NaOD/D_2O solution.

[19] K. A. Connors, *Binding Constants. The Measurement of Molecular Complex Stability*, Wiley, New York, **1987**.

[20] It can be shown (D. R. Alston, T. H. Lilley, J. F. Stoddart, *J. Chem. Soc. Chem. Commun.* **1985**, 1600) that for 1:1 complex formation, the observed chemical shift difference Δ between the free and complexed components, for an appropriate ^{1}H NMR probe, is dependent upon the concentration c of the 1:1 complex, according to equation, $\Delta = \Delta_0 - (\Delta/c)^{1/2}(\Delta_0/K_a)^{1/2}$, where Δ_0 is the chemical shift difference between the ^{1}H NMR probe in the fully formed 1:1 complex and in the free components. Measurements of the chemical shift differences for H3 in DM-β-CD at various concentrations and a subsequent plot of Δ against $(\Delta/c)^{1/2}$ gave rise to straight lines, which confirmed 1:1 complex formation. The K_a values were calculated directly from the slopes and the ordinate intercepts of these lines. Note that the K_a value for DM-β-CD · **2** has still to be determined.

[21] No acylation of DM-β-CD seems to take place during the Schotten-Baumann reaction. Polyamides were also produced during the course of the reaction between **2** and terephthaloyl chloride, but they could be separated easily from the desired products by the purification procedure described in the Experimental Procedure.

[22] However, it is conceivable that the formation of **3** and **4** is controlled by templates of sodium or hydrated sodium ions in the 0.01 N NaOH solution.

[23] The [2]catenane **6** is only sparingly soluble in H_2O and MeOH. Catenanes **5**, **6**, and **7a** and **b** are all soluble in Me_2CO but not at all in Et_2O.

[24] W. Vetter, E. Logemann, G. Schill, *Org. Mass. Spectrom.* **1977**, *12*, 351.

[25] Saturation transfer experiments involving H3 and H5 in the DM-β-CD component and the aromatic protons in the synthetic macrocyclic component support the view that in organic solvents both the bitolyl and terephthaloyl units occupy the cavity of the CD at different times.

[26] For example, the bitolyl methylene group in **7a** can be identified in the ^{1}H NMR spectrum ($CDCl_3$) as *one* singlet at $\delta = 4.62$, whereas *two* singlets are observed at $\delta = 4.59$ and 4.65 for these protons in **7b**. In common with the ^{1}H NMR spectrum of the [2]catenane **6**, the diastereotopicities of the bitolyl methylene protons are not evident. Since this communication was accepted for publication, separation of **7a** from **7b** has been achieved by using reverse-phase HPLC under conditions where **7b** is eluted ahead of **7a**.

[27] Crystal data for **5** · H_2O: orthorhombic, $a = 14.989(2)$, $b = 23.147(8)$, $c = 31.254(7)$ Å, $V = 10843$ Å^3, space group $P2_12_12_1$, $Z = 4$, $\varrho = 1.25$ g cm^{-3}, 4159 independent observed reflections with $[|F_o| > 3\sigma(|F_o|)$, $2\theta \leq 116°]$ refined to a current $R = 0.143$, $R_w = 0.138$ [28].

[28] Siemens P3/PC diffractometer, ω-scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The structure was solved by direct methods and refined isotropically (there were too few observed data to permit meaningful anisotropic refinement). Further details of the crystal structure investigations can be obtained from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ (UK) on quoting the full journal citation.

[W(CH)(dmpe)$_2$(*n*Bu)], a Complex with a Bent Methylidyne Ligand**

By *Joseph Manna, Steven J. Geib,* and *Michael D. Hopkins**

Among the extensive class of transition metal alkylidyne (or carbyne) complexes,[1] the parent derivatives—those bearing the methylidyne ligand (CH)—are underrepresented.[2–4] That these particular complexes are scarce is unfortunate, as it is only in the context of their structures, properties, and reactivity that the electronic and steric effects of the alkylidyne R groups of all other types of alkylidyne compounds can be fully judged. Although the reactivity of methylidyne complexes has been explored in some de-

[**] This research was supported by the National Science Foundation, the Camille and Henry Dreyfus Foundation, the Alfred P. Sloan Foundation, and the David and Lucile Packard Foundation.

tail,[2-5] the only detailed X-ray crystallographic study of a compound with a terminal methylidyne ligand was unsuccessful due to disorder in the crystal.[6] As part of our studies of the electronic structures of alkylidyne complexes,[7] we have prepared and structurally characterized the methylidyne compound **1**. In addition to providing the first precise

$[W(CH)(dmpe)_2(n\text{Bu})]$ **1**

dmpe = $Me_2PCH_2CH_2PMe_2$

data for a methylidyne complex, compound **1** is significant in that it clearly illustrates that the molecular and electronic structure of the M≡C–H moiety can be strongly perturbed by the *trans* ancillary ligand, and because of the surprising observation that its methylidyne ligand is bent by nearly 20°.

Addition of *n*-butyllithium (1 equiv) to a pentane/toluene (4:1) solution of $[W(CH)(dmpe)_2(OTf)]$ (1 equiv; OTf = O_3SCF_3),[8] followed by workup and recrystallization from toluene at −40 °C, provides yellow **1** in 45% yield. Compound **1** was characterized by elemental analyses,[9] ^1H, ^{13}C, and ^{31}P NMR spectroscopy,[9] and X-ray crystallography.[10] The ^1H and ^{13}C NMR spectroscopic data for **1** are uniquely consistent with its formulation as an η^1-methylidyne complex. The ^1H and ^{13}C NMR signals of the methylidyne ligand are observed at $\delta = 6.01$ and $\delta = 244.9$, respectively, nearly identical to the positions of the corresponding signals in $[W(CH)(dmpe)_2Cl]$ (^1H, $\delta = 5.98$; ^{13}C, $\delta = 246$),[2b] and the splittings of the signals show that these nuclei are coupled to each other ($^1J_{C,H} = 121$ Hz), to tungsten ($^1J_{C,W} = 173$, $^2J_{H,W} = 67$ Hz), and to phosphorus. It is noteworthy, however, that the magnitudes of the couplings within the WCH unit are smaller than those of simple methylidyne compounds ($^1J_{C,H} = 130-150$, $^1J_{C,W} = 192-289$, $^2J_{H,W} = 79.6-90$ Hz),[2-4] as well as those of the Lewis acid adducts $[W(CH \cdot AlMe_3)(PMe_3)_3Cl]$ and $[W(CH \cdot AlMe_2Cl)(PMe_3)_3Cl]$ ($^1J_{C,H} = 129.4$ and 144.0, respectively, and $^2J_{H,W} = 83.5$ and 81.6 Hz, respectively).[2c] In fact, the value of $^1J_{C,H}$ for **1** is equal to that for the distorted methylidene complex $[W(CH_2)(PMe_3)_4I](OTf)$.[2c] These data suggest that the electronic structure of the W≡C–H core of **1** differs from those of previously reported methylidyne compounds; the differences between **1** and other compounds of the $[W(CH)L_4X]$ type can be traced directly to the presence of the strongly σ-donating *n*-butyl ligand in **1**.

The molecular structure of **1** was established by a single-crystal X-ray diffraction study (Fig. 1).[10] Although it is otherwise qualitatively similar to those of other *trans*-$[M(CR)L_4X]$ complexes,[1a,c,d] the structure of **1** is distinctive in two respects. First, the lengths of the W≡C (1.827(5) Å) and W–C (2.405(6) Å) bonds are longer than expected (cf. $d(W{\equiv}C) = 1.796(11)$ Å for $[W(CPh)(dmpe)_2Br]$ and $d(W{-}C) = 2.258(8)$ Å for $[W(CC\textit{t}Bu)(CH\textit{t}Bu)(CH_2\textit{t}Bu)(dmpe)]$),[7,11] since the *trans* influences of the methylidyne and *n*-butyl ligands are very strong. Although the above-mentioned W≡C distance does not lie outside of the range of known W≡C distances,[1a,c,d] it does, surprisingly, appear to be longer than that observed for the compositionally disordered Lewis acid adduct **2** ($x \approx 0.18$,

$[W(CH \cdot AlMe_{2-x}Cl_{1+x})(PMe_3)_3Cl]$ **2**

$d(W{\equiv}C) = 1.807(6)$ Å),[6] and is roughly equal to that found for the methylidene complex $[W(CH_2)(PMe_3)_4I](OTf)$

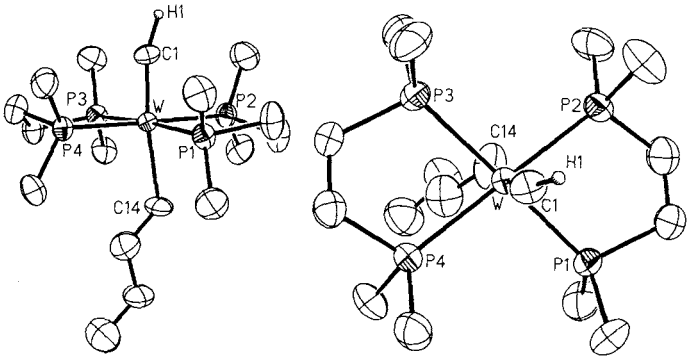

Fig. 1. Two views of the molecular structure of **1**. All hydrogen atoms except H1 have been omitted for clarity. Non-hydrogen atoms are represented by their thermal ellipsoids, which are drawn at the 50% probability level; the sphere for hydrogen is of arbitrary size. Selected bond lengths [Å] and bond angles [°]: W-C1 1.827(5), C1-H1 1.137(73), W-P1 2.436(2), W-P2 2.448(1), W-P3 2.452(2), W-P4 2.452(1), W-C14 2.405(6); W-C1-H1 162.3 (39), C1-W-C14 172.6(2), C1-W-P1 90.5(2), C1-W-P2 90.9(2), C1-W-P3 94.2(2), C1-W-P4 89.0(2), C14-W-P1 87.5(2), C14-W-P2 81.8(2), C14-W-P3 87.9(2), C14-W-P4 98.3(2), P1-W-P2 80.9(1), P2-W-P3 99.3(1), P3-W-P4 80.9(1), P4-W-P1 98.9(1).

(1.83(2) Å).[5c] Second, and more striking, is that the methylidyne ligand of **1** is decidedly bent (∢ W≡C–H = 162.3(39)°).[12] This result is unexpected in view of the fact that 70 of the 75 structurally characterized alkylidyne complexes possess M≡C–R bond angles greater than 170°; the bending for **1** is the largest yet observed.[1a,c,d] Remarkably, the methylidyne bond angle in **1** is comparable to that of **2** (163.8(44)°) (Scheme 1),[6] for which the bending of the W≡C–H linkage has been interpreted as being the result of the interaction between the methylidyne ligand and the aluminum center.

Scheme 1. Comparison of the important structural data of **1** and **2**.

There are several possible explanations for the bending of the methylidyne ligand of **1**. The first stems from the observation that molecules of **1** are arranged in the crystal in a head-to-head fashion (Fig. 2). In this dimer, which is formed about a crystallographic center of inversion, there is significant interdigitation among the methylidyne ligands and dmpe methyl groups; the intermolecular distances between the methylidyne ligands ($d(W{\equiv}C\cdots C{\equiv}W) = 3.58$, $d(W{\equiv}C{-}H\cdots C{\equiv}W) = 3.02$, $d(W{\equiv}C{-}H\cdots H{-}C{\equiv}W) = 2.84$ Å) are 0.2–0.4 Å larger than the sums of the corresponding van der Waals radii ($2r_C = 3.4$, $r_C + r_H = 2.9$, $2r_H = 2.4$ Å). It is well known that C≡C–H bending force constants are small by comparison to those of C=C–H and C–C–H groups;[13] if W≡C–H bending force constants are also small, the bending of the methylidyne ligand may simply be a response to the forces of crystal packing, and specifically to the methylidyne ligand of the adjacent molecule. Arguing against this possibility, however, is the fact that the bending

of the methylidyne ligand results in even closer van der Waals contacts for H1 elsewhere in the dimer (d(H1 ··· H(dmpe)) = 2.41, 2.42, 2.68 Å); a smaller bend would seem to be required if avoidance of such contacts is the only important factor.

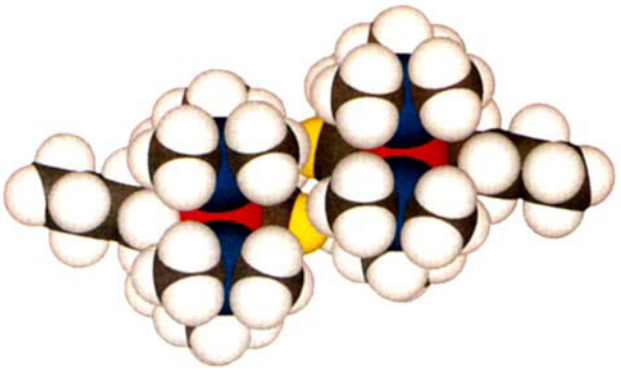

Fig. 2. Space-filling representation of the head-to-head docking of two molecules of **1** in the crystal. The hydrogen atoms of the methylidyne ligand are highlighted in yellow. Selected intermolecular distances [Å] and angles [°] between the methylidyne ligands: d(WC ··· CW) = 3.577, d(WCH ··· CW) = 3.023, d(WCH ··· HCW) = 2.842, ∢(W≡C ··· C) = 139.0.

A second possibility is that the methylidyne ligand of **1** is intrinsically bent. An ab initio theoretical study of the hypothetical ion $[Cr(CH)(CO)_5]^+$ specifically addressed the question of methylidyne bending, and found the linear geometry to be the most stable.[14] One difference, though, between the M≡C π orbitals of **1** and those of $[Cr(CH)(CO)_5{}^+]$ is that those of **1** are nondegenerate in the limiting C_{2v} symmetry imposed by the dmpe ligands (∢ PWP ≈ 81° and 99° within and between the dmpe ligands, respectively). Calculations by Hall et al. indicate that the slight (3°) tilting of the ethylidyne methyl group of $[Cr(CMe)(CO)_4Cl]$ induced by crystal-packing is responsible for the widely differing Cr–CO bond lengths found for this molecule (Δd(Cr–C) = 0.056 Å);[15] it is possible, in a reverse fashion, that the inequivalency of the W≡C π orbitals that arises from the asymmetry of the dmpe ligands results in the bending of the C–H bond. Alternatively, the W≡C–H linkage could be bent for electronic reasons related to the *trans n*-butyl ligand. It has been noted that the C–H coupling constants for methylidyne ligands are about 100 Hz smaller than those for alkynes, indicating that the methylidyne C–H bonds are derived from a hybrid orbital at the triply bonded carbon that has greater p-orbital character than a first-order sp hybrid orbital.[4] The methylidyne C–H coupling constant for **1** is smaller still, suggesting an even higher degree of p-orbital character in its C–H bond relative to those of other methylidyne complexes. While a bonding description for **1** based upon formal sp^2 hybridization at the multiply bonded carbon atom is clearly inappropriate, the bending of the methylidyne ligand may reflect partial double-bond character of the W≡C bond resulting from rehybridization to accommodate the strongly σ-donating *n*-butyl ligand *trans* to it; this would be consistent with the elongated W≡C bond.

Finally, it is interesting to consider the crystal structure of **1** in the context of the rich C–C bond-forming chemistry of alkylidyne complexes. These species react with alkynes to give metallacyclobutadienes, metallatetrahedranes, and cyclopentadienyl metal compounds, as well as alkyne polymerization and metathesis products.[1a–c] In addition, intramolecular alkylidyne–alkylidyne coupling reactions are observed for bis(alkylidyne) compounds,[16, 17] and are a key step in the reductive coupling of carbon monoxide.[16, 18] Electronic factors aside, it is reasonable to expect that these reactions should be more facile for methylidyne complexes than for other alkylidyne complexes, because of the minimal steric demands of the methylidyne ligand. Consistent with this hypothesis is the recent observation by Templeton et al. that $[Tp'M(CH)(CO)_2]$ (M = Mo, W; Tp' = $HB(3,4\text{-}Me_2C_3HN_2)_3$) spontaneously dimerizes to give the unique vinylidene-bridged species $[\{Tp'M(CO)_2\}_2(\mu\text{-}CCH_2)]$.[4] In light of this, a particularly intriguing possibility is that the head-to-head docking and the bent C–H bond of **1** in the solid state represent an early intermediate along the reaction coordinate for the intermolecular methylidyne–methylidyne coupling of **1**, this coupling being sterically arrested by interferences among the dmpe methyl groups.

Correct C,H analyses.

[10] Crystal data for $C_{17}H_{42}P_4W$: Triclinic, $P\bar{1}$, a = 9.198(2), b = 9.337(2), c = 15.084(2) Å, α = 82.55(2), β = 82.35(2), γ = 72.75(2)°, V = 1220.6(4) Å^3, Z = 2, ϱ_{calcd} = 1.508 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 49.91 cm^{-1}, T = 224 K. The structure was solved by direct methods. All 3421 reflections measured ($4° < 2\theta < 46°$) were used in the refinement of the structure. A semiempirical absorption correction (XABS) and an extinction correction were applied to the data. All non-hydrogen atoms were located and refined anisotropically. The methylidyne hydrogen atom H1 appeared as a distinct feature in a Fourier difference map ($\Delta\rho$(H(1)) = 0.58 e Å^{-3}; $\sigma(\rho)$(average) = 0.20 e Å^{-3}) and was refined isotropically (U = 0.110(27) Å^2). Although there are larger difference peaks in the map than that for H1, these either lie near the tungsten center (d < 1.14 Å), and hence are attributable to noise associated with that atom, or, in one case, is the result of slight disorder within the *n*-butyl ligand (near C15). For this reason, and because of the well-behaved refinement of this atom, we believe the H1 peak to be genuine. All other hydrogen-atom positions were calculated (d(C–H) = 0.96 Å); R_F = 0.0298, R_{wF} = 0.0341, GOF = 0.94, δ/ρ = 1.08 e Å^{-3} (near W), data:parameter ratio = 16.8:1. Further details of the crystal structure investigation are available on request from the

Gaseous Mercury(IV) Fluoride, HgF_4: An Ab Initio Study**

By *Martin Kaupp** and *Hans Georg von Schnering*

The group 12 elements are usually considered to be main group rather than transition elements, since the completely filled $(n-1)$d shell does not participate in chemical bonding.[1, 2] Hence, the known chemistry of these elements is restricted to the M^{II} or lower oxidation states.[2] In general, the maximum achievable oxidation numbers increase from left to right within the first half of a given transition metal row (up to Mn^{VII}, Ru^{VIII}, and Os^{VIII}, respectively) but drop back in the second half. While the discovery of Cu^{IV} in Cs_2CuF_6[3a] and of Au^{V} in $CsAuF_6$[3b] have stimulated interest in group 12 elements exhibiting oxidation states beyond II, there is only one report of a short-lived, electrochemically generated Hg^{III} species in solution.[4]

The first four ionization potentials of Zn, Cd, and Hg (cf. Table 1) clearly show that mercury is the most likely candidate for the occurrence of oxidation states higher than II (which invariably involve d orbitals in bonding) within this group. At least in part this is due to relativistic effects which stabilize and contract the 6s orbital but destabilize and expand the 5d orbitals (spin-orbit coupling also splits the d levels).[5] Thus, ionization from d levels becomes easier and simultaneously sd hybridization is energetically more favorable with Hg than with Zn or Cd. The same effects are responsible for the great importance of the III or V oxidation states in gold chemistry compared to copper or silver[6].

Table 1. Ionization energies [eV] of the group 12 elements.

	I	II	III	IV

[**] We thank Prof. Dr. H. Stoll and Dr. H. Borrmann for valuable discussions.

We have carried out high-level ab initio calculations, by using relativistic pseudopotentials, on the structure, stability, and vibrational frequencies of gaseous HgF_4. Our results strongly suggest it to be a viable molecular species. For comparison we have also studied KrF_2, one of the few known and well-characterized[7] endothermic fluorine compounds.

The structure of HgF_4 (in D_{4h} symmetry), optimized at the Hartree–Fock (HF),[8a] MP2,[8a, b] and QCISD levels[9, 10] of theory is shown in Figure 1. Harmonic vibrational frequency analysis at the HF level[8a] (see below) confirms the square-planar structure to be a minimum on the potential energy surface, in agreement with the expectations for a tetracoordinate low-spin $5d^8$ species,[1] and with previous results for the isoelectronic AuF_4^-.[6c]

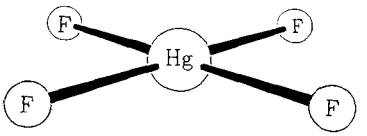

Fig. 1. Structure of HgF_4. Calculated Hg–F distances [Å] (D_{4h} symmetry): 1.886 (HF, cf. refs. [8a,b]); 1.962 (MP2, cf. refs. [8a,b]); 1.923 (MP2, with one additional f function at the metal); 1.904 (ANO–MP2, cf. refs. [8a,b, 9, 10]); 1.884 (ANO–QCISD, cf. refs. [9, 10]).

The results of large-scale ANO-QCISD and ANO-QCISD(T) calculations[9, 10] of the energies of several important reactions involving HgF_4 or KrF_2[11] are shown in Table 2. Experimental data for KrF_2 are also included. The most probable decomposition pathway for HgF_4 in the gas phase (at least at low concentrations) is the reductive elimination of F_2 [Table 2, Eq. (a)]. This reaction is slightly exothermic at the QCISD level ($\Delta E = -12.5\ kJ\,mol^{-1}$) but slightly endothermic ($\Delta H_0 = +11.6\ kJ\,mol^{-1}$) when contributions from connected triple excitations to the wavefunction (QCISD(T)) and zero point vibrational energy corrections (ZPE) are included. In contrast, loss of F_2 from KrF_2 [Table 2, Eq. (b)] is considerably exothermic ($\Delta H = -75.5\ kJ\,mol^{-1}$). Hence, the oxidation of (gaseous monomeric) HgF_2 by KrF_2 [Eq. (c)] also is remarkably exothermic ($\Delta H_0 = -94.2\ kJ\,mol^{-1}$).

Table 2. Reaction energies [kJ mol^{-1}] involving HgF_4 or KrF_2 [a].

Reaction	ZPE [b]	QCISD [c]	QCISD(T) [c]	exp.
(a) $HgF_4 \rightarrow HgF_2 + F_2$	−7.1	−12.5	+18.7	
(b) $KrF_2 \rightarrow Kr + F_2$	−3.8	−93.3	−75.5	−60.2 [d]
(c) $HgF_2 + KrF_2 \rightarrow HgF_4 + Kr$	+3.3	−80.8	−94.2	
(d) $F_2 \rightarrow 2\,F$	−7.1	+114.5	+142.9	+159.7
				(+154.2) [e,f]
(e) $KrF_2 \rightarrow Kr + 2\,F$	−10.9	+21.3	+67.4	+99.5 [d]
(f) $HgF_4 \rightarrow Hg + 4\,F$	−23.4	+562.2	+642.7	
(g) $HgF_2 \rightarrow Hg + 2\,F$	−9.2	+460.2	+481.2	
(h) $HgF_4 \rightarrow HgF_2 + 2\,F$	−14.2	+102.9	+161.6	

[a] Calculations at the QCISD-optimized structures. [b] Unscaled HF zero-point vibrational energy contributions. [c] Quadratic CI results [9, 10] without vibrational energy corrections. [d] Cf. ref. [7c]. [e] Cf. ref. [17]. [f] $D_e(D_0)$ values given.

At the ANO-QCISD(T) level of theory, the F_2 and KrF_2 atomization energies [Table 2, Eqs. (d) and (e)], which are quite demanding to calculate,[7d, 12] agree within about 17 and 40 kJ mol^{-1} to those values obtained from experiment (i.e. the average binding energies are underestimated by ca. 17 and 20 kJ mol^{-1}, respectively). The accuracy for the at-

omization energies of HgF_4 and HgF_2 [Eqs. (f) and (g)] is somewhat less certain as, for example, spin-orbit coupling was not included in the QCI calculations. Unfortunately no accurate experimental value for gaseous HgF_2 is available. However, the remaining correlation energy errors in HgF_4 will be larger than those in HgF_2 (as seen by the larger contribution of triple excitations to the average binding energy, cf. Table 2). Thus we probably *underestimate* rather than overestimate the stability of HgF_4 relative to HgF_2! Due to error compensation the F_2 elimination reactions will exhibit smaller errors than the atomization energies (in these reactions the number of electron pairs is kept constant). Indeed, the error in the QCISD(T) reaction energy for F_2 elimination from KrF_2 [Eq. (b)] is only about 19 kJ mol^{-1}. We estimate the error in the energy for oxidation of HgF_2 by KrF_2 [Eq. (c)] also to be below about 20–30 kJ mol^{-1}. A detailed account of the performance of various theoretical approaches, and of the influence of relativistic effects on the reaction energies, will be published elsewhere.[13]

The atomization energies given in Table 2 [Eqs. (e)–(g)] show that, while the average Hg–F binding energy in HgF_4 (ca. 160 kJ mol^{-1}) is considerably smaller than that in HgF_2 (ca. 240 kJ mol^{-1}), it is still significant and much larger than the average Kr–F binding energy in KrF_2 (50 kJ mol^{-1} [7c]). The two additional Hg–F bonds in HgF_4 together account for a gain of about 160 kJ mol^{-1} compared to $HgF_2 + 2$ F [Eq. (h)]. Thus, in the gas phase the formation of HgF_4 from HgF_2 and atomic fluorine also would be significantly exothermic. In the solid state HgF_2 will be favored by its lattice energy: Preliminary calculations indicate that there is no significant stabilization of HgF_4 by aggregation or anionic complexation.[13] We expect HgF_4 to be a rather volatile substance.

The results of the harmonic vibrational frequency analysis (at the HF level[8a]) for HgF_4 are listed in Table 3. Due to the high symmetry present, the IR and Raman spectra are expected to contain only four and three bands, respectively. Thus, it should be possible to identify HgF_4, if obtained, by means of vibrational spectroscopy (the wavenumbers calculated for HgF_2[14] are significantly different). In view of the good agreement between Hartree–Fock and experimental frequencies of HgF_2[14] and AuF_4^-,[6c] we expect a similar accuracy (ca. 10–20 cm^{-1}) in the calculated wavenumbers for HgF_4.

Table 3. Calculated harmonic vibrational wavenumbers for HgF_4 [a].

Symmetry	ω [cm^{-1}]	Character	IR [b]	Raman [b]
b_{2u}	179	out of plane	yes	no
A_{2u}	233	out of plane	yes	no
b_{2g}	252	in plane	no	yes
E_u	261	in plane	yes	no
b_{1g}	650	stretch	no	yes
A_{1g}	652	stretch	no	yes
E_u	721	stretch	yes	no

[a] Cf. ref. [8a]. [b] Infrared or Raman activity.

In conclusion, our calculations indicate that it should be possible to prepare and characterize (e.g. by matrix isolation spectroscopy) mercury(IV) fluoride. Even if decomposition into $HgF_2 + F_2$ [Eq. (a)] were slightly exothermic, the significant nuclear reorganization involved (two Hg–F bonds are broken and one F–F bond is formed), and the small reaction energy suggest a significant activation barrier for this reaction. Unfortunately, our attempts to obtain an accurate estimate for the barrier height have failed up to now. The wavefunction near the transition state has strong multireference character (i.e. large nondynamical electron correlation effects have to be considered), and the internal nuclear coordinates are strongly coupled (spin–orbit coupling may also complicate the situation).

The gas-phase reaction $HgF_2 + KrF_2 \rightarrow HgF_4 + Kr$ [Eq. (c)] is considerably exothermic. Perhaps, a solvent-based low-temperature variant of this reaction is a route into Hg^{IV} chemistry. The calculated vibrational frequencies should aid in the experimental characterization of HgF_4.

Reduced $[Fe_8S_6]$ Clusters: Binding Links between FeS and Active Centers of Iron-Sulfur Proteins**

By *Siegfried Pohl** and *Ulrich Opitz*

Iron–sulfur clusters form the active centers of a series of proteins. Their function is not only limited to the transfer of electrons, but they are also able to bind different substrates.[1, 2] The structural diversity of these Fe–S clusters, in particular, in the various nitrogenases and hydrogenases, is probably greater than that of the compounds known to date. This is also indicated by the first model of the FeMo cofactor of the nitrogenase of *Azotobacter vinelandii* based on an X-ray structure analysis by Kim and Rees.[3]

The wide spread of iron–sulfur clusters, their formation, probably at a very early stage of evolution, as well as their different ways of functioning gain additional significance in the light of a new theory from Wächtershäuser about the origin of life.[4, 5] Thus, a central role is played by the reaction of FeS with H_2S to give FeS_2 and H_2, which was recently reproduced under "geochemical" conditions in the laboratory.[6]

With $[Fe_8S_6I_8]^{4-}$ we have isolated the first Fe–S cluster, containing exclusively iron(II) centers (see Fig. 1). The $[Fe_8S_6]^{4+}$ cores of such clusters may not only serve as molecular models for the mentioned reduction of H^+ to H_2, but may also be suitable precursors for the modeling of active centers.

The iodo ligands, which cannot be described as biomimetic, seem to preclude the use of $[Fe_8S_6I_8]^{4-}$ as precursor for models of active centers of Fe–S proteins. However, under certain conditions the frequently used thiolato ligands are unsuitable for redox reactions, and this is probably not only valid in synthetic models. Thus, the distinct lack of cysteinyl ligands in the FeMo cofactor of *Azotobacter vinelandii* is striking.[3] Possibly also in Nature one reason for this lack of cysteinyl ligands is the avoidance of the formation of disulfide in multielectron processes such as N_2 reduction. Against this background, in synthetic model compounds iodide can in some cases be even more suitable than thiolate as a—for the occurring potentials—non-redox active ligand.

Furthermore, the existence of Fe–S clusters raises the question of whether similar cluster fragments could not be (have been) present on FeS surfaces (e.g. mackinawite). Thus, in addition to the assumptions of Wächtershäuser,[5] electron transfer *and* substrate binding would be possible at such "active centers". The relatively simple reaction summarized in Equation (a) (non-stoichiometric) yields the octanu-

$$[Fe_4S_4I_4]^{2-} \xrightarrow[THF/CH_3CN]{[FeI_2(PR_3)_2]} [Fe_8S_6I_8]^{4-} \quad (a)$$

$PR_3 = PMePh_2$

clear Fe–S cluster as ammonium salt **1**, in the form of black prismatic crystals, which are stable in air for a short period.

$(PhCH_2NEt_3)_4\,[Fe_8S_6I_8]$ **1**

Formally, reaction (a) can be reduced to reaction (b). However, we have only obtained amorphous iron sulfide from reaction (b). Thus, an Fe^{II} excess seems favorable or even

$$2[Fe_4S_4I_4]^{2-} + 2PR_3 \longrightarrow [Fe_8S_6I_8]^{4-} + 2SPR_3 \quad (b)$$

necessary for the formation of the $[Fe_8S_6]$ cluster. Thus, for the optimized synthesis [Eq. (c)] (see also Experimental Procedure), an even greater Fe^{II} share is used. It is noteworthy

$$[Fe_4S_4I_4]^{2-} + 3FeI_2 + 3I^- + 4PMePh_2 \xrightarrow[THF/CH_3CN]{} 1/2[Fe_8S_6I_8]^{4-} + SPMePh_2 + 3[FeI_3PMePh_2]^- \quad (c)$$

that with only a slight variation of the reaction conditions and with identical stoichiometric ratios as for the preparation of **1** according to Equation (a) exclusively the hexanuclear cluster **2** is isolated.[7] Such a cluster with a slightly

$[Fe_6S_6I_2(PR_3)_4]$ **2**

different phosphane was previously characterized by Holm et al. a few years ago and was described as a "basket cluster".[8, 9] An X-ray structure analysis of **2** confirmed the identical construction.[10] Evidently, the formation of the $[Fe_8S_6]$ cluster occurs via the intermediate **2**. This hypothesis is supported by the reaction of **2** with $[FeI_3PR_3]^-$ in CH_2Cl_2, which also yields the octanuclear Fe–S cluster.[10] Reaction (d) shows, however, that **2** does not necessarily occur as intermediate.

$$[Fe_4S_4I_4]^{2-} \xrightarrow[THF/CH_3CN]{[Fe_2I_4(dppe)_2]} [Fe_8S_6I_8]^{4-} \quad (d)$$

$dppe = Ph_2PCH_2CH_2PPh_2$

The use of a bidentate phosphane ligand, which as a result of the distance of its coordinating centers should not be in the position to stabilize a compound analogous to **2**, nevertheless leads to the octanuclear Fe–S cluster according to (d), which can be isolated in the form of the salt **3** (see also Fig. 2), even if in significantly lower yield. Apparently, PR_3

$[Fe(dppe)(CH_3CN)_4]_2\,[Fe_8S_6I_8]$ **3**

is essential for the given reactions as a sulfur acceptor.[11] The formed phosphane sulfide can be easily separated. Thus, this route to $[Fe_8S_6]$ clusters is much more favorable and more unambiguous than the one described several years ago, which by using elemental iron led to the $[Fe_8S_6I_8]^{3-}$ anion.[12, 13]

Compounds **1** and **3** were characterized by X-ray structure analyses.[14] Both compounds contain $[Fe_8S_6I_8]^{4-}$ anions,

but with different cations. The cluster anion in **1** has crystallographic C_{4h} symmetry, whereas the anion of **3** lies on an inversion center. Possibly, the occupation of different crystallographic point groups is the reason why the extent of the observed tetragonal distortion of the Fe_8 cube in **1** and **3** is very different (Figs. 1 and 2). In **3** this distortion leads to differences in the Fe–Fe distances of on average almost 11 pm.

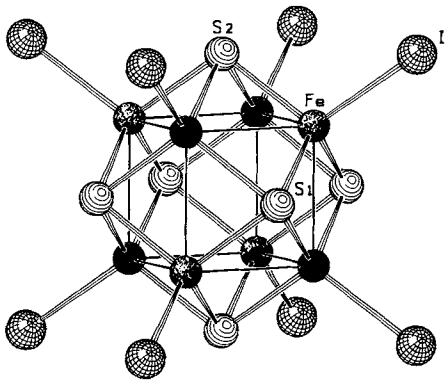

Fig. 1. Crystal structure of the anion of **1** (C_{4h} symmetry). Important distances [pm] and angles [°]: Fe-I 259.1(2), Fe-Fe 269.2(2) (eight distances) and 272.5(3) (four distances), Fe-S 231.3(3) and 232.6(3); Fe-S-Fe 107.8(1)–111.8(1) and 70.7(1)–72.2(1).

Rhombic dodecahedral $[M_8S_6]$ clusters such as in **1** and **3** were not only confirmed in other synthetic compounds such as $[Fe_8S_6I_8]^{3-}$,[12] $[Co_8S_6(SR)_8]^{4-}$,[15] $[Fe_3Ni_5S_6I_8]^{4-}$,[16] or $[Ni_8S_6Cl_2(PR_3)_6]$[17] (an inverse variant is $[Fe_6S_8(PR_3)_6]^{2+}$ [18]), but also observed in minerals such as the pentlandites,[19] bartonite,[20] or djerfisherite[21] (for the calculation of the electronic structure of $[M_8S_6]$ clusters see refs.[22, 23]).

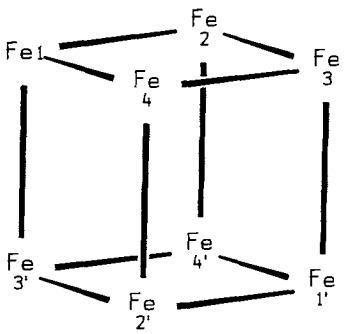

Fig. 2. Schematic representation of the Fe_8 cube in **3**. The cluster anion $[Fe_8S_6I_8]^{4-}$ is constructed as in **1**, and in **3** has C_i symmetry. Important distances [pm] and angles [°]: Fe1-Fe2 266.1(2), Fe2-Fe3 269.5, Fe3-Fe4 264.0, Fe4-Fe1 265.5, Fe1-Fe3' 276.1, Fe2-Fe4' 277.8.

According to preliminary investigations compound **1** reacts with elemental sulfur again to give the $[Fe_4S_4]$ cluster used as the starting material. In view of the reaction of FeS with H_2S, an almost analogous reaction seems to be of particular interest, that is the question of whether the cluster reacts according to Equation (e) with the formation of hydrogen. Similar is true for the reactions with thiols RSH. Such reactions are being carried out at present.

$$[Fe_8S_6I_8]^{4-} + 2H_2S \xrightarrow{?} 2[Fe_4S_4I_4]^{2-} + 2H_2 \qquad (e)$$

Experimental Procedure

All operations were carried out under a nitrogen atmosphere in dry, N_2 saturated solvents.

1: FeI_2 (0.928 g, 3 mmol), $(PhCH_2NEt_3)I$ (0.957 g, 3 mmol), $PMePh_2$ (0.801 g, 4 mmol), and $(PhCH_2NEt_3)_2[Fe_4S_4I_4]$ (1.234 g, 1 mmol) were dissolved in a mixture of THF and CH_3CN (1:1) (40 mL). The solution was kept at room temperature for six days. Then the solvent was removed and the residue was taken up in CH_3CN (40 mL). Insoluble material was separated by filtration and the solution was concentrated stepwise. After every step a fraction of **1** crystallized within two days. The solution was decanted each time, and the crystals were washed with CH_2Cl_2. After five steps a total of about 0.5 g (ca. 40%) **1** was obtained. Correct elemental analysis.

3: $[Fe_2I_4(dppe)_2]$ (1.416 g, 1 mmol) and $(PhCH_2NEt_3)_2[Fe_4S_4I_4]$ (1.234 g) were heated under reflux for a short time in a mixture of THF (40 mL) and CH_3CN (20 mL). After the mixture had cooled it was filtered and the precipitate formed was discarded. The solution was concentrated to 20 mL. After six days black, rod-like crystals of **3** were formed, which crystallized as $3 \cdot 2THF \cdot 2CH_3CN$. Yield: 0.1 g (ca. 6%). The high solvent content prevented exact quantitative analyses; however, we have always obtained a correct ratio of Fe:S:I.

Contrasting Structures of Pyramidal Carbocations and Their Silicon Analogues**

By *Eluvathingal D. Jemmis,* Govindan Subramanian, Bharatam V. Prasad, Seiji Tsuzuki,* and *Kazutoshi Tanabe*

Extension of the structure of *nido*-B_5H_9 (**1**) to the isoelectronic pyramidal carbocation $C_5H_5^+$ (**2**)[1] was "obvious".[1a,b] At the time the bridging hydrogen atoms of the basal B_4H_8 unit were eliminated to give the C_4H_4 unit in $C_5H_5^+$.[1a] In the meantime, derivatives of **2** have been synthesized.[2] Herein we present theoretical calculations on the homologous $Si_5H_5^+$ compound and on related compounds. These calculations suggest that the structures with bridging H atoms and not those isostructural to $C_5H_5^+$ (**2**) with terminal H atoms correspond to minima on each of the potential energy surfaces. If, however, for the structures with terminal H atoms the calculated negative vibrational frequencies are followed, more stable structures of lower symmetry are obtained.

The structures considered in this study are shown in Figure 1. In the classical isoelectronic analogues of **1**, namely **2**–**5**, the base of the pyramid is formed from a carbon square. The replacement of four BH_2 groups in **1** for SiH groups results in the structures **6**–**8**, when the terminal H atoms are retained, and the structures **9**–**11**, when the bridging H atoms are retained.[3]

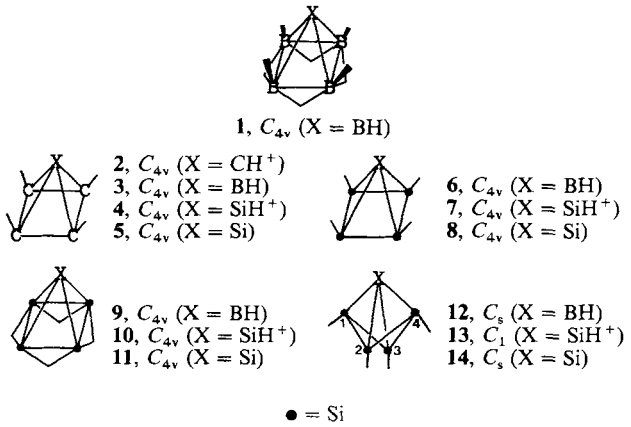

Fig. 1. Structures of B_5H_9 **1**, C_4H_4X (X = CH^+, BH, SiH^+, Si; **2**–**5**), and Si_4H_4X (X = BH, SiH^+, Si; **6**–**14**).

Geometries of **1**–**11** were initially optimized with imposed C_{4v} symmetry at the HF/6-31G* level[4a,b] by using the Gaussian 82[4c] and Gaussian 90[4d] series of programs. Frequency analysis at the same level showed that structures **1**–**3**, **5**, and **9**–**11** represent true minima (Table 1). The significance of electron correlation was examined by optimizing structures **6**–**14** further at the MP2/6-31G* level.[4e,f] Finally single-point calculations at the MP4SDTQ(fc)/6-31G* level[4g] were carried out on the HF/6-31G* optimized geometries of **6**–**14**. The total and relative energies obtained from these calculations are given in Table 1, and Tables 2 and 3 list the important structural parameters used in the discussion.[5]

The bonding in half-sandwich compounds has been well documented.[1b,6,7] The compatibility of the overlapping orbitals has been used to explain the distortion of the ring

Table 1. Absolute energies E [Hartree], relative energies E_{rel} [kcal mol^{-1}] [a], and unscaled zero-point energies ZPE [kcal mol^{-1}] of **1**–**14**.

substituents from the carbocyclic pyramid base.[7a] Similar parallels are expected when the carbocyclic ring is replaced by the homologous silacyclic ring (Si_4H_4 as base). The Si–Si distances in the base in **6**–**8** (Table 2, second column) lie between the values for standard single (2.353 Å as calculated for disilane[8]) and double (2.129 Å as calculated for planar disilene[9]) bonds, which reflects the delocalization of the bonding electrons in the basal four-membered Si ring. A similar trend was observed in **2**.[7]

The silicon compounds **6**–**8**, however, were found to correspond to higher order stationary points (imaginary frequencies, see Table 1). This is because the Si_4 ring is larger than the C_4 ring (Table 2), which forces large Si–H out-of-plane bending to obtain optimum ring-cap overlap.[7] Hence caps with more diffuse orbitals[10] are required in order to reduce the out-of-plane bending of the ring substituents and increase the binding with the cap.

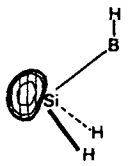
While the BH cap has the optimum interaction with a carbocycle, it is least favored for a silacycle (**6**). This is evident from the larger out-of-plane bending of the ring substituents (cf. **3** and **6**, Table 2, far right) and the exothermicities of the reactions (a) and (b) calculated at the HF/6-31G* level.

4 + **6** ⟶ **3** + **7** $-47.3\ \mathrm{kcal\,mol^{-1}}$ (a)

5 + **6** ⟶ **3** + **8** $-13.1\ \mathrm{kcal\,mol^{-1}}$ (b)

Even the orbitals of SiH^+ and Si are not sufficiently diffuse to allow optimum overlap with the four-membered Si ring (Table 1). Hence, these prefer puckered structures **12**–**14** with puckering angles of 29.5 (**12**), 0.9 (**13**), and 36.2° (**14**) (values calculated at the HF/6-31G* level) between Si1Si2Si3-Si2Si3Si4 planes. The Si–Si distances in the puckered structures **12**–**14** are not very different from those in structures **6**–**8** with C_{4v} symmetry (cf. entries in columns 2 and 3 of Table 2 with those in Table 3). The distortion from C_{4v} to C_s or C_1 symmetry (**6** → **12**, **7** → **13** and **8** → **14**) led to only marginal net gains in stabilization. Correlation diagrams show that the destabilization of σ-type orbitals is nearly equal to the stabilization gained by π-type orbitals. This is reflected in the relative stabilities of these isomers (Table 1). It is interesting to note, however, that these puckered structures of lower symmetry are not minima for pyramidal carbocations.[1b, 11]

In contrast, structures **9**–**11** obtained from **1** by retaining the bridging hydrogen atoms in the basal ring were found to be minima, though higher in energy than the structures **6**–**8** and **12**–**14** (Table 1). In these structures, the silicon atoms of the four-membered ring are divalent and participate in three-center two-electron bonding. Such structures with low valent silicon and bridging hydrogen atoms have been well documented.[3, 12] The Si–Si distances are appreciably longer than expected in hydrogen-bridged structures (2.585 Å in HSi-(μ-$H)_2$-SiH)[13]). Interestingly, the corresponding carbon compounds are not known. Although the Si_4 basal ring with the bridging hydrogen atoms in **9**–**11** is larger than that in **6**–**8** (Table 2), a cap with a less diffuse p-orbital (BH) is also a minimum (**9**). The stability of the structures **9**–**11** can be best explained by considering a tetrahedral environment around silicon with two hydrogen atoms in one plane and a lone pair orbital and the rehybridized p_π orbital in the other plane (Scheme 1). The lone pair orbitals, which lie in the plane of the Si_4 ring, orientate the π orbitals towards the cap. This enhances the overlap between the cap and the ring orbitals,[7] which is confirmed by the MO coefficients.



Scheme 1. Section of **9** showing the orbital of the lone pair.

In summary, the puckering in **12**–**14**, and the orientation of the rehybridized π orbitals in the bridged isomers **9**–**11** are the key factors responsible for the stability of the silicon analogues of **1**. Their structures are contrary to those expected and observed in **2** and its isostructural analogues **3**–**5**. Similar results have also been observed in silicon clusters.[14] A square pyramidal Si_5 cluster is calculated to be higher in energy than a trigonal bipyramidal structure, which is similar to the distorted structures discussed here. Furthermore, our results suggest that $Si_6H_6^{2+}$ may prefer geometries other than the pentagonal pyramidal structure, as observed for $C_6H_6^{2+}$.[15]

The Use of Radical Cyclization in the Preparation of Substituted Methyl Carbapenem Antibiotic Precursors**

By *Josefa Anaya,* Derek H. R. Barton, Stephan D. Gero, Manuel Grande, Nieves Martin*, and *Catherine Tachdjian*

The pharmaceutical importance of β-lactam antibiotics with resistance to β-lactamase, such as theinamycin and other related compounds,[1] as well as the inhibition of human leukocyte elastase (HLE) by cephalosporins[2] and the remarkable properties of monocyclic β-lactams,[3] have provoked a continuing high level of interest in the chemical synthesis of β-lactams.

The potent antibacterial properties and the challenging chemical problems have made carbapenem-type compounds major synthetic objectives. Due to the chemical instability of the bicyclic ring system, the main synthetic strategies start with an appropriate monocyclic β-lactam with the correct configuration at C3 and C4. The second ring is then formed by manipulations at N1 and C4. The well-established methods that are employed are Wittig-type reactions, aldol condensations, and, in particular, insertion reactions via carbenoid-type intermediates.[4]

We report here the synthesis of 1,2,3,6-tetrasubstituted carbapenams and 1,3,6-trisubstituted carbapenems from the readily available[5] 1,3,4-trisubstituted azetidin-2-ones **1**, in which the five-membered ring is formed by radical cyclization.[6, 7] The starting monobactams we used were the 3α,4α and 3β,4β monobactams **1a** and **1b**, respectively.

Our first aim was to study the tin radical cyclization to **2a** and **2b** in an *exo*-trig process.[8] In contrast to C. Gutiérrez et al.,[9] we found that when the monobactams **1a** and **1b** were treated with tri-(*n*-butyl)stannane and 2,2′-azobis-(isobutyronitrile) (AIBN), the corresponding carbapenams **2a** ($[\alpha]_D = +3.4$ (CHCl$_3$, $c = 1$)) and **2b** ($[\alpha]_D = -13$ (CHCl$_3$, $c = 0.8$)) were obtained in 68 and 62% yield, respectively (Scheme 1). Their IR, ^{1}H NMR, ^{13}C NMR, and mass spectra as well as the elemental analyses are consistent with the assigned structures.

The relative configuration at C1 and C2, for both carbapenams has been deduced from the vicinal coupling constants of the hydrogen atoms H1 and H2. In the carbapenam **2a**, the *trans* orientation of the substituents at C1/C2, C2/C3, and C5/C1 was based on the large values for the coupling constants: $J_{1,2} = 10$, $J_{2,3} = J_{5,1} = 8$ Hz. This *trans* arrangement is only possible with the 1β,2α-substituted carbapenam **2a**, because C3 and C5 have the configuration 3β,5α. In the carbapenam **2b**, the coupling constants in the ^{1}H NMR spectrum ($J_{1,2} = 8$, $J_{2,3} = 4$ Hz) were in agreement with the calculated theoretical values[10] ($J_{1,2} = 6.6$, $J_{2,3} = 5.4$ Hz) for a *cis* and a *trans* arrangement of the protons H1/H2 and H2/H3, respectively. The *trans* arrangement of H5 and H1 ($J_{5,1} = 8$ Hz) was deduced from the stereochemical assignment in **2a**. The sulfone derivatives **3a** (m.p. 125 °C, $[\alpha]_D = +11$ (CHCl$_3$, $c = 0.8$)) and **3b** ($[\alpha]_D = -17$ (CHCl$_3$, $c = 0.7$)) were prepared in order to elucidate the absolute configuration at C1 and C2. An X-ray crystal structure determination of **3a** (Fig. 1) allowed the unequivocal assignment of the absolute configuration (1*R*,2*S*) to this compound, and consequently to its sulfide carbapenam precursor **2a**.[11]

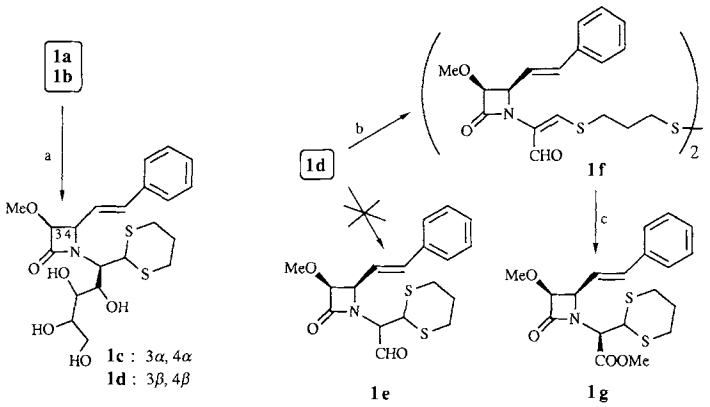
[**] Penem is an abbreviation for the basic framework of unsaturated penicillins: 4-thia-1-azabicyclo[3.2.0]hept-2-en-7-one.

Conversion of the carbapenams **2a** and **2b** into the corresponding 1,3,6-trisubstituted carbapenems, unfortunately, was not possible; all attempts to remove the isopropylidene protecting groups in **2a**, **2b**, **3a**, and **3b** were unsuccessful. This failure prompted us to change our synthetic strategy to the synthesis of carbapenem systems from the monocyclic β-lactams **1a** and **1b**. A suitable approach might be the removal of the isopropylidene groups, then oxidative cleavage of the glycol units of the monobactams **1c** and **1d** (Scheme 2), and finally intramolecular cyclization to form the carbapenam ring. In this way we obtained the tetraol

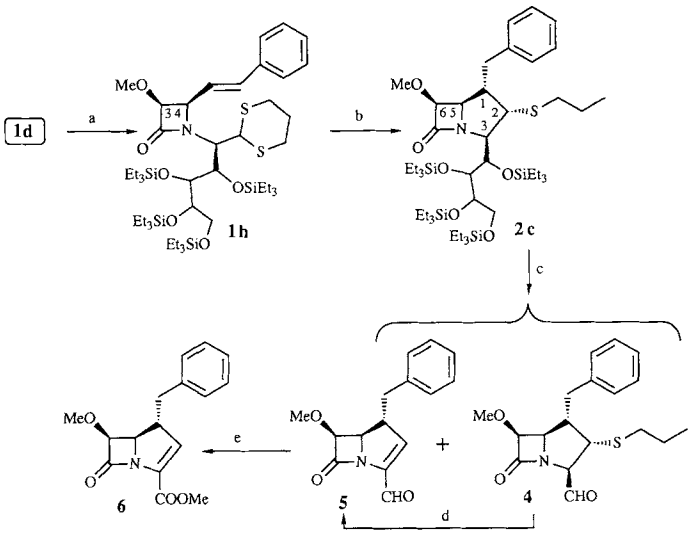


Scheme 2. a) CF_3COOH, MeOH, 20 °C. b) Ph_3BiCO_3, CH_3CN, reflux. c) MnO_2, NaCN, MeOH, 20 °C.

monobactam derivatives **1c** (m.p. 125 °C, $[\alpha]_D = +53.5$ (MeOH, $c = 0.85$)) and **1d** (m.p. 177 °C; $[\alpha]_D = -82$ (MeOH, $c = 1$)) in 82 and 90% yield, respectively. Classical methods for the oxidative cleavage of diols (sodium periodate, potassium permanganate, etc.) were carried out on compound **1d**, but these did not give the desired compound **1e**. Mild oxidants such as triphenylbismuth carbonate,[12] gave the disulfide **1f** in 85% yield. Several ways to regenerate the 1,3-dithiane ring system from **1f** were examined:[13] The methyl ester **1g** (m.p. 156 °C, $[\alpha]_D = -84$ ($CHCl_3$, $c = 0.7$)) was obtained by the use of manganese(IV) oxide and sodium cyanide in methanol,[14] however, in only 10% yield.

Finally, we found that our synthetic strategy to obtain 1,3,6-trisubstituted carbapenems from the monocyclic β-lactams **1** could be realized by using the silylated monobactam **1h** as an intermediate (Scheme 3). The silylated compound **1h** ($[\alpha]_D = -48$ ($CHCl_3$, $c = 1$)) was prepared in 70% yield from the monobactam **1d** and then transformed with tri-(*n*-butyl)stannane and AIBN into the carbapenam **2c** in 75% yield. The *cis* arrangement of the substituents at C1 and C2 for **2c** was assigned from the ^1H NMR data ($J_{1,2} = J_{5,1} = 8.2$, $J_{2,3} = 4$ Hz), which are in agreement with those reported for **2b**.

The carbapenam **2c** was converted into a mixture of aldehydes **4** and **5** by deprotection of the silyl groups and oxidative cleavage of the glycol units. The aldehydes **4** ($[\alpha]_D = -12$ ($CHCl_3$, $c = 1$)) and **5** ($[\alpha]_D = -32$ ($CHCl_3$, $c = 0.8$)) were obtained in 40 and 20% yield (based on **2c**), respectively, after column chromatography. The carbapenam **4** was transformed into the carbapenem **5** in 80% yield by treatment with MCPBA followed by thermolysis of the sulfoxide in refluxing toluene. Finally, the methyl ester carbapenem **6** ($[\alpha]_D = -26$ ($CHCl_3$, $c = 0.5$)) was prepared in 75% yield from **5**.[14]



Scheme 3. a) Et_3SiCl, pyridine, 4-dimethylaminopyridine (catalyst), 20 °C. b) 3.2 equiv. Bu_3SnH, AIBN, toluene, 90 °C. c) Bu_4NF, THF, 0 °C; Ph_3BiCO_3, CH_3CN, reflux. d) MCPBA, CH_2Cl_2, 20 °C; toluene, reflux. e) MnO_2, NaCN, MeOH, 20 °C.

From the results reported here and those previously disclosed,[15] we have demonstrated that the synthetic strategy based on the use of *D*-glucosamine as chiral auxiliary in the Staudinger reaction[5] is an efficient and versatile approach for the synthesis of the most important types of β-lactams. Further studies on the application of these results in the synthesis of optically active carbapenems and carbacephems[16] are now underway.

Synthesis, Structure, and Thermolysis of a 3-Methoxycarbonyl-1,2 λ^5-oxaphosphetane**

By *Takayuki Kawashima,* Katsuhiro Kato,* and *Renji Okazaki**

The study of 1,2-oxaphosphetanes by NMR spectroscopy at low temperature has played an important role in elucidating the factors that influence the stereochemistry of the Wittig reaction.[1] These studies were carried out mainly on nonstabilized ylides, although a few examples of semistabilized ylides were also investigated.[2] By contrast, 1,2-oxaphosphetanes derived from stabilized ylides have so far not been observed.[1d, 3] Recently we succeeded in synthesizing isolable 1,2-oxaphosphetanes with a pentacoordinate P atom and Martin ligand.[4] We now report the synthesis, structure, and thermal reactivity of a 3-methoxycarbonyl-1,2 λ^5-oxaphosphetane, the first 1,2 λ^5-oxaphosphetane with a pentacoordinate P atom to be formally derived from a stabilized ylide.

4,4-Bis(trifluoromethyl)-1,2 λ^5-oxaphosphetane **1a**, prepared in 93% yield by the method previously reported for **1b**,[4] was treated with *n*BuLi and then with excess $ClCO_2Me$ in THF to give 3-methoxycarbonyl-4,4-bis(trifluoromethyl)-1,2 λ^5-oxaphosphetane **2a** as colorless needles in 54% yield (Scheme 1). The structure of **2a** is strongly supported by its ^{31}P ($\delta = -36.7$) and ^{19}F NMR spectra (two sets of doublets of quartets). In the ^1H NMR spectrum a doublet due to the methine proton is observed at $\delta = 5.25$ ($^2J_{(H,P)} = 25.8$ Hz). In the ^{13}C NMR spectrum, the signals for the quaternary C4 atom and the carbon atom of the carbonyl group occur at $\delta = 74.31$ (doublet of septets, $^2J_{(C,P)} = 13.8$ Hz, $^2J_{(C,F)} = 32.4$ Hz) and at $\delta = 162.92$ (d, $^2J_{(H,P)} = 6.5$ Hz), respectively. This is the first isolation and spectroscopic observation of a 1,2-oxaphosphetane with a carbonyl group at the C3 atom.

The X-ray crystallographic analysis of **2a** indicates that the P atom is in a distorted trigonal bipyramidal environment, in which two oxygen atoms are in the apical positions (Fig. 1).[5] The bond angle O1-P1-O2 deviates from linearity by 14.1(3)°; the P1–O1 bond (1.781(6) Å) is longer than the P1–O2 bond (1.716(6) Å). The lengths of the three equatorial bonds P1–C1, P1–C8, and P1–C16 are very similar. The dihedral angles O1-P1-C8-C7 and C7-O1-P1-C8 are −3.7(5) and 4.2(5)°, respectively, indicating that the four-membered ring is slightly puckered. This is one of the common structural features of 1,2-oxaphosphetanes reported previously.[4, 6]

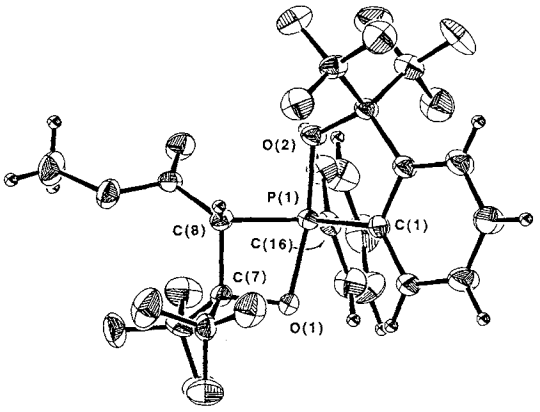

Fig. 1. Crystal structure of **2a** (ORTEP, the CH_3Cl is omitted for clarity). Selected bond lengths [Å] and bond angles [°]: P1-O1 1.781(6), P1-O2 1.716(6), P1-C1 1.805(9), P1-C8 1.823(9), P1-C16 1.823(9), C7-C8 1.55(1), O1-C7 1.40(1); O1-P1-O2 165.9(3), O1-P1-C8 75.5(3), P1-O1-C7 97.0(5), O1-C7-C8 97.0(7), P1-C8-C7 90.2(5), C1-P1-C8 125.0(4), C1-P1-C16 114.7(4), C8-P1-C16 119.8(4).

The phenyl group at the P atom in **2a** is *cis* to the methoxycarbonyl group, indicating that the methoxycarbonylation at the C3 atom occurred stereoselectively from the side of the phenyl group. This selectivity was also observed in the reactions of the lithium derivative **1b–Li**[7] with AcOD and $PhCH_2Br$, which gave **2b** (deuterated to 86%) and **2c**[8] (55%), respectively.

Compound **2a** was heated to about 70 °C under argon to give the olefin **3a** and the cyclic phosphinate **4** quantitatively. A kinetic study on the olefin formation from **2a** by ^{19}F NMR spectroscopy showed that the reaction was first order with respect to **2a**. The rate constants k of the reactions at 69.0 °C in the deuterated solvents [D_8]toluene (ε[9] = 2.38), [D_3]acetonitrile ($\varepsilon = 36.2$), and [D_6]dimethyl sulfoxide ($\varepsilon = 49$) were 8.36×10^{-6}, 1.22×10^{-4}, and $2.93 \times 10^{-4}\ s^{-1}$, respectively, showing a significant solvent effect for **2a** in comparison with that reported for **1b** (k(acetonitrile)/k(toluene) = 1.28).[4]

Hongo, Bunkyo-ku, Tokyo 113 (Japan)

[**] This work was partially supported by a Grant-in-Aid for Scientific Research on Priority Area of Organic Unusual Valency (No. 04217205, T. K.) and a Grant-in-Aid for Scientific Research (A) (No. 04403005, R. O.) from the Ministry of Education, Science, and Culture, Japan. We are grateful to Dr. N. Tokitoh, The University of Tokyo, for the determination of the X-ray structure of **2a**. We also thank Central Glass and Tosoh Akzo Co. Ltd. for gifts of fluorine compounds and alkyllithium compounds, respectively.

The parameters $\Delta H^{\neq} = 24.4 \pm 0.31$ kcal mol^{-1} and $\Delta S^{\neq} = -10.6 \pm 0.84$ cal mol^{-1} K^{-1} were estimated from the temperature dependence of the rate constants for the decomposition of **2a** in [D_8]toluene.[10] The rate constant at 200 °C of the olefin formation from **1a** was measured to be 1.12×10^{-5} s^{-1} in the same solvent, that for the decomposition of **2a** (calculated from the above-mentioned thermodynamic parameters) was 2.50×10^{-1} s^{-1}. This shows that **2a** decomposes about 22000 times faster than **1a**.

The introduction of a methoxycarbonyl group at the C3 position of **1a** did not lead to any noticeable structural change. However, the decomposition of **2a** with the formation of an olefin shows a significant solvent effect, and an acceleration of the rate of reaction in comparison with the decomposition of **1a** or **1b**. This indicates that the transition state for the decomposition of **2a** is more polar, and that negative charge generated on the C3 atom is stabilized by the electronic effect of the methoxycarbonyl group, thus the activation barrier for the olefin formation is lowered.[11]

Experimental Procedure

*n*BuLi (1.68 M solution of hexane, 3.6 mL, 4.0 equiv) was added to a solution of **1a** [12] (0.797 g, 1.50 mmol) in THF (7 mL) at −40 °C. After 2 h $ClCO_2Me$ (0.6 mL, 4.4 equiv, excess) was added to the mixture under argon. The reaction mixture was stirred at −40 to −30 °C for 3 h. After usual workup, the crude mixture was recrystallized from $CHCl_3$, and gave **2a** as colorless needles in 54.1% yield.

[7] The lithium derivative **1b–Li** shows a ^{31}P NMR signal at δ = −28.2 at −40 °C; this indicates that here also the P atom is pentacoordinate. The signal is shifted to δ = 36.7 above −30 °C. The 3-methoxycarbonyl derivative **2d**, prepared from **1b–Li**, was observed by ^{31}P NMR spectroscopy (δ = −42.0), but decomposed to afford the corresponding olefin during purification by chromatography on SiO_2.

[8] Besides **2c**, the 3-butyl derivative (**2**: R = Ph; E = *n*Bu) was obtained in 14% yield as a minor product.

[9] Dielectric constants at 25 °C; C. Reichardt, *Solvents and Solvent Effects in Organic Chemistry*, 2nd ed., VCH, Weinheim, **1988**, p. 408.

[10] Rate constants: 8.36×10^{-6} s^{-1} (69.0 °C), 2.61×10^{-5} (80.0), 7.82×10^{-5} (90.0), 1.76×10^{-4} (100.0), and 4.96×10^{-4} (111.3).

[11] The present solvent effect is too small in comparison with those reported for the reactions involving a zwitterionic intermediate (ref. [9], p. 153). Pseudorotation was not observed experimentally. Therefore, we think the present results support a concerted but non-synchronous mechanism rather than a P–C bond heterolysis mechanism: H. J. Bestmann, *Pure Appl. Chem.* **1980**, *52*, 771.

[12] **1a**: M.p. 70–75 °C (decomp) (EtOH); ^{1}H NMR ($CDCl_3$): δ = 4.02 (dd, ^2J(H,P) = 23.6, ^2J(H,H) = 17.0 Hz, 1H; PC*H*H'), 4.32 (dd, ^2J(H,P) = 19.7, ^2J(H,H) = 17.0 Hz, 1H; PCH*H'*), 7.40–7.48 (m, 3H; *p*, *m*-H of P-Ph), 7.70–7.79 (m, 3H; C*H*), 7.98 (dd, ^3J(H,P) = 15.3, ^3J(H,H) = 7.2 Hz, 2H; *o*-H of P-Ph), 8.45 (dd, ^3J(H,P) = 13.0 Hz, ^3J(H,H) = 7.4 Hz, 1H; C*H*); ^{31}P NMR ($CDCl_3$): δ = −33.3; satisfactory ^{13}C and ^{19}F NMR spectra and correct O,H,N analyses were obtained.

UO_2^{2+}-Catalyzed Oligothioadenylate Synthesis with High Regio- and Stereoselectivity**

By *Masamitsu Shimazu, Kazuo Shinozuka,* and *Hiroaki Sawai**

Phosphorthioate analogues of oligonucleotides with a defined configuration at the phosphorous atom are of importance for the investigation of the stereochemical course of enzymatic reactions[1] and for the development of new chemotherapeutic drugs.[2] Among these analogues, 2′-5′-oligothioadenylates have been reported to possess effective anti-HIV activity[3] and to activate 2′-5′-oligoadenylate-dependent endoribonuclease (RNase L), inducing mRNA degradation.[4] Enzymatically, 2′-5′-oligothioadenylates with *Rp* configuration are produced from *Sp*-ATP$_\alpha$S by 2′-5′-oligoadenylate synthetase.[5] Synthesis of 2′-5′-oligothioadenylates with a variety of thiophosphoryl configurations has been accomplished by conventional phosphite triester[6] and hydrogenphosphonate approaches.[7] In 1989 we showed that UO_2^{2+} salts catalyze the polymerization of adenosine-5′-phosphoroimidazolide (ImpA) very efficiently in aqueous solution, yielding 2′-5′-oligoadenylates.[8] The use of adenosine-5′-thiophosphoroimidazolide (Imp(S)A) should make it possible to study the stereochemical features of the UO_2^{2+}-catalyzed polymerization and to prepare biologically active 2′-5′-oligothioadenylates. We report here that the UO_2^{2+} ion catalyst controls the oligomerization with remarkably high regio- and stereoselectivity.

Synthesis of adenosine-5′-thiophosphoazolide (Xp(S)A) was carried out as shown in Scheme 1. Adenosine was first thiophosphorylated[9] and then treated with imidazole (ImH) or benzimidazole (BzimH) to give adenosine-5′-thiophosphodiimidazolide. After alkaline hydrolysis with pyri-

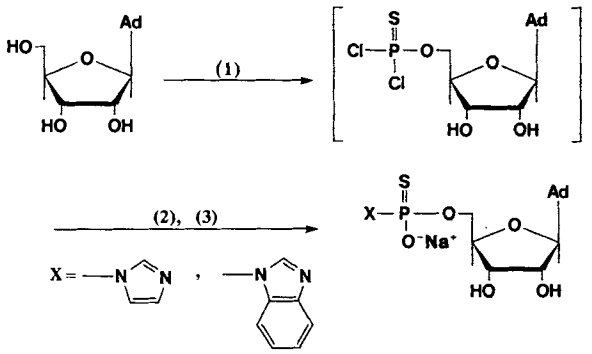

Scheme 1. Preparation of adenosine-5′-thiophosphorazolides (Xp(S)A). (1) $PSCl_3$ in $(EtO)_3PO$; (2) imidazole or benzimidazole; (3) weak alkaline hydrolysis.

dine/H_2O and purification by DEAE-Sephadex column chromatography, the resulting Imp(S)A or Bzimp(S)A was obtained as a nearly 1:1 diastereoisomeric mixture. The yields of Imp(S)A and Bzimp(S)A from adenosine were 30% and 19%, respectively. The *Rp* and *Sp* diastereomers of Bzimp(S)A were resolved by HPLC, and the configurations at thiophosphoryl group were determined by ^{31}P NMR spectroscopy[11] (Table 1).

Table 1. HPLC retention times t, ^{31}P chemical shifts, and stability toward SVPD (half-life $\tau_{1/2}$ at 37 °C) of the diastereomers of Bzimp(S)A and 2′-5′-$(p(S)A)_2$.

Compound	t [min] [a]	δ (^{31}P) [b]	$\tau_{1/2}$ [h]
Rp-Bzimp(S)A	44.1	61.43	–
Sp-Bzimp(S)A	44.8	60.33	–
Rp-$(p(S)A)_2^{2'-5'}$	19.0	56.49 [c]	8.5
Sp-$(p(S)A)_2^{2'-5'}$	−21.2	55.57 [c]	≫48.0 [d]

[a] HPLC retention time for a linear gradient of MeOH (2.4 → 51.2% in 60 min) in 10 mM triethylammonium acetate (TEAA), pH 7.3, flow rate 1.0 mL min^{-1}, ODS-silicagel column. [b] Measured at 36.44 MHz in 100 mM TEAA, pH 7.3, containing 50% D_2O. [c] The chemical shift for the thiophosphoryl group at the internucleotidyl bond. [d] No digestion directed by time indicated.

Oligomerization of Xp(S)A was carried out in a mixture of Xp(S)A (50 mM) and $UO_2(NO_3)_2$ (2 mM) in 0.2 M *N*-ethylmorpholine/HNO_3 buffer (pH 7.0) at 25 °C. According to HPLC analysis no more starting material was present in the reaction mixture after 5 days. The reaction products were isolated by HPLC, and their structures were ascertained by COSY ^1H NMR. The configuration of the thiophosphoryl group of the oligomers was determined by susceptibility toward snake venom phosphodiesterase (SVPD) digestion (half-life), retention time of reverse-phase HPLC, and ^{31}P chemical shift (Table 1). The *Rp* diastereomers had shorter retention times,[6,7] larger (δ ^{31}P) values,[11] and were more easily digested with SVPD than the corresponding *Sp* diastereomers.[1a,10]

Table 2 shows the yields of the oligomerization of the several azolides. The imidazolide with normal phosphoryl group, ImpA, yielded oligonucleotides up to the hexadecamer,[8] whereas chain elongation from Imp(S)A was significantly suppressed and the main products were 2′-5′-linked dimers and trimers. The 2′-5′-internucleotidyl bond was preferentially formed in all of the UO_2^{2+}-catalyzed polymerizations.

Figure 1a shows the HPLC elution profile of the reaction mixture obtained from Imp(S)A. Oligomers with *Rp* configurations were preferentially formed, although the starting Imp(S)A was a nearly 1:1 mixture of diastereomers. In order to achieve a better understanding of the stereoselectivity we carried out the oligomerization of the *Rp*- and *Sp*-Bzimp(S)A diastereoisomers both separately and as a mixture.

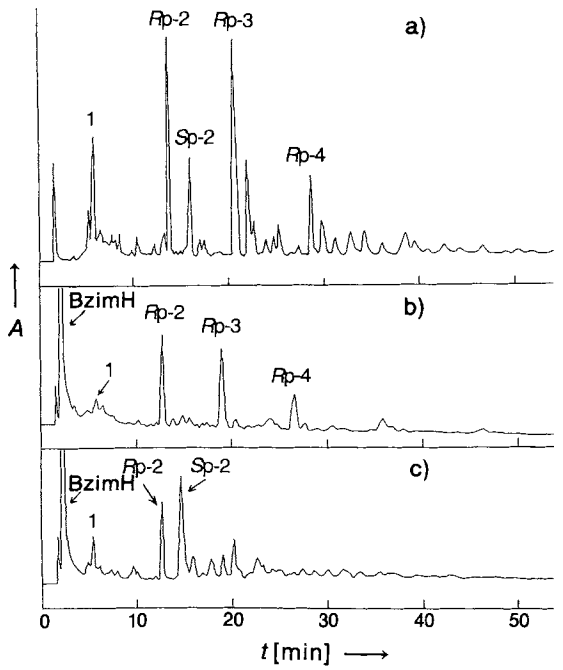

Fig. 1. HPLC profiles of oligothioadenylates obtained from the UO_2^{2+}-catalyzed oligomerization of (a) (*Rp*)- + (*Sp*)-Imp(S)A, (b) (*Sp*)-Bzimp(S)A and (c) (*Rp*)-Bzimp(S)A. 1, p(S)A; *Rp*-2: (*Rp*)-$(p(S)A)_2^{2'-5'}$; *Sp*-2: (*Sp*)-$(p(S)A)_2^{2'-5'}$; *Rp*-3: (*RpRp*)-$(p(S)A)_3^{2'-5',2'-5'}$; *Rp*-4: (*RpRpRp*)-$(p(S)A)_4^{2'-5',2'-5',2'-5'}$. Chromatography column: RPC-5 (250 × 4 mm); flow rate: 1.0 mL min^{-1}, elution: A → B (60 min), A: 2 mM TRIS acetate, pH 7.5 + 0.1 mM EDTA, B: 70 mM $NaClO_4$ + 2 mM TRIS acetate + 0.1 mM EDTA; detection: UV absorption at 260 nm.

HPLC profiles of the reaction mixtures are shown in Figures 1b and 1c. The *Sp* monomer (Fig. 1b) effectively promoted the formation of 2′-5′-oligomers up to the hexamer. These oligomers were digested easily with SVPD,[1a,10]

Table 2. UO_2^{2+}-catalyzed formation of 2′-5′-oligoadenylate analogues.

Substrate	Reaction time [days]	c (UO_2^{2+}) [mM]	HPLC yield of 2′-5′-oligoadenylate [%] monomer	*Rp* dimer	*Sp* dimer	*RpRp* trimer	tetramer	≥ pentamer
ImpA	4	1	0.1		6.0 [a]	12.8 [a]	10.7	30.9 [b]
(*Rp*)- + (*Sp*)-Imp(S)A	5	2	7.2	12.6	7.4	20.6	7.0

[a] Phosphodiester linkage (no stereoisomer). [b] Oligomer up to hexadecamer.

which indicates that they were only *Rp* isomers. On the other hand, the main products from the *Rp* monomer (Fig. 1c) were 2′-5′-linked *Sp* and *Rp* dimers, and further chain elongation was not observed. It was ascertained by HPLC that the *Sp* monomer was consumed faster than the *Rp* monomer in the reaction. When the diastereoisomeric mixture of Bz-imp(S)A was used as a starting monomer, the oligomerization proceeded insufficiently and hydrolysis of the monomer predominated.

Our studies have thus shown that *Sp*-Bzimp(S)A leads to the 2′-5′-linked *Rp* oligomers in high yields, whereas *Rp*-Bz-imp(S)A also forms the *Sp* dimer. We thus propose that the oligomerization involves an inversion mechanism.

The available results lead to a working hypothesis for the course of UO_2^{2+}-catalyzed regio- and stereoselective oligomerization: Kainosho et al.[12] and Feldman et al.[13] reported that UO_2^{2+} forms a cluster-type complex with adenosine-5′-monophosphate, in which the phosphate group and 3′-hydroxy group coordinate to the UO_2^{2+} ion. We postulate that the stereoselective oligomerization takes place via similar types of complexes formed from the UO_2^{2+} ion and Xp(S)A (Fig. 2). The enhanced nucleophilicity of the 2′-hydroxy

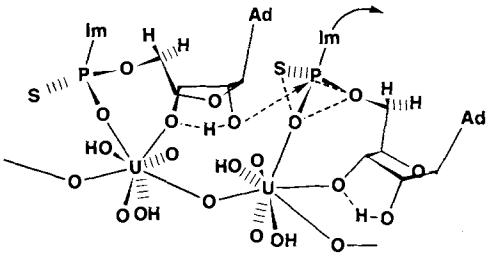

Fig. 2. Proposed stereochemical course of the UO_2^{2+}-catalyzed oligothioadenylate formation from (*Sp*)-adenosine-5′-thiophosphoroimidazolide (the protons of the ribose ring are omitted). The imidazole leaving group is oriented favorably with the incoming 2′-OH group in the complex. The *Rp* monomer also forms a complex with the UO_2^{2+} ion, but in this case the leaving and incoming groups are not oriented favorably with one another.

group is ascribed to a hydrogen-bonded ring in the anion of the coordinated state.[14] Sequential 2′-5′-internucleotidyl bond formation is likely to occur through attack of the 2′-hydroxy group of a coordinated Xp(S)A molecule at the thiophosphoryl group of the adjacently coordinated Xp(S)A molecule. The thiophosphoryl oxygen atom, but not the corresponding sulfur atom of the Xp(S)A, coordinate to the UO_2^{2+} ion, since sulfur is a weaker electron donor than oxygen toward the UO_2^{2+} ion.[15] The orientation of the thiophosphoryl monomers imposed by the coordination of the oxygen atom to the UO_2^{2+} ion allows a degree of stereoselectivity that is rarely encountered except in enzymatic reactions.

Suhadolnik et al.[3] reported that oligomers with *Rp* configuration reveal strong biological activities, for example the (*RpRp*)-trimer-5′-triphosphate inhibits HIV-1 reverse transcriptase.

2′-5′-oligothioadenylates with *Rp* configuration are preferentially formed in aqueous solution in the oligomerization catalyzed by UO_2^{2+} ions, without the need for protecting groups. The reaction is very useful, therefore, for the simple stereoselective synthesis of 2′-5′-linked oligothioadenylates.

A Branched-Chain Nonacarbene with a Nonadecet Ground State: A Step Nearer to Superparamagnetic Polycarbenes

By *Nobuo Nakamura, Katsuya Inoue*, and *Hiizu Iwamura**

While ferromagnetism of transition metals and lanthanoids is ascribed to the macroscopic ordering of their 3d and 4f electron spins, respectively, the 2s and/or 2p electron spins of open-shell organic molecules can, in general, contribute only to paramagnetism due to their small magnetic moment (typically $S = 1/2$, $\mu_{eff} = 1.73\,\mu_B$). If an organic molecule acquires a huge magnetic moment, it might form a single magnetic domain and exhibit superparamagnetic behavior, such as pseudo-hysteresis. Even organic ferromagnets could be realized if ferromagnetic coupling between high-spin molecules in the solid were to occur. The basic principles leading to these molecules are based on the orthogonality of the singly occupied orbitals in space and on

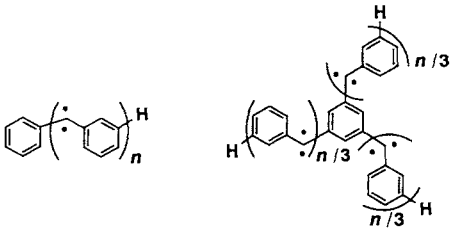
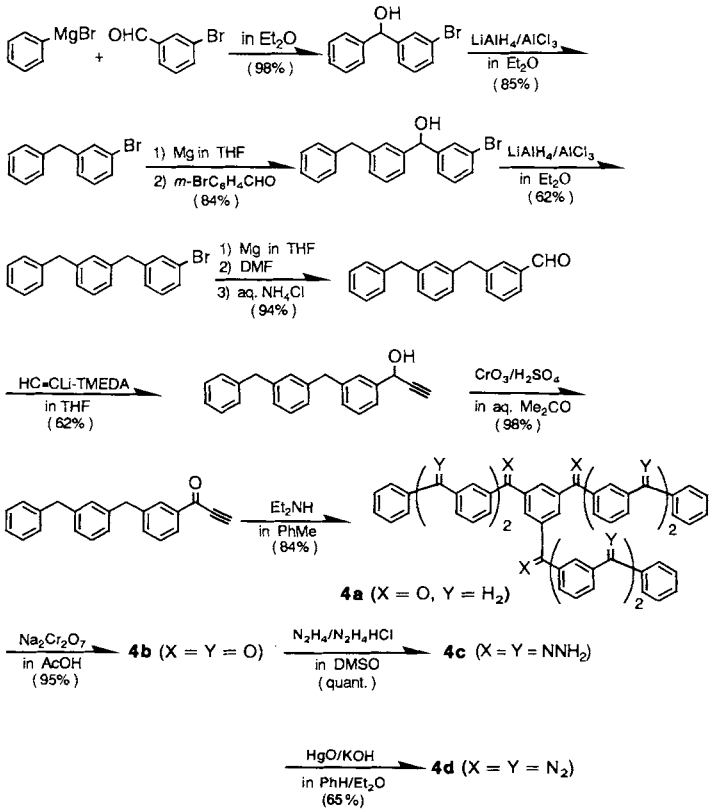
the topological symmetry.[1] Carbenes in triplet ground states are examples of the former,[2] and a Schlenk diradical $R_2C^{\cdot}$–m-C_6H_4–$^{\cdot}CR_2$ with the triplet ground state is a representative of the latter.[3] It is amply demonstrated by the one-dimensional poly(m-phenylenecarbenes) **1** that combination of these two concepts is effective in the construction of organic molecules with higher spin quantum numbers.[4] Extension of this system to the two-dimensional branched-chain hexacarbene **2** with a tridecet ground state ($S = 6$) has also been successful.[5] In order to ensure this branched-chain strategy for organic molecules with higher spin and to obtain information on any restriction which might arise in this approach, studies on higher homologues of the hexacarbene, **2**, are extremely important. In the present communication, the synthesis and magnetic properties of the nonacarbene **3** are reported.



1 (n = 1 ~ 5) **2**, n = 6 **3**, n = 9

The synthetic route to the precursor of **3**, namely **4d**, via nonaketone **4b** is illustrated in Scheme 1. The diethylamine-catalyzed trimerization of the aryl ethynyl ketone served as a key step in the synthesis of 1,3,5-tris(aroyl)benzene.[5] The nonadiazo compound **4d** was purified by chromatography and characterized by IR, UV/VIS, and NMR spectroscopy.



Scheme 1. Synthetic pathway for the nonadiazo compound **4d** via the nonaketone **4b** and the nonahydrazone **4c**.

The connectivity of the H and C atoms of **4b** was confirmed by H,H- and C,H-COSY spectra.

Photolysis of **4d** in 2-methyltetrahydrofuran (MTHF) glasses at 6.5 K in an X-band ESR spectrometer resulted in the appearance of strong, complex ESR signals centered at about 330 mT, which are characteristic of unoriented high-spin species. The shape of the signals and the position of the center of the signals were dependent on both the modulation amplitude and the scan direction of the main external field. This suggests considerable anisotropy of the principal axes of the zero-field tensor and slow relaxation.

UV light was introduced through a quartz light guide and used to photolyze a solution of **4d** in MTHF glasses in a quartz basket suspended in the superconducting solenoid (≤ 7 T) of an Oxford Faraday magnetic balance at 2 K. The magnetic measurements on **3** thus produced were performed in situ. The plots of magnetization M versus the applied magnetic field strength H at 2.1 and 10.0 K were analyzed in terms of the Brillouin function to give a spin quantum number $S = 9.0_0$ for **3**, a new record for a purely organic molecule (Fig. 1). When the external magnetic field was switched

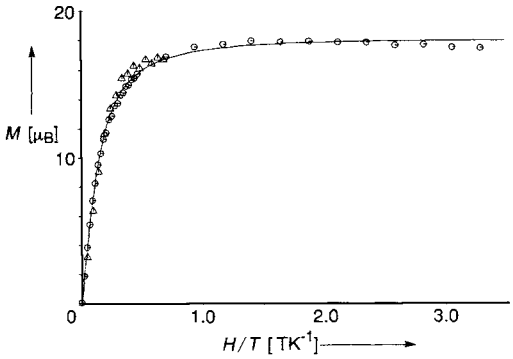


Fig. 1. Magnetization M of nonacarbene **3** in MTHF glasses at 2.1 K (o) and 10.0 K (Δ). Solid line corresponds to the theoretical curve of $S = 9$.

on and off by a SQUID magnetometer, the magnetization did not follow instantaneously, but required a half-life of about 30 min to recover at 5 K.

At least two prerequisites must be fulfilled for the observation of the $S = 9$ state of **3**: First the wavelength of the light must be in the range 400–480 nm, otherwise ESR signals due to triplet carbenes, quintet dicarbenes, and other high-spin species, are observed. Second the concentration of the sample should be < 1 mmol L^{-1}, otherwise the effective magnetic moment is lowered by about 15% at 2 K relative to that at 20 K, probably due to antiferromagnetic intermolecular interactions.

There are two important messages from this work. First the branched-chain pseudo-two-dimensional framework in **2** and **3** is appropriate for controlling its high-spin ground state, at least up to nonacarbene ($S = 9$) in **3**. Second, there are indications that the rotation of the principal axis of dipolar coupling and magnetization at cryogenic temperatures is hindered.

Experimental Procedure

1,3,5-Tris[3-((3-benzoyl)benzoyl)benzoyl]benzene (**4b**): 1,3,5-Tris[3-((3-benzyl)benzyl)benzoyl]benzene **4a**, obtained by trimerization of 1-[3-((benzyl)benzyl)phenyl]prop-2-yn-1-one, was oxidized with $Na_2Cr_2O_7 \cdot 2H_2O$ in acetic acid to give the nonaketone **4b** [6]. After chromatography on silica gel with hexane and dichloromethane **4b** was obtained in 95% yield. M.p. 118–119 °C; IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 1690 (C=O); FAB-MS: m/z 1016.4 (M^+ + H, 14%), 1015.4 (M^+, 13).

1,3,5-Tris[diazo(3-(diazo(3-(diazo(phenyl)methyl)phenyl)methyl)phenyl)-methyl]benzene (**4d**): The nonaketone **4b** was converted to the corresponding nonahydrazone **4c** by the addition of anhydrous hydrazine and hydrazine hydrochloride in dimethyl sulfoxide (DMSO) at 90 °C. The nonahydrazone **4c** was then oxidized with HgO in a benzene/CH_2Cl_2 mixture in the presence of a 3 M solution of KOH in ethanol. The mixture was stirred for 7 days at room temperature. Filtration of the reaction mixture followed by concentration of the filtrate in vacuo left a deep wine-red oil, which was immediately chromatographed on alumina (Woelm neutral, activity IV) at 0 °C with hexane and benzene. This afforded the nonadiazo compound **4d** as a deep red oil in 65% yield. ^{1}H NMR (270 MHz, $CDCl_3$, 21 °C): $\delta = 7.43-6.85$ (m); IR(Nujol): $\tilde{\nu}$[cm^{-1}] = 2060; UV/VIS(MTHF): λ_{max}[nm](ε) = 520 (950).

Photolysis and magnetic measurement: A solution of about 20 μg of **4d** in 80 μL of MTHF in a quartz sample basket suspended in a superconducting solenoid was irradiated with UV light ($480 > \lambda > 400$ nm). The UV light was obtained by a combination of a Kenko B-390 band-path filter and an OCLI type B cold mirror. During the magnetic measurement the field gradient was kept constant at 5 Tesla m^{-1} while the main field was changed from 0 to 7 Tesla.

Dedicated to Professor Bruce West on the occasion of his 65th Birthday

Pyrazolate (pz) ions mainly behave as bridging ligands owing to the directional characteristics of the lone pairs on the nitrogen atoms,[1] but some f-block complexes have chelating η^2-pyrazolato ligands.[2–5] In all these complexes, the f-block metal atoms also have either cyclopentadienyl ligands[2, 3] or bridging pz ligands.[4, 5] No tris(η^2-pyrazolato) lanthanoid complexes have been reported; the simple [Ln-(pz)$_3$] complexes (Ln = Nd,[5] Yb[6]) have low solubility and are probably polymeric with only bridging pz groups, whilst [Nd(Me$_2$pz)$_3$(thf)] (Me$_2$pz$^-$ = 3,5-dimethylpyrazolate; thf = tetrahydrofuran) is dimeric with μ-Me$_2$pz and η^2-Me$_2$pz ligands and, unexpectedly, bridging THF ligands.[5] We now have used the bulky 3,5-di(*tert*-butyl)pyrazolato (tBu$_2$pz$^-$) ligand to give tris(η^2-pyrazolato)lanthanoid compounds as monomeric, petroleum ether-soluble [Ln(η^2-tBu$_2$pz)$_3$(thf)$_2$] complexes, the first metal complexes of any element with η^2-bound pyrazolate ions as the sole anionic ligands. The X-ray structure of the neodymium complex confirms the monomeric nature of the compounds.

Reaction of bis(pentafluorophenyl)mercury and 3,5-di(*tert*-butyl)pyrazole with an excess of lanthanoid metal in THF at room temperature gave the air- and water-sensitive complexes **1**–**4** (Ln = La (**1**), Nd (**2**), Gd (**3**), or Er (**4**)) in 36–55% yield [Eq. (a)].

$$2\,Ln + 3[Hg(C_6F_5)_2] + 6\,Ht\text{Bu}_2pz \xrightarrow{THF} \underset{\mathbf{1-4}}{2[Ln(t\text{Bu}_2pz)_3(thf)_2]} + 3\,Hg\downarrow + 6\,C_6F_5H \quad (a)$$

The mass spectra of **1**–**4** show mononuclear [Ln-(tBu$_2$pz)$_3^+$] parent ions, in contrast to the [Nd(Me$_2$pz)$_3$(thf)] complex,[5] which gives dinuclear ions and no [Nd-(Me$_2$pz)$_3^+$]. This result and the high solubility of **1**–**4** in petroleum ether infer monomeric structures, and this was established by the X-ray crystal structure of **2** (Fig. 1).[7]

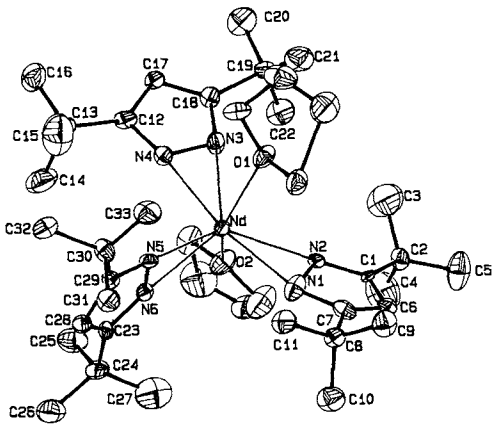

Fig. 1. Crystal structure of **2** (H atoms omitted for clarity). Selected distances [pm] and angles [°] (Cen 1, Cen 2, and Cen 3 denote the centers of the bonds N1-N2, N3-N4 and N5-N6, respectively): Nd-N1 243(1), Nd-N2 246(1), Nd-N3 241.8(8), Nd-N4 238.1(8), Nd-N5 249.2(9), Nd-N6 247.7(6), Nd-O1 247.5(6), Nd-O2 243.2(8), N1-N2 136(1), N3-N4 138(1), N5-N6 140(1); N1-Nd-N2 32.2(3), N3-Nd-N4 33.3(3), N5-Nd-N6 32.7(2), O1-Nd-O2 145.2(6), Cen1-Nd-Cen2 140.3(4), Cen2-Nd-Cen3 109.2(3), Cen1-Nd-Cen3 110.6(4), Cen1-Nd-O1 84.5(3), Cen1-Nd-O2 88.0(4), Cen2-Nd-O1 81.0(4) Cen2-Nd-O2 88.5(3), Cen3-Nd-O1 112.0(6), Cen3-Nd-O2 102.5(3).

Coordination of three η^2-(tBu$_2$pz) ligands and two THF ligands gives irregular eight coordination for the central Nd atom. The Nd–N distances (Fig. 1) increase from silimar to those for η^2-Me$_2$pz to near those for μ-Me$_2$pz in [{Nd-(η^2-Me$_2$pz)$_2$(μ-Me$_2$pz)(μ-thf)}$_2$] (**5**).[5] Although the elongation can be attributed to the steric demands of three η^2-tBu$_2$pz$^-$ ligands, the Nd–O distances are normal for Ln–O(thf) lengths.[11] A clearer picture of the stereochemistry around the neodymium center is obtained if the arrangement of oxygen atoms of the THF ligands and the mid points (Cen 1–Cen 3) of the N–N bonds is considered.[15] This arrangement is intermediate between a trigonal bipyramid

with O1 and O2 apical, and Cen 1, Cen 2, and Cen 3 in the equatorial positions (Cen 1, Cen 2, Cen 3, and Nd are coplanar, deviation $\leq 0.08(4)$ pm), and square pyramidal with Cen 3 apical, and transoid Cen 1, Cen 2, and O1, O2 relationships in the square plane (Nd 75.71(2) pm above the plane). In either case, the skeletal angles (Fig. 1) deviate considerably from those for regular arrangements. Although tBu$_2$pz is bridging in the only reported complex of this ligand [{Ni(tBu$_2$pz)(NO)}$_2$],[16] it is sufficiently bulky (cf. pz[5, 6] and Me$_2$pz[5]), in conjunction with the nondirectional ionic character of lanthanoid–ligand bonding, to promote formation of monomeric [Ln(η^2-pz)$_3$] complexes.

The petroleum ether-soluble compounds **1**–**4** are potential synthetic reagents of comparable utility to [Ln{N(SiMe$_3$)$_2$}$_3$] species[17] in protolytic ligand exchange reactions. To illustrate this, **6** [Odpp$^-$ = 2,6-diphenylphenolate; Eq. (b)] has been readily prepared from **2**. The high solubility of 3,5-di(*tert*-butyl)pyrazole in petroleum ether facilitates the separation of products.

$$\underset{\mathbf{2}}{[\mathrm{Nd}(t\mathrm{Bu_2pz})_3(\mathrm{thf})_2]} + 3\,\mathrm{HOdpp} \longrightarrow \underset{\mathbf{6}}{[\mathrm{Nd}(\mathrm{Odpp})_3(\mathrm{thf})_2]} + 3\,\mathrm{H}t\mathrm{Bu_2pz} \quad \text{(b)}$$

Experimental Procedure

Syntheses and characterization. All operations were carried out under a purified N_2 or Ar atmosphere. **1**: La powder (0.80 g, 5.7 mmol), [Hg(C_6F_5)$_2$] [18] (1.48 g, 2.8 mmol), and HtBu$_2$pz [19] (1.00 g, 5.5 mmol) were stirred together in THF (40 mL) at room temperature for 2 days. The reaction mixture was filtered and evaporated until solid deposited. Dissolution by warming and cooling to room temperature gave **1** (0.84 g, 55%) as a white powder. Correct C,H,La analyses. ^{1}H NMR (200 MHz, C_6D_6): δ = 1.13 (m, 8H, β-H(thf)), 1.39 (s, 54H, tBu), 3.25 (t, J = 6.5 Hz, 8H, α-H(thf)), 6.37 (s, 3H, H4(tBu$_2$pz)). MS (L = tBu$_2$pz): m/z 676 (NdL_3^+, 0.3%), 661 (NdL_3^+ – Me, 0.3%), 497 (NdL_2^+, 0.8%), 481 (NdL_2^+ – MeH, 0.9%), 180 (LH^+, 20%), 165 (LH^+ – Me, 100%). IR (Nujol/Fluorolube, strong bands only) $\tilde{\nu}$[cm^{-1}] = 2948, 2895, 2858, 1456, 1430, 1412, 1357, 1250, 1224, 1031, 1016, 993, 875, 787. After analogous preparations, **3** was isolated similarly, and **2** and **4** were obtained by evaporation of the filtered reaction mixture to dryness and crystallization of the residue from pentane/THF at –10 °C. The IR spectra of **2**–**4** were essentially identical with that of **1**, and their mass spectra showed features corresponding with those of **1**.

Reaction of **2** with HOdpp: A solution of **2**, prepared in situ from Nd powder (0.68 g, 4.7 mmol), [Hg(C_6F_5)$_2$] (0.74 g, 1.4 mmol), and HtBu$_2$pz (0.50 g, 2.8 mmol) in THF (40 mL) was filtered onto HOdpp (0.68 g, 2.8 mmol) and stirred briefly at room temperature. The blue solution was concentrated to about 8 mL, which resulted in deposition of light blue [Nd(Odpp)$_3$(thf)$_2$]. After addition of pentane the mixture was stirred to dissolve any HtBu$_2$pz and the blue solid was collected (0.78 g, 55%). The IR and mass spectra were in agreement with those of the authentic compound [20, 21]. Evaporation of the filtrate gave a white residue of HtBu$_2$pz (IR identification).

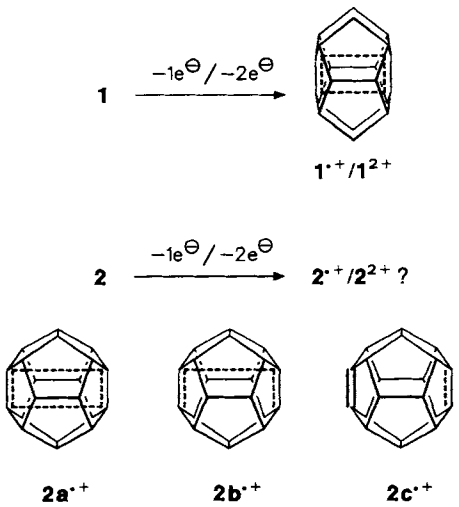
1 2

two-electron oxidations. In the resulting radical cation $\mathbf{1}^{\bullet+}$ and dication $\mathbf{1}^{2+}$ cyclic electron delocalization is effective (σ homoaromaticity).[4-6]

Of general importance is the question whether the ions $\mathbf{2}^{\bullet+}$ and $\mathbf{2}^{2+}$ derived from **2**, in which the π,π distance is much larger (ca. 3.5 Å), can still profit from transannular electron delocalization ($\mathbf{2a}^{\bullet+}$, $\mathbf{2b}^{\bullet+}$; $\mathbf{2a}^{2+}$, $\mathbf{2b}^{2+}$). The borderline situation of nonbonding π,π interactions[7] in **2** and in the radical cations and dications is emphasized by the fact that in contrast to reactions of **1**, direct irradiation of **2** and addition of bromine do not lead to the formation of transannular C–C bonds.[11]



We report here on the preparation of the radical cation $\mathbf{2}^{\bullet+}$ and its characterization by ESR spectroscopy. The radical cation of the monoene $\mathbf{3}^{\bullet+}$ serves as a "localized" reference compound (cf. $\mathbf{2c}^{\bullet+}$). This study could be carried out because the unusually bent and highly reactive (towards O_2) olefins **2** ($\phi = 42.9°$) and **3** ($\phi = 43.5°$) are surprisingly thermally stable and isolable.

The first attempts at generating $\mathbf{2}^{\bullet+}$ and $\mathbf{3}^{\bullet+}$ in liquid phase in analogy to $\mathbf{1}^{\bullet+}$ (electrochemically, by reaction with $AlCl_3$ or tris(*p*-bromophenyl)ammonium hexachloroantimonate), failed;[13] however, the radical cations could be produced in Freon matrices by γ irradiation (^{60}Co source, 77 K, $CFCl_3$, $CF_2ClCFCl_2$ or CF_3CCl_3).[14] The ESR spectra of these rigid solutions of $\mathbf{2}^{\bullet+}$ (moss green) and $\mathbf{3}^{\bullet+}$ (colorless) exhibit pronounced *g* anisotropy in all matrices used ($g_1 = 1.9881$, $g_2 = 2.0039$, $g_3 = 2.0329$) and, accordingly, consist of three groups of equidistant lines (Fig. 1). For $\mathbf{2}^{\bullet+}$

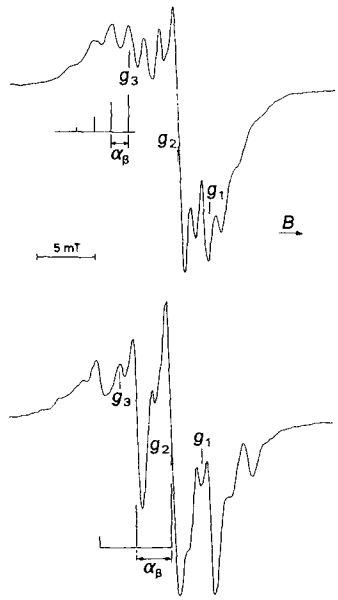


Fig. 1. ESR spectra of the radical cations $\mathbf{2}^{\bullet+}$ (top) and $\mathbf{3}^{\bullet+}$ (bottom).

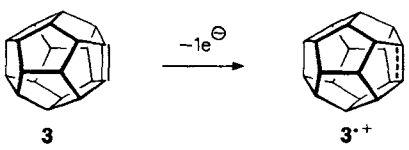
with eight symmetry-equivalent β protons, the hyperfine coupling constant *a* has an average value of 1.45 ± 0.05 mT, while for $\mathbf{3}^{\bullet+}$ with four symmetry-equivalent β protons the average value is 3.10 ± 0.05 mT. These values are corroborated by ^1H ENDOR studies. All ENDOR signals are split into a parallel and a perpendicular component of a quasi-axial hyperfine tensor.[15] The parallel components of *a* throughout have larger absolute values than the perpendicular ones, a finding that indicates a positive sign of the coupling constants, as expected for β protons.[16]

The following relation can be applied to the coupling constants *a* of the β protons:[17] $a_\beta = B \cdot \rho \cdot \cos^2\theta$, where *B* is a proportionality factor, ρ the spin population on the adjacent π center, and θ the dihedral angle formed by the $2p_z$ axis at this center and the C–H_β bond. The factor *B* was estimated from the coupling constant of the methyl protons of tetramethylethene ($a_\beta = 1.72$ mT).[18] Since the methyl groups are freely rotating, the average value of $\cos^2\theta$ is 0.5; hence $B = 6.88$ mT. Based on this *B*-value and the experimentally determined coupling constants a_β, the dihedral angle θ for $\mathbf{2}^{\bullet+}$ is 23° ($\rho = 0.25$, spin population distributed evenly over four π centers) and for $\mathbf{3}^{\bullet+}$ is 18° ($\rho = 0.5$, spin population distributed evenly over two π centers). These dihedral angles are in good agreement with those calculated for $\mathbf{2a}^{\bullet+}$ and $\mathbf{3}^{\bullet+}$ ($\theta(\mathbf{2a}^{\bullet+}) = 19$, $\theta(\mathbf{3}^{\bullet+}) = 21°$; MMX[19] followed by UHF-AM1 calculations[20] for the radical cations). The agreement between the experimentally determined coupling constants and those from INDO calculations is equally good:[21] for $\mathbf{2a}^{\bullet+}$ 1.45 vs. 1.68 mT, for $\mathbf{3}^{\bullet+}$ 3.10 vs. 3.29 mT. Indeed, the SOMO of $\mathbf{2a}^{\bullet+}$ has the π_- character expected for the HOMO in the early stages of the "symmetry-forbidden" dimerization of two ethene molecules (Fig. 2).

In analogy to $\mathbf{1}^{\bullet+}$ ($a_\beta = 1.544$ mT), $\mathbf{2a}^{\bullet+}$ has a delocalized structure with D_{2h} symmetry on the hyperfine timescale. According to the UHF-AM1 calculations, the π,π distance in $\mathbf{2a}^{\bullet+}$ (3.53 Å) is almost unchanged relative to that in **2**; the pyramidalization ($\phi = 47.3°$) is more pronounced by ap-



3 $\mathbf{3}^{\bullet+}$

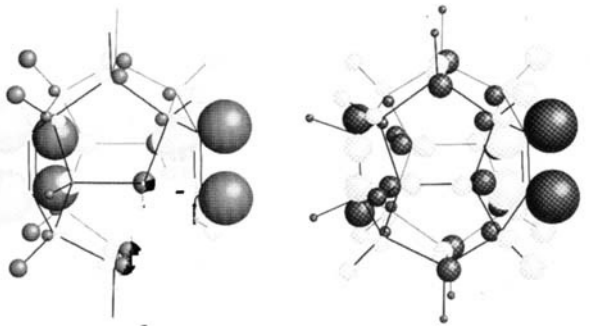


Fig. 2. Highest occupied molecular orbital (SOMO) of $2a^{\bullet+}$ (left) and $3^{\bullet+}$ (right).

proximately 4° (the rigidity of the dodecahedrane framework prevents the compression of the cage, as is possible in the bisseco reference pair $1/1^{\bullet+}$), and the olefinic bonds are somewhat longer (1.35 vs. 1.33 Å). In comparison, the change in pyramidalization between **3** and $3^{\bullet+}$ ($\phi = 51.3°$) is much larger and the olefinic bond becomes even longer (1.43 Å). The significantly weaker through-space homoconjugation[22] in $2a^{\bullet+}$ and the considerably greater strain energy ($E_{str}(2) = 105.3$, $E_{str}(1) = 73.9$ kcal mol^{-1}) are reflected in the markedly reduced persistence of $2a^{\bullet+}$ relative to $1^{\bullet+}$ (2 d at 293 K vs. 2 d at 77 K in Freon matrices, 1–2 h at temperatures above 110 K). Considering the coefficients in the SOMO of the radical cation, through-bond conjugation should be negligible. Photoelectron spectra and electrochemical measurements are anticipated to provide quantifiable experimental data on the interactions between the π bonds in **2**.[23]

[15] Depending on the type of matrix used, the sets of eight ($2^{\bullet+}$) and four ($3^{\bullet+}$) β protons give rise to single or several close-lying sets of ENDOR signals, indicating that the medium can cause a reduction in symmetry. For $2^{\bullet+}$, the signals appear between 32 and 38 MHz and correspond to $1/2\,a + \nu_H$, where a is the coupling constant in MHz and ν_H is the frequency of the free proton (14.56 MHz). (The corresponding signals for $1/2\,a - \nu_H$ between 3 and 9 MHz are too weak to be detected in the ENDOR system.) For $3^{\bullet+}$, the signals for both $1/2\,a + \nu_H$ and $1/2\,a - \nu_H$ are observed at 57–60 and 28–31 MHz, respectively. The average values of a are 41 MHz or 1.45 mT for $2^{\bullet+}$, and 87 Hz or 3.10 mT for $3^{\bullet+}$. Other signals associated with smaller couplings ($a < 13$ MHz or 0.46 mT) appear in the region from 9 to 22 MHz ($\nu_H \pm 1/2\,a$) for both radical cations. The assignment of these signals to more distant sets of equivalent protons is problematic. For information on the ENDOR technique: H. Kurreck, B. Kirste, W. Self-Assembly of a New Class of Tetranuclear Copper(I) and Silver(I) Complexes**

By *Raymond Ziessel** and *Marie-Thérèse Youinou**

Achieving spontaneous and selective formation of self-assembled systems is one of the major goals in supramolecular chemistry.[1, 2] Of recent interest is the formation of double- and triple-helical structures by complexation of two or three ligands twisted about metal ions lying on the helical axis.[3–5] It was recently demonstrated that one of the key points in the assembly of helicate structures is the subtle design of ligands with suitable spacers.[6] We have been particularly interested in the synthesis of oligomultidentate ligands in which the spacer groups are also capable of specific coordination of metal ions. To our knowledge, self-organization processes with ligands possessing two different types of complexation sites composed of a macrocyclic framework and complexing side-arms have not yet been studied. As a first step towards the specific complexation of different metal ions by a self-assembly process, we report herein on a novel ligand containing a bipyridine-based macrocycle with phenanthroline side-arms, and on the spontaneous formation of tetrameric copper(I) and silver(I) complexes of this hybrid ligand possessing double-helicate structures.

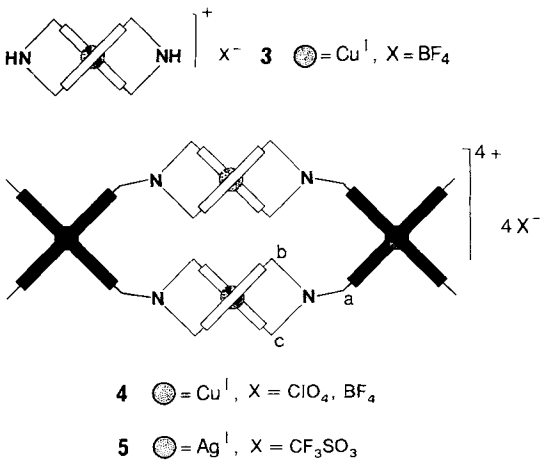
1 2

Ligand **2** was synthesized in 75% yield in a straightforward manner by reaction of 2-chloromethyl-9-methyl-1,10-phenanthroline[7] with macrocycle **1**[8] in anhydrous CH_3CN with triethylamine as base. 1,10-Phenanthroline (phen) groups were chosen as the pendant subunits since they favor specific binding with d^{10} metals and their rigidity serves to increase the stability of polymetallic systems. As expected, complexation of macrocycle **1** (1 equiv) with $[Cu(CH_3CN)_4]BF_4$ (1 equiv)[9] in degassed CH_2Cl_2/MeOH (1:1) under argon gave $[Cu(\mathbf{1})]BF_4$ (**3**) (Scheme 1; yield 67%, FAB^+-MS: m/z 456.9



3 ○ = Cu^I, X = BF_4

4 ○ = Cu^I, X = ClO_4, BF_4

5 ○ = Ag^I, X = CF_3SO_3

($M^+ - BF_4$), λ_{max} = 460.0 nm). In the ^1H NMR spectra of **3** in coordinating solvents such as $[D_3]$acetonitrile (oxygen-free), the broad signals observed can be explained in terms of a fast exchange process between ligand-coordinated Cu^I ions and solvated forms, for example, $[Cu(CH_3CN)_4]^+$; the equilibrium lies on the side of the ligated complex. This type of process does not occur in noncoordinating solvents such as CD_2Cl_2. Similar behavior was previously observed for flexible binuclear macrocyclic complexes.[10] The reaction of the novel ligand **2** with $[Cu(CH_3CN)_4]X$ (X = BF_4, ClO_4) in CH_3CN led instantaneously to an air-stable, deep-red complex which analyzed as the tetranuclear species $[Cu_4(\mathbf{2})_2]X_4$ (**4**) (Scheme 1, X = BF_4, yield 95%, FAB^+-MS: m/z 2128.4 ($M^+ - BF_4$), λ_{max} = 456.4 nm, ε = 11 800 L cm^{-1} mol^{-1}).

The well-defined ^1H NMR spectrum of **4** (Fig. 1 A) reveals that the two ligands **2** are equivalent and that the two halves of each ligand **2** are also equivalent. The signals of the methylene protons are split into three AB patterns (J_{AB} = 16.4, 11.3, 14.6 Hz; $\Delta\nu$ = 237.7, 191.1, 47.3 Hz) and shifted significantly upfield by $\Delta\delta \approx 1.5$ due to the shielding of either

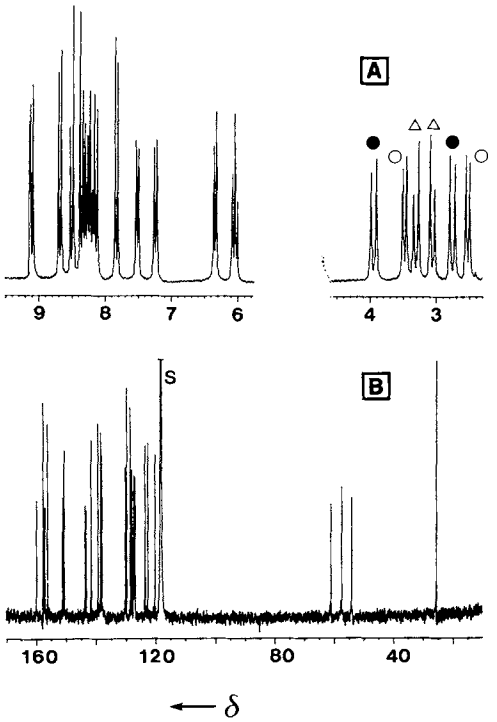

Fig. 1. NMR spectra of complex **4**, X = BF_4, in $[D_3]$acetonitrile. A) 200 MHz ^1H NMR; signals due to CH_3 and solvent molecules are omitted for clarity; Δ, ○, and ● denote the CH_2 AB systems. B) 50.3 MHz ^{13}C-{^1H} NMR (S = solvent).

the bpy or the phen subunits. The observation of the diastereotopic methylene protons (labeled a, b, c in Scheme 1) is certainly due to the chirality of the molecule,[4, 6] which is illustrated by the D_2-symmetric structure in Scheme 1. The ^{13}C NMR spectrum with its pattern of resonances including only 1 methyl, 3 methylene, and 22 signals of aromatic carbon atoms (Fig. 1 B) also confirms such a conclusion.

When a solution of **2** in CD_2Cl_2 was treated with successive aliquots (0.25 equiv) of $[Cu(CH_3CN)_4]BF_4$ in $[D_3]$acetonitrile, complex **4** formed spontaneously. Since this was the only species detected by ^1H NMR spectroscopy, even at a ligand to copper ratio of 2:1, this indicates a positive cooperativity in copper complexation, as previously observed in helicate formation.[11]

The X-ray structure analysis of the perchlorate derivative of **4**[12] shows that the complex contains $[Cu_4(\mathbf{2})_2]^{4+}$ ions and uncoordinated perchlorate ions. The structure of the complex cation is represented in Figure 2. The four coplanar copper(I) ions form a rhombus with sides of 7.133(2) Å and interior angles of 40.75(3)° and 139.25(5)°; two copper ions (Cu2 and Cu3) lie on the imposed C_2 axis of the molecule. Each copper(I) ion has distorted tetrahedral coordination. Cu1 (and Cu1′) is coordinated to four nitrogen atoms of two phen subunits belonging to two distinct ligands, whereas Cu2 and Cu3 are coordinated to nitrogen atoms of two bpy units of the same macrocycle. Each ligand wraps around two crystallographically independent copper(I) ions, and not surprisingly, the coordination about Cu1 and Cu3 have different distortions as a result of geometric demands of the macrocycle and the phen subunits (Fig. 2 A). As required by the C_2 symmetry of the structure, the phen subunits are arranged in a *cis* fashion, and the two bpy moieties of each macrocycle form a cross at Cu2 and Cu3, as represented in Scheme 1. The overall structure is best described as a double-stranded helicate (Fig. 2 B), as already suggested by the NMR data. However, in the solid state, a lowering of the symmetry of

Selected distances [Å] and angles [°]: Cu1-Cu2 and Cu1-Cu3 7.133(2), Cu2-Cu3 4.966(3), Cu1-Cu1′ 13.372(3), Cu1-N1 2.03(1), Cu1-N2 2.017(9), Cu1-N6 2.05(1), Cu1-N7 1.999(9), Cu2-N9 and Cu2-N9′ 2.023(9), Cu2-N10 and Cu2-N10′ 2.174(9), Cu3-N4 and Cu3-N4′ 2.00(1), Cu3-N5 and Cu3-N5′ 2.24(1); Cu3-Cu1-Cu2 40.75(3), Cu1-Cu2-Cu1′ 139.25(5); N1-Cu1-N2 82.7(4), N6-Cu1-N7 83.3(4), N1-Cu1-N6 131.7(4), N2-Cu1-N7 134.6(4), N1-Cu1-N7 115.5(4), N2-Cu1-N6 116.4(4), N9-Cu2-N9′ 153.0(5), N10-Cu2-N10′ 142.0(5), N9-Cu2-N10′ and N9′-Cu2-N10 79.3(4), N9-Cu2-N10 and N9′-Cu2-N10′ 109.7(4), N4-Cu3-N4′ 159.8(6), N5-Cu3-N5′ 140.0(5), N4-Cu3-N5′ and N4′-Cu3-N5 78.6(4), N4-Cu3-N5′ and N4′-Cu3-N5 108.5(4). B) View of the cation in **4** showing the double-stranded helicate.

complex **4** is observed, although the symmetrical Cu_4 core is still maintained. The macrocyclic spacer (bpy · bpy) seems to favor self-assembly as long as the stereochemical demands of the Cu^I ions are satisfied. As recently described by one of us,[13] very few complexes are known in which four copper atoms each possessing a tetrahedral geometry are in a planar arrangement.[14]

The synthetic method that led to **4** was used in the preparation of the tetranuclear silver(I) complex. Mixing $AgCF_3SO_3$ (2 equiv) with ligand **2** (1 equiv) in CH_3CN/CH_2Cl_2 solution gave, after workup, white crystals of complex **5** (yield 70%, FAB^+-MS: m/z 2491.1 ($M^+ - CF_3SO_3$)). In the ^1H NMR spectrum three distinct AB patterns due to the CH_2 groups with upfield shifts of $\Delta\delta \approx 1.6$ are observed ($J_{AB} = 13.0, 15.1, 14.6$ Hz; $\Delta\nu = 14.1, 42.2, 199.7$ Hz) in analogy to complex **4**. Consequently a double-helical structure is also proposed for complex **5**. Physicochemical studies are currently in progress in order to gain more insight into this unusual self-assembly process.

Experimental Procedure

The synthesis and characterizations of **2** will be fully reported in due course.

Complex **4**, X = BF_4: To a stirred solution of macrocycle **2** (0.100 g, 0.124 mmol) in 15 mL anhydrous CH_2Cl_2 was added a solution of $[Cu(CH_3CN)_4]BF_4$ (0.081 g, 0.260 mmol) in 15 mL anhydrous CH_3CN at room temperature and under argon. During the addition the color of the solution instantaneously turned deep-red, indicating fast Cu^I complexation. After 12 h the solution was filtered over celite and evaporated to dryness. Slow diffusion of THF into a solution of the perchlorate salt in CH_3CN provided crystals of **4** suitable for X-ray analysis. (Yield for X = BF_4 95%.) UV/Vis (CH_3CN) λ_{max} [nm] (ε) = 456.4 (11800), 274.1 (117000), 225.8 (128800); ^1H NMR (200.1 MHz, [D$_3$]acetonitrile, 25 °C): δ = 9.10 (d, 4H, ^3J(H,H) = 8.4 Hz), 8.68 (d, 4H, ^3J(H,H) = 8.3 Hz), 8.50 (d, 4H, ^3J(H,H) = 8.9 Hz), 8.35 (d, 4H, ^3J(H,H) = 8.9 Hz), 8.28 (d, 4H, ^3J(H,H) = 7.5 Hz), 8.22 (t, 4H, ^3J(H,H) = 7.5 Hz), 8.13 (d, 4H, ^3J(H,H) = 8.4 Hz), 7.82 (d, 4H, ^3J(H,H) = 8.3 Hz), 7.51 (d, 4H, ^3J(H,H) = 7.2 Hz), 7.24 (d, 4H, ^3J(H,H) = 7.9 Hz), 6.34 (d, 4H, ^3J(H,H) = 7.5 Hz), 6.04 (t, 4H, ^3J(H,H) = 7.8 Hz), 3.35 (ABq, 8H, J_{AB} = 16.4 Hz, $\Delta\nu$ = 237.7 Hz), 3.19 (ABq, 8H, J_{AB} = 14.6 Hz, $\Delta\nu$ = 47.3 Hz), 3.00 (ABq, 8H, J_{AB} = 11.3 Hz, $\Delta\nu$ = 191.1 Hz), 2.19 (s, 12H); ^{13}C-{^1H} NMR (50.3 MHz, [D$_3$]acetonitrile, 25 °C): δ = 159.89, 157.68, 157.11, 156.25, 151.18, 150.70, 143.68, 143.35, 141.63, 139.38, 138.46, 138.05, 130.15, 129.75, 128.50, 128.03, 127.40, 127.13, 126.91, 123.57, 122.62, 120.19, 61.07, 57.45, 54.11, 25.48; MS (FAB^+ in mNBA (*meta*-nitrobenzyl alcohol) matrix): m/z 2128.4 ($M^+ - BF_4$, expected isotopic profile), 2041.1 ($M^+ - 2BF_4$), 1953.7 ($M^+ - 3BF_4$), 1021.1 ($M^{2+} - 2BF_4$), 933.1 ($M^+ - 2 - 2Cu - 4BF_4$), 869.3 ($M^+ - 2 - 3Cu - 4BF_4$), 725.1 ($M^+ - 2 - 4Cu - 4BF_4$), 661.1 ($M^+ - 2 - phen - 4Cu - 4BF_4$); MS (Electrospray ($ES^+$) in H_2O/CH_3CN 1:1, grammicidin as internal standard: m/z 1020.2 (2(**2**) + 2Cu + BF_4), 869.8 (2(**2**) + 2Cu), 651.9 (2(**2**) + 4Cu + BF_4), 467.1 (2(**2**) + 4Cu); correct C,H,N-analysis for $[C_{104}H_{84}N_{20}Cu_4](BF_4)_4$ (M_r = 2215.30).

Complex **5**: To a stirred solution of macrocycle **2** (0.100 g, 0.124 mmol) in 25 mL anhydrous CH_2Cl_2 was added a solution of $AgCF_3SO_3$ (0.080 g, 0.311 mmol) in 5 mL anhydrous CH_3CN at room temperature. After 8 h the solution was filtered over celite and evaporated to ca. 2–3 mL. Slow diffusion of Et_2O into the solution led to a white precipitate, which after recrystallization from CH_2Cl_2/hexane afforded complex **5** as light-sensitive microcrystals (yield 70%). UV/Vis (CH_3CN): λ_{max} [nm] (ε) = 302 (sh, 20700), 278.1 (52400), 231.3 (54000); ^1H NMR (200.1 MHz, [D$_3$]acetonitrile, 25 C): δ = 8.53 (d, 4H, ^3J(H,H) = 8.3 Hz), 7.99 (d, 4H, ^3J(H,H) = 8.3 Hz), 7.83 (d, 8H, ^3J(H,H) = 4.6 Hz), 7.72 (d, 4H, ^3J(H,H) = 8.9 Hz), 7.66 (d, 8H, ^3J(H,H) = 8.3 Hz), 7.60 (d, 4H, ^3J(H,H) = 7.1 Hz), 7.47 (d, 4H, ^3J(H,H) = 8.9 Hz, 7.38 (t, 4H, ^3J(H,H) = 4.6 Hz), 6.73 (d, 8H, ^3J(H,H) = 8.1 Hz), 3.99 (ABq, 8H, J_{AB} = 13.0 Hz, $\Delta\nu$ = 14.1 Hz), 3.58 (ABq, 8H, J_{AB} = 15.1 Hz, $\Delta\nu$ = 42.2 Hz), 3.02 (ABq, 8H, J_{AB} = 14.6 Hz, $\Delta\nu$ = 199.7 Hz), 3.00 (s, 12H); ^{13}C-{^1H} NMR (50.3 MHz, [D$_3$]acetonitrile, 25 °C): δ = 160.67, 160.34, 157.36, 155.99, 151.41, 151.07, 143.84, 143.02, 140.65, 140.04, 139.58, 138.03, 128.12, 127.37, 126.97, 126.12, 125.82, 125.02, 124.21, 123.78, 121.41, 121.12, 66.71, 63.87, 63.09, 28.18. MS (FAB^+ in mNBA as matrix): m/z 2493.1 ($M^+ - CF_3SO_3$, expected isotopic profile), 2344.1 ($M^+ - 2CF_3SO_3$), 2195.1 ($M^+ - 3CF_3SO_3$), 1171.0 ($M^{2+} - 2CF_3SO_3$), 1024.4 ($M^+ - 2 - 2Ag - 4CF_3SO_3$); MS ($ES^+$ in H_2O/CH_3CN 1:1): m/z 1171.9 (2(**2**) + 4Ag + $2CF_3SO_3$), 511.1 (2(**2**) + 4Ag), 707.2 (**2** − phen + Ag), 407.0 (2(**2**) − 2phen + 4Ag); correct C,H,N-analysis for $[C_{104}H_{84}N_{20}Ag_4](CF_3SO_3)_4$ (M_r = 2641.62).

Controlling Valence Tautomerism of Cobalt Complexes Containing the Benzosemiquinone Anion as Ligand**

By *David M. Adams, Andrea Dei, Arnold L. Rheingold,* and *David N. Hendrickson**

Several different types of transition metal complexes are electronically labile, where electronic degeneracy or near-degeneracy leads to vibronic interactions and an appreciable sensitivity to the environment. Electronic lability is characteristic of mixed-valence,[1] spin-crossover,[2] and valence-tautomeric[3] metal complexes. Electronically labile complexes have been indicated as potential building blocks for molecular electronic devices.[4] Small collections of these molecules could be expected to exhibit bistability; thus, as a result of an external perturbation they could be made to flip-flop between two states. In fact, polycrystalline samples of Fe^{II} spin-crossover complexes have been shown to exhibit bistability in the LIESST (light-induced excited spin state trapping) effect discovered by Gütlich et al.[5] When a polycrystalline spin-crossover complex is maintained at low temperatures (< 50 K), the whole crystalline sample can be interconverted between the stable low-spin state and the metastable high-spin state with photons of different wavelengths. The metastable high-spin state will remain indefinitely as long as the sample is kept below about 50 K. In this paper we will show that thermally driven bistability is possible for cobalt complexes that exhibit valence tautomerism.

Complexes of transition metal ions with the benzosemiquinone and catecholate anions as ligands have been described in terms of localized bonding.[3] One of the most intriguing aspects of these complexes is the thermally driven valence tautomerism that has been observed for some complexes in solution.[6] One cobalt complex[6] exists in solution in two valence tautomeric forms [Eq. (a)]. One complex consists of

$$[Co^{II}(bpy)(3,5\text{-dtbsq})_2] \rightleftharpoons [Co^{III}(bpy)(3,5\text{-dtbsq})(3,5\text{-dtbcat})] \quad (a)$$

Co^{II} with two benzosemiquinonate anions (3,5-dtbsq$^-$ = 3,5-di-*tert*-butylbenzosemiquinone anion) as ligands and a 2,2′-bipyridine (bpy) ligand, and the other of Co^{III} with one dtbsq and one catecholato (3,5-dtcat^{2-}) ligand. The room-temperature X-ray structure[6] of [Co^{III}(bpy)(3,5-dtbsq)-(3,5-dtbcat)] shows that the ligands are in two different oxidation states and that the metal is trivalent. In order to see if these valence tautomeric complexes exhibit bistability, we systematically changed the bipyridine ligand to other diiminium ligands. The goal was to find a compound that exhibits the $Co^{II} \leftrightarrow Co^{III}$ tautomeric transformation in the solid state.

A series of complexes with the composition [Co($\overset{\frown}{N\,N}$)(3,5-dtbsq)("3,5-dtbq")], where "3,5-dtbq" is either the benzosemiquinone anion or catecholate form of the ligand and the $\overset{\frown}{N\,N}$ diiminium ligand is 4,4′-diphenyl-2,2′-bipyridine (dpbpy), 4,4′-dimethyl-2,2′-bipyridine (dmbpy), 1,10-phenanthroline (phen, complex **1**), 2,2′-bipyrimidine (bpym), or 2,2′-bipyrazine (bpz, complex **2**), was prepared. Magnetic susceptibility

[Co(phen)(3,5-dtbsq)$_2$] **1** [Co(bpz)(3,5-dtbsq)$_2$] **2**

data for polycrystalline samples of the dpbpy, dmbpy, and bpy complexes show that they are Co^{III} complexes with one unpaired electron on the dtbsq ligand (μ_{eff} is 1.83–2.12 μ_B in the 100–300 K range). On the other hand, the phen, bpym, and bpz complexes have μ_{eff} values of 5.17, 5.03, and 4.38 μ_B, respectively, at 300 K. These three complexes are clearly [Co^{II}($\overset{\frown}{N\,N}$)(3,5-dtbsq)$_2$] complexes at 300 K in the solid state.

X-ray crystal structures were determined at 238 K for **1** · ($C_6H_5CH_3$)[7] and at 296 K for **2**.[8] Complex **2** has C_2 symmetry, in which the two equivalent dtbsq ligands have Co–O bond lengths of 2.046(4) and 2.057(4) Å, and Co–N distance is 2.130(4) Å. This is clearly a high-spin Co^{II} complex with two dtbsq ligands. For comparison, the Co–O bond lengths for the Co^{III} complex [Co(bpy)(3,5-dtbsq)(3,5-dtbcat)] range from 1.851(6) to 1.906(6) (Å) with Co–N lengths of 1.940(7) and 1.957(7) Å.[6] The fact that this bipyridine complex is a Co^{III} complex was established[6] by the bond lengths in the ligands, the presence of an intervalence charge-transfer electronic absorption band in the near-IR region associated with the mixed-valence ligand structure, and the observation of a relatively isotropic EPR signal for an organic radical. The X-ray structure of the phen complex **1** is shown in Figure 1. The two dtbsq ligands are not related by symmetry; the Co–O bond lengths of one are 2.004(4) and 2.011(4) Å and of the other are 2.002(4) and 1.987(4) Å. These values together with the average Co–N bond length (2.082 Å) suggest that **1** is intermediate between the Co^{II} and Co^{III} forms at 238 K. The values of C–O bond lengths for *o*-quinone-derived ligands are known[3] to reflect the oxidation state of the ligand: 1.29(1) Å for a coordinated benzosemiquinone anion and 1.35(1) Å for a catecholate ligand. In the case of the phen complex, one ligand has C–O lengths of 1.291(8) and 1.294(8) Å, and the other 1.302(7) and 1.305(7) Å. These two ligands appear to be dtbsq ligands. Perhaps at 238 K the phen complex has converted from high-spin Co^{II} into low-spin Co^{II}, and at lower temperatures it will finally experience the tautomeric shift to a Co^{III} complex.

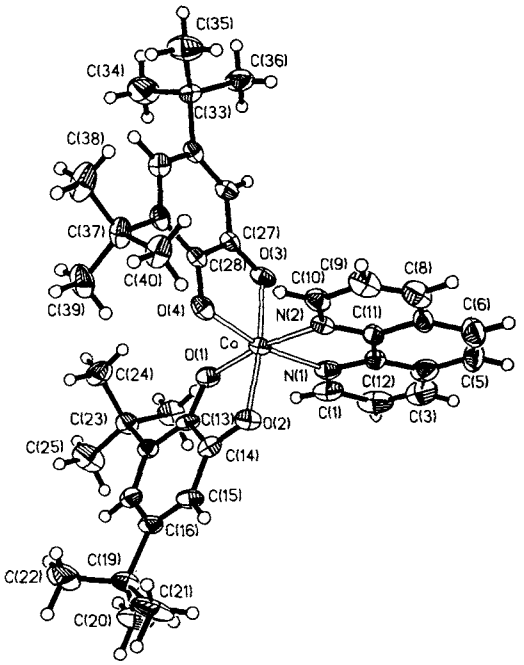

Fig. 1. Structure of $1 \cdot (C_6H_5CH_3)$ with atom labeling scheme. The toluene solvate molecule is not shown.

In the [Co(N N)(3,5-dtbsq)("3,5-dtbq")] series, three of the complexes are Co^{II} and three are Co^{III} tautomers in the solid state at room temperature. The variation in properties is understandable in view of the changes in reduction potentials[9] for the series of diiminium ligands: −2.40 V (dmbpy); −2.18 V (bpy); −2.04 V (phen); −1.80 (bpym); and −1.70 V (bpz). If the ligand is more easily reduced (i.e., has a more positive reduction potential), it can stabilize the Co^{II} form of the complex by accepting electron density into its π^* orbital. Variable-temperature electronic absorption spectra (320–820 nm) were run for all of the complexes dissolved in toluene. In solution they all show temperature-dependent spectra that indicate the presence of the valence tautomerism equilibrium as in Equation (a). The temperature dependence

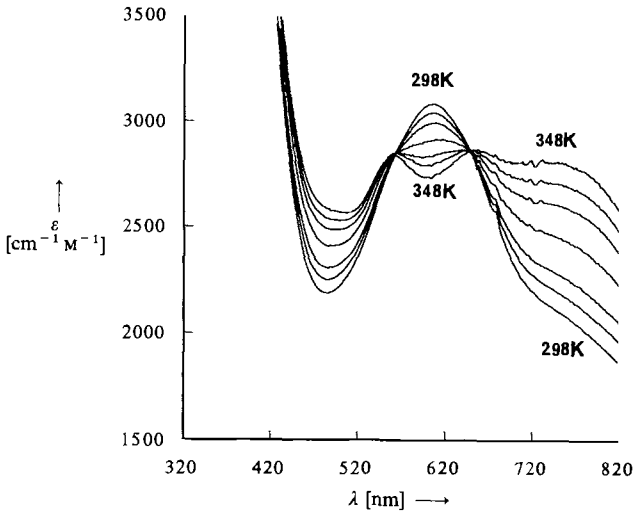

Fig. 2. Temperature dependence of the electronic absorption spectrum of a toluene solution of [Co(dpbpy)(3,5-dtbsq)(3,5-dtbcat)]; at $T = 298$, 303, 308, 318, 328, 338, and 348 K. The molar extinction coefficient ε is plotted versus wavelength λ.

of the electronic spectrum of [Co(dpbpy)(3,5-dtbsq)(3,5-dtbcat)] in toluene is shown in Figure 2. At room temperature there is a band at about 600 nm, which is characteristic of the Co^{III} form of the complex. As the temperature is increased to 333 K a band at about 770 nm increases in intensity; this band belongs to the Co^{II} form of the complex. The temperature at which there is approximately equal amounts of Co^{II} and Co^{III} complexes correlates well with the variation in redox potential of the diiminium ligand.

It is more difficult to find a complex which exhibits the valence tautomeric transformation in the solid state. We have now found the first example. In Figure 3 are shown magnetic susceptibility data for a polycrystalline sample of the cobalt–phen complex **1**. At low temperatures (< 200 K)

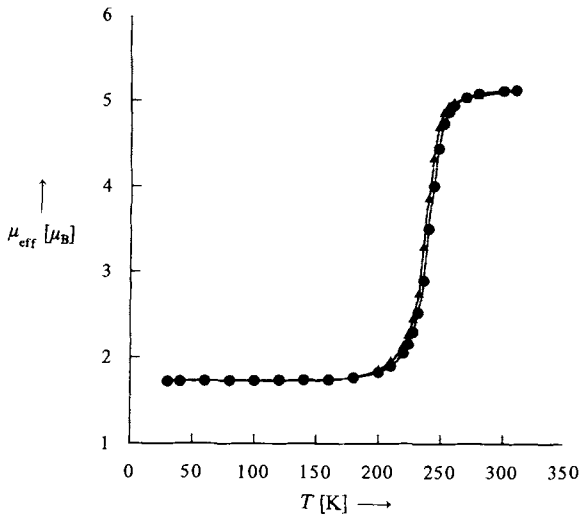

Fig. 3. Plot of effective magnetic moment per molecule μ_{eff} versus temperature T for a polycrystalline sample of $1 \cdot (C_6H_5CH_3)$. The sample was first cooled to 30 K, and measurements were carried out as T was increased (●). After the measurement was completed at 320 K, data were collected (▲) as the sample T was decreased to 30 K.

μ_{eff}/molecule is 1.7 μ_B, whereas above about 270 K the value is 5.1 μ_B. This complex undergoes a relatively abrupt transformation centered around approximately 240 K, which explains why the X-ray structure was done at 238 K. Thus, this complex is [Co^{III}(phen)(3,5-dtbsq)(3,5-dtbcat)] below 200 K and converts into [Co^{II}(phen)$(3,5\text{-dtbsq})_2$] above about 270 K. It is important to emphasize that it is very necessary to have the toluene solvate molecule present, for without it the complex does not undergo the transformation. The sensitivity to solvate molecules observed for this valence-tautomeric transformation is reminiscent of solvate sensitivities observed for spin-crossover[2] and mixed-valence[11] complexes.

The transformation seen for the Co–phen complex **1** (Fig. 2) is so abrupt that it probably involves a phase transition, which is somewhat substantiated by the small (ca. 5 K) hysteresis measured (see Fig. 3). The valence-tautomeric transformation $Co^{II} \rightarrow Co^{III}$ is entropy driven. At low temperatures in the Co^{III} complex an $S = 1/2$, ground state is thermally populated, whereas at high temperatures in the Co^{II} complex one $S = 5/2$, one $S = 1/2$, and two $S = 3/2$ states are thermally populated, because of weak Co^{II}–dtbsq exchange interactions.[10] Not only is there electronic entropy gain associated with the Co^{III}-to-Co^{II} conversion, but as the energy of the vibrations for the CoO_4N_2 modes in the

Co^{II} complex is higher, there is also a vibrational entropy gain. Efforts are ongoing to prepare several more complexes that exhibit the valence-tautomeric transformation in the solid state.

Experimental Procedure

The synthesis of [Co(phen)(3,5-dtbsq)$_2$] is given as a general scheme for preparation of cobalt complexes containing benzosemiquinone anions as ligands. All reactions were carried out under an inert atmosphere of Ar in Schlenkware with degassed reagent-grade solvents (Aldrich). The starting tetramer [Co$_4$(3,5-dtbsq)$_8$] was prepared by a published procedure [11], and a portion (0.646 g) suspended in 100 mL of methylcyclohexane. This reactant and the ligand phen (0.220 g in 100 mL of methylcyclohexane) were dissolved in their separate solutions by heating to 100 °C. The phen solution was then added dropwise over 30 min to the tetramer solution. After half the solution had been added, a purple microcrystalline precipitate was visible. After the addition was complete, the solution was stirred for an additional 30 min at 100 °C. Upon cooling, 0.700 g of a purple microcrystalline solid was filtered off. This solid was recrystallized by dissolving 0.200 g in 100 mL of toluene, filtering hot, and then slowly evaporating the solution under a steady flow of N_2 gas. All cobalt complexes gave good chemical analyses for C, H, N, and Co.

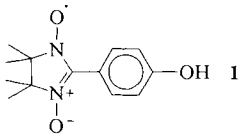
Hydrogen Bonds as a Crystal Design Element for Organic Molecular Solids with Intermolecular Ferromagnetic Interactions**

By *Esteve Hernàndez, Montse Mas, Elies Molins, Concepció Rovira*, and *Jaume Veciana**

Ferromagnetism in purely organic molecular solids has attracted considerable interest in the last few years.[1] Up to now, only three open-shell organic molecules—free radicals or radical ions—exhibiting such a magnetic property in the solid state are known.[2] In order to obtain this cooperative property it is necessary not only to choose suitable open-shell molecules but also to orient them properly relative to each other in a three-dimensional network, because ferromagnetism is a three-dimensional phenomenon.[3] In these supramolecular organizations, the correct electronic mechanisms that give rise to the parallel, or ferromagnetic (FM), spin alignment between neighboring molecules along three (or two) directions of space must be established.[4] Appropriate structural modifications and chemical functionalizations of stable open-shell molecules represent a promising approach to supramolecular organizations[5] in which the natural predilection for antiparallel, or antiferromagnetic (AF), spin alignment is avoided.[1, 4] In fact, the use of *crystal design elements* provides one of the most direct ways to control the relative orientations of molecules[6] and, therefore, of their electronic interactions in crystalline and noncrystalline solids.[7] Hence, basic studies devoted to the control of crystal packings and, through them, the magnetic properties of organic molecular solids are in great demand.[5]

We report here an example of the nitronyl nitroxide free radical **1**,[8] in which hydrogen bonds have been used for the first time as a crystal design element to obtain a crystalline supramolecular organization showing intermolecular ferromagnetic interactions.



1

The study of the radical **1** seemed promising, because this compound combined a priori most of the structural and electronic prerequisites to show at least a short-range FM ordering of hydrogen-bonded molecules: 1) semiempirical molecular orbital (MO) calculations revealed strong electronic polarizations of NO and OH bonds ($N^{+0.09}$–$O^{-0.34}$ and $O^{-0.27}$–$H^{+0.24}$),[9] indicating that the NO groups could act as acceptors and the OH group as a donor in hydrogen bonds; 2) the noncollinear relative orientation of NO and OH groups, together with the strong directionality usually observed for hydrogen bonds,[7] could favor the formation in the solid state of a hydrogen-bonded network with a high dimensionality, and 3) MO calculations based on the UHF approximation[9] showed that **1** fulfilled most of the electronic requirements that were considered relevant for the

attainment[10] of FM couplings in molecular solids, either through the so-called McConnell I mechanism or the charge transfer mechanism involving frontier orbitals.[4, 11, 12]

Radical **1** was prepared by the reported method and was crystallized from toluene.[13] An X-ray structure determination revealed that it crystallizes with two crystallographically independent molecules A and B in the asymmetric unit, which are almost identical in structure (Fig. 1).[14] The

phenyl rings in both molecules are almost coplanar with the OH groups, but form angles of 32.7(1) and 33.6(2)° with the plane of the α-nitronyl nitroxide O-N-C-N-O grouping. The crystal packing of radical **1** is shown in Figure 2. Unexpectedly only one of the two NO groups forms strong hydrogen bonds with the OH groups of neighboring molecules.[15] Such hydrogen bonds exist between molecules with identical conformations and give rise to zigzag chains along the a axis (see Fig. 2a). Each one of these chains meshes with the translationally related chains along the b axis. The meshing occurs through interactions between the O atoms of the free NO groups of one chain and the H atoms belonging to vicinal CH_3 groups of neighboring chains. Such C-H···O interactions have the crystallographic requirements to be considered as weak hydrogen bonds.[7] Moreover, spectroscopic evidence supports this description.[15] Thus, two-dimensional hydrogen bonded networks, parallel to the ab plane, are present in the crystal structure of **1** (see Fig. 2a). Such 2-D networks are, in addition, closely packed along the c axis with intermolecular contacts ranging from 3.5 to 4.0 Å (see Fig. 2b). The most relevant feature observed from all the short contacts of this densely packed structure is the absence of significant intermolecular overlaps between SOMOs, which are usually considered responsible for AF interactions in molecular solids.[4, 12] In fact, both within and between the 2-D molecular sheets only short contacts that are generally claimed as the origin of intermolecular FM interactions are observed.[16] Therefore, these local structural features suggest the possibility of FM interactions with distinct intensities along the three spatial axes.

The presence of three-dimensional magnetic interactions in **1** was supported by single-crystal electron spin resonance (ESR) experiments at room temperature. These experiments showed an exchange-narrowed single line with a pure Lorentzian line shape whatever the orientation of the crystal. This behavior is characteristic of exchange coupling in 3-D spin systems.[17] Static magnetic susceptibility data were collected on a SQUID magnetometer in the $1.8 \leq T \leq 250$ K temperature range at an applied magnetic field of 10 kOe for a 20 mg sample consisting of several crystals of **1**. Paramagnetic susceptibilities are shown in Figure 3. Above 5 K, the data obey the Curie–Weiss law, $\chi_p = C/(T-\theta)$, where $C = 0.379$ emu K mol^{-1} and $\theta = +0.8$ K. The high temperature value of $\chi_p T$ (0.37 emu K mol^{-1}) is close to that expected (0.376) for noninteracting $S = 1/2$ units, with $g = 2.006$. Below 50 K, $\chi_p T$ increases continuously with decreasing temperature, reaching 0.48 emu K mol^{-1} at 1.8 K. Such a large value is a clear indication of the existence of intermolecular FM interactions in **1**. Below 5 K, paramagnetic susceptibility data gradually deviate downwards from the Curie–Weiss curve (Fig. 3a) extrapolated from the data at high temperatures. A much better fit of the experimental data is obtained over the whole temperature range of 1.8–250 K with the theoretical curve (Fig. 3a) calculated from the ferromagnetic 1-D Heisenberg model[18] with an intrachain coupling of $J/k = +0.49$ K and $S = 1/2$. Therefore, this result suggests that the FM coupling within a chain is dominant. Unfortunately, the rest of the magnetic interactions in this spin system are too weak to be observable at temperatures higher than 1.8 K with this static technique.

The field dependence of the magnetization of **1** is also shown in Figure 3 at several temperatures, together with the theoretical curve for an ideal paramagnet with $S = 1/2$ and $g = 2.006$. It is clear that radical **1** magnetizes more rapidly than an ideal paramagnet and also that the magnetization curve is steeper when the temperature is lowered. This is

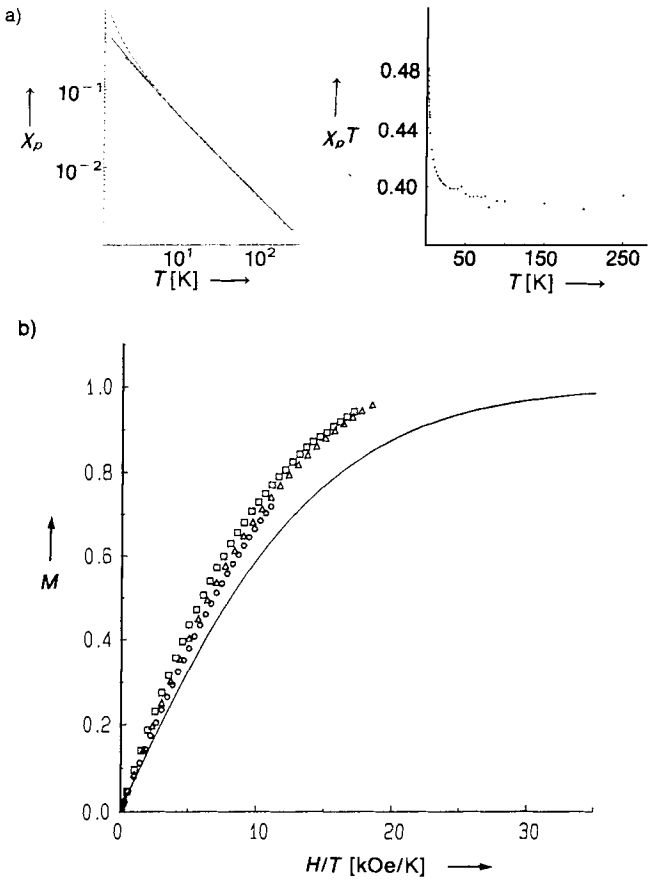

Fig. 3. a) Left: Temperature dependence of the paramagnetic susceptibility χ_p [emu mol^{-1}] of **1**. The dashed line represents the fit of the experimental data (see the text) to the Curie–Weiss law and the solid line the fit to the ferromagnetic 1-D Heisenberg model. Right: The plot of the product χ_pT[emu kmol^{-1}] versus T. b) Field dependence of the magnetization M [μ_B per molecule] of **1** at 2 (□), 3 (△), and 5 (○) K, measured in the applied magnetic field range $0.1 \leq H \leq 55$ kOe.

further evidence of the presence of intermolecular FM interactions in this spin system, which is in full agreement with the susceptibility results. The magnetic behavior described above is very similar to that recently reported for the β phase of an analogous nitronyl nitroxide bearing NO_2 substituents instead of the OH groups, which undergoes a transition to a bulk ferromagnetic ordered state below 0.65 K.[2a, 19] It is therefore important to extend the magnetic measurements with **1** at low temperatures to the mK region in order to determine the nature of all the operative intermolecular magnetic interactions and to check whether a long-range ferromagnetic ordering occurs. Such experiments are in progress.

We have shown above that the establishment of hydrogen bonds between open-shell molecules is a suitable strategy for preparing molecular solids with a high dimensional organization. Our work culminated in a case where ferromagnetic intermolecular interactions have been achieved.

A Two-Dimensional Ice with the Topography of Edge-Sharing Hexagons Intercalated between $CdNi(CN)_4$ Layers

By *Ki-Min Park, Reiko Kuroda,* and *Toschitake Iwamoto**

The topography of two-dimensional ice, that is, a two-dimensional network of H_2O molecules in the solid state, is related to the connection mode for O atoms participating in the network. The hydrogen-bonded network of the H_2O

[*] Prof. Dr. T. Iwamoto, Dr. K.-M. Park, Prof. Dr. R. Kuroda,

molecules in $Cd(H_2O)_2Ni(CN)_4 \cdot 4H_2O$ (**1**) consists of edge-sharing hexagons whose corners are three-connected O atoms, as has been revealed in its single-crystal structure. There are more H atoms than can be accounted for in the full formation of hydrogen bonding in the network.

A number of 2D ice-like networks have been found in "2D hydrates" or "hydrate intercalation compounds" with specific topography.[1] Typical networks seen for organic hydrates comprise edge-sharing pentagons enclosing diols or amines as guests:[2] the puckered edge-sharing pentagons in $(CH_3)_2C(OH)(CH_2)_2C(OH)(CH_3)_2 \cdot 4H_2O$[2d] consist of H_2O molecules and OH groups of the diol in a 2:1 ratio; the three- and four-connected O atoms (in a 2:1 ratio) form a hydrogen-bonded network in which all H atoms participate. In $[N(C_3H_7)_4]F \cdot 11H_2O$ both O and F atoms are at four-connected centers in the 2D network built of H_2O and F^- ions.[3] When a network of edge-sharing hexagons is built of H_2O molecules only, the O atoms should be three-connected, which leaves one of the H atoms or lone pairs out of the network formation at every O atom. The network in **1** has this type of 2D structure. The free protons and/or lone pairs may be expected to show the characteristic behavior of proton or electron transfer along the 2D network. Although the ligating and intercalated H_2O molecules in $[SnCl_2(H_2O)] \cdot H_2O$[4] appear to form a 2D network of edge-sharing tetragons and octagons whose corners are three-connected O atoms, the distance between the corners of the tetragons, that is, an edge of the octagon, is rather long (3.02(5) Å) for the hydrogen bond between two H_2O molecules.

Pale yellow single crystals of **1** were obtained unexpectedly from an aqueous solution containing $CdCl_2$, $K_2[Ni(CN)_4]$ and pn (1,2-diaminopropane), in an attempt to prepare the inclusion compound $[Cd(pn)Ni(CN)_4] \cdot 0.5$ guest.[5] As shown in Figure 1, the crystal has a double layer structure in

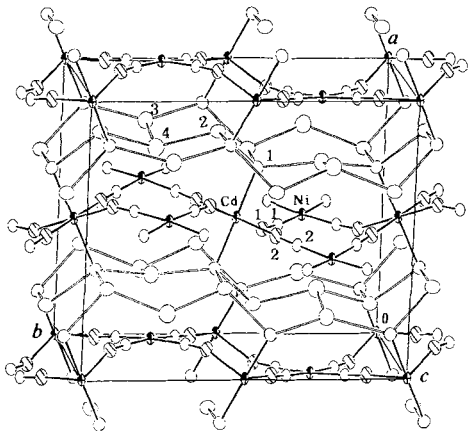

Fig. 1. A perspective view of $Cd(H_2O)_2Ni(CN)_4 \cdot 4H_2O$ along the *c* axis (50% probability for thermal ellipsoids whose sections are shown for Cd and Ni). The atomic numbering for C, N (hatched) and O is indicated by numeral only; the sequences are C2-N2-Cd-N1-C1-Ni for the metal complex network and Cd-O1-O2-O4-O3 for the water network. Atomic coordinates *x/a*, *y/b*, *z/c*: Cd, 0.5, 0.5, 0.5; Ni, 0.4335(1), 0.25, 0.0115(2); N1 0.4254(6), 0.3984(5), 0.2978(9); N2 0.4720(6), 0.3977(5), 0.7290(9); C1 0.4252(6), 0.3415(5), 0.1883(9); C2 0.4559(6), 0.3414(5), 0.8364(9); O1 0.6708(5), 0.4343(4), 0.4285(8); O2 0.8205(5), 0.5695(5), 0.5466(9); O3 0.7879(9), 0.75, 0.064(1); O4 0.7467(9), 0.75, 0.442(1).

which the puckered networks of $[CdNi(CN)_4]_\infty$ and of H_2O molecules are stacked alternately along the crystal's *a* axis.[6] The network of $[CdNi(CN)_4]_\infty$ extending along the *bc* plane is very similar to those observed for the host structures of $Cd[NH_2(CH_2)_nNH_2]Ni(CN)_4 \cdot x$ guest clathrates.[7]

Two H_2O molecules coordinate *trans* to each other at the Cd atom in the metal complex sheet; each of them participate in the hydrogen-bonded network of H_2O molecules intercalated between the sheets. As shown in Figures 1 and 2,

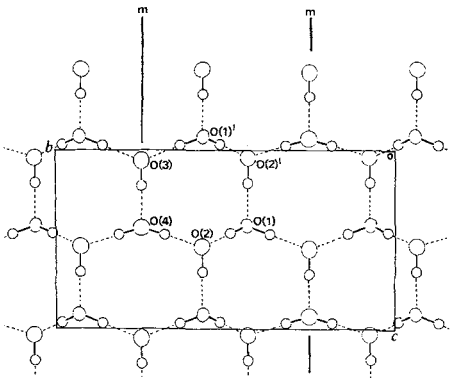

Fig. 2. Proposed hydrogen-bonding scheme for water molecules in edge-sharing H_2O hexagons extending along *bc* plane at $a \approx 3/4$. Positions of H atoms have been tentatively assigned according to the symmetry elements of the *Pnma* space group. O1' and O2' are generated by a 2_1 rotation followed by a translation of $-c/2$. m = mirror plane.

there are four kinds of crystallographically independent O atoms for the six water molecules in the formula unit: O1, the ligating oxygen, and O2 are on general positions, and O3 and O4 are on the mirror plane at $b = 3/4$. These O atoms are arranged with the usual O···O distances for hydrogen bonding from 2.821(9) to 2.86(2) Å, to form puckered networks of edge-sharing boat-shaped hexagons along the *bc* plane at $a \approx 1/4$. Those O-O-O angles bisected by the mirror plane at O3 (133.7(4)) and O4 (130.0(5)°) are considerably larger than the tetrahedral angle, whereas the others are within the range of 107.4(3) to 113.8(3)°. Viewed along the *a* axis, the hexagon with the larger angles is surrounded by six other smaller hexagons. A similar puckered network of edge-sharing boat-shaped hexagons is seen in the *ac* plane of hexagonal ice (I_h).

Since each edge of the edge-sharing hexagons is an O–H···O hydrogen bond, the structure requires nine of the H atoms and lone pairs of six H_2O molecules to participate in the hydrogen bond formation. There are, however, twelve H atoms and twelve lone pairs in total, of which two lone pairs are used in coordination bonds to the Cd atoms. If both H atoms of the ligating O1 participate in the hydrogen bond formation in the network, nine H atoms and nine lone pairs can be tentatively assigned according to the symmetry elements of the *Pnma* space group as shown in Figure 2. Three H atoms and one lone pair remain still unassigned.

The Ni–O3 distance of 2.81(1) Å suggests that a H atom on O3 is directed toward the $3d_{z^2}$ occupied orbital of the Ni^{2+} ion; the angles about O3 are not unreasonable for such an arrangement. A lone pair directed toward this center appears less probable because of the π-electron-rich environment in the vicinity of the Ni^{2+} ion coordinated to four CN^- ligands. The angles about O2 indicate that a H atom on O2 may be directed toward the opening in the mesh of the cyanometal complex network. Unfortunately we were unable to assign any signals in the final difference Fourier syntheses with highest electron density of 0.6 e $Å^{-3}$ to H atoms.

The puckered network of water molecules appears to be commensurate with that of the metal-containing layers in the structure of **1**. Recently $Fe(H_2O)_2Ni(CN)_4 \cdot 4H_2O$ was determined to be isomorphous to **1**.[8] The powder X-ray data

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1993 0570-0833/93/0606-0885 $ 10.00+.25/0

for $Ni(H_2O)_2Ni(CN)_4 \cdot xH_2O$ ($x > 3$) (orthorhombic, $a = 12.20$, $b = 13.84$, and $c = 7.09$ Å, converted from reported values[9]) suggest that this compound is also isomorphous to the hydrate described here. Hence similar 2D networks of water molecules appear to be ubiquitous in $M(H_2O)_2Ni(CN)_4 \cdot 4H_2O$ (M a divalent cation in the last half of the first transition series) in the analogy with the Hofmann-type clathrates $M(NH_3)_2Ni(CN)_4 \cdot 2G$ (M: Mn, Fe, Co, Ni, Cu, Zn, or Cd; G: C_6H_6, $C_6H_5NH_2$, etc.).[7]

Dimeric and Trimeric Aminoalanes with Inverse Bridging Functions

By *Christiane Klein, Heinrich Nöth,* Matthias Tacke,* and *Martina Thomann*

Dedicated to Dr. Wolfgang Fritsche on the occasion of his 65th birthday

Monomeric aminoalanes $AlX_n(NR_2)_{3-n}$ (X = H, Cl, Br, CH_3) have not been detected to date, because they are stabilized by the formation of cyclic dimers and trimers with an AlN framework, which includes μ-diorganoamino groups. Thus in the solid state Me_2NAlH_2 occurs as the trimer **1**[1] and Me_2NAlCl_2 as the dimer **2**, which contains a planar Al_2N_2 four-membered ring.[2] Not unexpectedly according to this scheme, steric factors influence the ring size. NMR data show that **3**, the dimer of $ClAl(NMe_2)_2$, also contains μ-dimethylamino groups besides terminal Me_2N groups that are *trans* to one another.[3] The dimer of $HAl(NMe_2)_2$ (**4**) is analogous to **3**.[4] The oligomerization of the aminoalanes can be kinetically suppressed, as the transition from dimeric $Al(NMe_2)_3$ (**5**) to monomeric $Al(NiPr_2)_3$[5] or $Al[(N(SiMe_3)_2]_3$ (**6**) shows. We hoped to obtain monomeric bis(diorganoamino)alanes and perhaps even monomeric mono(diorganoamino)alanes by the introduction of bulky R_2N groups.

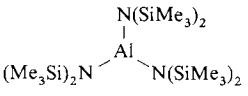
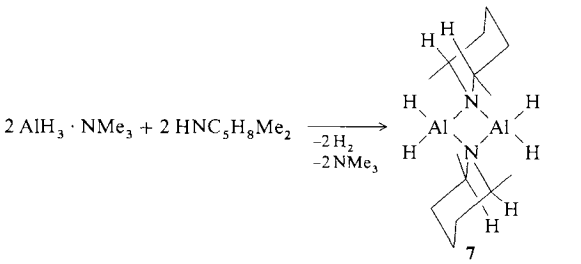
3, X = Cl
4, X = H
5, X = NMe_2



6

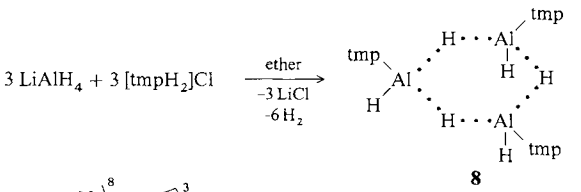
According to known procedures[7] the reaction of $AlH_3 \cdot NMe_3$ with 2,6-dimethylpiperidine [Eq. (1)] gave 2,6-dimethylpiperidinoalane (**7**) in 79% yield, which in contrast to the trimer Me_2NAlH_2,[1] exists as a *dimer*.[8, 9]

The trimeric 2,2,6,6-tetramethylpiperidinoalane **8** is readily formed from $LiAlH_4$ and 2,2,6,6-tetramethylpiperidinium chloride [Eq. (2)]. IR and NMR spectra confirm a μ-H-trialane structure.



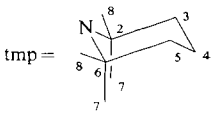
(1)

7



(2)

8



The presence of terminal 2,2,6,6-tetramethylpiperidino groups (tmp) is deduced from the position of the ^{13}C NMR signals,[10] which precludes the possibility of tetracoordinated nitrogen atoms. Because the signals for only one type of tmp group are observed, these must all be identical (all axial or equatorial for a chair conformation, or all *cis* for planar conformations of the ring).[11] The *cis* arrangement of the tmp groups indicated in the structural formula **8** follows from the IR spectrum, which shows three bands of approximately equal intensity in the region expected for Al–H stretching modes at 1863, 1834, and 1778 cm^{-1}. The first two are assigned to the in-phase and out-of-phase vibrational modes of the terminal Al–H groups. The broader band at longer wavelength is attributed to the vibrational mode of the Al_2H bridge. For an arrangement of the terminal H atoms in $(tmpAlH_2)_3$ with two *cis* and one *trans* H atom, three IR bands would be expected in the region of the terminal Al–H stretching vibrations.

The compound $(tmp_2AlH)_2$ **9** is obtained in a reaction according to Equation (3) in toluene at reflux. The replace-

[**] This work was supported by the Fonds der Chemischen Industrie and the Chemetall GmbH. M. Tacke thanks the DFG for a post-doctoral grant and Prof. Dr. A Oskam for time on a matrix apparatus.

ment of the hydride hydrogen atoms in **9** by tmp groups was not accomplished even after 16 h in the presence of a large excess of tmpH in boiling toluene. There is no μ-amino

$$2\,AlH_3\cdot NMe_3 + 4\,tmpH \xrightarrow[-2NMe_3]{-4H_2} \underset{\mathbf{9}}{\text{tmp}_2Al(\mu\text{-H})_2Al\text{tmp}_2} \quad (3)$$

group in **9**. Instead, as the X-ray structure analysis shows, a doubly H-bridged aminodialane is present. Characteristic for this compound, which is thermally stable at 255 °C, is the broad IR band at 1770 cm^{-1} that is assigned to the vibrational mode of the bridging H atoms. Since the ^{13}C NMR spectrum shows only a set of four signals, the rotation of the tmp groups about their Al–N bonds is not hindered.

The structural parameters[12] (Fig. 1) of **9** are in accord with an Al–Al interaction, because the Al–Al distance of 2.680(2) Å, though longer than in $(Me_2AlH)_2$ (2.62 Å),[13] is

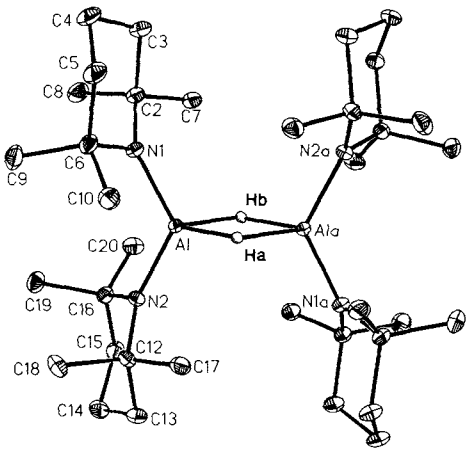

Fig. 1. Molecular structure of **9** *in the crystal. Ellipsoids represent 25% probability.* Selected bond lengths: Al-Ala 2.680(2), Al-N1 1.836(3), Al-N2 1.835(2), Al-Ha 1.68(2), Al-Hb 1.67(2). Selected bond angles [°]: Ha-Al-Hb 74.8(13), N1-Al-N2 126.9(1), Al-N1-C2 126.4(2), Al-N1-C6 116.5(2), Al-N2-C12 126.7(1), Al-N2-C16 116.4(1). The N atoms lie in the same plane as the C and Al atoms. Hydrogen atoms of the tmp groups have been omitted for clarity.

nevertheless only a little longer than the Al–Al distance of 2.660(1) Å in the dialane(4) $[(Me_3Si)_2CH]_4Al_2$.[14] The N-Al-N bond angle of 126.9(1)° is much wider than the tetrahedral angle and is certainly the result of the steric requirement of the tmp group, as confirmed by a comparison with the C-Al-C angle of 118.5(9)° and 117(1)° in $Me_2AlH_2AlMe_2$[13] or $Me_2AlMe_2AlMe_2$.[15] Also the lengthening of the Al···Al distance in **9** is probably attributable to these steric effects. The Al–N bond length in **9** is 1.835(3) Å. It is therefore somewhat longer than the Al–N bond in $Al[N(SiMe_3)_2]_3$ (1.78(2) Å), but distinctly shorter than the Al–N bonds of tetracoordinate Al and tetracoordinate N, for example in **7** (1.951(3) Å).

The Al–H distances in **9** of, on average, 1.68(2) Å are similar to those in $(Me_2AlH)_2$ (1.68(2) Å) and $[(Me_3C)_2AlH]_3$ (1.726(5) Å),[16] and are thus longer than in many hydridoaluminates (examples: $Li[AlH_4]$, 1.54–1.69(1) Å;[17,18] $Li[HAl(NMe_2)_3]$, 1.52(2) Å;[19] $Li[H_2Al\{N(SiMe_3)_2\}_2]\cdot 2OEt_2$, 1.55–1.62(2) Å or $Li[H_3AlN(SiMe_2)]\cdot OEt_2$ (1.58–1.62(2)).[20] This can be interpreted as an indication of an only weak association between the two monomeric $HAl(tmp)_2$ units in **9**, and therefore the formation of the monomers **10**[22] from **9** as depicted in Equation (4) should be possible.

$$\underset{\mathbf{9}}{(tmp_2AlH)_2} \longrightarrow \underset{\mathbf{10}}{2\,tmp_2AlH} \quad (4)$$

On evaporation of **9** in vacuum at 50 °C followed by condensation of the vapor together with a thousandfold excess of argon to form a matrix,[21] the IR spectrum (Fig. 2) show a

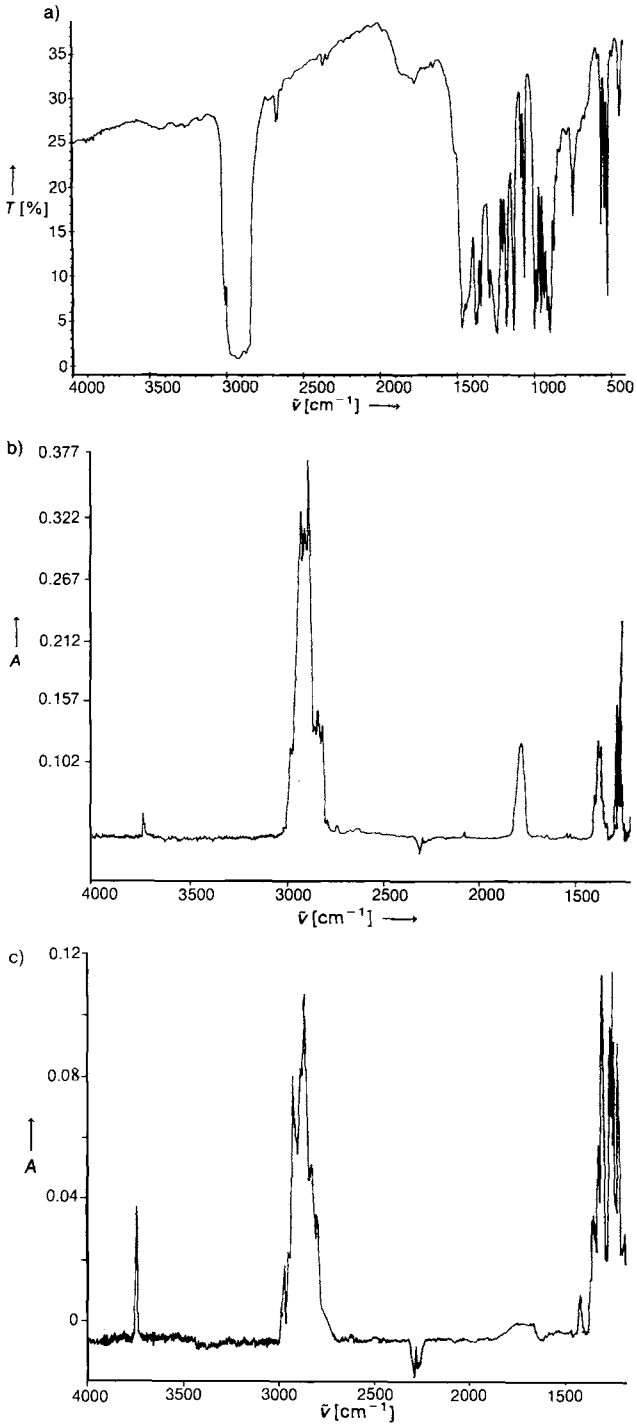

Fig. 2. IR spectra of monomeric (**10**) and dimeric tmp_2AlH (**9**). a) Before evaporation: **9** (recorded in Nujol over the range 4000–400 cm^{-1}. b) After evaporation of **9** and freezing of the vapor in an Ar matrix: **10** (absorption IR spectrum over the range 4000–1210 cm^{-1}). c) After evaporation of the Ar matrix. T = transmission, A = absorption (arbitrary units).

single, sharp band in the region of the Al–H stretching vibration at 1858 cm^{-1}, which is shifted by 88 cm^{-1} to higher wavenumbers relative to the corresponding band in **9**. This reflects the conversion of **9** to the monomeric $(tmp)_2AlH$ **10**.[22] On evaporation of the argon, **10** dimerizes again to **9**.

To our knowledge, **10** is thus the second alane of type $HAlX_2$ beside $HAlCl_2$[23] that has been characterized by IR spectroscopy. The ν(Al–H) frequency, shifted by 110 cm^{-1} to longer wavenumbers relative to that of $HAlCl_2$ (ν(Al–H) = 1968 cm^{-1}) is consistent with the smaller negative inductive effect of the amino group; the trend parallels the change in the B–H frequencies in the series $HBCl_2$, $HB(OR)_2$, and $HB(NR_2)_2$.[24]

Therefore **8** and **9** are the first examples of aminoalanes in which the amino groups are no longer in the role of bridging ligands. Rather, in the compounds $(tmp_nAlH_{3-n})_2$ ($n = 1, 2$) the inverse bridging function Al···H···Al, which is not predicted by chemical intuition, is present.

Experimental Procedure

7: 2,6-Dimethylpiperidine (10.8 mL) was added dropwise to a stirred solution of $AlH_3 \cdot NMe_3$ (3.59 g, 40 mmol) in toluene (30 mL) at −40 °C. Hydrogen evolution began at room temperature. After stirring for 12 h the solvent was removed under vacuum, and pure **7** remained. Single crystals of **7** were grown in a small volume of toluene. Yield: 4.45 g **7** (79%), m.p. 150 °C. ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.16–1.37 (γ-CH_2), 1.38 (CH_3), 1.55–1.88 (β-CH_2), 3.46 (α-CH); ^{13}C NMR (100 MHz): δ = 22.09, 22.27 (C4), 30.61, 30.72 (C3, 5), 34.53 (CH_3), 51.21 (C2, 6); ^{27}Al NMR (70 MHz, standard $[Al(OH_2)_6]^{3+}$): δ = 145 (broad). IR: ν(Al-H) = 1828 cm^{-1}.

8: $LiAlH_4$ (1.0 g, 26 mmol) was suspended in ether (50 mL) and stirred. At −40 °C [tmpH$_2$]Cl (4.25 g) was added in portions. After stirring for 12 h the insoluble matter was separated, the ether removed from the solution under vacuum, and the residue sublimed at 60 °C under high vacuum. Yield: 1.3 g **8** (30%), decomp. > 280 °C; molar mass (in benzene): 528 g mol^{-1}; calculated for the trimer, 507. As yet no single crystals could be obtained from **8**. ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.27 (γ-CH_2), 1.36 (CH_3), 1.55–1.76 (β-CH_2), 4.54 (AlH); ^{13}C NMR (100 MHz): δ = 18.52 (C4), 33.75 (C7, 8), 40.11 (C3, 5), 51.72 (C2, 6); ^{27}Al NMR (70 MHz): δ = 112; IR: ν(Al-H) range: (Nujol): $\tilde{\nu}$[cm^{-1}] = 1863, 1834, 1778; (toluene) 1867, 1850, 1797, 1734.

9: At −40 °C tetramethylpiperidine (15 mL) was added dropwise to a stirred solution of $AlH_3 \cdot NMe_3$ (3.31 g, 37 mmol) in toluene (30 mL). After the mixture had reached room temperature and the gas evolution had stopped, it was heated at reflux for 10 h. On cooling **9** precipitated. Yield: 3.5 g (31%). More **9** was obtained on reducing the volume of the solution. Decomp. > 255 °C. ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.06 (CH_3, 12H), 1.25–1.55 (CH_2, 6H); ^{13}C NMR (100 MHz): δ = 18.81 (C4), 32.03 (C7, 8), 38.59 (C3, 5), 49.58 (C2, 6); ^{14}N NMR (14 MHz, $NaNO_3$): δ = −257; ^{27}Al NMR (70 MHz): δ = 135; IR: ν(Al-H) range: $\tilde{\nu}$[cm^{-1}]: 1770 (broad).

[8] In contrast to $(Me_2NAlH_2)_3$ [1], Me_2NGaH_2 is dimeric: P. L. Baxter, A. J. Downs, D. W. H. Rankin, H. E. Robertson, *J. Chem. Soc. Dalton Trans.* **1985**, 807–814. The same holds for the "inverse" compounds Me_2ENH_2 (E = Al, Ga): L. V. Interrante, G. A. Siegel, M. Garbauskar, C. Hejna, G. A. Slack, *Inorg. Chem.* **1989**, *28*, 252–257; M. J. Almond, M. G. B. Drew, G. F. Jenkins, D. A. Rice, *J. Chem. Soc. Dalton Trans.* **1992**, 5–9.
[9] For **7** the following crystallographic data were determined: **3**: a = 16.055(3), b = 8.906(2), c = 11.886(2) Å, $\alpha = \beta = \gamma = 90°$, V = 1699.5(9) Å^3. The structure solution in the centrosymmetric orthorhombic space group *Ibam* gave a model with disorder of the dimethylpiperidino group. On consideration of the position of the ellipsoids the model did not fulfil the expected symmetry. The structure solution in the acentric space group *Iba2* did not remove this disorder and, similar to the refinement in *Ibam*, yielded unrealistic C–C distances. In principle the same was valid in monoclinic systems. Also at −80 °C the collected data provided no satisfactory structure solution. Thus only the dimeric nature of the compound was ascertained.
[10] If a μ-amino structure were present, $\delta(^{13}C)$ of the C atoms adjacent to N atoms (C2,6) should lie in the range δ = 58–64 (S. Weber, Dissertation, Universität München, **1983**; H. Nöth, S. Weber, *Z. Naturforsch. Teil B* **1983**, *38*, 1460–1465.

CD Exciton Chirality Method: New Chromophores for Primary Amino Groups**

By *Dario Gargiulo, Guolin Cai, Norihiro Ikemoto, Nina Bozhkova, Joshua Odingo, Nikolina Berova,* and *Koji Nakanishi**

The circular dichroic (CD) exciton chirality method is a microscale procedure for determining the absolute configurations and conformations of compounds containing two or more chromophores.[1, 2] Hydroxyl groups are converted into various *para*-substituted benzoate groups, and other symmetric chromophores, which may or may not be identical. When two identical benzoate groups interact through space,

Scheme 1. Top: Neutral and protonated Schiff bases formed from a primary amine and *para*-dimethylaminobenzaldehyde (pDMBA). Bottom: Schiff bases from cyclohexylamine and pDMBA, julolidinecarbaldehyde [9], and *para*-dimethylaminocinnamaldehyde. The chromophoric groups are designated chrom-I, chrom-II, and chrom-III, respectively. The λ_{max} and ε values (in parentheses) for the neutral (n) and protonated (p) compounds were determined in acetonitrile for **1** and **2**, and in methanol for **3**. The Schiff base species were protonated by addition of trifluoroacetic acid (TFA) to the cell.

they give rise to CD curves split into a positive and a negative component (that is, they are bisignate) the signs of which are defined by the absolute orientation of the two electric transition moments. The CD curves of compounds containing two different chromophores, for example, methyl galactopyranoside-2,4-bis(*p*-bromobenzoate)-3,6-bis(*p*-methoxycinnamate), are complex and constitute a fingerprint of that compound. The finding that such characteristic CDs can be reproduced by pairwise summation of interacting chromophores is currently being applied to structural studies of oligosaccharides.[2, 3] Conventionally amino groups are also acylated and have been treated similarly to hydroxyl groups.[3–7]

In the following, we describe three chromophores that can be prepared selectively from primary amines in the presence of free hydroxyl groups (Scheme 1). The three aldehydes, *para*-dimethylaminobenzaldehyde,[8] julolidinecarbaldehyde,[9] and *para*-dimethylaminocinnamaldehyde,[8] all react readily under very mild conditions and afford the imines, chrom-I, chrom-II, and chrom-III, respectively, in high yields. Upon protonation these Schiff bases undergo drastic bathochromic shifts, and the extinction coefficients ε are intensified two- to threefold by formation of cyanine-type dyes.[10] Since the coupling of chromophores is approximately proportional to the absorption intensity, chromophores with intense absorptions increase the sensitivity of the method. Furthermore, chromophores absorbing at long wavelengths are important when samples themselves contain chromophoric groups or impurities whose absorbance bands may overlap with those of the chromophores and interfere with analysis.

The model chiral amines, (*R,R*)-(−)-1,2-diaminocyclohexane, the 1,3-diamine derived from kasugamycin,[11] and methyl-α-L-acosaminide were derivatized with the three aldehydes (Scheme 2),[12] and their UV/VIS[1] and CD spectra were recorded before and after protonation (Fig. 1, Table 1). The 1,3-diamine was converted directly into the bis(Schiff bases) **7** and **8** without protection of the hydroxyl groups. In the acosamine derivative **9**, chrom-III was used for amino derivatization, while ethyl *para*-methoxyphenylpentadienoate was employed to yield the chromophore (chrom-IV) for the hydroxyl group.

All derivatives displayed very strong CD bisignate curves (evident in the large *A* values in Table 1); the signs of the CD curves correctly represent the absolute sense of twist between the C–N and C–O bonds. In compounds containing chromophores I–III the *trans* configuration of the N=C bond and the *syn* orientation of the H_a and H_b hydrogen atoms in both the neutral and protonated species (see structures **4**–**6** in Scheme 2) result in parallel electric transition moments and C–N bonds. In chromophore IV also, the direction of the electric transition moment coincides with the direction of the original C–O bond.[13]

Note that this is unlike the cyanine dye reported earlier by us, and 2,4-hexadienylidenimine, in which sign reversal of

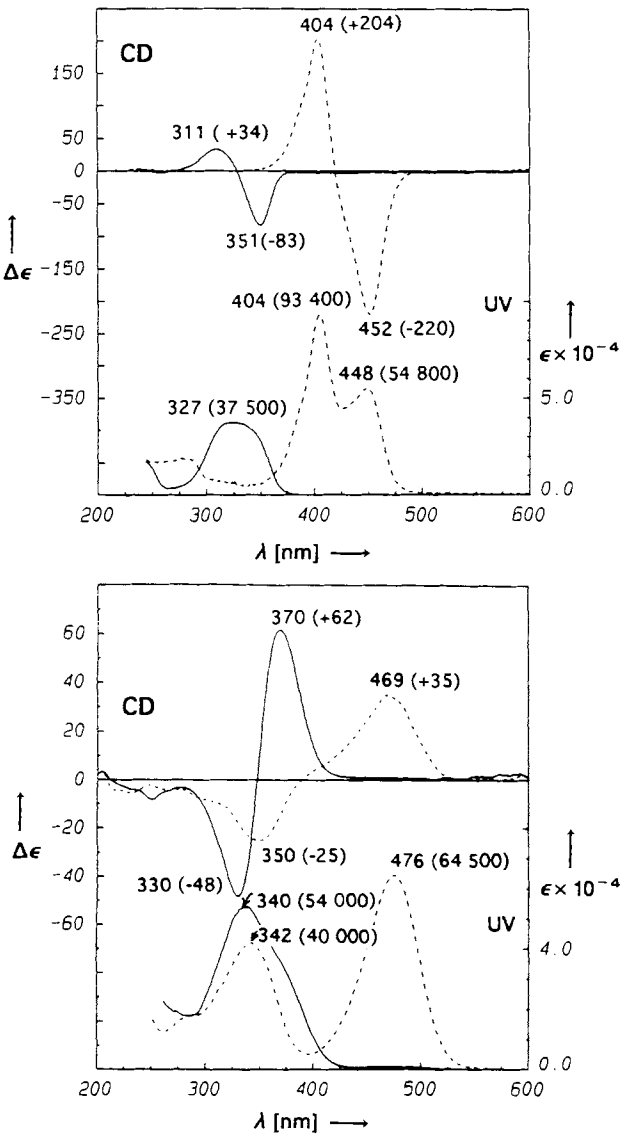

Fig. 1. UV/VIS and CD spectra: Top: neutral **5** (solid line) and protonated **5** (dashed line) in acetonitrile. Bottom: neutral **9** (solid line) and protonated **9** (dashed line). In the CD spectrum of **9** a bisignate couplet is still observed between the red-shifted protonated chrom-III and neutral chrom-IV. Above the CD curves, $\lambda_{ext}(\Delta\varepsilon)$ values are given. Above the UV bands, $\lambda_{max}(\varepsilon)$ values are given.

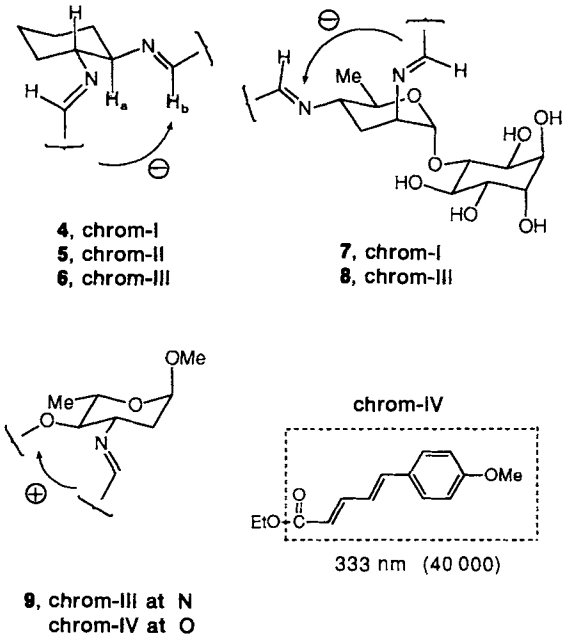

Scheme 2. Bis(Schiff base) derivatives of (*R,R*)-(−)-1,2-diaminocyclohexane (**4**–**6**), kasugamine (**7**, **8**) and L-acosamine (**9**). The braces indicate the position of the chromophoric groups. For the definitions of chrom-I, chrom-II, and chrom-III, see Scheme 1. The $\lambda_{max}(\varepsilon)$ of the chrom-IV source, ethyl *para*-methoxyphenylpentadienoate, was determined in methanol (synthesis of this ester: K. Nakanishi et al. unpublished). In the partial structure shown for the neutral **4**–**6**, the protons H_a and H_b are in *syn* orientation; the same conformation holds for the protonated species also (to be published).

the exciton couplet was observed because direction of the electric transition moment of the chromophore and C–N bond are not parallel.[10, 14, 15]

The UV/VIS and CD spectra of compounds **5** in their unprotonated and protonated forms are displayed in Figure 1 (top). The bisignate curves that reveal a negative Cotton effect are centered at the λ_{max} of the UV/VIS spectrum of the chromophores; protonation induces a red shift of about 100 nm in the absorption maximum and increases the *A* value from −117 to −424 (Table 1). As in the case of cyanine dyes,[10] the UV/VIS spectra of protonated species **4**, **5**, and **6** showed doubling of the signals due to exciton coupling between the red-shifted chromophores.[16]

Table 1. UV/VIS and CD data of neutral (n) and protonated (p) species **4**–**9**. The *A* values (amplitudes) are the differences ($\Delta\varepsilon$) of the two extrema of the split CD curves. A negative sign for *A* indicates that the Cotton effect at longer wavelengths has a negative sign and that at shorter wavelengths a positive sign. The reverse is true for a positive sign for *A*.

Cmpd.	λ_{max} (ε)	λ_{ext} ($\Delta\varepsilon$)	*A*	Solvent
4n	300 (43000)	332 (−83.1)/292 (+53.4)	−136	MeCN

9n	340 (54000)	370 (+61.8)/330 (−48.2)	+110	MeOH
9p	342 (40000)/476 (64500)	469 (+35.0)/350 (−25.0)	+60	MeOH

In the presence of added water, the Schiff base and its protonated derivatives prepared from chrom-I hydrolyzed back to the starting amine and aldehyde; the protonated Schiff base hydrolyzed faster than its unprotonated counterpart.[17] The derivatives with chrom-III were relatively stable to hydrolysis.[18] Therefore, anhydrous conditions must be used during manipulation of the derivatives containing chrom-I, and this chromophore is recommended when recovery of the starting amine is desired.

Chromophores I–III are useful for microscale stereochemical assignments of compounds with primary amino groups because of 1) ease of preparation of Schiff bases and protonated Schiff bases, 2) the strong CD couplets lying at long wavelengths, and 3) possible recovery of the starting amine. Further studies on other natural products containing an amino group, especially those of biochemical significance, are underway.

Experimental Procedure

4n: A solution of (*R,R*)-1,2-diaminocyclohexane (4.2 mg, 0.037 mmol) and pDMBA (11.0 mg, 0.074 mmol) in anhydrous methanol (0.5 mL) was stirred for 12 h at room temperature in the presence of anhydrous Na_2SO_4. After filtration and concentration, the residue was dissolved in ethyl acetate with few drops of triethylamine, and hexane was added to precipitate the product as a white solid. Yield: 12.6 mg, 91% m.p., 148.5–149.5 °C, uncorrected (from EtOAc/*n*-hexane).

9n: A solution of methyl-α-L-acosaminide hydrochloride (2.0 mg, 0.010 mmol) and *para*-dimethylaminocinnamaldehyde (1.8 mg, 0.010 mmol) in anhydrous methanol (0.5 mL) was heated at reflux for 2.5 h in the presence of anhydrous Na_2SO_4. The reaction mixture was filtered, and the solvent evaporated. The residue was redissolved in dichloromethane and precipitated with hexane to yield the Schiff base hydrochloride (3.4 mg, 96%), which was then heated at reflux with 1-(5-(4-methoxyphenyl)-1-oxo-2,4-pentadienyl)-1*H*-1,2,4-triazole (5.6 mg, 0.020 mmol) and diazabicycloundecane (3.0 mg, 0.020 mmol) in anhydrous dichloromethane (2 mL) for 45 min. Flash chromatography (silica gel, 50% ethyl acetate/hexane, ca. 0.1% Et_3N) of the reaction mixture afforded bis-(Schiff base) **9**n as a yellow solid. Yield: 2.2 mg, 43%.

[16] The intensity ratio of the first and second absorption bands is dependent on the dihedral angle θ between the transition moments; when θ is larger than 90°, the first band at longer wavelengths is stronger, and vice versa. In the present case, θ is less than 90°: N. Harada, H. Uda, *J. Chem. Soc. Chem. Commun.* **1982**, 230.
[17] The CD of **4n** (10^{-5} M, 1% water in MeCN) disappeared after 48 h, while the UV of **4p** (ca. 10^{-5} M, 1% water in MeCN, 0.2% TFA) disappeared completely after 7 h at room temperature.
[18] In protonated compounds with chrom-III, it is necessary to measure the CD immediately after addition of TFA, because the N=C bond undergoes partial *trans* to *cis* isomerization with time. In contrast, with chrom-I and chrom-II neither the neutral nor the protonated derivatives isomerize. A detailed account of these aspects will be published shortly.

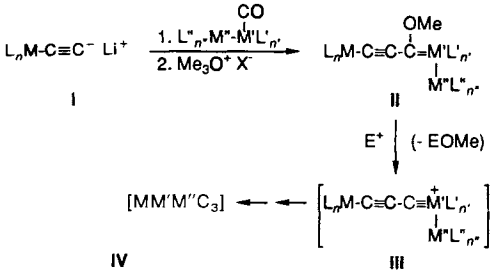
A New Form of Coordinated Carbon: A C_3 Chain That Is Anchored by a Transition Metal on Each End and Spanned by a Third**

By *Weiqing Weng, Atta M. Arif*, and *J. A. Gladysz**

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

Diverse forms of elemental carbon (C_x) have been incorporated into isolable polynuclear transition metal complexes.[1–3] These range from single carbon atoms sepulchered in metal clusters to unsupported C_1–C_4 chains that span two metals. Such species have been found to have promising catalytic and materials properties.[4] In particular, the pioneering efforts of Shriver et al. and Bradley established that unique reactivity is associated with cluster complexes with *exposed* carbon atoms.[1] We therefore sought to develop new approaches to polynuclear complexes containing unusual types of C_x fragments.

We recently demonstrated that "terminal" transition metal acetylide complexes [$L_nMC{\equiv}CH$] can be lithiated to give complexes containing C_2Li ligands ([$L_nMC{\equiv}C^-Li^+$], **I**).[5] These have proven to be valuable building blocks that can be derivatized by electrophiles in high yields. We sought to synthesize a trimetallic C_3 species—a heretofore unknown type of carbon adduct—via Fischer carbene complexes derived from binuclear carbonyl compounds (**II**), as sketched in Scheme 1.[6] Alkoxy groups have been abstracted from many Fischer carbene complexes by electrophiles to give either cationic or neutral carbyne complexes.[7] In the case of **II**, this would initially yield the C_3 species **III**, which could undergo further reaction because of the proximity of another metal (M″) to the electrophilic C≡M′ center.



Scheme 1. Planned route to trimetallic C_3 complexes [MM′M″C_3].

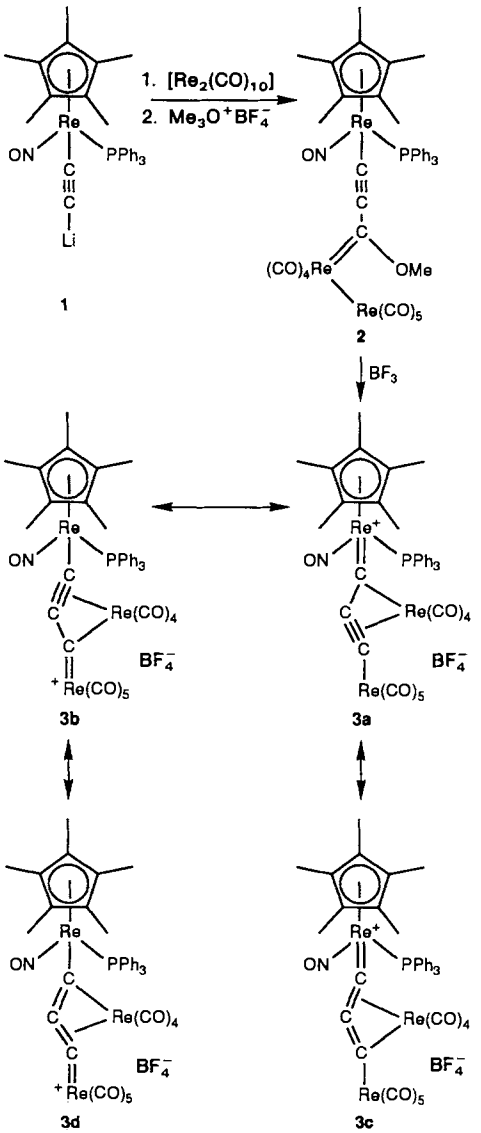
The rhenium/lithium C_2 complex **1** was generated as reported earlier,[5] and sequentially treated with [$Re_2(CO)_{10}$] and $Me_3O^+BF_4^-$. Workup gave the alkynylcarbenetrirhenium complex **2** in 92% yield, as shown in Scheme 2. Complex

[{Re*}(C≡CLi)] **1**, {Re*} = (η^5-C_5Me_5)Re(NO)(PPh_3)

cis-[{Re*}(C≡C-C(OMe)=)Re(CO)$_4${Re(CO)$_5$}] **2**

2 was characterized by microanalysis, and NMR (^1H, ^{13}C, ^{31}P) and IR spectroscopy ($\nu_{C\equiv C}$ 2097 cm^{-1}).[8]

Many properties of **2** were similar to those of the dirhenium carbene complexes [RC(OR′)=Re(CO)$_4${Re(CO)$_5$}],[9] which had been analogously prepared by Fischer et al. earlier. The *cis* arrangement of ligands was established by ^{13}C NMR (−50 °C/C_7D_8; δ), which gave one signal for the four equivalent CO ligands of the Re(CO)$_5$ group (197), and four signals for the remaining types of CO ligands (201, 200, 196, 192; 1:2:1:1).[10] However, the C=Re ^{13}C NMR signal (240) was not as far downfield as those of the dirhenium



Scheme 2. Synthesis of Re_3C_3 complexes.

carbene complexes (318–377). Also, the ReC≡ signal (203, d, $J_{C,P}=14$ Hz) and the ν_{NO} band in the IR spectrum (1664 cm^{-1}) were intermediate between those of acetylide complexes [{Re*}(C≡CR)] (98–86, d, $J_{C,P}=16-18$ Hz; 1629–1637 cm^{-1}) and vinylidene complexes $[\{Re^*\}(=C=CHR)]^+BF_4^-$ (329, d, $J_{C,P}=10-11$ Hz; 1681–1698 cm^{-1}).[5a] These data suggest a significant contribution by a zwitterionic $^+Re=C=C=C(OMe)-Re^-$ resonance form to the structure of **2**.

Fischer found that the dirhenium carbene complexes reacted with Al_2X_6 to give cationic carbyne complexes $[(RC\equiv)Re(CO)_4\{Re(CO)_5\}]^+AlX_4^-$, which exhibited diagnostic downfield C≡Re ^{13}C NMR signals (e.g., at $\delta=356$).[9c] Thus, **2** was similarly treated with BF_3. A cationic C_3 complex (**3**) was isolated in 64% yield that gave a microanalysis and an ion in the FAB mass spectrum consistent with an analogous carbyne product. The ^{13}C NMR spectrum showed three signals that could be attributed to the C_3 fragment (297.1, d, $J_{C,P}=10$ Hz; 146.6, s; 95.1, s). However, the downfield resonance exhibited a P–C coupling constant characteristic of carbon bound to the cyclopentadienyl rhenium moiety.

Therefore, the crystal structure of **3** was determined. The result, shown in Figure 1, reveals **3** to be the novel

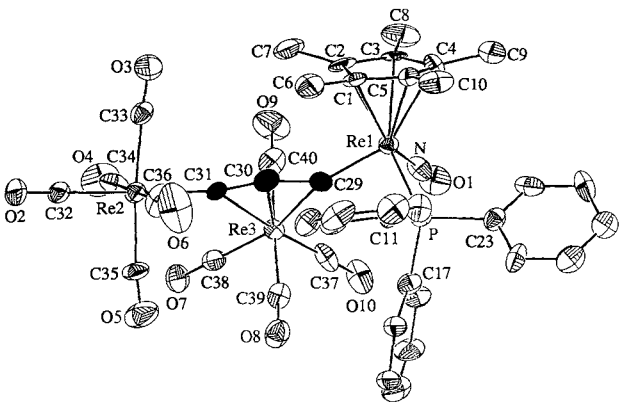

Fig. 1. Structure of the cation of **3**. Selected bond lengths [Å] and angles [°]: Re1-C29 1.94(3), C29-C30 1.41(6), C30-C31 1.28(5), C31-Re2 2.09(4), Re3-C29 2.24(3), Re3-C30 2.27(4), Re3-C31 2.43(4), Re1-P 2.440(9), Re1-N 1.73(3), Re1-C29-C30 140(3), C29-C30-C31 152(4), C30-C31-Re2 155(3).

rearrangement product $[\{Re^*\}(\mu\text{-}\eta^1:\eta^3:\eta^1\text{-}CCC)(Re(CO)_4)\{Re(CO)_5\}]^+BF_4^-$. Complex **3** contains a C_3 chain that is bent (152(4)°), anchored by rhenium atoms on each end, and spanned by a third rhenium. Several pathways for its formation are possible. We suggest that the linear C_3 complex $[\{Re^*\}(CCC)Re(CO)_4\{Re(CO)_5\}]^+BF_4^-$ is initially generated. One carbon terminus then bridges the $Re(CO)_4$ and $Re(CO)_5$ moieties, and the former migrates to the CCC π system.

Structurally, **3** can be viewed as a composite of two resonance forms with the Re=C–C≡C–Re backbones **3a** and **b**, as illustrated in Scheme 2. The pattern of Re–C and C–C bond lengths (Fig. 1) shows that **3a** dominates, consistent with the stronger donor properties of the Ph_3P-substituted rhenium atom. Indeed, the $Ph_3PRe=C$ bond length is identical to those in two cyclopentadienyl alkylidene complexes of the formula $[\{Re\}(=CRR')]^+X^-$.[11] Alternatively, **3** can be formulated with Re=C=C=C–Re backbones (**3c,d**). However, these resonance forms predict nearly equal carbon–carbon bond lengths.

We can identify only remote analogies between **3** and compounds that have been previously reported. For example, **3** can be considered a π-propargyl (η^3-RC≡C–CR′R″)[12] complex of $Re(CO)_4$, or an alkylidene-substituted variant (η^3-RC≡C–C=CR′R″),[13] in which all of the substituents on the C_3 core have been replaced by rhenium atoms. The physical and chemical properties of **2** and **3** are under investigation. Importantly, their visible spectra show unique intense absorptions.[14] Additional characteristics, and extensions of the methodology in Scheme 1, will be described in the near future.

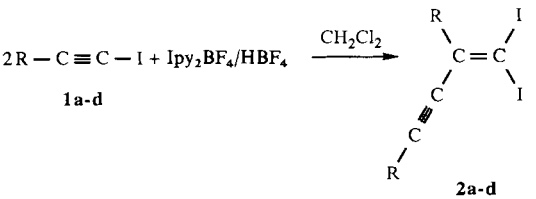
1-Iodoalkynes Can Also Be Dimerized: A New Head-to-Tail Coupling**

By *José Barluenga,* José M. González, Isidro Llorente,* and *Pedro J. Campos*

The oligomerization of alkynes by transition metals has been studied extensively.[1] Although linear dimerization is an attractive alternative, only a limited number of examples are known.[1, 2] A terminal alkyne is required for this reaction, and usually mixtures of dimers are formed. The current interest in selective dimerization of terminal alkynes[3] prompted us to investigate the reaction of readily available 1-iodoalkynes,[4] in which Ipy_2BF_4 (py = pyridine)[5] is used to mediate C–C bond formation.[6] In fact, when the starting alkyne was allowed to react with Ipy_2BF_4/HBF_4[7] in CH_2Cl_2, an unprecedent coupling of 1-iodoalkynes took place furnishing the corresponding head-to-tail dimers (Scheme 1).



Scheme 1. Linear dimerization of 1-iodoalkynes catalyzed by Ipy_2BF_4/HBF_4. **1**, **2**: **a**, R = C_6H_5; **b**, R = 4-$CH_3C_6H_4$; **c**, R = 4-ClC_6H_4; **d**, R = 4-$CH_3OC_6H_4$.

A number of 1-iodoalkynes were examined, and so far the best results were obtained by employing aryl substituted alkynes and a 1:2 mol ratio of Ipy_2BF_4 to HBF_4. Alkynes **1** were converted quantitatively into 1,3-diaryl-4,4-diiodobutenyne, in the other words, into the head-to-tail dimers **2a–d**. Typically, the alkyne was added to a solution of one equivalent of Ipy_2BF_4 and two equivalents of HBF_4 in CH_2Cl_2 (Scheme 1). Once the reagents were mixed at low temperature (−80 °C), the reaction mixture was allowed to warm to room temperature over approximately 15 h. We found that different experimental conditions were required depending on the aromatic substituent. Thus, for instance, the reaction of **1c** required 35 hours for completion, while that of **1d** was complete in only 3 minutes. Conventional isolation and purification techniques afforded pure samples of the dimers **2**, which were characterized by spectroscopy (Table 1) and gave correct elemental analyses.

From a mechanistic point of view, the formation of the dimer should regenerate an equivalent amount of "I^+". In good agreement with this assumption, when we used a 3:1 mol ratio of iodoalkyne to Ipy_2BF_4 and then hydrolyzed the reaction mixture, we observed the presence of the dimer and iodinated ketone in the crude product.[8] The latter arises from the nucleophilic attack of water on the likely intermediate iodonium ion.[5a] If an appropriate excess of the starting alkyne were employed, the catalytic head-to-tail dimerization of 1-iodoalkynes by Ipy_2BF_4 should be possible (Scheme 2).

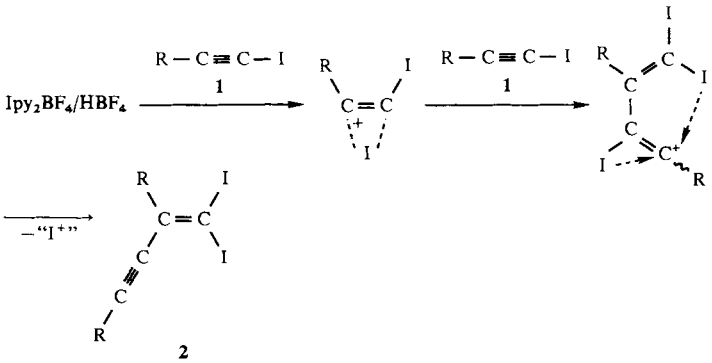
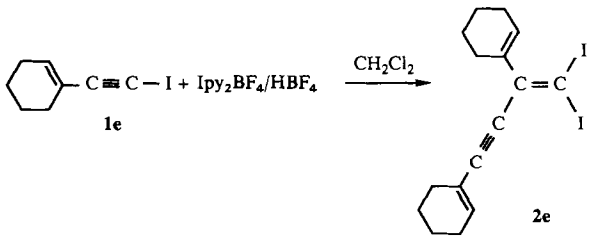


Scheme 2. Proposed mechanism for the catalytic dimerization of 1-iodoalkynes. The catalytic cycle depends on the liberation of "I^+".

We have been able to find conditions to for the successful coupling of 1-iodoalkynes using a catalytic amount of Ipy_2BF_4. The concentration of the iodinating reagent is a critical factor. Dilute (5×10^{-2} M) solutions of Ipy_2BF_4 in CH_2Cl_2 have proven to be valuable for the catalytic dimerization of **1a** and **1b**. Specifically, the reaction of the iodoalkyne and Ipy_2BF_4 in a mol ratio of 11:1 gave **2a** and **2b** in yields of 71 and 81%, respectively (yields of the pure isolated dimers based on the starting iodoalkyne). The reaction time was five days for **2a** and three days for **2b**. For the more reactive iodoalkyne **1d**, the concentration of the catalyst was lowered to 1×10^{-2} M. The reaction time was one hour, and the temperature was allowed to increase from −80 °C to −60 °C. Under these conditions **2d** was obtained in 77% yield. To explore the efficiency of this dimerization, we have also analyzed the reaction in the presence of larger excesses of iodoalkyne. Thus, for instance, when 50 mmol of **1d** was allowed to react for five hours with 1 mmol of Ipy_2BF_4 (2% with respect to the alkyne) and 2 mmol of acid under the previously described conditions, iodoalkyne **1d** was converted almost quantitatively into dimer **2d**.

This new reaction should be applicable to other iodoalkynes. In this context, we have found that 1-(1-cyclohexenyl)-2-iodoethyne (**1e**) can also be dimerized by reaction with Ipy_2BF_4/HBF_4 in CH_2Cl_2 (Scheme 3). Running the reaction



Scheme 3. Synthesis of a cross-conjugated (dienyl)enyne by the head-to-tail coupling of an iodoenyne.

at $-50\,^{\circ}C$ for 24 h, and using a 2×10^{-2} M solution of Ipy_2BF_4 and a 3:1 ratio of iodoalkyne to Ipy_2BF_4 gave a 32% yield of pure **2e**. Although these results are preliminary, this conversion of an iodoalkenyne suggests the feasibility of extending this reaction to other type of substrates. Studies on the optimization and further applications are at present in progress.

In short, a new catalytic protocol for dimerizing 1-iodoalkynes has been established. The strategy is based on the electrophilic character of iodine in Ipy_2BF_4/HBF_4 solutions. The reaction affords head-to-tail dimers with no evidence for the significant formation of other oligomers. The final products have an attractive functionality and could nicely compete with those derived from the transition metal coupling of alkynes.[9]

[7] HBF_4 was used as a 54% ethereal solution, which is commercially available from Merck. The acid protonates the two pyridine units, liberating "electrophilic iodine". Nucleophilic incorporation of pyridine into the substrate is thus avoided.
[8] Mixtures of the ketones $ArCOCHI_2$ and $ArCOCH_2I$ (Ar = aryl) are obtained. The longer the delay in performing the analysis, the higher the proportion of the latter ketone. Among other spectroscopic data, α,α-diiodo- and α-iodoketones have distinctive features in their ^1H NMR spectra. Monoiodo derivatives (CH_2I) show a singlet at $\delta \approx 4.3$, the corresponding diiodo derivatives (CHI_2) at $\delta \approx 6.5$.
[9] Concerning the functionality in the final products, two synthetic aspects deserve special attention. First, their potential applicability to the preparation of radialenes; see: H. Hopf, G. Maas, *Angew. Chem.* **1992**, *104*, 953–977; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 931–954. Second, their usefulness in the preparation of unsaturated compounds having a high carbon content and a low hydrogen content; see, for instance, F. Diederich, Y. Rubin, *Angew. Chem.* **1992**, *104*, 1123–1145; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 1101–1123. A. M. Boldi, J. Anthony, C. B. Knobler, F. Ion-Spray Mass Spectrometry and High-Performance Liquid Chromatography—Mass Spectrometry of Synthetic Peptide Libraries**

By *Jörg W. Metzger, Karl-Heinz Wiesmüller, Volker Gnau, Jente Brünjes*, and *Günther Jung**

Dedicated to Professor Theodor Wieland on the occasion of his 80th birthday

Synthetic peptide libraries are composed of equimolar mixtures of immobilized or free peptides with defined length and sequence motifs which are gaining increasing interest for the screening for new lead structures (e.g. for antibiotics and enzyme inhibitors) and the investigation of ligand–receptor interactions.[1] Novel analytical tools are required for optimization of the synthesis and characterization of such complex mixtures.[2] In order to evaluate the potency of ion-spray (IS) mass spectrometry[3] for this purpose, we investigated a representative peptide library of 100 synthetic 48-component mixtures of octapeptides **1** (O defined, X un-

$$O_1O_2O_3O_4O_5X_1X_2X_3 \quad \mathbf{1}$$

defined positions, see Experimental Procedure) exhibiting the murine major histocompatibility complex (MHC) class I H2-K^b restricted sequence motif.[4] In addition, a second more complex library consisting of 24 576 nonapeptides **2**

$$X_1 - X_6OX_7X_8 \quad \mathbf{2}$$

representing the binding motif of the nonclassical murine MHC class I complex Qa-2^a[5] was analyzed. Such synthetic peptide mixtures resemble the isolated natural mixtures with defined length and "anchor amino acids" in defined positions.[4–6] These natural peptides originate from proteins processed within the cell and are presented in the MHC groove to cytotoxic T lymphocytes (CTL).[4, 7] Virus-specific CTL kill cells after recognition of MHC-bound foreign peptides processed, for example, from viral proteins.[8]

Peptides **1** and **2** were synthesized by solid-phase peptide synthesis on a multiple peptide synthesizer using Fmoc chemistry.[1, 6] The peptide mixtures **1** and **2** were obtained by treatment of the respective resins with trifluoroacetic acid followed by precipitation from diethyl ether. The monoisotopic relative molecular masses (RMM) of the 48 peptides **1** range between 1011.6 (octapeptide LNYRFSNV) and 1099.5 (octapeptide LNYRFEKM). Only 17 different mass values were obtained for these 48 peptides, since several peptides of the mixture are isobaric, that is, they have an identical molecular mass (± 0.1 u). As many as eight peptides (LNYRFTNL, LNYRFTNI, LNYRFSKL, LNYRFSQI, LNYRFSKI, LNYRFTQV, LNYRFTKV and LNYRFSQL) of this mixture, for example, have a RMM of 1039.6. The IS mass spectrum of **1** shows two groups of peaks with m/z values that correspond to the singly protonated molecular ions $[M + H]^+$ (m/z 1012.6–1100.5) and doubly proton-

ated molecular ions $[M + 2H]^{2+}$ (m/z 506.8–550.8) of the individual peptides (the region of the singly charged ions is depicted in Fig. 1). Multiple charges result from the protona-

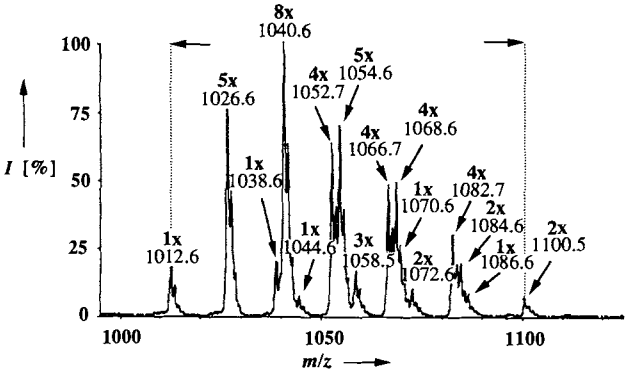

Fig. 1. IS mass spectrum of the 48-component peptide mixture **1** showing the region of the singly charged quasi-molecular ions (the m/z values of the smallest and largest peptides of the mixture are indicated by vertical dashed lines; peaks are labeled with the m/z value and the number isobaric peptides corresponding to this mass).

tion of the basic centers of the peptides.[9, 10] All peptides **1** contain at least two basic centers, the free N-terminus and the arginyl residue at position 4. Sixteen peptides of **1** have an additional positive charge located at the lysyl residue at position 7. Triply charged ions $[M + 3H]^{3+}$ of these peptides are observed between m/z 338.2 and 367.5. All m/z values expected for the $[M + H]^+$ ions of **1** can be found in the mass spectrum (Fig. 1). The absence of additional peaks in the mass spectrum is a strong hint that the mixture is free of possible by-products such as deletion peptides (masses lower than expected) and peptides containing noncleaved protecting groups (masses higher than expected).

Despite possible MS-related discrimination effects (e.g. due to the different basicity and hydrophilicity of the peptides) and the distribution of ion intensities to several charge states, the intensity distribution of the $[M + H]^+$ ions seems to reflect the number of isobaric peptides (Fig. 1) in the mixture.

Side products in peptide synthesis are easily detected by IS mass spectrometry and high-performance liquid chromatography combined with IS (HPLC-IS) mass spectrometry.[11, 12] In contrast to HPLC-UV detection, HPLC-IS mass spectrometry is capable of revealing the presence of

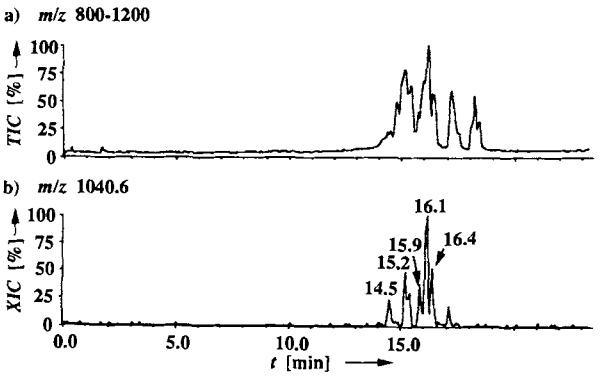

Fig. 2. HPLC-IS mass spectrum of **1**. a) Reconstructed total ion chromatogram (m/z 800–1200) and b) ion chromatogram of m/z 1040.6 corresponding to the monoisotopic $[M + H]^+$ ions of eight isobaric peptides of the mixture (TIC: total ion current; XIC: extracted ion current).

two or more peptides eluting at the same time. We used this on-line technique to confirm the presence of isobaric peptides in **1**. Mixture **1** was subjected to narrow-bore reversed-phase HPLC-IS mass spectrometry. After the gradient was optimized, the 48 peptides could be partially separated (see reconstructed total ion chromatogram; Fig. 2a). The ion chromatogram of m/z 1040.6 corresponding to the monoisotopic $[M + H]^+$ ions of eight different peptides shows five major peaks and indicates that three peptides coelute with other peptides with RMM 1039.6 (Fig. 2b). The mass spectra in the maxima of the five major peaks in the ion chromatogram of m/z 1040.6 show not only this ion but also further ions revealing other coeluting peptides (Fig. 3). Se-

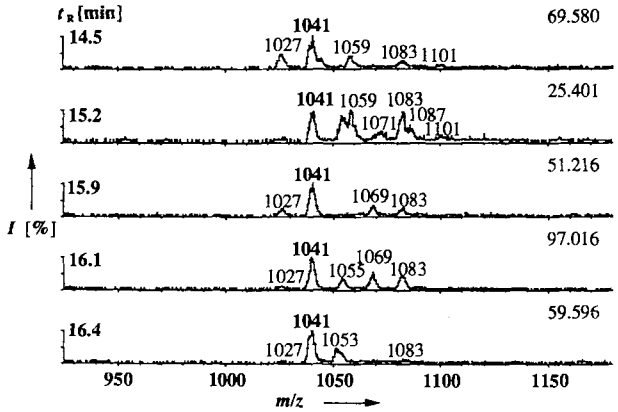

Fig. 3. IS mass spectra obtained in the peak maxima of the major peaks of the ion chromatogram of m/z 1040.6 (see Fig. 2b; t_R: retention time).

quence information on single peptides of **1** was obtained by tandem mass spectrometry (low-energy collison-induced dissociation).[13] When other isobaric peptides were present, on-line HPLC-MS/MS was used (data not shown).

Not only small peptide libraries can be analyzed by IS mass spectrometry. The IS mass spectrum of the 24576 nonapeptides of **2** (Fig. 4a) is very similar to the spectrum of the 48-component mixture **1** (cf. Fig. 1). Distinct peak groups corresponding to the singly protonated molecular ions are evident. The dashed vertical lines in the spectrum represent the m/z values expected for $[M + H]^+$ of the smallest (m/z 977.6, AITPVIHNI and corresponding isobaric peptides) and largest peptides (m/z 1179.5, EMNEIMHEF and corresponding isobaric peptides) of this mixture.

The number of isobaric peptides of **2** was calculated with a computer program and plotted versus the monoisotopic masses calculated for $[M + H]^+$ of these peptides (Fig. 4b). This representation is very similar to the IS mass spectrum of **2** (Fig. 4a). As in the case of the 48-component mixture, the observed intensity distribution of $[M + H]^+$ roughly reflects the number of isobaric peptides (see above) and therefore gives further information on the constituents of this mixture. A more detailed investigation of these quantitative aspects with defined mixtures of single purified peptides is in progress.

In summary, IS mass spectrometry alone or in combination with HPLC is a valuable tool for estimating the identity (for example the differentiation between hexa- and octapeptide libraries), composition, and purity of small and larger peptide mixtures. More detailed characterization of single peptides (i.e. sequence information) is possible only with mixtures consisting of a small number of peptides. According to our limited and preliminary experience with peptide

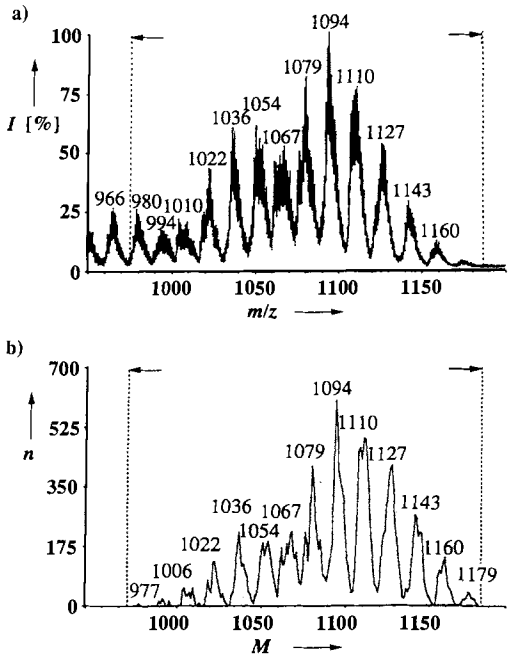

Fig. 4. a) IS mass spectrum of the synthetic nonapeptide library **2** consisting of 24575 components (region of the singly charged quasi-molecular ions; vertical dashed lines indicate calculated masses for the smallest and largest peptides of the mixture). b) Calculated number of isobaric peptides n of **2** vs. the monoisotopic molecular mass M of $[M + H]^+$ ions.

libraries in bio-assays, however, the construction of huge libraries seems to have restricted application.

Experimental Procedure

Peptide synthesis. The synthesis of 100 mixtures of octapeptides **1** (defined positions O_1: R,I,L,S,A; O_2: N; O_3: Y,P; O_4: R,D,E,K,T; O_5: F,Y; undefined positions X_1: T,I,E,S; X_2: N,Q,K and X_3: L,M,I,V) was performed by using premixed Fmoc-X_3-Wang resins (*p*-benzyloxybenzylalcohol–polystyrene cross-linked with 1% divinylbenzene) and the Fmoc/*t*Bu strategy. The moist resins were divided into equivalent amounts and coupled with amino acids X_2. The Fmoc protecting groups were removed and the resin-bound amino acids coupled with amino acids X_1. The amino acids were used in threefold excess; TBTU (*O*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate) was used for activation. Aliquots of the Fmoc–$X_1X_2X_3$ resin mixture were elongated to octapeptide mixtures on a multiple peptide synthesizer (SMPS 350, Zinsser Analytic, Frankfurt, FRG) (see ref. [1]). After cleavage of the peptide mixtures from the resins (trifluoroacetic acid/thioanisole/thiocresol 190:5:5, v:v:v) the synthetic 48-component mixture LNYRF$X_1X_2X_3$ was selected for mass spectrometric analysis.

Identical procedures were used for the synthesis and cleavage of the nonapeptide library **2** (defined position O: H; undefined positions X_1: A,E,K,Q; X_2: M,I,L,Q; X_3: L,I,N,T; X_4: D,E,K,P; X_5: V,I; X_6: M,I,L,K; X_7: E,Q,N,K; X_8: L,I,F.

IS mass spectrometry: Samples of the synthetic peptide mixtures (ca. 100 μg) were dissolved in methanol/1% formic acid (1:1, 1 mL). IS mass spectra were recorded on a triple-quadrupole mass spectrometer API III equipped with an ion-spray (nebulizer-assisted electrospray) source (Sciex, Thornhill, Ontario, Canada). The solutions were continuously infused with a medical infusion pump (Model 22, Harvard Apparatus, South Natick, USA) at a flow rate of 5 μL min^{-1}. Cesium iodide was used to calibrate quadrupoles Q_1 and Q_3. IS mass spectra were acquired at unit resolution by scanning from m/z 800 to 1200 with a step size of 0.1 Da and a dwell time of 10 ms. Five to eight spectra were summed. The potential of the spray needle was held at +4.9 kV. Spectra containing singly, doubly, and triply charged quasi-molecular ions were recorded at an orifice voltage of +60 V. A higher orifice voltage of +120 V was chosen to enhance the intensity of $[M + H]^+$ and to suppress the formation of multiply charged ions. The mass values above the (not centroided) mass peaks in the mass spectra (Figs. 1–4) correspond to the observed peak maxima. The observed intensities for the monoisotopic $[M + H]^+$ ions (calculated with C = 12.000) are higher than for the isotopic ^{13}C ions, which is in agreement with the natural isotope distribution calculated for the molecular peaks of the investigated peptides. Accuracy of mass assignment was ±0.1 u. Tandem mass spectrometry (collision-induced dissociation) was performed with argon as collision gas.

For on-line HPLC-MS an Applied Biosystems ABI 140A HPLC system and a narrow-bore column (Nucleosil C-18, 2 × 100 mm; 5 μm; Grom, Herrenberg, FRG) equipped with a precolumn (2 × 10 mm; same filling) at a flow rate of 200 μL min^{-1} were used. A linear gradient of 5 to 20% solvent B in 40 min was used (solvent A: 0.1% aqueous trifluoroacetic acid; solvent B: 0.1% trifluoroacetic acid in acetonitrile). The flow was split so that 40 μL min^{-1} entered the IS interface. A solution of 500 pmol of **1** in 5 μL of water was injected.

Computer program: A program for calculation of the molecular masses of the peptides and the number of isobaric peptides in libraries was designed, which generated all possible permutations within the peptide sequences as defined by the variable positions. The mass distribution was approximated by counting the number of different peptides within one atomic mass unit. In order to assist assignment of additional mass peaks in the IS mass spectrum corresponding to by-products, the expected masses for uncleaved protecting groups or deletion peptides can be calculated and displayed, too.

$[P(MeNCH_2CH_2)_3N]$ as a Superior Catalyst for the Conversion of Isocyanates to Isocyanurates

By *Jian-Sheng Tang* and *John G. Verkade**

Triaryl isocyanurates are useful as activators for the continuous anionic polymerization and postpolymerization of ε-caprolactam to nylon-6 possessing a low unreacted monomer content and a highly stable melt viscosity.[1] Recently the superior thermal properties and hydrolytic stability of isocyanurate-based foams and plastics have generated considerable interest in the development of efficient isocyanate trimerization catalysts.[2] A wide variety of catalysts for the trimerization of aryl isocyanates to triaryl isocyanurates has been reported.[1, 3] Because impure triaryl isocyanurates are detrimental to the quality of nylon-6, much attention has been given to obtaining such activators in high purity.[1a] However, purification often results in substantial lowering of product yield, and attempts to increase the yield of trimer frequently require large amounts of catalyst, ex-

tended reaction times, and vigorous conditions. Here we report on the superior properties of **1** as a unique catalyst for the trimerization of aryl isocyanates, and we present evidence for the catalytic pathway.

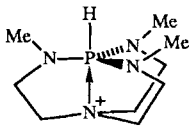
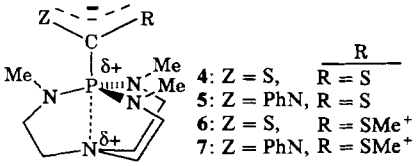
2



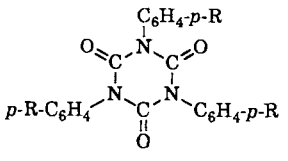
3

Because reported catalysts for the trimerization of isocyanates are typically Lewis bases, it has been proposed that their activity depends upon their basicity[4] and/or upon the stability of zwitterionic intermediates such as **2**.[3c, d] This suggests that a strong base capable of forming a stable zwitterionic intermediate could function as an efficient catalyst for the trimerization of aryl isocyanates. Recently we reported that **1** is an exceptionally strong base whose conjugate acid **3** has a pK_a of about 27 in DMSO,[5, 6] and that zwitterionic adducts such as **4** and **5** can be isolated.[7] The partial transannular bond in **4** was verified by an X-ray structure determination; the transannular distance between the bridgehead atoms in **4** (3.008 Å[7]) is intermediate between that presumed in **1** (ca. 3.35 Å[8]) and that measured in cation **3** (1.967 Å[7]). This distance in **4** is about 0.3 Å longer than that in its methylated derivative **6** (2.771 Å[7]), suggesting that the corresponding distance in **5** (ca. 2.5 Å; suitable crystals for X-ray crystallography could not be grown) is probably longer than in **7** (2.190 Å[7]).



4: Z = S, R = S
5: Z = PhN, R = S
6: Z = S, R = SMe^+
7: Z = PhN, R = SMe^+

Trimers **8** and **9** can be synthesized in pure form (purity checked by thin-layer chromatography (TLC)) from the corresponding aryl isocyanates in respective yields of 97 and 99% and respective reaction times of 3 and 8 min at room temperature with only 0.33 mol% **1** as catalyst. By contrast, $P(NMe_2)_3$, an acyclic analogue of **1**, produces only a small yield of the cyclic dimer of phenyl isocyanate, even over an extended period of time. Catalyst **1** is also superior in comparison with the other catalysts previously described. Thus, for example, the conversion of phenyl isocyanate with Et_3N as a catalyst was reported to be complete at 100 °C but required 10% catalyst and a pressure of 800 MPa for 20 h;[3a, b] the reaction with $AsBu_3$ proceeded in 18 to 99% yield over 12–34 min, but the reaction is very sensitive to temperature.[3f] Moreover, criteria of purity were not addressed. While **1** is very soluble in organic solvents, benzene is best if a solvent is used for the reaction because the reagents are soluble and the product is insoluble. Thus simply washing the product with benzene provides **8** or **9**, pure by TLC, in nearly quantitative yield.

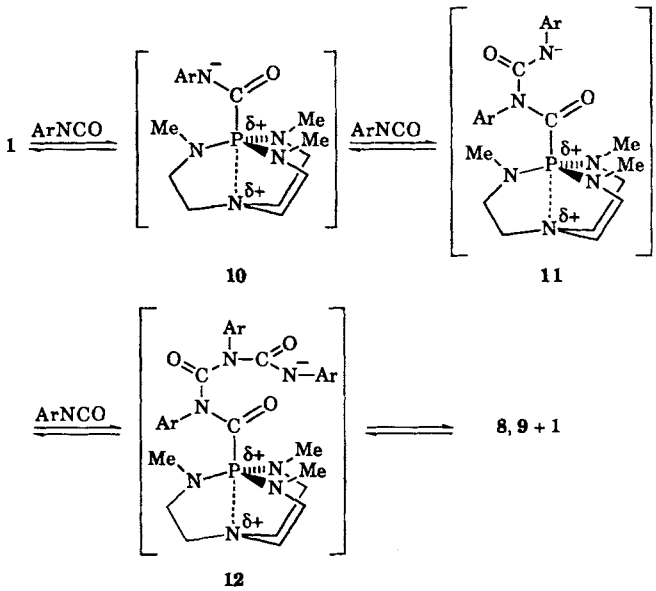


8: R = H
9: R = OMe

An electron-donating group on the aryl substituent of aryl isocyanates renders the carbonyl carbon atom less electrophilic, and hence makes trimerization more difficult, as has been shown for *p*-MeC_6H_4NCO.[3c, d] With **1** as the catalyst, we find that even a substrate with a *para*-methoxy substituent on the aryl ring can be trimerized in 99% yield upon extension of the reaction time to 8 min.

The reaction pathway shown in Scheme 1 is analogous to those proposed previously[3c, d, h] for other catalysts, although none of the zwitterionic catalyst–arylisocyanate adduct intermediates were detected previously. In our reaction with PhNCO with **1** as a catalyst, however, we observe a transient peak in the ^{31}P NMR spectrum (in C_6D_6) at $\delta = 29.46$ and a peak in the FAB mass spectrum at m/z 336.1 ($M + H$) for an isolated solid apparently containing an intermediate. With *p*-$MeOC_6H_4NCO$ a corresponding ^{31}P NMR signal is seen at $\delta = 29.23$ in C_6D_6. It is tempting to attribute these data in both cases to the corresponding intermediates **10**. The stability of adduct **5** (the sulfur analogue of **10**) to further reaction with PhNCS[7] can be ascribed to the diminished nucleophilicity of the PhN nitrogen atom and reduced electrophilicity of the PhNC carbon atom, induced by the less electronegative sulfur atom.

In the cyclodimerization of PhNCO, the equilibrium is reported to lie on the side of the starting material at higher temperatures,[9] and trimer formation is reported to be thermodynamically allowed from 0 to 850 K.[10] Thus the dimer/trimer ratio decreases with increasing temperature in the presence of the (weak) catalyst $P(NMe_2)_3$.[11] The much stronger catalytic action of **1** may be attributed to its substantial stabilizing influence on adducts **10** and **11** (Scheme 1), and particularly on **11**, which enables this adduct to nucleophilically attack the third ArNCO molecule.



Scheme 1. Reaction pathway for the trimerization of ArNCO catalyzed by **1**.

The basicity of the nucleophilic nitrogen atom in **11** is undoubtedly enhanced by induction effects from the bridgehead nitrogen atom in the quasi- transannular bond shown to exist, for example, in **4**, **6**, and **7**.[7] It is reasonable to suppose that when intermediate **12** undergoes ring closure to

give the trimer, the resulting increased electron density on the PC carbon atom weakens the transannular bond, thereby facilitating departure of trimer and regeneration of the catalyst **1**, in which the transannular interaction is weakest.[7, 8] Strong support for the postulated flexibility of the transannular interaction in **1** (depending upon the phosphorus substituent) is the stepwise reduction of this distance over a series of eight compounds from 3.33 Å (which is essentially the sum of the P and N covalent radii) to 1.967 Å.[7]

Experimental Procedure

To a one-necked round-bottomed flask (250 mL, filled with N_2 and closed with a septum) containing a solution of **1** (0.11 g, 0.50 mmol) in dry benzene (10 mL) was added by syringe phenyl isocyanate (18.0 g, 99% pure, 150 mmol, Aldrich). After the mixture was stirred at room temperature for 3 min, the white precipitate that had very rapidly formed solidified into a mass within a few seconds. The solid was cooled to room temperature, dried under vacuum, ground to powder, stirred with 30 mL of dry benzene for 2 h, filtered in vacuo, washed again with 15 mL of dry benzene, and finally dried in vacuo to give 17.2 g (96.6%) of **8** (pure by ^{1}H NMR spectroscopy and TLC (silica gel, hexane:ether = 2:1, or $CHCl_3$, or $CHCl_3$:acetone = 50:1 as eluents)). M.p. (uncorrected) 279.0–279.5 °C (lit. 281–281.5 °C[1b]); ^{1}H NMR ($CDCl_3$): δ = 7.35–7.51 (m, C_6H_5); ^{13}C NMR (CD_3CN): δ = 128.21, 128.74, 129.16, 133.39, 148.46; HRMS (*m/z*): calcd and found for $C_{21}H_{15}N_3O_3$ 357.11134 (54, M^+); correct C,H,N-analysis.

The analogous reaction with *p*-$MeOC_6H_4NCO$ carried out over 8 min gave a 98.7% yield of **9** (pure by ^{1}H NMR spectroscopy and TLC (silica gel, same solvent systems as used for **8**)) after the product was washed with benzene (80 mL) and dried in vacuo at 50 °C. M.p. (uncorrected): 261.0–261.5 °C (lit. 261–2 °C[1b]); ^{1}H NMR ($CDCl_3$): δ = 3.81 (s, 9H, OCH_3), 6.96 (d, 4H, C_6H_4; $^3J_{HH}$ = 8.7 Hz), 6.27 (d, 4H, C_6H_4; $^3J_{HH}$ = 8.7 Hz); HRMS (*m/z*): calcd for $C_{24}H_{21}N_3O_6$, 447.14304. Found, 447.14358 (50, M^+).

To detect intermediates by ^{31}P NMR spectroscopy the reaction was carried out with 0.037 g (0.17 mmol) of **1** and 0.062 g (0.52 mmol) of PhNCO in 0.7 mL of C_6D_6, and with 0.057 g (0.26 mmol) of **1** and 0.094 g (0.79 mmol) of *p*-$MeOC_6H_4NCO$ in 0.7 mL of C_6D_6. When 0.08 g (0.7 mmol) of PhNCO was added by syringe to a solution of 0.1 g (0.5 mmol) of **1** in ether (10 mL), a colorless solid precipitated which was dried in vacuo to give 0.14 g of a colorless solid. ^{31}P NMR (CD_3CN): δ = 31.11, −9.35; MS (*m/z*, FAB): 336.1 (M + H, 10, 52) and 217.1 (M + H, 1, 100).

The analogous reaction with $P(NMe_2)_3$ (0.17 g, 1.0 mmol) was carried out in 45 mL of dry benzene with 11.9 g (0.10 mol) of PhNCO. The reaction mixture was heated at 60–70 °C for 5 d at 60–70 °C then left at room temperature for 10 h, whereupon a small amount of white precipitate appeared. The volatiles were removed under vacuum, the residue was stirred with 5 mL of benzene, and then the suspension was filtered, washed with acetonitrile (5 × 2 mL), and dried to give 0.48 g (4%) of cyclic dimer. M.p. 182–183 °C (lit. 175 °C[10]); ^{1}H NMR (CD_3CN): δ = 7.4–7.5 (m); HRMS (*m/z*): calcd for $C_{14}H_{10}N_2O_2$, 238.07423. Found, 238.07428 (3.5, M^+).

The Importance of the Rigidity of the Peptide Backbone for the Inhibitory Properties of BPTI Demonstrated by Semisynthetic Structural Variants**

By *Christian Groeger, Herbert R. Wenzel,* and *Harald Tschesche**

Proteinases play an essential role in metabolic processes. Their antagonists, the protein–proteinase inhibitors, block the action of proteinases in vivo, and this important control function makes them interesting as potential therapeutics.

Rational drug design requires detailed knowledge of all aspects of the mode of action of inhibitors; the results of investigations into the relationship between structure and function of naturally occurring inhibitors are the ideal basis for the development of new synthetic proteins with inhibitory properties.

Many proteinase inhibitors function as substrate analogues; therefore, besides a low dissociation constant of the corresponding enzyme-inhibitor complexes, the resistance to proteolysis (permanence) of the inhibitors against the target enzymes is essential.

In this paper we want to demonstrate with three semisynthetic "backbone" variants of the trypsin-kallikrein inhibitor BPTI (BPTI = basic pancreatic trypsin inhibitor = Kunitz trypsin inhibitor) from bovine organs, that a strong permanent trypsin inhibitor can be converted into a trypsin substrate by minor changes in the peptide backbone.

In contrast to the specificity-determining amino acid $P_1 = Lys^{15}$,[1] the P′ region of BPTI, ($P'_1 = Ala^{16}$, $P'_2 = Arg^{17}$, Fig. 1), can be replaced by a variety of residues without significantly reducing the anti-tryptic activity of the inhibitor.[2, 3] Even the complete removal of the side chains in this region is tolerated. Thus, the dissociation constant of the [Gly^{16},Gly^{17}] BPTI–trypsin complex is 2×10^{-12} M, only one order of magnitude higher than that of the native complex.

Since the influence of the side chains in this region is apparently small, it seemed instructive for further investiga-

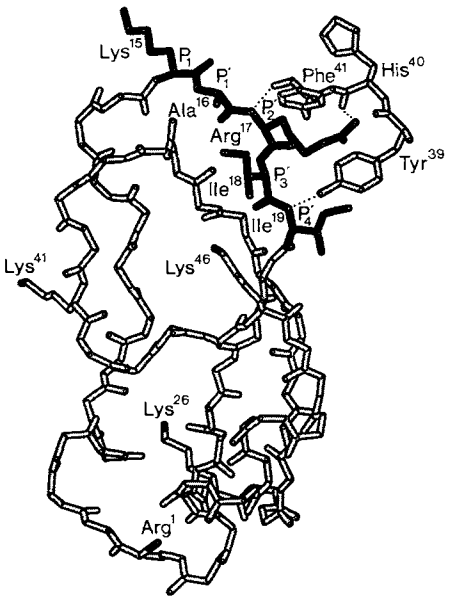

Fig. 1. A projection of the tertiary structure of the BPTI–trypsin complex [6] (section), residues Tyr^{39}, His^{40}, and Phe^{41} belong to trypsin. The P′ strand including side chains and the specificity-determining amino acid Lys^{15} as well as the N terminus and ε-amino groups of BPTI are shown in boldface. The dotted lines represent hydrogen bonds.

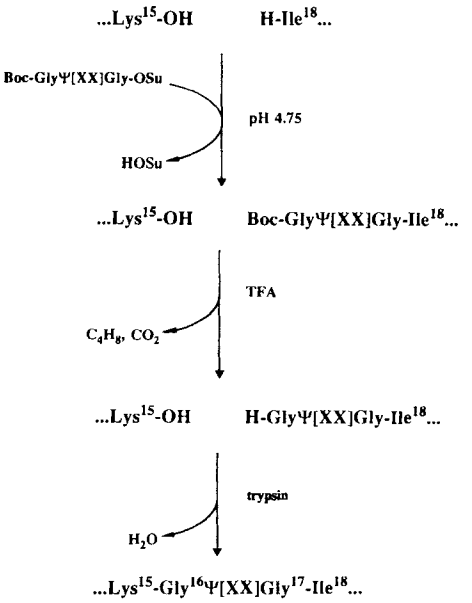

Scheme 1. The exchange of Ala^{16} and Arg^{17} by peptide analogues, (exemplified by a Boc-protected activated ester), starting from de(Ala^{16}-Arg^{17})-[*seco*-15/18]BPTI (XX = CH_2CH_2, CH_2NH, $COCH_2$). TFA = Trifluoroacetic acid.

tions into structure–function relationships to replace positions P′$_1$ and P′$_2$ with a series of peptide analogues derived from glycylglycine (Fig. 2). The introduction of the struc-

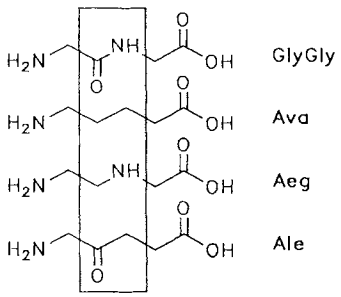

Fig. 2. Peptide analogues derived from glycylglycine. The box indicates the changed amide bond.

turally related building blocks 5-aminovalerianic acid (Ava), *N*-aminoethylglycine (Aeg), and 5-aminolevulinic acid (Ale), into the P′region of the inhibitor results in a complete or partial replacement of the P′$_1$–P′$_2$ amide bond with methylene groups. To introduce the building blocks, the P$_1$–P′$_1$ (Lys^{15}-Ala^{16}) bond in the reactive site of the inhibitor is cleaved with trypsin, and the amino acids Ala^{16} and Arg^{17} are removed with aminopeptidase K. This results in the formation of the inactive fragment de(Ala^{16}-Arg^{17})-[*seco*-15/18]BPTI.[4] The new N terminus at P′$_3$ = Ile^{18} can now be acylated by using the *N*-hydroxysuccinimide ester of Boc-Ava, (Boc = butoxycarbonyl), (Boc)$_2$-Aeg, and Z-Ale (Scheme 1).

Although the inhibitor fragment possesses a total of six potential sites for acylation (two N termini as well as ε-amino groups of four lysine residues, Fig. 1), the reaction can be carried out with a high degree of selectivity by controlling the pH value. For example, at a pH of 4.75, up to 25% of the product is monoacylated at Ile^{18}. After cleavage of the Boc or Z protecting group, the open Lys^{15}, Gly^{16}Ψ[XX]Gly^{17} bond is closed by using trypsin.[5]

Compared with [Gly^{16}-Gly^{17}]BPTI, [Ava$^{16-17}$]BPTI and [Aeg$^{16-17}$]BPTI have proved to be much weaker and, furthermore, temporary trypsin inhibitors; that is, they are degraded by the enzyme. The dissociation constants are about 2×10^{-9} and 7×10^{-9} M, respectively.

In contrast, the inhibitor [Ale$^{16-17}$]BPTI with a dissociation constant of 5×10^{-11} M is a strong and permanent inhibitor of trypsin.

A look at the subsite interactions[6] in the native BPTI–trypsin complex (Fig. 1) shows that the keto function of the P′$_1$–P′$_2$ amide bond is involved in neither intramolecular hydrogen bonds in BPTI nor intermolecular hydrogen bonds between BPTI and the enzyme. The NH group alone serves as donor for a hydrogen bond to the CO unit of Phe^{41} in trypsin and thus should contribute to the stability of the complex. The experiment shows, however, that [Aeg$^{16-17}$]BPTI has a slightly higher dissociation constant than [Ava$^{16-17}$]BPTI.

The good inhibitory properties and especially the resistance of the Ale derivative to breakdown by trypsin must be due to the restricted flexibilty of the bonding loop, because the keto function fixes four atoms in the same plane; the Ale derivative thus possesses some of the rigidity of [Gly^{16}-Gly^{17}]BPTI. A rigid binding region of the inhibitor means easier docking and a lower entropy loss[7] during complexation by the enzyme, which also leads to a higher affinity for the enzyme. At the same time the rigidity of the binding region explains the extremely slow proteolysis of the P$_1$–P′$_1$ peptide bond.[8]

In contrast, a flexible bonding loop, which additionally forms a hydrogen bond to the enzyme in the complexed state (Aeg derivative), leads to a much stronger reduction in degree of freedom than in a reaction with a loop with the same degree of flexibility that cannot form this bond (Ava derivative). Only the combined effects of backbone rigidity and hydrogen bond formation—as in [Gly^{16}-Gly^{17}]BPTI—result in the net energy gain for the complex formation, as shown by the lower dissociation constant of 2×10^{-12} M in contrast to the Ale derivative.

The structural variants of the peptide backbone of BPTI described here show that complementarity in the sense of a

perfect fit between enzyme and inhibitor is not as important as the rigidity of the peptide structure in the binding region. This rigidity is an absolute requirement for the proper function of the inhibitor as a permanent inhibitor.

Experimental Procedure

Ava·HCl was produced by acid hydrolysis of 2-piperidone. Aeg was synthesized from 1,2-diaminoethane and chloroacetic acid according to [9]. Ale·HCl was purchased from Merck. The addition of Boc or Z protecting groups and the esterification with hydroxysuccinimide were carried out according to standard procedures [10]. All derivatives and intermediates were characterized by ^{1}H NMR spectroscopy and mass spectrometry.

A general procedure for the synthesis of BPTI derivatives: De(Ala^{16}-Arg^{17})-[*seco*-15/18]BPTI (25 mg) (preparation see refs.[2,3]) was dissolved in bidistilled water (5 mL) and treated with a 30-fold molar excess of activated ester, dissolved in 1 mL of dioxane or dimethyl sulfoxide. The pH was maintained at 4.75 by addition of NaOH. After 4–5 h the solution was gel filtrated on Sephadex G-25, and the monoacylated product was separated by ion-exchange chromatography on CM Sepharose FF at pH 8.6 (NaCl gradient). The corresponding fractions were desalted on Sephadex G-25, and the protecting groups were cleaved with trifluoroacetic acid (15 min for Boc; 10 h for Z). The acid was removed under vacuum, and the residue taken up with the equivalent amount of bovine trypsin in Tris buffer pH 8. After 10 min the pH was lowered to 1.7 with dilute HCl, and the solution was subjected to gel filtration on Sephadex G-50 at pH 1.7. Finally, the inhibitor-containing fractions were repurified on CM Sepharose FF by ion-exchange chromatography, desalted on Sephadex G-25, and lyophilized. Yield: 0.5–2.5 mg, 2–10%. Ion-spray mass spectra of the synthesized inhibitor variants gave the expected molecular weights. The identity of the Aeg derivative was also confirmed by complete sequencing with the Edman degradation method. [Gly^{16}-Gly^{17}]BPTI was synthesized as described in [3].

Synthesis and Complexation Studies of Neutral Anion Receptors

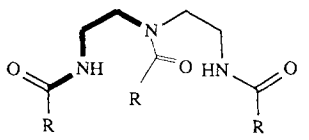
By *Suresh Valiyaveettil, Johan F. J. Engbersen, Willem Verboom*, and *David N. Reinhoudt**

The design and synthesis of receptor molecules for the selective complexation of ions has attracted much attention during the past two decades.[1] However, the number of host molecules for anions is very low compared to the number for cations. The reported host molecules contain either positively charged sites[2] or Lewis acid metal centers[3] to accomplish anion binding.[4]

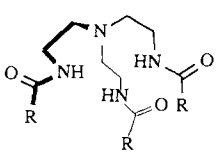
In nature, the selective ion flow to and from the cell is regulated by ion-binding proteins that act as ion carriers and channels across the cell membrane. Quiocho et al.[5] have shown that the high specificity of phosphate transport by proteins is determined by extensive hydrogen bonding in the binding site. The phosphate binding site is formed by two similarly folded globular protein domains and is located in a cleft approximately 8 Å inside from the protein surface. Phosphate binding involves the formation of twelve hydrogen bonds, five from the main chain and seven from the side-chain residues.[5a]

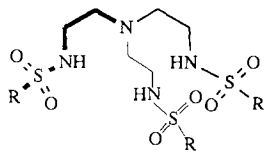
In our attempts to mimic nature in the recognition of anions by the formation of multiple hydrogen bonds in three-dimensional arrangements, we have designed a new series of ligands with hydrogen-bond donor as well as acceptor sites. This strategy was based on the known structures of phosphate binding sites of proteins. In this communication we demonstrate that surprisingly strong anion binding can be achieved with relatively simple, neutral host molecules in which the H-bond donor and H-bond acceptor sites are present in a tetrahedral arrangement and interact with complementary groups on the anions. Since these receptor molecules are uncharged they are of particular interest as ionophores in membrane transport and for the introduction of anion selectivity in potentiometric membrane sensors.

The host molecules **1**, **2**, and **3**–**8** were synthesized starting from diethylenetriamine and tris(aminoethyl)amine, respectively, by reaction with the appropriate acid chlorides in the presence of triethylamine as base.[6] Compounds **1**–**8** were isolated in 70–90% yield after recrystallization from methanol, and were characterized by ^{1}H and ^{13}C NMR spectroscopy, mass spectrometry, and elemental analysis.



1 R = CH_2Cl
2 R = $(CH_2)_4CH_3$





3 R = CH_2Cl
4 R = $(CH_2)_4CH_3$

8 R =

In ^{1}H NMR titration experiments of the ligands with $Bu_4N^+A^-$ ($A^- = H_2PO_4^-$, HSO_4^-, Cl^-) in chloroform, the NH signal of the ligands shifted $\Delta\delta \approx 1.5$–2.0 to lower field until a host–guest ratio of 1:1 was reached. No shift was observed in the NMR signal when the concentration of the anion was increased; however, in the titration with $H_2PO_4^-$ the NH signal shifted until a host–guest ratio of 1:2 was attained. These stoichiometries were confirmed by the characteristic $\delta(^{31}P)$ values for all host–guest complexes in acetonitrile upon addition of two equivalents of $Bu_4N^+H_2PO_4^-$. For example, the signal for ligand **8** showed a shift of $\Delta\delta = 0.345$ with one equivalent of $H_2PO_4^-$ and a further shift

[*] Prof. Dr. Ir. D. N. Reinhoudt, Dr. S. Valiyaveettil, Dr. J. F. J. Engbersen, Dr. W. Verboom
Laboratory of Organic Chemistry
University of Twente
P.O. Box 217, NL-7500 AE Enschede (The Netherlands)

of $\Delta\delta = 0.374$ with two equivalents. This host–guest complexation ratio of 1:2 was also reported by others and is attributed to dimerization of the $H_2PO_4^-$ ion by the formation of intermolecular hydrogen bonds.[7] The observed chemical shifts do not arise from proton transfer from $H_2PO_4^-$ and HSO_4^- to the ligands, since no shifts in the position of the CH_2N signal were observed in the ^1H NMR spectra of the complexes. Moreover, when ligands **1**–**8** were protonated by addition of *p*-toluenesulfonic acid or picric acid, a distinct downfield shift of the CH_2N signal of $\Delta\delta = 1.0-1.1$ was observed. The FAB^- mass spectra of the complexes of all the host molecules H with $Bu_4N^+A^-$ exhibit strong signals corresponding to $[HA^-]^-$ and $[HBu_4N^+A^-]^-$. The association constants (Table 1) for the complexation of ligands **1**–**8** with anions A^- (Bu_4N^+ as the counterion) were determined in acetonitrile by conductometry.[8]

Table 1. Association constants K [M^{-1}] for the reaction of **1**–**8** with the anions $H_2PO_4^-$, HSO_4^-, and Cl^- determined by conductometry [a].

	$H_2PO_4^-$	HSO_4^-	Cl^-
1	4700	36	96
2	870	65	63
3	6100	170	1740
4	280	31	290
5	870	56	100
6	510	73	190
7	3500	79	540
8	14200	38	1600

[a] Reactions in acetonitrile. The counterion in all cases was Bu_4N^+. Measurements were conducted at constant ionic strength with starting concentrations of **1**–**8** of 1–3 mM and of the salt of 0.9–1.1 mM. The concentrations of the salt and ligand were varied by dilution of the sample solution with a stock solution of the free salt. Initial concentrations were prepared by adding the appropriate amount of free ligand to 10 mL of the stock solution. The K values were determined with curve-fitting methods. The error is 5% for $K > 10^2\ M^{-1}$ and 10% for $K < 10^2\ M^{-1}$.

From this data it is clear that all ligands bind phosphate ions preferentially ($H_2PO_4^- > Cl^- > HSO_4^-$). The reference compound chloroacetamide was not complexed in these conductometric titrations. Ligand **8** shows highest affinity towards the phosphate ion, probably because of the increased electrophilicity of the sulfonamide NH group and preorganization of the binding sites by π-stacking interactions of the naphthyl groups.[9] The chloroacetamide derivatives **1** and **3** have a larger binding affinity than the caproamides **2** and **4**, which may be attributed to the higher polarization of the amide moieties in **1** and **3** caused by the inductive electron-withdrawing effect of the α-chloro substituents.

In conclusion, host molecules **1**–**8** show selective binding affinity towards anions exclusively by hydrogen-bond formation, and are thereby a unique mimic for anion-binding proteins. Although the association constants are not as high as those of the natural proteins, the simple structure of the models offers the possibility for synthetic manipulation. To achieve higher association constants and selectivities we are currently examining calixarenes and crown ether templates for organizing H-bond donor and acceptor binding sites for anions.

Experimental Procedure

The synthesis of **8** described is representative for the preparation of **1**–**8**: To a solution of tris(aminomethyl)amine (1.0 g, 6.8 mmol) and triethylamine (3.5 mL) in CH_2Cl_2 (100 mL) at 10 °C was added 2-naphthalenesulfonyl chloride (5.4 g, 23.9 mmol). The reaction mixture was stirred for 3 h, allowed to warm up to room temperature, stirred for another 3 h, and poured into water (200 mL). The aqueous layer was extracted with CH_2Cl_2 (2 × 100 mL). The combined organic layers were concentrated, and the resulting solid was recrystallized from methanol to give **8** in 84% yield. M.p. 127–128 °C; ^1H NMR (250 MHz, $CDCl_3$, 25 °C): δ = 8.48 (s, 3H, ArH), 7.9–7.7 (m, 12H, ArH), 7.5–7.6 (m, 6H, ArH), 6.28 (s, 3H, NH), 2.98 (t, 6H, CH_2), 2.56 (t, 6H, CH_2); ^{13}C NMR: δ = 136.5, 134.8, 132.1, 129.7, 129.4, 128.7, 128.5, 127.9, 127.4, 122.5 (ArC), 54.4 (CH_2NH), 40.9 (CH_2N); FAB MS (NBA matrix): m/z 717.1 ($M+1$); correct C,H,N analysis.

[8] The data obtained for the ^1H NMR chemical shifts in chloroform did not allow quantitative determination of the complexation constants, mainly because of the high association of the host and guest species in this moderately polar solvent and the relatively high concentrations required to obtain the NMR signals. In the conductometric experiments, however, complexation constants could be determined in the more polar solvent acetonitrile with much lower concentrations of host and guest molecules. Under these conditions the formation of only 1:1 host–guest complexes was observed.

Electron Transfer-Catalyzed Diels–Alder Reactions with 2-Vinylindoles**

By *O. Wiest* and *E. Steckhan**

Electron Transfer (ET) is one of the most important elementary processes in chemistry.[1] During the last 15 years, mechanistic-theoretical investigations of ET reactions have made a great comeback, culminating in the award of the Nobel Prize for Chemistry to R. A. Marcus in 1992. In certain cases, reactions which proceed too slowly or not at all with neutral molecules can be effected by electron transfer. Thus, the [4 + 2] cycloaddition between two electron-rich

[*] Prof. Dr. E. Steckhan, Dipl.-Chem. O. Wiest

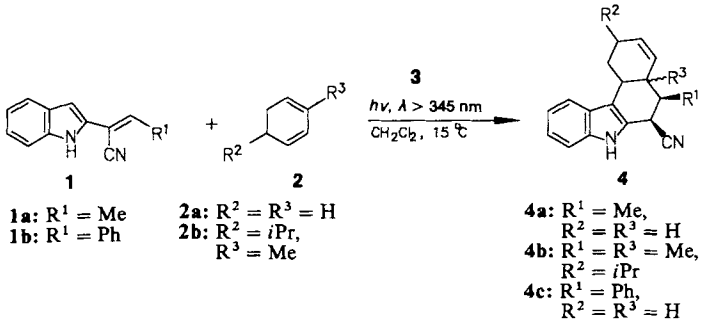
[**] This work was supported by the Deutsche Forschungsgemeinschaft (Ste 227/14-2), the Fonds der Chemischen Industrie, and the BASF AG. We thank Prof. Dr. G. P. Kreishman, University of Cincinatti, USA, for recording the NMR spectra.

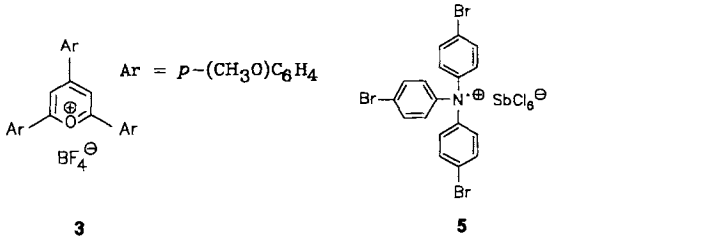
substrates can be initiated by a one-electron oxidation of one of the components to its radical cation. After a cycloaddition at the radical cation stage, a back-electron transfer terminates the reaction sequence. The reaction is thus catalyzed by ET in the sense of a redox umpolung. The synthetic potential of these reactions has not until recently been investigated systematically.[2]

The importance of 2-vinylindoles as building blocks for indole alkaloids has been pointed out several times.[3] Compounds of the type **1** with a wide variety of substituents are easily accessible by using the method of Blechert et al. However, their use as 4π-electron components in Diels–Alder reactions is limited to very electron-deficient dienophiles, sometimes demanding drastic reaction conditions.[4]

We now report for the first time electron transfer-catalyzed Diels–Alder reactions of **1** with electron-rich dienophiles under mild reaction conditions and in good to moderate yields.

Based on our studies on the photoinduced electron transfer(PET)-catalyzed cycloadditions of indole,[5] we wanted to establish whether compounds of the type **1** react as dienes or dienophiles. Therefore, **1a** was allowed to react with 1,3-cyclohexadienes **2** under PET conditions. As PET sensitizers, triarylpyrylium salts such as **3** were used, since they have proven to be efficient electron transfer catalysts even in catalytic amounts.[2b, 5, 6] The cycloadduct **4a** is smoothly formed with **2a**, that is **1** reacted as a diene. If the chiral dienophile (5*R*)-**2b** is used, (*R*)-configurated **4b** is isolated as the only isomer. As a side reaction, the dimerization of the





1,3-cyclohexadienes is observed, a reaction known[7] to be also catalyzed by PET. Alternatively, the reaction can be initiated by thermal ET with tris(4-bromphenyl)aminium hexachloroantimonate **5**.[8] However, lower yields are obtained in this case. The indole **1b** (Table 1) reacts in an analogous manner.

From previous investigations,[6] it was established that a cycloaddition can only take place if the oxidation potentials E_p (Ox) of the starting materials do not differ by more than 500 mV. Hence, styrenes **6** were chosen for further investigations because their oxidation potentials could be varied by suitable substitution over a wide range with negligible steric interference.

Table 1. Results of the ET-catalyzed Diels–Alder reaction of 2-vinylindoles **1** with 1,3-cyclohexadienes **2**.

Diene	Dienophile	Product	Yield [%]	*endo*/*exo*-Ratio

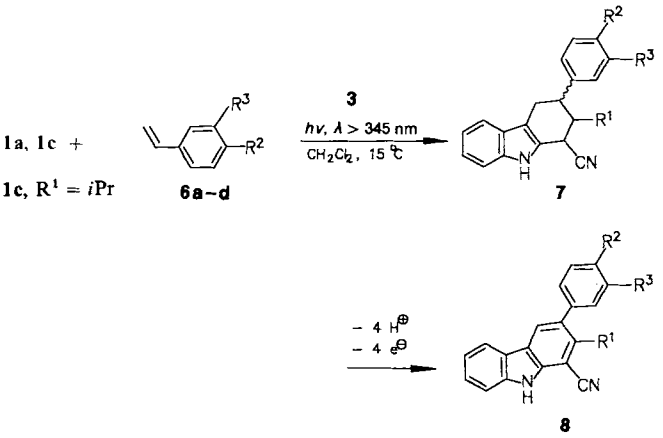
1b	**2a**	**4c**	35	3.4/1 [a]

[a] Determined by gas chromatography in the crude product. [b] Thermal electron transfer with 10 mol% **5** (based on **1**).

Under PET conditions, the primary adduct **7** is aromatized by double dehydrogenation[9] to give the carbazole derivative **8**. If the reaction is performed under conditions



for thermal electron transfer, the *endo*/*exo* isomers of **7** are obtained in good yields. It can be seen from the results (Table 2) that the difference of the oxidation potentials determines the outcome of the reaction.

Table 2. Results of the ET-catalyzed Diels–Alder reaction of 2-vinylindoles **1** with substituted styrenes **6** and dependence on the difference of the oxidation potentials of the starting materials.

Diene	Dienophile	R^2	R^3	$\Delta Ep(Ox)$ [V]	Product	Yield [%]

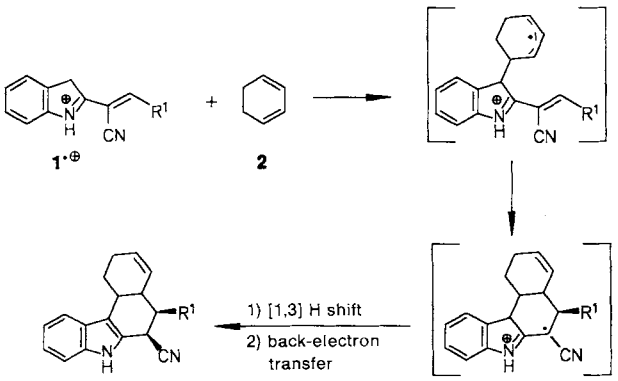
[a] Thermal electron transfer with 10 mol% **5** (based on **1**). [b] Traces of the product detected by GC/MS.

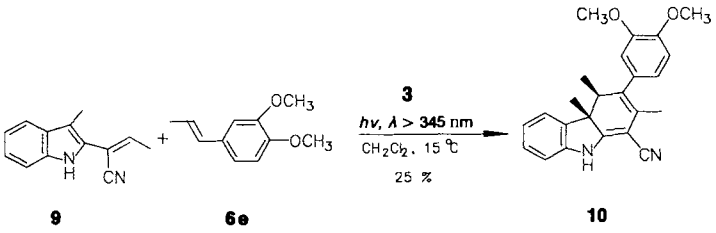
Non-conjugated dienophiles such as 1-methoxycyclohexene do not react despite their suitable E_p(Ox) values. Therefore, we conclude that the intermediate stabilization of a benzyl or allyl radical plays a decisive role. Based on our experiences with the indole system[5, 10] and the preliminary results of mechanistic investigations,[11] the mechanism outlined in Scheme 1 for the reaction of the distonic radical cation formed by ET appears probable.

For the rearomatization of the indole system, the most likely mechanism is a thermal $[1_s,3_s]$ H shift followed by back-electron transfer. The $[1_s,3_s]$ H shift is symmetry forbidden for the neutral molecule, but not for the radical cation.[12] Shift reactions of this type have been well investigated by using spectroscopic[13] and theoretical[14] methods.



Scheme 1. Proposed mechanism of the ET-catalyzed [4 + 2] cycloaddition between **1** and **2**.

If the [1,3] H shift is prevented by suitable substitution (**9**) of the 2-vinylindole,[15] the double bond remains in the 1,9a-position of the tetrahydrocarbazole intermediate after back-electron transfer. Under the reaction conditions, in situ dehydrogenation takes place to give the highly substituted 4,4a-dihydrocarbazole **10** as the only product.[16]



9 **6e** **10**

The reactions presented here open a new pathway for Diels–Alder reactions with 2-vinylindoles. The exact mechanism and the application of the reactions to the synthesis of indole alkaloids are currently under investigation.

Experimental Procedure

a) General procedure for PET-catalyzed reactions: Vinylindole **1** (0.5 mmol), dienophile **2** (0.7 mmol) or **6**, and **3** (0.02 mmol) were dissolved in anhydrous CH_2Cl_2 (50 mL), and the solution was degassed with argon in a Schlenk tube. The solution was irradiated in a water bath (15 °C) with a 450 W xenon lamp ($\lambda > 345$ nm). The pyrylium salt **3** was removed after the reaction with a short filtration column.

b) General procedure for the thermal electron transfer: Vinylindole **1** (0.5 mmol) and dienophile **2** (0.7 mmol) or **6** were dissolved in anhydrous CH_2Cl_2 (50 mL) and degassed with argon. The solution was cooled to 0 °C and a suspension of **5** (0.05 mmol) in CH_2Cl_2 (10 mL) was added dropwise.

For workup, in both cases the solvent was removed, and the residue was purified by chromatography. The *endo*/*exo* isomers were separated by HPLC (LiChrospher RP18-5, water/acetronitrile mixtures). All new compounds were identified spectroscopically. Regio- and stereochemistry were proven by two-dimensional NMR spectroscopy (COSY, HETCOR, NOESY), for example for **4b**: ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.04$ (br, 1H, H-7a), 7.65 (1H, d, $J = 7.8$ Hz, H-11), 7.33 (1H, d, $J = 8$ Hz, H-8), 7.18 (1H, t, $J = 7.8$ Hz, H-9), 7.09 (1H, t, $J = 8$ Hz, H-10), 5.71 (1H, d, $J = 10.8$ Hz, H-4), 5.66 (1H, d, $J = 10.8$ Hz, H-3), 3.93 (1H, d, $J = 4.9$ Hz, H-6), 2.99 (1H, m, H-11c) 2.36 (1H, m, H-1), 2.08 (1H, qd, $J = 6.8$ and 4.9 Hz, H-5), 1.94 (1H, ddd, $J = 12.6$, 9.7 und 2.9 Hz, H-1), 1.55 (2H, m, H-5, H-12), 1.36 (3H, d, $J = 6.8$ Hz, H-16), 1.18 (3H, s, H-15), 0.86 (3H, d, $J = 6.1$ Hz, H-12), 0.85 (3H, d, $J = 6.1$ Hz, H-14); ^{13}C NMR (100.6 MHz, $CDCl_3$): $\delta = 136.7$ (C-7a), 132.8 (C-3), 129.9 (C-4), 126.5 (C-6a), 125.6 (C-11a), 122.4 (C-9), 119.6 (C-10, C-11), 118.4 (C-17), 113.8 (C-11b), 111.2 (C-8), 39.5 (C-5), 38.6 (C-11c), 38.15 (C-2), 38.1 (C-4a), 31.5 (C-13), 30.9 (C-6), 26.8 (C-16), 26.03 (C-1), 19.9 (C-12), 19.5 (C-14), 14.2 (C-15); $[\alpha]_D^{23} = 94.5$ ($C = 0.49$ in CH_2Cl_2).

[16] The [4 + 2] cycloaddition of **9** and **6e** can be induced alternatively by potentiostatic electrolysis (undivided cell, working electrode: graphite, auxilary electrode: Pt, CH_3CN/CH_2Cl_2 1:1, 0.1 M $LiClO_4$, working potential 670 mV vs. $Ag/AgNO_3$). Thus, it is shown that the key intermediate of the reaction is the radical cation of **9**.

C–H Bond Addition to a V=NR Bond: Hydrocarbon Activation by a Sterically Crowded Vanadium System

By *Jan de With* and *Andrew D. Horton**

Electrophilic complexes whose central atom is a metal from Group 3 or 4, or an f-block element catalyze alkene polymerization[1] and activate C–H bonds;[1a, 2] the related vanadium chemistry has been hindered by the perceived instability of V^V complexes with σ-bound hydrocarbon ligands.[3] Recent reports of the highly reactive nature of M=NR bonds in coordinatively unsaturated imido complexes,[4] together with our development of a series of robust V^V complexes with bulky nitrogen ligands,[5] led us to attempt to synthesize three-coordinate imidovanadium complexes. We postulated that generation of **1** on thermolytic expulsion of R′–H from $[RN{=}V(NHR)_2R']$, would be facilitated by the small covalent radius and relatively labile na-

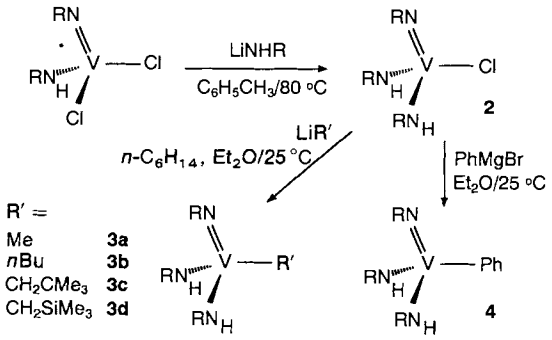
ture of M–C bonds for metals of the first transition series. Increased competition for the metal π-acceptor orbitals in bisimido complexes[6] was expected to lead to greater nucleophilicity of the imido N atom, and better polarization of C–H bonds. We report here the successful addition of a wide range of C–H bonds to a reactive V=N bond.

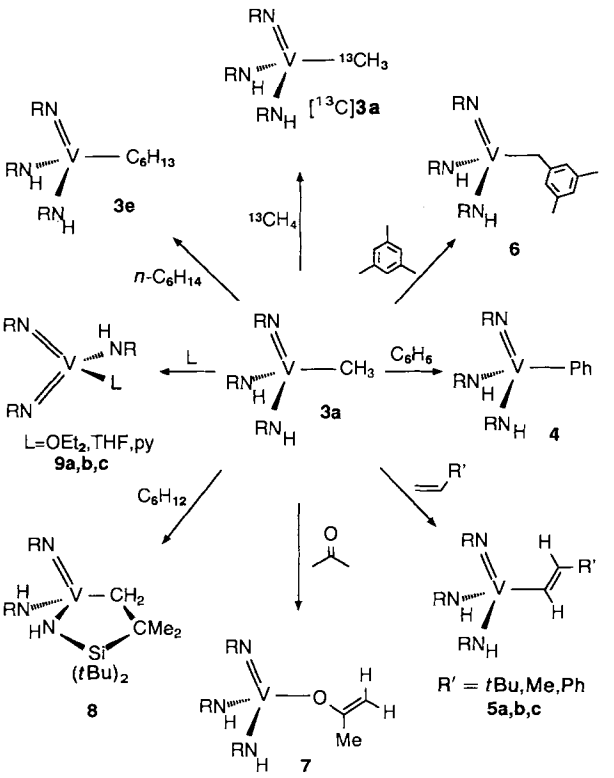
$[(RN=)_2V\text{–}NHR]$ ($R = tBu_3Si$) **1**

Crystalline complexes with σ-bound hydrocarbon ligands, stabilized by three bulky nitrogen ligands, were obtained in good yield in two steps from readily available $[RN=V(NHR)Cl_2]$[5] (Scheme 1). The presence of a plane of



Scheme 1. Synthesis of sterically crowded hydrocarbylvanadium complexes. $R = tBu_3Si$.

symmetry in the monomeric pseudotetrahedral complexes is indicated by the observation of identical amido ligands and a single VCH_2 resonance signal in the ^1H NMR spectra of **3b–d** as well as **3e** and **6** (see Scheme 2). In line with previ-



Scheme 2. Methane elimination reactions of **3a** (16 h, 80 °C; $R = tBu_3Si$; [^{13}C]**3a** formed in C_6D_{12} and **5a–c** and **7** formed in C_6H_{12}).

ous studies the ^{51}V NMR resonance signals for $[RN=V(NHR)_2R']$ show a clear upfield progression as the π-donating ability of the ligand R′ increases ($\delta(^{51}V)$: R′ = alkyl > alkenyl, Ph > Cl > OR).[3b, 5]

That the complexes **3** could activate C–H bonds was first confirmed by the clean formation of phenyl species **4** on thermolysis of the methyl compound **3a** in C_6H_6 (5 h at 80 °C). Reaction of **3a** at 80 °C with a range of substrates, either neat, or as solutions in inert cyclohexane, cleanly afforded activation products (Scheme 2) on a preparative scale. Other alkyl complexes exhibit similar C–H activation activity and no evidence was obtained for competitive, sterically demanding, β-H elimination reactivity for complexes containing β-hydrogen atoms (e.g. **3b**).

The formation of R′–H (rather than R′–D) on thermolysis of complexes **3** in C_6D_6 indicates that C–H activation does not occur by a simple sigma bond metathesis mechanism.[2] The intermediacy of unstable three-coordinate complex **1**, which may undergo C–H bond addition across one of the two V=N bonds, is strongly supported by the formation of Lewis base adducts **9a–c**, on thermolysis of complexes **3** in ether, THF, and pyridine/C_6D_{12}, respectively.

The clean first-order thermolysis of **3a** in C_6D_6, to give $[RN=V(NDR)_n(NHR)_{2-n}(C_6D_5)]$ ($n = 2$) via the observable intermediate with $n = 1$,[7] has been monitored by ^1H NMR spectroscopy and has allowed rate constants for CH_4 elimination at four temperatures in the range 60–90 °C to be obtained (e.g. $k = 11.4 \times 10^{-5}\ s^{-1}$ at 80 °C).[8] A significant rate enhancement for the first-row metal, compared to CH_4 elimination from $[(RNH)_3ZrMe]$, is found ($k_{Zr} = 10.6 \times 10^{-5}\ s^{-1}$ at 96.6 °C).[4a] The kinetic parameters determined from an Arrhenius plot are consistent with significant V–C bond breaking ($\Delta H^{\neq} = +123(8)\ kJ\,mol^{-1}$) in a late transition state, in which CH_4 formation is advanced ($\Delta S^{\neq} = +38(25)\ J\,K^{-1}$). Increased crowding in the precursor complexes, $[RN=V(NHR)_2R']$, appears to result in slightly more facile alkane expulsion, as shown by the relative reactivities with C_6D_6: **3d** > **3b** > **3a**.[9] Hydrocarbon elimination also appears to be more facile for complexes containing hydrocarbyl ligands bonded through an sp^2-carbon atom[4a] (e.g. **5**) than for those bonded through sp^3-carbon atoms,[10] although quantitative studies have not been carried out.

Selective formation of the *trans*-alkenyl complexes **5** from the reaction of **3a** with 1-alkenes, rather than the alternative *cis*-alkenyl or η^3-allyl complexes (for propene), is shown by the characteristic *trans*-$^3J_{H,H}$ coupling constant of 17 Hz (e.g. in **5a**). A clear preference for formation of the sterically, least crowded product is also seen in the selective activation of an sp^3 rather than an sp^2 C–H bond of 1,3,5-trimethylbenzene, as confirmed by the observation of resonance signals for the VCH_2 unit and those of three arene hydrogen atoms. Crystalline **5a** and **6** (but not **5b**, **c** or other $[RN=V(NHR)_2R']$ complexes) each show two sets of similar ^1H and ^{13}C NMR resonance signals. Restricted rotation about the metal–carbon bond, as previously observed in $[(RO)_3W(=O)(HC=CHtBu)]$,[11] may perhaps lead to two rotational isomers for sterically crowded **5a** and **6**. Formation of an *O*-enolatovanadium complex **7** on activation of an sp^3 C–H bond in acetone, rather than a less crowded α-metalated ketone species, reflects the greater affinity of the electrophilic V^V center for oxygen rather than carbon atoms.

The activation of alkanes by **3a** also shows a remarkable sensitivity to the steric environment of the C–H bonds: Methane and the primary C–H bonds of *n*-hexane react with **3a** to give alkyl species, whereas cyclohexane is inert. Intramolecular metalation of the NHR ligand leads in the lat-

ter case to a stable five-membered ring system in **8**. Achievement of the challenging goal of the activation of C–H bonds of CH_4 was confirmed by observation of the intense broad $V-^{13}CH_3$ resonance signal at $\delta = 32$ ($\Delta\nu_{1/2}$ 1000 Hz) in the product [^{13}C] **3a** obtained on pressurizing a C_6D_{12} solution of **3a** under $^{13}CH_4$ (10 bar; 4 h, 80 °C). The characteristic broad (plateau-like) nature of VCH_n signals is caused by a combination of unresolved coupling between the ^{13}C and ^{51}V nuclei ($I = 7/2$) and quadrupolar relaxation effects. ^{13}C incorporation was estimated at 80% by the formation of a 4:1 ratio of $^{13}CH_4$:$^{12}CH_4$ on thermolysis of the product in C_6D_6 in a sealed NMR tube.

The use of bulky nitrogen ligands has permitted the development of a family of thermally robust hydrocarbylvanadium(v) complexes, which show remarkable C–H bond activation by addition to a M=NR bond. The successful extension of such novel reactivity to a complex with a first-row transition metal,[4b, 12] in contrast to monomeric imido complexes containing coordinated Lewis bases which show no such activity,[8a, 13] is due to the sterically and electronically unsaturated nature of the proposed three-coordinate intermediate **1**. Although C–H activation with the V complexes **3** is somewhat more facile than with Zr complexes,[4a] the small size of the V^V ion hinders the activation of crowded cyclohexane. Attempts to isolate the intermediate **1** have so far been unsuccessful, but we have recently found that the labile nature of coordinated ether in **9a** allows this complex to act as a useful surrogate for **1** under mild conditions. The remarkable reactivity of **9a** will be reported elsewhere.[14]

Experimental Procedure

The products were characterized by ^{1}H, ^{13}C, and ^{51}V NMR spectroscopy, and, the crystalline products **2**, **3a–d**, **5a**, **7**, and **9a**, additionally by elemental analysis (C,H,N,Si,V). Yellow **2** and **3a** were obtained in 62 and 86% yield, respectively, as shown in the Scheme. Yellow **4** was obtained as shown in Scheme 1, or, more cleanly, by thermolysis of **3a** in C_6H_6 (Scheme 2); the complex decomposed on attempted crystallization from pentane. All thermolytic C–H activation reactions occurred quantitatively, as judged by ^{1}H NMR spectroscopy of the crude products; the high alkane solubility of the complexes frequently resulted in significantly lower isolated yields.

5a: A mixture of **3a** (0.41 g, 0.57 mmol) and *t*BuCH=CH_2 (0.37 mL, 2.87 mmol) in C_6H_{12} (10 mL) in a 25 mL autoclave was stirred at 80 °C for 16 h, and the solvent was then removed to afford a pure yellow product, which could be recrystallized from hexane. 1-Propene (5 bar) and styrene (5 equivalents) led analogously to **5b** and **5c**, respectively, which decomposed on attempted crystallization.

6, **8**: Heating a solution of **3a** in 1,3,5-trimethylbenzene or C_6H_{12} (16 h, 80 °C), followed by removal of the solvent, and crystallization from pentane or hexane, afforded red **6** and yellow **8**, respectively.

7: Treatment of **3a** with acetone (5 equivalents), analogous to the formation of **5a**, afforded pure yellow crystalline **7** (71% yield).

9a: Reaction of *n*BuLi (0.69 mmol) with **2** (0.48 g, 0.66 mmol) in hexane (20 mL) for 30 min at 25 °C, followed by removal of the solvent and extraction with hexane, afforded pure **3b**. Thermolysis of an Et_2O solution of **3b** (autoclave, 80 °C, 5 h), followed by removal of the solvent, afforded 0.39 g (85% overall yield) of spectroscopically pure red **9a**, which could be recrystallized from pentane. Selected ^{1}H NMR data (300 MHz, C_6D_{12}, 25 °C): **3a**: $\delta = 8.9$ (br, 2H; N*H*), 1.33 (s, 27H; CMe_3), 1.21 (s, 54H; CMe_3). **3b**: $\delta = 2.17$ (m, 2H; α-CH_2), 2.00 (m, 2H; β-CH_2), 1.19 (m, 2H, γ-CH_2), 0.79 (t, 3H; δ-CH_3). **4** (CD_2Cl_2): $\delta = 9.5$ (br, 2H; NH), 7.65 (m, 2H; Ph), 6.98 (m, 3H; Ph), 1.19 (s, 54H; CMe_3), 1.18 (s, 27H; CMe_3). **5a** [minor isomer]: $\delta = 7.36$ [7.09] (d, 1H; V*CH*=), 6.28 (br d, 1H; =*CH*(CMe$_3$)), 0.90 [0.88] (s, 9H; =CH(CMe_3)). **6** [minor isomer]: $\delta = 6.68$ [6.71] (s, 2H; *o*-H), 6.38 [6.30] (s, 1H; *p*-H), 3.36 [3.03] (br, 2H; VCH_2), 2.10 [2.08] (s, 6H; *Me*). **7**: $\delta = 4.30$, 3.95 (s, 1H; =CH_2), 1.81 (s, 3H; VOC(*Me*)=). **8**: $\delta = 8.4$, 8.0 (br, 1H; N*H*), 3.34 (br, d, 1H; VCH_2), 2.00 (s, 3H; CH_3), 1.50 (d, 1H; vCH_2), 1.33 (s, 27H; CMe_3), 1.28 (s, 3H; CH_3), 1.25 (s, 9H; CMe_3), 1.21 (s, 27H; CMe_3), 1.19 (s, 9H; CMe_3). **9a**: $\delta = 8.7$ (br, 1H; NH), 4.38 (q, 4H; CH_2CH_3), 1.25 (s, 81H; CMe_3). Selected ^{13}C NMR data (75.43 MHz, C_6D_{12}, 25 °C): **3a**: $\delta = 31.8$ (9C; CMe_3), 31.5 (18C; CMe_3), 25.5 (3C; CMe_3), 24.1 (6C; CMe_3). **4** (CD_2Cl_2): $\delta = 140.6$ (*m*-Ph), 126.3 (*o*-Ph), 125.8 (*p*-Ph). **5a**: $\delta = 156.6$ (d, ^1J(C,H) = 147 Hz, =*CH*(CMe$_3$)). **6** [minor isomer]: $\delta = 150.2$ [152.6] (*ipso*-Ph), 137.4 [137.0] (*m*-Ph), 127.3 [126.9] (*o*-Ph), 125.6 [124.5] (*p*-Ph), 21.5 (Me). **7**: $\delta = 167.6$ (VOC(Me)=), 92.3 (t, ^1J(C,H) = 158 Hz; =CH_2), 30.5 (VOC(Me)=). **8** (C_6D_6): $\delta = 33.8$ (VCH_2). **9** (CD_2Cl_2): $\delta = 73.5$ (CH_2CH_3), 12.8 (CH_2CH_3). Selected ^{51}V NMR data (78.86 MHz, C_6D_{12}, 25 °C; $\Delta\nu_{1/2}$ in Hz; $VOCl_3$: $\delta = 0$): **2**: $\delta = -34$ (370). **3a**: $\delta = 172$ (235). **3b**: $\delta = 264$ (290). **4** (CD_2Cl_2): $\delta = 81$. **5a**: $\delta = 99$ (220). **6** [minor isomer]: $\delta = 294$ [90] (310 [480]). **7**: $\delta = -229$ (180). **8**: $\delta = 449$ (1190). **9a**: $\delta = -65$ (1700).

[7] Consumption of **3a** was followed by ^{1}H NMR monitoring of the total CMe_3 integral for **3a** (amido and imido groups). Formation of [RN=V(NDR)$_n$(NHR)$_{2-n}$(C_6D_5)] ($n = 1, 2$) in C_6D_{12} solution is effectively zero order relative to the concentration of C_6D_6 for > 5 equivalents C_6D_6.

[8] The following rate constants for CH_4 elimination from [RN=V(NHR)$_2$$CH_3$] in C_6D_6 were obtained: $k \times 10^5 = 1.15$ (60 °C); 5.26 (70 °C); 11.4 (80 °C) 59.4 (90 °C) s^{-1}.

[9] Rough rate constants at about 25 °C for R'–H elimination from [RN=V(NHR)$_2$R'] in C_6D_6 (to give [RN=V(NDR)$_n$(NHR)$_{2-n}$(C_6D_5)] ($n = 1, 2$)) were obtained: $k \times 10^7 = 2.5$ (**3a**); 5.0 (**3b**); 9.0 (**3d**) s^{-1}.

[10] For example, solutions of the alkenyl complex **5a** in C_6D_{12} at 25 °C eliminate H_2C=CH(*t*Bu) with concomitant formation of [RN=V(NHR)$_3$] (40% conversion after 4 days). Similar hydrocarbon elimination from **4**, **5b**, **c** may be responsible for the decomposition observed during attempted crystallizations from alkane solutions.

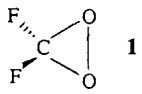
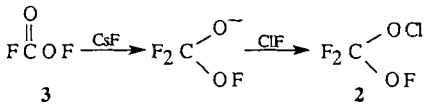
[**] This work was supported by Ausimont, Milan.

two most studied dioxiranes, dimethyldioxirane and methyl(trifluoromethyl)dioxirane, can only be isolated as solutions with the parent ketone. Difluorodioxirane (**1**) has been predicted to have a relatively high thermodynamic stability,[2] and based on the high thermal stability of the related difluorodiazirine,[3] **1** might be the most stable dioxirane. Compound **1** is claimed in a patent,[4] and as a possible intermediate in the pyrolysis of $CF_3O_2CF_3$[5] and in the reaction of $^3CF_2$ with O_2 in the presence of alkenes,[6] but it has never been isolated. Herein we report the synthesis and characterization of this rather stable molecule.



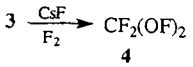
1

A potential route to **1** was envisioned by us to be the photochemical or thermal elimination of chlorine monofluoride from the unknown molecule $CF_2(OF)OCl$ (**2**). A potential route to compound **2** would be the oxidation of the anion $FOCF_2O^-$ by ClF. This anion could be generated in principle by the nucleophilic attack of fluoride ion on the unstable molecule FC(O)OF (**3**).[7]



3 **2**

This idea was reinforced by the fact that **3** is converted to $CF_2(OF)_2$ (**4**) by reaction with elemental fluorine in the presence of CsF in a bomb.[7]

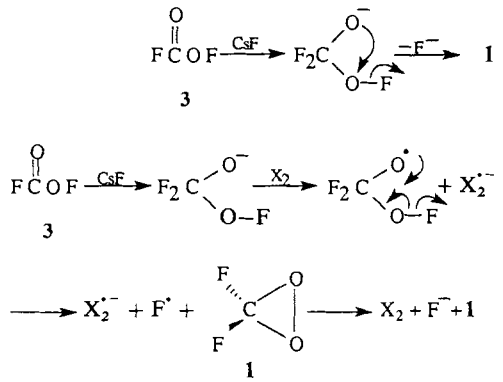


4

While **2** can indeed be prepared with an appropriate CsF catalyst,[8] it does not readily decompose into the desired compound **1**. However, in the process of refining the synthesis of **2**, in which the yields are highly variable (0–70%), we observed small amounts of an unusual low boiling product which we ultimately identified as difluorodioxirane (**1**). When this reaction was run in a flow system using a pelletized CsF catalyst, **1** became a major product (20–50%).

The mechanism for the formation of **1** was of interest since as stated previously, **2** is not a ready source of the dioxirane. At first we concluded that **1** might be formed by an intramolecular nucleophilic attack not involving ClF (Scheme 1 top). Under all conditions the reaction of **3** with CsF formed only COF_2 and O_2 as volatile products, and the presence of ClF was essential for the formation of **1**. When ClF was substituted by Cl_2 in this reaction, good yields of dioxirane **1** were also obtained. Since there are no examples of the oxidation of a perfluorinated alkoxide to a hypochlorite by Cl_2, this result further confirmed that **2** is not an intermediate in the formation of **1**. Similarly, the use of F_2 also gave **1**, however, only in low yield. We therefore propose the following electron transfer mechanism to explain the formation of **1** (Scheme 1 bottom).

The by-products in the reaction of **3** with CsF/ClF are CF_3OCl, COF_2, and O_2, whereas in the reaction with CsF/Cl_2 only COF_2 and O_2 are formed as by-products. With CsF/F_2, other products are CF_3OF, COF_2, O_2, and perhaps



Scheme 1. Proposed reactions for the mechanism of the formation of **1**. Top: Intramolecular nucleophilic attack (rejected); bottom: Electron transfer; $X_2 = Cl_2$, ClF, F_2.

a small amount of **4**. The formation of CF_3OCl and CF_3OF arises from the known CsF-catalyzed oxidation of COF_2 by chlorine monofluoride and F_2, respectively.[9, 10]

Support for an intermediate $FOCF_2O^{\bullet}$ radical in the formation of **1** is evident in the reactions of **4** with alkenes. The latter has been shown to undergo cycloaddition with a variety of halogenated alkenes to give 1,3-dioxolanes.[11] In these reactions significant amounts of epoxides are observed under certain conditions. It is proposed that the dioxolanes arise via an $FOCF_2O^{\bullet}$ radical after initial F atom abstraction from **4** by excess alkene. Thus the epoxides in these reactions may arise from the formation of **1** as an intermediate by the cyclization of $FOCF_2O^{\bullet}$, and the subsequent reaction of **1** with the excess alkene.

The dioxirane structure **1** is significantly more likely than the alternative isomeric carbonyl oxide structure by theoretical calculations[6] and is consistent with our observed data and the reactivity of **1** towards alkenes. The IR spectrum of **1** is shown in Figure 1. Type A, B, and C bands are apparent

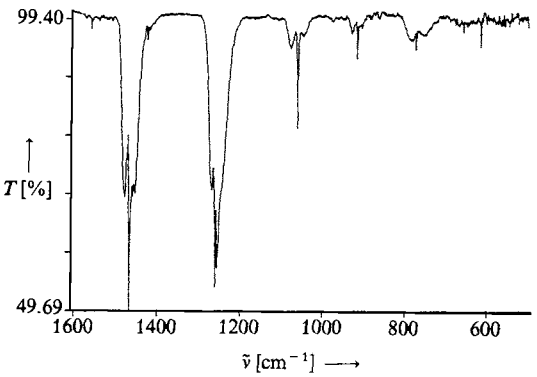


Fig. 1. The gas phase IR Spectrum of **1** (6 Torr).

as expected for the cyclic dioxirane with C_{2v} symmetry. In Table 1, the preliminary IR and Raman spectroscopic data for **1** are compared with the calculated values from Francisco and Williams.[12] The agreement for the observed nine fundamental vibrations is remarkably good. A detailed IR, Raman, and microwave investigation of **1** is in progress.

Difluorodioxirane is a pale yellow liquid below its boiling point of about −80 to −90 °C, and it exhibits a very low melting point (< −160 °C). Gas samples of pure **1** at 15 Torr and 22 °C show no decomposition after 12 h when moni-

tored in a glass IR cell. In contrast samples of **1** contaminated with small amounts of ClF are less stable under these conditions and significant amounts of the decomposition products COF_2 and O_2 are observed after 1 h. As expected **1** is a powerful oxidant and it readily transfers oxygen to alkenes, forming epoxides and COF_2 in high yield. With $CF_3CF=CF_2$, $F_2C=CFCl$, and $F_2C=CHF$ the respective epoxides are formed in >95% yield in the absence of solvent. With $CFCl_3$ as a solvent, similar results are observed. These are the first examples of the epoxidation of fluorinated alkenes by a dioxirane.

Experimental Procedure

1: In a typical reaction a mixture of equimolar amounts (0.5–2.0 mmol) of **3** and ClF at 23 °C were passed at reduced pressure through a Teflon FEP tube (35 cm × 1 cm outer diameter) containing 20 g of a pelletized CsF catalyst. The calculated flow rate of the mixture through the tube was 0.37 cm^3s^{-1}. The effluent exited into a trap cooled to −196 °C and under dynamic vacuum. The gases condensed at −196 °C were vacuum distilled several times through traps at −152 and −196 °C. This procedure gave **1** in the −196 °C trap, contaminated with small amounts of COF_2 and unreacted ClF. The unreacted ClF was separated from **1** by condensing excess SO_2 onto the mixture at −196 °C and allowing the sample to warm to about −100 °C. The ClF reacted with SO_2 to form SO_2ClF which was easily removed along with SO_2 by vacuum distillation through a −140 and −196 °C trap. **1**: M.p. < −160 °C/b.p. ≈ −80 to −90 °C; ^{19}F NMR (188 MHz, $CFCl_3$, 25 °C, CCl_4): $\delta = -29.9$ (s); IR (gas): see Table 1; Raman ($CFCl_3$, ca. −100 °C): see Table 1; MS (20 eV): *m/z* 82 ($M^{\oplus}$, trace), 66 ($CF_2O^{\oplus}$, 84), 50 ($CF_2^{\oplus}$, 4), 47 ($FCO^{\oplus}$, 100), 44 ($CO_2^{\oplus}$, 28), 32 ($O_2^{\oplus}$, 6), 28 ($CO^{\oplus}$, 10), 16 ($O^{\oplus}$, 3). The peak for the molecular ion in the MS was confirmed by selective ion monitoring.

The reactions of neat **1** (0.2 mmol) with CF_3CFCF_2 (0.5 mmol), CF_2CFCl (0.5 mmol), and CF_2CFH (0.5 mmol) were carried out in a 50 mL glass reactor by adding **1** and the alkene by vacuum transfer to the reactor at −196 °C. The mixture was then allowed to warm to 22 °C over 4 h and the products were identified by IR and NMR spectroscopy. Reactions of **1** in $CFCl_3$ (0.5 mL) were carried out on the same scale by mixing the alkene and $CFCl_3$ at 22 °C in the 50 mL reactor. The mixture was then cooled to −196 °C and **1** was added by vacuum transfer. The mixture was then warmed to 22 °C over 4 h and the solvent was removed by vacuum distillation. Yields of the respective epoxides in both reaction types were about 95% (determined by ^{19}F NMR spectroscopy). The epoxides were not separated from the excess alkene.

Bis(*P*,*P*-di-*tert*-butyl-*N*-cyclohexylphosphinic amidato-*N*,*O*)nickel(II): Whether Planar or Tetrahedral—Both Isomers are Paramagnetic

By *Thomas Frömmel, Wilfried Peters, Hartmut Wunderlich,* and *Wilhelm Kuchen**

Dedicated to Professor Dietrich Mootz on the occasion of his 60th birthday

Complexes with tetracoordinated Ni^{II} are mostly planar, and more rarely tetrahedral. Occasionally, a ligand forms both structures, or in solution there is an equilibrium between the two isomers. This is true, as we have shown in previous work, also for the bidentate chelate ligands $[R_2P(S)NR']^-$, as they occur in complexes of the type **1**.[1] So far the diamagnetism and the lack of absorption bands in the electronic spectrum at wavelengths < 10000 cm^{-1} for the planar complexes, and paramagnetism ($\mu_{eff} \approx 3.0-3.4\ \mu_B$) for the tetrahedral complexes have been regarded as safe characteristics for the discrimination of the complexes. Whereas these assignment criteria, based on general experience, proved to be true in the case of **1**, they failed in the case of complex **2**. Complex **2** is paramagnetic in the solid state and shows an absorption at 7300 cm^{-1} in the powder spectrum: It contains, however, as the crystal structure determination showed, the exactly planar *trans*-NiN_2O_2 chromophore.[1]

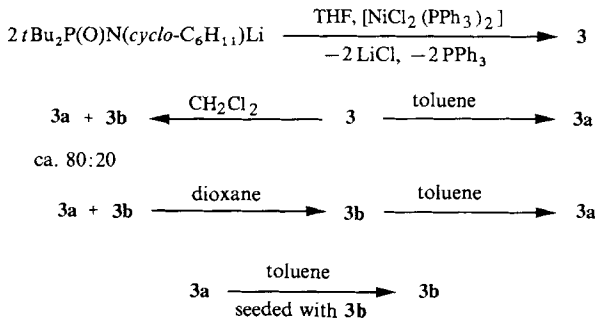

Scheme 1. Syntheses of the isomers **3a** (olive-green) and **3b** (ink-blue).

from the clear solutions of the complexes in the given solvents within a few days at 4 °C as well-formed crystals. Crystals of **3b** are obtained from a solution of **3a** after the addition of a few seed crystals.

Complexes **3a** and **3b** change slowly in air. In benzene they are monomeric. The ^{31}P NMR signal is, as for **2**, strongly shifted to higher field and both for **3a** and **3b** appears at $\delta = -813$ (CD_2Cl_2, 290 K). Both isomers exhibit identical magnetic properties: $\mu_{eff} = 3.3\ \mu_B$ (298 K), Curie–Weiss behavior between 280 and 80 K (solid state). The same magnetic moment was determined in CD_2Cl_2 at 293 K and Curie–Weiss behavior was observed between 293 and 190 K. Accordingly, the isotropic shift of the NMR signals (^1H, ^{31}P) in this temperature range is strictly linear with respect to T^{-1}.

The positions of the absorption bands in the powder spectra of **3a** and **3b** (Fig. 1, top) differ only slightly; however,

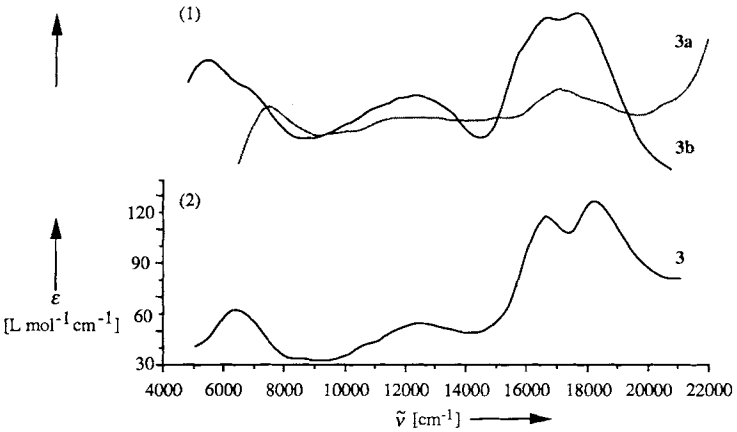

Fig. 1. 1) Powder spectra of **3a** and **3b** (in remission, $BaSO_4$ as standard); 2) solution spectra of **3** (toluene). I = intensity in arbitrary units.

with respect to the intensity of these bands the difference is considerable. The single-crystal transmission spectra[3] of both substances correspond to the powder spectra, and for **3b**, because of the lack of centrosymmetry in the tetrahedral complex, significantly more intense bands are observed. The latter statement is vindicated, since the structural investigation (see below) shows that crystals of **3a** and **3b** contain almost the same number of molecules per volume unit, and crystals of almost the same thickness were used for the recording of the spectra. It may also be mentioned, that the powder spectrum of **3a** is almost identical with that of the paramagnetic complex **2**, which is planar in the solid state.

The solution spectra of **3a** and **3b** (Fig. 1, bottom) did not vary whether they were recorded in toluene, CH_2Cl_2, or dioxane. These spectra are similar to the powder spectrum of **3b**, which corresponds to that of the tetrahedral thio complexes **1** (R = *t*Bu; R′ = *i*Pr, *cyclo*-C_6H_{11}),[1,4] whose powder and solution spectra are the same.[2] It can, therefore, be assumed that in solution at room temperature complex **3** is predominantly tetrahedral. The same is also valid for **2**, whose solution spectrum is almost superimposable with that of **3**, that is to say **2** does not remain planar in solution.[1]

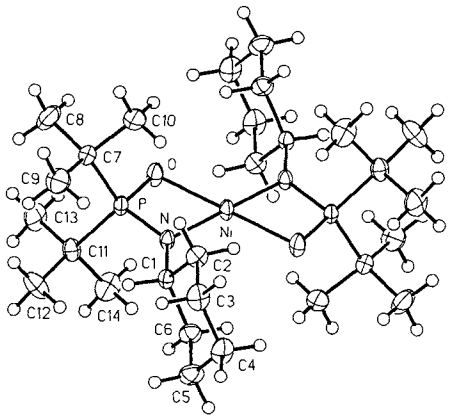

Fig. 2. Molecular structure of **3a** (ellipsoids drawn at 25% probability level) and atom designation [6]. The complex has $\bar{1}$-C_i symmetry with the Ni atom in the center of the symmetry. The H atoms are represented with a radius of 15 pm.

The crystal structure analysis (Fig. 2)[5] shows that the Ni atom in **3a** is exactly planar surrounded by two O and two N atoms (Ni–O 212.0(1) and Ni–N 190.0(1) pm). A higher coordination of the Ni atom by symmetry equivalent molecules can be excluded since the shortest distances to atoms of neighboring molecules are too large (Ni···H 476, Ni···C 548 pm). The O-Ni-N bond angle is 74.3(1)°, all the other angles at the Ni atom result from the centrosymmetry. The Ni-O-P-N four-membered ring is planar within 1.6 pm.

In contrast, the coordination of the Ni atom in **3b** is distorted tetrahedral (Fig. 3),[5] the most important bond angles being O-Ni-N 74.5(1), O-Ni-N′ 126.4(1), O-Ni-O′ 122.3(1), and N-Ni-N′ 140.6(1)°. The two planes through the

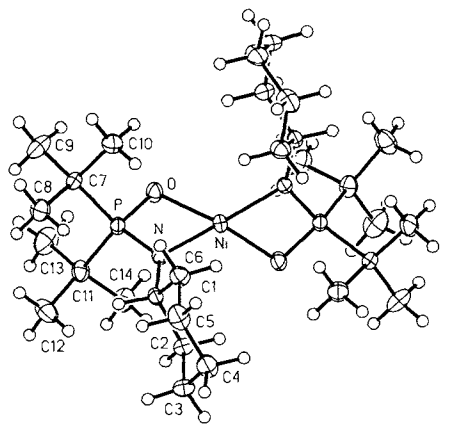

Fig. 3. Molecular structure of **3b**. The complex has 2-C_2 symmetry. Other information as in Figure 2.

atoms Ni,O,N and Ni,O′,N′ form an angle of 86.2°. It should be emphasized that the bond lengths Ni–O (205.9(2) pm) and Ni–N (194.5(2) pm) differ significantly from those of the planar complexes **2** and **3a**. To show the homogeneity of the

investigated crystalline material, an X-ray powder diffractogram of **3a** was recorded. The agreement between this and the diffraction pattern calculated from the single-crystal structure analysis was excellent; however, the X-ray powder diffractogram of **3a** showed large discrepancies with the one calculated for **3b**.[7, 8]

Once more the uniqueness of the $[t\mathrm{Bu_2P(O)NR'}]^-$ (R' = *i*Pr, *cyclo*-$\mathrm{C_6H_{11}}$) ligands is shown here: An apparently favorable combination of electronic and steric factors allows the formation of planar high-spin complexes of Ni^{II}. This is surprising, since for the analogous thio complexes **1** the tetrahedral coordination is preferred as the bulkiness of R' increases.[4] How great the influence of R' is on the properties of the complex is shown by the following preliminary results: According to the powder spectrum, complex **4** (R' = *t*Bu) is planar. Its μ_{eff} values vary from 1.7 (280 K) to 0.6 μ_B (80 K) (solid state) and suggest a spin-crossover between singlet and triplet state.

Experimental Procedure

Magnetic measurements were carried out according to Faraday (solid substance) and Evans (solution). ^{31}P NMR spectroscopy: Bruker AM 200 (81.026 MHz, CD_2Cl_2, 293 K, 85% H_3PO_4).

P,P-di-*tert*-butyl-*N*-cyclohexylphosphinic amide: 30% aqueous H_2O_2 (ca. 18 g) was slowly added to $t\mathrm{Bu_2PNH(cyclo\text{-}C_6H_{11})}$ [9] (160 mmol) in toluene (100 mL) and the mixture was stirred vigorously. After the exothermic reaction had subsided the organic phase was separated and the solvent was slowly evaporated at room temperature. The amide precipitated, generally in the form of colorless needles. Yield approximately 65%. Correct elemental analysis, m.p. 175 C, $\delta(^{31}P) = 54$ (toluene).

3 was prepared and handled under inert conditions. $t\mathrm{Bu_2P(O)NH(cyclo\text{-}C_6H_{11})}$ (19 mmol) in THF (25 mL) was treated with *n*-butyllithium (19 mmol, 1.6 M solution in hexane) and heated to reflux for a short time. The cooled solution was added to $[NiCl_2(PPh_3)_2]$ (9.63 mmol), and the resulting solution was stirred for 2 h at room temperature. Subsequently the solvent was removed under vacuum.

For the isolation of **3a** the residue was taken up in toluene (5 mL), centrifuged, and the clear solution obtained was kept at 4 °C. As a result olive-green crystals of **3a** precipitated slowly from the solution. Yield > 40%. Correct elemental analysis, m.p. 206 °C (decomp), molecular masses (cryoscopic in benzene): 550 (0.079 molal) 589 (0.085 molal).

For the isolation of **3b** the residue was taken up in CH_2Cl_2 (5 mL) and the solution was centrifuged. **3a** and **3b** precipitated from the solution as a mixture of olive-green and blue crystals, which was dissolved in the smallest amount of dioxane by mild heating. When the solution was left to stand mainly blue crystals of **3b** were obtained. If necessary, the latter process was repeated until the crystalline material was homogeneous. Yield > 40%. Correct elemental analysis, m.p. 193 °C (decomp).

Alternatively, a saturated solution of **3a** in toluene was allowed to react with a few seed crystals of **3b**. Ink-blue crystals of **3b** precipitated at 4 °C slowly in the course of several days.

Control of the Linkage of Inorganic Fragments of V–O Compounds: From Cluster Shells as Carcerands via Cluster Aggregates to Solid-State Structures**

By *Achim Müller,** *Ralf Rohlfing, Erich Krickemeyer,* and *Hartmut Bögge*

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

The control of the linkage of fragments of inorganic complexes or molecules to form oligomers or infinite three-dimensional structures is of general interest, amongst other purposes, for the understanding of prebiotic processes and for the molecular engineering of materials; the laws governing these processes, however, are almost unknown. We can now show that the linking of $V^{n+}O_x$ polyhedra (tetrahedra, octahedra, and square pyramids) and the spin organization of the V centers in the aggregates under construction can be controlled over a wide range by predominantly anionic reagents (templates). Depending on the choice of these reagents, shell-like clusters (molecular containers, carcerands[11]) in which the directing agent is situated inside the cavity (**1**, **2a**, **3**, and **4**) or V–O aggregates in which the directing agent is positioned on the outer surface of the shell (**6**, **7**) are formed. The cluster anions of **2b** and **5** are transition forms of these two types and reveal novel host–guest systems and structural types. The results model fundamental processes that control the propensities for organization in material systems.[2]

$K_{10}[HV_{18}O_{44}(NO_3)] \cdot 14.5\,H_2O$ **1**

$(NEt_4)_6[HV_{22}O_{54}(SCN)]$ **2a**

$(NEt_4)_5(NH_4)_2[H_2V_{22}O_{54}(CH_3COO)] \cdot 7\,H_2O$ **2b**

$Na_{10}[H_2V_{18}O_{44}(H_2O)] \cdot 30\,H_2O$ **3**

$K_7[H_4V_{15}O_{40}(PO_4)] \cdot 10\,H_2O$ **4**

$Na_6[H_6V_{12}O_{30}F_2] \cdot 22\,H_2O$ **5**

$Na[V_2O_2(OH_2)_2(\mu\text{-}OH)(\mu\text{-}OH_2)(C_4O_4)_2] \cdot 6\,H_2O$ **6**

$K_2[H_6V_{10}O_{22}(CH_3COO)_6] \cdot 25\,H_2O$ **7**

The mixed valent (**1**–**5**, **7**) and reduced (**6**) vanadium–oxygen compounds were synthesized by reduction (**1**, **3**–**7**) of vanadate(V) or oxidation (**2a**,**b**) of vanadate(IV)/vanadate(V)

species in water by controlling the type of linkage of the $V^{n+}O_x$ polyhedra by templates. The compounds were characterized by elemental analysis (including manganometric titration of the V^{IV} content, thermogravimetric determination of the water of crystallization, and ion-chromatographic determination of NO_3^-, PO_4^{3-}, and F^-), IR spectroscopy, single-crystal X-ray crystallography,[3] and determination of bond valence sums.[3]

The structures of the anions in the compounds **1**–**7** are depicted in Figure 1 (cagelike cluster shells (carcerands) containing templates in the center: type I), Figure 2 ("central" aggregates of clusters built up from $V^{n+}O_x$ polyhedra with terminal organic anions as ligands, that is, with a hydrophobic (screening) part as in squaric acid (3,4-dihydroxy-3-cyclobutene-1,2-dione): type II),[4] as well as in Figure 3. The structural types are shown schematically in Figure 4 and the number of the different $V^{n+}O_x$ polyhedra, the symmetry (point groups) of the V–O aggregates and the V^{IV}/V^V ratios are collated in Table 1. When the attractive type of interaction between the central nucleophilic anion or molecule (e.g. NO_3^- in **1**) and the electrophilic or Lewis acidic V^{n+} centers is weak, square pyramids are linked to form a carcerand[5] (**1**–**3**). If this interaction is strong, for instance when the anion bears a high charge (e.g., PO_4^{3-} in **4**), other polyhedra, primarily octahedra) also occur in the structures

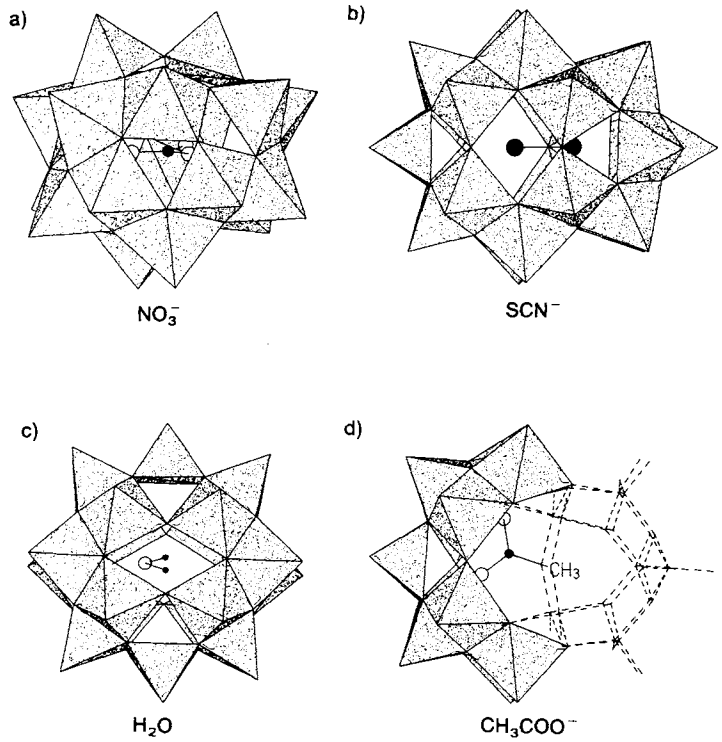

Fig. 1. Polyhedral representation of the anions of **1** (a), **2a** (b), **2b** (d; only one of the $V_{22}O_{54}$ half shells)), and **3**(c). The enclosed anions or molecules are given under the polyhedra for clarity. Selected distances [pm]: $V–O_{term}$ 156–163, $V–\mu_2$-O 171–193, $V–\mu_3$-O 178–212; special data for **1**: $V–\mu_2$-O(H) 195–196, N–O 120–129, $V\cdots O(NO)_2 > 278$, $O\cdots O(NO_2) > 274$; for **2a** S(CN)–S(CN) 209, $V\cdots S(CN) > 365$, $O\cdots S(CN) > 353$ (SCN^- disordered and CN not resolved); **2b**: C–O 124–130, C–C 147, $V\cdots O(CO) > 251$, $O\cdots O(CO) > 262$, $V\cdots C(O_2) > 344$, $O\cdots C(O_2) > 337$, $V\cdots C(H_3) > 398$, $O\cdots C(CH_3) > 359$; for **3**: $V–\mu_2$-O(H) 185–189, $V\cdots O(H_2) > 325$; $O\cdots O(H_2) > 314$, $O\cdots H(OH) > 279$ (exception: for the two O atoms of the shell that fix the H_2O molecule in the center by hydrogen bonds, $O\cdots O(H_2)$ 291–292 and $O\cdots H(OH) > 229$).

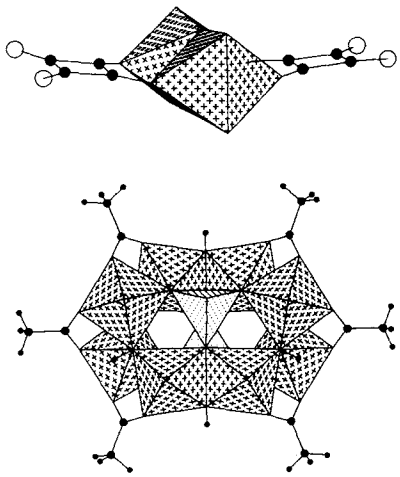

Fig. 2. Polyhedral representation of the anions of **6** (top) and **7** (bottom). Selected distances [pm]: $V–O_{term}$ 157–161, $V–\mu_2$-O(H) 194–199, V–O(C) 198–203; special data: for **6**: $V–O(H_2)_{term}$ 202–207, $V–\mu_2$-O(H_2) 236–240, C–O 121–131, C–C 142–148; for **7**: $V–\mu_3$-O 175–228, $V–\mu_3$O(H) 204–226, C–O 125–127, C–C 149–150.

(mainly formed by incorporating an atom of the template). In **5** the F^- ion is too small to be a guest in the cavity, but it creates a strong V–F interaction. In all cases, however, electronic influences can also play a role (see, for instance, the occurrence of VO_4 tetrahedra only in the case of V^V compounds. The salt **2b** includes a new type of host–guest cluster: the hydrophobic CH_3 group of the acetate anion hardly protrudes from one of the two $V_{22}O_{54}$ half-shells (see Fig. 1), and the carboxy group interacts relatively strongly with the V centers (refer to the relevant distances).

In particular, the following can be said of **1**–**7**: the structure of the anion of **4** is interesting, because three different VO_x polyhedra are present ($x = 4, 5, 6$), the special feature of the anion of **1** is the shell that is almost complementary to the central NO_3^- unit (but the C_2 axes of the shell and the NO_3^- ion do not coincide). The SCN^- ion in the anion of **2a**, which is situated disordered on the S_4 symmetry axis in the known $V_{22}O_{54}$ shell and therefore is formally located perpendicular to the smaller but topologically identical N_3^- ion in the similar $V_{18}O_{44}$ shell of $[H_2V_{18}O_{44}(N_3)]^{5-}$,[6] appears, as it were, to float within the carcerand (long V–(SCN) distances reveal extremely weak interactions). Whereas in the binuclear complex **6** two $V^{IV}O_6$ octahedra share edges, in **7** two sets of four edge-sharing $V^{IV}O_6$ octahedra are linked through two V^VO_4 tetrahedra in such a way that a novel double layer structure arises. Compound **5** has a structure

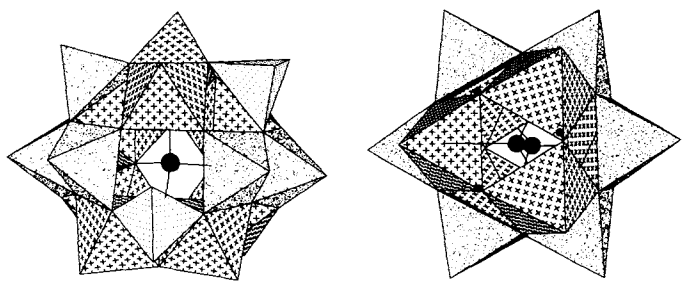

Fig. 3. Polyhedral representation of the anions of **4** (left) and **5** (right). Selected distances [pm]: $V–O_{term}$ 160–165, $V–\mu_2$-O(H) 181–205, $V–\mu_3$-O 181–213; special data: for **4**: $V–\mu_2$-O 169–204, P–O 152–155, V–O(PO_3) 218–230; for **5**: V–F 217–219, F···F 311 (octahedra indicated by crosses, square pyramids by random dots, and tetrahedra by regular dots).

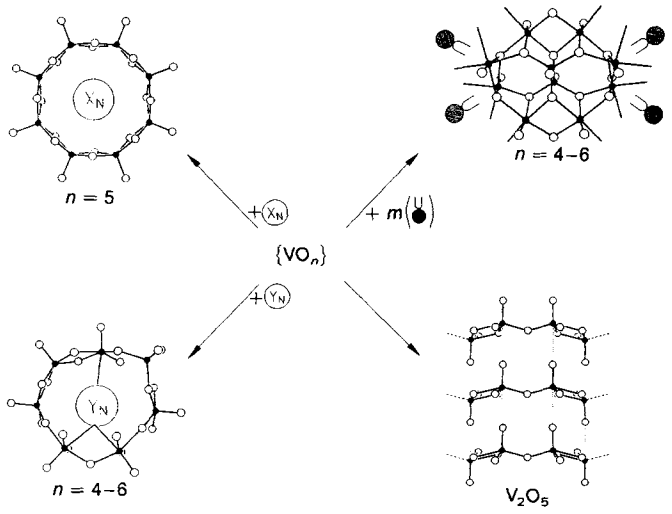

Fig. 4. Schematic representation of the possibilities for connecting VO_n units (n = coordination number; nucleophilic substrates: Y_N (strong) and X_N (weak); anionic substrate containing a hydrophobic part: ⌒).

Table 1. Structural types [a], VO_x polyhedral types, and the number of formal V^{IV}/V^{V} centers [b] of cluster anions in **1**–**7**.

	Type	V^{IV}/V^{V}	Octahedra	Square pyramids	Tetrahedra	Symmetry of the V-O-aggregate
1	I	12/6	-	18	-	C_2
2a	I	8/14	-	22	-	D_{2d}
2b	(II)	10/12	-	22	-	D_{2d}
3	I	14/4	-	18	-	D_{2h}
4	(I)	3/12	8 [c]	5	2 (V^{V})	C_1
5	(I)	10/2	6 [d] (V^{IV})	6	-	D_{3d}
6	II	2/-	2 [e] (V^{IV})	-	-	C_{2v}
7	II	8/2	8 [e] (V^{IV})	-	2 (V^{V})	C_{2h}

[a] I: Cagelike, containing a hydrophilic central template (guest) interacting weakly with the cluster shell; II: central cluster aggregate with the directing reagent containing a hydrophobic residue on the outside; (I): like I, but containing a hydrophilic central template and strong interactions; (II): like I, but with a central template containing a hydrophobic part (transition type between I and II). [b] Delocalized valence states, if not specifically designated otherwise. [c] One face-sharing and three edge-sharing pairs of octahedra. [d] Edge-sharing VO_5F octahedra. [e] Edge-sharing.

novel for the polyanion chemistry of transition metals.[7] It consists of two groups of three octahedra sharing edges as in a Keggin ion but with μ_3-F centers, linked through six square pyramids. Apparently the repulsion or direct contact of the F^- ions in the center ($F\cdots F = 311$ pm) determine the structure.

The topological and electronic diversity of vanadium–oxygen complexes is exceptional (compare also the many vanadium oxide minerals[8]). The pyramidal $O{=}V^{n+}O_4$ unit that dominates in the structural hierachy plays a central role. The manner of its linkage is directed by weak $O{=}V\cdots X$ interactions (X = nucleophile),[9–11] which result in molecular containers, but also in typical solid state structures as in V_2O_5[12] (O=V as nucleophile). A template principle underlies the formation and stacking of the V_2O_5 layers: layer $n+1$ forms on layer n through the weak $O{=}V\cdots O{=}V$ interactions. The distance d between the layers of 279.1 pm is correspondingly relatively large. The $O{=}V\cdots O{=}V$ interaction in V_2O_5 is apparently similar to that in the container compounds described here, though in these the weak repulsive interaction between the O=V groups influences the curvature of the shell. The interaction between the layers of the V_2O_5 lattice can also be compared with the $O{=}V(\text{shell})\cdots O{=}V(\text{cluster})$ interaction of the central $\{V_4O_4\}O_4$ cluster with the shell of the $[V_{34}O_{82}]^{10-}$ anion in $K_{10}[V_{34}O_{82}]\cdot 20H_2O$[13] ($V{=}O(\text{shell})\cdots O{=}V(\text{cluster}) > 254$ pm). Prerequisite for the presence of $O{=}V^{n+}O_4$ units in all cases is the relatively weak nucleophilicity and low basicity of the relevant centers of the directing agent (for example, in the case of the anions of strong acids like ClO_4^- and X^- (X = halogen), but also of H_2O and the O=V groups of a layer of V_2O_5). The V_2O_5 layer is stabilized, because the O=V groups of edge-sharing pyramids (with short V–V distances) are situated on different sides of the plane.

Experimental Procedure

1: A solution of KVO_3 (3.45 g, 25.0 mmol) in H_2O (50 mL) in a wide-necked Erlenmeyer flask (100 mL) covered with a watch glass was treated at 90 °C with N_2H_5OH (100%, 182 μL, 3.75 mmol) and maintained for 1 h at this temperature without stirring. Thereafter the pH of the dark brown solution was adjusted to about 8.0 with HNO_3 (65%) and held constant for 2 h by additions of more acid every 15 min. The solution was cooled to 20–25 °C after a further 3 h at 90 °C, and the precipitated black needles were filtered off after 1 day, washed with a little aqueous 2-propanol (50%) and air-dried. Yield: 1.6 g. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1355(m, NO_3^-), 965(s, $V{=}O_{term}$), 815(w, NO_3^-), 700(s), 615(sh, V-O-V).

3–**7** were synthesized analogously by reduction of aqueous vanadate(v) solutions and subsequent addition of the anions PO_4^{3-} (**4**), F^- (**5**), $C_4O_4^{2-}$ (**6**), and CH_3COO^- (**7**) (instead of NO_3^- in **1**).

2a: A solution of NEt_4SCN (4.0 g, 21.2 mmol) in H_2O (100 mL) in a wide-necked Erlenmeyer flask (100 mL) covered with a watch glass was treated at 75 °C with freshly prepared $(NH_4)_8[H_9V_{19}O_{50}]\cdot 11H_2O$ [14] (0.83 g, 0.4 mmol) and maintained for 2–3 days at this temperature without stirring. The precipitated black crystals were filtered from the hot solution, washed with a small amount of cold H_2O, and air-dried. Yield: 0.5 g. IR (KBr): $\tilde{\nu}$[cm^{-1}]: 2040(m, SCN), 995(s, $V{=}O_{term}$), 835(m), 785(m), 705(s), 625(s, V-O-V).

2b was synthesized analogously in the presence of air from $(NH_4)_8[H_9V_{19}O_{50}]\cdot 11H_2O$ in the presence of CH_3COO^- (instead of SCN^- in **2a**).

The positions of the H atoms of the H_2O molecule were determined from difference Fourier maps according to a high-angle refinement and refined as riding on the relevant oxygen atoms with a fixed U value. **4**: $P2_1/n$, $a = 1251.2(2)$, $b = 1893.0(4)$, $c = 2062.0(3)$ pm, $\beta = 90.03(1)°$, $V = 4884.1(15)\times 10^6$ pm^3, $Z = 4$, $R = 0.050$ for 8558 independent reflections ($F_0 > 4\sigma(F_0)$). **5**: $P2_1/n$, $a = 1002.3(1)$, $b = 1267.0(2)$, $c = 1945.7(3)$ pm, $\beta = 100.33(1)°$, $V = 2430.8(5)\times 10^6$ pm^3, $Z = 2$, $R = 0.040$ for 3998 independent reflections ($F_0 > 4\sigma(F_0)$). The positions of the H atoms of the anion were determined from difference Fourier maps according to a high-angle refinement and refined as riding on the relevant O atoms with a fixed U value. **6**: Cc, $a = 1501.1(2)$, $b = 648.5(1)$, $c = 2032.3(3)$ pm, $\beta = 97.21(1)°$, $V = 1962.6(5)\times 10^6$ pm^3, $Z = 4$, $R = 0.097$ for 1722 independent reflections ($F_0 > 4.4\sigma(F_0)$). **7**: $P\bar{1}$, $a = 1021.4(2)$, $b = 1031.7(2)$, $c = 1558.5(3)$ pm, $\alpha = 78.12(1)$, $\beta = 78.66(1)$, $\gamma = 85.82(1)°$, $V = 1574.8(5)\times 10^6$ pm^3, $Z = 1$, $R = 0.040$ for 6402 independent reflections ($F_0 > 4\sigma(F_0)$). Measurements in the mother liquor.

The positions of the H atoms of the anion were determined from difference Fourier maps according to a high-angle refinement and refined as riding on the relevant O and C atoms with a fixed U value. The powder diagrams calculated from the single crystal data agree with those obtained from experiment. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-56998, the names of the authors, and the journal citation. From the difference Fourier synthesis after a high-angle refinement, the following positions of the hydrogen atoms were determined crystallographically for **3**, **5**, and **7**: for **3** those of all water molecules (water of crystallization and the guest molecule); for **5** and **7** those of the anion, including the methyl protons of **7** (cf. Fig. **1**–**3**). Through the determination of the bond valence sums (I. D. Brown in *Structure and Bonding in Crystals, Vol. II* (Eds.: M. O'Keeffe, A. Navrotsky), Academic Press, New York, **1981**, p. 1) according to the equation $n = \exp[-(R-R_0)/B]$ (n is the bond valence, R = V-O distance in pm, $R_0 = 179$ pm, $B = 31.9$ pm), all protonated O atoms of the anions of **1**, **3**, **4**, and **6** were found by a characteristic lowering of the sum of the bond valences. Thus one μ_2-O(H) bridge is found for **1**, two for **3**, four for **4**, and one for **6**, which also has a μ_2-O(H_2) bridge (*trans* to $V{=}O_{term}$) and two terminal H_2O ligands (*trans* to μ_2-O(H) bridge). For the anions of **2a** and **2b** the protonations at the anion indicated by the equation followed from the charge balance. If not explicitly mentioned, the protonations occur at bridging O atoms.

[4] Anions of organic acids, that is, those with a hydrophobic residue, can function as terminal ligands to stabilize aggregates of $V^{n+}O_x$ polyhedra and screen these within the crystal lattice. (They adopt the function of the O=V groups in the container compounds.) Small or highly charged ligands such as F^- or PO_4^{3-} are not suitable, because they interact strongly with the V centers.

[5] After the isolation of the first host–guest compound of the V–O system with weak interaction and complementarity of the shell and the central spherical unit, the synthesis of $[H_2V_{18}O_{44}(N_3)]^{5-}$ and $[HV_{22}O_{54}(ClO_4)]^{6-}$ [6] were expected. However, an analysis of the cavities showed that, for example, in the $V_{18}O_{44}$ shell the incorporation of larger guests should also be possible (instead of the N_3^- ion, a NO_3^- ion, as in $[H_6V_{18}O_{44}(NO_3)]^{11-}$; unpublished results). This means that the space in this shell can also be used thus. (A container or carcerand function [1], of course, does not necessarily imply complementarity). A remarkable example of this is the compound **2a**. The size of the SCN^- ion hinders the isomorphous substitution of the topologically analogous N_3^- ion in the shell of $[H_2V_{18}O_{44}(N_3)]^{5-}$. Nevertheless control by the anionic template according to the argument in [6] is valid in all cases, because the size of the cluster shells always correlates with the size of the template. In the above-mentioned context the following results are particularly impressive for the control mechanism: 1. Shells of identical composition but different structures occur as a direct result of the dependence on the central anion (cf. O_{24} arrangement as rhombicuboctahedron in the $V_{18}O_{42}$ shell with central XY_4 or as the 14th archimedean body with a spherical guest like a halide ion: A. Müller, M. Penk, R. Rohlfing, E. Krickemeyer, J. Döring, *Angew. Chem.* **1990**, *102*, 927; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 926, as well as [6]). 2. The central cubelike $\{V_4O_4\}O_4$ unit in $[V_{34}O_{82}]^{10-}$, which represents a section (though strongly distorted) of a cubic solid-state defect structure of the NaCl type, has almost a nucleation function for the genesis of the cluster shell [13]. One can talk of an "initiation–causality". It is also remarkable that all known cluster shells of type I can formally be derived from the V_2O_5 lattice [12] (e.g., the $V_{18}O_{44}$ and $V_{22}O_{54}$ shells (W. G. Klemperer, T. A. Marquart, O. M. Yaghi, *ibid.* **1992**, *104*, 51 and **1992**, *31*, 49), as well as the shell of $[V_{15}O_{36}Cl]^{6-}$ (A. Müller, E. Krickemeyer, M. Penk, H.-J. Walberg, H. Bögge, *ibid.* **1987**, *99*, 1060 and **1987**, *26*, 1045) and of **1**). (Some aspects of related host–guest chemistry are given in H. Reuter, *ibid.* **1992**, *104*, 1210 and **1992**, *31*, 1185, as well as in *Naturwiss. Rundschau* **1992**, *45*, 368.)

[6] A. Müller, E. Krickemeyer, M. Penk, R. Rohlfing, A. Armatage, H. Bögge, *Angew. Chem.* **1991**, *103*, 1720; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1674.

[7] However, a similar structure occurs in the $[(i\text{PrSn})_{12}O_{14}(OH)_6]^{2+}$ ion: H. Puff, H. Reuter, *J. Organomet. Chem.* **1989**, *373*, 173.

[8] H. T. Evans, Jr., J. S. White, Jr., *Mineral. Rec.* **1987**, *18*, 333; A. Müller, J. Döring, M. I. Khan, V. Wittneben, *Angew. Chem.* **1991**, *103*, 203; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 210.

[9] In the carcerands with a centered anion the repulsive (O···anion) and attractive (V^{n+}···anion) forces are balanced (see also A. Müller, K. Hovemeier, R. Rohlfing, *Angew. Chem.* **1992**, *104*, 1214; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 1192). This is plausibly demonstrated by the fact that in the compounds $(NEt_4)_2[V_4O_8(NO_3)(tca)_4]\cdot H_2O$ (D. D. Heinrich, K. Folting, W. E. Streib, J. C. Huffman, G. Christou, *J. Chem. Soc. Chem. Commun.* **1989**, 1411; tca = $C_4H_3SCOO^-$) and $[K\{V_4O_8(O_2CCH_2t\text{Bu})_4\}]\cdot[O_2CCH_2t\text{Bu}]\cdot 2\,t\text{BuCH}_2CO_2H$ (W. Priebsch, D. Rehder, M. von Oeynhausen, *Chem. Ber.* **1991**, *124*, 761) the $\{V_4O_{16}\}$ unit can complex a cation as well as an anion. Apparently more than four Lewis acidic V centers must be present to complex anions only.

[10] The type of linkage of the $O{=}V^{n+}O_4$ pyramids varies from weak, that is, linkage only through μ_2-O atoms according to the stoichiometry $\{(O{=}V)_1O_3\}_n$ of the Keggin type, to maximal, that is, linkage only through μ_3-O atoms according to the stoichiometry $\{(O{=}V)_3O_4\}_n$ of the extended $V_{18}O_{42}$ Keggin shell (M. T. Pope, A. Müller, *Angew. Chem.* **1991**, *103*, 56; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 34). The molecular containers of type I, but also V_2O_5, with both μ_2-O and μ_3-O functions have on this scale an intermediate type of linkage, unpublished results.

Biosynthesis of Iridodials in the Defense Glands of Beetle Larvae (Chrysomelinae)**

By Michael Lorenz, Wilhelm Boland, and Konrad Dettner*

Cyclopentanoid natural products based on an iridoid structure are widespread in plants and insects.[1] In plants the iridoid glucosides, in particular, are of interest because some of these compounds exhibit pharmacological activity, while others are intermediates via secoiridoids in pathways leading to many alkaloids.[2] Thus, the biosynthesis of these compounds has been the subject of intensive investigation over the last 30 years. The key steps in the biosynthesis are the ω-hydroxylation of geraniol to 8-hydroxygeraniol and its further oxidation to 8-oxocitral. 8-oxocitral can be cyclized directly or after further transformations to the iridoid unit[2, 3] (analogous to Scheme 1). Additional oxidation and cyclization steps follow and lead to more than 1000 plant iridoids known today.[1, 4] In insects some volatile iridoids serve as pheromones,[5] while others such as **1**–**6** which are produced in defense glands serve as glues, insecticides, fixatives, or fumigants in defense secretions.[6]

[**] This work was supported by the Deutschen Forschungsgemeinschaft (DFG) (SPP: Chemische Ökologie) and the Fonds der Chemischen Industrie.

The larvae of the leaf beetles *Phaedon cochleariae*, *Gastrophysa viridula*, and *Plagiodera versicolora* have nine pairs of glands which can be everted upon molestation. These are located on the meso or metathorax as well as on the first seven abdominal segments. A drop of a defense secretion appears at the gland openings, and for *P. cochleariae* and *G. viridula* this secretion consists mainly of chrysomelidial **1** and epichrysomelidial **2** as low molecular weight components[7] (see Fig. 1). In contrast, the glands of *P. versicolora* secrete

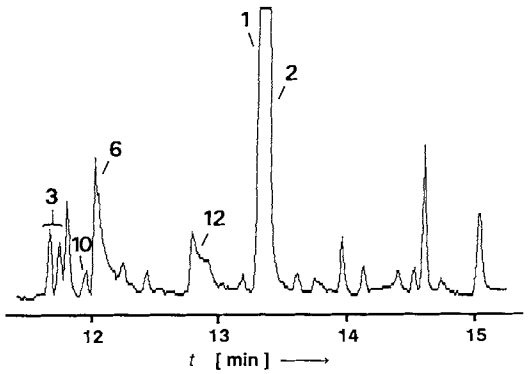

Fig. 1. Part of the gas chromatographic profile of volatile compounds from the defense secretion of *P. cochleariae* 24 h after the injection of [$^2H_5$]-**8** into the hemolymph. Elution conditions: RSL 300 (15 m × 0.32 mm) under programmed conditions (50 °C for 2 min, then at 10 °C min^{-1} to 200 °C); Finnigan Ion Trap ITD 800 as detector (scan range 35 → 250 Da sec^{-1}). Identified compounds: **1** = chrysomelidial, **2** = epichrysomelidial, **3** = plagiolactone and epiplagiolactone, **6** = actinidine, **10** = 1-nor[$^2H_5$]chrysomelidial, **12** = alkylindols.

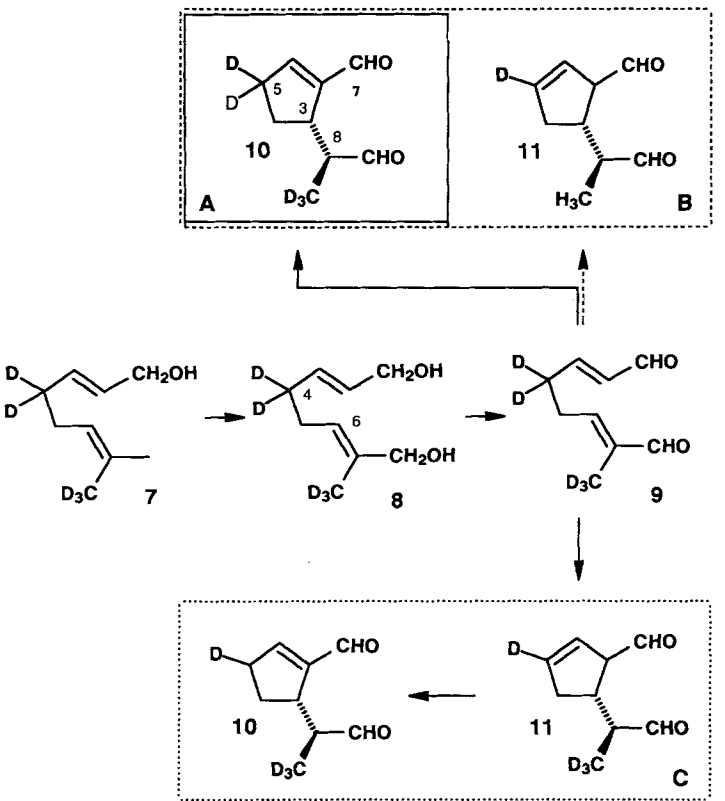
the plagiodial **3** as well as the plagiolactone **5**, named after the insect itself.[7] While the biosynthesis of plant iridoids has been well-studied up to now there have been no detailed investigations into the biosynthesis of iridodials in insects. That the synthesis of iridodials in insects is part of terpene metabolism was established by the incorporation of [^{14}C]mevalonolactone into the dialdehyde anisomorphal **4** in the stick insect *Anisomorpha buprestoides*.[8] We report here that the biosynthesis of the iridodials **1**, **2**, and **3** in the larvae of the aforementioned beetles is, in principle, similar to the known plant metabolism but that the details reveal a surprising range of variations (see Scheme 1).

The experimental procedure was as follows: Aqueous solutions of deuterated precursors, (ca. 1 μL; 0.9% solution),[9] were injected into the hemolymph of 10 to 14-day-old larvae. About 4–36 h after the injection of the precursors, the animal is stimulated into secreting defense secretion from the everted glands. The resulting secretion was shown to contain [^{2}H]iridodials by using mass spectrometry.

The first traces of deuterated metabolites are detected as early as one hour after injection. Alternatively, the precursors can be fed to the larvae in the form of impregnated leaves; however, with this technique it took three days before significant incorporation could be detected. This experiment reveals that the larvae of the leaf beetles are able to take up plant precursors like geraniol or 8-hydroxygeraniol and to use them for the biosynthesis of iridoids. In order to obtain usable mass spectra from the minute quantities of [^{2}H]-metabolites present, 3-norprecursors of the types **7** and **8** were used; additional metabolic probes were labeled with deuterium at positions C1, C2, or C8.[9] The nor compounds allow a complete gas chromatographic separation of the metabolites and naturally occurring iridoids (Fig. 1). The experiments are based on the assumption that the synthetic 3-norprecursors are transformed in an analogous manner to the naturally occurring substrates. The appropiate reference substances, the 1-nor[^2H_n]chrysomelidials such as [$^2H_5$]-**10**, can be obtained by biomimetic reactions from the acyclic dialdehydes **9** by acid[10] or base[11] catalysis. Both variants yield 1-nor[$^2H_5$]chrysomelidial **10** without significant loss of deuterium at the C4 position of the precursor[12] (> 95% retention). This finding means that the mechanism of the acid-catalyzed cyclization (50% HCOOH)[10] of 8-oxocitral has to be partially modified. The base-induced cyclization of **9** (MeOH, 0.01 N NaOH, 10 min) is to be considered as a tandem-Michael addition starting by addition of H_2O or MeOH followed by cyclization and elimination of the conjugate base. In incubation experiments **7** and **8** were quickly converted by all three kinds of larvae into the corresponding 1-noriridodials, **10** and **11**, respectively. In addition, for *P. versicolora* and *G. viridula* the acyclic dialdehyde **9** was firmly established as an intermediate in the biosynthesis of **1** and **3**. This means that the biosynthesis of chrysomelidial **1** and plagiodial **3** in larvae of the aforementioned insects proceeds in an anologous manner to the biosynthetic sequence in plants (similar to Scheme 1). It can therefore be expected that both lifeforms possess similar enzymes.



Scheme 1. The metabolism of deuterated 3-norgeraniols **7** and 3-nor-8-hydroxygeraniols **8** in different leaf beetle larvae. **A**, **B**, and **C** refer to the synthetic pathways of *G. viridula*, *P. versicolora*, and *P. cochleariae*, respectively.

However, the fate of the two deuterium atoms at position C4 in the precursors **7** and **8** also reveals differences in the biosynthetic pathways in the three leaf beetle larvae. Analogous to the biomimetic cyclizations the larvae of *G. viridula* convert **8**, (via **9**), into 1-nor[$^2H_5$]chrysomelidial **10** (Scheme 1, **A**) without loss of a deuterium atom from the C4 position of the precursor. The number of deuterium atoms at

C5 can be reliably determined from the mass spectra of **10** by using the base peak (*m/z* 69 corresponds to a fragment ion with C5–$^2H_2$; *m/z* 67 corresponds to C5–$^1H_2$).[12, 13] The deuterium at C2 in **8** is lost as expected; the deuterium on the aldehyde groups in **9** is not lost and thus rules out additional redox reactions on the way to **10** or **11**. The isomeric diol (6*Z*)-**8** is not metabolized.

When the larvae of *P. versicolora* are treated with the diol **8** and the resulting metabolites are subjected to analysis by mass spectrometry, the results indicate that two separate (Scheme 1, **B**) cyclases might be operating in the defense glands of this larva. The resulting 1-nor[$^2H_5$]chrysomelidial **10** has two deuterium atoms attached to C5, whereas the typical main product for this larva, 1-nor[$^2H_4$]plagiodial **11**, has lost one of the two hydrogen isotopes from the C4 atom of the precursor **8**. In addition, a 3-nor[$^2H_4$]plagiolactone corresponding to **5** has also only one deuterium atom attached to C5, which shows that it is derived from 1-nor-plagiodial **11**. Whether the lack of the methyl group of the nor precursor causes this kind of product distribution still needs to be examined. The two deuterium atoms attached to C5 of 1-nor[$^2H_4$]chrysomelidial **10** rule out the possibility that 1-nor[$^2H_4$]plagiodial **11** is first formed and that the thermodynamically more stable **10** is produced by isomerization of **11**.

Interestingly, the larvae of *P. cochleariae* have developed precisely this pathway (Scheme 1, **C**; see also Fig. 1). After the injection of **8** exclusively 1-nor[$^2H_4$]chrysomelidial **10** is found in their defense secretion. In **10**, one of the two enantiotopic deuterium atoms attached to C4 in the precursor is missing. The use of chiral (4*R*,5*S*)- or (4*S*,5*R*)-3-nor[4,5-$^2H_2$]geraniol of the type **7** (≥97% *ee* at C4) as precursor[9] leads to the enantiospecific removal of the C4-H_S hydrogen atom. Since the loss of a hydrogen atom from the C5 atom of the iridoid skeleton, regardless of the cyclization mechanism, determines the position of the ring double bond, for *P. cochleariae* it must be assumed that plagiodial **3** occurs as an intermediate on the way to chrysomelidial **1**. This finding is in formal accordance with the current theory of an acid-catalyzed cyclization[10] of 8-oxocitral to **1**. It can be supposed that the direct formation of **10** and **11** from a common intermediate of the cyclization occurs through the loss of a hydrogen atom from C2 and C5, respectively. Regardless of mechanistic aspects, it is, however, clear that in the course of evolution, at least within the genus Phaedonini (subfamily Chrysomelinae), two different pathways have been developed for synthesis of **1**. Further biogenetic studies on iridoid-producing larvae of the Phaedonini should make it possible to characterize members of this genus chemotaxonomically.

[12] A 1:1 mixture of 1-norchrysomelidial and 1-norepichrysomelidial [$^2H_5$]-**10** was obtained by boiling the dialdehyde [$^2H_5$]-**9** (0.15 g, 0.95 mmol) in 60% HCOOH for 1 h [10]. Chromatography on SiO_2 with hexane/Et_2O (3:7 v/v) yielded 63 mg (42%) [$^2H_5$]-**10**. MS (Finnigan, Ion Trap ITD 800, 70 eV): *m/z* 157 (M^+, 1.4%), 139(6), 138(5), 129(14), 128(6), 114(4), 113(4), 112(8), 111(15), 110(11), 109(6), 100(18), 99(13), 98(12), 97(29), 96(35), 95(36), 94(17), 93(12), 92(6), 85(7), 84(9), 83(19), 82(18), 81(18), 80(18), 79(16), 78(11), 71(9), 70(29), 69(100), 68(75), 67(43), 66(28), 65(11), 64(8), 59(12), 58(11), 57(9), 56(11), 55(11), 54(11), 53(15), 52(14), 46(12). High-resolution MS; calcd. for $C_9H_7{}^2H_5O_2$: 157.1151; found: 157.1182.
[13] According to high-resolution mass spectrometry (Finnigan MAT 90), the base peak for [$^2H_5$]-**10** (*m/z* 69) corresponds to a fragment ion of the structural formula $C_5H_5{}^2H_2^+$ and contains the C atoms of the ring; with the exception of a deuterium atom from the aldehyde group (C7) (cf. Scheme 1) no deuterium from the side chain is transferred to the ring during the fragmenation of **10**. This was confirmed by using reference substances of varying degrees and patterns of deuteration [9]. A hypothetical fragmentation scheme for iridodial is discussed in ref. [14].

Cage Extension to Clusters with Co_2/Co_3MoAs_6 Polyhedron Frameworks**

By *Michaela Detzel, Karl Pfeiffer, Otto J. Scherer,** and *Gotthelf Wolmershäuser*

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

The synthesis of molecules exclusively constructed from L_nM and naked E_n units (E = P, As, Sb, Bi) has developed into an unusually manifold area of research, particularly in recent times.[1] Little is known, however, about the reactivity of such complexes.[1]

The desired extension of Co_2/Co_3As_6 cage frameworks to nona- and decanuclear heteroatom clusters has now been achieved by allowing **1**[2] and **2**[2] (Cp* = η^5-C_5Me_5) to react with [Mo(CO)$_5$(thf)]. The respective products, **3** (violet crystals) and **4** (black crystals), are stable in air for a short period and dissolve scarcely in *n*-hexane, better in benzene and toluene, and easily in dichloromethane. The complexes are formed in satisfactory (**3**: 47%) and good (**4**: 74%) yields, respectively.

The X-ray structure analysis[3] shows that for **3** the trapezoidal face of the As_6 ligand in **1** which is still free is capped by the 12e$^-$ fragment [Mo(CO)$_3$], which, however, does not change the total number of the skeletal electron pairs (SEP). With 11 SEP, **1** belongs to the arachno type (n + 3) and **3** to the nido type (n + 2) of structure. The framework of the nonanuclear cluster **3** can be described as a stretched, triply capped trigonal As_4CoMo prism (Fig. 1), in which the three long edges are almost of the same length (As1 ··· As3 3.032, As4 ··· As6 3.023, Mo–Co1 3.030 Å; sum of the covalent radii according to Pauling: As–As = 2.42, Mo–Co = 2.46 Å). This leads to parallel triangular faces (dihedral angle 0.6°) and to six As–As bond lengths, whose average value is 2.47 Å. The framework of the Co_2MoAs_6 polyhedron of **3**

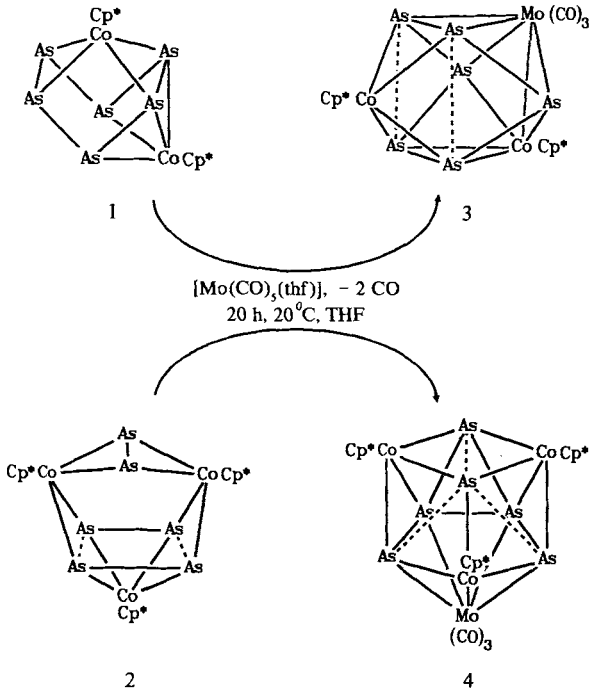
[+] X-ray structure analyses

[**] This work was supported by the Fonds der Chemischen Industrie.



shows interesting parallels to the Bi_9^{5+} cluster ion **5**,[4] both with regard to the number of skeletal electrons (22, i.e. $n + 2 = 11$ SEP) and to the h/e ratio (h = average value of the three long edges of the prism, e = average value of the six edges of the triangles), which for **3** is 1.17 and for **5** is 1.15. In **5** (11 SEP) the occupation of the antibonding a_2'' orbital (HOMO) is responsible for the elongation of the trigonal prism;[4] in $B_9H_9^{2-}$ (10 SEP) this orbital is the LUMO.[5]

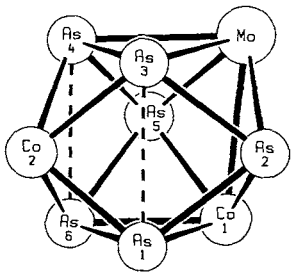


Fig. 1. Molecular structure of **3** without ligands. Selected distances [Å] and angles [°]: Co1-Mo 3.030(3), Co1-As1 2.518(3), Co1-As2 2.434(3), Co1-As5 2.426(3), Co1-As6 2.516(3), Co2-As1 2.364(3), Co2-As3 2.413(3), Co2-As4 2.412(3), Co2-As6 2.364(3), Mo-As2 2.588(2), Mo-As3 2.813(2), Mo-As4 2.817(3), Mo-As5 2.604(2), As1-As2 2.481(3), As2-As3 2.509(3), As3-As4 2.433(3), As4-As5 2.509(3), As1-As6 2.423(3), As5-As6 2.492(3), As1-As3 3.32, As4-As6 3.023, As2-As5 3.873; As1-As2-As3 74.8(1), As4-As5-As6 74.4(1), As2-As3-As4 106.4(1), As3-As4-As5 107.0(1), As2-As1-As6 107.0(1), As1-As6-As5 106.9(1); torsion angle As1,2,5,6/As2,3,4,5 78.6°.

^{1}H NMR investigations at different temperatures[6] show that the singlet for the Cp* ligands of **3** at room temperature splits into two separate signals for the Cp* ligands at Co1 and Co2 only at low temperature. These spectroscopic results indicate a rapid framework rearrangement often observed for nonanuclear clusters.[4]

The X-ray structure analysis[3] for the decanuclear heteroatom cluster **4** reveals a Co_3MoAs_6 polyhedron framework (Fig. 2a), which corresponds to a distorted sphenocorona[7] (Fig. 2b).[9] In comparison with the ideal polyhedron (Fig. 2b), the following important deviations are observed for the framework of **4** (Fig. 2a): a) The planar

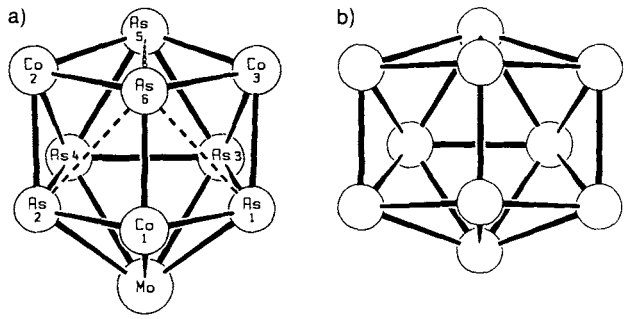

Fig. 2a) Molecular structure of **4** without ligands. Selected distances [Å] and angles [°]: Co1-Mo 2.933(3), Co1-As1 2.285(4), Co1-As2 2.286(3), Co1-As6 2.400(4), Co2-As2 2.407(4), Co2-As4 2.424(4), Co2-As5 2.315(4), Co2-As6 2.434(3), Co3-As1 2.422(4), Co3-As3 2.425(4), Co3-As5 2.309(4), Co3-As6 2.447(4), Mo-As1 2.667(3), Mo-As2 2.679(3), Mo-As3 2.714(3), Mo-As4 2.716(3), As1-As3 2.594(3), As2-As4 2.565(3), As3-As4 2.579(3), As3-As5 2.587(3), As4-As5 2.585(3), As1-As6 2.874, As2-As6 2.872, As5-As6 2.831; Co2-As5-Co3 110.1(1), Co2-As6-Co3 101.9(1), As5-Co2-As6 73.2(1), As5-Co3-As6 73.0(1), As1-Co1-As2 105.7(1), Co1-As2-As4 115.2(1), Co1-As1-As3 115.0(1), As1-As3-As4 101.4(1), As2-As4-As3 102.4(1). b) Sphenocorona; the ideal polyhedron was simulated by refinement of the structural model of **4** with suitable fixation of the bond lengths.

four-membered rings Co1, As2, Co2, As6, and Co1, As1, Co3, As6 (sum of the angles each 359.9°) are rhomboidally distorted, leading to an As···As diagonal distance of 2.87 Å (shown as a dashed line in Fig. 2a). b) In contrast to the five-membered ring As1, As2, As3, As4, Co1, (sum of the angles 539.7°; maximum deviation of the least-squares plane = 0.05 Å) the corresponding ring in sphenocorona is not planar (maximum deviation of the least-squares plane = 0.30 Å). c) The rhomboidally distorted, almost planar four-membered ring Co2, As5, Co3, As6 (sum of the angles 358.2°, fold angle 167.4°, As5···As6 2.83 Å) in **4** is contrasted by two neighboring three-membered rings (fold angle 159.9°) in the ideal polyhedron (Fig. 2b). The remaining five As–As bonds are almost identical in length (average 2.58 Å).

In spite of the Co_3MoAs_6 heteroatom cluster framework the asphericity[10] determined for **4** (23.4%) deviates only slightly from that of sphenocorona (18.9%[10]), a M_{10} polyhedron framework, which has so far not been found for transition metal clusters.[11] Compound **4**, however, shows a noteworthy structural parallel to gold clusters of the composition $[Au_{11}(PR_3)_7X_3]$.[11, 12] Inside the Au_{10} framework (cf. Fig. 2), consisting of ten triangles and three nonplanar quadrangles, is an interstitial gold atom, which obviously makes a significant contribution to the stability of the peripheral Au_{10} framework.[11, 12]

In contrast to the complexes **1**,[2] **2**,[2] and **3**, compound **4** shows no dynamic behavior as revealed by ^{1}H NMR studies.[6]

Experimental Procedure

3 [**4**]: To **1** [2] (81 mg, 0.094 mmol) [**2** (300 mg, 0.29 mmol) [2]] was added a solution of $[Mo(CO)_5(thf)]$, prepared by irradiation (90 min) (water-cooled 150 W mercury high-pressure lamp) of $[Mo(CO)_6]$ (240 mg, 0.091 mmol) in freshly distilled THF (50 mL). After the mixture had been stirred for 20 h at room temperature the reaction mixture was concentrated, adsorbed on to Al_2O_3 (ca. 1 g) (basic, 2% H_2O), and dried. In the purification by column chromatography (column 25 × 2.5 cm, packed with Al_2O_3/petroleum ether) with petroleum ether/toluene (1/1), exclusively **3** was eluted as an aubergine-colored [**4** as a dark brown] fraction. After the solvent had been removed **3** (47 mg, 47%) [260 mg, 74%, **4**] was obtained spectroscopically pure. Recrystallization was achieved by layering a concentrated solution of **3** [**4**] in dichloromethane with *n*-hexane at room temperature; **3** formed violet, hexagonal crystalline platelets [**4** dark brown to black crystal needles].

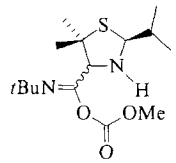
Corrigendum

In the communication "The Seven-Component Reaction" by A. Dömling and I. Ugi (*Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 563–564) structural formula **14** is incorrect. The correct formula is:



14

BOOKS

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Book Reviews

Perspectives in Coordination Chemistry. Edited by *A. F. Williams, C. Floriani*, and *A. E. Merbach*. VCH Verlagsgesellschaft, Weinheim/Verlag Helvetica Chimica Acta, Basel, 1992. XII, 486 pp., hardcover DM 148.00.—ISBN 3-527-28487-7/3-906390-02-0

It has now become common practice for the organizers of regular international conferences to ask the invited speakers to provide manuscripts, which are then published in collected form, either as a special section in one of the established journals or as a monograph. This procedure does not always ensure that the result is both up-to-date and of high quality from a scientific or publishing standpoint, since the manuscripts, often in camera-ready form and varying with regard to the care in their preparation, are in many cases not thoroughly checked before publication. However, this book, which contains about half of the main papers presented at the 29th International Conference on Coordination Chemistry (ICCC) in Lausanne in July 1992, demonstrates in an exemplary way that such "congress reports" can be produced so that they satisfy the needs of not only the editors, authors, and publisher, but also the consumers of scientific literature. The determination to make this high-quality book available within a very short time after the conference on which it is based has meant that not all the 23 articles could be published in the format of *Helvetica Chimica Acta*, but the camera-ready form in which the manuscripts were provided is of a quality that gives no grounds for complaint. Three of the articles (by Corbett, Cotton, and Shilov) have been reproduced directly from *Pure and Applied Chemistry*.

This collection of articles on "Perspectives in Coordination Chemistry" emphasizes the great diversity of the subject and its relevance to aspects of bioscience, materials science, and applications in fields such as industrial catalysis and

organic synthesis. Research on coordination chemistry shows a trend towards studying compounds of ever increasing complexity, with improvements in the reliability of synthesis through control of reactions proceeding alongside developments in analytical methods.

It is therefore not surprising that most of the articles in this volume are concerned with the area of "supramolecular structures", including clusters, with special attention not only to structure and chemical selectivity but also to physical and catalytic properties and the factors controlling them. Here it becomes evident that the intelligent design and skillful synthesis of complex organic ligands now plays a very important role. Mono- und polynuclear complexes with specially designed ligands are the subject of the contributions by Seel and Vögtle, Braunstein, Gatteschi et al., Hancock, Denti and Balzani et al., Hosseini, and Lehn. The related area of bioinorganic and relevant model systems is represented in articles by Fenton, Shilov, Luchinat et al., and R. J. P. Williams. Cluster formation and its coordinative aspects are also relevant to some current problems of solid-state chemistry, as shown in the articles by Dance, Corbett, Burdett, and Bürgi. The latter, in outlining the fascinating Bürgi–Dunitz concept, leads into studies of reaction mechanisms, which are represented in this volume by the articles by van Eldik and Ryabov. The role of solvents in relation to coordination compounds is discussed in articles by Burger and Enderby. Other aspects of coordination chemistry are treated in the articles on high-resolution optical spectroscopy (Güdel et al.), the δ bond (Cotton), and the reactivities of organometallic compounds (Carmona, Sanchez, et al.), while the special relevance to organic synthesis is discussed by Bäckvall et al.

There are, of course, differences in the nature and degree of complexity of the various contributions, varying from laboratory reports through informal essays to short reviews. For example, whereas Hancock's review of the size-selective complexation of metal ions by polydentate chelate ligands can be commended even to advanced students (cf. also a similar recent article in the *Journal of Chemical Education*), the article by Lehn suffers from the disadvantage of having no diagrams or structural formulas whatsoever, so that anyone who does not keep up with the details of published work on supramolecular structures will have the irksome task of referring to the cited papers to discover the structures of compounds such as helicates, carcerands, or speleands.

Altogether the book presents an up-to-date and representative overview of the current state of coordination chemistry, its many different aspects, and its future potential. Because of the central position that this subject occupies, linking such widely different areas as solid-state research, biochemistry, organic synthesis, and industrial catalysis, it is essential to learn something about it or to renew one's knowledge, even for nonspecialists.

der Universität Stuttgart (FRG)

Chemistry. The Central Science. By *T. L. Brown, H. E. LeMay, Jr.*, and *B. E. Bursten*. Prentice Hall, Englewood Cliffs, NJ (USA), 1991. XXX, 1045 pp. (glossary and index 40 pp.), hardcover ca. DM 120.—ISBN 0-13-126210-6

This book provides a *first* text in chemistry for students at universities and colleges, and presents the core material typically followed at such institutions in the United States. Its aim is to help instructors to plan a coherent and well-organized course, and to give the students parallel material which amplifies, exemplifies, and illustrates the material they receive in lectures and classes.

The fifth edition of this text represents a considerable achievement. From the very beginning the authors convey the excitement and variety of their subject matter, while developing a very careful and rigorous presentation of concepts and material. Many beautiful color illustrations are one tool used to this end. But there is also a wealth of supplementary sections interspersed in the text. These are of three types; the "Chemistry at Work" sections introduce applications of the concepts being presented, those entitled "A Closer Look" tackle a topic more deeply and would enhance subsequent readings, and the "Historical Perspective" sections, which are rather fewer in number, give some sense of the way our fundamental chemical ideas evolved. These learning aids, together with an attractive and colorful layout, serve to complement the central text, which is the heart of the book. It is in the text itself that the thoughtfulness and craft of the authors is most evident. The presentation is lucid and easy to read. The organization and ordering of the introduction of ideas, concepts, and facts is very impressive and can hardly be faulted.

Any successful course book for instructors and pupils must contain good exercises, and "Chemistry. The Central Science" is no exception. Numerous problems at the end of each chapter help reinforce the material presented.

On the physical side of chemistry one can gain a clear idea of the level of the presentation by the mathematical knowledge presumed. The student needs to have mastered simple proportion; logarithms are used in presentation of pH and so forth, but there is a helpful appendix on them and on exponential notation. Differential calculus is not employed, so the treatment of rates, thermodynamics, and the Schrödinger equation is only descriptive. In the context of the British educational system, this places the book as one most likely to be useful to Advanced Level courses in schools, and as such would be a good addition to a school library. The coverage of descriptive inorganic and organic chemistry is less than that expected in most A-level syllabuses, so it would not serve as a central sixth-form text. However, it can be strongly recommended to chemistry teachers as an exemplary presentation of the core of the subject, and to prospective university students to reinforce their school work and whet their appetites for further study.

Simple Views on Condensed Matter. (Series in Modern Condensed Matter Physics, Vol. 4.) By *P. G. de Gennes*. World Scientific, Singapore, 1992. X, 408 pp., paperback £ 25.00, hardcover £ 44.00.—ISBN 981-02-0910-X (paperback)/ 981-02-0909-6 (hardcover)

In 1992 Professor de Gennes was awarded the Nobel Prize for Physics in recognition of his numerous scientific achievements, which relate to a wide range of different phenomena. The great variety of his research activities and their importance to scientific progress resulted in many awards and honors, culminating finally in this Nobel Prize. All de Gennes' work up to now is contained in four books and over 350 scientific papers; to these is now added this new book "Simple Views on Condensed Matter", in which the author presents a personal selection of important publications. Thus it is not a textbook in the ordinary sense, but a collection of

interesting articles that have previously only appeared in specialist journals. It contains 40 articles, of which 13 are in French and the rest in English, and is divided into six chapters dealing with different areas of current interest. The first chapter is concerned with the basic principles of wave propagation and superconductivity in the solid state, and the second with phenomena in thermotropic liquid crystals. The latter materials show ordering phenomena like those in solid crystals, but are mobile like ordinary liquids, and consequently they have unusual optical properties. In liquid crystals one observes phenomena such as domain formation or dislocations that also occur in solids, and these analogies are especially emphasized here. The third chapter deals with the properties of flexible macromolecules, with the main emphasis on chain statistics, chain dynamics, conformational changes, and the different types of phase transformations. The topics covered also include modern methods of investigation such as low-angle neutron diffraction, which enables one to study chosen regions of a given molecule by the contrast variation technique. The fourth chapter is devoted to interfacial phenomena. The topics covered include adsorption by polymers, the stability of soap films, and the formation of emulsions and microemulsions. This is followed by a chapter on wetting and spreading; the topics treated in detail include the surface tension of solutions, melts, and solids, together with contact angles, film formation, and adhesion properties. The final chapter contains a detailed discussion of chirality phenomena, including studies of specific properties and interactions that are only found between enantiomers.

The publications reproduced here touch on many different topics, and are representative of the most important of de Gennes' areas of work. Many of the articles carry comments telling the reader about errors or new results. Much of the material presented is in such a form that it can serve as a source of rapid and up-to-date information, even without previous knowledge. Thus, readers whose interest is confined to one specific subject area will nevertheless profit from using the book. The chapters are of a high scientific standard, and contain interesting examples relating to many different aspects of condensed matter. The choice of topical subject matter will be of interest to a wide readership including chemists, physicists, engineers, and technologists. However, nonspecialists too will find this new book useful when they wish to learn more about new methods and modern insights. The articles contain many stimulating views and original ideas, and thus the book can be recommended most emphatically.

Heinz Rehage

Geschichte der deutschen Großchemie. Entwicklung und Einfluss in Staat und Gesellschaft. By *W. Teltschik*. VCH Verlagsgesellschaft, Weinheim, 1992. XIV, 426 pp., hardcover DM 58.00.—ISBN 3-527-28444-3

The three largest chemical companies in the world are German-based; there is no other section of the German economy where a similar situation exists. Walter Teltschik, a chemist who has worked for many years in BASF, has set himself the task of describing the checkered history of German large-scale chemical industry in a book of a little over 400 pages.

The author makes an excellent and thorough job of covering the many developments that have occurred in nearly 130 years of industrial history and analyzing these in relation to the contemporary situation in the German state and in society. The book has been written with the benefit of much inside knowledge of the industry, supported by an extensive compilation of source material. Teltschik writes with a lively and engaging style. He enlivens the narrative with many quotations, while the passages containing statistics on production and consumption are kept agreeably brief or are relegated to the appendix. The clear division into subchapters with suitably informative titles and the inclusion of an excellent index section make the book a very useful reference source.

The first chapter, "Aufbruch" (beginnings), is especially successful. The author rightly honors Liebig and his chemist contemporaries as the originators of the German chemical industry, the successes of which he attributes (in later years also) mainly to the close and fruitful relationship between research in the universities and in industry. These successes eventually led to the German chemical industry gaining a dominant position in Europe. The three following chapters, entitled "Rückschläge" (setbacks), "Konzentration" (consolidation), and "Größenwahn" (megalomania), are excellent accounts of the splendors and miseries experienced by German chemical manufacturing during the years 1914 to 1945. The regeneration of the industry after World War II, at first hesitant then with near-explosive vigor, is also well described. Teltschik describes the great period of growth during the sixties under the title "Zügellosigkeit" (unbridled growth), the significance of which we can only appreciate with the wisdom of hindsight. The book concludes with the oil crisis and its effects ("Verunsicherung", i.e. uncertainty) and the recovery during the eighties ("Schubkräfte", thrusting forward); these chapters too are packed with absorbing accounts of the momentous events of those years.

In view of the wealth of topics covered, one is prompted to ask whether some important matters have received inadequate treatment. The description of the Fonds der Chemischen Industrie (Chemical Industry Research Fund of the FRG) as merely a provider of research scholarships fails to do it justice. In fact, since its formation in 1950 the Fonds has raised DM 370 million, mainly for the advancement of fundamental research, thereby making an important contribution to the high standard of research and teaching in German universities. It is an institution much envied in other countries. A further question concerns the objectivity of the presentation. The preface emphasizes the care that has been taken to present a balanced overall picture, but this does not mean that the author cannot have opinions. It is pleasing to find that Teltschik has not held back from making his own position clear when discussing people and events. This brings the text to life and stimulates the reader to examine his or her own position, whether in agreement or opposition.

The picture that Teltschik presents of Duisberg certainly invites disagreement. Much has been written about Duisberg, often in his praise. Teltschik takes an opposite view, showing as if through a magnifying lens the darker side of this historical figure, supported by quotations and accounts of events. To translate the key passage: "The rather mediocre chemist Duisberg had a predilection for long and pathetic speeches and knew how to present himself to advantage as the center of attention. His clever and energetic promotion of his idea of a 'community of interests' gained for him the status of a pioneering industrialist." Well! Another controversial passage appears near the end of the book, where Teltschik writes "The chemical industry remained an unloved child. However, even unloved children can earn attention through good behavior." However, it cannot be assumed that the reaction of the chemical industry to an exces-

sive amount of government legislation and regulation bordering on absurdity will always be one of docile adjustment. It is more likely that the affected manufacturing processes will be closed down or will be transferred, together with the associated research, to a country where the external constraints are more favorable. This has already started to happen in genetic engineering. I would therefore have preferred the book to end with an appeal to the legislators that, before enacting laws and regulations, they should ask themselves whether their proposals are sensible and feasible, and especially whether they are comparable with conditions in other countries.

In summary, this is a book well worth reading, and can be recommended not only for chemists but for everyone interested in the history of German industry.

Hans Rudolph
Krefeld (FRG)

Molecular Design of Electrode Surfaces. (Series: Techniques of Chemistry, Vol. 22. Series editors: *A. Weissberger, W. H. Saunders, Jr.*) Edited by *R. Murray*. Wiley, Chichester, 1992. XI, 427 pp., hardcover £ 105.00.—ISBN 0-471-55773-0

The title of this book sounds very promising, reflecting as it does the desire of every electrochemist to be able to prepare electrodes with tailored surface properties. However, even before opening it one suspects that it is concerned with chemically modified electrodes, then it at once becomes clear that the title describes the long-term aim and not the reality (yet). The subject of this multiauthor work edited by Royce Murray is in fact highly topical and is receiving much attention from electrochemists; this is the chemical modification of electrode surfaces with the aim of optimizing their catalytic properties. The idea is attractive, despite the fact that in practice there is often an inverse relationship between the stability of the modified surfaces and their efficiency for electron transfer.

The book begins with an introductory article by R. Murray on the wide variety of applications of modified electrodes, which are well documented here with 442 literature references. This is followed by a contribution by G. N. Salaita and A. T. Hubbard on the adsorption of organic molecules at well-defined single-crystal surfaces. The article mainly describes the authors' own ultra-high vacuum studies using low-energy electron diffraction (LEED) and electron energy loss spectroscopy (EELS), which impressively demonstrate that these methods can yield a wealth of detailed structural information about the adsorbed molecules. The third article, by J. S. Facci, is concerned mainly with Langmuir–Blodgett films; the examples are taken entirely from the author's work on C_{18}-ferrocene, which unfortunately fails to do justice to the highly interesting topic of Langmuir–Blodgett films. The next two articles deal with redox polymers. The first, by M. Majda, is mainly concerned with the transport mechanisms for electrons and positive charges in the polymer, while the second, by C. P. Andrieux and J.-M. Savéant, discusses catalytic reactions at electrodes coated with redox polymers. Chapter 6, by J. A. Bard and T. Mallonk, describes the chemical modification of electrode surfaces using microporous substances such as zeolites, and in Chapter 7 C. R. Leidner gives a short review of charge transport in polymers doped with metal complexes (mainly of Group VIII metals). In Chapter 8 N. Oyama and T. Ohsaka describe the use of voltammetry (mainly measuring current transients) to study charge transport, yielding information in the form of diffusion coefficients. The book ends with an article by C. R. Martin and L. S. van Dyke on material and charge transport in electronically conducting polymers (polyacetylene, polypyrrole, etc.).

The editor claims that this work is of special significance because it is the first to range over the whole field of modified electrodes, and after looking through it I am inclined to agree with that view. Royce Murray has not only been able to enlist a thoroughly competent team of authors, but has also assembled their contributions into a unified whole, giving a very good overview of this complex subject. However, this book is certainly not suitable as an introduction to modified electrodes for the newcomer, as it does not cover the fundamentals sufficiently for that, and the individual problems are mostly only treated very briefly (often with no more than a reference to the original papers). However, it gives an excellent overview of the different problem areas, the approaches to finding solutions, and the present state of research. The many literature references included in the individual chapters make this a valuable reference work. However, in this respect I found the index quite inadequate, as it is not very detailed. Moreover, for some of the words that I looked up (e.g. Prussian blue) the index led only to rather unimportant mentions in the text, whereas important ones were not listed. Nevertheless, considering the book as a whole, its purchase can be emphatically recommended for specialists and relevant libraries.

Dieter M. Kolb
Ableitung für Elektrochemie
der Universität Ulm (FRG)

Science and Practice of Liquid–Liquid Extraction, Vols. 1 and 2. (Oxford Engineering Science Series, Vol. 27. Series editors: *J. M. Brady, C. E. Brennen, A. L. Cullen, T. V. Jones, J. van Bladel, L. C. Woods* and *C. P. Wroth.*) Edited by *J. D. Thornton*. Clarendon Press, Oxford, 1992. Vol. 1: XVI, 603 pp., Vol. 2: XV, 436 pp., hardcover £ 60.00 each volume, £ 108.00 set.—ISBN 0-19-856236-5 (Vol. 1), 0-19-856237-3 (Vol. 2), 0-19-856178-4 (set)

Nine years after the publication of the *Handbook of Solvent Extraction*, edited by T. C. Lo, M. H. I. Baird, and C. Hanson, we now have a new work which collects together the latest knowledge of the science and technology of liquid–liquid extraction. Altogether there are 13 chapters, each reviewing a specific topic area.

Volume 1 is essentially concerned with the basic science of liquid–liquid extraction. Chapter 1 deals with the thermodynamics of the phase equilibria, with calculations to predict these equilibria, and with the choice of suitable solvents. The following chapter treats the basic theory of mass transfer and its application to exchange processes such as those occurring at the surfaces of jets and droplets (but omits to describe recent studies carried out in German-speaking countries on mass transfer in liquid–liquid systems). Chapter 3 summarizes work on the Marangoni effect, and its importance for mass transfer is examined in more detail in Chapter 4. The last of these five chapters on the basic science deals with the important subject of dispersion and coalescence. This is followed by three chapters on choosing apparatus and on design calculations. Chapter 6, on "Plug Flow Analysis", describes methods of calculation for "normal" counter-current extraction processes, and also for back-flow columns, for fractionating extraction processes using two solvents, and for crossflow and batch processes. Chapter 7 ("Axial Dispersion") describes the well-known residence time models, in-

cluding the relevant methods of measurement and their evaluation. Volume 1 ends with a further chapter on the design of extractors, and on choosing a design and layout using data from pilot experiments.

Volume 2 begins with four chapters on the application of liquid–liquid extraction methods in some special areas. Chapter 1 describes the use of reactive extraction techniques in metal refining. The basic principles and special extra conditions that apply to this field of application are first explained, then the processes currently used for individual metals or groups of metals are described. Chapter 2 is concerned with the reprocessing of nuclear fuel elements, beginning with a general introduction and a description of the different types of equipment, then going on to describe the processes currently used and possible future developments. However, it is questionable whether the details of the associated control technology and safety measures included at the end of this chapter are relevant to the main theme of the book. The following two chapters deal with applications of extraction technology in the pharmaceutical and food industries, with details of some special processes used, such as high-pressure extraction and the use of two-phase aqueous systems. The final chapter summarizes the various areas of application and indicates the directions in which these are now developing.

The work does not claim to be an introduction to the subject; instead the contributions by recognized experts are intended to summarize the current state of knowledge and to indicate topics for further research. The material is presented from a scientifically orientated standpoint, and is thus likely to be mainly of interest to engineers and chemists in universities and industrial research laboratories. The volumes give a good overview of the fundamental theory and some important areas of application of extraction processes. The comprehensive subject index makes it easy to locate information on special topics. There is some overlapping of subject matter between the individual contributions, but one can hardly expect that to be completely eliminated in a work of this kind. The fundamental theory is covered thoroughly and forms the basis for a treatment that emphasizes recent developments, including some unconventional ones, and this is therefore a valuable addition to the literature on liquid–liquid extraction.

Eberhard Aufderheide
Degussa
Antwerp (Belgium)

Selective Biocatalysis. A Synthetic Approach. By *L. Poppe* and *L. Novák*. VCH Verlagsgesellschaft, Weinheim, 1992. XII, 319 pp., hardcover DM 168.00.—ISBN 3-527-28372-2

Biotransformations in Organic Chemistry. By *K. Faber*. Springer, Berlin, 1992. IX, 319 pp., hardcover DM 128.00.—ISBN 3-540-55762-8

Methods based on enzyme catalysis have become firmly established in the standard repertoire of asymmetric synthesis techniques because of their high selectivities—in some instances serving to complement, in others to compete with, the conventional chemical methods of organic synthesis—as is documented by the almost exponential growth of the literature on new applications of enzymes for the preparation of chiral intermediates. Both methods based on fermentation and, more especially, the use of isolated enzymes, are benefiting from the continuing growth in the numbers of known enzyme types (now over 2500) and of those that are commercially available (over 350). The task of collecting together the huge wealth of reactions that can be performed, critically reviewing the possibilities, and presenting this information clearly in book form as a guide for synthetic chemists interested in applying these methods is a difficult one from several viewpoints. Firstly, this area of research is undergoing rapid development, and consequently by the time the book is printed the contents will no longer be completely up-to-date. Secondly, the resulting publication is in competition with a steadily growing number of review articles in the relevant specialist journals, which are usually read by synthetic chemists and can cover matters of detail from a more expert standpoint. The authors of the two monographs reviewed here have taken up this challenge, and have almost simultaneously produced works that cover the same topics and have also turned out to be very similar in content. Thus it is appropriate to compare them.

In both volumes a general introduction to the methods is followed by the main part in which enzyme-catalyzed (and also some selected yeast-mediated) transformations are treated in a hierarchical sequence. Some noticeable differences between the two treatments will be mentioned here. In the book by Poppe and Novák the discussion of some process-related problem areas (the characteristics, classification, kinetics, and immobilization of enzymes; the reaction medium; microbial transformations; the modification of biocatalysts; catalytic antibodies) is preceded by a detailed chapter of 40 pages on stereochemistry, in which the nomenclature, basic principles, and especially the classification of the different possible types of selectivity (diastereomeric, diastereotopic, enantiomeric, and enantiotopic) are defined. The latter system, although somewhat unconventional, serves as a very useful means of classifying the asymmetric reactions discussed in the main part of the book. However, the rigid arrangement according to types of biocatalysts means that specific chemical themes are scattered throughout widely separated chapters (e.g., hydrolysis by enzymes is treated in Chapter 3, by baker's yeast in Section 5.4, and by other microorganisms in Section 6.2.1). In contrast Faber, after a short introduction (probably based on a lecture manuscript), plunges straight into the main business and follows the general arrangement used in a successful earlier work with a similar title and subject (H. G. Davies, R. H. Green, D. R. Kelly, and S. M. Roberts, *Biotransformations in Preparative Organic Chemistry*, Academic Press, London, **1989**). In a less helpful arrangement, however, he treats the reversal of hydrolytic reactions in a separate chapter on "Special Techniques", in which the action of enzymes in organic solvents leading to the formation of esters, lactones, and amides is described. In both books the grouping together of basic principles and general features of the methods should help to prevent the contents from losing their usefulness too quickly as the more detailed material becomes outdated.

The main parts of both books provide the reader with what is promised by the title, namely a wealth of information with examples of reactions sensibly chosen from the synthetic organic chemist's viewpoint, i.e. with due regard to preparative usefulness (high chemical and optical yields). Both books place emphasis on hydrolytic and reductive transformations with their respective reverse reactions, which are at present the reaction types of greatest practical importance. The authors have made liberal use of figures and tables to present the material in a way that is textually and visually clear. Both monographs concentrate on "main-stream" preparative applications, and consequently some aspects of enzyme-catalyzed reactions are not treated as thoroughly as

one might wish (in particular Poppe and Novák devote a mere $11\frac{1}{2}$ pages to "Other Enzymes and Microorganisms", thus barely scratching the surface of this topic). However, the surveys are well written (apart from the minor faults mentioned below) and each chapter includes a comprehensive and up-to-date bibliography ("Poppe and Novák" contains 1660 citations altogether and "Faber" 1456, extending up to about mid-1991 in both cases), with references to the most important original papers and recent review articles. Scientists who keep up with the current literature will find few surprises here (though occasionally they may be surprised to find which publications are *not* cited), but they will appreciate the clearly presented comparisons. For others these books offer a rapid and detailed survey of the main areas of activity and new methodological developments in this highly topical and expanding field of research. Of the two books, "Poppe and Novák" is more in the nature of a scientific review, with a hierarchical arrangement of contents according to selectivity types which is best suited to the needs of the researcher. "Faber", on the other hand, has a more general approach based on types of transformations, with some of the character of a textbook, and didactic qualities that make some parts of it really enjoyable to read.

"Poppe and Novák" has been carefully edited, and only a few small isolated and unimportant errors are evident in the formula schemes (e.g., in Fig. 4.6. a the oxidizing and reducing agents have been interchanged) and in the Latin names of the microbe species (e.g., "*Penicillinum camamberti*" instead of *Penicillium camembertii*). That Faber has not been afraid to tackle the hard work of desktop publishing only becomes apparent on close examination of the book (actually on the imprint page), which accounts for the lower price. However, the risk involved in this has exacted a penalty, as careful reading unfortunately reveals a higher incidence of errors in formula diagrams (e.g., an extra OH group in Scheme 2.160, and a vinyl instead of an allyl substituent in Scheme 2.164), in the numbering of references, and in captions (e.g., Table 2.8), despite the fact that the author acknowledges the help of an internationally respected colleague in checking the work. In particular Chapter 2.1.4, "Hydrolysis and Formation of Phosphate Esters", contains many errors that need to be corrected, including inaccurate formulations (e.g., glucose-6-phosphate as an essential cosubstrate of dehydrogenases) and many incorrect statements (e.g., that carbohydrate *tri*phosphates are involved in glycosyl transfer reactions, that *phosphatases* are employed for the synthesis of phosphate esters, that kinases are a subgroup of *phosphatases*—could this misunderstanding be the reason for the inclusion of enzymic phosphorylations in Chapter 2.1 on "Hydrolytic Reactions"?—that nucleoside triphosphates are intrinsically *stable* in solution, and so on). Also the index (only 7 pages) is less than perfect with regard to completeness and conciseness of the entries.

Although Faber's book is more attractively priced and, for this reason especially, might help to fill a gap in the training of organic chemistry students, I have slight reservations about recommending it as a textbook to accompany a special lecture course. As a reference work for the desks of chemists engaged in research in this field "Poppe and Novák" seems more suitable, although the higher price may be an obstacle to individuals buying it. As the subject matter covered by each book alone is (rather surprisingly) considerably less than the sum of the two, chemical libraries should not hesitate to buy both.

Methods for the Synthesis of μ-Hydrocarbon Transition Metal Complexes without Metal–Metal Bonds

By Wolfgang Beck,* Burkhard Niemer, and Michael Wieser

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

Transition metal complexes in which hydrocarbons serve as σ,σ-, σ,π-, or π,π-bound bridging ligands are currently of great interest. This review presents efficient and directed syntheses for such compounds, which often have very aesthetic structures. These reactions are among the most important reaction types in modern organometallic chemistry. They can be a useful aid for the synthesis of tailor-made compounds, for example, for models of catalytic processes and, specifically, for the construction of heterometallic compounds. We will discuss reactions of electrophilic complexes with nucleophilic ones, numerous transformations of (functionalized) hydrocarbons with metal complexes, the currently very topical complexes with bridging acetylide and carbide ligands, and organometallic polymers, which can be expected to have interesting and novel materials properties. Chisholm[1] has described the importance of these complexes as follows: "Central to the development of polynuclear and cluster chemistry are bridging ligands and central to organometallic chemistry are metal–carbon bonds. Thus bridging ligands hold a pivotal role in the development of dinuclear and polynuclear organometallic chemistry".

1. Introduction

Complexes incorporating hydrocarbons as bridges between metal atoms were known soon after the advent of modern organometallic chemistry. They are formed, for instance, by the reaction of metal carbonyls with alkynes[2] or by the dimerization of dicyclopentadienylrhodium.[3a] Cyclopolyenes such as cyclooctatetraene can act as bridges between two iron, cobalt, or platinum atoms.[3b] The synthesis of complexes with bridging polymethylene ligands from α,ω-dibromoalkanes and $[CpFe(CO)_2]^-$ was the first directed synthetic pathway.[4]

Why are complexes with hydrocarbon bridges of such great interest? They are models for intermediates in the Fischer–Tropsch process,[5] in the polymerization of alkenes[6a] and alkynes,[6b] and for unsaturated hydrocarbons chemisorbed on metal surfaces[7]—a first step during heterogeneous catalyses. It is possible to prepare in a directed way heterometallic species that can act as precursors for heterogeneous catalysts which incorporate different metals in stoichiometric proportions.[8] In addition, "early" and "late" transition metals, for example, zirconium and cobalt,[9] can be linked with hydrocarbon ligands. In organometallic polymers, unsaturated hydrocarbons can act as electronic bridges[10] ("molecular wires"[11]) between metal atoms. Electrochemical studies on compounds with bridging π ligands yield insights into the intramolecular electron transfer between two metal atoms.[12]

Due to the large number of currently known complexes with hydrocarbon bridges, this review cannot be complete; cluster compounds and polynuclear complexes with metal–metal bonds or supporting bridging ligands[9b, 13, 14] will be

excluded for the most part. We will stress methods for the synthesis of μ-hydrocarbon complexes not having metal–metal bonds. Other reviews in the literature have organized these complexes according to compound type.[3, 15–17]

2. Reactions between Electrophilic and Nucleophilic Complexes

In general, complexes with bridging hydrocarbon ligands are formed in a predictable and unique fashion when organometallic nucleophiles are combined with corresponding electrophiles. In nearly all cases these are reactions of cationic and anionic complexes, yielding neutral products. Kochi coined the term "ion pair annihilation" for these in principle extremely simple reactions.[18] The reactions described in the following sections and the abbreviations used are summarized in Table 1.

Table 1. Overview of the reactions in Section 2[a].

Nucleophile	Electrophile	Section
$[L_m(OC)_nM]^-$	$[(\pi\text{-}Z)ML_n]^+$	2.1.
$[L_nM(Z)Nu]^-$	$[(\pi\text{-}Z)ML_n]^+/[ML_n]^+$	2.2.
$[L_nM(\pi\text{-}Z)]^-$	$[(\pi\text{-}Z)ML_n]^+$	2.3.
$[L_m(OC)_nM]^-$	$[(X\text{-}\pi\text{-}Z)ML_n]$	2.4.
$[L_nM(Z)]^-$	$[(X)ML_n]$	2.5.
$[L_nM]$ [19]	$[(X\text{-}Z)ML_n]$	2.6.

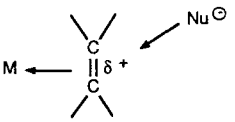
[a] $[L_mM(CO)_n]^-$ = carbonylmetalate ion, e.g., $[Re(CO)_5]^-$; M = metal; Z = hydrocarbon; Nu = nucleophilic substituent, e.g., S; X = halide; L = ligand; $[ML_n]^+$ denotes, e.g., $[Re(CO)_5]^+$; $[L_nM]$ denotes, e.g., $[(PPh_3)_2Pt]$; Cp = η^5-C_5H_5, Cp* = η^5-C_5Me_5; Fp = $[Fe(CO)_2Cp]$; Fp* = $[Fe(CO)_2Cp^*]$; Fc = ferrocenyl.

2.1. Reactions between Unsaturated Hydrocarbon Ligands in Cationic Metal Complexes and Carbonylmetalate Ions, and Redox Reactions

2.1.1. Addition Reactions

The addition of organic nucleophiles to unsaturated hydrocarbon ligands is one of the most investigated and important reactions in organometallic chemistry.[20] It has found broad application in organic synthesis[21] and is also a crucial step in industrial processes such as the Wacker process.[22]

The unsaturated hydrocarbon, for example, an olefin, is activated (becomes at least partially positively charged) by coordination to a transition metal atom and is thereby made susceptible to nucleophilic attack (Scheme 1). These reactions are characterized by high regio- and stereospecificity, which is also supported by theoretical studies.[20a, g, 23] Davies, Green, and Mingos formulated general, meanwhile well-established rules that predict that acyclic hydrocarbon ligands as well as those with an even number of coordinated carbon atoms (η^2, η^4...) are attacked preferentially (DGM rules: "even before odd" and "open before closed").



Scheme 1. Nucleophilic attack on a carbon atom activated by coordination.

The addition of organometallic nucleophiles (carbonylmetalate ions) to unsaturated hydrocarbon ligands in cationic complexes opened up a direct pathway to various compounds with hydrocarbon bridges.[24] The first example of this reaction type was found by us when $[CpM(CO)_3(\eta^2\text{-}C_2H_4)]^+$ (M = Mo, W) was allowed to react with $[Re(CO)_5]^-$.[25] This pathway to complexes like **1** with ethylene bridges has been briefly discussed by Ellis.[26] Interestingly, the $Cp(OC)_3M$ unit in complex **1** can be replaced by the stronger nucleophile $[Re(CO)_5]^-$.[27] Compound **2** can

$$[CpM(CO)_3(C_2H_4)]^+ + [Re(CO)_5]^- \longrightarrow [Cp(OC)_3MCH_2CH_2Re(CO)_5]$$
1

M = Mo, W

$$+ [Re(CO)_5]^- \quad - [CpM(CO)_3]^-$$

$$[(OC)_5Re(C_2H_4)]^+ + [Re(CO)_5]^- \longrightarrow [(OC)_5ReCH_2CH_2Re(CO)_5]$$
2

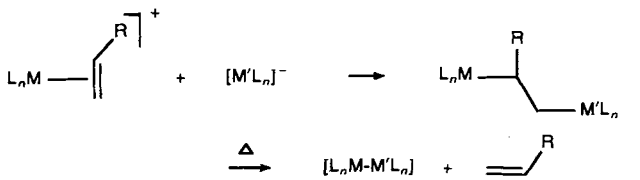
Wolfgang Beck was born in Munich in 1932 and completed his dissertation in 1960 with Professor W. Hieber at the Technische Hochschule in Munich. After his habilitation at the TH Munich in 1963, he accepted the offer of the chair for Inorganic and Analytical Chemistry at the University of Munich in 1968. He was awarded the Karl-Winnacker-Stipendium and the Chemiepreis der Akademie zu Göttingen. In 1977 he was a visiting professor at the University of Wisconsin in Madison. His research interests lie in coordination chemistry (metal complexes of pseudohalides and reactions of their coordinated ligands, metal complexes with biologically relevant ligands and of dyes) and organometallic chemistry.

Burkhard Niemer, born in Essen in 1962, studied chemistry from 1981 to 1987 at the Universities of Giessen and Munich. In 1990 he completed his dissertation under the supervision of Professor W. Beck on complexes with hydrocarbon bridges. After a stay with Professor H. D. Kaesz at the University of California, Los Angeles, he returned to Munich in 1992.

Michael Wieser was born in Munich in 1965 and studied chemistry from 1984 to 1990 at the Technische Universität and the University of Munich. He is currently a doctoral student with Professor W. Beck and working on the topic discussed in this review.

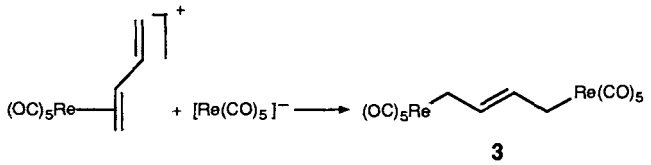
be obtained more directly by the reaction of $[(OC)_5Re(\eta^2\text{-}C_2H_4)]^+$ with $[Re(CO)_5]^-$.[28] The cationic rhenium ethylene complex can be prepared under very mild conditions (1 bar, room temperature) from $[(OC)_5Re]FBF_3$ and ethylene.[28, 29]

A number of μ-ethylene complexes could be prepared as outlined in Scheme 2. The cationic alkene complexes $[(OC)_5M(\eta^2\text{-}CH_2{=}CHR)]^+$ (M = Mn, Re), $[CpM(CO)_3(\eta^2\text{-}C_2H_4)]^+$ (M = Mo, W), $[(\eta^6\text{-}C_6H_6)Ru(PMe_3)_2(\eta^2\text{-}C_2H_4)]^+$[30] and the anionic species $[M(CO)_5]^-$ (M = Mn, Re), $[CpM(CO)_3]^-$ (M = Mo, W), and $[CpRu(CO)_2]^-$ were used for this purpose. In general, the μ-alkene complexes decompose upon heating with loss of the olefin and form dimetallic complexes with a M–M bond (compound **2** decomposes only at 140 °C!).



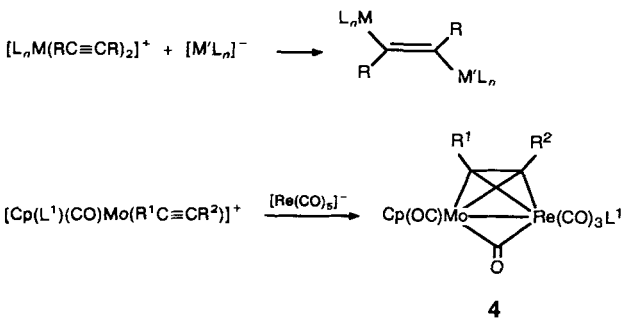
Scheme 2. Synthesis and decomposition of complexes with ethylene bridges.

The addition of $[Re(CO)_5]^-$ to the η^2-coordinated butadiene ligand in $[(OC)_5Re(\eta^2\text{-}H_2C{=}CHCH{=}CH_2)]^+$ gives as final product the stable μ-but-2-ene-1,4-diyl complex **3**.[31]



3

The use of cationic alkyne complexes as electrophiles leads to the formation of $\mu\text{-}\eta^1\text{:}\eta^1$-alkyne complexes (Scheme 3).[32] In contrast, molybdenum alkyne complexes in which the alkyne acts as a four-electron donor[33] react with $[Re(CO)_5]^-$ to give the heterodimetallatetrahedranes **4**.[34] When unsymmetrically substituted alkynes are used, it is thus possible to prepare chiral dimetallatetrahedranes with four different corner atoms. Two aspects of these reactions

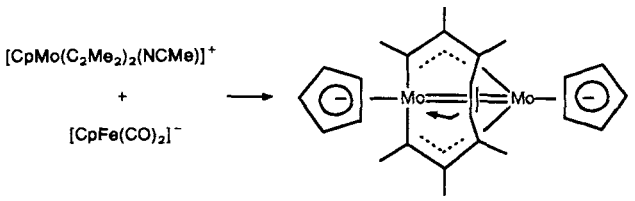


4

Scheme 3. Synthesis of $\mu\text{-}\eta^1\text{:}\eta^1$-alkyne complexes (top) and tetrahedranes (bottom) from alkyne complexes. R = COOMe, Me; $M'L_n$ = $Ru(CO)_2Cp$, $Re(CO)_5$, $Mn(CO)_5$; L_nM = $Cp(PMe_3)_2Ru$, etc.; L^1 = CO, PPh_3; R^1 = Me, Ph; R^2 = Me, Ph.

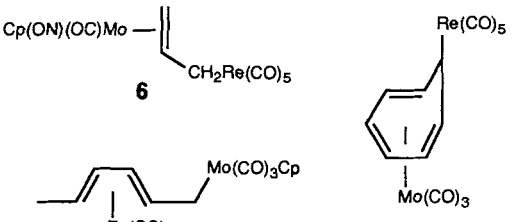
are remarkable: the elimination of CO from the $Re(CO)_5$ anion, which occurs under very mild conditions, and the migration of the ligand L^1 from Mo to Re. Analogous reactions were performed with $[Mn(CO)_5]^-$, $[CpW(CO)_3]^-$,[34b] and $[Ir(CO)_4]^-$.[35]

According to work by Green et al.,[36a] the $[CpFe(CO)_2]^-$ anion acts—in contrast to $[Re(CO)_5]^-$ and $[CpW(CO)_3]^-$—as a reducing agent towards the cationic molybdenum alkyne complex $[Cp(L)Mo(MeC{\equiv}CMe)_2]^+$. The products of the reaction are $[\{CpFe(CO)_2\}_2]$ and the 17-electron radical, $[CpMo(MeC{\equiv}CMe)_2]$,[36b] which yields dimers such as **5** with C_6 or C_8 bridges ("flyover" complexes, see also Section 2.1.2).



5

Organometallic nucleophiles, and especially $[Re(CO)_5]^-$, can be added to cationic complexes incorporating the following ligands: allyl,[37] η^4-diene,[38] trimethylenemethane,[38, 39] dienyl,[18, 39, 40] benzene,[41, 42] cycloheptatriene,[43] and tropylium.[38] In all cases, homo- and heterodimetallic complexes with σ,π-hydrocarbon bridges are formed (e.g. **6**–**8**). The first example of an addition of a carbonylmetalate ion to a *cyclic* hydrocarbon ligand (cycloheptatriene) was reported by Angelici et al.[43]

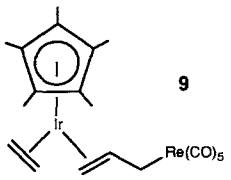


6 **7** **8**

The reaction of the chiral allyl complex $[CpMo(CO)(NO)(\eta^3\text{-}C_3H_5)]^+$ and $[M(CO)_5]^-$ (M = Mn, Re) proceeds as stereospecifically as with organic nucleophiles[44] to form *one* isomer (**6**, M = Re), a fact which is supported by theoretical calculations.[45]

The cation $[Cp^*Ir(\eta^2\text{-}C_2H_4)(\eta^3\text{-}C_3H_5)]^+$ can serve as a test compound for the DGM rules.[46] Contrary to these rules, $[Re(CO)_5]^-$ is added—presumably for steric reasons[46]—to the terminal carbon atom of the allyl ligand, forming **9**, which was characterized by X-ray crystallography.[47] The reaction of the Ir cation with organic nucleophiles leads to metallacyclobutanes by selective addition to the central carbon atom of the allyl ligand.[46]

The crystal structures show that the attack of the organometallic nucleophile on the π-bound hydrocarbon occurs always *exo* to the metal. Surprisingly, a MoRu complex with an $\eta^1\text{:}\eta^6$-cycloheptatriene bridge is also formed by the



9

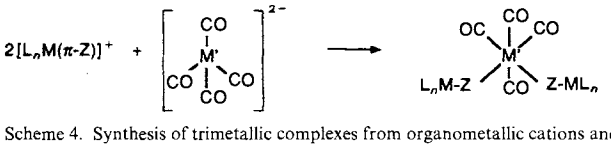
reaction of $[(\eta^7\text{-}C_7H_7)Mo(CO)_2Br]$ and $[Cp^*Ru(CO)_2]^-$. This reaction proceeds with an intermolecular CO transfer.[48] The $\mu\text{-}\eta^6\text{:}\eta^1\text{-}C_7H_7$ complexes have temperature-dependent NMR spectra, which suggests dynamic behavior in solution.[38, 48]

The adduct formed from $[(\eta^6\text{-}C_6H_6)Mn(CO)_3]^+$ and $[Re(CO)_5]^-$ gives an excellent example for fluxional behavior in organometallic compounds.[41, 42] We assume the transition state to be a benzene-bridged structure $[(OC)_3Mn^-(\mu\text{-}\eta^4\text{:}\eta^2\text{-}C_6H_6)Re^+(CO)_5]$ with 18 valence electrons on each metal atom. Such σ,π shifts are of great theoretical and practical interest owing to their role in homogeneous catalysis.[49] Alternatively, a transition state with a π,π-benzene bridge or a contact ion pair is also possible for the MnRe complex. Planar benzene bridges are known, for instance, in the dinuclear triple-decker complexes $[(CpV)_2(\mu\text{-}\eta^6\text{-}C_6H_6)]$[50] and $[(C_6H_3Me_3)_3Cr_2]$.[51] The formulation as contact ion pair also retains the noble gas configuration for both metal atoms.

$[Re(CO)_5]^-$ reacts with $[(\eta^5\text{-}C_6H_7)Ru(CO)_3]^+$, initially—in accord with the DGM rules—at the terminal carbon atom of the dienyl ligand. A subsequent transformation in solution, presumably an H migration, leads to the $\mu\text{-}\eta^1\text{:}\eta^4$-cyclohexadiene complex in which the $Re(CO)_5$ complex fragment is bound to a sp^2 carbon atom.[40]

Thiophene coordinated to a manganese atom is also activated towards the pentacarbonylrhenate ion. The reaction provides $[(OC)_3Mn(\mu\text{-}\eta^4\text{:}\eta^1\text{-}C_4H_4S)Re(CO)_5]$, in which the $Re(CO)_5$ complex fragment is attached to the carbon atom adjacent to the sulfur.[42] In the reaction of $[HFe(CO)_4]^-$ and $[HW(CO)_5]^-$ with $[(CO)_3Mn(C_4H_4S)]^+$, on the other hand, a hydride is added to the thiophene ligand.[52]

The extension of this synthetic strategy to organometallic dianions as nucleophiles leads to trinuclear heterometallic complexes with two hydrocarbon bridges (Scheme 4).



Scheme 4. Synthesis of trimetallic complexes from organometallic cations and carbonylmetalate dianions. Z = unsaturated hydrocarbon.

Complexes **10**–**17** were prepared by the reaction of $[Os(CO)_4]^{2-}$ or $[Ru(CO)_4]^{2-}$ with the cations $[(OC)_5Re(C_2H_4)]^+$, $[Cp(OC)(ON)Mo(C_3H_5)]^+$, $[Cp(OC)_2Mo(diene)]^+$, $[(OC)_3Fe(dienyl)]^+$, $[(OC)_3Mn(C_4H_4S)]^+$, $[(OC)_3Mn(C_6H_6)]^+$, $[(OC)_3M(C_7H_7)]^+$ (M = Cr, Mo).[53] In the same fashion, the cations $[(\eta^6\text{-}C_6H_6)(Me_3P)_2Ru(C_2H_4)]^{2+}$, $[Cp(OC)_2Re(C_3H_5)]^+$, $[(OC)_4M(C_3H_5)]^+$ (M = Fe, Ru),

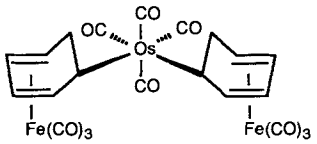
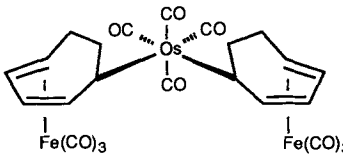
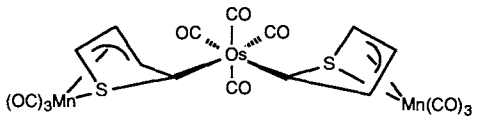
12 (M=Ru,Os; R=H,Me)



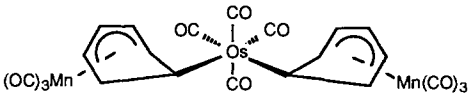
13



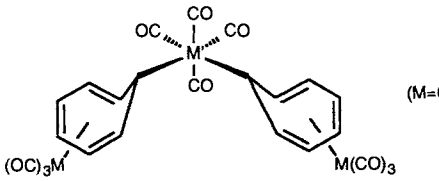
14



15



16

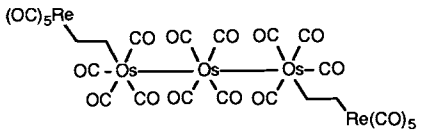


17 (M=Cr,Mo; M'=Ru,Os)

and $[Cp^*Ir(C_2H_4)(C_3H_5)]^+$ can be added twice to $[Os(CO)_4]^{2-}$.[47]

The $Re(CO)_5$ unit is isolobal with the methyl group. According to Hoffmann,[54] compound **10** can therefore also be termed 4-osma-1,7-dirhena-*n*-heptane. X-ray crystal structure determinations show that the hydrocarbon bridges on the Os atom always have a *cis* orientation in analogy to $[Me_2Os(CO)_4]$.[55] The carbon atoms bound to osmium in **13**–**15** are stereogenic. In solution it is possible to show that diastereomers are present, while in the crystal structures of **14** and **15** the carbon atoms that are σ-bound to osmium have the same configuration. Surprisingly, even the trinuclear complex **16** shows the fluxional behavior observed in solutions of $[(OC)_5Re(\mu\text{-}\eta^1\text{:}\eta^5\text{-}C_6H_6)Mn(CO)_3]$.

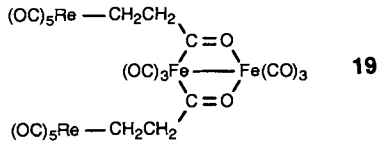
The pentanuclear complex **18** (4,5,6-triosma-1,9-dirhena-*n*-nonane), which has two ethylene bridges, forms when $[(OC)_5Re(\eta^2\text{-}C_2H_4)]^+$ is added to the trinuclear dianion



18

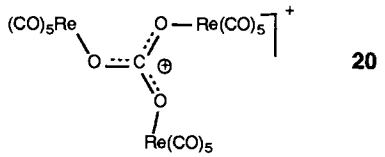
$[Os_3(CO)_{12}]^{2-}$, which in turn is prepared by deprotonation of the corresponding hydride.[56]

The reaction of the dianion $[Fe_2(CO)_8]^{2-}$ with the cationic rhenium ethylene complex leads, by insertion of CO into the Fe–C bond, to complex **19**, which has two bridging acyl ligands.[57] This is due to the lower stability of the Fe–C bond compared to its Os–C analogue. Similar complexes with organic substituents on the acyl-CO group have been described by Fischer et al.[58] and Kaesz et al.[59]



19

The use of highly reduced anions (Ellis compounds)[60] in reactions with cationic π complexes should, in principle, also lead to multinuclear complexes. However, the reaction of $[Ir(CO)_3]^{3-}$ with $[(OC)_5Re(\eta^2\text{-}C_2H_4)]^+$ yielded, under loss of ethylene, the linear, heterometallic, trinuclear hydrido complex $[(OC)_5Re{-}Ir(H)(CO)_3{-}Re(CO)_5]$ as the main product.[61] Attempts to crystallize this compound produced a crystal which, surprisingly, contained the chiral, trimetalated carbonate **20**, which exhibits a "windmill" structure.

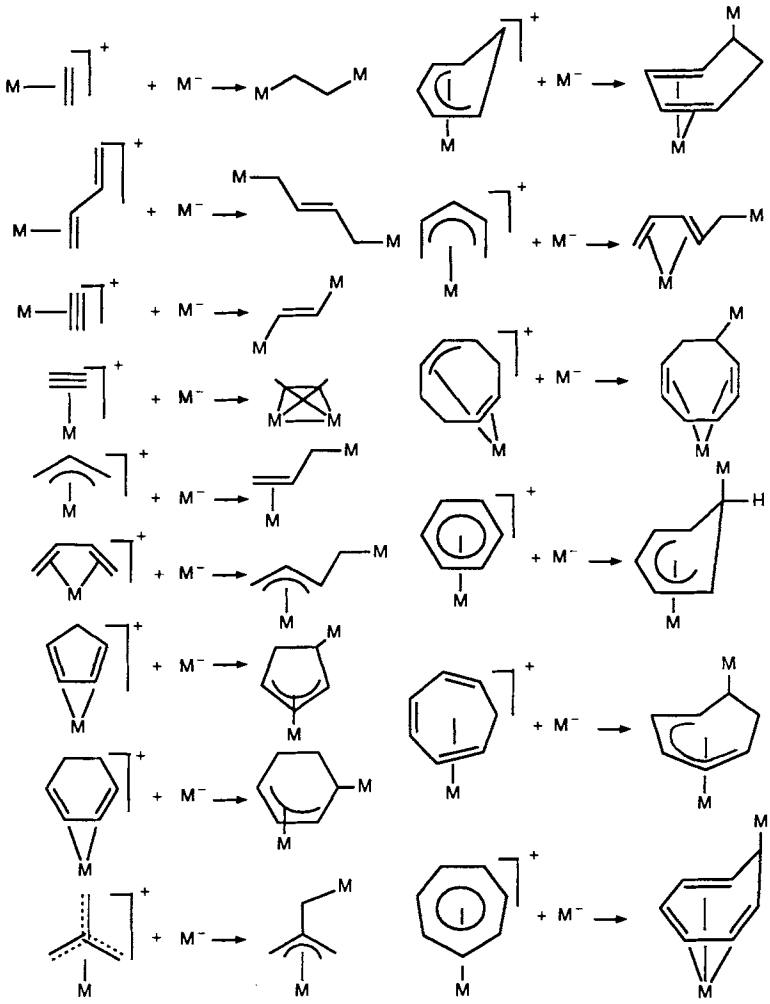


20

This compound can be regarded as a derivative of a trihydroxycarbenium ion[62] and could react with nucleophiles.[62c] The carbonate could be formed from CO_2 according to Equation (a).[63]

$$[Ir(CO)_3]^{3-} + 2\,CO_2 \longrightarrow [Ir(CO)_4]^- + CO_3^{2-} \qquad \text{(a)}$$

The organometallic nucleophiles $[Re(CO)_5]^-$ and $[Os(CO)_4]^{2-}$ are especially suited for the addition to π-coordinated hydrocarbons. These anions possess a relatively high degree of nucleophilicity,[27] and the metal–carbon σ bond formed is very stable.[64] Nearly constant metal–carbon σ bond lengths of 2.2–2.3 Å were found in the X-ray crystal structure determinations of a number of complexes. Scheme 5 summarizes the additions of carbonylmetalate ions to unsaturated hydrocarbon ligands in cationic complexes. Fischer et al.[65] studied the reactions of cationic carbyne complexes with carbonylmetalates; the addition of $[Co(CO)_4]^-$ to $[Cp(OC)_2Mn{\equiv}CR]^+$ afforded the complex $[Cp(OC)_2Mn{=}C(R){-}Co(CO)_4]$ with a carbyne bridge.

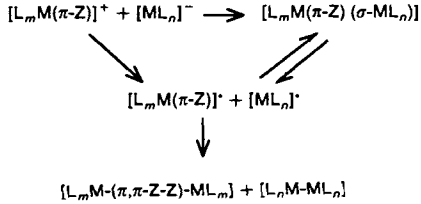


Scheme 5. Addition of organometallic nucleophiles M^- to π-bound hydrocarbons in cationic complexes.

2.1.2. Nucleophilic Addition or Electron Transfer between Cation and Anion? Redox Reactions

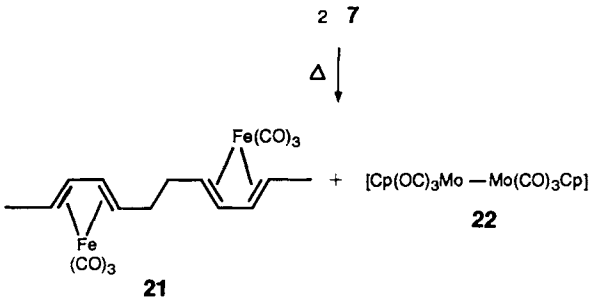
Evidence of electron transfer between cation and anion is found in many reactions. For instance, in reactions employing $[Re(CO)_5]^-$, $[Re_2(CO)_{10}]$ is often formed as a by-product; when $[Mn(CO)_5]^-$ is used, $[Mn_2(CO)_{10}]$ is actually the major product. The competition between nucleophilic addition and electron transfer has been particularly stressed by Kochi et al.[18] During the course of these reactions, 19- and 17-electron complexes can form, which can then combine to give the nucleophilic adduct, the C–C coupling product, or the dimer with a metal–metal bond (Scheme 6).

For instance, the reaction of $[(\eta^5\text{-hexadienyl})Fe(CO)_3]^+$ with $[CpMo(CO)_3]^-$ yields the heterometallic adduct **7**,



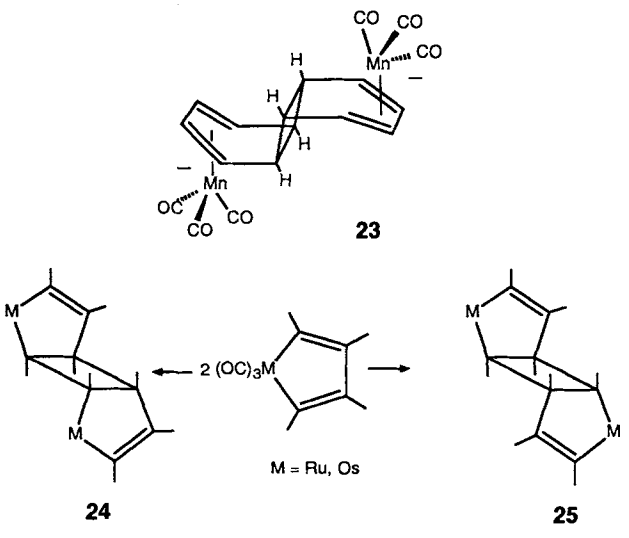
Scheme 6. Z = unsaturated hydrocarbon.

which decomposes thermally to the C–C coupling product **21** and dimer **22**.[18] After extensive studies, which included kinetic work, on the reaction between $[(\eta^5\text{-dienyl})Fe(CO)_3]^+$ and $[CpMo(CO)_3]^-$, Kochi concluded that nucleophilic addition is preferred over electron transfer (SET).[18]



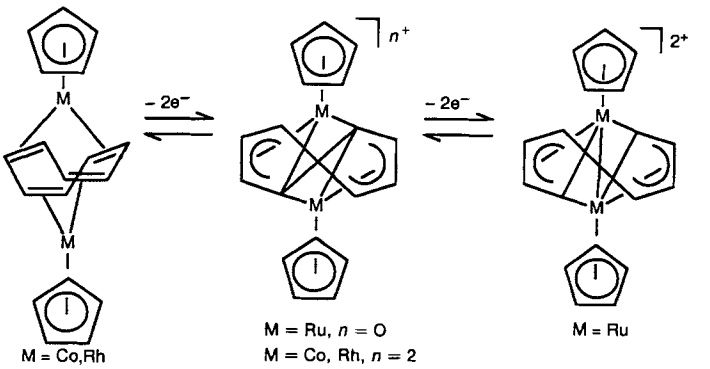
During the reaction of the tropylium complex $[(C_7H_7)Mo(CO)_3]^+$ with organometallic nucleophiles, the C–C coupling product is frequently observed.[25b, 38] These bis(cycloheptatrienyl) complexes can also be prepared from the cations by reduction with Zn, Cr^{II}, Na/Hg, and $NaC_{10}H_8$.[66]

In general, neutral 17-electron radicals preferentially dimerize with formation of a product with a metal–metal bond. In contrast, coupling reactions of 19-electron radicals that contain π ligands give rise to dimers with C–C coupled π ligands.[67] Examples include the dimerization of $[CpCo(\eta^5\text{-}C_7H_9)]$,[67] $[Cp_2Rh]$,[3a, 68] $[(\eta^5\text{-}C_8H_9)Fe(CO)_3]$,[69] $[(\eta^7\text{-}C_7H_7)M(CO)_3]$ (M = Cr, Mo, W),[25b, 66] and $[(\eta^6\text{-}C_6H_6)FeCp]$.[70] In the reduction of a cationic carbyne complex C–C coupling leads to the dinuclear bis(carbene) complex $[(OC)_5Cr{=}C(NEt_2){-}C(NEt_2){=}Cr(CO)_5]$.[71] The syntheses of the dimetallic complexes $[(OC)_3Mn(\mu\text{-}\eta^5{:}\eta^5\text{-}C_6H_6{-}C_6H_6)Mn(CO)_3]$ and $[(OC)_3Mn(\mu\text{-}\eta^4{:}\eta^4\text{-}C_6H_6{-}C_6H_6)Mn(CO)_3]^{2-}$ (**23**, by [2 + 2] cyclodimerization of coordinated benzene), were achieved by the reduction of $[(\eta^6\text{-}C_6H_6)Mn(CO)_3]^+$.[72a] The [2 + 2] cycloaddition of 16-electron osma- and ruthenacyclopentadiene leads to complex **24** and its "*trans*" isomer **25**.[72b] A Mn_2 complex with an $\eta^5{:}\eta^5$-dicyclohexadienyl bridge is formed as a by-product



of the reaction between $[(OC)_3Mn\text{-}(\eta^6\text{-}C_6H_3Me_3)]^+$ and $AlMe_3$.[73] The 17-electron radical cations $[(\eta^4\text{-}C_8H_8)Fe(CO)_3]^+$[74] and $[CpFe(CO)_2CH_2C(R){=}CR_2]^+$[75] also undergo C–C coupling reactions.

The oxidation of $(\eta^4\text{-}C_8H_8)ML_n$ complexes yields the binuclear complexes $[M(\mu\text{-}\eta^5{:}\eta^5\text{-}C_8H_8{-}C_8H_8)M]^{2+}$ (M = $Fe(CO)_2P(OPh)_3$, $Fe(CO)_3$, RhCp, CoCp*) and other interesting products.[76] Geiger, Salzer, et al. observed especially remarkable structural changes in the cyclooctatetraene bridge during the (reversible) oxidation of the pseudo-triple-decker complexes $[(C_5R_5)M(\mu\text{-}C_8H_8)M(C_5R_5)]$ (M = Co, Rh, R = H, Me; Scheme 7).[77] Several bonding modes are



Scheme 7. Structural changes in the C_8H_8 ligand upon oxidation.

known for bridging cyclooctatetraene ligands.[78] Equally interesting is the oxidation of $[CpRu(\mu\text{-}C_8H_8)RuCp]$, which proceeds by insertion of both Ru atoms into a C–C bond of the cyclooctatetraene bridge to yield a so-called flyover complex.[79] Flyover complexes such as **5** may also be prepared by reducing cationic bis(alkyne) molybdenum complexes.[36b, 80] In attempted preparations of the sandwich complex $[CpV(C_8H_8)]$ from $C_8H_8^{2-}$, C–C coupling leads to three isomers of $[CpV(\mu\text{-}C_8H_8{-}C_8H_8)VCp]$.[81] A review article by Connelly comprehensively describes dimerizations of π-coordinated hydrocarbons induced by one-electron oxidations or reductions.[82]

The C–C coupling of two Cp ligands is achieved by lithiation of $[CpMn(CO)_3]$ and subsequent oxidation with $CuCl_2$.[83a] The reductive coupling of $[BrCCo_3(CO)_9]$ results in the linkage of two $[CCo_3(CO)_9]$ units by a C–C bond.[83b]

2.2. Reactions of Anionic Metal Complexes Containing a Nucleophilic Heteroatom Ligand with Coordinated Unsaturated Hydrocarbons or Organometallic Lewis Acids

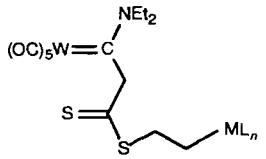
In this section reactions following Scheme 8 are discussed.

Raubenheimer et al. were able to show that CS_2 adds to the anionic Fischer carbene $[(OC)_5Cr{=}C(OEt)CH_2]^-$ and that the CS_2 adduct can be alkylated at the sulfur atom.[84] Possible "alkylating agents" for Fischer carbene dithiolates

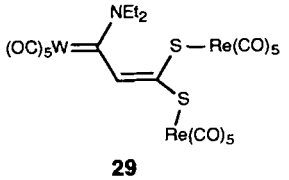
$$[L_nM(Z\text{-}Nu)]^- + [(Z)ML_n]^+ \longrightarrow [L_nM(Z\text{-}Nu\text{-}Z)ML_n]$$

Scheme 8. Nu = nucleophile.

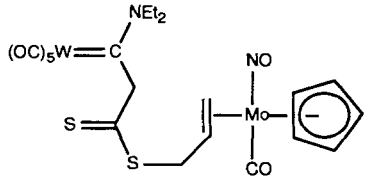
include $[(OC)_5Re(\eta^2\text{-}C_2H_4)]^+$, $[CpW(CO)_3(\eta^2\text{-}C_2H_4)]^+$, and $[Cp(OC)(ON)Mo(\eta^3\text{-}C_3H_5)]^+$ or $[Re(CO)_5]^+$. Depending on whether one or two equivalents of base are employed, the di- or trimetallic complexes **26**–**29** are formed.[85, 86a]



26: $ML_n = CpW(CO)_3$
27: $ML_n = Re(CO)_5$

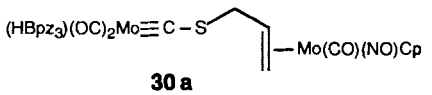


29

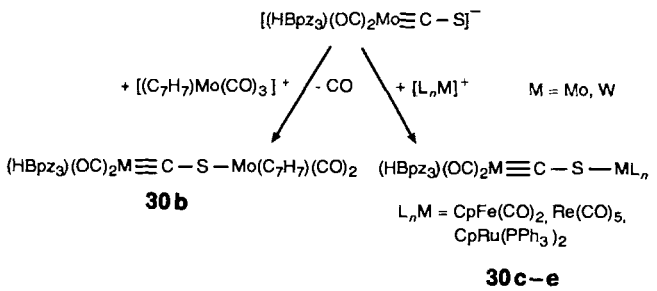


28

A further example for this type of reaction is the addition of the anionic thiocarbyne complex $[(HBpz_3)(OC)_2M(CS)]^-$ (M = Mo, W; pz = 3,5-dimethylpyrazol-1-yl)[87] to unsaturated hydrocarbons or to the metal atom in cationic complexes, giving rise to, for example, **30a,b**.[85, 86b] The use of cationic organometallic Lewis acids leads to rare[88] complexes like **30c–e** with thiocarbonyl bridges.[85, 86b]



30a



30b

L_nM = $CpFe(CO)_2$, $Re(CO)_5$, $CpRu(PPh_3)_2$

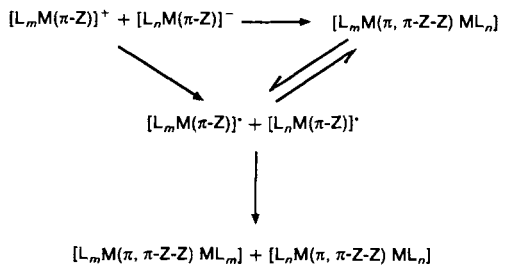
30c–e

The carboxylate ion $[Cp(OC)(Ph_3P)Fe{-}COO]^-$ can be "esterified" with the cationic ethylene complex $[(\eta^2\text{-}C_2H_4)Fe(CO)LCp]^+$, leading to $[Cp(OC)(Ph_3P)Fe{-}C(O){-}OCH_2CH_2{-}Fe(CO)(L)Cp]$, a complex with a carboxyethylene bridge.[89]

Adducts of tertiary diphosphanes and $[(OC)_3Cr(\eta^7\text{-}C_7H_7)]^+$ react with the cationic iron complex $[CpFe(CO)_2(thf)]^+$ to yield an FeCr complex with an η^6-$C_7H_7(Ph_2PCH_2CH_2CH_2PPh_2)$ bridge.[90]

2.3. C–C Coupling Reactions

C–C coupling of coordinated nucleophilic and electrophilic hydrocarbons enables the synthesis of numerous complexes with hydrocarbon bridges (Scheme 9).



Scheme 9. Coupling of hydrocarbon ligands (Z) by C–C bond formation.

The first report on the C–C coupling of metal-coordinated hydrocarbons in cationic and anionic complexes was published by Kane-Maguire et al.[91] The addition of Li-ferrocene to the cyclohexadienyl ligand in $[(OC)_3Fe(\eta^5\text{-}C_6H_7)]^+$ leads to complex **31**. Other electrophilic and nucleophilic precursors, yielding, for instance, compounds **31**–**38**, are listed in Table 2.

38 [106]

A large number of multinuclear complexes can be prepared from the anion of bis(tricarbonylchromium)diphenylmethane (Scheme 10).[109] The addition of the tropylium ion to tricarbonylcycloheptatrieneiron leads to polymeric complexes.[110]

Rosenblum et al. described C–C coupling reactions of σ-bound allyl ligands with cationic π complexes, for instance,

Table 2. C–C coupling reactions of metal-coordinated hydrocarbons.

Electrophile	Nucleophile	Ref.

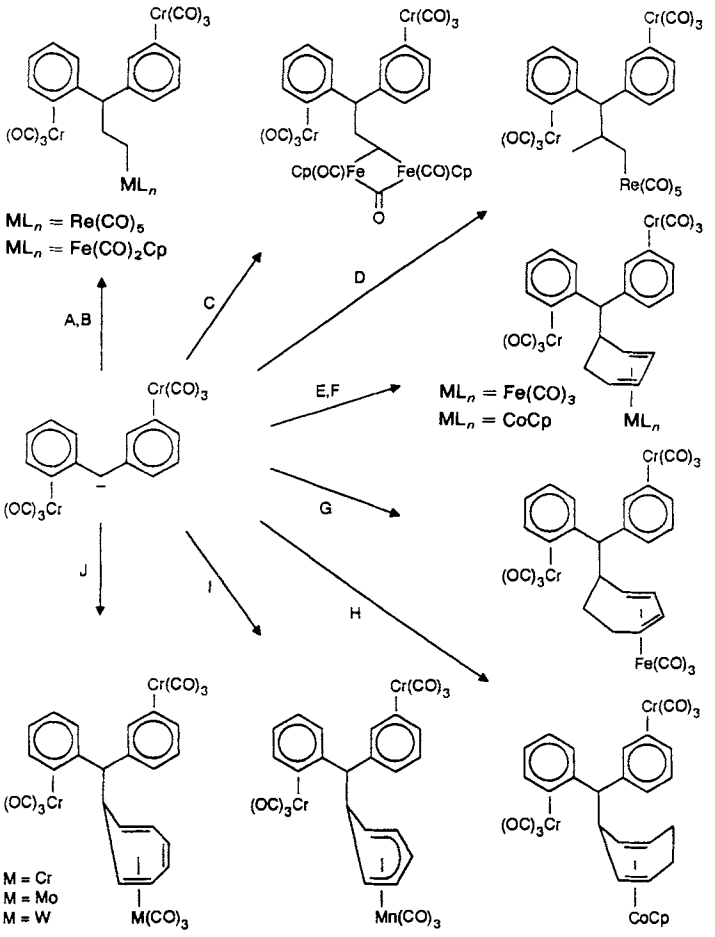
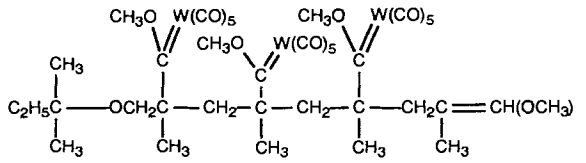


Scheme 10. A = $[(OC)_5Re(\eta^2\text{-}C_2H_4)]^+$, B = $[(OC)_2CpFe(\eta^2\text{-}C_2H_4)]^+$, C = $[Cp_2(OC)_2Fe_2(\mu\text{-}CO)(\mu\text{-}\eta^1{:}\eta^2\text{-}CH{=}CH_2)]^+$, D = $[(OC)_5Re(\eta^2\text{-}C_3H_6)]^+$, E = $[(OC)_3Fe(\eta^5\text{-}C_6H_7)]^+$, F = $[CpCo(\eta^5\text{-}C_6H_7)]^+$, G = $[(OC)_3Fe(\eta^5\text{-}C_7H_9)]^+$, H = $[CpCo(\eta^5\text{-}C_7H_9)]^+$, I = $[(OC)_3Mn(\eta^6\text{-}C_6H_6)]^+$, J = $[(OC)_3M(\eta^7\text{-}C_7H_7)]^+$ (M = Cr, Mo, W).

$[(OC)_2CpFe(C_2H_4)]^+$ and $[(OC)_3Fe(C_7H_7)]^+$.[111, 112] The cationic iron methylene complex $[Cp(OC)_2Fe{=}CH_2]^+$ adds to unsaturated σ-bound vinyl and allyl ligands to form dinuclear iron complexes.[112, 113] Cationic vinylidene complexes of iron or ruthenium as well as 2-ferrocenylpropene can dimerize or react with acetylide complexes.[114] In the same manner, (1,3-di(ferrocenyl)allyl)$^+$ can attack 2,4-bis(ferrocenyl)penta-1,3-diene.[115] A novel tricyclic dicarbene bridging two $Mn(CO)_2Cp$ units was obtained by Herrmann et al. by [2 + 2] cycloaddition of cyclopentadienylidene (prepared from diazacyclopentadiene)[116] in the presence of $[Mn(CO)_2Cp(thf)]$. Macomber et al. used α,β-unsaturated carbene complexes as electrophiles and were able to prepare numerous di- and even tricarbene complexes such as **39** by reactions with α-deprotonated carbene complexes.[117]



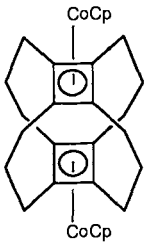
39

Transition metal complexes with aldehyde or ketone groups, for example, ferrocenylaldehyde, ferrocenylbis(aldehyde), [(2-formylnorbornadiene)RhCp], or $[(OC)_3Cr(acetophenone)]$, can act as electrophiles in reactions with anionic carbene complexes,[118] organometallic enolates,[119] or lithiated compounds like lithioferrocene or $[(OC)_3Cr\text{-}(C_6H_5Li)]$.[120] These lithiated species can also be employed in the Fischer carbene synthesis starting with metal carbonyls, allowing access to many dimetallic carbene or carbyne complexes.[121a]

When *p*-dilithium phenylene,[121c] *p*-dilithium biphenyl,[121d] or $o\text{-}C_6H_4(CH_2MgCl)_2$[121e] are used in the Fischer carbene or carbyne synthesis, complexes with bridging bis(carbene) and bis(carbyne) units such as $[(OC)_5W{=}C(OEt){-}p\text{-}C_6H_4{-}C(OEt){=}W(CO)_5]$, $[Br(OC)_4W{\equiv}C{-}p\text{-}C_6H_4{-}C{\equiv}W(CO)_4Br]$ are obtained directly.

A number of organometallic acid chlorides with the general formula $[L_nM(\eta^5\text{-}C_5H_4C(O)Cl)]$ undergo Friedel–Crafts acylation with ferrocene or $[(OC)_3ReCp]$.[122] The Wittig reaction can also be employed to couple two hydrocarbon ligands, for example, $[(OC)_3Fe(\eta^4\text{-}C_6H_7PR_3)]^+$ with $[(OC)_3Cr(\eta^6\text{-}C_6H_5C(O)H)]$ or $[(\eta^4\text{-}MeCH{=}CH{-}CH{=}CHCHO)Fe(CO)_3]$.[123] Two ferrocene molecules can be coupled by using acetals,[124] and two cobaltocene molecules can be linked by employing alkynes having electron-withdrawing groups.[125]

Dimetallic complexes can also be constructed by the [2 + 2] cycloaddition of one π- and one σ-bound alkyne ligand.[126] The [2 + 2] cycloaddition of cyclic alkadiynes to $[CpCo(CO)_2]$ leads, by formation of cyclobutadiene, to interesting superphane complexes[127] like **40**. During the reaction of $[Cp^*Rh(\eta^2\text{-}C_2H_4)_2]$ with thiophene, both a C–C coupling reaction and C–S bond cleavage in thiophene occur, giving rise to a dimetallic complex in which a $S(CH)_8S$ chain bridges two Cp*Rh units.[128]

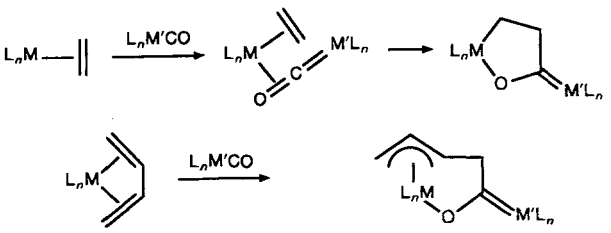


40

Other established methods in organic synthesis can be used to prepare μ-hydrocarbon complexes, for example, the McMurry reaction,[129] the Ullmann coupling of halocyclopentadienyl complexes,[130] the reaction of lithioferrocene[131] or anionic Fischer carbene complexes with dihalohydrocarbons[132a] or acid chlorides,[132b] the addition of $[(\eta^5\text{-}LiC_5H_4)Mn(CO)_3]$ to $[RC(O)C_5H_4Mn(CO)_3]$,[132c] and the condensation of ferrocenylaldehyde with acetone.[132d]

Trimethylstannylethynylcyclopentadienyl complexes react with iodo- and η^5-(1-iodovinyl)cyclopentadienyl complexes by C–C coupling to yield complexes $[L_nM(\eta^5\text{:}\eta^5\text{-}C_5H_4)CH{=}CH{-}C{\equiv}C(C_5H_4)M'L_n]$ and $[L_nM(\eta^5\text{:}\eta^5\text{-}C_5H_4)\text{-}C{\equiv}C(C_5H_4)M'L_n]$.[103, 133a] By reaction of $Bu_3SnC{\equiv}CSnBu_3$ with iodocyclopentadienyl complexes two Cp ligands can be coupled.[133b]

An interesting C–C coupling reaction of a CO ligand with olefin and diene ligands in titanium, zirconium, and hafnium complexes was observed by Erker et al. and expanded to a general synthetic approach (Scheme 11) for metallacyclic oxocarbene complexes.[9a, 134]

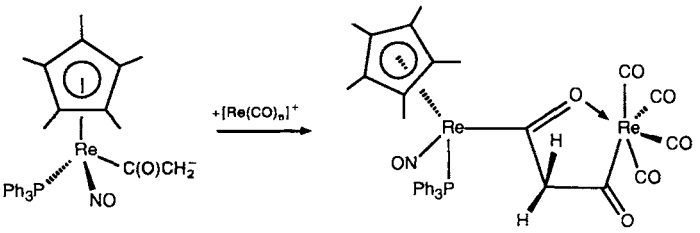


Scheme 11. M = Ti, Zr, Hf; M' = V, W, Fe, Co, Pt, etc.

The addition of the organometallic enolate $[Cp^*(Ph_3P)(ON)ReC(O)CH_2]^-$ to a CO ligand in cationic complexes yields interesting μ-malonyl complexes $[L_nM{-}C(O)CH_2C(O){-}ML_n]$ like **41**.[135]

Carbyne complexes of type $[Cp(CO)_2M{\equiv}C{-}R]$ (M = Mo, W) can be inserted into Pd–C bonds of palladacycles[136] in the same way as the isolobal alkynes (see Section 6).[14]

Finally, two unusual C–C coupling reactions should be mentioned: the reaction of an η^1-allenyl complex

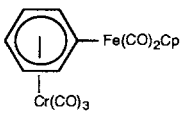


41

$[Cp(OC)_3W{-}CH{=}C{=}CH_2]$ with $[Fe_2(CO)_8(\mu\text{-}CH_2)]$ leads to a tungsten-substituted trimethylenemethane complex $[Cp(OC)_3W\{\mu\text{-}\eta^1\text{:}\eta^4\text{-}CHC(CH_2)_2\}Fe(CO)_3]$;[137] the photochemical reaction of a μ-vinylidenediplatinum complex with diphenylacetylene yields a complex with a $\eta^1\text{:}\eta^3$-butadiene bridge.[138] Redox reactions leading to C–C coupling are described in Section 2.1.2.

2.4. Nucleophilic Substitution of Halogen Atoms in Unsaturated Hydrocarbon Ligands by Carbonylmetalates

Arene(tricarbonyl)chromium complexes are among the most studied organometallic compounds. Stereo- and enantioselective nucleophilic substitution reactions have been investigated especially thoroughly.[139] Since 1988, Heppert et al.[121b, 140] and Hunter et al.[141] have obtained a series of complexes like **42** with bridging σ,π-arene ligands. These complexes are prepared by the substitution of the halogen atom in $[(C_6H_5X)(OC)_3Cr]$ complexes with the strongly nucleophilic organometallic anions $[Fe(CO)_4]^{2-}$, $[M(CO)_5]^{2-}$ (M = Cr, W), $[CpFe(CO)_2]^-$, and $[Cp^*Fe(CO)_2]^-$.



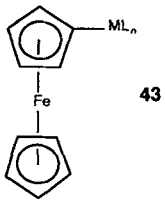
42

Less reactive carbonylmetalate ions like $[CpMo(CO)_3]^-$, $[CpNi(CO)]^-$, $[Mn(CO)_5]^-$, and $[Co(CO)_4]^-$ do not undergo this reaction.[140] As in the nucleophilic addition reactions discussed in Section 2.1, redox reactions compete with substitution. For instance, the reaction of $[(\eta^6\text{-}C_6H_5Cl)Cr(CO)_3]$ with $[M(CO)_5]^{2-}$ (M = Cr, W) proceeds by reductive dehalogenation and yields $[(\eta^6\text{-}C_6H_6)Cr(CO)_3]$. The use of $[CpFe(CO)_2]^-$ at low temperatures leads to the substitution product;[141] at higher temperatures, the SET reaction product is preferred.[140] Interestingly, it was not possible to replace the chlorine substituent in $[(OC)_3Cr(\mu\text{-}\eta^6\text{:}\eta^1\text{-}C_6H_4Cl)Fe(CO)_2Cp]$ with excess $[CpFe(CO)_2]^-$.[141] The reaction of $[(\eta^6\text{-}C_6H_4Cl_2)FeCp]^+$ and excess $[Re(CO)_5]^-$, on the other hand, yields the trimetallic complex $[CpFe(\mu\text{-}\eta^6\text{:}\eta^1\text{:}\eta^1\text{-}C_6H_4)\{Re(CO)_5\}_2]^+$ besides the monosubstituted product.[142] The Cl atom in $(\eta^6$-benzylchloride)chromium tricarbonyl can be replaced by $[Co(CO)_4]^-$.[142]

2.5. Reaction of Metal Complexes Containing an Anionic Hydrocarbon Ligand with Halo Complexes

Numerous σ,π-bridged complexes can be synthesized in a straightforward manner from lithiated arene complexes by

"umpolung". For instance, the reaction of lithioferrocene with halometal complexes leads to compounds of type **43** (Scheme 12).

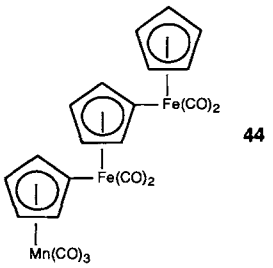


43

Scheme 12. ML_n = $CpFe(CO)_2$[143], $CpW(NO)_2$[144], $Mn(CO)_5$[143,145], $Ir(CO)(PPh_3)_2$[143], $CpM(CO)_3$ (M = Mo, W)[143], $Cp^*Ru(CO)_2$[146a], Cp_3U[146b], $V(C_5H_4Me)_2$[147].

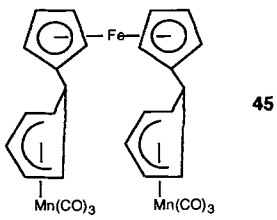
The related half-sandwich compound $[Cp^*Ru(PMe_3)_2Fc]$ is formed from $[Cp^*Ru(PMe_3)_2CH_2tBu]$ and $[Cp_2Fe]$ by C–H bond cleavage.[148] When lithioferrocene is employed, trinuclear complexes can be prepared.[146] Lithiated di(benzene)chromium reacts with $[CpFe(CO)_2I]$ and $[(OC)_5ReI]$ in the same fashion, forming complexes with μ-η^6:η^1-arene bridges.[149] It was also possible to prepare compounds with bridges between early and late transition metal centers.[150] Complexes with a σ,π-C_5Cl_4 bridge can also be prepared, for example, $[(OC)_3Mn(\mu\text{-}\eta^5\text{:}\eta^1\text{-}C_5Cl_4)ML_n]$ (ML_n = $Re(CO)_5$, $Au(PPh_3)$, Cp_2TiCl, etc.).[151]

Lithiation of the dimetallic complex $[Cp(OC)_2Fe\text{-}(\mu\text{-}\eta^1\text{:}\eta^5\text{-}C_5H_4)Mn(CO)_3]$ with BuLi and subsequent reaction with $[Cp(CO)_2FeI]$ yields the corresponding trimetallic compound **44**.[152]



44

It is possible to coordinate metal complex fragments or Fe^{II} ions to the Cp rings of $[(OC)_3Mn(\eta^5\text{-}C_5H_4\text{–}CH_2\text{–}C_5H_4Li)]$[153] and $[(OC)_3Mn(\eta^5\text{-}C_6H_6\text{–}C_5H_4Li)]$[154] to form, for example, **45**. Rhodium, iridium,



45

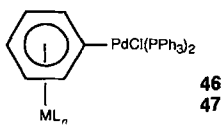
iron, and ruthenium complexes with η^3:η^4-cycloheptatrienyl bridges can be prepared from $[(OC)_3M(\eta^3\text{-}C_7H_7)]^-$ (M = Fe, Ru) and $[Rh(CO)_2Cl_2]_2$, $[\{(cod)RhCl\}_2]$ (cod = cyclooctadiene), or $[Ir(CO)_3Cl]$.[155]

The complex $[(\eta^5\text{-}C_6H_5Li)Cr(CO)_3]$ was used by Lotz et al. to prepare a number of benzene-bridged complexes[156] containing early and late transition metal atoms. A pseudo-triple-decker complex is formed from $[(\eta^6\text{-indene})(\eta^5\text{-indenyl})Re]^-$ and $[\{(cod)RhCl\}_2]$.[157]

Lithiated ethynylferrocene reacts with $[Cl_2Pt(PPh_3)_2]$ to give $[cis\text{-}(Ph_3P)_2Pt(C{\equiv}C\text{–}Fc)_2]$.[158] The tautomers with ketene bridges $[Cp^*(OC)_2Fe\text{–}C(=CH_2)\text{–}O\text{–}Zr(Cl)Cp_2]$ and $[Cp^*(OC)_2Fe\text{–}C(O)\text{–}CH_2\text{–}AuPPh_3]$ were obtained from the enolate $[Cp^*(OC)_2FeC(CH)_2O]^-$ and the corresponding chloro complexes.[159]

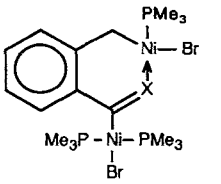
2.6. Oxidative Addition of Halogenated Hydrocarbons to Complexes with Metal Atoms in Low Oxidation States

An alternative route to complexes with σ,π-arene bridges is the oxidative addition of coordinated chlorobenzene to Pd^0 centers.[160, 161] The reaction of $[Pd(PR_3)_4]$ with $[CpFe(\eta^6\text{-}C_6H_5Cl)]^+$ and $[(OC)_3Cr(\eta^6\text{-}C_6H_5Cl)]$ yields complexes **46** and **47**, respectively. The CrPd compounds are intermediates in the Pd-catalyzed carbonylation of $[(\eta^6\text{-}C_6H_5Cl)Cr(CO)_3]$.[161]



46: ML_n = $Cr(CO)_3$
47: ML_n = $[FeCp]^+$

Complexes of palladium and platinum with hydrocarbon bridges are prepared by double oxidative addition of $I(CH_2)_nI$ (n = 3–5)[162a] and of dibromoxylene to $[Me_2Pt(phen)]$ and $[Me_2M(bpy)]$ (M = Pd, Pt; phen = phenanthroline, bpy = bipyridine).[162b] *o*- and *p*-Bromobenzylbromide react with Ni^0 compounds to yield dinuclear nickel complexes with η^1:η^3-benzyl bridges.[162c] Isocyanide and carbon monoxide insert into the Ni–C σ bond of the products, leading to the formation of compounds **48** and **49**, among others.



48: X = NR
49: X = O

μ-Acetylide complexes (see Section 7) can be prepared by the oxidative addition of $[(Ph_3P)_2Pt(Cl)(C{\equiv}CCl)]$ to a Pt^0 center.[151] The coordinated 2-chloroallyl ligand in $[Pt\{\eta^3\text{-}CH_2C(CH_2Cl)CH_2\}(PPh_3)_2]^+$ can be oxidatively added to Pt^0 complexes.[163] The resulting σ,π-allyl bridge is of the same type as the one found in the adduct of cationic trimethylenemethane complexes and carbonylmetalate ions.[38]

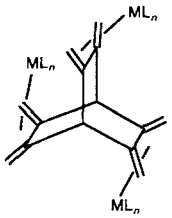
Oxidative addition can also be employed for the preparation of organometallic polymers.[164] The C–Br bond of 2-bromoethyl methacrylate can be added to the electron-rich dimethylplatinum complex $[PtMe_2(2,2'\text{-bipyridine})]$. The re-

sulting adduct can then be transformed by radical polymerization, with azobis(isobutyronitrile) (AIBN) as initiator, to the polyethylene derivative.

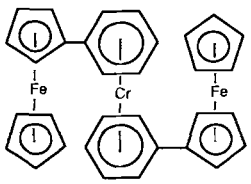
3. Addition of Lewis Acidic Complex Fragments to Free and Coordinated Unsaturated Hydrocarbons

A number of linear and cyclic polyenes can undergo addition of, for instance, two $[Fe(CO)_3]$, $[Fe(PMe_3)_3]$, $[Mn(CO)_2Cp]$, [CoCp], or $[Fe(CO)_2Cp]^+$[165] units to form complexes like **50a, b**.[165b] This opens up the possibility of forcing two organometallic complex fragments into close proximity. As a result of the intramolecular interactions between the metal atoms, these complexes should have different properties from those of the mononuclear analogues.[165b] Bis(arenetricarbonylchromium) complexes bridged by rigid polynorbornyl spacers show efficient through-bond coupling between the Cr atoms through 6.5 Å.[165c]

Many polymetallic arene complexes are known, for example, **50c**, which was obtained by the Fischer–Hafner method[166a] from $CrCl_3$, aluminum, $AlCl_3$, and phenylferrocene as arene.[166b] The same method allows the replacement of two Cp ligands in bis(ferrocene) by hexamethylbenzene.[166c]

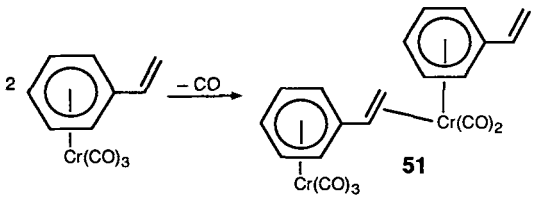


50a: $ML_n = Fe(PMe_3)_3$
50b: $ML_n = CoCp$

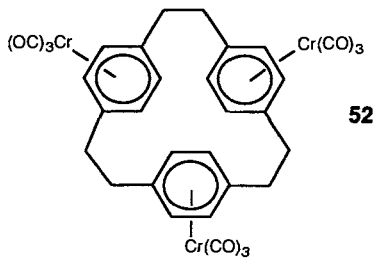


50c

In general, it is possible to bind the $Cr(CO)_3$ unit to compounds containing phenyl groups.[167] For instance, the reaction between $[Cr(CO)_6]$ and styrene yields $[(OC)_3Cr(styrene)]$,[168a] which can be irradiated to form the dimeric complex **51**.[168b] The complex $[(OC)_5Re{-}CH_2CH_2Ph]$ reacts with $[(OC)_3Cr(C_5H_5N)_3]$ and $Et_2O{\cdot}BF_3$ to form $[(OC)_5Re(\mu\text{-}\eta^1{:}\eta^6\text{-}CH_2CH_2C_6H_5)Cr(CO)_3]$.[169] An especially impressive example for a multinuclear complex with coordinated $Cr(CO)_3$ groups is the paracyclophane complex **52** synthesized by Elschenbroich et al.[170] Heterometallic compounds with $Cr(CO)_3$ complex fragments can be prepared by the reaction of $[(OC)_2CpFe(2\text{-}SC_4H_4)]$, $[(OC)_2CpFe(2\text{-benzofuran})]$, or $[(OC)_3Mn(\eta^5\text{-}C_5H_4Ph)]$ with $[Cr(CO)_6]$ or $[Cr(CO)_3(CH_3CN)_3]$.[171]

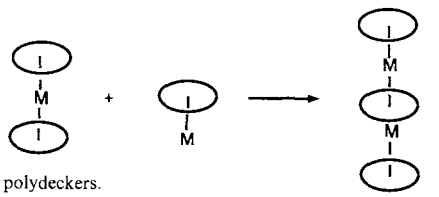


51



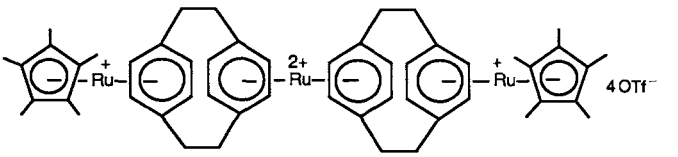
52

An important strategy for the synthesis of polydecker complexes is the addition of an unsaturated metal complex fragment to a π ligand of a sandwich compound (stacking reaction, Scheme 13).[172] Morrison et al. have used the Fischer–Hafner method (reaction of ferrocene with polyarenes in the presence of $AlCl_3$/Al) to bind $[FeCp]^+$ units to polyarenes.[173]

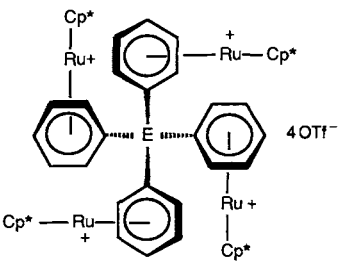


Scheme 13. Synthesis of polydeckers.

It was recently recognized that the $[Cp^*Ru]^+$ ion coordinates preferentially to arenes and polyarenes. This enables the preparation of interesting polynuclear compounds like **53–55** (see also Section 8).[174]

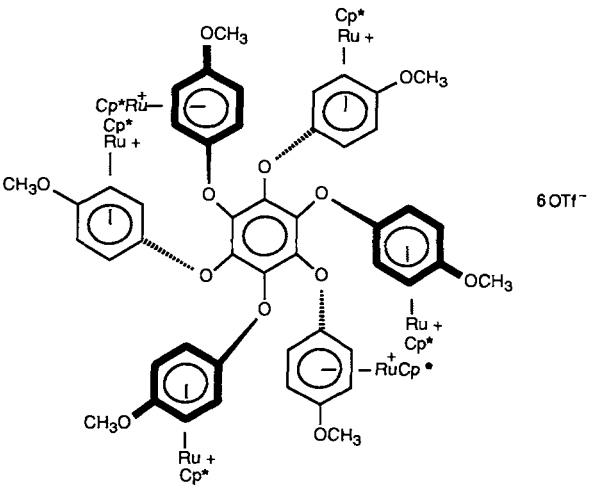


53



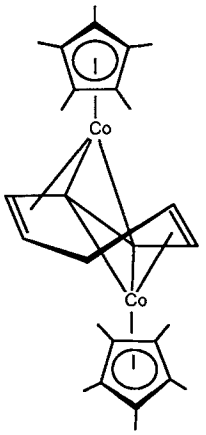
E = C, Si, Ge, Sn, Pb

54



55

The $[Cp^*Ru]^+$ ion can bind twice to anthracene,[175] diphenylacetylene,[176] chrysene,[177] and diindenylruthenium (to give a tetradecker complex[178a]), as well as to indigo and its metal complexes.[178b] The Cp*Co group also adds to coordinated cyclopentadiene and cycloheptatriene[179, 180] to form triple-deckers like **56**. The $[Cp^*Ru]^+$ cation reacts with the half-sandwich complex $[Cp^*Ru(pentadienyl)]^+$ to form a complex with a ruthenabenzene bridge.[181]

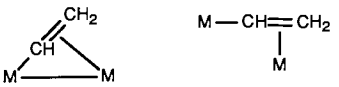


56

Fulvalene complexes with two different metal centers can be prepared by treating η^4-dihydrofulvalene complexes with substitutionally labile metal compounds (see Section 5).[182] The addition of the platinum(0) complex $[(Ph_3P)_2Pt]$ to the allene ligand in $[Cp(OC)(HPh_2P)Fe(CH_2{=}C{=}CH_2)]^+$ yields an FePt complex in which Fe is σ-bound to the central C atom of the $\eta^1{:}\eta^3$-allyl bridge.[183]

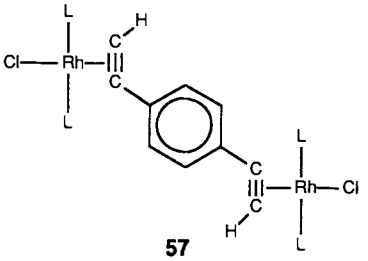
Kreiter et al.[184] examined photoreactions of $[M_2(CO)_{10}]$ (M = Mn, Re) with dienes, trienes, and allenes, and they were able to isolate a number of novel dinuclear complexes with bridging hydrocarbon ligands from the complicated reaction mixtures. Photoinduced [4 + 6] cycloaddition of conjugated dienes and bis(tricarbonylchromium)[μ-$\eta^6{:}\eta^6$-1,1′-bis(2,4,6-cycloheptatriene)] and bis(tricarbonylchromium)heptafulvalene complexes can also be used to prepare compounds with hydrocarbon bridges.[185]

Benzene and naphthalene can function as bridges between two or even three metal complex fragments.[7] Examples for the addition of a metal complex fragment to a σ-bound vinyl ligand can be found in the complexes with σ,π-vinyl bridges, $[(OC)_5Re(\mu\text{-}\eta^1{:}\eta^2\text{-}CH{=}CH_2)Fe(CO)_4]$,[186] $[(OC)_5Re(\mu\text{-}\eta^1{:}\eta^2\text{-}CH{=}CH_2)Re(CO)_5]^+$,[187a] and $[Fp(\mu\text{-}\eta^1{:}\eta^2\text{-}CH{=}CH_2)Fp]^+$ (Fp = $Cp(CO)_2Fe$).[187b] A large number of reports are found in the literature on μ-vinyl dimetallic complexes with a metal–metal bond[188] (Scheme 14) or a second supporting ligand.[189]

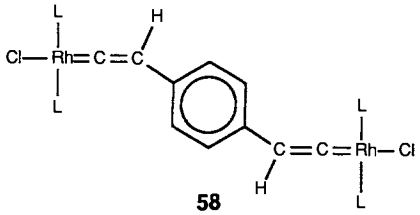


Scheme 14. Dimetallic μ-vinyl complexes.

During the course of their work on vinylidene complexes,[190] Werner et al. found that the $[Rh(Cl)L_2]$ unit can be added to the C=C bond in $[Cp(iPr_3P)Rh{=}C{=}CH_2]$.[191a] The highly reactive 14-electron species $[Rh(Cl)(PiPr_3)_2]$ coordinates to both C≡C bonds of 1,4-diethynylbenzene. The initially formed complex **57** (L = $PiPr_3$) rearranges to give the isomeric bis(vinylidene) complex **58**.[191b]



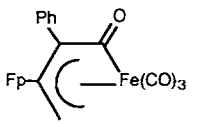
57



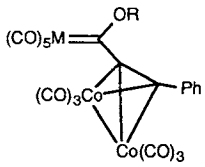
58

Following work by Wojcicki et al., a number of multinuclear compounds can be prepared from propargyl complexes $[L_nM{-}CH_2{-}C{\equiv}CR]$ and metal carbonyls.[192] Compound **59** is a σ,π-bridged complex without a metal–metal bond.

Polyynes and cyclopolyynes can undergo additions by several $[Co_2(CO)_6]$ units.[193a] Alkynyl-substituted Fischer carbene complexes react with $[Co_2(CO)_8]$ to form the trinuclear complex **60**, for example.[193b] The binding of $[Co_2(CO)_6]$ or $[Mo_2Cp_2(CO)_4]$ to $[Fc{-}CH{-}C{\equiv}C{-}C_3H_7]^+$ stabilizes the carbenium ion between two complex fragments.[194]

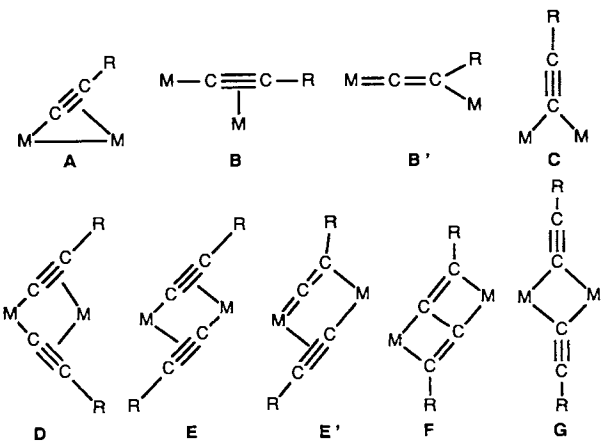


59



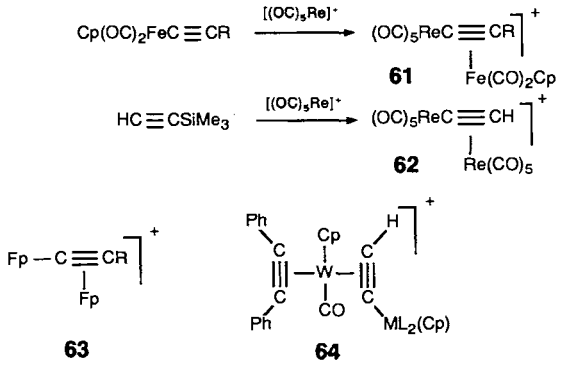
60

Numerous alkyne complexes are known in which the bridging alkyne ligand is σ,π-bound (Scheme 15).[195] Com-

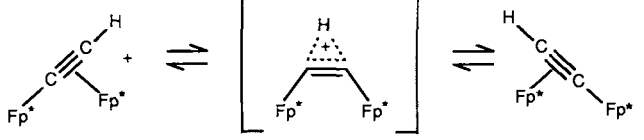


Scheme 15. Types of alkynyl complexes.

plexes **61** and **62** with σ,π-bound acetylide bridges (type **B**) were prepared by the reactions of the organometallic Lewis acid $[(OC)_5Re]^+$[196] with $[Cp(OC)_2Fe-C\equiv CR]$ and $HC\equiv CSiMe_3$, respectively.[197]



Selegue et al.[198] and Akita et al.[199] were able to synthesize the corresponding cationic σ,π-alkynyl complexes **63** and **64** (type **B**; Scheme 16). They obtained iron, ruthenium, and tungsten complexes by the addition of organometallic Lewis acids to σ-bound acetylide ligands. The X-ray crystal structures of **61**,[197b] **63**,[198], and **64**[199] prove the significance of the vinylidene structure **B'**. Interestingly, the diiron complex **63** shows fluxional behavior corresponding to a 1,2 proton shift.[199]



Scheme 16. Fluxional behavior of an Fe_2 complex.

The structure of $[(MeC_5H_4)Mn(CO)_2\{=C=C(H)-Fp^*\}]$, obtained from $[Fp^*-C\equiv C-H]$ and $[(MeCp)Mn(CO)_2(thf)]$, indicates zwitterionic contributions.[199b] The $[Pt(PPh_3)_2]$ complex fragment can be bound to the C≡C bond of the chloroethynyl complex $[Cl(Ph_3P)_2Pt-C\equiv C-Cl]$.[151] The σ-acetylide complex $[(dppe)(OC)_3Mn\ C\equiv CR]$ can add twice to Cu^+, Ag^+, and Au^+ ions.[200a]

Heterometallic complexes with two σ,π-acetylide bridges can be synthesized by using σ-bis(alkynyl) complexes. For instance, $[Cp_2Ti(C\equiv CR)_2]$ reacts as a type **D** chelating ligand with $FeCl_2$,[200b] $[Ni(CO)_4]$,[201] $[Co_2(CO)_8]$,[202] and $[(Ph_3P)_2Pt(C_2H_4)_2]$.[203] *cis*-$[M(C_6F_5)_2(thf)_2]$ (M = Pd, Pt) forms type **D** complexes with *cis*-$[Pt(C\equiv CR)_2L_2]$ (R = Ph, *t*Bu, $L_2 = 2PPh_3$, dppe, cod),[204a] while bridges of type **G** are obtained with $[TiCp_2(C\equiv CH\,tBu)_2]$.[204b] Complexes of type **E** can be prepared by the reaction of *cis*-$[Pt(C_6F_5)_2(C\equiv CR)_2]^{2-}$ (R = Ph, *t*Bu) and *cis*-$[M(C_6F_5)_2(thf)_2]$.[204a] In contrast, *cis*-$[(dppe)Pt(C\equiv CR)_2]$ and $[Rh_2Cl_2(CO)_4]$ react to yield a dinuclear compound with a single σ,π-acetylide bridge.[205]

Further complexes of type **E** are known for titanium,[206] iridium,[207] and zirconium.[208] The bonding in the latter species is best described by the participation of resonance structures of type **E** and **E'**. The reaction of $[(MeC_5H_4)_2TiCl_2]$ with $NaC\equiv CPh$ leads to an oxidative coupling of two acetylide ligands, forming complexes with type **F** bridges.[209, 210] A similar type **F** arrangement of phenylethynyl ligands was also found in a samarium complex.[211] Recently, variations in the conditions for the reaction of $[Me_2Si(C_5H_4)_2TiCl]_2$ with $LiC\equiv CPh$ made it possible to identify compounds of type **E**, **F**, and **G**.[212]

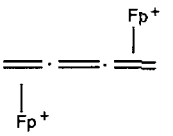
4. Substitution of Halogen or Triflate Substituents in Hydrocarbons by Nucleophilic Complexes

μ-Polymethylene complexes are among the oldest known compounds containing hydrocarbon bridges.[4, 17a] These compounds have been investigated primarily by the research groups led by King, Lindner, Moss, and Puddephatt and are models for hydrocarbons bound to the surface of metal catalysts.[5] They can generally be prepared with $n \geq 3$ from α,ω-dihalo compounds and carbonylmetalate ions (Scheme 17). Particularly useful starting materials were α,ω-bis(triflate) compounds,[213] as the triflate group is a much better leaving group than the halogen substituent. For instance, $[(OC)_5Mn(CH_2CH_2CH_2)Mn(CO)_5]$ was obtained by the bis(triflate) method.[213b] In contrast, the reaction of 1,3-dibromopropane with $Na[Mn(CO)_5]$ led to a cyclic carbene complex.[214]

$$X\text{-}(CH_2)_m\text{-}X + 2[L_nM]^- \xrightarrow[-2X^-]{} [L_nM\text{-}(CH_2)_m\text{-}ML_n]$$

Scheme 17. X = Br; $ML_n = FeCp(CO)_2$; $m = 3-6$ [4, 215, 216]. X = Br, I; $ML_n = RuCp(CO)_2$; $m = 1$, 3–10 [216–218]. X = Br, I; $ML_n = Co(DH)(pyridine)$; $m = 3-7$ [218b]. X = I, OSO_2CF_3; $ML_n = MoCp(CO)_3$, $CpW(CO)_3$; $m = 4$, 5, 10 [219, 220]. X = OSO_2CF_3, $ML_n = Mn(CO)_5$; $m = 2-6$, 10 [213, 216, 220]. X = OSO_2CF_3; $ML_n = Re(CO)_5$; $m = 2-5$, 10 [213a, 220, 221]. X = OSO_2CF_3; $ML_n = ReCp(NO)(PPh_3)$; $m = 3-5$, 8 [222].

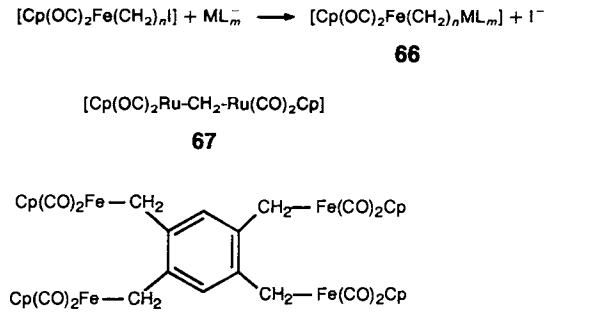
The compounds $[L_nMCH_2C\equiv CCH_2ML_n]$ (ML_n = $Fe(CO)_2Cp$, $W(CO)_3Cp$) were obtained analogously. The iron complex can be oxidized to the butatriene complex **65**[223a] and can be employed as a building block for cluster synthesis.[223b]



65

Heterometallic compounds of type **66** can be prepared from ω-iodoalkyl metal complexes by substituting a carbonylmetalate for the iodine group (Scheme 18).[224] This method also makes accessible the cobaltoxime complexes with hydrocarbon bridges $[py(DH)Co-R-Co(DH)py]$ ($R = (CH_2)_n$, $n = 4-8$; $CH_2C_6H_4CH_2$) from $[py(DH)Co(CH_2)_nCl]$, $(CH_2)_nBr_2$, or $C_6H_4(CH_2Br)_2$ and $[py(DH)Co]^-$[218b].

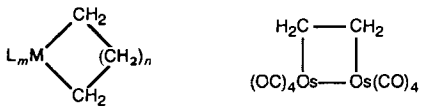
1,2-Dihaloalkanes and anionic transition metal complexes usually react to form ethylene and dimers with a metal–metal bond, while, in general, dihalomethane does not undergo such a reaction.[4, 214] An exception is its reaction with $[CpRu(CO)_2]^-$, which yields **67**.[217] The tetranuclear com-



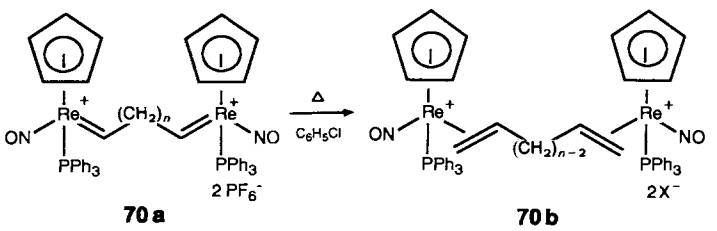
Scheme 18. Complex **66**: $n = 3$–6; ML_m = $CpMo(CO)_3$, $CpW(CO)_3$, $Re(CO)_5$, $Ru(CO)_2Cp$.

plex **68** was recently prepared in a corresponding fashion.[224c]

The dianions $[Fe(CO)_3L]^{2-}$,[225] $[CpRe(CO)_2]^{2-}$,[226] $[Ru(CO)_4]^{2-}$,[227a] $[Os(CO)_4]^{2-}$,[227b] and $[Os_2(CO)_8]^{2-}$[228] react with alkanediylbis(triflate) to form metallacycles such as **69a, b**. These reactions have been reviewed in the literature.[72b, 229]

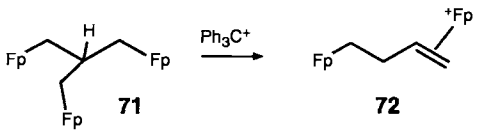


Of special interest is a type of complex with an unusual and rare ethylene bridge, which is perpendicular to the metal atoms. This complex is formed by the reaction of 1,2-dichloroethane with the dimer $[M_2X_6(PEt_3)_4]$ (M = Zr, Hf; X = Cl, Br).[230] A similar μ-η^2:η^2-ethylene bridge is also present in $[Cp^*Yb(\mu\text{-}C_2H_4)Pt(PPh_3)_2]$,[231a] $[(Cp_2^*Sm)_2(\mu$-η^2:η^4-RCH=CHPh)],[231b] and—in a distorted fashion—in $[(\mu\text{-}C_2H_4)(Cp_2Zr{-}Cl{-}AlEt_3)_2]$.[232] Hafnium complexes with alkanediyl bridges cannot be prepared by substitution of halogen substituents but rather by the reaction of $[Cp_2^*HfH_2]$ with α,ω-dienes (formally a double insertion of the olefin into the Hf–H bond).[233a] CO and SO_2 can be inserted into the metal–carbon bond of many μ-polymethylene complexes.[220, 233b]

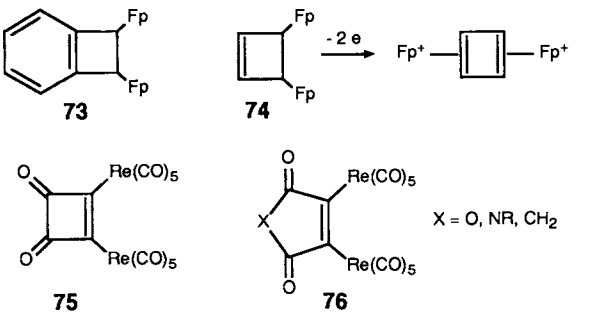


Abstraction of hydride from the μ-polymethylene complexes $[\{Cp(ON)(Ph_3P)Re\}_2(CH_2)_n]$ (n = 3, 4, 5, 8) leads to dicationic bis(carbene) complexes **70a**, which isomerize at higher temperatures to give the diene-bridged complexes **70b**.[222]

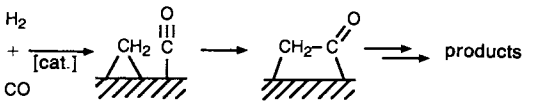
The trinuclear complex **71**, which can be oxidized to **72** with trityl salts, is formed when $[CpFe(CO)_2]^-$ is combined with the tris(sulfonate) $HC(CH_2OSO_2CH_3)_3$.[234]



A large number of μ-hydrocarbon complexes can be prepared by allowing carbonylmetalate ions to react with cyclic dihalo or polyhalo compounds (octafluorocyclooctatetraene[236c]). The complexes **73**–**76** were prepared in this manner from the corresponding dihalo species and organometallic anions.[223a, 235, 236] Bis(triflates) with a THF framework



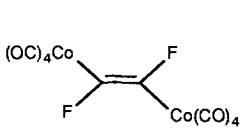
react with carbonylmetalate ions in the same fashion to yield hydrocarbon-bridged complexes.[236b] A series of homo- and heterometallic μ-η^1:η^1-ketene complexes $[L_nM{-}CH_2{-}C(O){-}M'L_n]$ was prepared by Akita et al. from metal-substituted acetylchlorides $[L_nM{-}CH_2C(O)Cl]$ and carbonylmetalate ions (examples of L_nM: Fp, $M'L_n = Mn(CO)_5$, Fp, Ni(CO)Cp).[237] Organometallic Lewis acids (e.g., Fp^+) can be added to the carbonyl oxygen atom of the ketene bridge.[237] The μ-ketene complexes are models for an important step in the Fischer–Tropsch process (Scheme 19).[5, 237] Seppelt et al. described the reactions of



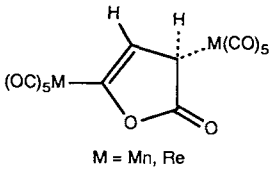
Scheme 19. μ-Ketene complexes as models for intermediates in the Fischer–Tropsch process.

difluoromalonyl dichloride with carbonylmetalate ions.[238] They were able to identify the complexes $[(OC)_5Mn{-}C(O){-}CF_2{-}C(O){-}Mn(CO)_5]$ and $[(OC)_5Mn{-}CF_2{-}C(O){-}Mn(CO)_5]$, among others.

Lentz et al. were able to obtain the (μ-η^1:η^1-difluoroethylenediyl) complex **77** by the reaction of $[Co(CO)_4]^-$ with difluorofumaric acid dichloride.[239] This reaction presumably proceeds via a bis(acyl) complex. We wanted to prepare a corresponding *trans*-bismetalated ethylene by the reaction of $[M(CO)_5]^-$ (M = Mn, Re) with fumaric acid dichloride. Unexpectedly, complexes **78** were formed.[240]

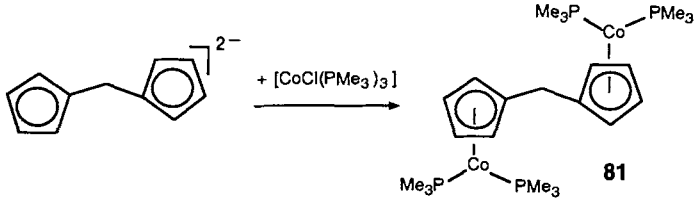


77



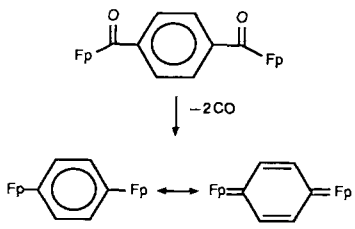
M = Mn, Re

78



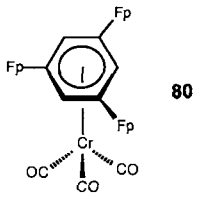
81

Decarbonylation of aroyl complexes often leads to complexes such as **79** with arene bridges. These have been the focus of recent studies, primarily by Hunter et al., on account of their potential as "electronic bridges".[214, 242]



79

Quinoid structures have been suggested for the 1,4-dimetalated μ-phenylene complexes.[242a] Reactions with $[Cr(CO)_6]$ lead to complexes like **80** with σ,π-bridges (see Section 3).[242c]



80

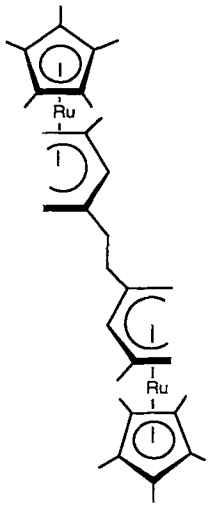
Electrochemical studies show that polymetalation of the arene ligand in $[(\eta^6\text{-}C_6H_6)Cr(CO)_3]$ leads to a stabilization of the corresponding radical cations.[242c] Numerous complexes of the type $[(OC)_3Cr(\mu\text{-}\eta^6\text{:}\eta^6\text{-}C_6H_5\text{–}C_6H_5)Cr(CO)_3]$, $[L_nM(\ \text{-}\eta^1\text{:}\eta^1\text{-}C_6R_4)ML_n]$, and $[(OC)_3Cr(\mu\text{-}\eta^6\text{:}\eta^1\text{-}C_6H_5)\text{-}ML_n]$ have been described in the literature.[165a, 166b, 167]

The decomposition of the μ-oxalyl complexes $[(OC)_5M\text{–}C(O)\text{–}C(O)\text{–}M(CO)_5]$ leads to the dimetal carbonyls $[(OC)_5M\text{–}M(CO)_5]$ (M = Mn, Re).[243] 1,8-Diferrocenylnaphthalene can be obtained from the reaction of 1,8-diiodonaphthalene with dilithioferrocene.[244]

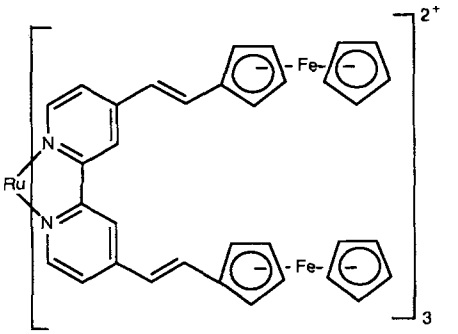
5. Reactions of Dianionic Hydrocarbons with Metal Complexes

The reaction of dianionic hydrocarbons with halometal complexes can also lead to complexes with hydrocarbon bridges. Werner et al. used this method to synthesize homo- and heterometallic transition metal complexes containing a bis(cyclopentadienyl)methane bridge, for example, **81**.[245]

Bis(η^5-pentadienyl)-diruthenium complexes like **82** can be obtained by analogous methods.[246] Dilithiated 4,4'-dimethyl-2,2'-bipyridine and ferrocenecarbaldehyde can be used to synthesize redox-active ligand systems.[247] Complex **83** can be electrochemically polymerized to an electrochromic film.[247]

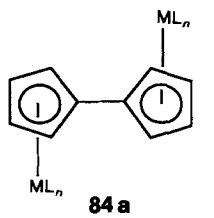


82

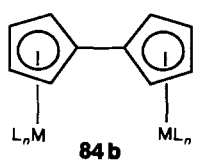


83

The homo- and heterodimetallic fulvalene complexes **84a**[83, 130, 131], studied primarily by Vollhardt et al.,[182] are currently of special interest. They can be obtained directly by the reaction of the fulvalene dianion with metal complexes.[248, 249] Fulvalene transition metal complexes **84b** with a cisoid arrangement and no metal–metal bond can be prepared in this manner as well.[248c]

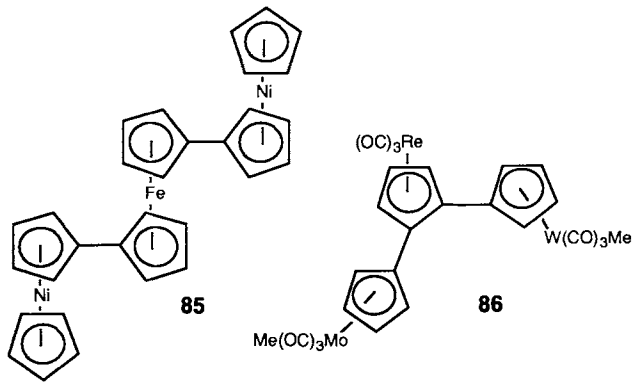


84a



84b

A particularly elegant and selective synthetic method for heterometallic fulvalene complexes employs 3-cyclopentadienyl-2-cyclopentane-1-one as precursor.[182, 250] The reaction of 3,4-dimethylcyclopentanone with dilithioferrocene leads to cyclopentadienyl-substituted ferrocene; the lithium salt of the latter can be transformed into the triiron complex by reaction with $FeCl_2$.[251] Trinuclear heterometallic complexes with a fulvalene bridge, for example, 1,1'-di(nickelocenyl)ferrocene **85**[252] and numerous tercyclopentadienyl complexes like **86**,[253] have been reported as well. The synthesis and properties of bis(fulvalene)diiron ([0.0]-ferro-

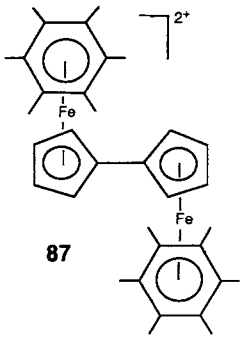


85 86

cenophane) and other [*m*,*m*]-metallocenophanes have recently been thoroughly reviewed.[249]

Why this special interest in fulvalene complexes? Cooperative effects between the metal centers are expected due to the spatial proximity of the metal atoms (even when a metal–metal bond is not present) and the high degree of electron delocalization in the fulvalene bridge.

The comprehensive synthetic and electrochemical studies by Astruc et al. regarding "electron storage" complexes (i.e. mixed-valence complexes) deserve special mention.[166c, 254, 255] For instance, the dicationic $Fe^{II}Fe^{II}$ complex **87** can be reversibly reduced to the corresponding $Fe^{I}Fe^{I}$ and $Fe^{0}Fe^{0}$ compounds.[166c] Electron transfer studies were also performed on di, tri, and tetrametallocenes[255b, 256, 257] and bis(fulvalene) complexes.[258] The dianions of pentalene,[259a] indacene,[259b] and tetraphosphafulvalene[259c] can be used in the same fashion as the fulvalene dianion in the construction of dimetallic complexes.

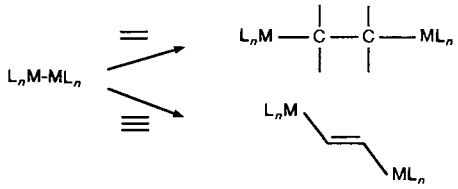


87

"Magnesium butadiene", MgC_4H_6, reacts with [Cp*La-(μ-Cl)$_2$K(dme)] (dme = dimethoxyethane) to yield a dilanthanum complex with a butadiene bridge, [Cp$^*_2$La(μ-η^1:η^3-C_4H_6)LaCp$^*_2$(thf)].[260a] The reaction of the di-Grignard compound [Cp$_2$M($CH_2MgBr)_2$] and [Cp$_2$M'Cl$_2$] (M, M' = Ti, Zr, Hf) leads directly to 1,3-dimetallacyclobutanes.[260b]

6. Insertion Reactions

The insertion of unsaturated hydrocarbons into metal–metal bonds to form complexes with hydrocarbon bridges is a relatively rare reaction type (Scheme 20). Examples include reactions of dimeric (oep)rhodium(II) complexes (oep = octaethylporphyrinato) with olefins.[261] By using kinetic methods, Halpern et al. were able to deduce a radical chain mechanism for this insertion.[261c] The μ-propene complex [(oep)Rh–$CH_2CH(CH_3)$–Rh(oep)] undergoes a dyotropic 1,2-exchange of the (oep)Rh groups.[262] The monomeric ruthenium porphyrin complex [(Ru(tmp)] (tmp = tetramesitylporphyrinato) reacts with acetylene by formal hydrocarbon insertion and formation of the binuclear complex [(tmp)Ru(μ-C_2H_2)Ru(tmp)].[263] NMR data indicate the presence of a μ-η^1:η^1-bis(carbene) complex.[263]



Scheme 20. Insertions of alkenes and alkynes into metal–metal bonds.

Corresponding reactions involving Co complexes (particularly $[Co(CN)_5]^{3-}$ and acetylenes) have been known for some time.[264] These complexes contain a *trans*-dimetallaethylene unit.[264] *cis*-Dimetalated olefins usually have a metal–metal bond or other bridging ligands.[72b, 265]

The insertion of tetrafluoroethylenes into the metal–metal bond of $[Co_2(CO)_8]$[266a] and [{(μ-SCH_3)Fe(CO)$_3$}$_2$][266b] leads to dinuclear complexes with a C_2F_4 bridge. At higher temperatures, these species rearrange to give complexes with carbene bridges. A 1,4-dimetallacyclohexane derivative is formed by the reaction of C_2F_4 with [Pt(cod)$_2$].[267]

Recently, the insertion of acetylene carboxylic acid esters into the Re–Re bond of [$Re_2(CO)_9(CH_3CN)$] was observed which led to the formation of [(OC)$_4$Re{*trans*-μ-η^1:η^2-RC=C(CO_2Me)}Re(CO)$_5$].[268]

The complexes [(R_3P)AuMe] (R = Me, Ph) react with F_3C–C≡C–CF_3 by means of insertion into the Au–Me bond, loss of ethane, and formation of the *cis* compounds [(R_3P)Au(CF_3)C=C(CF_3)Au(PR_3)].[269] A complex with an η^2:η^2-$C_2(CF_3)_2$ bridge is assumed as intermediate.[269b] In analogy to alkynes, isolobal[14, 54] carbyne complexes [Cp(OC)$_2$M≡C–R] (M = Mo, W) can be inserted into the Pd–C bond of metallacycles.[136] Isocyanides can also be inserted into the Pd–C bond of μ-acetylide palladium complexes.[270] According to work by Herberhold et al.,[271] the products of the insertion of chalcogens into the Li–C bond of lithiated cyclopentadienyl complexes can serve as starting materials for numerous multinuclear complexes with chalcogen bridges between the ring ligands.

7. Complexes with C_n Bridges

Complexes with acetylide bridges are a rapidly expanding class of materials. This type of complex can be prepared by several methods, which in principle have already been described: 1) from alkaline metal acetylides and alkyl complexes or metal halides, 2) from alkyne complexes having acidic protons and metal halides or alkyl complexes, 3) from cationic complexes containing σ,π-ethynyl bridges, 4) from

metal alkyls and acetylene, 5) from dihaloacetylene and carbonylmetalate ions, 6) from lithiated metal alkynes and metal halides, 7) by oxidative addition of dihaloacetylene, 1,3-diyne, or "$RC{\equiv}C^+$" to Pt^0, Rh^I, or Ir^I centers (Table 3).

Table 3. Dinuclear transition metal complexes containing a C_2 bridge. mes = mesityl.

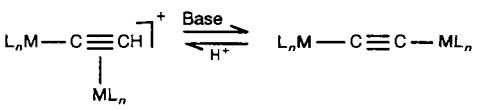
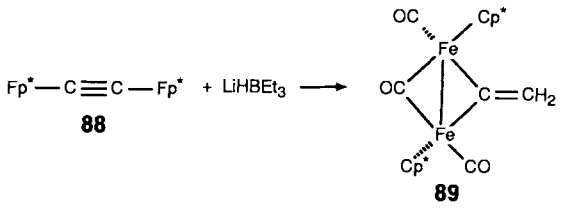
The H atom is made acidic by the π-coordination mode of the C≡CH ligand and can then be easily removed by bases (Scheme 21). This provides a direct way to μ-ethynediyl com-



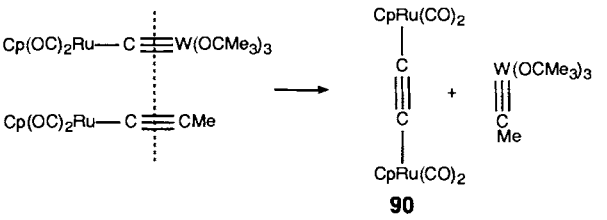
Scheme 21.

plexes.[197a, 199, 276–278] The cationic complex can be regenerated by addition of acid. When Me_3O^+ is used instead of an acid, the corresponding σ,π-propynyl complex can be obtained.[86a] The superhydride $K[BHEt_3]$ acts solely as base towards $[(OC)_5Re(\mu\text{-}\eta^1{:}\eta^2\text{-}C{\equiv}C{-}H)Re(CO)_5]^+$,[86a] while its addition to **88** leads—by attack of the hydride on the β carbon atom—to the μ-vinylidene complex **89**.[199]



The formation of a W_2C_2 complex with an acetylide bridge from the ketene species $[Cp(OC)_2W(\mu\text{-}CO)(\mu\text{-}CH_2CO)W(CO)_2Cp]$ is unusual. The reaction proceeds by formal H_2O loss and intramolecular CO transfer.[285] Binger et al. described the reaction of $[Cp_2Ti(PMe_3)_2]$ with 2-methylene-1,1′-diphenylcyclopropane, which surprisingly also leads to a dititanium complex with an acetylide bridge.[286]

Of interest are the metathesis reactions between W≡W and C≡C[287, 289a–c] or C≡N[289d] triple bonds, leading to complexes like **90**. μ-Acetylide complexes are as suitable as alkynes[290a] and σ-alkynyl complexes $[L_nM{-}C{\equiv}C{-}R]$[290b] as building blocks for the synthesis of clusters.[292]



A μ-dicarbide tantalum complex with three cumulated double bonds is formed according to reaction (b) by CO

$$2[(t\text{Bu}_3\text{SiO})_3Ta] + CO \longrightarrow [(t\text{Bu}_3\text{SiO})_3Ta{=}O] + 1/2[\{(t\text{Bu}_3\text{SiO})_3Ta{=}C\}_2] \quad (b)$$

cleavage.[288] The cleavage of two C≡C bonds in 3,5-octadiyne leads to the complex $[\{(t\text{BuO})_3W{\equiv}C\text{-}\}_2]$.[289a]

The C–C distances in the bridging ligands of most of the complexes listed in Table 4 are only slightly different from the C–C bond lengths in acetylene, ethylene, and ethane (121, 134, 153 ppm, respectively). These complexes can

Table 4. Bond lengths in metal complexes with C_2 bridges.

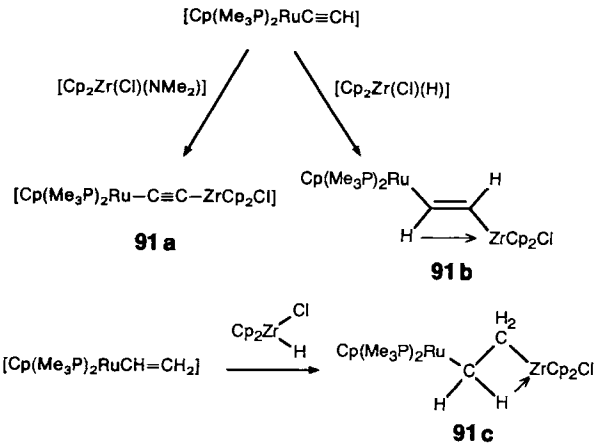
therefore be regarded as dimetalated hydrocarbons, which is in agreement with the calculations for $[(OC)_5ReC_2Re(CO)_5]$ reported by Trogler et al.[276b] As is the case for the free hydrocarbons, an increase in the participation of the carbon s orbital leads to a decrease in the metal–C distance.[276b, 278b] The RuZr complexes **91** synthesized by Bullock et al. are the only known series with all three types of C_2 bridges, C≡C, C=C, and C–C.[278] These complexes are prepared from the corresponding alkynylruthenium complexes by reaction with the amidozirconium complex, by hydrozirconization with the Schwartz reagent $[Cp_2Zr(H)Cl]$, or by hydrozirconization of the vinylruthenium complex.

Agostic interactions between the Zr atom and the β hydrogen atom in **91b,c** have been proven by NMR spectroscopy.[278b] Hydrozirconization of alkenyl complexes

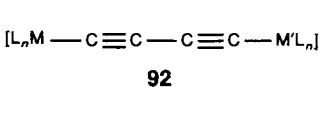


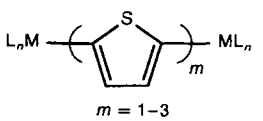
was first applied by Erker et al. for the synthesis of an ethylene-bridged dizirconium complex that also contained an agostic bond.[290c] Casey et al. used the Schwartz reagent for the hydrogenation of the carbene complex $[Cp(OC)_2Re{=}CHCH_3]$ (which is isolobal to an alkene). This reaction led to μ-alkylidene heterodimetallic complexes such as $[Cp(OC)_2Re(\mu\text{-}CHCH_3)Zr(Cl)Cp_2]$.[290d] In this context, the unusual Zr_2 complexes prepared by Orpen and co-workers are noteworthy.[291] They contain a type **C** alkyne bridge (see Scheme 15).

Attempts to prepare the μ-ethyne complex $[(OC)_5Re{-}C(H){=}C(H){-}Re(CO)_5]$ by proton abstraction from $[(OC)_5Re(\mu\text{-}\eta^1{:}\eta^2\text{-}CH{=}CH_2)Re(CO)_5]^+$ were not successful.[187]

CO, CO_2, and isocyanide can be inserted into the metal–carbon bond of complexes **91a,b**.[293]

Dimetallic complexes of type **92**, containing a bridging 1,3-butadiyne-1,4-diyl ligand, are known as well. They are prepared by the oxidative addition of HC≡C–C≡CH to $[Rh(Cl)(PiPr_3)_2]$,[294] by the reaction of $[CpL_2Fe{-}C{\equiv}C{-}C{\equiv}C{-}Li]$ and $[CpL_3MCl]$ (M = Mo, W),[295] or by the Pd-catalyzed reaction of $[Cp(OC)_2FeI]$ with $[Me_3Sn{-}C{\equiv}C{-}C{\equiv}C{-}SnMe_3]$.[296] Lappert et al.,[297a] Wrackmeyer et al.,[297b] and Brune et al.[298] have shown that vinyl, alkynyl, and aryl trimethylstannanes are especially suitable for the introduction of vinyl, alkynyl, and aryl ligands into metal complexes. Further examples of the application of these trimethylstannanes to the preparation of





93a: $ML_n = Ru(CO)_2Cp$
93b: $ML_n = Pt(PBu_3)_2Cl$

94

complexes with bridging vinyl, acetylene, and *p*-phenylene ligands are described in the literature[133, 187, 298] and in Section 8. When 2,5-trimethylstannyl-substituted thiophenes and chloro complexes are employed, oligothiophene-bridged complexes **93** are formed, which are of interest due to the electrical conductivity of polythiophenes.[299]

Stang et al. discovered that alkynyl(phenyl)iodonium trifluoromethylsulfonate $[RC{\equiv}CIPh{\cdot}OSO_2CF_3]$ is a new, effective source of electrophilic alkynes $RC{\equiv}C^+$.[300a] The umpolung of the usual acetylene reactivity allows the preparation of σ-acetylide complexes in high yields.

The addition of bis(phenyliodonium)diyne bis(triflates) to chlororhodium complexes and Vaska-type iridium(I) complexes yields rod-shaped dicationic metal(III) complexes of type **92**.[300a] Similar complexes are formed from *p*-$HC{\equiv}C{-}C_6H_4{-}C{\equiv}CH$, NaOMe, and dichloroiron complexes.[300b] Cobalt clusters that are linked by a C≡C bridge are also known.[301]

Only a small number of μ-carbide complexes of type **94** are known to date (Scheme 22). They can be prepared by metathesis,[287, 302] radical reactions,[303] or by nucleophilic substitution.[304, 305] They are of interest as model systems for surface-bound carbide species.[5]

[(TPP)Fe=C=Fe(TPP)] [303]

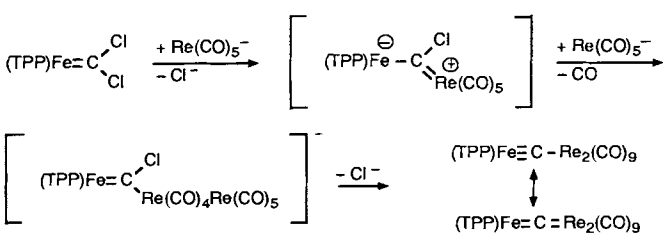
Scheme 22. Known carbido complexes of type **94**. TPP = tetraphenylporphyrinato, pc = phthalocyaninato(2–), pz = 3,5-dimethylpyrazolyl.

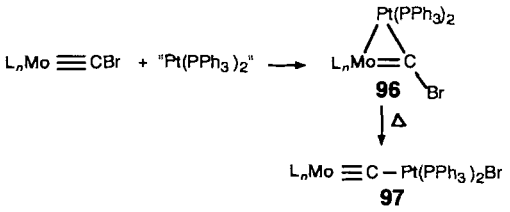
Complex **95**[304] contains what is to the best of our knowledge the shortest metal–carbon bond known (Fe–C 160(1) pm) and can therefore be considered a metalated metal carbyne. Its preparation from the dichlorocarbene complex $[(TPP)Fe{=}CCl_2]$ and $[Re(CO)_5]^-$ proceeds presumably according to the reaction in Scheme 23. During the



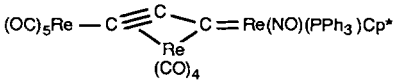
Scheme 23.

reaction of 1,3-dibromopropane and $[Mn(CO)_5]^-$, Casey also observed that the reaction does not proceed by substitution of the second bromine atom, but by the attack of an additional $[Mn(CO)_5]^-$ ion on the original metal center.[214b] When the carbonylmetalate ions $[Mn(CO)_5]^-$, $[Fe(CO)_4]^{2-}$, and $[Cr(CO)_5]^{2-}$ are employed, the corresponding compounds $[(TPP)Fe{=}C{=}ML_n]$ ($ML_n = Mn_2(CO)_9$, $Fe(CO)_4$, and $Cr(CO)_5$) are obtained.[86b, 304]

A novel synthetic pathway to μ-carbide complexes is found in the reaction of Lalor's halocarbyne complexes[305d] with platinum(0) complexes.[85, 86b] Compound **96**, which is prepared by this route, isomerizes at higher temperatures to give the carbide complex **97**. Less stable compounds can also be obtained with Ni^0 and Pd^0 complexes.[86b] A large number of heterodimetallacyclopropenes have been prepared by Stone et al. from Pt^0 compounds and arylcarbyne complexes (arylcarbynes are isolobal to alkynes).[14, 306]



The elegant application by Gladysz et al. of the now-classical Fischer carbene and carbyne synthesis in a reaction sequence led to complexes with a novel type of C_3 carbon bridge (**98**).[307]



98

Templeton et al. reported the dimerization of the methylidyne complex $[tp'(OC)_2M{\equiv}CH]$ (M = Mo, W; tp' = $HB(3,5\text{-}Me_2C_3HN_2)_3$) to give the nonclassical μ-vinylidene complex **99**.[305b, c]

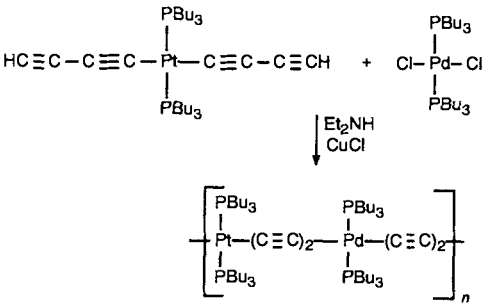
99

Complexes with C_{60} and C_{70} bridges have been synthesized, for example, the fullerenehexametal complexes $[\{(Et_3P)_2M\}_6C_{60}]$ (M = Pd, Pt)[308] and the diiridium complexes $[(R_3P)_2(Cl)(OC)IrC_nIr(CO)(Cl)(PR_3)_2]$ (n = 60, 70).[309a] Further transition metal compounds with bridging carbon ligands have been comprehensively reviewed recently by Diederich et al.[309b]

8. Organometallic Polymers with Hydrocarbon Bridges

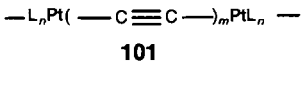
Organometallic polymers, which are frequently obtained by the polymerization or copolymerization of monomers such as $[(\eta^6\text{-styrene})Cr(CO)_3]$ and $[(\eta^5\text{-}CH_2{=}CH{-}C_5H_4)Fe(CO)_2Me]$, are currently the subjects of intensive investigations.[310a] For instance, the polymerization of vinylferrocene—although first reported nearly 40 years ago[310b]—is still of active interest.[310c]

Studies of metal-containing polyenes and polyynes are quite topical because of the expected novel properties (rod-shaped molecules, liquid-crystal properties, nonlinear optical behavior, one-dimensional electrical conductivity) of these materials.[311] The first of these novel polymers **100** were obtained by Takahashi, Hagihara, et al.[312]

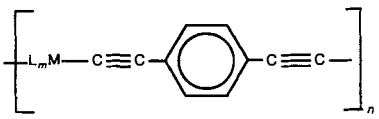


100

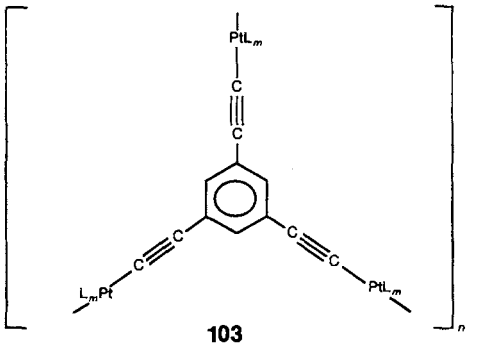
A general method for the preparation of polymers **101** and **102** is the stoichiometric reaction of dihalo complexes with bis(trimethylstannyl)diynes. Lewis et al. used this approach very successfully for the synthesis of oligomeric and polymeric μ-acetylide complexes.[313] The polymers obtained had an average molar mass of up to 200000. Using the same methodology, Lewis et al. prepared cross-linked Pt-containing polymers **103**.[314a] Polymers have also been obtained by reactions of $[(o,p\text{-}\eta^6\text{-}C_6H_4Cl)Cr(CO)_3]$ with $Me_3Sn{-}C{\equiv}C{-}SnMe_3$.[314b]



101



M = Ni, Pd, Pt, Fe, Rh **102**

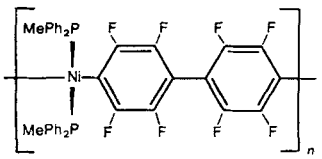


103

Polymer chains with metal-containing terminal groups are formed by the insertion of arylisocyanides (up to 100 times) into the Pd–C bond of the μ-acetylide complex

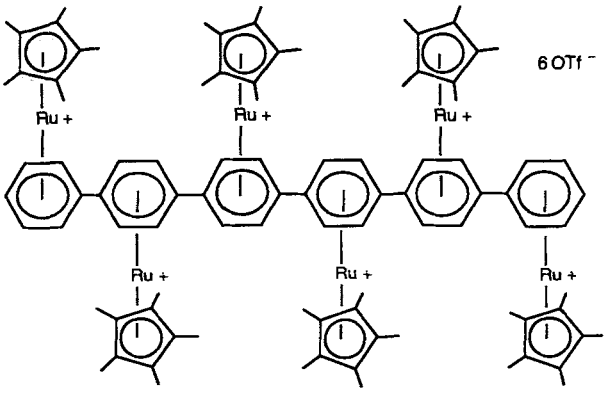
$[Cl(R_3P)_2Pd-C\equiv C-Pt(PR_3)_2Cl]$.[315] According to studies by Marder et al., terminal dialkynes react with $[Rh(PnBu_3)_4Me]$ to yield the corresponding polymers.[316] Hanack et al. reported layered (μ-acetylide)phthalocyaninatoiron complexes and described them as models for one-dimensional electrical conductors.[317]

Metallapolyynes with alkynyl and carbyne ligands $[-C\equiv M-C\equiv C-]_n$ are also of great interest.[318a] A corresponding monomer, the π-conjugated metallabutadiyne $[HC\equiv W(dmpe)_2(C\equiv C-H)]$, has been recently reported.[318b] The first reported organometallic polymer with arene bridges is **104**. This polymer is formed in the same

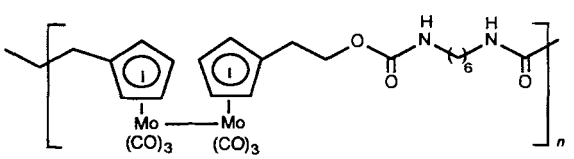


104

fashion as di- and trimetallic bis(methyldiphenylphosphine)nickel complexes containing tetra- and octafluoro-*p*,*p*′-biphenylene bridges: by the reaction of the corresponding organolithium compounds with bromonickel complexes.[319] Recent examples of ferrocene-containing polymers are polyferrocenyldisulfide[320] and polyferrocenylsilane.[321] Rosenblum et al. reported the Pd°-catalyzed synthesis of interesting face-to-face metallocene polymers from 1,8-diiodonaphthalene and dimetalated ferrocene or $CpCu\cdot SMe_2$.[244] The coordination of $M(CO)_3$ units (M = Cr, Mo) to the benzene rings of poly(*p*-phenylene) has also been reported.[322a] The oxidation of these molybdenum polymers increases their electrical conductivity.[322a] The same effect is observed in the ferrocene-containing polymer $[-Fc-CH=CH-(p\text{-}C_6H_4)-CH=CH-]_n$, which can be prepared by the Wittig reaction.[322b] Recently a conjugated polymer has been synthesized by metallacyclization of $[Cp\text{-}Co(PPh_3)_2]$ with 4,4′-diethynylbiphenyl.[322c]



105

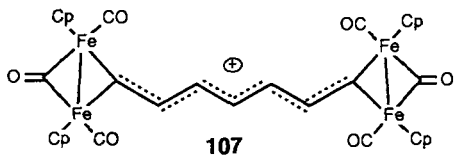


106

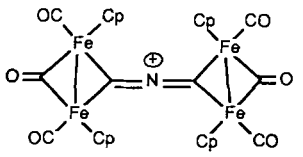
The $[Cp^*Ru]^+$ ion, which can be added to nearly all types of benzene rings (see Section 3), can serve as a building block for the construction of metal-containing organic solids having the desired shape (molecular engineering of solid-state materials).[174] An example of these interesting compounds is **105**. Metal-containing polyurethanes such as **106** are formed by the condensation of hexamethylenetriamine with β-hydroxyethyl-substituted cyclopentadienyliron and -molybdenum complexes.[323] The Mo–Mo bond in **106** can be cleaved photochemically.

9. Miscellaneous

The thermodynamically very stable diiron system $[Cp(OC)Fe(\mu\text{-}CO)(\mu\text{-}CR)Fe(CO)Cp]^+$ has significant synthetic potential. It has been used primarily by Casey et al.[324] for the synthesis of a large number of complexes with various hydrocarbon bridges. Reactions with the analogous Ru compound have been reported by Knox et al.[325] In general, the metal–metal bond remains intact in these reactions; however, hydride abstraction from the μ-alkylidenediiron complex $[\{Cp(OC)Fe\}_2(\mu\text{-}CO)(\mu\text{-}CHCH_2CH=CH_2)]$ is an exception. This reaction proceeds by cleavage of the metal–metal bond and yields, after a rearrangement, a μ-η^4:η^1-butadiene complex.[326] The formation of a C_3-bridged tetrairon complex from a methylidyne and a vinylidene complex is also of interest.[327] Tetrairon complexes with C_5 and C_7 bridges are known as well.[328] The cation **107**, an organometallic cyanine, could have interesting electron-transfer and nonlinear optical properties. In an unexpected fashion, Fehlhammer et al. obtained complex **108**, which has an N rather than a CH bridge.[329]



107



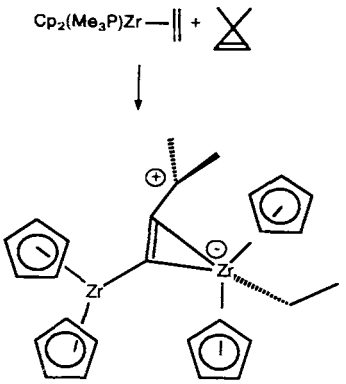
108

Complexes with bis(carbene) bridges are formed by Herrmann's diazo method[115] from bis(diazo) compounds and the coordinatively unsaturated metal complexes $[Cp(OC)_2Mn]$, $[Cp^*Rh(\mu\text{-}CO)_2RhCp^*]$, and $[(OC)_2CpMo\equiv MoCp(CO)_2]$.[330]

Zenneck exploited highly reactive intermediates from co-condensation reactions of metal vapors and arenes to prepare several multinuclear complexes (e.g., triple-decker complexes).[331] Dititanacyclobutane can be obtained by the thermolysis of 2-isopropyl-2-methyl-titanacyclobutane.[332a] Other dialkyl-substituted titanacyclobutanes combine with reactive Rh^{II}, Ir^{II}, Pd^{II}, and Pt^{III} complexes to yield, by loss of

olefin, μ-methylene heterodimetallic compounds $[Cp_2Ti(\mu\text{-}Cl)(\mu\text{-}CH_2)M(Cl)(L)Me]$ (M = Rh, Ir, Pd, Pt).[332b] TaIr complexes with two methylene bridges are formed by hydrogen abstraction from $[Cp_2Ta(CH_2)CH_3]$ with $[(\eta^5\text{-indenyl})Ir(CO)_2]$.[332c] Of interest is the formation of dimetallic complexes with a $\eta^5\text{:}\eta^5\text{-}Me_4C_5CH_2CH_2C_5Me_4$ bridge from tungstacyclobutadienes $L_nW{=}C(Me){-}C(Me){=}C(Me)$ and η^5-cyclopentadienyl complexes with a $-CH_2CH_2C{\equiv}CMe$ substituent.[332d] The metathesis reactions of Schrock carbene complexes and octatetraenes or 1,4-divinylbenzene produces bis(carbene) complexes, for example, $[L_nMo{=}CH{-}CH{=}CH{-}CH{=}CH{-}CH{=}ML_n]$.[333]

A complex with an $\eta^3\text{:}\eta^3$-1,3-butadiene bridge was found as the product of the reaction of a μ-dihydridorhodium(I) complex with butadiene.[334] The ethylene complex $[Cp_2(Me_3P)Zr(C_2H_4)]$ undergoes a novel reaction with cyclopropene; the ethylene ligand is protonated and subsequently a $\mu\text{-}\eta^1\text{:}\eta^2$-allenediyl complex is formed **109**.[335]



109

10. Outlook

Even though the selection of known complexes discussed in this review is certainly subjective, the wide array of multinuclear transition metal complexes with σ- or π-bound hydrocarbon bridges is evident. The reactions of carbonylmetalate ions with cationic π complexes clearly follow the isolobal principle.[14, 54] For instance, $[Re(CO)_5]^-$ acts like a carbanion and $[Re(CO)_5]^+$ like a carbenium ion, while the $[Re(CO)_5]$ unit acts like a methyl group. Cationic ethylene complexes such as $[(OC)_5Re(\eta^2\text{-}C_2H_4)]^+$ can be compared to carbenium ions, while μ-acetylide complexes like $[(OC)_5Re{-}C{\equiv}C{-}Re(CO)_5]$ behave like alkynes.

Since efficient syntheses are now available, it is important to investigate more closely the reactivity of these compounds and their applications. Can novel organic compounds be prepared with these complexes? One example is the synthesis of a novel polycycle by oxidation of **40** with Ce^{4+}.[127] The dimetallic iron complexes synthesized by Astruc et al.[254, 255] are interesting compounds for electron storage with electrochemical properties that may lead to application in electron transfer catalysis. Electrochemical investigations on heterodimetallic complexes might lead to new mixed-valence organometallic compounds.

Metal complexes with conjugated hydrocarbon bridges (double and triple bonds) or with donor and acceptor ligands are candidates for electrically conducting materials and for materials with second- and third-order nonlinear optical properties. These compounds have been only rarely studied as precursors for heterometallic catalysts. These applications appear to be attractive in the future. However, basic research, driven by scientific curiosity and independent of any potential application, should not be neglected.[336]

W. B. expresses his sincere thanks to the co-workers mentioned in the references for their exemplary efforts, their experimental and creative contributions, and the harmonious collaboration. The generous support of the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, Wacker Chemie, Munich, and DEGUSSA AG, Frankfurt, is gratefully acknowledged. We thank the following colleagues for valuable literature references and for providing us with unpublished manuscripts: Profs. D. H. Gibson, B. Angelici, M. Akita, D. A. Astruc, J. E. Bercaw. R. G. Bergman, R. M. Bullock, C. P. Casey, C. Elschenbroich, G. Erker, G. L. Geoffroy, J. A. Gladysz, J. A. Heppert, M. Herberhold, A. D. Hunter, C. G. Kreiter, E. Lindner, S. Lotz, J. R. Moss, A. Salzer, J. P. Selegue, J. Takats, J. L. Templeton, H. Werner, A. Wojcicki, U. Zenneck, Drs. P. Härter, and D. Wadepohl. We thank Dr. K. Sünkel for valuable discussions.

The Role of Chemistry in the Development of Boron Neutron Capture Therapy of Cancer

By M. Frederick Hawthorne*

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

A therapeutic method that selectively destroys malignant cells in the presence of normal cells is a highly valued goal of oncologists and the possible salvation of cancer patients afflicted with some incurable forms of the disease. Selective cell destruction is, in principle, possible with a binary therapeutic strategy based upon the neutron capture reaction observed with the ^{10}B nucleus and a neutron of low kinetic energy (thermal neutron). This nuclear fission reaction produces both ^{4}He and $^{7}Li^{+}$ nuclei along with about 2.4 MeV of kinetic energy and weak γ-radiation. Since the energetic and cytotoxic product ions travel only about one cell diameter in tissue one may specify the cell type to be destroyed by placing innocent ^{10}B nuclei on or within only the doomed cells. This article describes the current status of chemical research aimed at the eventual adoption of this therapeutic method (boron neutron capture therapy or BNCT). The multidisciplinary nature of this research effort involves chemistry, biology, nuclear physics, medicine, and related specialties. Methods devised for bringing ^{10}B nuclei to tumor cells in therapeutic amounts are correlated with the structure of a generalized cell and the various cellular compartments available for boron localization. The synthesis methods employed for the creation of boron-containing biomolecules and drugs are presented along with representative data concerning their efficacy in tumor localization. The outlook for BNCT is especially bright at this time because of rapid developments in the fields of bioorganometallic chemistry, microbiology, immunology, and nuclear science, to name but a few. Very effective boron delivery vehicles have been demonstrated, and through the interaction of chemistry and biology these species are undergoing further improvement and evaluation of their suitability for BNCT.

1. Introduction

What would result if it were possible to selectively attach a nontoxic species **A** to cancer cells and, upon command, destroy only these malignant cells by converting their cell-bound **A** to a deadly cytotoxin through its activation with a second nontoxic reagent **B**? One would have created a *binary* method for cancer therapy characterized by greater selectivity, efficacy, and safety than the unitary, single agent, radiation and chemotherapy protocols commonly in use today. Most importantly, tumors now beyond any hope of long-term control could be destroyed. The key to this proposed binary therapy is the requirement that the innocent **A** and **B** species have a great propensity for mutual reaction and that the extremely energetic products of this reaction, **X** and **Y**, are confined to an extremely small volume by their very brief lifetimes. However, while **X** and **Y** exist they must function as efficient killers of cells. This binary process is described by the equations of Scheme 1, and an example of such a process, boron neutron capture therapy (BNCT), forms the subject of this article.

A + B $\longrightarrow$ **[AB]** $\longrightarrow$ **X + Y (short-lived cytotoxins)**

B + cell $\not\longrightarrow$

A + cell $\longrightarrow$ **A · cell (interactions specific to cancer cells)**

A · cell + B $\longrightarrow$ **[AB · cell]** $\longrightarrow$ **[(X + Y) · cell] (cell death)**

Scheme 1. A hypothetical binary cytotoxic reaction of two innocent reagents **A** and **B** to form the cell-killing reaction products **X** and **Y**. In BNCT, **A** represents a ^{10}B nucleus selectively emplaced in or on a malignant cell. **B** is a slow neutron, and **X** and **Y** represent high-energy $^{4}He^{2+}$ and $^{7}Li^{3+}$ ions.

2. Boron Neutron Capture and Therapy

2.1. Historical Account of the Conceptualization of Boron Neutron Capture Theory

The rampant development of quantum mechanics, nuclear physics, and associated chemistry that occurred in the 1930s led James Chadwick[1] to the discovery of the neutron in 1932. Studies of the interactions of neutrons with a variety of materials uncovered the phenomenon of neutron scattering by elastic collisions[2] with atomic nuclei, especially the ubiquitous proton of the H atom. Capture of slow (or thermal) neutrons by certain nuclei was observed by Fermi,[3] and the disintegration of other specific nuclei by interaction with these thermal neutrons was observed by others, as well.[4] By 1935 a great mass of such experimental information had been collected; it was then clear that the ability of an atomic nucleus to capture a neutron was related not to the mass of the target nucleus, but to the actual structure of that nucleus. The concept of a characteristic effective cross-sectional area of a nucleus, expressed as units of 10^{-24} cm^2 (known as barn units), was introduced with this early work. The effective nuclear cross-section of boron for neutron capture was known to be exceptionally large, while boron's neighbors in the periodic table, nitrogen and carbon, exhib-

ited nuclear cross-sections that were comparatively quite small. An important 1935 paper by Taylor[5] described the capture of thermal neutrons by ^{10}B nuclei followed by the production of $^{4}He^{2+}$ (α-particles) and $^{7}Li^{3+}$. About 2 MeV of kinetic energy is distributed between these two heavy ion products. The translational range of the product ions was particularly short:[5] about 7.6 μm in photographic gelatin and 1.1 cm in air. Consequently, the lithium nucleus and the α-particle were short-lived, energetic products capable of doing immense local damage to organic materials through ionization processes. Thus, by 1936 the stage was set for the suggestion of the concept of boron neutron capture therapy (BNCT).

Gordon L. Locher of the Bartol Research Foundation of the Franklin Institute in Philadelphia, Pennsylvania, pointed out[6] in 1936 the potential medical applications of neutrons and boron neutron capture (BNC). His concept invoked the simple neutron capture reaction by boron for the basis of a binary therapeutic method as defined in Scheme 1. Accordingly, Locher's analogues of species **A** and **B** were the ^{10}B nucleus contained in a compound that specifically localizes in tumor and a thermal neutron, respectively. The energetic cytotoxic reaction products **X** and **Y** correspond to the α-particle and the lithium nucleus. The beauty of this proposal is the fact that no radioactive materials are involved and that the therapeutic process may be modulated by controlling the supply of neutrons to the tumor site.

The two necessary components of the boron neutron capture (BNC) process, a controllable source of low-energy neutrons with a usefully high flux and suitable boron compounds for concentration in tumors, were unknown in 1936, and Locher's concept was to remain prophetic until nuclear reactors were available to support an initial experimental test with thermal neutrons. This initial event did not occur until 1954 when Sweet, Farr et al.[7] attacked human brain tumors (glioblastoma multiforme) using ^{10}B-enriched borate as the ^{10}B target species in terminal patients at the Brookhaven National Laboratory (BNL) in cooperation with the Massachusetts General Hospital (MGH). These initial experiments will be discussed in Section 3.1. In these first examples, BNCT was applied to the problem of killing malignant glioma cells that remained at the tumor site following normal surgical procedures.

As expected from its potential medical applications, neutron capture therapy embraces a wide spectrum of scientific disciplines. The research literature pertinent to BNC and BNCT abounds with studies derived from such highly specialized fields as cell biology, nuclear science and engineering, radiation oncology, pathology, pharmacology, immunology, and others, in addition to chemistry. The present article is, however, restricted to topics at the interface of chemistry with these other disciplines, and it is written from the viewpoint of a chemist.

2.2. Rudimentary Aspects of BNCT

The correct description of the boron neutron capture reaction obtained with thermal neutrons (293 K $\triangleq$ 0.025 eV) is given in Scheme 2. The ^{11}B nucleus is incapable of undergoing a BNC reaction, whereas the effective nuclear cross-section of ^{10}B is 3837 barns. Table 1 presents the accepted nuclear cross-sections of the elements having unusually high values, as well as those elements of physiological importance commonly found in tissue. The ^{157}Gd nucleus has been considered as a target for neutron capture therapy due to its very high nuclear cross-section. However, the products of neutron capture are photons and Auger electrons of low energy. If ^{157}Gd can be placed in contact with DNA, double strand breaking may occur upon neutron capture.[8]

$$^{10}B + {}^{1}n_{th} \longrightarrow [^{11}B] \begin{cases} \nearrow {}^{4}He + {}^{7}Li + 2.79\ MeV \quad (6\%) \\ \searrow {}^{4}He + {}^{7}Li + 0.48\ MeV\ \gamma + 2.31\ MeV \quad (94\%) \end{cases}$$

Scheme 2. The two parallel nuclear fission reactions that occur upon capture of a slow (thermal) neutron, n_{th}, by a ^{10}B nucleus.

Two nuclides abundant in tissue (Table 1 A) stand out as participants in important neutron capture side-reactions

M. Frederick Hawthorne was born in 1928 in the state of Kansas. He entered the Missouri School of Mines and Metallurgy as a chemical engineering student in 1944. In 1947 he transfered to Pomona College and obtained his B.A. degree in 1949. In 1953 he completed his Ph.D. under Donald J. Cram at the University of California at Los Angeles (UCLA). After a year of postdoctoral research with George S. Hammond at Iowa State University, he accepted a position with the Rohm and Haas Co. in Huntsville, Alabama, in 1954, where he began his investigations in boron chemistry two years later. He was appointed Professor at the University of California, Riverside, in 1962. In 1969 he took up his present position as Professor of Chemistry (Inorganic) at UCLA. From that year he has been Editor-in-Chief of Inorganic Chemistry. Among his numerous awards are the American Chemical Society Award in Inorganic Chemistry (1973) and the Distinguished Service in the Advancement of Inorganic Chemistry Award (1988). He is a member of the U.S. National Academy of Sciences and the American Academy of Arts and Sciences. He was awarded an Honorary Ph.D. from Uppsala University in 1992 and is currently an Alexander von Humboldt Senior Scientist associated with Professor Nöth in Münich. He is a member of the Executive Committee of the International Society for Neutron Capture Therapy. His major research themes are centered about the use of boron clusters as building blocks in host-guest and supramolecular complexes, in homogeneous catalysis, as components of nanomechanical assemblies, and in the chemistry of BNCT biodelivery systems.

Table 1. Neutron capture cross-sections measured with thermal neutrons and natural isotopic abundances of physiologically important elements (A) and elements that display the greatest cross-sections, including ^{10}B (B) [a].

	Nuclide	Nuclear cross-section [Barn]	Natural abundance [%]
(A)	^{1}H	0.33	99.8
	^{12}C	3.4×10^{-3}	98.9
	^{14}N	1.8	99.6
	^{16}O	1.8×10^{-4}	99.8
	^{23}Na	0.43	100.0
	^{31}P	0.18	100.0
	^{32}S	0.53	95.0
	^{35}Cl	43	76.0
(B)	^{3}He	5.3×10^{3}	1.4×10^{-4}
	^{6}Li	9.4×10^{2}	7.5
	^{10}B	3.8×10^{3}	19.8
	^{113}Cd	2.0×10^{4}	12.2
	^{149}Sm	4.2×10^{4}	13.9
	^{155}Gd	6.1×10^{4}	14.8
	^{157}Gd	2.6×10^{5}	15.7
	^{235}U	5.8×10^{2}	7.2×10^{-1}

[a] Data taken from G. Friedlander, J. W. Kennedy, E. S. Macias, J. M. Miller, *Nuclear and Radiochemistry*, 3rd ed., John Wiley, New York, **1981**.

that occur during BNCT and thus contribute important doses of background radiation to the subject. These two neutron capture reactions play a role, not because of enhanced nuclear cross-sections of the target nuclei, but because of their very high concentrations in tissue. The neutron capture reactions[9b] of these nuclides, ^{1}H and ^{14}N, are detailed in Scheme 3. The passage of a neutron through hydro-

$$^{1}H + {}^{1}n_{th} \longrightarrow [^{2}H] \longrightarrow {}^{2}H + 2.23\ \text{MeV}\ \gamma$$

$$^{14}N + {}^{1}n_{th} \longrightarrow [^{15}N] \longrightarrow 0.63\ \text{MeV}\ p + {}^{14}C$$

Scheme 3. Neutron capture reactions involving ^{1}H and ^{14}N. Capture by ^{1}H releases high-energy γ-photons and a deuteron, whereas capture by ^{14}N yields an energetic proton and ^{14}C.

gen-rich media such as tissue results in the slowing and scattering of these neutrons by collisions with nuclei of the H atoms. Occasionally, a slowly moving neutron will be captured by such a proton to produce a deuteron accompanied by characteristic γ-radiation, which contributes to the total radiation dose. In another competing capture reaction, the nitrogen atoms available in tissue may capture a low-energy neutron and generate ^{14}C and a proton whose kinetic energy is 0.63 MeV. The kinetic energy imparted to the $^{7}Li^{3+}$ and $^{4}He^{2+}$ ions derived from the BNC reaction and that similarly associated with the proton and γ-photons produced as shown in Scheme 3 is transferred to the surrounding media. Since all of these energetic nuclear reaction products with the exception of the γ-photons, are heavy particles, this kinetic energy transfer is rapid and takes place along a very short path length. The rate of linear energy transfer (LET) of these particles is characteristically high; the immense energy of these reactions is therefore dissipated in a very small volume. As an example, the $^{7}Li^{3+}$ and $^{4}He^{2+}$ ions generated in the BNC reaction leave ionization tracks about 0.01 mm long or the equivalent of approximately one cell diameter. Thus, the high LET characteristic of particles produced by nuclear reactions that occur within tissue are especially lethal to affected cells because of the high density of deposited energy. Ideally, those cells that carry large numbers of ^{10}B nuclei are subject to destruction by BNC, while neighboring cells that are free of ^{10}B would be spared save for the contribution of the background $^{1}H(n,\gamma)^{2}H$ and $^{14}N(n,p)^{14}C$ reactions. In order to achieve this desired effect in BNCT, ^{10}B delivery should be as selective as possible to tumor tissue and should avoid normal tissue that will be subject to neutron irradiation. In addition, the actual concentration of ^{10}B in tumor must be sufficiently high to offer a localized binary therapeutic effect well above the background radiation dose delivered by the neutron capture processes of Scheme 3. The minimum ^{10}B concentration necessary for effective BNC has been repeatedly calculated and is generally accepted to be between 10 and 30 μg ^{10}B per g tumor depending upon the precise location of the ^{10}B with respect to vital components of the tumor cell structure. As the position of the ^{10}B nuclei is changed from the external cell wall to the cytoplasm to the nucleus of the cell, the required concentration of ^{10}B for effective BNCT decreases, as expected. Thus, if the ^{10}B is bound to the cell wall, 30 ppm or greater concentrations might be required, while if ^{10}B is localized within the nucleus of the tumor cell, a concentration of only 10 ppm or less might be required. Obviously, an additional factor is the steady state concentration of thermal neutrons in the targeted volume of tissue, since very low neutron intensities require proportionally longer irradiation times to produce the required number of BNC events for effective therapy. The quantification of the effective lethality of product particles or γ-radiation from neutron capture reactions is expressed in terms of their relative biological effectiveness (RBE) relative to γ-radiation. The RBE of particulate species or photons is expressed as the ratio of the energy dose of γ-radiation to the energy delivered by the particles or photons in question that accomplishes equivalent cell-killing or physiological damage to living tissue. While the precise values of RBE characteristic of commonly encountered particles and photons depend somewhat upon the conditions of the measurement, the heavy $^{7}Li^{3+}$ and $^{4}He^{2+}$ ions that arise from BNC have the commonly accepted (conservative) value of about 2.5 when taken together, (per neutron captured), although much higher values have been suggested. Similarly the products of the $^{14}N(n,p)^{14}C$ reaction are assigned an RBE of 2.7. Thermal (0.025 eV) neutrons themselves are relatively harmless (negligible RBE). The $^{1}H(n,\gamma)^{2}H$ reaction mainly contributes the energy of its characteristic γ-radiation (RBE of approximately 1.0) (Scheme 3). In practice, the total effective radiation dose delivered to a volume of tissue containing a fixed concentration of homogeneously distributed ^{10}B would be the sum of the energies delivered by each of the independent $^{1}H(n,\gamma)^{2}H$, $^{14}N(n,p)^{14}C$, and $^{10}B(n,a)^{7}Li$ reactions after multiplication by their respective RBE values. The ^{1}H and ^{14}N capture reactions obviously provide a radiation background upon which is superimposed the ^{10}B concentration-dependent (binary) BNC reaction.

The discussion thus far has centered upon the use of thermal neutrons as the applied neutron source, since their energy is sufficiently low for immediate nuclear capture to occur. However, the scattering of thermal neutrons as they encounter hydrogen atoms in tissue very seriously diminishes their availability at tumor sites located below the tissue surface.

Such deeply buried tumors can be addressed with BNCT by applying more energetic neutrons found in the 0.5 eV–1.0 keV region of the epithermal[10] range. Neutrons of this type are not sufficiently energetic to cause destructive ionization in tissue through hydrogen-recoil processes, but they are effectively slowed by continual encounters with H atoms in the media. These collisions are accompanied by the generation of heat, which is not destructive to tissue. However, as these epithermal neutrons pass through tissue, they will lose sufficient kinetic energy to become thermal neutrons and subject to capture by ^{10}B, ^{14}N, and ^{1}H nuclei. Thus, while directly applied thermal neutrons will give the maximum dose due to capture processes at the point of entry into tissue (zero depth), epithermal neutrons are not sufficiently slowed for effective capture until they have penetrated some distance into tissue.[10] This is the desired condition for noninvasive BNCT of deeply buried tumors.

Fast neutrons ($E > 10$ keV) are capable, through collision, of causing the ionization of hydrogen atoms from hydrogen-containing substrates, and in so doing, they create a severe type of radiation damage (hydrogen-recoil reaction).[11] This process is so biologically disruptive that an RBE as large as 5 has been suggested for fast neutrons.[12b] Fast neutrons are encountered as impurities in epithermal neutron beams, but they may be reduced in population by neutron beam moderation devices[13b] including specific band-pass filters. Whenever fast neutrons are present in a neutron beam used in BNCT, the effective radiation dose supplied by hydrogen recoil must be added to the total background dose supplied by the $^{1}H(n,\gamma)^{2}H$ γ-photons and the $^{14}N(n,p)^{14}C$ protons.

2.3. Neutron Sources for BNCT

2.3.1. Nuclear Reactors

As noted in Section 2.1, BNCT was conceptualized before a viable source of neutrons had been discovered. This restriction was lifted following the initial development of nuclear reactor technology in the 1940s, and Farr and Sweet could conduct the first clinical trials of BNCT with a thermal neutron beam in 1954.[7e] Epithermal beams have replaced thermal beams as the neutron source of choice for the reasons presented in Section 2.2.

It is currently believed that a dose (fluence) of 5×10^{12} epithermal neutrons per cm^2 will be required[14] for successful BNCT if every epithermal neutron is converted to a thermal neutron. To minimize the duration of patient exposure to the neutron source, reactors not less powerful than one megawatt would be required to achieve a clinically useful flux[14] of at least 10^9 neutrons per cm^2 per s. In addition, these epithermal neutron beams must be relatively free of both extraneous γ-photons and fast neutrons ($E > 10$ keV) and collimated to the greatest extent possible. Potentially, these therapeutic flux requirements could be met, in the United States alone, by approximately thirty-five nuclear reactors[15b] which could be modified for BNCT. Among the reactors of this type that have already been specifically dedicated for medical research are the Brookhaven Medical Research Reactor, the MIT (Massachusetts Institute of Technology) Research Reactor, the Georgia Institute of Technology Research Reactor, and the European Collaboration Reactor located at Petten, the Netherlands. The Power Burst Nuclear Reactor Facility located at the Idaho National Engineering Laboratory also has a reactor potentially capable of producing an intense therapeutic neutron beam if it were to be modified for BNCT research and therapy. The potential of epithermal neutron beams for the noninvasive therapy of internal tumors has yet to be fully realized; research efforts now underway promise the availability of such 1–1000 eV neutron beams with intensities of greater than 10^9 neutrons per cm^2 per s. The many interdependent variables that come into play in any actual BNCT experiment are the subject of extensive studies carried out by radiation physicists, radiation biologists, and nuclear reactor specialists, to name but a few. The interested reader is referred to the extensive work on computational modeling of BNCT radiation effects coupled with experimental verification exemplified by the pioneering work of Fairchild et al.[16b] at the Brookhaven National Laboratory, the work of Wheeler and Nigg et al.[17] at the Idaho National Engineering Laboratory, and Harling et al.[18] at MIT.

The fact remains that nuclear reactors are the only sources of thermal and epithermal neutrons available for research and clinical trials today. The limited number of potentially available reactors capable of clinical applications and the immobility of these reactors would limit the general usefulness of BNCT even if efficacious modalities for particular tumor types were developed. Consequently, the search for epithermal neutron beam sources other than nuclear reactors has begun.[19, 20]

2.3.2. Neutron Sources Other Than Nuclear Reactors

The development of BNCT as a generally available therapy depends upon securing a useful, safe, and relatively inexpensive epithermal neutron beam source that can be widely distributed in hospitals and medical centers located in populated urban areas. Research directed to this end is currently in progress.[19–21]

Collision of low energy protons, produced in an accelerator, with a lithuim target will produce epithermal neutrons. To secure epithermal neutrons for BNCT in this manner, proton currents would necessarily be high, and lithium target cooling problems would be severe. In addition, the high energy neutrons produced would require thermal moderation with materials such as D_2O. In an alternative procedure, the bombardment of heavy elements with high energy protons provides an array of neutrons whose energy distribution is generally richer in high energy neutrons than that observed in nuclear fission. These very energetic neutrons may be brought into the desired epithermal region through the use of moderating materials.

The synthetic nuclide, californium-252, is the only practical spontaneous neutron-emitter.[14, 22] This isotope has a half-life of 2.65 years. The neutron spectrum produced by ^{252}Cf decay is similar to that produced by a one megawatt nuclear reactor. Since it isotropically emits 2.3×10^6 neutrons per sec per μg, large (gram) quantities of this nuclide would be required to obtain the desired neutron

beam strength following thermal moderation and collimation, etc. The continual synthesis of large quantities of ^{252}Cf to fulfill the world's need of epithermal neutrons for BNCT would be a technically formidable and very expensive task, and, at the same time, would create a new set of international problems in nuclear safety and security.

The available sources of epithermal neutrons for BNCT based on the proton accelerator are now well understood in principle, and remaining problems are in the realm of engineering. Hopefully, these obstacles can be overcome, so that safe, economically viable neutron beams can become established in a variety of clinical settings.

2.4. Modeling BNCT for Clinical Applications

The interaction of the components of a specific neutron beam with the ^{10}B nuclei present in tumor, the normal tissues near the tumor, and the blood raise questions that must be answered before a complete BNCT system can be employed in actual therapy experiments. These questions concern the spatial distribution and effective dose (physical dose in rads × RBE = effective dose in rads or cGys) of each of the component radiation processes that came into play during the experiment and procedural matters such as choosing between a single-dose therapy mode versus the delivery of the required radiation dose in increments[10] (fractionation) with intervening time alotted for repair of radiation damage arising from low LET processes, principally γ-photon interactions. Since epithermal neutron beams are most desired because of their deeper tissue penetration, one must be able to quantify the effective dose contributed by the processes of Scheme 3 (γ-dose and nitrogen capture), fast neutron beam contaminant (H-recoil dose), and the $^{10}B(n,\alpha)^7Li$ capture reactions in both tumor (^{10}B tumor capture) and normal tissues (^{10}B tissue capture) as a function of depth and radial distance from the hypothetical neutron beam centerline.[10, 23] Precision is required in these calculations to avoid the delivery of a total effective dose to normal tissue that surpasses its ability to survive. The total effective dose that can be safely delivered to innocent tissues during tumor therapy limits the total effective dose that may be given to tumor. Blood and the vascularity associated with its distribution within the radiation volume present additional problems, which are now under scrutiny. As a general premise, one wishes to minimize the ^{10}B content of blood during therapy, and a high $^{10}B(tumor)/^{10}B(blood)$ concentration ratio is desired. However, in certain circumstances a tumor/blood concentration ratio for ^{10}B of unity is acceptable.[24] It is beyond the scope of this article to develop the reasons for, and the consequences of, these observations.

In order to approach the generalized problem of quantifying the effective radiation doses delivered to each point in the irradiated volume comprising normal tissues and tumor, use has been made of very refined microdosimetry measurements within phantom tissues during actual neutron beam irradiation. As an example, brain tumors (gliomas) have been popular subjects for study and consequently phantom human (and dog) heads have been constructed from acrylic polymers and provided with instruments for the determination of the effective doses from each of the various radiation sources encountered during neutron beam irradiation.[25] Due to the unique nature of each neutron beam employed, this procedure must be repeated for each beam in order to thoroughly characterize the flux and characteristics of its neutrons as well as the dose rate arising from indigenous γ-photon and fast neutron beam contaminants. After the complete characterization of the neutron beam and its interaction with tissue through the phantom procedure, one then employs these data using Monte Carlo methods for the description of neutron transport.[26] The resulting calculation of the therapeutic performance of defined concentrations of ^{10}B placed at various points within the phantom simulates the selective accretion of ^{10}B by tumor.[27] The concentration of ^{10}B simultaneously delivered to normal tissues within the radiation volume is usually assumed to be a definite fraction of the tumor ^{10}B concentration and to be homogenously distributed. Thus, a boron compound or boronated delivery system that provided a tumor/normal tissue selectivity factor of 10 would be assumed to be homogeneously distributed in normal tissue with a concentration of 2.5 μg ^{10}B per g tissue if the simultaneous tumor concentration were 25 μg ^{10}B per g. The performance of the therapeutic system is time-dependent, since each boron delivery system will have a characteristic biological half-life, and the concentration of ^{10}B in tumor, tissue, and blood will decrease with time.

Figure 1 is a graphical representation of the results of a typical BNCT simulation calculation supported by microdosimetry data obtained with a phantom human head.[28] The epithermal beam employed here is typical of those obtained from large multimegawatt reactors. Fast neutrons are present in the beam giving a significant H-recoil dose, while the beam is relatively free of significant γ-photon contamination. The beam port is 10 cm square. The hypothetical boron delivery system described above is used in the calculations; the concentration of ^{10}B in tumor and in tissue are 25 and 2.5 μg ^{10}B per g, respectively. The boron is assumed to be homogeneously distributed within both tumor and normal tissue. Blood is not treated as a separate tissue, but it is included in the normal tissue category. Recently, sophisticated treatments of expected damage rendered to the epithelial cells of the cranial capillaries due to the presence of ^{10}B in blood have been advanced.[24] The interesting result obtained is that sufficiently small capillaries with diameters similar to the 0.05 mm length of the ^{10}B fission fragment track are spared, because the effective ^{10}B concentration within them is reduced by their geometry and the simultaneous presence of the blood–brain barrier, which prevents the migration of the ^{10}B-containing species to positions behind the capillary endothelial cells. This effect can be incorporated into estimations of effective dose (rads × RBE) to normal tissue by using a reduced value for the RBE of the $^{10}B(n,\alpha)^7Li$ reaction in normal brain tissue that is 0.33 rather than 2.5. The higher value of the RBE was used in the construction of Figure 1, which represents the worst possible case for glioma therapy, but fairly approximates the results to be expected in the therapy of tumors located outside the cranium.

Curve C in Figure 1 (total effective dose rate to tumor) clearly shows a maximum at a depth of 2 cm. Normal tissue would also receive a maximum total effective dose rate near

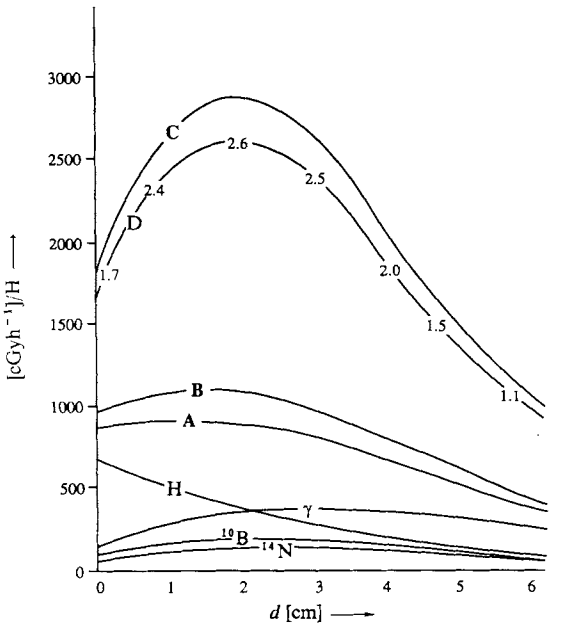

Fig. 1. Graphical display of the relative effective dose rate I of component energy imputs as a function of depth in tissue d, viewed on the centerline of a hypothetical epithermal neutron beam that impinges upon a human head. RBE values employed in these calculations were as follows: $^{10}B(n,\alpha)^7Li$ 2.5, $^{14}N(n,p)^{14}C$ 2.7, H (H-recoil from fast neutron-beam impurity) 5.0, and γ-photons contributed by $^1H(n,\gamma)^2H$, $^{10}B(n,\alpha)^7Li$, and beam impurity photons 1.0. The curves labeled ^{14}N, γ, and H refer to the contributions of the individual processes to the background radiation dose rate as a function of depth in tissue. The curve labeled ^{10}B is the contribution from 2.5 μg of ^{10}B per gram of tissue homogeneously distributed throughout normal tissue. Curve A is the sum of curves ^{14}N, γ, and H, while in curve B the dose rate provided by ^{10}B in normal tissue (Curve ^{10}B) is added. Curve C is the sum of the dose rate provided by 25 μg of ^{10}B per g of tissue homogeneously distributed in tumor and the background dose rate of curve A. The therapeutic gain (curve D) at any depth is obtained by dividing the dose rate of curve C by the maximum of curve B (1100 cGy h^{-1}). See the discussion for details.

2 cm in depth; thus, the total effective dose rate of approximately 1100 cGy h^{-1} in normal tissue would deliver the maximum allowable total effective dose for normal brain of about 1300 cGy (or 13 Gy) in approximately 71 minutes if the ^{10}B concentration remained unchanged throughout this irradiation period. Regardless of the tumor depth, the 71 minute irradiation period and the appropriate total effective dose rate for tumor (Curve C) would determine the total effective dose that could be given to the tumor site. For example, this dose is equal to 2200 cGy $\times$ 71/60 $\approx$ 2600 cGy at a tumor depth of 4 cm, while the corresponding value at 2 cm is 3500 cGy.

The efficacy attained in a particular BNCT experiment is defined as the dimensionless parameter known as therapeutic gain[27c] and defined as the total effective dose rate available to tumor at a specified depth (Curve C) divided by the maximum total effective dose rate delivered to normal tissue (Curve B). Thus the therapeutic gain at a depth of 2 cm is 2900 cGy h^{-1}/1100 cGy h^{-1} $\approx$ 2.6. At a tumor depth of 4 cm this value is 2200/1100 $\approx$ 2.0. In practice, therapeutic gain values less than 1.2, that is, at a depth greater than 5.5 cm in the example of Figure 1 (see Curve D), would probably not be considered to be useful. Since effective dose rates and exposure times must be computed prior to therapy, knowledge of the tumor's position must be accurately determined along with the concentration of ^{10}B in both tumor and normal tissue. These data, when combined with the biological half-life of the ^{10}B delivery system, permit dosimetric calculations to be made to determine the length of the neutron radiation period. The safety and convenience of the patient as well as the effect of ^{10}B loss from the tumor with time suggests that the beam exposure time must be minimized. Thus large reactors are required to provide the necessary optimized flux of greater than 10^9 epithermal neutrons per cm^2 per s. Calculations show that a single irradiation of 5×10^{12} thermalized[14] epithermal neutrons per cm^2 would provide the desired therapeutic dose.

Thermal neutron beams have not been treated in this article, since it is apparent that the analog of Figure 1 would contain total effective dose vs depth curves that have their maxima at the surface and decay rapidly with depth in tissue. While thermal neutron beams comparable in flux to the epithermal beam of Figure 1 provide therapeutic gain values greater than 2 at the surface, this parameter rapidly decreases to the useful limit of 1.2 at about 2 cm depth. These observations clearly support the need for epithermal neutron beams of high flux derived from a large nuclear reactor or an as yet unavailable proton accelerator discussed above (Section 2.3.2).

It is important at this point to compare the radiation damage mechanism of the $^{10}B(n,\alpha)^7Li$ process with that produced by the more conventional radiation source, γ-photons.[29] Conventional γ-photon doses of therapeutic significance result from an average of tens of thousands of γ-photon-initiated ionization tracks per cell, and stochastic principles do not apply since the γ-photons are presented to the tumor target cells in a homogeneous manner. On the other hand, BNC provides a therapeutic 10 Gy dose of about 25 high LET events per cell. Damage resulting from nonlethal doses of γ-photons is reparable with time, whereas the extreme damage per BNC event is not reparable, since heavy α and ^7Li fission products with a high LET are involved. The average number of BNC events per cell during a fixed exposure period will vary with the depth of the cell and the spatial distribution and concentration of ^{10}B nuclei within cells.[30] Since the ranges of the α and ^7Li fission products are short in tissue and comparable to one cell diameter, the response of individual cells will vary with intra- and intercellular distribution of ^{10}B and target cell geometry. Consequently, stochastic effects are of great importance in BNCT. If ^{10}B can be placed in or near a vital cellular component such as the nucleus, the number of BNC events required for cellular death is greatly reduced. ^{10}B that resides in the intercellular volume or on external cell walls is much less effective. Thus, the most highly prized boron compounds and associated delivery systems are those that enter the cell and bind to intracellular components. Furthermore, the visualization of boron within individual cells has great importance as an aid to boron compound design.

In addition to the heterogeneous nature of the ^{10}B distribution within and immediately surrounding individual tumor cells, additional heterogeneity introduced by the actual tumor morphology must be recognized. Large tumors are often characterized by a necrotic center that is poorly nourished surrounded by a vasculature that is capable of supplying nutrients for rapid peripheral tumor growth. This peripheral array of blood vessels is pressed into service as rapidly

as it can be created. As a consequence of this type of tumor growth and morphology, considerable macroscopic heterogeneity exists within the BNC target volume. The resulting gross inhomogeneity of ^{10}B distribution must be quantitatively evaluated and taken into account during therapy experiments and in the in vivo evaluation of new boron compounds and their associated delivery systems.

2.5. Methods of Analysis for Boron Pertinent to BNCT

Analytical methods for boron required for BNCT research, boron compound evaluation, and eventual clinical applications span a broad spectrum of useful and some not yet perfected procedures. These include the macroscopic and noninvasive estimation of ^{10}B concentrations in tumor and surrounding tissue with ^{10}B magnetic resonance imaging (MRI), which is under development, and the microscopic visualization of ^{10}B localization in tumor and tissue sections with α-track autoradiography. Intracellular boron distribution and quantification is another subject that has begun to yield important results. These and other related subjects are discussed in the following sections.

2.5.1. Noninvasive Macroscopic Estimation of ^{10}B Concentrations In Vivo

As pointed out above, safe and effective BNCT requires knowledge of the tumor's location, the concentrations of ^{10}B in tumor, blood, and normal tissues, and the rate at which the ^{10}B-containing species is eliminated from these biological compartments. Noninvasive methods for both tumor visualization and the determination of ^{10}B concentrations will be required. In principle, a chemically stable radiolabel having suitable characteristics for imaging and attached to a small fraction of the ^{10}B compound in question[31] could be employed, coupled with planar imaging as well as single photon emission computer tomography (SPECT) to visualize the compound in both primary and secondary metastatic tumors.[32] However, each double-labeled ^{10}B delivery system introduces complications and time constraints that are best eliminated.

Very recent research has explored the potential capability of NMR-active ^{11}B and ^{10}B nuclei in MRI and in the determination of the boron content of tumors loaded with the appropriate isotope. ^{1}H NMR imaging would be employed as an adjunctive modality. Continued development of this technique has achieved some success[33-36] with the more responsive ^{11}B nucleus, and the ^{10}B nucleus may prove to be useful in the near future. It may eventually be possible not only to locate tumors with $^{10}B/^{1}H$ MRI methods, but also to visualize in a quantitative fashion the local ^{10}B concentrations in tumor and normal tissue. These analytical methods would be noninvasive, relatively rapid, and involve the ^{10}B BNCT target nuclei as the signal-generating species. The reader is referred to the original literature[33-36] for the details of this developing technology.

2.5.2. Methods for the Macro and Micro Determination of Boron in Biological Samples

The need exists to determine accurately the concentration of boron present in biological research samples taken at biopsy and tissues obtained from animal biodistribution experiments. Such samples are often available in macroscopic quantities of 50 to 100 mg or more. Following the oxidative dissolution of weighed tissue samples, boron analysis of the aqueous sample is accomplished with the newly developed, inductively coupled or direct current plasma–atomic emission spectroscopy (ICP–AES[37] and DCP–AES,[38] respectively) methods. These AES methods determine boron in tissue reliably at levels of 1 ppm. Extension of this method to microscopic tissue samples of 1 mg obtained by needle biopsy is feasible with a modified sample preparation procedure.

An alternative to ICP-AES and DCP-AES for the analysis of biological samples utilizes the quantification of the prompt γ-photons emitted during thermal neutron capture by the ^{10}B present in the sample,[39-41] and comparison of the result with calibration measurements. This method requires a source of thermal neutrons and lacks the precision at low ^{10}B concentrations characteristic of the plasma–AES methods.

2.5.3. The Visualization and Microdosimetry of Boron in Biological Specimens
