The discussion of the stochastic nature of the inter- and intracellular BNC processes in Section 2.4 pointed up the need for experimental methods capable of providing the spatial distribution of boron in tumor and surrounding tissue sections taken from experimental animals or humans at biopsy. The inhomogeneous structure of tumors makes such studies vital to the understanding of the effectiveness of candidate boron-containing compounds in reaching individual tumor cells in the tumor structure. The α-track autoradiography method[42, 43] is ideally suited for this purpose. The procedure involves the placement of very thin (6–10 μm) tissue sections upon nitrocellulose sheets followed by exposure of the array to a thermal neutron source. The high LET α and ^{7}Li products of the resulting $^{10}B(n,\alpha)^{7}Li$ reaction that are generated within the tissue sample sensitize the nitrocellulose for hydrolytic attack by strong aqueous base. Because of the limited track range of these particles and their high LET characteristics, individual neutron capture events are recorded and converted into visible tracks on the base-developed nitrocellulose film. Superposition of this track data upon that obtained from conventional optical representations of the same tissue section gives the relative density of ^{10}B nuclei with respect to the histology of the sample. By using calibration samples, this method can also be employed to obtain the ^{10}B concentration in tissue from track density data at ^{10}B concentrations as low as 1 μg per g sample.[44]

In addition to conventional histological samples taken from tumors, the α-track radiographic method has often been applied to whole-body cross sections of experimental mice and rats.

2.5.4. *Techniques for Imaging Boron on a Subcellular Scale*

The design of new boron-containing drugs and the elucidation of their associated tumor localization mechanisms could best be served if the movement and relative concentration of the drug within the targeted tumor cells could be followed in time-course experiments. The importance of such a capability to drug design derives from the fact that the most effective drugs will be those with the ability to enter tumor cells and bind with the cytoplasm, organelles, or even the nucleus. For example, if one were to synthesize a candidate DNA-binding boron system, it would be important to confirm this proposed intracellular targeting by direct observation of boron within the cell nucleus. At present, methods for such subcellular imaging have demonstrated their usefulness in specific examples and await further development.

The first method referred to here is the secondary-ion mass spectroscopic (SIMS) microscopy method,[45, 46] which may be applied to the quantitative determination of boron in single, freeze-fractured and dried, boron-containing cells taken from culture. This method has been applied to the imaging of cells targeted by efficacious boron drugs; it has a spatial resolution of 1 μm.

The second method is electron energy loss spectroscopic (EELS) imaging,[47] which employs elemental mapping with an analytical electron microscope or an energy-filtering transmission electron microscope. Preliminary results for boron with EELS have been reported,[48] but as in the case of the SIMS method, further development is required before this method of drug evaluation becomes generally useful.

3. Early Clinical Trials of BNCT and the Related Search for Suitable Boron-Containing Target Species

3.1. Initial Clinical Investigations (1951–1962)

The idea of actually applying Locher's binary BNCT concept[6] to medicine originated[49] with William H. Sweet, neurosurgeon at the Massachusetts General Hospital (MGH), Boston, and L. E. Farr, of the Brookhaven National Laboratory (BNL) Medical Department. Sweet and Farr proposed to improve the prognosis for brain tumor patients by employing BNCT to destroy the fibrils of residual tumor cells, which always remained following radical surgery to remove the accessible tumor.[50, 51] This procedure would remove the fibrils as foci for the reestablishment of the tumor. The life expectancy of patients with such malignant gliomas was usually less than six months, even with surgery. The fact that gliomas did not metastasize, the protection provided normal brain by the blood–brain barrier, and the resistance of these malignancies to all known forms of chemo- or radiotherapy made them excellent candidates for BNCT trials.

Earliest thoughts regarding the enhancement of distribution ratios for boron compounds in tumor and brain evolved from the concept that cerebral gliomas were accessible to the blood or "wet" side of the blood–brain barrier and would thus favor the uptake of hydrophilic species, while normal brain was relatively "dry" and less hydrophilic. Therefore, hydrophilic, nontoxic species were sought.[52]

Volunteer patients undergoing neurosurgical biopsy or resection were found to tolerate sodium borate ($Na_2B_4O_7$) in concentrations of up to 200 mg per kg body weight without severe side effects.[53] Biodistribution and time-course data indicated that shortly after intravenous injection of borate the concentration of boron in tumor was three times that found in normal brain and could be as high as 50 μg per g tumor. Boron was present in blood at concentrations as high, or higher, than those found in tumor.

Initial clinical trials were conducted by Farr and Sweet in 1954 with a thermal neutron beam from the Brookhaven Graphite Research Reactor and ^{10}B-enriched sodium borate on ten patients with glioblastoma multiforme.[54] Five patients received a single radiation dose, and five received multiple fractionated doses. No statistical prolongation of life was achieved. In 1959 the then new Brookhaven Medical Research Reactor was employed to treat sixteen more patients[55, 56] with ^{10}B-enriched borates as the target species. As before, no enhancement of survival times was observed, nor was α-particle-induced radiation damage observed in patients' brains at autopsy.

In the early 1960s the MGH/MIT Reactor, complete with a surgery located below a thermal beam port, became operational. Also during the 1950s and early 1960s, boron compounds were synthesized by several research groups and evaluated by Soloway et al.[57] of the MGH, who used murine models such as implanted ependymoblastomas for biodistribution experiments and time-course experiments. Many of the approximately 140 compounds evaluated by Soloway et al. were substituted phenylboronic acids (including 4-dihydroxyborylphenylalanine (BPA), which is of great interest today (see Section 7.9.1). During this same period the polyhedral borane anions $B_{10}H_{10}^{2-}$[58] and $B_{12}H_{12}^{2-}$[59] were discovered and their derivative chemistry extensively explored. In addition, the icosahedral carboranes[60] *closo*-1,2- and *closo*-1,7-$C_2B_{10}H_{12}$, were synthesized and derivatives prepared. The unusual kinetic stabilities of these polyhedral ions and carboranes immediately made them and their derivatives attractive candidates as BNCT target compounds. These developments coincided with the beginning of a new area of inorganic cluster chemistry. This subject is more fully described in Section 5.

Soloway evaluated the salt, $Na_2B_{10}H_{10}$, as a potential BNCT target species in animals and humans. Large quantities of $Na_2B_{10}H_{10}$ could be administered by intracarotid injection to humans (LD_{50} 1.0 g per kg in C3H mice) and later recovered and identified by ^{11}B NMR in urine specimens. In another experiment with CD1 Swiss mice[61] (male), the observed LD_{50} of $Na_2B_{12}H_{12}$ was 1025 ± 15 mg per kg body weight. Toxicity of the polyhedral ions was low, whereas the substituted phenylboronic acids often presented toxic reactions in animals.

Two boron compounds in ^{10}B-enriched form, 4-carboxyphenylboronic acid and $Na_2B_{10}H_{10}$ were chosen for a new set of human trials to be carried out at the MGH/MIT Reactor and MGH during 1961 and 1962. Eighteen patients[62] were subjected to a tumor "debulking" procedure, which removed extraneous tumor tissue and opened the skull for exposure to the poorly penetrating thermal neutron beam.

Two of these patients were given $Na_2{}^{10}B_{10}H_{10}$[*] by intracarotid injection, while sixteen received ^{10}B-enriched 4-carboxyphenylboronic acid. Patients were irradiated after reopening the craniotomy site. Again, no therapeutically useful effect was observed, and patients died between 10 days and 11.5 months post-irradiation. Neuropathological examination of patients at autopsy indicated radiation necrosis with vascular lesions of different types in the brains of 9 of 14 patients.[62] The cause of these effects was attributed to high concentrations of boron in blood at the time of neutron irradiation. Henceforth, it was thought to be desirable to employ boron reagents that were selectively accreted by tumor to ensure a mininal boron concentration in blood at the time of neutron irradiation. A second generation of candidate compounds were synthesized both by Soloway and by workers at the Du Pont Central Research Laboratory with this objective. For the most part these compounds were designed to function as tumoristatic alkylating agents or compounds capable of other covalent-bond-forming reactions with protein, and were based upon polyhedral borane anion[58, 59] and carborane[60] structures. The reader is referred to Sections 5.0 and 7.1 for a fuller description of these species. Of the compounds evaluated in biodistribution studies by Soloway for selective tumor accretion and effective clearance of the vasculature, the sodium salts of $B_{12}H_{11}SH^{2-}$ and 1,10-$B_{10}Cl_8(SH)_2^{2-}$ stood out,[61] but only the former salt was sufficiently nontoxic (LD_{50} in male CD1 Swiss mice was 73 ± 4 mg per kg body weight) to warrant further study. It was given the acronym BSH.

3.2. The Emergence of a BNCT in Japan: Hiroshi Hatanaka and $Na_2B_{12}H_{11}SH$

After spending several years at the MGH working with the BNCT team headed by Sweet, the neurosurgeon Hiroshi Hatanaka returned to Japan in 1968 and created a new chapter in the BNCT story. Hatanaka initiated a clinical trial with Japanese glioblastoma patients using ^{10}B-enriched BSH and primitive thermal neutron beams of low intenisty, which were available in the Tokyo area. The Shionogi Research Laboratories, Osaka, supplied $Na_2{}^{10}B_{12}H_{11}SH$ for these studies and synthesized the sodium salts of 1- and 2-$B_{10}H_9SH^-$ as alternatives (see Section 7.1).

The procedure developed in Japan was similar to that employed by Sweet in the 1961/1962 clinical trials. Patients with tumors near the periphery of the brain underwent a craniotomy followed by surgical debulking of the tumor mass. One to two weeks following this procedure the patients were given an intracarotid infusion of ^{10}B-enriched BSH at dosages between 30 and 80 mg per kg body weight delivered over one to two hours. Approximately twelve hours later, the cranium was opened and the surgical site exposed for thermal neutron irradiation. Only reactors of low flux were available (10^9 neutrons per cm^2 per sec), and irradiation times were of the order of three to five hours on a patient under remotely controlled anesthesia. Protection of the scalp was necessary to prevent radiation damage, since skin contained a moderate concentration of ^{10}B. Tumor samples taken at the time of irradiation indicated the presence of 13 to 60 μg ^{10}B per g tumor. The boron concentration in normal brain was not measured.[63] Because thermal neutrons were necessarily employed in these studies, penetration of the beam in tissue was less than 6 cm due to neutron scattering and attenuation.

Hatanaka's work has been published and widely discussed.[63–66] Noteworthy is the fact that no necrosis of the normal brain was observed, except in one atypical patient, who received an extraordinarily large neutron dose. This suggests that BSH was cleared from the blood before neutron irradiation commenced. However, recent work by Gavin et al.[24] suggests that the small diameter of the capillary vessels in normal brain coupled with the intact blood–brain barrier at all points other than tumor interfaces is the criterion for the blood-vessel-sparing mechanism, which effectively reduces the apparent boron concentration in blood. BSH is a small hydrophilic anion that does not cross the blood–brain barrier; its apparent inability to do so must also be related to its moderately strong complexation with high molecular weight proteins present in blood serum[67] that also do not penetrate the blood–brain barrier. This process was discussed above in Section 2.4. In general, the patients of Hatanaka fared well considering the deadly nature of their disease.[14] Of thirty-eight patients with Grade III and IV glioblastoma multiforme who were treated and twelve with tumors in the cerebral mantle less than 6 cm from the cortical surface, the reported mean survival was 44 months, and the median was about 26 months. Among them are several long term survivors: a man now 65 years old is alive and unaffected twenty years later; a 70-year-old woman and a 13-year-old girl also appear to be completely cured.

Hatanaka's results are remarkable, but they have stimulated some criticism within the medical community. The questions raised are centered about the consistency of data collection regarding patients and procedures, and the poor performance of the neutron beams that had to be employed. One must realize that Hatanaka demonstrated the efficacy of BNC in glioma therapy under conditions that were far from ideal. It is clear that thorough documentation could have been obtained if greater resources had been available.

The demonstration that BSH could be successfully applied as a target compound in the BNCT of glioblastoma multiforme has stimulated an international effort with this species as the centerpiece. Research groups located in the EC countries and others associated with the Idaho National Engineering Laboratory have initiated detailed pharmacokinetic studies of BSH with the aim of elucidating the mechanism responsible for its accretion in cerebral gliomas. Other studies pertain to the use of BSH in neutron irradiation experiments with large animals and its pharmacokinetics in humans. Clinical trials are being prepared in which the European consortium will employ the Petten reactor with BSH.

One complication in the use of BSH in therapy is the ease with which air-oxidation, perhaps catalyzed by traces of redox-active metal ions, takes place to form the disulfide dimer $[B_{12}H_{11}S]_2^{4-}$ and the corresponding oxodisulfide.[68, 69] Animal experiments have shown the former ion to be superior to BSH in tumor accretion,[70] but much more

[*] ^{10}B in constitutional formulas is used here to indicate that the compound contains 95–96% ^{10}B. See Section 5.1.

toxic. A blue, reactive radical is observed in acidified aqueous solutions of the disulfide ion.[68, 69] These oxidation reactions may be necessary in vivo to establish the presumed covalent coupling of BSH to cysteine residues. The reader is referred to Section 7.1 for futher information. These same reactions require tedious purification of BSH used for drug purposes. However, at the present time BSH is the only acceptable boron target compound that could be used today in clinical trials in Europe or the USA. As we shall see, other suitable target species are under rapid development, but BSH will probably remain as the baseline compound for clinical studies conducted in the immediate future.

4. Chemical Intermezzo

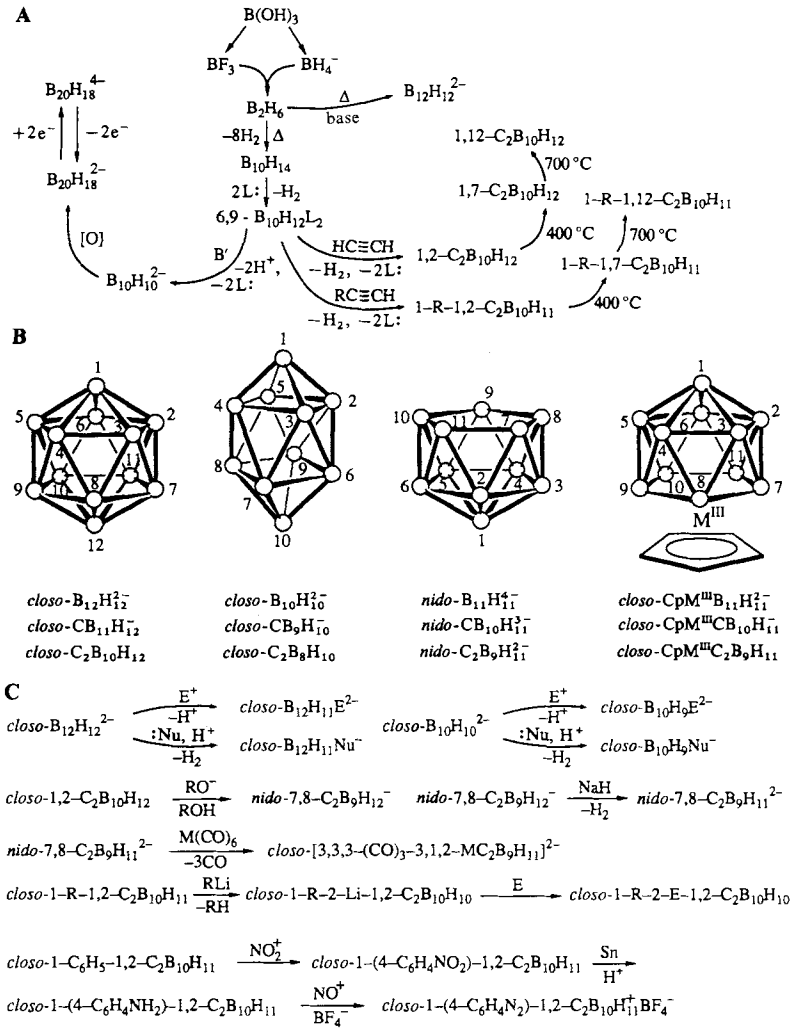
With the exception of certain of Hatanaka's patients, BNCT has thus far not proven to be an outright success. Aside from the rationale that relates the probable success of BNCT to the level of development of radiation oncology, the characteristics of available neutron beams, or the sophistication of dosimetry, the key to success was, and remains, the availability of nontoxic boron target compounds that selectively accumulate in neoplasms as opposed to normal tissues. The synthetic chemist encounters a major problem in the logical development of these useful neutron target species: the paucity of quantitative and even qualitative information pertaining to the chemical and biological differences between malignant and normal cells. Such information is vital, since these differences identify possible pathways for the selective uptake and retention of boron by tumor cells. However, two important areas of existing clinical practice make use of such tumor cell differentiation: chemotherapy and the radioimmunoimaging of tumors. Chemotherapeutic drugs are evaluated for their ability to kill cancer cells selectively without great concern for the concentration differences between malignant and neighboring normal tissues, since the effective differentiation between cancerous and normal cells is based upon disparate cell reproduction and metabolism rates. The precision of radioimmunoimaging techniques now available is possible, because radiopharmaceuticals, through their attachment to monoclonal antibodies, can differentiate between normal and tumor cells with such exquisite selectivity that high tumor-to-normal-cell concentration ratios are attained while the actual concentration of the radiopharmaceutical in tumor is miniscule.

Ideally practiced, BNCT requires even more demanding characteristics: the selectivity for tumor displayed by immunomediated radiopharmaceuticals coupled with concentrations of tumor-bound boron drugs greater than those used in chemotherapy and persisting in tumor for a period sufficient for effective neutron irradiation to be safely accomplished. Toxicity issues must also be controlled. Thus, the initial challenges to the chemist are: 1) identificaton of biodelivery (bioutilization) pathways that effectively differentiate between the targeted tumor and other tissues, and 2) design and synthesis of boron compounds that may be coupled to these biodelivery systems without serious compromise of biodelivery performance, but that maintain at least the lowest practical concentration of ^{10}B in tumor required for therapy (approximately 10^9 target atoms per cell). In addition, boron must accumulate in tumor, while its concentration in blood is simultaneously minimized. If these challenges can be met, the use of the blood–brain barrier to augment tumor cell differentiation is no longer necessary, and BNCT can be increased in scope to include malignancies other than cerebral gliomas. Thus, tumors such as melanoma, lymphoma, adenoma, sarcoma, and others, as well as their metastases, become candidate diseases for BNCT with epithermal neutron sources.

5. The Timely Discovery of Modern Borane Chemistry

The development of BNCT research beyond the level of effort seen in the 1950s is due to the discovery of new boron chemistry in the late 1950s and early 1960s that exceeded the greatest hopes of the chemists involved with the earliest clinical trials of BNCT. The discovery of whole new families of polyhedral borane derivatives that were stabilized by three-dimensional electron delocalization, and also capable of being incorporated into organic molecules as substituents, allowed the concept of BNCT to survive the early clinical trials that were conducted with inappropriate boron compounds and to progress to its present promising status.

These first aromatic polyhedral borane species to be discovered were the predicted icosahedral *closo*-$B_{12}H_{12}^{2-}$ ion[59] and the unpredicted *closo*-$B_{10}H_{10}^{2-}$ ion[58, 71] having the structure of a bicapped, square Archimedian antiprism. These ions were soon followed by the icosahedral *closo*-$C_2B_{10}H_{12}$ carborane isomers,[72, 73] which are isoelectronic and isostructural with the *closo*-$B_{12}H_{12}^{2-}$ ions. Other polyhedral anions of the general formula *closo*-$B_nH_n^{2-}$ were discovered, and the entire family with $n = 6$ through 12 became available.[74] Similarly, other *closo*-$C_2B_{n-2}H_n$ carboranes, likewise with $n = 6$ through 12, were synthesized.[75] These carborane molecules reacted with organic molecules, and isomers could be generated by movement of the polyhedral carbon atoms[72, 75] relative to each other over the polyhedral surface (polytopal rearrangements). Later research uncovered the corresponding *closo*-$CB_{n-1}H_n^-$ carborane series,[76, 77] whose members also form organic derivatives. Metallacarboranes in which one or more BH vertices of carboranes is replaced by a metal vertex were soon discovered,[78, 79] as were the corresponding metallaboranes.[80] The familial relationships of these and many other borane cluster derivatives have been integrated with chemical bond theory[81] and served as a generalized basis for the evolution of inorganic cluster chemistry[82] as a whole. The scope of modern boron chemistry extends far beyond the boundaries suggested here, and the interested reader is referred to specialized reviews of the many aspects of borane cluster chemistry.[83, 84] These seminal discoveries in inorganic and organometallic chemistry have made the search for effective BNCT compounds a feasible proposition, since these borane cluster compounds offered high boron content, excellent kinetic stabilities, and relatively simple derivativization for incorporation in organic molecules. Scheme 4 outlines several major features of borane cluster interconversions and some numbering conventions.



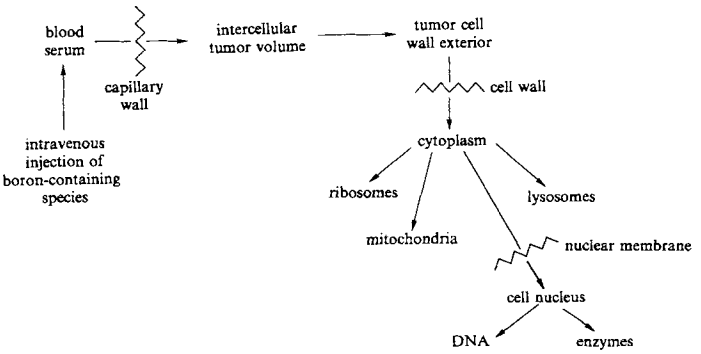
Scheme 4. An abbreviated presentation of some highlights of contemporary boron cluster chemistry of potential importance to BNCT. **A**: syntheses; **B**: structures; **C**: reactions. B′ = base, E = electrophile, :Nu = nucleophile, L: = ligand.

5.1. The Synthesis of ^{10}B-Enriched Species Required for BNCT

Scheme 4 is an abridged depiction of the familial relationship of the most accessible borane and carborane species that have been, or could be, employed in the synthesis of BNCT reagents. To achieve their full potential as ^{10}B delivery vehicles these building-block molecules must be enriched in the ^{10}B isotope. Enrichment to 95–96% ^{10}B is commonly employed, because the boric acid starting material is commercially available at this level of isotopic purity. In Scheme 4, diborane, $^{10}B_2H_6$, is the key intermediate for the synthesis of the three major families of ^{10}B-enriched borane derivatives: $^{10}B_{10}H_{10}^{2-}$, 1,2-$C_2{}^{10}B_{10}H_{12}$, and $^{10}B_{12}H_{12}^{2-}$ (see Scheme 4). Since the majority of the species that comprise the armamentarium of BNCT research may be derived from one of the three precursors described above, the requirement for ^{10}B-enrichment does not present difficulties, but considerable additional costs may arise from the purchase of commercially available ^{10}B-enriched compounds. The need for ^{10}B-enrichment should be considered in the design of synthesis routes for new compounds.

6. Classes of Boron Compounds and Bioutilization Pathways of Current Interest

Although it may be possible to administer boron-containing target species to animals and humans by oral or perilesional pathways, the majority of boron biodistribution data are collected following intravenous injection of the experimental compound. The diagram presented in Scheme 5



Scheme 5. A greatly simplified representation of the transport pathway required to bring a boron-containing species from the point of intravenous injection to the interior of a cell nucleus.

traces the possible pathway of a hypothetical boron-containing species as it approaches, binds, and later enters a tumor cell. As previously pointed out, the lethal potential of a ^{10}B nucleus increases markedly after entering the cell, and again after approaching the nucleus. Nuclear DNA is the target of greatest value, because in this case, only a single high LET neutron capture event within the DNA would be lethal to the cell.

The earliest attempts to correlate molecular structure and biodistribution of boron compounds[57] were concerned with cerebral gliomas, normal brain tissue, blood, and the influence of the blood–brain barrier. Now that tumors other than those related to the brain are under investigation as BNCT subjects, a wider variety of tumor morphological and metabolic features are considered in the development of new boron carriers.

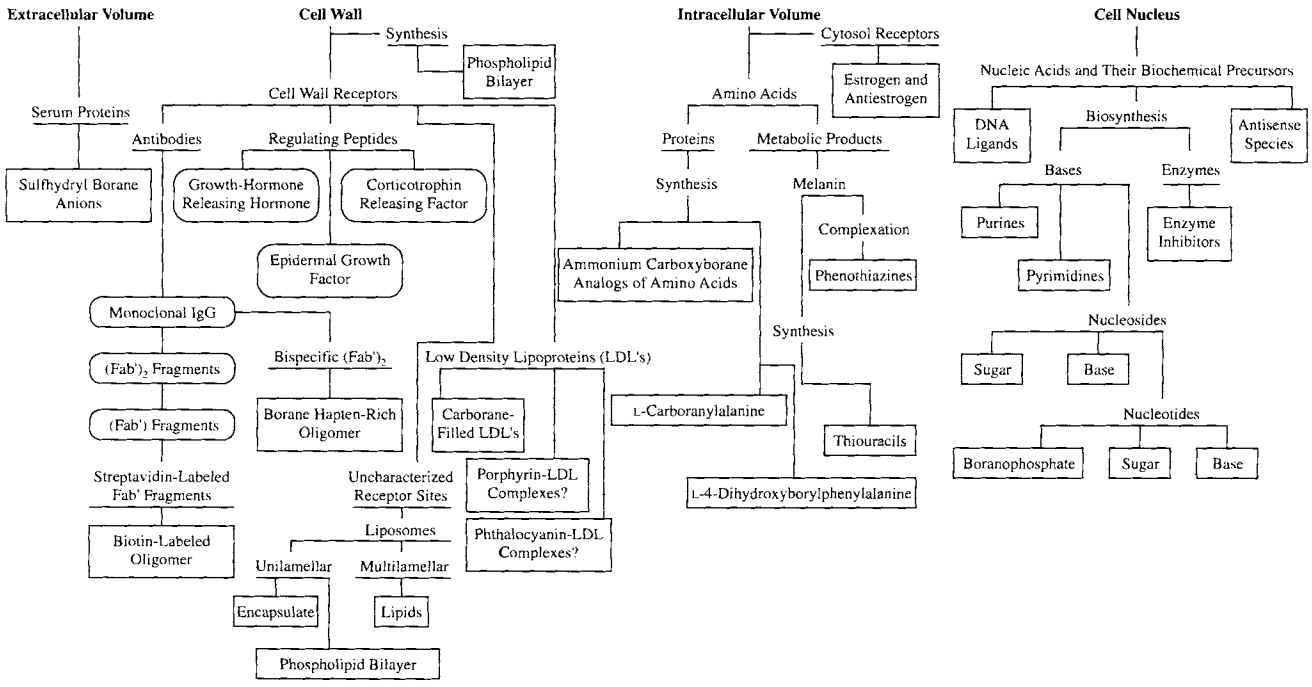
Carrier species under investigation today for the delivery of boron to some particular locus of the targeted tumor cell may have been designed to enter a specific bioutilization pathway as a mimic of a known cellular constituent or metabolite. Other molecules, exemplified by monoclonal antibodies and their fragments, are selectively bound to tumor-cell receptor sites in the plasma membrane that are either overexpressed or uniquely expressed by tumor cells as opposed to normal cells. Such receptor-mediated molecules may be conjugated with boron-containing reagents and converted into very selective boron carriers. Small vesicles such as synthetic liposomes or modified low-density lipoproteins (LDLs), while not of molecular dimensions, may be employed as boron-carriers of a different type. Finally, some simple molecules such as porphyrins have proved to be useful for accumulation of boron in tumor (also termed boron localization), although the biological basis of this utility has not yet been clearly defined. Scheme 6 matches currently important boron-containing compounds with the biosynthesis of specific cellular components or the utilization of their characteristic receptors for BNCT. These items are found in the extracellular volume, the cell wall, the intracellular volume, and the cell nucleus.

6.1. A Brief Overview of Biodelivery Schemes

Molecular mimicry is employed in the design of compounds that may serve as boron-containing substitutes for molecules normally used in cell construction and metabolism. Species of this type have been employed, or proposed for use, in cellular phospholipid[85] and protein synthesis.[86] In addition, L-dopa surrogates[87] are under investigation for incorporation in melanin synthesis by melanotic melanoma cells.

Recent advances in nucleic acid chemistry have stimulated efforts to incorporate boron-containing base molecules, nucleosides, and nucleotides in target cell DNA or its precursors during biosynthesis.[88] The interaction of boron-containing "antisense" nucleotides and DNA ligands[89] with existing nuclear DNA molecules provides related avenues to the radiologically vulnerable nucleus.

Specialized molecules that, after attachment of boron-containing entities, bind with specific receptor sites of the tumor cell wall are also assumed, for the most part, to be endocytosed by the tumor cell. In some examples the receptor site is regenerated. This selective boron internalization process has broad scope and presents the capability of bringing a particular type of tumor cell under either successive or simultaneous attack by more than one type of receptor-specific boron carrier. An example would be two or more immunoglobulins targeted for different antigens which are



Scheme 6. A classification of boron-delivery vehicles based upon their method of incorporation into one of four biological compartments; extracellular volume, the cell wall, intracellular volume, and the cell nucleus. These assignments are subject to change as further progress is made. □: boron-containing species; ○: conjugate of a boron-containing reagent.

simultaneously expressed by the same tumor cell. The multiple attack, in principle, amplifies the effective concentration of ^{10}B nuclei associated with specific cell types.

The requirement of 10^9 B atoms per targeted cell for effective BNCT is difficult, but not impossible, to achieve by using individual molecules as the carrier species. However, organized aggregates of boron-rich molecules may enter delivery mechanisms specific to tumor cells and bring relatively huge quantities of boron to targeted cells with each delivery event. Such "supertanker" systems known at present are unilamellar liposomes[90] containing polyhedral borane anion solutes within the liposome's aqueous core and reconstituted LDLs in which the natural cholesteryl esters have been replaced with hydrophobic esters derived from carborane.[91] The reconstituted LDLs retain their ability to bind LDL receptor sites of tumor cells and become internalized through the still-functional apoprotein B-100 attached to the original LDL. Cell differentiation is observed, since compared to normal cells LDL receptor sites are extravagantly expressed on growing tumor cells. While the precise mechanisms responsible for selective liposome localization are presently unknown, receptor sites amenable to liposome binding and internalization must surely exist, since it is possible to observe fluorescent species[92] within tumor cells following their in vivo delivery by liposomes. Furthermore, the results obtained with boron-containing liposomes are understandable only if liposomes are selectively internalized by tumor cells. The liposome cell differentiation process is thought to be based upon the immature ad hoc vasculature unique to rapidly growing tumors. The capillaries present in such tumors will be permeable to very small liposomes (< 80 nm diameter), as observed, and allow their selective leakage into the tumor bed.[93] This size selection process may be amplified by more rapid endocytosis of liposomes bound to tumor cells than of liposomes bound to normal cells.

The porphyrin macrocycle is capable of highly selective incorporation into tumor cells in very high concentrations. Although a specific receptor-driven process appears to be responsible for these results, as in the case of liposomes, no discrete receptor sites have been identified. It is possible, however, that the LDL receptor sites serve porphyrin endocytosis through initial hydrophobic binding of the porphyrin derivatives in LDL vesicles and incorporation of the resulting LDL–porphyrin host–guest complex in the usual fashion.[94]

7. Boron-Containing Species and Their Delivery to Tumor Cells

Specific classes of boron-containing molecules and delivery vehicles are described below organized according to their targeted locations within the tumor cell in accord with Scheme 6. Interestingly, the progression of boron compound development actually follows the organization of Scheme 6, proceeding sequentially from left to right. Thus, as time passes chemists are brought ever closer to the tumor-cell nucleus and increasingly sophisticated chemistry. This is possible due to continued development of borane cluster chemistry and its close alliance with organic and bioorganic chemistry.

7.1. Species Localized in the Extracellular Volume

As pointed out in Sections 3.1 and 3.2, the serious consideration of BNCT for tumors other than cerebral gliomas is of relatively recent origin. The presence of the blood–brain barrier, which protects normal brain tissue from the entry of very hydrophilic species and which is degraded at the tumor site, provided a mechanism for tissue differentiation. Nontoxic and very hydrophilic boron compounds were sought, which would be localized in useful amounts in tumor.[57] With the level of sophistication of boron chemistry and related analytical methods of the early 1950s, no consideration could be given to the design of boron compounds specifically targeted for intracellular localization in tumor cells or other such niceties. In fact, the class of boron compounds most readily available at the time were the series of arylboronic acids evaluated by Soloway.[57] From a large number of candidates, ^{10}B-enriched 4-carboxyphenyl boronic acid was selected for use in clinical trials of 1959/1961 with terminal cancer patients, and DL-4-(dihydroxyboryl)phenylalanine (BPA), which is of current interest,[87] was set aside. In general, the relatively high toxicity and low boron content of the arylboronic acids make them less attractive than compounds that were to appear following the discovery of the boron chemistry described in Sections 3.1 and 5.0.

The characteristics of the $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ ions[58, 59] suggested that their sodium salts would have the hydrophilic properties then sought for BNCT. Evaluation of these salts in animals proved that they display low toxicity, are incapable of crossing the blood–brain barrier, and have promising characteristics with respect to tumor localization and blood clearance rates.[57] The $Na_2B_{10}H_{10}$ salt was employed in human trials (Section 3.1). Later work led to the synthesis of the polyhedral borane anion derivatives $B_{12}H_{11}SH^{2-}$[95, 69] and 1,10-$B_{10}Cl_8(SH)_2$.[96] The octachloro derivative proved to be too toxic for use, but the $B_{12}H_{11}SH^{2-}$ ion has gained notoriety as the well-known BSH ion. The thiol function was introduced in order to provide covalent disulfide bonding with thiol groups presented by serum and tumor proteins. It has been established that approximately 60% of injected $Na_2B_{12}H_{11}SH$ is weakly and noncovalently bound to serum proteins.[67] Neither free nor bound BSH crosses the intact blood brain barrier, although the tumor is accessible. Hatanaka's results in human glioma trials[63] and other results with humans[97] demonstrate that therapeutic quantities of BSH (> 20 ppm) are present in tumor, while low concentrations are simultaneously present in normal brain. Blood concentrations of boron are comparable to or higher than simultaneous tumor concentrations.

The thiol derivatives of the borane anions are potentially unstable with respect to air-oxidation. As an example, BSH is easily oxidized to the corresponding disulfide $B_{12}H_{11}SSB_{12}H_{11}^{4-}$ and its oxide $B_{12}H_{11}SS(O)B_{12}H_{11}^{4-}$,[68, 69] which has caused complications in product surety and analyses for its use as a drug. Acidified solutions of the disulfide rapidly turn blue, which indicates the presence of the radical

anion[68,69] $B_{12}H_{11}SH^-$ and/or a related radical dianion $B_{12}H_{11}\dot{S}^{2-}$.

The disulfide derived from BSH has been found to be taken up more efficiently than BSH itself by tumors in small animals.[98] Other in vitro data obtained by Fairchild et al. indicate that the disulfide, like BSH, is not taken up by the cell, but accumulates extracellularly.[99] Very recently Coderre et al. demonstrated[100] that the disulfide gave physically unrealistic RBE values of 1.1–1.4 for in vitro neutron irradiation experiments with 9L gliosarcoma cells. These results suggest that the radiation damage that leads to tumor death is actually extracellular and most likely located in the endothelial cells of the vasculature sustaining tumor metabolism. The precise mechanism of BNCT with BSH is, of course, unknown and will remain so until detailed pharmacokinetic studies are completed. Perhaps BSH becomes bound to the rich tumor vasculature at a fairly rapid rate, but leaves this compartment at a reduced rate as BSH is cleared from blood. At some time an optimal tumor/blood BSH ratio will be reached; neutron irradiation can then be carried out within the time window during which these conditions exist.

Shionogi Research Laboratories, Osaka, have synthesized two isomeric $B_{10}H_{10}^{2-}$ derivatives that correspond to BSH:[101] 1- and 2-$B_{10}H_9SH^{2-}$. Evaluation of these compounds is incomplete, but the $B_{10}H_{10}^{2-}$ framework probably offers no real advantage over $B_{12}H_{12}^{2-}$. Scheme 7 presents the synthesis of the $B_{12}H_{11}SH^{2-}$ ion and its more common reactions.

7.2. Boron Localization Processes Utilizing Carborane Derivatives of Phospholipids as Constituents of Tumor Cell Walls

Scheme 6 suggests that boron can be delivered to tumor cells by mechanisms that selectively introduce boron-containing phospholipids as components of the plasma membrane bilayer of malignant cells. The accelerated rate of cell reproduction in tumor compared to that of normal tissue causes selective accretion of boron in tumor cells.

Carborane derivatives of phosphocholine glyceryl ethers have been proposed as boron carriers,[85] since it has been shown that naturally occuring lipid ethers such as **1** selectively accumulate in the plasma membrane of tumor cells giving attractive tumor/normal-tissue concentration ratios. In fact, 8–18% of the total phospholipid contained in the plasma membrane of cells grown in vitro can consist of the synthetic phopholipid ether **1**. Consequently, Lemmen and Werner[85] have synthesized DL-**2** with a 1,2-carboranyl group appended as shown. Results pertaining to the efficacy of **2** have not been reported.

7.3. Boron Localization Through Selective Targeting of Antigens of the Tumor Cell Wall with Immunoglobulins

7.3.1. Boron-Conjugated Antibodies and Their Fragments as Boron Carriers

As suggested by Scheme 6, tumor cell walls carry a variety of receptor sites (antigens) for the recognition and binding of specific immunoglobulins. The existence of antigens which are specific to certain types of tumor cells or the overexpression of other antigens by tumor cells compared to normal cells allows the selective targeting of antigens in the tumor cell wall with the corresponding antibodies. Bale and Spar[102] first pointed out in 1967 that such tumor-targeted antibodies could probably be conjugated with suitable ^{10}B species and employed to deliver these boron atoms to the corresponding antigen sites of the tumor cell wall. The very selective immunoglobulin would then become the carrier of therapeutic quantities of boron. Since a maximum of about 10^6 antigenic sites of any one idiotype are present on each tumor cell and each malignant cell must carry about 10^9 ^{10}B atoms to achieve therapeutic levels, it is clear that each antigen-bound antibody must carry about 10^3 ^{10}B atoms. This assumes[103] that the equilibrium constant for antibody–antigen complexation is at least 10^9 M^{-1}. The fact that the binding constants associated with currently available antibodies can be as large as 10^{11} is encouraging. In addition, the observed internalization of antibody–antigen complexes on the cell surface offers hope that the boron delivered to the cell surface will actually move toward more effective regions of the cell, thus reducing the high density of boron atoms required if situated on the surface alone.[104] The simultaneous expression of several specific types of potentially useful antigenic sites by tumor cells suggests the possible use of "cocktails" of boron-conjugated antibodies, which would concurrently target several different antigens. This option effectively increases the total number of useful antigenic binding sites, which, in turn, could allow a reduction of the number of ^{10}B atoms required per antibody molecule.

These immunochemical guidelines could not be achieved until the early 1980s when Milstein and Köhler[105] developed hybridomas as a source of unlimited quantities of chemically homogeneous monoclonal IgG antibodies

(Mabs). Prior to this development, research workers hoping to employ immunoglobulins as boron delivery vehicles were restricted to the use of chemically heterogeneous polyclonal IgG antibodies tediously isolated from the sera of immunized animals.[106] Developments in genetic engineering have led to the essentially unlimited availability of a wide variety of antibody types such as IgG, $(Fab')_2$, and Fab' species, which may contain large segments of human immunoglobulin as well as customized functional groups for the directed conjugation of drugs, radioisotopes, and toxins. The humanized (chimeric) immunoglobulins offer a reduced risk of illiciting an unwanted immune response when administered to humans.[107] Figure 2 illustrates the general relationship of IgG Mabs and their $(Fab')_2$ and Fab' fragments, which may be obtained by enzymatic and chemical cleavage of parent IgG Mabs, or most conveniently, from engineered clones.

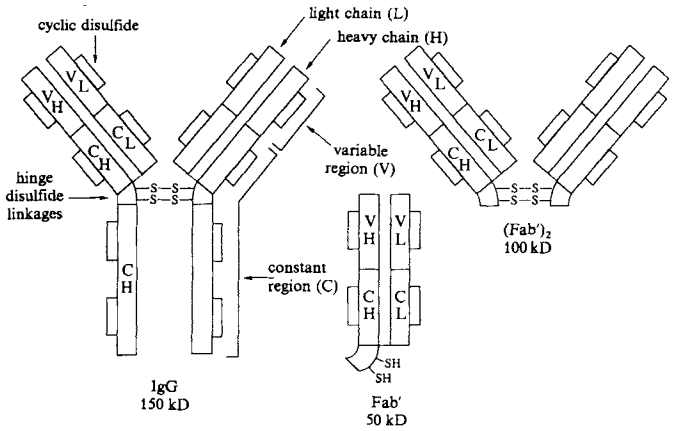

Fig. 2. Simplified representations of the immunoglobulins IgG, $(Fab')_2$, and Fab' and their structural relationships. Antigen binding occurs at the terminus of the VH and VL chains in each of the immunoglobulin types represented here. V_H and V_L chains are joined by S-S bonds represented by lines.

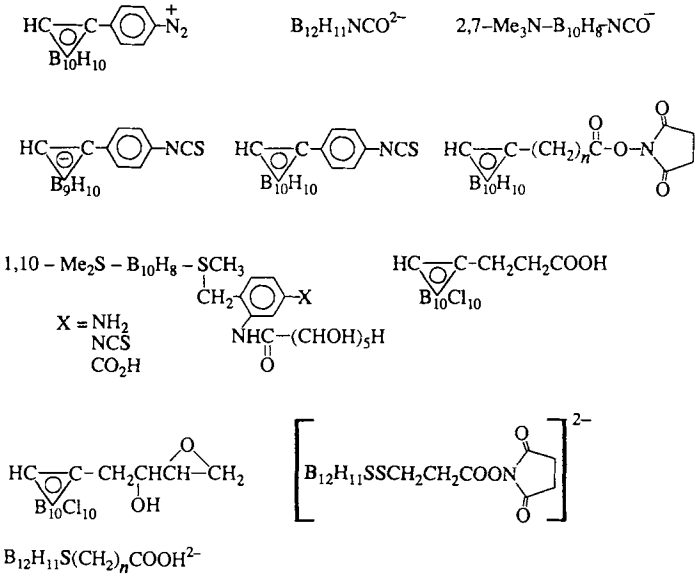
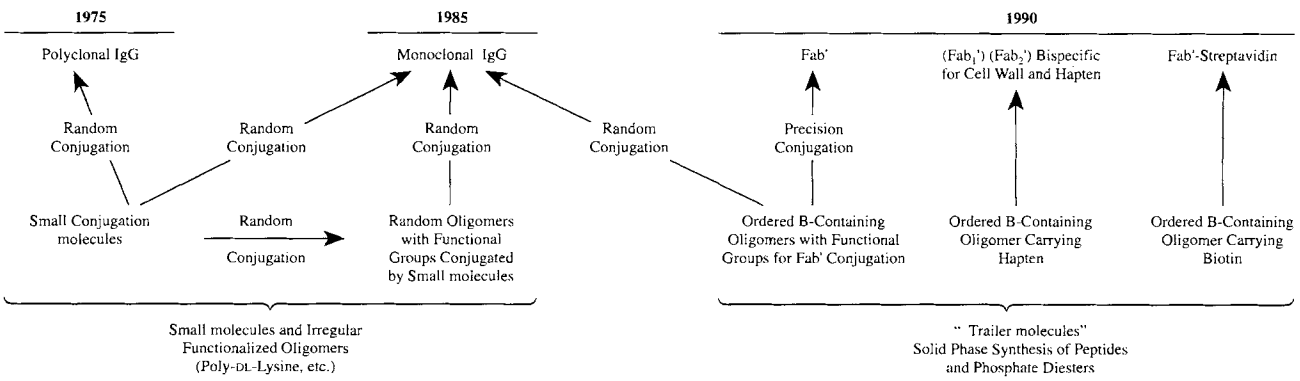
Scheme 8 diagrams the evolution of antibody conjugation and boron delivery methods as they have evolved with time. The initial investigation of boron-conjugation chemistry with model protein substrates such as bovine serum albumin and human γ-globulin was initiated nearly simultaneously in several laboratories in the 1970s. The initial chemical goal was the synthesis of useful boron-rich reagent molecules that contained nine to ten boron atoms each and displayed good reactivity for pendant ε-NH_2 or -SH groups of lysine and cysteine residues contained in the antibody structure.[108] Scheme 9 illustrates several representative examples of these early reagents together with others that were developed at a later date. Work of this sort progressed slowly with polyclonal IgG antibodies of various types and large protein molecules such as bovine serum albumin as model substrates.[109]



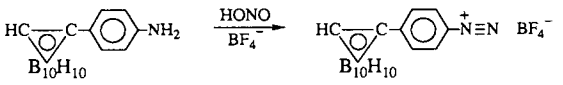
Scheme 9. Representative reagents investigated in past studies of immunoglobulin conjugation. Certain of these species are discussed elsewhere in this article. $n = 1-4$

The earliest attempt to demonstrate the feasibility of the antibody approach using polyclonal antibodies and simple conjugation reagents such as the diazonium salt **4** derived from 1-(4-aminophenyl)-1,2-carborane[110] (**3**) were seemingly successful. The diazonium salt **4** was conjugated with polyclonal antibodies directed against both human and murine histocompatibility antigens, and the conjugate employed for in vitro cell-killing of peripheral blood lymphocytes with a thermal neutron beam. Specific, antibody-directed cytotoxicity was observed, although the number of boron atoms attached to each antibody molecule was only of the order of 30 to 50 and these were of natural isotopic abundance (20% ^{10}B). In another experiment, identical cell-killing (30% survival after two minutes of radia-



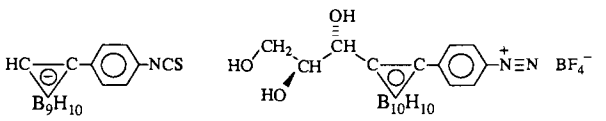
Scheme 8. The evolution of immunoglobulin conjugation methods to the discovery of highly specific bispecific antibodies potentially useful for the delivery of ^{10}B to tumor cells without resort to covalent conjugation.

tion) was observed with lymphocytes in contact with a solution of $K_2B_{10}H_{10}$ containing 2 μg of B per μL or 3.8×10^{-3} μg of B per μL conjugated to 1.9 μg antibody per μL (0.2% B of natural abundance). The efficacy of boron attached to antibody associated with the cell thus appears to be 500 times greater than when present in solution as $K_2B_{10}H_{10}$.



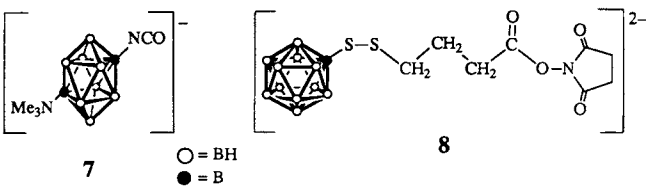
3 **4**

Later the diazonium salt **4** was conjugated with polyclonal caprine antibodies targeted at carcinoembryonic antigen (CEA). The conjugates, which contained up to eighty B atoms per antibody molecule, were employed in both in vitro[106a] and biodistribution studies with human colon tumor xenografts in golden hamsters.[106b] The results of these experiments demonstrated the immunological integrity of the boron conjugates, since good tumor localization was observed in the in vivo experiments. However, the injected dose of antibody conjugate was very low in all of these experiments and the boron content of the conjugate was relatively small. If attempts were made to increase the boron content of the antibody conjugates by increasing the extent of the conjugation reaction, the protein was denatured, precipitated, and lost immunoreactivity.[106, 111] In later work, reagents such as the anionic **5** were synthesized,[112] as well as other carborane derivatives of simple sugars[113] (for example **6**), in order to enhance the water solubility of the carborane derivative with hydrophilic groups. These attempts were unsuccessful.



5 **6**

The complexity and heterogeneity of highly burdened antibody conjugates of either polyclonal or monoclonal origin led to the adoption of an alternative approach to boron-carrying Mabs having at least 10^3 B atoms per molecule. This new tactic recognized that large numbers of boron atoms might be attached to Mabs with minimal alteration of the Mab structure and function by connecting boron-rich oligomer molecules to only a few random sites on the Mab surface. For example, approximately five oligomer molecules carrying 200 boron atoms each might be randomly attached to available NH_2 or SH groups of the Mab and the resulting mixture of conjugates separated from unreacted Mab. As indicated in Scheme 8, this approach was first investigated in the early 1980s by several investigators.[114, 115] With the exception of the dextran-bridged systems of Gabel,[116] oligomeric boron-rich conjugation reagents were themselves randomly constructed species, prepared by reacting poly-DL-lysine[114] or poly-L-ornithine[115] with reagents such as DL-**7** or **8**. The chain lengths of the resulting conjugated oligomers were not known, and the number of unchanged NH_2 groups was variable. Further coupling of oligomers of this sort with Mabs of various idiotypes produced conjugated Mabs with average boron atom populations of 1×10^3–2×10^3. Unfortunately, the immunoreactivities of these conjugated Mabs were markedly lower than those of the parent Mabs. Also, time course experiments with mice proved the modified Mabs to be avidly bound to liver, whereas uptake by tumor was diminished. Recent studies with a starburst dendrimer bearing 48 amino groups as a substrate for reaction with DL-**7** gave similar results after conjugation with Mab.[117]



7 **8**

○ = BH
● = B

Contemporary with this approach through randomly constructed oligomers, we[118b, 119] began the investigation of precisely synthesized oligomeric peptides ("boron trailers") constructed from boron-rich α-amino acids using Merrifield's solid-phase synthesis method. Scheme 10 illustrates the amino acids employed in these studies:[120, 121] the hydrophobic *closo* species **9** and its ambiphilic *nido* derivative **10**. Scheme 11 depicts the synthesis of a fluorescence-labeled undecapeptide **11** from **9** and its conversion to the more hydrophilic structure **12** containing *nido* **10** residues. A similar fluorescence-labeled *nido* dipeptide **13** was prepared analogously. Random conjugation of **13** and **11** with anti-carcinoembryonic antigen IgG Mab T84.66 through active ester methods produced conjugated Mab molecules having an average of 63 and 490 boron atoms, respectively.[121] Biodistribution data were collected with nude mice bearing LS 174T xenografts and ^{125}I-labeled Mab conjugates. While the dipeptide conjugate gave biodistribution results that resembled those obtained with native Mab, the undecapeptide conjugate displayed greatly enhanced liver uptake and decreased tumor accretion. These observations[121] suggested that as the boron loading of the conjugate is increased the loss of circulating conjugate to liver effectively competes with localization in tumor. specifically labeled with a definite small number of hydrophilic oligomer reagent molecules would reduce the heterogeneity and complexity of the conjugate and perhaps lead to selective localization in tumor rather than in liver.[119]

The generalized Fab′ molecule depicted in Figure 2 represents a class of immunoglobulins that may be obtained from reductive cleavage of the two disulfide linkages in the hinge region of the corresponding $(Fab')_2$ species or possibly from engineered clones designed to express Fab′ or customized variants of its basic structure. The Fab′ derived from an IgG Mab having an antigen binding constant of $10^{11}\,M^{-1}$ might exhibit a binding constant of 10^{9}–$10^{10}\,M^{-1}$ and thus be useful as a carrier molecule. The two SH groups of each Fab′

molecule or the single SH group of a Fab–SH molecule may be employed for the conjugation[119] of arrays of precisely synthesized, boron-rich trailer molecules collected upon small precisely structured poly-L-lysine manifold molecules as shown in Scheme 12. Although the first trailer molecules such as **12** were diastereomeric mixtures of small amphiphilic peptides derived from DL-α-amino acids bearing anionic *nido*-carborane residues and fluorescent marker groups,[119–121] it is possible to assemble oligomers based upon the diphosphate esters of boron-rich diols[122] as shown in Scheme 13. The hydrophilic phosphate ester link-

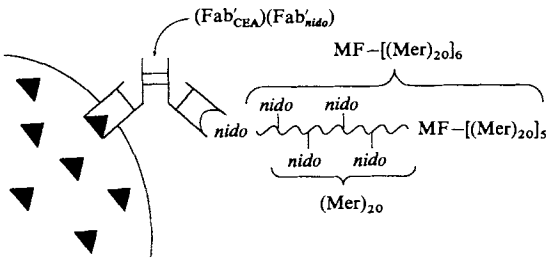
age combined with anionic *nido*-carborane residues ensures hydrophilicity of the oligomeric reagents. The attractiveness of phosphate oligomers is further enhanced by their rapid automated synthesis with experimental procedures developed for DNA syntheses coupled with the ease with which UV-absorbent nucleoside residues, fluorescent marker groups, biotin, segments of polynucleotides, and terminal linker groups may be built into the oligomeric structure.[123] In one day it is possible to construct a phosphate trailer reagent, which could, in principle, contain many hundreds of boron atoms and be directly or indirectly linked to the SH functions of a Fab′ molecule.[119] Scheme 13 illustrates the structural scope of this new trailer chemistry and suggests a phosphate oligomer for linkage to Fab′ species through a suitable linker molecule. Research in this new area of chemistry is being actively pursued.

7.3.2. Binding of Boron and Hapten-Rich Oligomers to Cell Wall Antigen with Bispecific Antibodies and Other Host–Guest Interactions

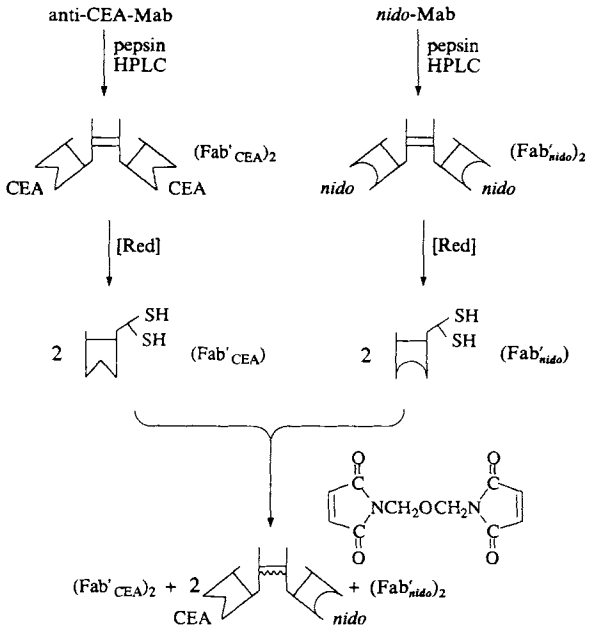
Bispecific antibodies[124] such as the unsymmetrical $(Fab')_2$ species, $(Fab'_{nido})(Fab'_{CEA})$, offer the opportunity of binding a cell wall antigen, such as CEA, to a *nido*-carborane anion hapten group present in high concentration within a boron-rich hydrophilic trailer species. Immunochemical interactions of this sort would allow the concentration of large quantities of boron at cell wall antigenic sites without the use of covalent bonds. In practice the bispecific antibody would

be injected intravenously into the experimental tumor-bearing animal. Complexation of the Fab'_{CEA} segment of the bispecific antibody with CEA antigen sites ensues, the blood is cleared of excess circulating antibody, and then the boron- and hapten-rich trailer species is injected. Trailer-hapten-Fab'_{nido} binding occurs, and the selective (antigen-Fab'_{CEA})(Fab'_{nido}-hapten-trailer) bond formation process is completed. Scheme 14 illustrates the completed antigen complex. The boron-rich trailer molecule could contain an anionic *nido*-carborane-hapten group in each repeating unit and at least 10^3 boron atoms per trailer.



Scheme 14. The schematic representation of the use of a bispecific antibody (Fab'_{CEA})(Fab'_{nido}) for the simultaneous bonding of antigen of a tumor cell wall to boron- and *nido*-hapten-rich oligomer containing 10^3 boron atoms, similar to the manifold shown in Scheme 12.

The synthesis of a bispecific antibody of the type described here ultimately requires a source of the Fab'_{nido} fragment such as the parent IgG_{nido}. Such a Mab is now available from a murine hybridoma.[125] Scheme 15 illustrates the synthesis route for the bispecific antibody. Alternatively, this antibody might also be available from quadroma sources formed by gene fusion of available anti-CEA Mab and IgG_{nido} hybridomas.[126]



Scheme 15. The synthesis of a bispecific antibody from its IgG precursor molecules, anti-CEA–Mab and IgG_{nido}–Mab. Such a bispecific system is also illustrated in Scheme 14. [Red] = reduction.

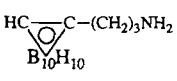
A variant of the bispecific antibody concept is the application of the tightly associated streptavidin–$(biotin)_4$ complex.[127] In this instance Fab'_{CEA} is conjugated with two streptavidin molecules (one per SH group), and the experimental tumor-bearing animal injected intravenously. Following accretion of the Fab'_{CEA} at tumor and blood clearance, a boron-rich trailer species bearing a terminal biotin residue is administered in the same fashion. Ensuing in vivo complex formation would localize the boron-rich trailer molecule at antigenic sites occupied by Fab'_{CEA}. Recent progress toward the immunological approach to boron localization at tumors suggests that such delivery methods may eventually be useful with some tumor types. The use of antibody "cocktails" comprising mixtures of immunoglobulin carriers, each directed to a different antigen present on the same tumor cell, may be employed to enhance tumor boron concentrations. Difficulties such as tumor heterogeneity and uneven vasculaturization remain, but immunotransport methods may be combined with other completely different BNCT protocols.

7.4. Receptor-Mediated Bioregulatory Peptides as Boron Transport Vehicles

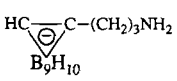
Related to the immunoglobulin carriage of boron to tumor cell antigens is the possible use of selected bioregulatory peptides as transport vehicles. The density of their receptor sites is far higher in tumor cell membranes than in normal cells.[128, 129] Although the actual number of such receptors present on each tumor cell may be as low as 10^4–10^5, receptors internalize their bound regulatory peptide and are regenerated. In effect, a pumping action exists for peptide internalization, which is itself regulated by the intracellular concentration of peptide. The useful rate of regeneration, coupled with the closer approach of internalized boron to the cell nucleus, lends validity to this boron delivery concept. Peptides such as epidermal growth factor (EGF)[128] and corticotropin-releasing hormone (CRH)[129] are candidate peptides having 53 and 41 amino acid residues, respectively. Both EGF and CRH are under evaluation as receptor-mediated boron delivery vehicles of relatively low molecular weight. EGF receptors are overexpressed by many human tumors found in the lung, breast, bladder, head, and neck. CRH is similarly targeted for pituitary tumors involving corticotrophic cells (Cushings disease). A third peptide of interest is growth hormone releasing hormone (GHRH), which, like CRH, is a pituitary-targeting peptide specific for somatotrophs (acromegaly) and composed of 40 amino acids. The successful application of CRH and GHRH delivery to BNCT of Cushing's disease and acromegaly would offer noninvasive procedures for these malignancies.

7.4.1. EGF Conjugation

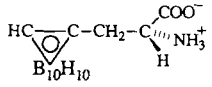
Carlsson, Sjöberg et al.[128] and Barth, Carlsson et al.[130] have begun the investigation of EGF conjugation with primary carboranyl amines[131] such as **14** and its anionic *nido* analog **15** as well as (*R*)- and (*S*)-carboranylalanine (**16**).[86] Their conjugation procedure utilizes the coupling of dextran



14

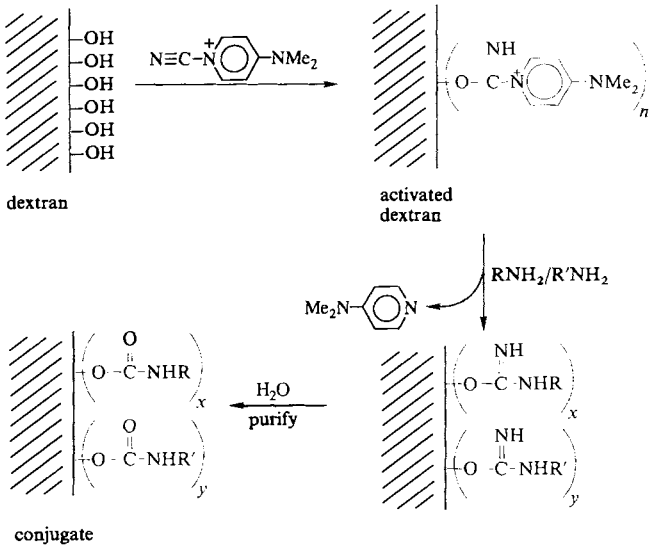


15



(*R*)-**16**

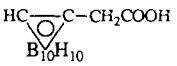
with the amino groups present in EGF and the amino groups of the amino carborane derivative, with 1-cyano-4-dimethylaminopyridinium tetrafluoroborate, as in Scheme 16, and provides relatively small conjugates (20–30 kD). They will be evaluated for boron delivery to glioma cells.



Scheme 16. Mechanism of the conjugation of EGF(RNH_2) with an amino-functionalized carborane derivative, $R'NH_2$ by means of dextran.

7.4.2. The Incorporation of Boron in CRH and GHRH Structures

CRH and GHRH are of similar size, but they differ with respect to their biologically important termini; CRH may be modified by the addition of an extraneous amino acid to its amino terminus without serious loss of corticotrophic cell activation.[129] GHRH may be similarly modified at its carboxyl terminus without significant loss of biological activity. Loriaux and Albertson et al.[129] have evaluated carborane-modified GHRH and ovine CRH species prepared by Chen et al.[132] CRH was synthesized with standard Merrifield solid-phase procedures except that the serine amino terminus was acylated with the carboranylacetic acid **17**. GHRH



17

was modified at its carboxyl terminus by the addition of a lysine residue whose ε-amino group was acylated with **17**. Both the modified peptides evoked biological responses in vitro similar to that of the unmodified species.[129] Their efficacy of boron delivery remains to be determined. The boron content of the peptides could most reasonably be increased by the attachment of small boron trailer molecules rather than **17**. The size, charge, and hydrophobicity of the trailer will require careful selection to retain receptor recognition and binding by the conjugate.

7.5. Cell-Wall Receptor-Mediated Low-Density Lipoprotein (LDL) Vesicles as Boron Carriers

The LDL vesicle[133–135] illustrated in Figure 3 and briefly discussed in Section 6.1 comprises a phospholipid/cholesterol shell with a diameter of approximately 15–20 nm, filled with cholesteryl esters of long-chain alkyl carboxylic acids. Apoprotein B-100 is attached to the external

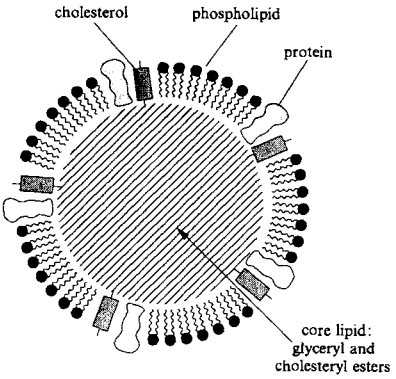


Fig. 3. A stylized cross-sectional view of a low-density lipoprotein vesicle filled with glyceryl and cholesteryl esters of fatty acids. The protein exposed on the vesicle surface responds to the LDL receptor sites present in the plasma membrane of cells.

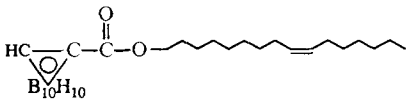
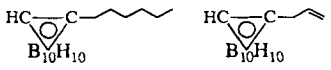
surface of the vesicle and serves as a specific anchor for receptor sites located on the external cell walls of both malignant and normal cells. Receptor–LDL complexes are internalized by endocytosis, the LDL is degraded to cholesterol by lysosomes, and the receptor returns to the external cell wall. This pathway provides about 90% of the cholesterol necessary for cellular membrane synthesis.[136] Malignant cells are expected to utilize cholesterol (and LDLs) at a much higher rate than normal cells because of higher replication rates, and therefore to have correspondingly higher receptor turnover rates. This provides a basis for cellular differentiation and the targeting of tumor cells with boron if the cholesteryl esters of the LDL core are replaced with a boron-rich material. This concept was proposed by Kahl et al.,[91,137] who exploited it through the substitution of esters derived from fatty alcohols and carborane carboxylic acid, such as **18**, for the native cholesteryl esters[138] after removal of the latter material from harvested LDL vesicles by solvent extraction. The reconstituted boron-containing LDL vesicles contained approximately 12×10^3 boron atoms each.[91,137] Later work has shown[91b] that simple hydrophobic carborane derivatives such as 1-hexyl (**19**) or 2-propenyl (**20**) derivatives efficiently reconstitute LDL vesicles. In vitro evaluation of these novel boron carriers on CHO and V-79 Chinese hamster cells in conjunction with thermal neutron irradiation at the Brookhaven Medical Research Reactor established that boron was taken up intracellularly in concentrations as high as 240 μg boron per g cells.[91a] This will be recognized as a spectacular result!



18



19 20

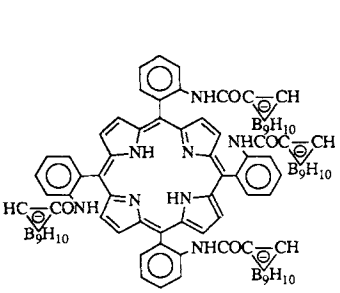
Kahl et al. have recently initiated biodistribution studies in small animals, but no results are available at this time.

7.6. LDL Complexes of Porphyrins and Phthalocyanines as Receptor-Mediated Boron Carriers

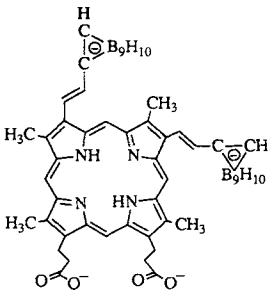
It has long been known that porphyrin, phthalocyanine, and related heterocyclic molecules have a propensity to localize in solid tumors and persist there in the long term. This property of porphyrins provides the basis of photodynamic therapy (PDT),[139] another binary therapeutic method that utilizes porphyrin derivatives localized in tumor as in situ photosensitizers for the production of singlet oxygen on irradiation with red light.[140] Candidate porphyrin derivatives that contain boron for BNCT purposes are also of interest for potential PDT applications. As pointed out in Section 6.1, the mechanism of this localization process or processes remains unknown, although the differentiation between uptake by normal and malignant tissues suggests that a receptor-mediated mechanism driven by very high turnover rates in tumor cells is involved. Porphyrins observed to be most effective in tumor localization are water soluble, amphiphilic species carrying hydrophobic substituents like BOPP (**23**). A plausible receptor-mediated mechanism might involve LDL vesicles,[94] which utilize their hydrophobic constituents to solvate and encapsulate circulating porphyrin. Rapid uptake of the porphyrin-loaded LDLs would then internalize the heterocycle.

The possible use of boron-containing porphyrins as BNCT agents has been explored from the early 1980s onward. Representative derivatives that have been synthesized are based upon tetraphenylporphyrin (e.g. BTPP (**21**))[141] and hematoporphyrin (e.g. VCDP (**22**)[142] and BOPP (**23**)).[143] The *nido*-7,8-$C_2B_9H_{11}^-$ residues present in **21** and **22** are necessary to lend water solubility to the array. Since the anionic *nido*-carboranyl substituent is an amphiphilic[119] rather than a hydrophilic substituent, this water-solubilizing tactic does not totally degrade the hydrophobic character of **21** and **22**. The porphyrin **23** would be expected to be more hydrophobic than **21** and **22**, since it contains four very hydrophobic *closo*-carboranyl groups,[144a] and only two hydrophilic carboxylate substituents enhance hydrophilic properties. The greater hydrophobicity of **23** may be a direct cause of its superior tumor localization and retention[144b,c] relative to **21** and **22**.

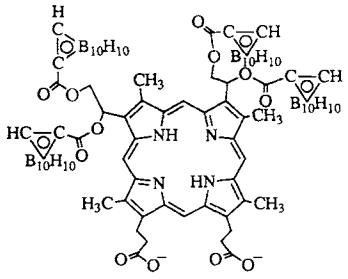
The biodistribution of **21**,[145] **22**,[142a,146] and **23**[143,147] was evaluated with a variety of murine tumor models. Tumor types included gliomas and melanomas. The porphyrin derivatives were administered by either intravenous or intraperitoneal injections. Although the boron localization data obtained in these experiments was dependent upon experimental details and the identity of the porphyrin derivative, all three compounds were taken up and retained for days, whereas **23** was retained for weeks. Concentrations of boron in liver were generally about twice that simultaneously observed in the tumor, and when measured, boron levels in spleen and kidney were also elevated. Boron cleared from blood with time. Injected doses of 25–50 mg B per kg body weight were often employed, and boron concentrations of 15 to 40 μg per g tumor were observed with carcinomas. Among porphyrin derivatives, **23**[147] provides the highest boron uptake by tumor combined with long retention times.



21 BTTP



22 VCDP



23 BOPP

Recent work with intracerebral glioma xenografts in CBA mice by Hill, Kahl et al.[148] proved that **23** injected intravenously or intraperitoneally (30 mg B per kg body weight) could be localized in glioma at concentrations greater than 20 μg B per g tumor, while the concentration in blood was less than half this value and in normal brain immeasurably low. Fluorescence studies with confocal laser scanning microscopy for **23** demonstrated that this compound was localized intracellularly and almost exclusively in organelles, both in vitro and in vivo. Density gradient ultracentrifugation studies proved these organelles to be mitochondria. It was calculated that this intracellular location of **23** could result in an up to tenfold reduction in the amount of boron required to achieve tumor necrosis by BNCT (2–3 μg B per g glioma). Porphyrin **23** is clearly an attractive candidate for a variety of tumors, and work pertinent to its adoption by the BNCT community is proceeding at a rapid pace.

Radiometal complexes of the phthalocyanines have been employed as diagnostic reagents, since they localize in tumors in a fashion reminiscent of porphyrins.[149] The sul-

fonated, water-soluble copper phthalocyanine has apparently been prepared by Soloway[149] through the reaction of 1-(4-aminophenyl)-*closo*-1,2-$C_2B_{10}H_{10}$ with copper tetra-(chlorosulfonyl)phthalocyanine followed by hydrolysis. No details on the purification, characterization, and efficacy of this species in tumor localization have yet been presented.

7.7. Synthetic Liposomes as Tumor-Differentiating "Supertankers" for Boron Delivery

In Sections 6.1 and 7.5, LDLs[91] and their cell wall receptors were discussed as potential systems for the delivery of boron in relatively large increments. Related to LDLs is the family of vesicles identified as synthetic unilamellar liposomes.[90] These liposomes consist of a phospholipid bilayer that forms a spherical shell surrounding an aqueous core. The liposomes that have been applied to BNCT have, for the most part, carried hydrophilic sodium salts of polyhedral borane anions as solutes in the aqueous center of the vesicle, although, in principle, the phospholipid bilayer could also carry dissolved lipophilic species. Small multilamellar liposomes having several discrete layers of phospholipids might be utilized with boron-containing lipids as constituents. Figure 4 presents a cross-sectional view of a typical unilamellar liposome on the right and details of the bilayer structure. The

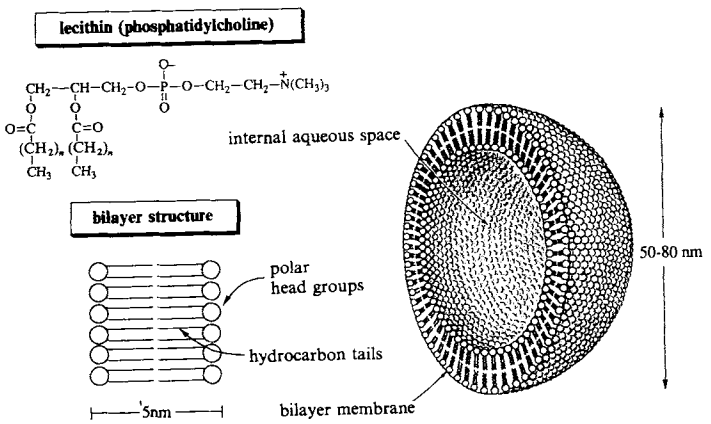


Fig. 4. Cross-sectional view of a liposome of the type found to be useful for boron delivery to tumors in mice. Synthetic phosphatidylcholine forms the bilayer membrane of these synthetic liposomes. Cholesterol is present in the bilayer, as well.

unilamellar liposomes employed for the localization of boron in tumor [90] range from 30–80 nm in diameter, and utilize cholesterol-rich bilayers of pure synthetic phospholipid to lend mechanical strength required for long-term circulation in the vascular system. Although the liposome shown in Figure 4 consists of a phospholipid having no net charge on its polar terminus, liposomes with net negative[150] or positive charges[151] can be prepared. Surface charge affects biodistribution and pharmacokinetics. As shown in Section 7.7.1, liposomes of the type employed for boron delivery are capable of excellent selective localization in a variety of tumors following intravenous injection. They have previously been employed as tumor-selective delivery vehicles for radiopharmaceuticals used in animal models[152] and in human diagnosis.[153] Unlike LDLs, synthetic liposomes carry no receptor-seeking appendages, although, as pointed out in Section 6.1, they are selectively internalized by tumor cells. This cellular differentiation process is believed to be due, at least to a large extent, to the immature and consequently abnormally porous vasculature of rapidly growing tumors.[93] The internalization process itself could arise by nonspecific endocytosis of the coated-pit → coated-vesicle type.[92, 154] Alternatively, LDL receptor sites may in some way be available to small liposomes and thereby provide a selective internalization pathway as in the case of LDLs themselves.

7.7.1. Unilamellar Liposomes

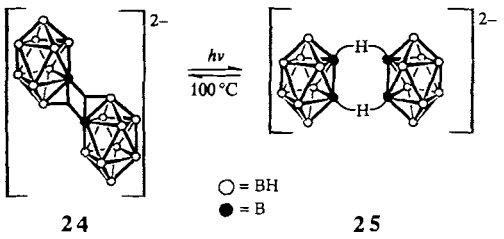
We have carried out extensive studies[90, 155] of unilamellar liposomes of the type illustrated in Figure 4 as boron delivery vehicles. Earlier results obtained by workers at Vestar, Inc. proved that liposomes of this type preferentially deliver their contents to tumor cells in animals and humans to provide levels of effector molecules in tumor five to ten times that of normal tissue, including blood.[151–153] Sodium salts of polyhedral borane anions based upon $B_{10}H_{10}^{2-}$, its oxidation product, n-$B_{20}H_{18}^{2-}$,[*] and their derivatives have provided water solutions (250–300 mM) of sodium salts with excellent hydrolytic stabilities, which were employed as the aqueous cores of 40–80 nm liposomes.[90, 155] These hyperosmotic vesicles proved to be generally stable; they can be stored for months and remain in circulation for 3–4 days. However, the stabilities observed in vivo were always a function of the identity of the solute present in the core. Biodistribution studies with many boron-containing liposomes of the type used here proved that liver and spleen (reticuloendothelial cells) accreted appreciable quantities of liposomes in competition with tumor. The initial liver-to-tumor boron concentration ratios were often about 2:1, but decreased with time. Blood always cleared with time, and tumor-to-blood boron ratios of 5:1 or higher were not uncommon when the concentration of boron in tumor was in the therapeutic range (20–40 μg B per μg tumor). Protocols exist for the suppression of liposome uptake by reticuloenthelial cells.[151] The effective toxicity of all compounds[90, 155] delivered by liposomes should be decreased as a result of encapsulation. Although detailed toxicity data is not yet available for the majority of the more interesting compounds studied, no acute effects have been observed in mice whose tumors acquire therapeutic levels of boron. The majority of the biodistribution work was accomplished with BALB/c mice bearing implanted EMT6 murine adenocarcinomas.[90, 155]

$Na_2B_{10}H_{10}$ was the first polyhedral borane anion to be encapsulated as outlined above.[90, 155] Time-course evaluation with low total injected boron doses (6 mg B per kg body weight) proved that although the $B_{10}H_{10}^{2-}$ ion was entering tumor, liver, and spleen, all of these tissues were cleared at similar rates, and boron was not retained in the tumor. BSH ($Na_2B_{12}H_{11}SH$, 7 mgB per kg body weight) gave essentially

[*] n here represents the "normal" isomer synthesized first and i its photoisomer.

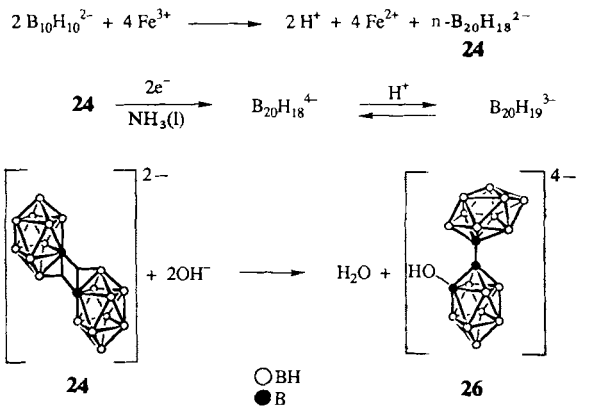
the same result as that obtained with $Na_2B_{10}H_{10}$. These initial results suggested that in order to be effective the borane derivative must be capable of reaction with components of the cytoplasm such as the ubiquitous amino groups indigenous to intracellular proteins.

The interconversion of the isomeric n-$B_{20}H_{18}^{2-}$ (**24**)[157] and i-$B_{20}H_{18}^{2-}$ (**25**)[158] ions, depicted in Scheme 17, and their chemistry,[156] illustrated with **24** in Scheme 18,[90, 155] suggested their possible intracellular incorporation as shown in Scheme 19. The $B_{20}H_{18}^{2-}$ ions deliver twice as many boron



Scheme 17. Reversible interconversion of thermodynamically favored n-$B_{20}H_{18}^{2-}$ (**24**) and its less stable photoisomer, i-$B_{20}H_{18}^{2-}$ (**25**).

atoms per three ions as $Na_2B_{10}H_{10}$ thus increasing boron availability for the same osmotic stress on the liposome. Scheme 4 indicates the preferred synthesis[71] of $B_{10}H_{10}^{2-}$ from $B_{10}H_{14}$, which could be adapted to the synthesis of ^{10}B-enriched $B_{10}H_{10}^{2-}$ to serve as a precursor for a series of compounds including n- and i-$B_{20}H_{18}^{2-}$.



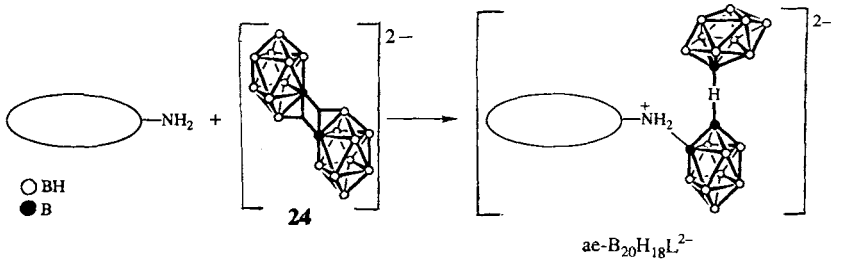
Scheme 18. The formation of n-$B_{20}H_{18}^{2-}$ (**24**) and its subsequent two-electron reduction to form e^2-$B_{20}H_{18}^{4-}$ (e = equatorial), which undergoes acid-catalyzed rearrangement to the ae and a^2 isomers (a = apical). The $B_{20}H_{19}^{3-}$ intermediates are observed, and the most stable a^2-$B_{20}H_{19}^{3-}$ isomer is easily isolated. The apical and equatorial positions of the component $B_{10}H_9^{2-}$ cages are joined by a normal two-election bond, which generates the three isomeric frameworks of $B_{20}H_{19}^{3-}$ and $B_{20}H_{18}^{4-}$. The *kinetically controlled reaction of* **24** *with* OH^- yields the 2-hydroxy isomer **26**, which is isoelectronic with ae-$B_{20}H_{18}^{4-}$.

As expected, liposomes containing Na_2(n-$B_{20}H_{18}$) (15 mg B per kg body weight) exhibited improved performance by increasing the quantity of boron available in a standard liposome dose. More significantly, the n-$B_{20}H_{18}^{2-}$ ion was retained by tumor, while other tissues were more rapidly cleared. The boron concentration in tumor was 24 μg B per g, and the tumor-to-blood ratio was 1.2:1 twenty-four hours after injection. These values changed to 3.3 μg and 14:1 after 48 h.

The more reactive photoisomer Na_2(i-$B_{20}H_{18}$) (11 mg B per kg body weight) was quite persistent. The boron concentration in tumor after 48 h (14 μg per g) was still 71% of the value at 6 h. During this period the tumor-to-blood concentration ratio increased to 12:1. Free Na_2(i-$B_{20}H_{18}$) in buffer was not retained when injected (11 mg B per kg body weight), but rapidly excreted; the tumor, blood, and liver concentrations of boron were only 1.9, 1.9, and 8.9 μg B per g, respectively, after 24 h. An experiment in which two injections of Na_2(i-$B_{20}H_{18}$)-containing liposomes (15 mg B per kg body weight injected at 0 and 24 h) were administered yielded similar results after 24 h. After the second injection and a total time of 48 h, the boron concentration in tumor was 27 μg B per g, and the tumor-to-blood concentraton ratio was 2.6:1. These are therapeutically useful values. The concentration of boron in the liver was about 60 μg B per g.

Evaluation of liposomes that contained derivatives of the isomeric $B_{20}H_{18}^{4-}$ ions provided the basis of new localization concepts. The isomeric hydrolysis products $B_{20}H_{17}OH^{4-}$[156a] of **24** (**26** in Scheme 18) or **25** are isoelectronic with the $B_{20}H_{18}^{4-}$ ions[159] produced by two-electron reduction of **24** or **25**. The potassium salt of **26** was evaluated for use in BNCT in the usual fashion and shown to be rapidly cleared from tumor as in the case of $Na_2B_{10}H_{10}$. However, $Na_3B_{20}H_{19}$[159] produced by protonation of a^2-$B_{20}H_{18}^{4-}$ (8 mg B per kg body weight) behaved differently. Nearly 30 μg B per g tumor was found after 6 h. Concentrations of boron in tumor decreased at a moderate rate, while concentrations in liver increased for 30 h. Boron levels in blood reached 7.5 μg B per g after 48 h, while the tumor concentration fell to 12 μg per g. These results preface the discovery of the most efficacious polyhedral borane anion yet evaluated.

The ammonia-substituted ae-$B_{20}H_{18}^{4-}$, $B_{20}H_{17}NH_3^{3-}$ (**27**, see Scheme 20) is similar to the parent anion except that an uncharged NH_3 molecule has been formally substituted for hydride ligand, thus reducing the ionic charge to −3. Evaluation of $Na_3B_{20}H_{17}NH_3$ in liposomes (11 mg B per kg body weight) produced spectacular results as shown in the time course plot of Figure 5.[160, 161] Even with the low injected dose employed, the boron concentration of 25 μg B per g



Scheme 19. Proposed reaction of an intracellular protein molecule, symbolized as ○–NH_2, with **24** to form an ae derivative. The i-$B_{20}H_{18}^{2-}$ isomer (**25**) would provide a similar, but more facile reaction.

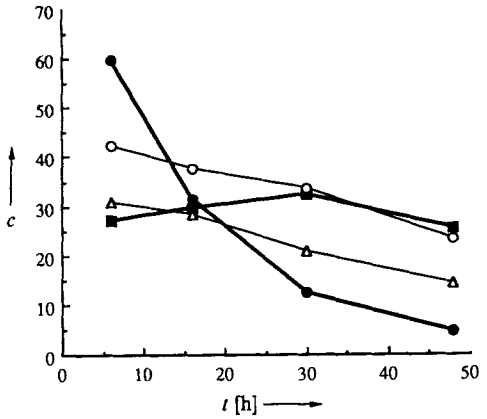


Fig. 5. Data from a time-course study on the distribution of liposomal $Na_3B_{20}H_{17}NH_3$ (**27**) in BALB/c mice bearing EMT6 mammary adenocarcinomas. c = boron concentration in tissue in μg per g. ● in blood, ■ in tumor, o in liver, Δ in spleen. The injected dose was 11 mg per kg body weight.

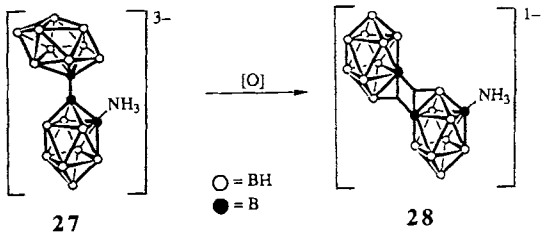
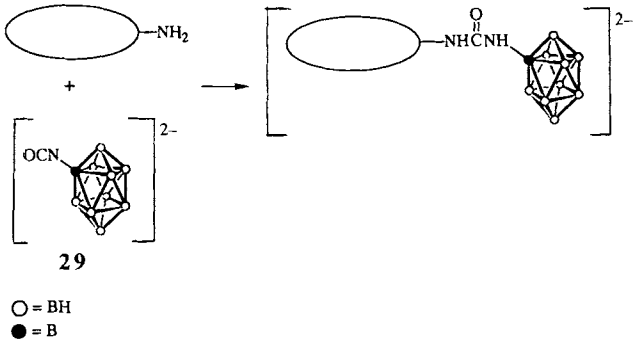
respectively. In fact, the boron concentration of tumor increases during the first 30 h and reaches a maximum of 35 μg per g. One plausible explanation of these results is based upon the possible intracellular two-electron oxidation of **27** to $B_{20}H_{17}NH_3^-$ (**28**) within tumor cells as shown in Scheme 20. The single negative charge of **28** would enhance



Scheme 20. Proposed intracellular oxidation of **27** to the very reactive, but hypothetical $B_{20}H_{17}NH_3^-$ (**28**), which should rapidly bind with intracellular protein. [O] = intracellular oxidation.

the electrophilicity of this ion compared to the $B_{20}H_{18}^{2-}$ ions, and could thus improve the intracellular bonding (see Scheme 19). In addition some other feature prevents the extensive uptake of **27** by liver and promotes the concomitant low final blood levels of boron. Extensive evaluation of **27** is underway, since its liposomes offer one of the most effective boron delivery systems yet described in small animals.

Another reactive polyhedral borane anion derivative has been recently described and evaluated for suitability for BNCT.[162] This species is 2-isocyanato-*closo*-$B_{10}H_9^{2-}$ (**29**)[163], whose isocyanate function is expected to form the corresponding urea derivative upon intracellular reaction with amino groups of protein as described in Scheme 21. Data from preliminary biodistribution studies with liposomes that contain the disodium salt of **29** (9 mg B per kg body weight) are presented in Figure 6 along with a comparable set of results obtained with $Na_2B_{10}H_{10}$ (6 mg B per kg body weight). These results prove that **29** is better retained by tumor, liver, and spleen than its unsubstituted parent, $Na_2B_{10}H_{10}$. One may conclude that the isocyanate function of **29** serves, as expected, by linking to intracellular protein.



Scheme 21. Proposed reaction of **29** with an intracellular protein molecule ○-NH_2.

The synthesis and evaluation of liposomes containing other polyhedral anions that bear functional groups continues.

Although Moore et al.[164] reported the delivery of hydrophobic thiouracil derivatives of carborane (see Section 7.10.1) dissolved in lipid bilayer to murine melanoma xenografts on use of 100 nm phospholipid-supported liposomes, the efficacy of this procedure could not be deduced from the reported results except that high tumor selectivity was observed.

The simplicity, broad scope, and exciting preliminary results obtained with liposomes have established them as one of the most promising boron delivery methods yet devised.

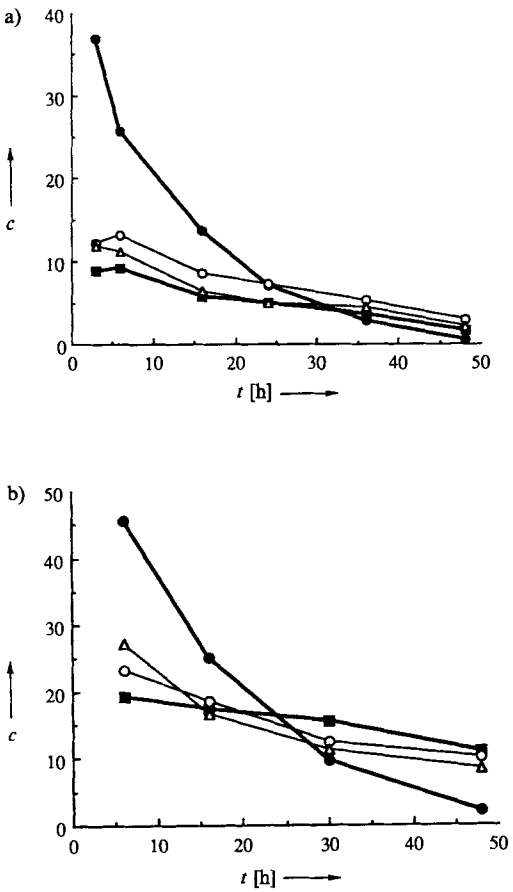


Fig. 6. Comparison of the distribution of liposomal $Na_2B_{10}H_{10}$ (a) and Na_2[2-OCN-$B_{10}H_9$] (b) from time-course studies on EMT6 mammary adenocarcinomas grown in BALB/c mice. The injected dose was 6 mg per kg body weight in a) and 9 mg per kg body weight in b). For explanation of other symbols, see Figure 5.

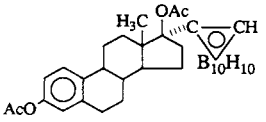
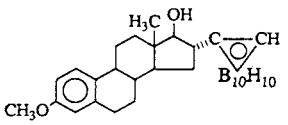
7.8. The Potential of Sex Hormone Receptors as Vehicles for the Delivery of Boron to the Cell Nucleus

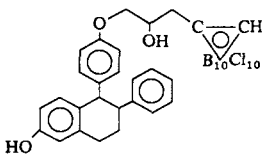
Both breast and prostate cancer have predominant cell lines that depend upon the constant uptake of estrogen and dihydrotestosterone, respectively. These hormones become effective following complexation with their respective receptors present in the cytosol of the proper cell, followed by translocation of the resulting hormone–receptor complex to the chromatin within the cell nucleus. Both Hadd[165] and Kahl[166] have synthesized carborane derivatives of estradiol (**30** and **31**, among others). Hechter and Schwartz[167] used available data pertinent to receptor site densities to calculate the probable concentration of boron that could be obtained with receptors of this type. With efficacious hormone surrogates carrying one carborane cage per molecule (ten boron atoms) only about 0.015 μg B per g tissue could be delivered to chromatin in this fashion. The goal of 1–2 μg B per g tissue was thought to be reasonable, since the boron targets were placed in the cell nucleus.



30



31



32

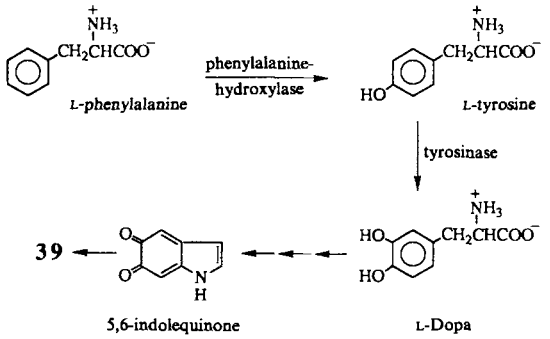
Work has apparently been abandoned with this aspect of selective boron delivery. However, Gabel et al.[168] synthesized a boron-rich analog, **32**, of the antiestrogen molecule U23 469-M that contained a decachlorocarborane substituent. This compound was taken up nonspecifically by ZR 75-1 breast cancer cells and partially inhibited the uptake of estradiol in these cells. The estimated 10^4–10^5 receptor sites available per cell are far less than the number required to achieve therapeutic levels of boron. This line of endeavor has been abandoned as well. Even though boron was placed within the cell nucleus, it has been impossible to approach the concentrations required for BNCT.

7.9. Boron-Containing Amino Acids as Prescursors in Protein Synthesis

Recent emphasis has been placed upon the evaluation of a variety of boron-containing amino acid derivatives that may carry boron to tumors by becoming incorporated in protein synthesis or metabolism within the rapidly growing tumor cell. L-4-Dihydroxyborylphenylalanine[87] has received particular attention. L-Carboranylalanine,[144a] an analog of phenylalanine, was only recently synthesized by improved methods.[86a, 86b] Spielvogel pioneered the synthesis of natural amino acid surrogates[169] in which a carbon atom has been replaced by an isoelectronic and isosteric boron atom having four valence electrons and a negative formal charge. These studies constitute one of the most dynamic areas of BNCT research currently under investigation.

7.9.1. Studies with L-4-Dihydroxyborylphenylalanine

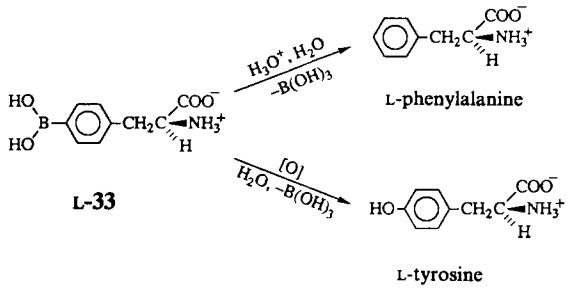
Snyder et al.[170] first reported DL-4-dihydroxyborylphenylalanine (BPA (DL-**33**); see Scheme 23), which was subsequently examined in animals by Soloway in the 1950s and found to provide the most favorable tumor/brain selectivity (8.5:1) of all the boronic acids similarly screened at that time.[57] Interest in BPA as a BNCT target compound was dormant until Mishima et al.[87, 171] discovered its efficacy against B-16 melanoma in vitro and in hamsters bearing Greene's melanoma during neutron irradiation experiments[171] with ^{10}B-enriched **33**. Further work with Duroc pigs[171] and humans[172] afflicted with melanoma proved that ^{10}B-enriched DL- or L-**33**, was effective in BNCT and that primary lesions that were highly pigmented were destroyed. Because of the extremely low solubility of **33** in water, the compound was administered by perilesional injection (i.p.) or orally. Esterification of **33** with sugars improved its solubility.[173] This use of **33** against melanoma was developed by Mishima et al.[87] based upon the fact that the melanin pigment normally present in active melanoic neoplasms is synthesized from natural amino acids containing aromatic rings such as L-dopa, L-tyrosine, and L-phenylalanine. Presumably, this process involves 5,6-indolequinone as an intermediate. It was assumed[87, 171] that **33** would fall into this class of melanin precursors[174] and enter the characteristic melanin produced by intracellular melanosomes. Scheme 22 illustrates the biosynthesis of melanin. However, the insertion of **33** in this mechanism would require that the



Scheme 22. The stepwise enzymatic oxidation of L-phenylalanine leading to the 5,6-indolequinone polymer melanin **39**. The structure of **39** has not been precisely determined.

4-dihydroxyboryl group be removed[175] prior to the formation of the quinone, presumably as boric acid. This loss of boric acid could occur through acid-catalyzed hydrolysis of the B–C bond or by oxidative cleavage of the C–B bond (Scheme 23). Migration of boric acid from the cell interior to the extracellular volume is a facile process that should preclude the accumulation of boron within tumor. The accre-

tion of therapeutic boron concentrations in melanomas (and other tumor types) is therefore likely to be due to another bioutilization process.



Scheme 23. Known reactions of L-33, which may occur in vivo and lead to the loss of boric acid.

Other experimental observations made with ion microscopy that shed light on this problem have been reported by Morrison et al.[46] These workers developed a cell-culture system for the study of drug uptake into a malignant, highly pigmented M-3 murine melanoma clonal strain. The pigment level (extent of melanization) could be matched, area for area, to ion intensities from superimposed photomicrographs and ion images by using the aryl-bound deuterium present in [D_4]-L-tyrosine and boron in DL-**33** as sources of the imaged ions. In any given area of the cell culture the increase in melanin concentration correlated linearly with an increase in deuterium concentration due to the uptake of tyrosine, a known melanin precursor (Scheme 22). The boron concentration did not change as melanin was produced; DL-**33** consequently does not deposit its boron in the melanin of developing melanoma cells.

Coderre et al. demonstrated that **33** is accreted by the weakly pigmented B-16 melanoma carried by C57BL mice.[176] This result suggests that **33** uptake, which according to other experiments favors the L-stereoisomer,[174] proceeds through active transport of the amino acid for purposes other than the synthesis of melanin. This is important to therapy since many forms of human melanoma are variably pigmented, and very dangerous metastases are not pigmented early in their development.

In addition, Coderre et al.[174] demonstrated that L-**33** was much more effective than its enantiomer against Harding–Passey melanoma, that oral administration of ^{10}B-enriched **33** achieved tumor concentrations of boron as high as 40 μg per g in BALB/c mice,[176] and that the growth inhibition of these tumors was directly related to the neutron fluence with the result that longer exposure time caused a longer delay tumor growth, as expected. More recent work by this same group[177] showed that boron was selectively delivered to tumors other than melanomas; the KHJJ murine mammary carcinoma in mice and GS-9L gliosarcoma grown in rat brain are representative of such tumors. Boron concentrations as high as 20 μg B per g tumor were attained in the gliosarcomas after oral administration of L-**33**. Other studies of this type are too numerous to mention, but they all support the useful application of L-**33** to amelanoic tumors.

Recently Coderre et al. reported[100] the experimentally determined RBE values of the BSH disulfide dimer BSSB (Scheme 7) and L-**33**, obtained from cell-survival data following thermal neutron irradiation of cells that were enriched in the boron compounds. Gliosarcoma cells (GS-9L) were employed both in vitro and in intracerebral rat tumors. The in vitro RBE values (Section 2.4) ranged from 3.5 to 4.1 for L-**33** and from 1.1 to 1.4 for BSSB. It was pointed out that these BSSB values were physically unrealistic and characteristic of a mechanism for in vivo tumor cell death dependent upon the destruction of vascular endothelial cells through BNC and a resultant loss of vasculature function at the tumor. On the other hand, the higher RBE values observed with L-**33** were consistent with neutron capture by intracellular L-**33**. The destruction of endothelial cells of the vasculature as the principal killing mechanism for BNCT with BSH and BSSB has been noted in Section 7.1.

As pointed out above, the low water solubility of L-**33** hydrochloride at physiological pH has complicated the use of L-**33** in experiments with large animals. This problem has been largely overcome[173] by converting L-**33** to water soluble boronate esters with fructose, diethanolamine, and cyclodextrin derivatives. These species offer the promise of an intravenous injection protocol.

A phase I clinical trial for L-**33**[178] is planned by the New England Medical Center–MIT Program in Neutron Capture Therapy. This clinical trial will join another in progress at the School of Medicine at Kobe University, Japan.

Both DL-2- and DL-3-dihydroxyborylphenylalanine have been synthesized and await thorough evaluation.[179] In addition, the 4-*closo* (**34**) and 4-*nido* (**35**) derivatives of DL-4-carboranylphenylalanine have been prepared[180] and are undergoing biological evaluation. An asymmetric synthesis

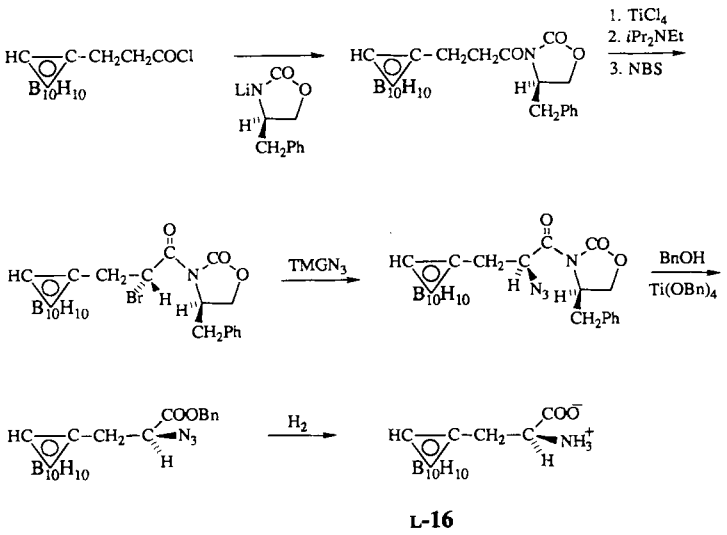
of L-**33** has also been developed,[181] which involves the hydrogenation, catalyzed by a chiral rhodium complex, of a substituted α-amino acrylic acid derivative.

7.9.2. *L-Carboranylalanine*

The accelerated rate of synthesis of proteins and amino acid metabolites exhibited by a malignant cell, coupled with the active transport mechanisms available for amino acid accumulation within cells, provides a bioutilization process that may allow boron-containing α-amino acids to enter tumor cells preferentially. The selective uptake of L-**33** by several types of malignant cells appears to follow this cell differentiation mechanism (see Section 7.9.1).

Since one of the most chemically attractive packages for the delivery of boron is the *closo*-1,2-$C_2B_{10}H_{12}$ cage, it is not surprising that the L-phenylalanine surrogate, L-carboranylalanine (**16**) is a highly desired species for biological evaluation. The initial synthesis of **16** was reported[144a] in 1976.

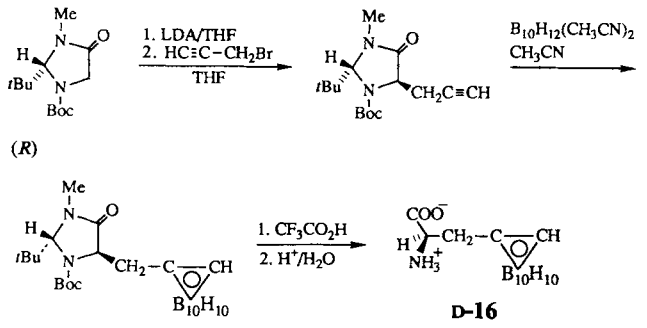
The asymmetric syntheses of the D and L enantiomers have recently become the goal of several research groups, most notably those of Kahl et al.[86a] and Sjöberg et al.[86b] (Schemes 24 and 25, respectively). It was noted by the discov-



L-16

Scheme 24. The asymmetric synthesis of D- and L-16, devised by Kahl and Radel [86a]. NBS = *N*-bromosuccinimide. $TMGN_3$ = tetramethyl guanidinium azide. The subsequent hydrogenation proceeds catalytically.

erers of **16** that the carborane cage imparted extreme hydrophobicity upon this amino acid,[144a] and Kahl et al.[86a, 128] has pointed out that the steric requirements of the carborane group in **16** is approximately the same as the volume swept out by the rotation of the phenyl group in phenylalanine. Small hydrophilic peptides that incorporate L-carboranylalanine may prove useful to enhance its effective water solubility and bioavailability. Alternatively, its anionic *nido*-



D-16

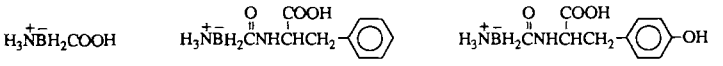
Scheme 25. An asymmetric synthesis of D- and L-**16**, described by Sjöberg et al. [86b, 128]. LDA = lithium diisopropylamide. The last step takes place on a cation exchange resin.

$C_2B_9H_{11}^-$ derivative will, at the least, be amphiphilic. Nonetheless, the synthesis of **16** makes an important biomolecule readily available for the first time. The results of in vitro and in vivo evaluation of **16** and its derivatives are awaited with great anticipation.

Related to **16** are the amino acids **9**[120, 121] and **10** (Section 7.3.1), which have not been investigated as enantiomerically pure compounds. The asymmetric synthesis of Sjöberg et al.[86b] makes these and related species generally available.

7.9.3. *Ammonium Carboxyborane Analogs of Amino Acids*

Replacement of a neutral carbon atom by an anionic boron atom bearing four valence electrons results in an isoelectronic and isosteric replacement as in the formal relationship of *closo*-$B_{12}H_{12}^{2-}$ and *closo*-1,2-$C_2B_{10}H_{12}$ (see Section 5). This process also provides a pathway for the introduction of boron into simple organic compounds such as α-amino acids and their derivatives. Spielvogel et al.[169, 182] have applied this principle to the BNCT of cerebral tumors by developing a synthesis of **36**, the ammonium carboxyborane analog of glycine. This particular molecule was of importance, because glycine has the lowest rate of transport across the blood–brain barrier of the amino acids, and the ^{14}C-labeled glycine molecule was shown to give a tumor/brain concentration ratio of 10:1 and a tumor/blood concentration ratio of 5:1 twenty-four hours after injection in BALB/c mice carrying brain inplants of Harding–Passey melanoma.[182] Injection of sufficient **36** to provide 40 mg per kg body weight in mice identical to those used in the ^{14}C-labeled glycine experiment gave very disappointing results; rapid total clearance of **36** from the animals and 2 h postinjection tumor, brain, and blood concentrations of 16.2, 7.6, and 8.8 μg B per g tissue, respectively. The blood–brain barrier was apparently more permeable to **36** than to glycine. Additional data obtained by Porschen et al.[183] on adenocarcinoma in C57 mice was consistent with these results. Even more recent data[184] pertaining to small peptide derivatives such as **37** and **38** were equally discouraging from the viewpoint of BNCT. However, it is now well estab-



36 **37** **38**

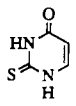
lished[169] that a variety of ammonium carboxyborane derivatives of the type discussed here have great promise as antineoplastic, hypolipidemic, and anti-inflammatory agents and are currently under development.

7.10. Melanoma Differentiation Based Upon Boron-Containing Melanin Precursors and Complexation Agents

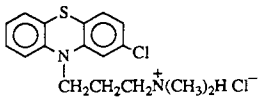
The production of the complex pigment, melanin (**39**), by melanosomes present in a preponderance of melanoma types was previously proposed as a tumor cell differentiation process[185] that rationalized the efficacy of L-**33** as a tumor-targetting amino acid.[87] Although this suggestion was not supported by accumulated evidence, and although the true mechanism of boron accretion in tumor with L-**33** is probably related to the accelerated uptake of amino acids such as tyrosine by tumor cells (Section 7.9.1), the actual incorporation of 2-thiouracil (**40**) into the melanin structure during its

in vivo synthesis has been demonstrated.[186–188] This provided an attractive possibility for the selective delivery of boron to the intracellular volume.

The ability of melanin and melanoproteins present in murine melanoma cells to tightly bind phenothiazine derivatives such as the potent tranquilizer chloropromazine[189] (**41**, known under the trade name Thorazine) also suggested a pathway for the selective deposition of boron into melanoma cells.[190] In this case preformed melanin must be available for reaction with the phenothiazine derivative.



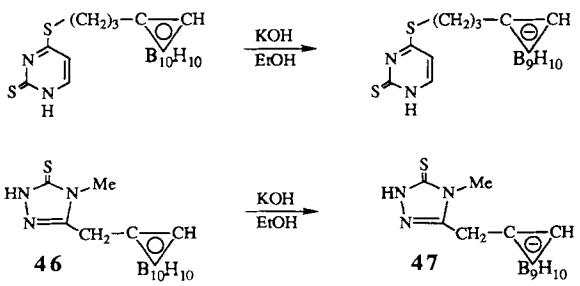
40



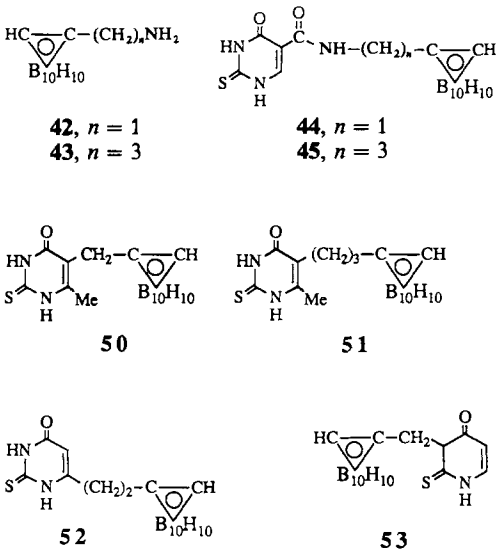
41

7.10.1. 2-Thiouracil Derivatives as Melanoma-Selective Boron Delivery Species

Although it had been determined by Dencker et al.[186,187] that 2-thiouracil (**40**) is selectively incorporated into melanin during its biosynthesis in melanoma cells, Fairchild et al.[188] quantified this process for the first time in 1982 by using ^{14}C-labeled 2-thiouracil ([^{14}C]TU) administered intraperitoneally or intravenously in BALB/c mice bearing Harding–Passey melanoma. The tumor uptake of TU was correlated with melanin content. The tumor uptake of [^{14}C]TU was as high as 9 to 12% of the injected dose per g tumor. Ratios of the concentration in tumor and normal tissue varied from 50:1 in metabolizing organs such as liver and lung, to 80:1 in pigmented whole eye, and 300:1 in muscle and brain. The percentage of uptake of [^{14}C]TU by tumor was virtually unchanged as the administered dose was varied by a factor of 5000 to give as much as 300 μg [^{14}C]TU incorporated per gram of tumor. This is equivalent to 26 μg B per g tumor if only one boron atom were incorporated in each molecule of **40**. These initial results stimulated a major effort to develop new boron-containing delivery agents based upon derivatives of 2-thiouracil and other compounds having at least a loose structural relationship to thiourea. Compounds that have been explored carry boron as a dihydroxyboryl group, an uncharged 1-(*closo*-1,2-$C_2B_{10}H_{11}$) appendage or its anionic 7-(*nido*-7,8-$C_2B_9H_{11}^-$) counterpart, which enhances hydrophilicity. The research groups responsible for the synthesis of this library of derivatives were headed by Gabel.[191,192] and Wilson,[193,194] whose representative contributions are illustrated in Schemes 26 and 27, respectively. In addition to carborane-substituted 2-thiouracil species, Wilson also synthesized the useful carboranylalkylamine building blocks **42** and **43**, which were in turn converted into the corresponding amides[194] **44** and **45** by reaction with 5-carboxy-2-thiouracil. Gabel et al.[192] reported the synthesis of **46** and **47** carborane derivatives of 5-thio-1,2,4-triazole, as well as of **48** and **49**.

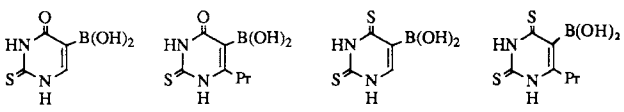


Scheme 26. Thiouracil and thiotriazol derivatives synthesized and evaluated by Gabel et al. [191,192].



Scheme 27. Carboranylalkylamine and thiouracil derivatives, synthesized and evaluated by Wilson et al. [193,194].

Evaluation of the selective uptake of these candidate species by murine melanoma models has proceeded slowly. Gabel et al.[191,192] report that the dihydroxyboryl derivatives **48a** and **48b** gave boron concentrations in B16 melanomas grown in C57/bl mice (4 h after intraperitoneal administration of 9–16 mg B per kg body weight) of about 30 μg B per g tumor with tumor-to-blood boron concentrations ratios of 4:1 to 7:1. The more hydrophobic 6-propyl



48a **48b** **49a** **49b**

derivative **49b** was taken up to the extent of only 1.7 μg B per g tumor, while **49a** gave intermediate results. The 5-thiotriazole species **46** and **47** gave poor selectivity and accumulated in the liver. The remaining carborane derivatives of Scheme 26 were less effective than the dihydroxyboryl compounds **48** and **49**.

The carborane derivatives **50** through **53** of Wilson et al.[193,194] were quite hydrophobic and too slowly taken up by nude mice bearing Harding–Passey melanoma xenografts to be useful. Incorporation of **51** in the phospholipid bilayer of a liposome (Section 7.7.1) was investigated by

Moore et al.[164] as a means of delivery for this hydrophobic species. High tumor specificity was observed, but no other data were reported.

While the efficacy of boron-containing 2-thiouracil and related compounds remains to be demonstrated and optimized by further molecular design and synthesis work, promising results were indeed obtained, and further work is warrranted. However, the presumed dependence of this delivery mode upon melanogenesis would seem to rule out the ability of these compounds to accumulate in amelanoic melanoma lines and immature premelanoic melanoma metastases having low tyrosinase activity.

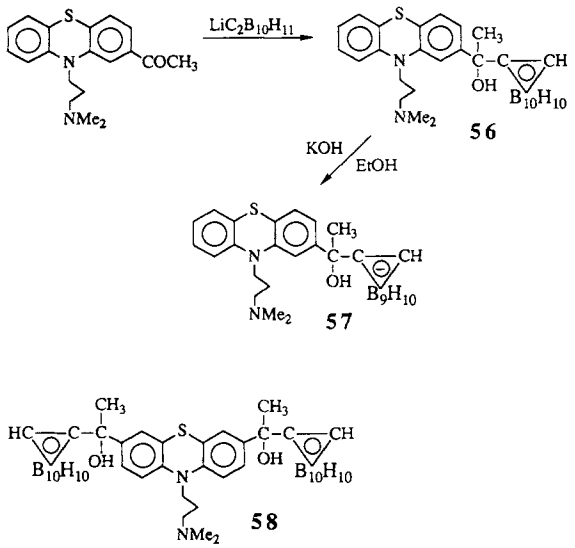
Scheme 28. Phenothiazine derivatives of the polyhedral $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ ions, synthesized by Nakagawa and Aono [199] and evaluated by Mishima et al. [200].

7.10.2 Phenothiazine Charge-Transfer Complexes with Existing Melanin as a Boron Delivery Mechanism

Investigation of the tranquilizing drug **41** known as chloropromazine in the early 1960s uncovered its remarkable ability to accumulate in the melanin-bearing eye tissues of experimental animals.[189] This apparently selective complexation of **41** and other phenothiazine derivatives was demonstrated with melanin and melanoproteins obtained from many other sources.[189] Melanin and its variations are complex polymeric pigments apparently derived from 5,6-indolequinone and other precursors,[195, 196] some of which contain sulfur (cysteine). It is now accepted that the melanin–phenothiazine complexation reaction is the result of electron-transfer reactions in which melanin serves as the electron acceptor.[197] The chemistry based upon these and other interesting observations is beyond the scope of this article, and the reader is referred to the original literature.

The accumulation of **41** in melanoproteins attracted the interest of Mishima et al.[190] with respect to the possibility of selective transport of boron to melanin-rich melanomas with boron-substituted derivatives of **41**. The biodistribution of ^{35}S-labeled **41** was thoroughly examined by Fairchild et al.[198] in a series of time-course experiments. Both Greene melanoma in Syrian golden hamsters (melanin content about 0.4% by weight of tumor) and Harding–Passey melanoma in BALB/c mice (melanin content about 0.7% by weight of tumor) were employed, since these models closely resembled human melanoma. The drug was administered by intraperitoneal injection. Twenty-four hours postinjection of up to 50 mg **41** per kg body weight, absolute concentrations of **41** in tumor that exceeded 100 μg per g tumor could be obtained; the concomittant tumor-to-liver concentration ratio is about 10:1. The ratios of boron concentration in tumor to that in other tissues such as blood and muscle were greater than 100:1. Computation of hypothetical tissue concentrations of ^{10}B were made with compound **54** as an example (25.4% ^{10}B by weight as sodium salt) and found to be sufficiently high (> 20 μg B per g tumor) for BNCT if this species provided the same performance as **41**.

The results of earlier investigators buttressed by the data of Fairchild et al.[198] stimulated a search for suitable boron-containing derivatives of phenothiazine. Consequently, Nakagawa and Aono[199] reported the syntheses of the polyhedral borane anion derivatives **54** and **55** (Scheme 28). Both **52** and **53** were investigated in BNCT experiments[200] with Greene's melanoma grown in Syrian golden hamsters. Although increased tumor destruction was observed in the presence of these compounds, their cell selectivity significantly differs from that of **41**, and they were not pursued. The compounds **52** and **53** both carried their borane groups as coordination centers on the pendant dimethylaminopropyl group of **41**.[199] Soloway et al.[201] attached 1-(*closo*-1,2-$C_2B_{10}H_{11}^-$) carborane cages to the phenothiazine structure (Scheme 29). The anionic 7-(*nido*-7,8-$C_2B_9H_{11}$) carbor-



Scheme 29. Phenothiazine derivatives synthesized and evaluated by Soloway et al. [201,202].

ane derivative **57** was obtained by the usual route: removal of a BH^{2+} vertex from **56** with base. The compounds **56** through **58** gave preliminary in vivo evaluation results which suggested that they were too hydrophobic to be of interest, and efforts are underway to synthesize derivatives with improved water solubilities.[202]

The results reviewed above suggest that phenothiazine derivatives may have a place in BNCT if the search for a properly solvated compound is continued. Nonetheless, the fact that **41** and other phenothiazines can be localized only with preformed melanin puts limitations upon the actual therapeutic value of such a compound, even if it were discovered. It is interesting to note that research with phenothiazine derivatives has not been presented at either of the last two international meetings of the International Society for Neutron Capture Therapy convened in 1990 (Sydney) and 1992 (Columbus, Ohio).

7.11. Approaches to the Selective Destruction of the Tumor Cell Nucleus

The spectacular development of the synthetic chemistry of nucleic acids and their derivatives[203] has led to the discovery of new therapeutic agents and useful biological probes based upon modified synthetic nucleosides, mononucleotides, and oligonucleotides. Among these new DNA and RNA precursors are found species that serve as antiviral and anticancer agents either through enzyme inhibition or "antisense" activity, which blocks oncogene expression.[204] Mono- and oligonucleotides have been synthesized which contain altered bases, sugars, and phosphorus-containing linker groups. It is, therefore, not surprising to discover research activities aimed at the modification of nucleotides by the incorporation of boron-containing motifs into all three of these essential structural components. While these boron-containing nucleic acid components are important as such, they also offer new methodologies for the localization of boron in the tumor cell nucleus for purposes of BNCT.

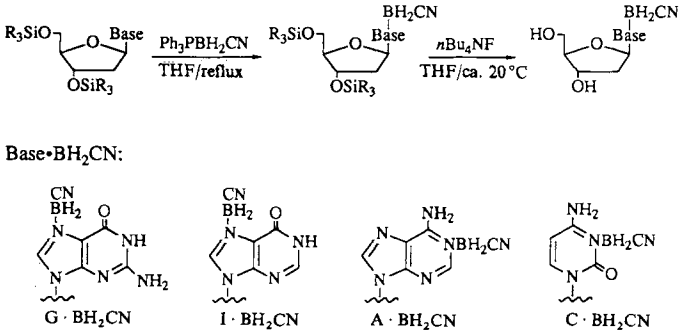
Selectivity for nuclear accretion of boron in tumor cells is provided by the very rapid rate of tumor cell reproduction compared to that of normal cells. An important aspect of this observation is the fact that glioma cells undergo mitosis at a much greater rate than surrounding normal glial cells. Thus, it is possible that boron-containing species useful in BNCT and based upon DNA incorporation might be developed if such an ideal species were capable of Watson–Crick base-pairing, were not susceptible to nuclease activity, and could penetrate cell membranes. Alternatively, if a BNCT reagent were a cytotoxic enzyme inhibitor or "antisense" species, the effective lethality of BNCT would be further enhanced. As stated previously, the nucleus of a malignant cell is the target of highest value, since ^{10}B is at least twice as effective in the cell nucleus as an equal quantity distributed throughout the cytoplasm.

Another approach to the intranuclear accretion of boron is the development of DNA ligand molecules that contain boron.[205, 206] The huge number of available DNA binding sites per tumor cell amplified by the very effective localization of the boron target atoms in the cell nucleus makes this an attractive approach.

The description of a representative variety of boron-containing nucleic acid components is presented in the following section. The mechanisms that provide cellular uptake of these species, where observed, is normally not known nor is their distribution within the cell's interior. Such problems are current research topics of great importance.

7.11.1. *Nucleosides Modified by Base Complexation with Cyanoborane, BH_2CN*

In keeping with their interest in synthesizing α-amino acids in which single carbon atoms are formally replaced by an anionic boron atom having four valence electrons (see Section 7.9.3), Spielvogel et al.[207, 208] have modified the base residues present in representative nucleosides by complexation of specific nitrogen centers with the Lewis acid, BH_2CN. The attachment of BH_2CN to the base residues was accomplished by the displacement of Ph_3P from Ph_3PBH_2CN with a base nitrogen center present in dG, dI, dA, and dC in which the hydroxyl groups are protected followed by deprotection of the nucleoside complex (Scheme 30). The BH_2CN moiety was selectively placed on N^7 of dG and dI, N^1 of dA, and N^3 of dC. The site of coordination in both dG and dI is well



Scheme 30. Nucleoside derivatives synthesized by Spielvogel et al., in which BH_2CN is coordinated to base nitrogen atoms [207,208].

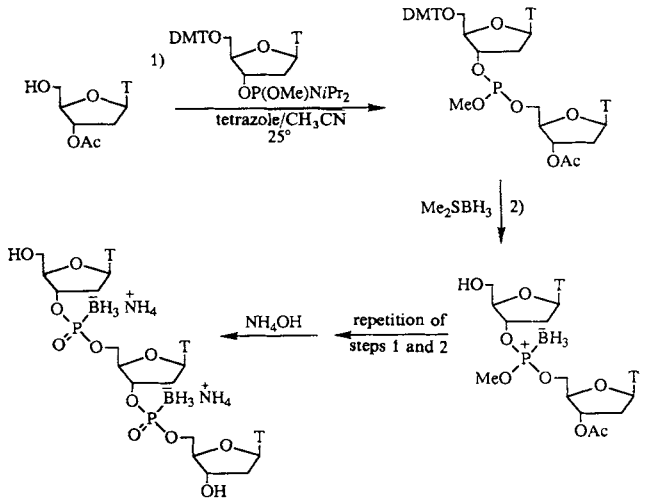
separated from the sites involved in Watson–Crick base-pairing. The dG–N^7-BH_2CN adduct was shown by ^1H NMR experiments to form base pairs with dC as effectively as unmodified dG.[208] Attempts to prepare the BH_2CN complex of dT were unsuccessful. In mice the dC–N^3-BH_2CN complex demonstrates biological activity as an inhibitor of inflammation, while dG–N^7-BH_2CN lowers serum cholesterol.[208] Tumor localization in mice bearing Ehrlich ascites carcinoma was demonstrated with ^{14}C-labeled dC–N^3-BH_2CN and gave a tumor-to-blood concentration ratio of 8.5:1 four hours postinjection.[208] The quantity of boron taken up by tumor was not determined.

7.11.2. *Nucleotide Analogs Containing Boranophosphate Linking Groups*

The formal replacement of the coordinated oxygen atom and its six valence electrons in a nucleotide phosphate linkage by a BH_3 molecule results in the formation of a negatively charged boranophosphate moiety. Such modified nucleotide linkers are isoelectronic with uncharged methylphosphonate linking groups, which have found use in "antisense" constructs.[204] The boranophosphates offer the advantage of a formal negative charge, largely on boron, and greater hydrophobicity than that presented by phosphate. The latter property is thought to be useful in assisting cell-membrane penetration. Modified nucleotides of the boranophosphate type were first prepared by Spielvogel et al.[208, 209] and proposed as boron delivery agents.

Scheme 31 describes the synthesis of typical boranophosphate oligonucleotides and suggests the feasibility of greatly extending the chains of these oligomers by the application of solid phase mediated synthesis methods.

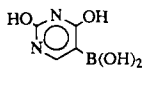
The scope of the biological activity of compounds of the boranophosphate type, including cytotoxicity and enzymatic incorporation into DNA, is presently undergoing evaluation.[210] Superior candidates for BNCT have not yet been identified.



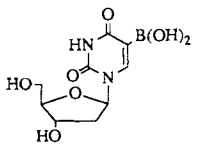
Scheme 31. The synthetic route to nucleotides containing boranophosphate linking groups, which was devised by Spielvogel et al. [208,209].

7.11.3. Boronic Acid Derivatives of Pyrimidine and Purine Nucleosides

The first DNA precursor to be synthesized that contained a carbon–boron bond was 5-dihydroxyboryluracil (**59**, Liao et al.[211] 1964). This was followed by the synthesis of the 5-dihydroxyboryl-2′-deoxyuridine (DBDU, (**60**)) first described by Schinazi and Prusoff[212] in 1978. The syntheses of **59** and **60** were accomplished by lithiation of suitable 5-bromo precursors in which the hydroxyl groups are protected, followed by reaction of the resulting lithium moiety with a trialkyl borate ester.[213] The stereochemical similarity of **60** and natural thymidine (5-methyl-2′-deoxyuridine) suggested this synthesis. The possible modes of incorporation of **60** into the nucleus of tumor cells was envisioned by Schinazi et al.[214] to possibly involve one or more of the following phenomena: 1) **60** is taken up selectively by malignant cells, and trapped within the cell as the 5′-monophosphate. This selectivity for tumor cells could be amplified if **60** were a better substrate for the thymidine kinase present in tumor cells than for the corresponding enzyme found in normal cells. 2) **60** could function as a inhibitor of enzymes involved in pyrimidine nucleoside biosynthesis. 3) **60** might become incorporated in DNA of tumor cells as a substitute for a pyrimidine nucleotide. 4) Any or all of the events listed above could provide ^{10}B-labeled **60** to the nucleus of the tumor cell for selective destruction through neutron capture. In principle, these mechanistic possibilities exist, to varying degrees, in every ^{10}B-labeled nucleoside or nucleotide molecule described here (Section 7.11).



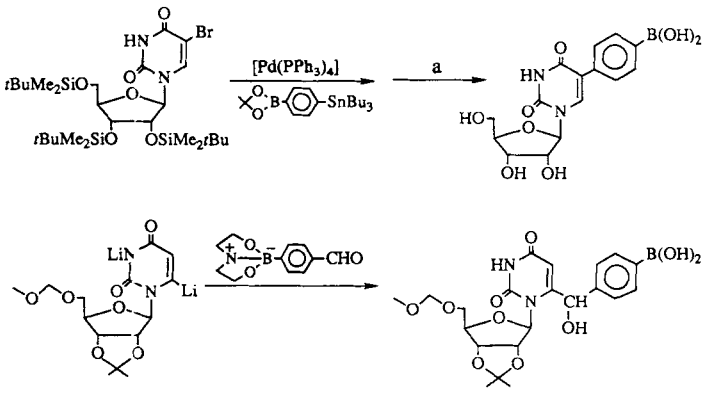
59



60 DBDU

Evaluation of the biological activity of **60** in vitro proved[214] that it was a good analog of thymidine and inhibited the replication of HSV-1. This inhibition of viral replication was nullified by added thymidine. Preliminary in vitro neutron irradiation experiments with solutions of ^{10}B-enriched **60** containing varying amounts of thymidine and V79 chinese hamster cells (washed) were carried out at the Brookhaven Medical Research Reactor. Pre-equilibration of the subject cells with **60** decreased their survival rate upon exposure to thermal neutrons, and the addition of thymidine to the **60** solution mitigated this effect. These results suggested to the authors that **60** was bound during DNA synthesis, but that it could not effectively compete with thymidine.

Using newly developed synthesis methods Yamamoto has obtained a wide variety of new base and nucleoside derivatives that contain either a 3- or 4-(dihydroxyboryl)-phenyl[215] or an α-hydroxy-4-(dihydroxyboryl)benzyl[216] substituent. Representative syntheses are outlined in Scheme 32. The dihydroxyboryl derivative prepared by these



Scheme 32 Examples of two general synthetic routes leading to dihydroxyboryl derivat ves of nucleosides, demonstrated by Yamamoto et al. [215,216]. a: Deprotection.

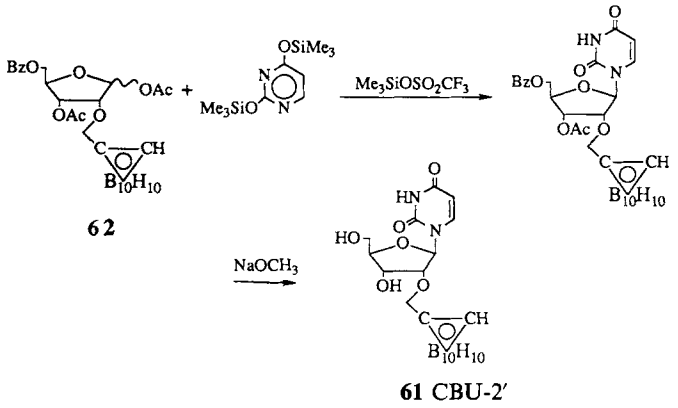
new procedures are numerous; however, they are most likely susceptible to acid-catalyzed deboronation to form the corresponding phenyl- or α-hydroxybenzyl-substituted nucleoside and boric acid. In addition, the added aryl groups will increase the hydrophobicity of the desired nucleosides with unpredictable results. Selected members of this group of nucleosides are undergoing evaluation with respect to their biological activities including efficacy in BNCT.

7.11.4. Carborane-Substituted Nucleosides

The relatively simple compounds described in the previous section which contain the dihydroxyboryl function are low in boron content and subject to hydrolytic deboronation reactions. As an alternative to these simpler boron compounds, the *closo*-1,2-$C_2B_{10}H_{12}$ carborane has been functionalized to produce carborane-substituted ribose and base components of nucleosides. These species may become trapped in the nucleus of the tumor cell as described in Section 7.11.3. Whereas the boron-rich *closo*-carborane substituent will markedly decrease the hydrophilicity of the substrate to which it is attached, conversion of the *closo*-carborane structure to the corresponding anionic *nido*-carborane structure

may produce an amphiphilic derivative. Because the carborane substituent is comparatively large and has hydrophobic properties, it would not be expected that carborane-substituted nucleotides would actually become incorporated as surrogates in oligomeric DNA or RNA molecules of natural origin. However, intranuclear phosphorylation of a carboranyl-substituted nucleoside may serve to immobilize the resulting monophosphate within the nucleus.

Soloway et al.[217] recently described the first carborane-substituted nucleoside, 2′-*O*-(1,2-carboran-1-ylmethyl)-uridine (**61**), which has been designated CBU-2′ by its discoverers. Both the 3′-*O*- and 5′-*O*-(1,2-carboran-1-ylmethyl)uridine isomers have been described,[218] as well as the anionic *nido*-carborane analog of **61**. More recently, Tjarks et al. have described[219] what may become a general synthesis of nucleosides, which they demonstrated with the synthesis of **61** (Scheme 33). The key precursor in these potential syntheses is 1,3-di-*O*-acetyl-5-*O*-benzoyl-2-*O*-(1′,2′-carboran-1′-ylmethyl)-D-ribofuranose (**62**), which has been shown to afford **61** by reaction with trimethylsilyl-protected uracil in the presence of trimethylsilyl trifluromethanesulfonate followed by alkaline hydrolysis. Only the β-configuration was observed at the 1-position of the ribose moiety. One hopes that this synthesis route will find wide application.

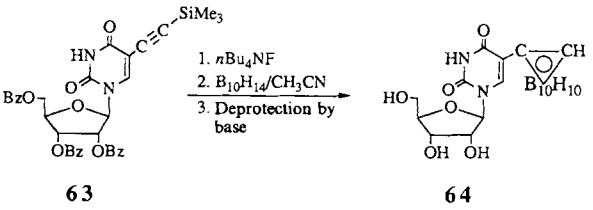


62 **61 CBU-2′**

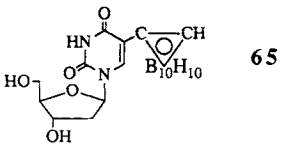
Scheme 33. An example of the generalized synthesis of carborane derivatives of nucleosides by Tjarks et al. in which **62** is a common precursor [219].

The carborane-substituted nucleoside **61** and its 3′ and 5′ isomers were efficiently taken up by F98 glioma cells in vitro.[218, 220] Morrison et al.[221] have recently shown by SIMS (see Section 2.5.4) that the concentration of **61** in F98 glioma is higher in the cytoplasm than in the cell nucleus by a factor which varies from 1.4 to 2.6. The mechanism of cellular localization of **61** is under investigation.[222]

Yamamoto et al.[223] has recently developed a route to uridine and 2′-deoxyuridine derivatives bearing either a 1,2-carboran-1-yl or 2-hydroxymethyl-1,2-carboran-1-yl substituent in the 5-position of the uracil ring. These syntheses were initiated by using the Pd-catalyzed coupling of 5-iodouridine or 5-iodo-2′-deoxyuridine in which the hydroxyl groups are protected with $HC{\equiv}C\text{-}SiMe_3$ or $HC{\equiv}C\text{-}CH_2OAc$. The resulting 5-alkynyl nucleoside derivatives were converted into the desired products, for example **64**, by the usual reaction with $B_{10}H_{14}$ and a Lewis base. Preliminary findings indicate that 5-carboranyluridine is cytotoxic against P-388 murine leukemia cells in vitro. Schinazi et al.[224] have independently synthesized 5-carboranyl-2′-deoxyuridine (**65**) by a route similar to that reported by Yamamoto et al. Schinazi's group has studied the metabolites produced in CEM cells treated with **65**. A new metabolite was isolated which displays the biochemical properties expected for a 5′-monophosphate of **65**, which is believed to arise by intracellular phosphorylation.[224]

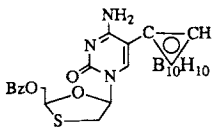


63 **64**

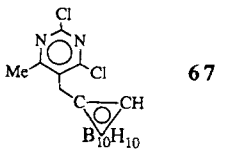


65

A synthesis of racemic 5-carboranyl-2′,3′-dideoxy-3′-thiacytidine (**66**) has been developed by using the Pd-catalyzed alkynylation of 5-iodo-2′,3′-dideoxy-3′-thiacytidine.[224] This and related compounds are undergoing biological evaluation.



66

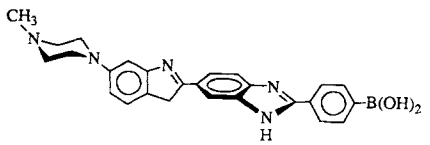


67

Reynolds et al.[225] have described the synthesis of 5-(1,2-carboran-1-ylmethyl)-2,4-dichloro-6-methylpyrimidine (**67**), which may prove to be useful as the synthetic equivalent of substituted pyrimidines.

7.11.5. Intranuclear Localization of Boron with DNA Ligands

The possibility of localizing boron in the DNA of target cells by complexing it with boron-containing ligand molecules has recently been investigated by Whittaker et al.[205] and Corder et al.[206] Dibenzimidazole reagents from Hoechst effectively bind to the minor groove of nuclear DNA, and a variety of reagents based upon this ligand sys-



68

tem have been developed. The simple phenylboronic acid derivative **68** has been the subject of preliminary in vitro investigations of cellular boron uptake. Fluorescence microscopy and spectrophotometric analyses of the ligand in isolated nuclei have demonstrated uptake of **68** by a variety of viable cells. Neutron capture experiments demonstrated enhanced cell killing in the presence of 2×10^{-5} M **68**. The observed effect was equivalent to that obtained with a solution of 4×10^{-6} g $^{10}B(OH)_3$ per mL in contact with the cells during irradiation. This result was viewed as quite encouraging, and work is underway with other boron-containing ligands carrying several ^{10}B atoms per ligand.

7.11.6. Selective Delivery of Boron-Containing Species to the Nucleus

Scheme 5 depicts the transport processes involved in bringing a boron-containing agent from blood serum into the nucleus of a tumor cell. Each of the methods outlined in Section 7.11.3 for the intranuclear accretion of boron depends upon the enhanced rate of mitosis of tumor cells, as opposed to normal cells, to provide the required bias for selective tumor cell destruction. In addition, the fact that the walls of malignant cells are penetrated may place structural limitations upon the reagent to be delivered that mitigates its desired function of intranuclear localization. These problems may be circumvented by coupling intranuclear reagents to delivery systems that are known to be biased toward malignant cells. Of the available tumor-selective delivery methods discussed in this review, unilamellar liposomes (Section 7.7.1) are distinguished by their apparent effectiveness in selectively penetrating plasma membranes of tumor cells and by their ability to carry a wide variety of hydrophilic species to the cell's interior. Hydrophilic bases, nucleosides, and nucleotides of all sizes that contain appreciable numbers of boron atoms per molecule are candidates for this mode of delivery. Such research has been initiated in my laboratory.

8. The Needs and Prospects of BNCT

In principle, Locher's original proposal has been demonstrated. BNCT offers great promise for the treatment of cancers not amenable to current management and characterized by high mortality rates such as cerebral glioma and metastatic melanoma. The war on cancer has evolved into trench-warfare, and therapeutic methods that depart from presently accepted therapeutic modalities must be brought to bear if progress is to be resumed. As a therapeutically unique, but superficially complex method, BNCT stands out as just such an opportunity if the research momentum of the present is further increased and applied to the problems that have been identified in this review.

The foremost prerequisite for the adaptation of BNCT as a readily accessible medical tool available for the treatment of patients from the general population requires that pure epithermal neutron beams must be made available from economical sources other than nuclear reactors and placed in urban areas. Such advanced neutron generators could be based upon the spallation of neutrons from a metallic target by accelerated protons (Section 2.3.2). Such devices could possibly be available in prototype form within two to five years.

Also associated with the clinical practice of BNCT is the potential use of real-time NMR imaging techniques (MRI), which employ ^{10}B as the active nucleus, to visualize and quantify ^{10}B-loaded tumor and surrounding tissues (Section 2.5.1). Such a rapid and reliable noninvasive method of obtaining data on ^{10}B targets would be invaluable for determining the required neutron dose, orienting the patient in the epithermal beam, and monitoring changes that occur at the tumor site between the application of fractional doses. Work is now in progress with the more NMR amenable ^{11}B nucleus, which, if successful, will be applied to the development of a more valuable ^{10}B MRI capability.

The outline of biodelivery modes presented in Scheme 6 is based upon data of variable reliability. Consequently, the precise determination of the positioning of ^{10}B target nuclei both on, or in, malignant cells is vital to the intelligent design of new boron-containing compounds. While the subcellular distribution of boron may now be visualized (Section 2.5.4) if the subject cells are derived from an in vitro source, it would be especially useful to have similar data available from cells harvested from in vivo experiments. Data now available from in vitro preparations have been extremely enlightening and prompt further elaboration.

As seems likely, future development of boron-containing compounds will be increasingly directed toward systems designed to enter the tumor-cell nucleus on a cell-selective basis (Section 7.11). In addition to the biosyntheses of DNA or other biochemical processes that take place in the nucleus, the requirement of bringing the molecular tools such as boron-containing DNA precursors, DNA ligands, or antisense species to bear selectively upon malignant cells remains a major challenge. Receptor-mediated species, which may provide a selective means of penetration of the plasma membrane, might be coupled to the nucleus-binding reagent and enzymatically decoupled following cell entry. Cellular selectivity would be provided by the enhanced rate of mitosis and overexpression of receptor sites characteristic of tumor cells. On the other hand, it might prove possible to deliver the nucleus-binding reagent to the cell's cytoplasm through tumor-selective liposomes (Section 7.7.1) followed by migration of the reagent to the nucleus. Regardless of the novelty and elegance of new reagents that specifically interact with nuclear components, the problem of assuring selective binding to tumor cells demands consideration during the conception of the boron-containing agent itself.

The future development of BNCT clearly depends upon the design and synthesis of boron-containing species capable of extensive accretion within tumor cells and the related bioutilization systems that assure their selective delivery to malignant cells. The discoveries of modern microbiology and immunology that are related to practical bioutilization pathways (Section 6) have appeared at such a great rate that the corresponding chemical research effort may have fallen behind. A plea is made here for an extensive expansion of synthesis efforts aimed at the development of new synthesis methodology in the organoborane area and at its interface with bioorganic chemistry. A need exists for boron-contain-

ing molecules and oligomers that may be coupled to biodelivery molecules in a modular fashion. Similarly, modular groups that may be used to overcome the innate hydrophobicity of the *closo*-carborane and the amphiphilic *nido*-anion substituents are needed.

The proper biological evaluation of a candidate boron-containing system is vital to the correlation of chemical structure with biological activity and provides the guidance for further molecular design and synthesis efforts. It may very well be, as shown by recent work with boron-containing nucleosides, that aside from obvious applications in BNCT, some of the new compounds may have biological response profiles that make them desirable for other important applications. The work of Schinazi, Soloway, Spielvogel, and Yamamoto (Sections 7.9.3 and 7.11) provide examples of antiviral, anti-inflammatory, antineoplastic, and hypolipidemic compounds originally developed for BNCT research.

At this time, the concept of BNCT is closer to realization than ever before. New clinical trials with the thioborane anion BSH and dihydroxyborylphenylalanine (BPA, **33**) are beyond the advanced planning stages in Europe and the United States. Trials with melanoma by Mishima and his colleagues continue in Japan, as do the therapeutic procedures of Hatanaka. It must be pointed out, however, that the clinical trials now in progress and those to be initiated in the near future, by necessity, employ boron delivery agents such as BSH (Section 7.1) and BPA (Section 7.9.1). These are not truly high-performance compounds, but they are reasonably well understood and offer reliability. The tumors to be attacked are cerebral gliomas and primary melanoma lesions; the nuclear reactors at Petten and MIT will serve as neutron sources.

Longer range plans for BNCT must proceed irregardless of the upcoming clinical trials, since by the time these trials are completed greatly improved boron delivery agents and new neutron sources could be available, provided increased financial support from both government and industry is forthcoming. It seems certain that the future of BNCT will brighten as more medical practitioners become aware of its virtues. The meeting of knowledge derived from physics, chemistry, biology, and medicine at one point in the multidimensional field of science is a unique circumstance that cries out for exploitation by mankind. Perhaps it was really planned!

I wish to thank my students, postdoctoral associates, and colleagues, both past and present, for their contributions to our group's efforts in BNCT chemistry, and boron cluster chemistry in general. Drs. Debra A. Feakes and Kenneth J. Shelly have made vital contributions to this article by collecting information and critically reviewing the product. I am grateful to Mrs. Diane Gromelski for the preparation of the manuscript, Mr. Albert Calleros for the artwork, and Karin Drechsel for proofreading. I also wish to thank my many friends in the BNCT community for stimulation and the National Institutes of Health (RO1-CA31753 and RO1-CA53870) and the U.S. Department of Energy Idaho National Engineering Laboratory, Office of Energy Research, under DOE Field Office, Idaho, Contract DE-ACO7-761DO1570 for their support of our BNCT research efforts.

Classical and Nonclassical Methyleneboranes

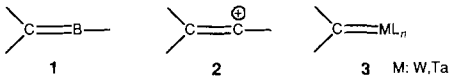
By Armin Berndt*

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

Methyleneboranes are stable compounds when their reactive C=B bonds are shielded by sterically demanding substituents and the electron deficiency at the dicoordinate boron atom is reduced through delocalization of adjacent electron pairs. In the classical amino(methylene)boranes of Nöth and Paetzold, the electron deficiency at the dicoordinate boron atom is relieved through π–π delocalization of a neighboring nitrogen atom's formally nonbonding electron pair, that is, through formation of a classical two-center, two-electron (2c–2e) bond. In *nonclassical* methyleneboranes, which are the focus of this review, the electron-deficient center at the dicoordinate boron atom forms nonclassical three-center, two-electron (3c–2e) bonds with neighboring σ bonds. These methyleneboranes exhibit structural and spectroscopic properties similar to carbenium ions having strong σ–π delocalization (hyperconjugation, bridging) and to transition metal complexes having strong agostic interactions.

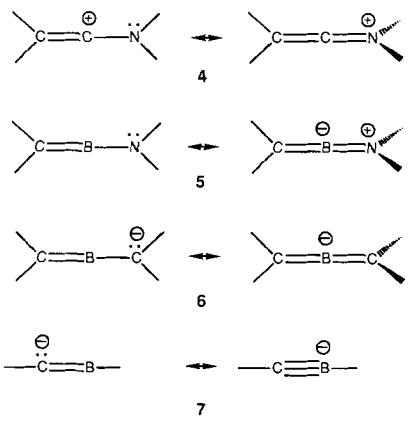
1. Introduction

Methyleneboranes (**1**)[1–4] are compounds with a C–B double bond, containing a boron atom which in classical representatives is dicoordinate. They are isoelectronic with vinyl cations (**2**)[5] and are closely related electronically to the carbene complexes of type **3** (M = W, Ta[6, 7]). The properties of compounds **1**–**3** are determined to a large extent by the high electron deficiency at the dicoordinate atoms in **1** and **2** and the metal atoms in **3**.



1 **2** **3** M: W,Ta

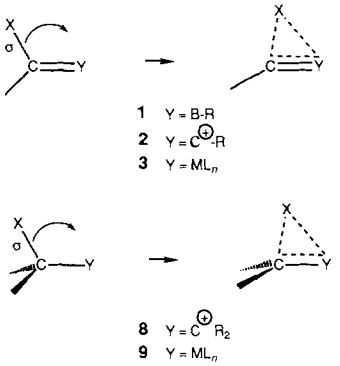
In classical methyleneboranes, as in the amino-substituted vinyl cations (ketiminium ions) **4**,[8] the electron deficiency at the dicoordinate atom is greatly reduced through π–π delocalization of the formally nonbonding electron pairs on the neighboring atom (Scheme 1). Typical examples are the amino(methylene)boranes **5** of Nöth[2] and Paetzold.[3a–c] The 2-borataallenes **6**[9] and the borataalkynes **7**[10] are considered here as special cases of classical methyleneboranes because of their stabilization through π delocalization of formally nonbonding electron pairs on the carbon atoms adjacent to the dicoordinate boron atom.



4 **5** **6** **7**

Scheme 1. π–π Delocalization in classical methyleneboranes and related compounds.

In compounds of the type **1** and **2**, and carbocations **8**,[11] where the electron deficiency at the di- or tricoordinate atom is not (or only weakly—see Section 3.2.2) reduced through π–π delocalization, and in **3** and other transition metal complexes of the type **9**,[7, 12] where the metal center has 16 or fewer valence electrons, the electron-deficient centers will form nonclassical 3c–2e bonds with the electrons of the neighboring C–X σ bonds.



1 Y = B-R
2 Y = C⊕-R
3 Y = ML_n
8 Y = C⊕R_2
9 Y = ML_n

Scheme 2. Nonclassical 3c–2e bonds through interaction of electron-deficient centers with neighboring σ electrons: the α-agostic type.

These interactions are called α agostic effects[7] if the electron-deficient center is a metal, but if it is a positively charged carbon atom, the name C–X hyperconjugation is used. Pronounced effects in carbocations are termed nonclassical bridging. The expression σ–π delocalization[11] is employed as the generic term. Depending upon the extent of the shift of the bonding electrons in the C–X bond towards the electron-deficient center—the X nucleus must follow for electrostatic reasons—a continuum[13] in the degree of 3c–2e bond development can be observed. The following series of formulas show examples of carbocations having no appre-

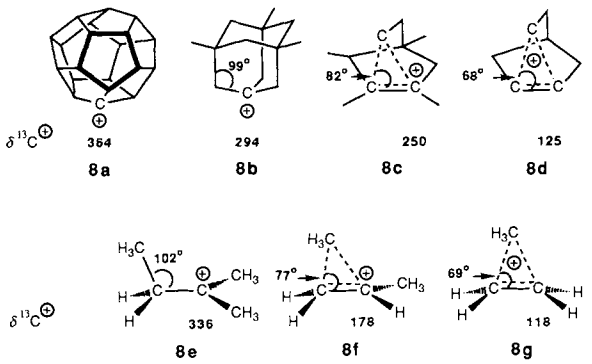
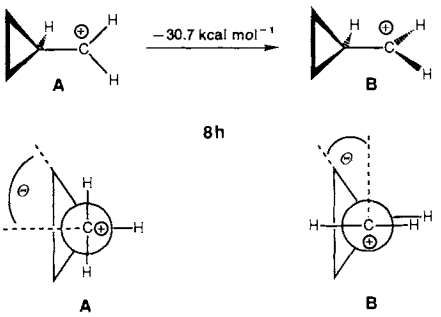
ciable hyperconjugation (**8a**[14]), strong C–C hyperconjugation (**8b**,[15] **8e**[16]), unsymmetrical bridging (**8c**,[17] **8f**[18]), and symmetrical bridging (**8d**,[19] **8g**[16]).



Bond angle distortion and NMR shielding of the electron-deficient center are the most obvious consequences of strong nonclassical interactions.[1d, 1f, 16, 18] The examples demonstrate the influence of geometry, ring strain, and electron deficiency on the extent of C–C hyperconjugation. Very strong C–C hyperconjugation appears with strained σ bonds of three-membered rings.[20, 21]



The above example also shows the effect that the dihedral angle θ between the σ and p orbitals has on the strength of the σ–π interactions. The bisected form **8hB** has a small dihedral angle and is 30.7 kcal mol^{-1} [21a] lower in energy than the perpendicular form **8hA** with the large θ.

The salient significance of the X atom's electronegativity is demonstrated by the energy differences between the conformations of the carbocations **8g** and **8i–8k** that *do* (**B**, $\theta = 0°$) and *do not* (**A**, $\theta = 90°$) exhibit C–X hyperconjugation.[22] The calculated stabilization energies for cations exhibiting the "β-Si effect" (that is, type **8i**), have been confirmed impressively by experiment.[23]

	X	ΔE [kcal mol^{-1}]
8g	C	− 8.3
8i	Si	− 29.1
8j	Ge	− 38.8
8k	Sn	− 47.9

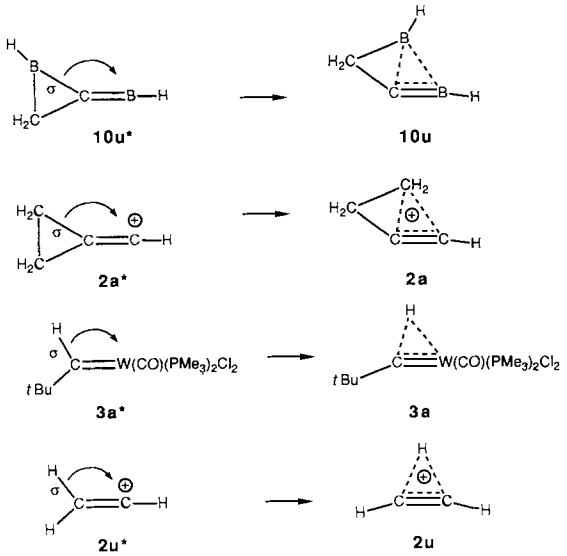
The strength of the nonclassical interactions can be estimated qualitatively with use of the HOMO/LUMO concept.[24] The effect is favored by high electron deficiency (**8g** > **8f** > **8e**, **8d** > **8c**), which induces a low-lying LUMO, and by ring strain (**8h**, **8c** > **8b**), which gives rise to a high-lying HOMO. The overlap between the orbitals of the C–X σ bond and the electron-deficient center will be promoted by a small dihedral angle θ, an electropositive X atom, and a short distance between the σ and p orbitals. Particularly strong effects are therefore to be expected in compounds in which X is an electropositive atom and the C–X bond is part of a three-membered ring bound to the electron-deficient center through a short double bond in an arrangement where $\theta = 0°$ is realized. These conditions are optimally fulfilled in the boriranylideneborane **10u***,[*] whose nonclassical bridged structure **10u** was predicted from ab initio calculations.[25, 26]

The boriranylideneborane **10a** (Sections 2 and 3), with sterically demanding substituents in place of the hydrogen atoms in **10u**, was the first experimentally available methyleneborane.[1a] Bond angle distortions of comparable magnitude to that in **10u** were calculated for the closely related vinyl cation **2a**,[27, 28] and observed in carbene complexes like **3a**.[6, 7] The latter resembles the H-bridged vinyl cation **2u**.[29] Carbocations having electropositive X atoms

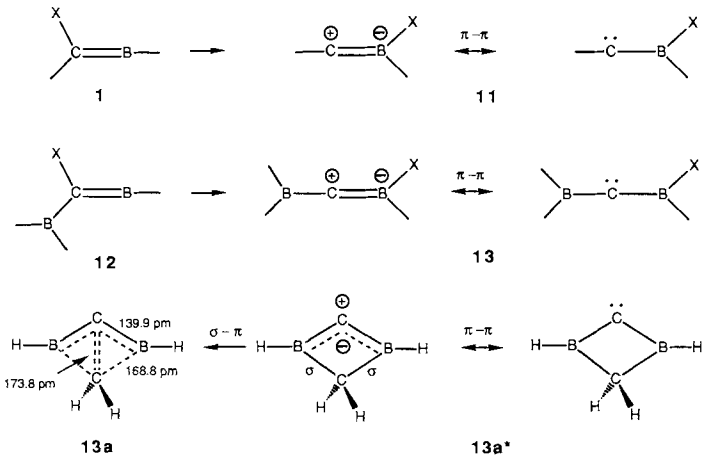
[*] The letter "u" will be used for the unsubstituted basic structure of a compound class, and a star "*" will indicate the (nonexistent but more familiar) classical forms of the nonclassical compounds.

Armin Berndt, born in Duisburg in 1936, studied Chemistry at the universities of Marburg and Munich and graduated in 1965 under the supervision of Karl Dimroth with a doctoral thesis on phenoxyl radicals. He completed his habilitation in 1970 with a study on sterically hindered nitro compounds and has been Professor of Organic Chemistry since 1972. At the core of his research interests are syntheses of compounds with sterically demanding substituents and the investigation of the interactions of electron-deficient centers with neighboring σ bonds that are revealed in unusual geometries and spectroscopic properties.

(Si and Sn) at the position β to the electron-deficient center are thermodynamically strongly stabilized by C–Si[22, 23, 30] and C–Sn hyperconjugation[22, 31] (see above) but extremely labile kinetically. NMR spectra of such cations have only recently been recorded,[32] and no crystal structures have been reported to date. Methyleneboranes lacking strong π donors on the dicoordinate boron atom have enabled the investigation by NMR spectroscopy and X-ray diffraction analyses (Section 3) of not only C–Si[1c] and C–Sn hyperconjugation,[1d, e] but also C–B hyperconjugation and the influence of substituents on it,[1i] and have filled a gap in our knowledge of strong σ–π delocalization.

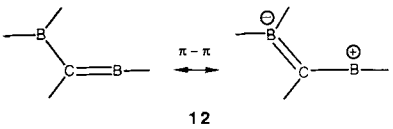


In the extreme form of strong, α-agostic type, nonclassical interactions, the X atom of the C–X σ bond will be transferred to the electron-deficient center. Thus, the borylcarbenes **11**,[33] which are isoelectronic with methyleneboranes and vinyl cations, will be formed from methyleneboranes, and the diborylcarbenes **13** from the (borylmethylene)boranes **12**.



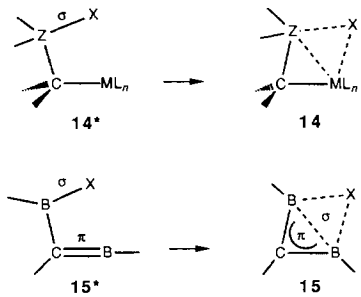
In these carbenes the electron deficiency at the dicoordinate carbon atom will be increased through π–π delocalization of its formally nonbonding electron pair to the boryl substituents. As a result, nonclassical interactions with σ bonds like B–X play a considerable role, as shown by the geometry in **13a**.[25b] Diborylcarbenes of the type **13a** are intermediates in the facile topomerization reactions of **10a–d** (see Section 4.1.2) and, probably, some addition reactions of **10a**.[1k–1o] Additionally, many rearrangement reactions of (borylmethylene)boranes (**12**, Section 2) can be explained, at least formally, by invoking diborylcarbenes (**13**) as intermediates.

The π electrons of the C–B double bond in **12** will be delocalized towards the boryl substituent in a way similar to the nonbonding electron pairs in the carbenes **11** and **13**. Thus, the electron deficiency at the dicoordinate boron atom will be increased in (borylmethylene)boranes, and their nonclassical interactions with neighboring σ electrons will be strengthened (Scheme 3; see 3.3.1.5).



Scheme 3. π–π Delocalization in (borylmethylene)boranes.

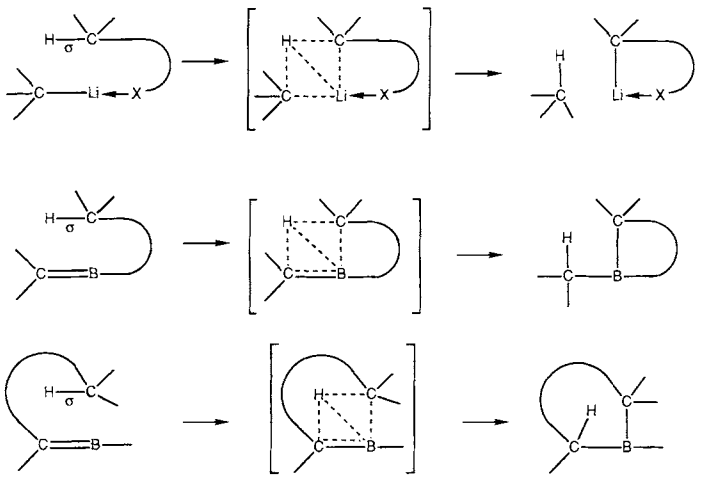
In the α-agostic effect and in C–X hyperconjugation, the C–X σ electrons are located in a similar position relative to the electron-deficient center as formally nonbonding electrons in π–π delocalization (compare Scheme 1). Electron-deficient centers can, however, also build nonclassical 3c–2e bonds with other spatially adjacent σ bonds (Scheme 4).



Scheme 4. Nonclassical 3c–2e bonds from interaction of electron-deficient centers with *neighboring* σ electrons: the β-agostic type.

The nonclassical interactions in the transition metal complexes of type **14** have been termed β-agostic effects.[7, 34] Such nonclassical bonds are found in (borylmethylene)-boranes like **15**[1g, 1h, 35] (see Section 3.3.3). The low activation energies of rearrangement reactions involving migration of an X atom from the tri- to the dicoordinate boron atom, which are characteristic of the (borylmethylene)boranes **12** (see Sections 2, 3, and 4), can be explained by stabilized transition states having the structure **15**.

In the extreme case, the weakening of the C–H bond through agostic effects will lead to the formation of a new metal–carbon bond and a transfer of the hydrogen atom to the metal (transition metal)[7] or to a carbanion coordinated to the metal (lithium) (Scheme 5).[36, 37]



Scheme 5. Extreme cases of agostic interactions with C–H bonds.

Intramolecular C–H bond additions to the C=B double bonds of methyleneboranes (Section 4.2) are reminiscent of such metalation reactions and are therefore described here as γ-, δ-, and ε-agostic effects. The reactivity of methyleneboranes resembles that of vinyl cations ([2 + 2] cycloadditions[1e, 1k, 2h, 38]) and, as Paetzold[3e] has pointed out, also that of methylenesilanes (silaethene $\rangle C{=}Si\langle$)[39]—the tricoordinate silicon atom is related to the dicoordinate boron atom through the diagonal relationship in the periodic system of elements.

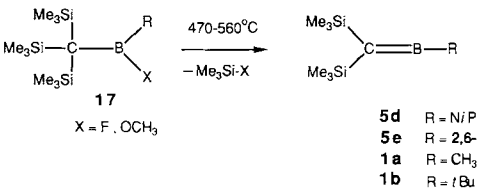
2. Syntheses

Like the amino(methylene)boranes **5**, the borataalkynes **7** and the 2-borataallenes **6** are methyleneboranes stabilized by π–π delocalization, but in contrast to **5** they carry a negative charge. Their syntheses will be described here for this reason and also because they can be used as reactants in the synthesis of other methyleneboranes. Clear-cut syntheses without rearrangement reactions will be handled before those involving rearrangements. Exceptions are syntheses of boriranylideneboranes, which are treated before their use in the preparation of methyleneboranes. Syntheses of anionic precursors will also be described prior to their transformation to methyleneboranes.

2.1. Elimination Reactions

Nöth et al.[2b] prepared the first stable amino(methylene)borane **5a** by dehydrohalogenation of the 9-fluorenyl-(2,2,6,6-tetramethylpiperidino)boron halides **16a**.

This procedure is also successful if the di-*tert*-butylamino or the *tert*-butyl(trimethylsilyl)amino derivatives are used instead of the tetramethylpiperidino derivative. With the bis(trimethylsilyl)amino derivative, only the dimer will be obtained.[2c] The intermediacy of fluorenylideneboranes having bulky aryl substituents instead of amino groups on boron can be deduced from their reaction products with the Lewis base tetrahydrofuran[40] or with 3-hexyne ([2 + 2] cycloaddition).[38] Paetzold et al. synthesized not only the amino(methylene)boranes **5d**[3a] and **5e**[3c] but also the methyleneboranes **1a** and **1b**[3d] with methyl and *tert*-butyl groups on the boron atoms by the elimination of fluorotrimethylsilane or trimethyl(methoxy)silane from **17** at temperatures between 470 and 560 °C. Compound **1a** rapidly dimerizes to the corresponding 1,3-diboretane.

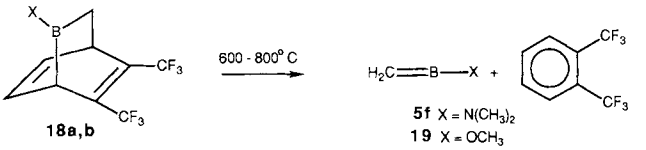


17 X = F, OCH_3

5d R = N*i*Pr$_2$
5e R = 2,6-dimethylpiperidino
1a R = CH_3
1b R = *t*Bu

2.2. Cycloreversion Reactions

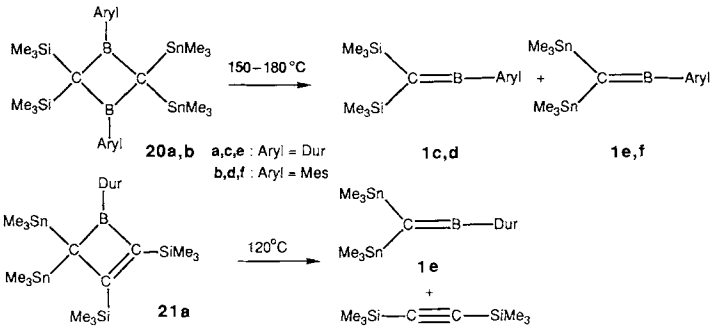
The methyleneboranes **5f** and **19** without substituents at the carbon atom of the C–B double bond have been generated by pyrolysis of the bicyclic compounds **18a** and **18b**, isolated in an argon matrix at 10 K, and characterized by IR spectroscopy by Maier et al.[4] As the matrix thawed, the characteristic IR bands disappeared at temperatures as low as 40 K (**19**) and 80 K (**5f**).



18a,b

5f X = $N(CH_3)_2$
19 X = OCH_3

The methyleneboranes **1c,d** and **1e,f** are obtained by melting the 1,3-diboretanes **20a,b** at 148 and 177 °C, respectively.[1c, 1e] 1,2-Dihydroborete **21a**[1e] yields the methyleneborane **1e** and bis(trimethylsilyl)acetylene on heating at 120 °C (reverse reaction to the formation of **21a**).



20a,b a,c,e : Aryl = Dur; b,d,f : Aryl = Mes

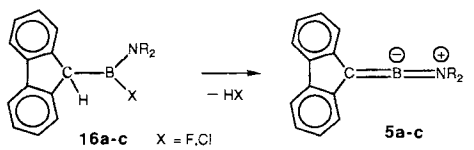
Dur = duryl = 2,3,5,6-tetramethylphenyl; Mes = mesityl = 2,4,6-trimethylphenyl

The [2 + 2] cyclo adduct **22**,[3b] obtained from the reaction of the amino(imino)borane $Me_3Si(tBu)N{-}B{=}NtBu$ with

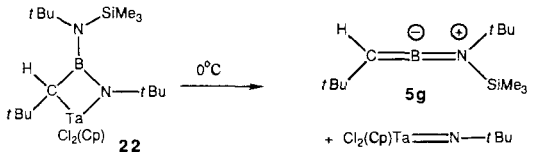


16a-c X = F,Cl

5a-c

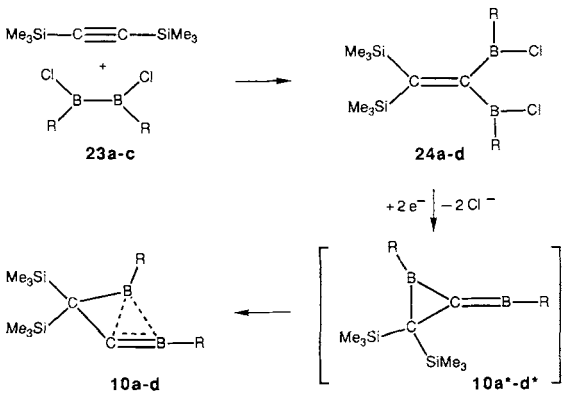
NR_2: **a** = 2,2,6,6-tetramethylpiperidino, **b** = $NtBu_2$, **c** = $NtBuSiMe_3$

the alkylidene complex $[(\eta\text{-}C_5H_5)Cl_2Ta{=}CHtBu]$, decomposes at 0 °C into the amino(methylene)borane **5g** and $[(\eta\text{-}C_5H_5)Cl_2Ta{=}Nt\text{-}Bu]$.



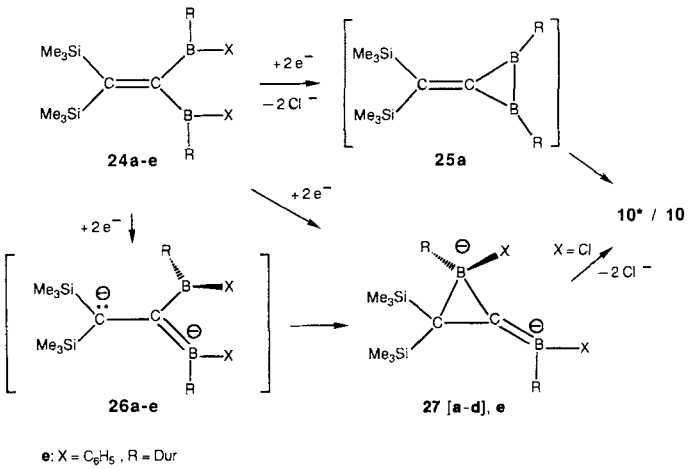
2.3. Boriranylideneboranes (Borandiylboriranes) through Reductive Elimination and Rearrangement

We obtained the methyleneborane **10a** from an attempt to trap an intermediate of the reductive dimerization of **23a**[41] by addition of bis(trimethylsilyl)acetylene. We found that **23a** itself reacted with the alkyne, and the adduct **24a** could be reduced by a sodium/potassium alloy to yield a product with unusual spectroscopic properties. Fortunately, our initial interpretation of the experimental results[42] was subjected to adept and constructive peer review by Budzelaar and van der Kerk, Utrecht, who suggested the constitution **10a*** [1a] with the following comment: "Finally we would venture to remark that all experimental data can also be reconciled with a structure... (**10a***) .... We do not suggest that ...(**10a***)... is a very likely structure; however, neither is [the original suggestion] (see ref. [42])...". Budzelaar and Schleyer[25] and Frenking and Schaefer III[26] have shown by ab initio calculations that the nonclassical structure **10a** is more likely.



a: R = *t*Bu, **b**: R = Mes
c, d: R = Dur **d**: Me_3Ge instead of Me_3Si

The synthesis of **10a** from **24a**[43] has been optimized by treatment with magnesium under ultrasonication in tetrahydrofuran.[44] In order to verify the calculated, nonclassical structure of the boriranylideneboranes experimentally by X-ray structure analysis, we replaced the *tert*-butyl groups in **23a** and **24a** with mesityl and duryl groups. In contrast to the thermally unstable **23a**, the diboranes(4) **23b** and **23c**[45] do not decompose up to about 90°C and slowly add bis(trimethylsilyl)acetylene in pentane under reflux (3 days to 4 weeks) to form the 1,1-diborylalkenes **24b** and **24c**.[45] Only **24b** reacted with Na/K alloy to form **10b**,[10a] which was, however, obtained as a noncrystalline solid and in only moderate and poorly reproducible yield. Only by employing the highly reactive Bogdanović-magnesium[46] could **10b** and **10c** be synthesized in good yields.[1f] Since the crystals of **10c** were unsuitable for X-ray structure analysis, we finally prepared the diborylalkene **24d** from the reaction of **23c** with bis(trimethylgermyl)acetylene, which gave **10d** upon reduction with Bogdanović-magnesium.[1f] In 1987 we proposed the methylenediborirane **25a** as an intermediate in the transformation of **24a** to **10a**.[47] This suggested a mechanism in which an initial reductive elimination is followed by a rearrangement to form the three-membered ring containing one boron atom.



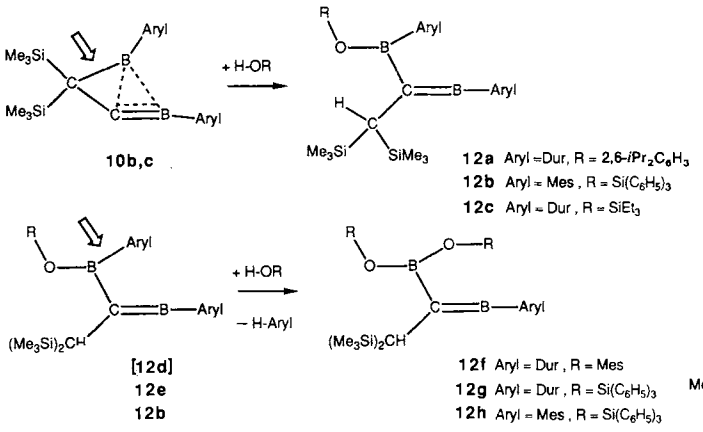
e: X = C_6H_5, R = Dur

Since then we have found that the diborylalkene **24e** can be reduced by lithium in toluene to the dianion **27e**,[48] probably via **26e**. Thus, a boron-containing three-membered ring can also be formed by direct reduction of a 1,1-diborylalkene, which offers an alternative pathway for the transformation of **24** into **10**, via **26** and **27**, in which the elimination reaction *follows* the formation of the boron-containing three-membered ring.

Siebert et al. observed that reduction of the 1,1-diborylalkene **24** bearing diisopropylamino groups in the place of the *tert*-butyl or aryl substituents in **24a–c** led to the formation of 1,3-bis(diisopropylamino)-2,4-bis(trimethylsilyl)-1,3-dihydro-1,3-diborete with migration of a silyl group.[49] Compound **10a** is transformed into the corresponding 1,3-dihydro-1,3-diborete only after heating for several hours at 170 °C.[50]

2.4. Cleavage of B–C Single Bonds in (Borylmethylene)boranes with Retention of the C=B Double Bond

The boriranylideneboranes **10b** and **10c** add sterically hindered phenols[1i] or silanols[51] under cleavage of the Si_2C–B bond of the borirane ring and retention of the C–B double bond to yield the (borylmethylene)boranes **12a–c** in which *one* oxygen atom is bonded to the boron atom of the boryl substituent. These can react with a further equivalent of HOR under cleavage of the B-aryl bond of the boryl

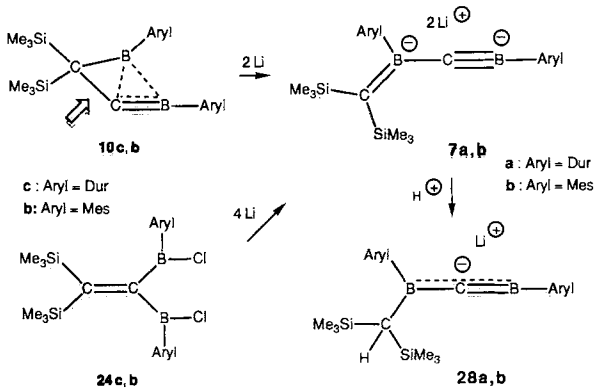


residue and form the (borylmethylene)boranes **12f–h** in which *two* oxygen atoms are bound to the boron atom of the boryl group. When 2,4,6-trimethylphenol is used, the second reaction is so fast that even if just one equivalent of HOR is employed, **12f** is obtained exclusively.[1i]

2.5. Borataalkynes from Reductive Cleavage of the C–C Bond of the Three-Membered Ring of Boriranylideneboranes

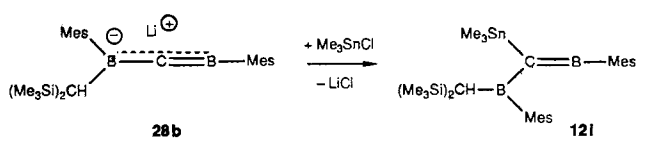
The C–C bond of the three-membered ring in the boriranylideneboranes **10b,c** having aryl substituents on the boron atoms is reductively cleaved by lithium in diethyl ether to give the borataalkynes **7a,b**;[10a] however, **7a,b** could be obtained more conveniently by reaction of the **10b,c** precursors **24b,c** with an excess of lithium in diethyl ether.[1b,45]

Protonation of **7a,b** with one equivalent of cyclopentadiene leads to the borylborataalkynes **28a,b**, of which only **28b** was obtained in pure form.[10a]

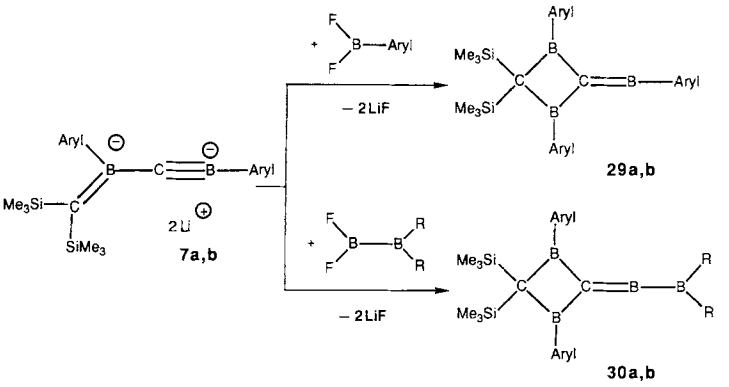


2.6. Reactions of Borataalkynes with Electrophiles

The reaction of the C-borylborataalkyne **28b**[45] with chlorotrimethylstannane yields the [boryl(stannyl)methylene]borane **12i**.[1d]

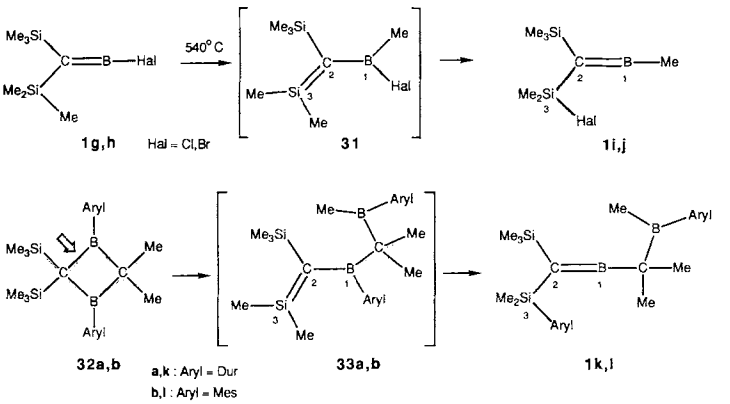


The borataalkynes **7a,b**[10a] react with aryldifluoroboranes to form the (diborylmethylene)boranes (1,3-diboretane-2-ylideneboranes) **29a,b**,[1b] and with 1,1-diaryl-2,2-difluorodiboranes(4) to form the B-boryl(1,3-diboretane-2-ylidene)boranes **30a,b**.[1h]



2.7. Rearrangements Involving 1,3 Migrations

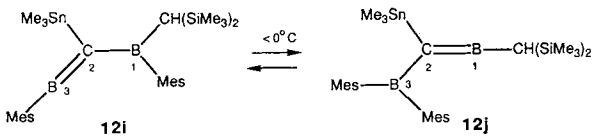
From attempts to produce the halo(methylene)boranes **1g,h** by elimination of trimethyl(methoxy)silane (see Section 2.1) from halo(methoxy)[tris(trimethylsilyl)methyl]-boranes, Paetzold et al. obtained the rearrangement products **1i,j**.[3e] The authors conjectured that the anticipated halo(methylene)boranes **1g,h** experienced a double 1,3-shift of the Me and Hal groups, via the intermediate **31**, while still in the hot reaction tube. They could show from the analyses



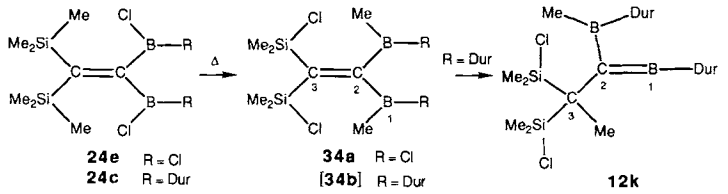
of trapping products that such a double shift is still possible when in place of the halogen a methyl group (in the experiment a CD_3 group) is bound to the boron atom of the methyleneborane (isotopomerization).[3e]

Analogously, the formation of the methyleneboranes **1k,l**[1c] from the thermal isomerization of the 1,3-diboretanes **32a,b** can be explained if one assumes that silaethene intermediates (**33a,b**) are formed. The [boryl(stannyl)-methylene]borane **12i**[1d] transforms below 0°C into the [boryl(stannyl)methylene]borane **12j** in solution,[1d] where **12j** and **12i** coexist in a rapidly established equilibrium. The mutual interconversion takes place by a 1,3-migration of a mesityl group from the tri- to the dicoordinate boron atom, which is a typical reaction for (borylmethylene)boranes (see Sections 3.3.3 and 4.1.1). Upon cooling, the methylene-

borane **12j**, with the bis(trimethylsilyl)methyl group on the dicoordinate boron atom, preferentially crystallizes from a solution of the two isomers in ether.



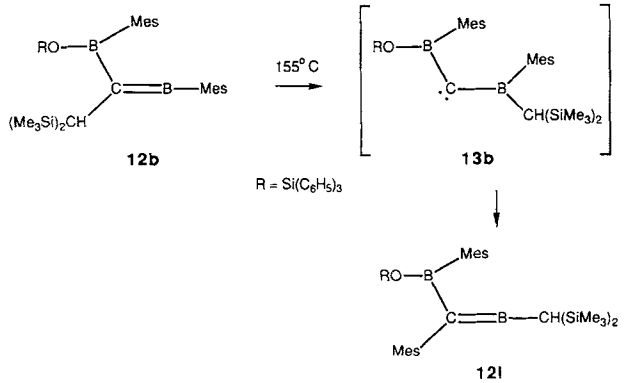
The (borylmethylene)borane **12k**[1i] is generated by thermolysis of **24c** either as a melt at 175°C or by heating under reflux in bis(trimethylsilyl)acetylene at 135°C (this reaction was originally observed when the cooling system failed during the synthesis of **24c**, which is performed in pentane under reflux).



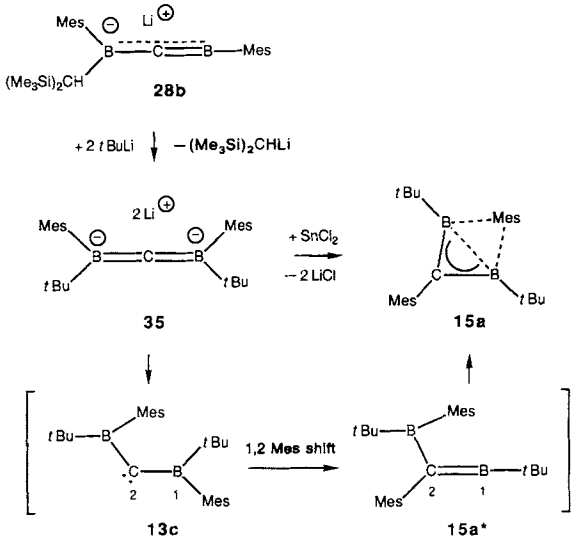
In this reaction, both chlorine atoms migrate from boron to silicon, whereas only one of the methyl groups migrates from silicon to boron, while the other moves to carbon. Analogous to the thermal transformation of **24e** into **34a** described by Siebert et al.,[52] **34b** might be formed as an intermediate, which then gives **12k** by a 1,3 methyl shift from boron to carbon. The remarkable aspect of the **24c** → **12k** isomerization is the thermal formation of a C–B double bond at the expense of a C–C double bond; the compound with the C–B double bond is apparently thermodynamically more stable than the isomer with the C–C double bond (for a discussion of this phenomenon see Section 3.3.1.5).

2.8. Rearrangements Involving 1,2 Migrations

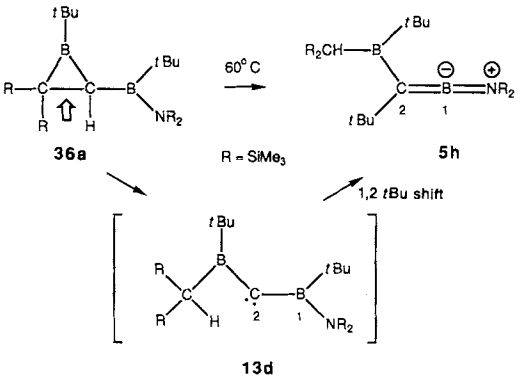
Upon melting at 155°C the (borylmethylene)borane **12b** transforms quantitatively into the (borylmethylene)borane **12l**.[51] In this isomerization the organic substituents on the C–B double bond exchange places (double 1,2 migration); the diborylcarbene **13b** may be an intermediate.



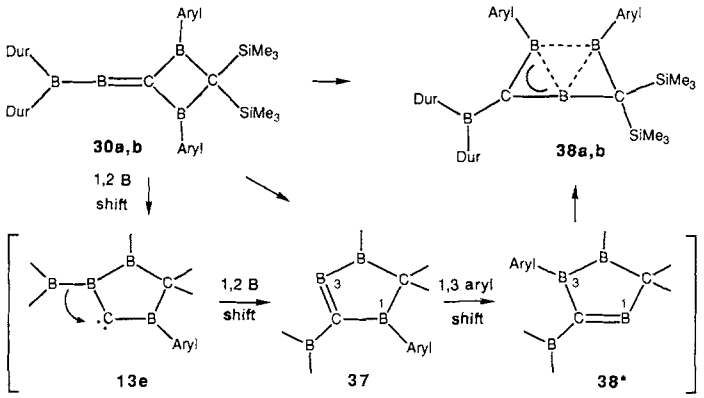
The 1,3-diborataallene **35**, obtained from reaction of the C-borylborataalkyne **28b** with two equivalents of *tert*-butyllithium,[53] can be oxidized by tin(II) chloride to the mesityl-bridged methyleneborane **15a**.[1g] The migration of a mesityl group from the boron to the carbon atom can be most simply explained by employing the diborylcarbene intermediate **13c** and the classical form **15a*** of **15a**.



The borylborirane **36a** is quantitatively transformed into the amino(borylmethylene)borane **5h** by heating at 60°C in chloroform or by sublimation at 130°C.[1j] In this reaction, the C–C bond of the three-membered ring is cleaved, a hydrogen atom migrates from the carbon atom bound to two boron atoms to the carbon atom bound to two trimethylsilyl groups, and the *tert*-butyl group migrates from the exocyclic boron atom to the carbon atom bound to the two boron atoms. As intermediate we suggest the diborylcarbene **13d**.



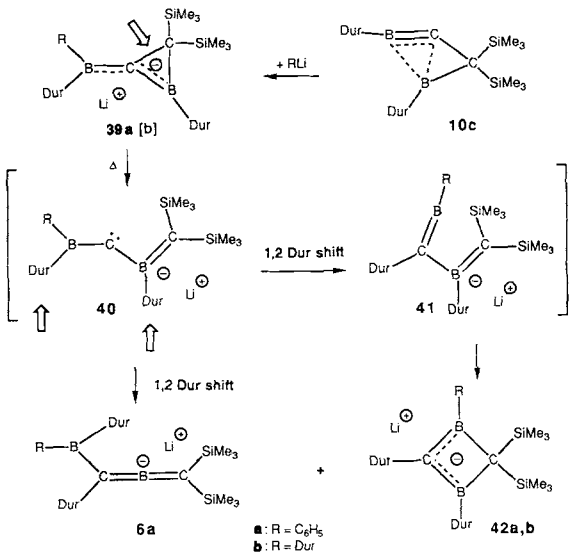
The cyclic methyleneboranes **38a,b**[1h] result from the spontaneous isomerization of the boryl(diborylmethylene)-boranes **30a,b**.[1h] Intermediate steps are likely to contain the diborylcarbene **13e** and the cyclic B-borylmethyleneboranes (dihydrotriboroles) **37**. These react further to form **38***, the classical form of the nonclassical methyleneborane **38a,b**, through a 1,3 migration of an aryl group from the tri- to the dicoordinate boron atom.

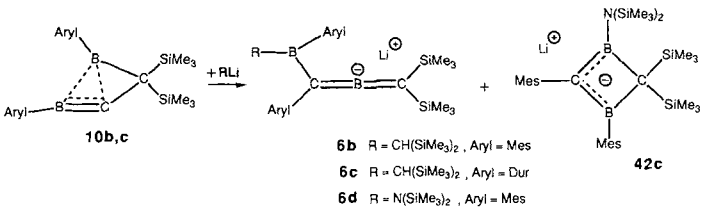


2.9. 2-Borataallenes.

2.9.1. Through Thermal Isomerization of C-Borylboriranides

The borylboriranide **39a**,[9b, 48] prepared from **10c** by reaction with phenyllithium, is transformed in refluxing toluene into a mixture of the 2-borataallene **6a** and the 1,3-diboretanide **42a** from which **6a** can be separated by crystallization. In this reaction, the C—C bond of the three-membered ring is cleaved, and for each product a different duryl group migrates from a boron atom to the carbon atom located between the two boron atoms. The first intermediate in this transformation is likely to be the carbene **40**. A 1,2 migration of the duryl group from the negatively charged boryl substituent to the neighboring coordinatively unsaturated center results in the 2-borataallene **6a**. Migration of the duryl group on the other boron atom would lead to formation of the 1-bora-3-boratabutadiene **41**, whose subsequent electrocyclic ring closure would yield **42a**.

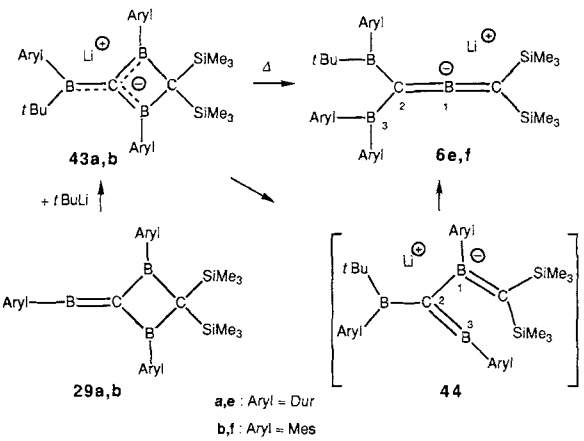




The only products that are formed from the reaction of **10b** or **10c** with $LiCH(SiMe_3)_2$ at room temperature are the corresponding 2-borataallenes **6b**[54] and **6c**,[48] whereas with duryl lithium only **42b** is formed from **10c**.[9b] A mixture of **6d** and **42c** is formed from the reaction of **10b** with $LiN(SiMe_3)_2$ at room temperature.[51]

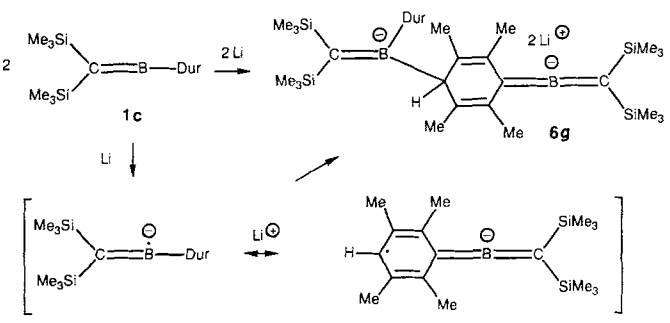
2.9.2. Through Thermal Isomerization of 2-Boryl-1,3-diboretanides

The 2-boryl-1,3-diboretanides **43a,b** accessible from the reaction of **29a,b** with *tert*-butyllithium are transformed in the melt (200°C) into the 2-borataallenes **6e,f**.[9a, 55] In this reaction, a Si_2C—B bond is cleaved and an aryl group migrates from the tricoordinate ring boron atom to the boron atom which has lost its third coordination partner as a result of the cleavage. We suggest the 1-bora-3-boratabutadiene **44** as an intermediate (compare **41**), whose transformation into **6e,f** requires a 1,3 migration of an aryl group from the tri- to the dicoordinate boron atom, a reaction described repeatedly in this review.



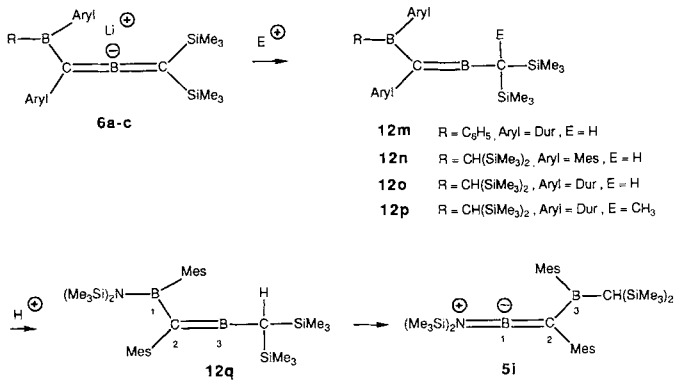
2.9.3. Through Reductive Dimerization of the Methyleneborane 1c

The main product of the reaction of the methyleneborane **1c** with lithium metal in toluene is the 2-borataallene **6g**[9a] (the unsymmetrical dimer of the radical anion of **1c**).

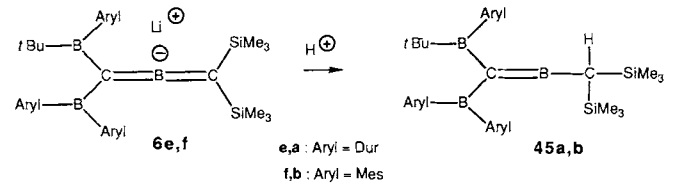


2.10. Reactions of 2-Borataallenes with Electrophiles

The 1-boryl-2-borataallenes **6a–c** react with electrophiles to form the (borylmethylene)boranes **12m–p**.[48, 54, 56] The product **12q**, expected from the protonation of **6d**, is spontaneously transformed into the amino(methylene)borane **5i** through 1,3 migration of a mesityl group.[51]

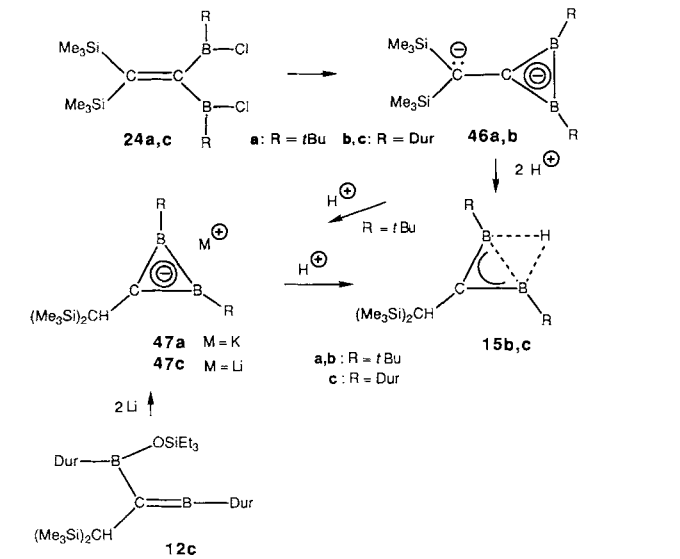


The 1,1-diboryl-2-borataallenes **6e,f** can be protonated with cyclopentadiene to form the (diborylmethylene)boranes **45a,b**.[55–57a] In all cases the electrophiles attack the carbon atom bonded to the two trimethylsilyl groups regioselectively, with the result that only (borylmethylene)boranes and not the isomeric (disilylmethylene)boranes result.



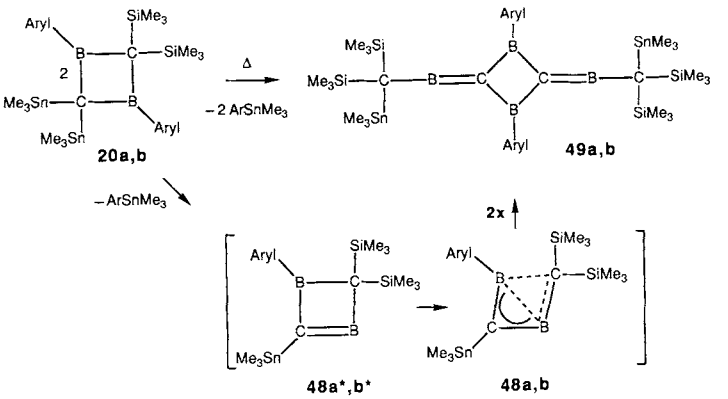
2.11. Protonation of Diboriranides to form H-bridged (Borylmethylene)boranes.

The diboriranides **46a**[44, 35] and **46b**[57b], obtained by reduction of **24a** and **24c** with potassium and Bogdanović-magnesium, respectively, can be protonated with HCl in ether to form the H-bridged (borylmethylene)boranes **15b,c**,[35, 51] as can the intermediate diboriranide **46a**[35] (formed upon monoprotonation of **46a**) and the diboriranide **47c**[51] (formed upon reduction of **12c** with lithium).



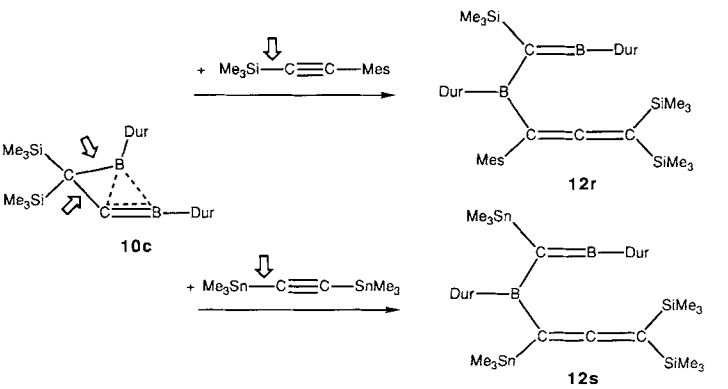
2.12. Elimination of Aryltrimethylstannane and Subsequent Reactions

Upon thermolysis of the 1,3-diboretanes **20a,b**, aryltrimethylstannane and small amounts of the methyleneboranes **49a,b** are formed in addition to the products of the cycloreversion (Section 2.2).[58–60] The primary products of these reactions are likely to be the cyclic methyleneboranes **48a,b (48a*, b*)**. In addition to the dimerization required in going from **48a,b** to **49a,b**, a migration of the trimethylstannyl group from the carbon atom located between the two boron atoms to the carbon atom bonded to the two trimethylsilyl groups must take place.



2.13. (Borylmethylene)boranes from Boriranylideneboranes and Alkynes

Boriranylideneborane **10c** reacts with mesityl(trimethylsilyl)acetylene to form the [boryl(silyl)methylene]borane **12r**[51, 61] and with bis(trimethylstannyl)acetylene to form the [boryl(stannyl)methylene]borane **12s**.[51] In these reactions, the three bonds indicated with arrows must be broken, the trimethylsilyl or trimethylstannyl groups of the alkyne must migrate to the carbon atom of the C–B double bond,



and the $C(SiMe_3)_2$ groups must combine with the alkyne residue to form an allene substructure, which is finally connected to the boryl-B-atom of the resulting methyleneborane.

Thus, stable methyleneboranes are obtained only when the C–B double bond is sterically shielded by large substituents. In addition, electronic stabilization is necessary either through formally nonbonding electron pairs on the atoms directly adjacent to the dicoordinate boron atoms ($=B-\ddot{N}R_2$, $=B-\ddot{C}R_2^{\ominus}-$, or $-^{\ominus}\ddot{C}=B-$) or through electropositive substituents at the position β to the dicoordinate boron atoms. The frequent occurrence of the (borylmethylene)boranes **12** is remarkable (compare Section 3.3).

3. Structures

3.1. Crystal Structure and Spectroscopic Data; Results from Ab Initio Calculations

Selected structural and NMR data of methyleneboranes whose electron deficiency at the dicoordinate boron atom is removed by π–π delocalization are compiled in Tables 1 and 2. Methyleneboranes whose electron deficiency is reduced to some extent through σ–π delocalization are listed in Tables 3 and 4. Table 5 contains the interatomic distances calculated for parent compounds of both types of methyleneboranes with ab initio methods at various levels. The C=B–N(C) bond angles of the methyleneboranes listed in Table 1 deviate from the ideal value for a dicoordinate atom (180°) by a maximum of 4.9°. This is also true for most of the methyleneboranes listed in Table 3. Significant deviations of this angle from 180° are observed when the X–C=B bond angle also deviates significantly from the ideal 120° (for example in **10d**, **15a**, **38a**, and **12j**). In all these cases the chemical shifts observed for the boron atom of the C–B

double bonds $\delta^{11}B_{C=B}$ differ widely from the maximum values ($\delta^{11}B \approx 80$). Correspondingly large differences for the methyleneboranes in Table 2 appear only for compounds having C–B triple bonds (borataalkynes **7a, b**).

3.2. π–π Delocalization in Methyleneboranes

3.2.1. Strong π–π Interactions of the Dicoordinate Boron Atom with Neighboring Nonbonding Electron Pairs in Classical Methyleneboranes

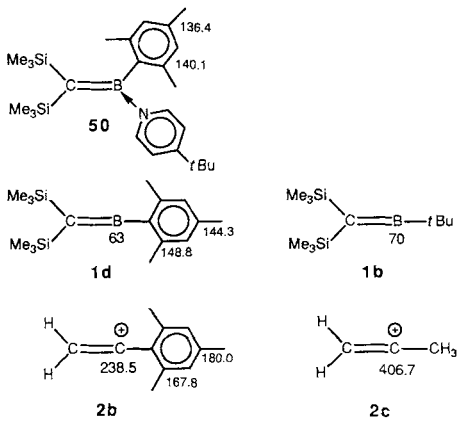
The short interatomic distances between the dicoordinate boron atom and the nitrogen atom in the amino(methylene)boranes **5** (135.3–136.7 pm) and between the boron and carbon atoms in the 2-borataallenes **6** (141.6–143.1 pm), and the short C–B multiple bonds in **28b** (133.9 pm) and **7a** (132.3 pm) relative to those found from ab initio calculations show that the electron deficiency at the dicoordinate boron atoms in these methyleneboranes is relieved through π–π delocalization of the formally nonbonding electron pairs on the atoms adjacent to the dicoordinate boron atom, that is, through the formation of classical 2c–2e bonds (see Scheme 1). Consistent with this are the NMR shieldings observed at the dicoordinate boron atom of the amino(methylene)boranes ($\delta^{11}B = 44.8-60$), the 2-borataallenes ($\delta^{11}B = 54-71$), and the borataalkynes ($\delta^{11}B = 41$ and 26) compared to those for methyleneboranes without π donors in the neighborhood of the dicoordinate boron atom ($\delta^{11}B = 82-83$; **12l**, **12p**). Characteristic heteroallene IR bands found for the amino(methylene)boranes support the general conclusion that compounds of type **5** are isoelectronic with allenes.

3.2.2. Weak π–π Interactions between the Dicoordinate Boron Atom and Aryl Groups

The electron deficiency at the boron atoms of the methyleneboranes listed in Tables 3 and 4 is reduced only to a small extent through π–π delocalization from the aryl group bound to these boron atoms, as illustrated in Scheme 6. This can be seen from a comparison of **1d**[1c] with

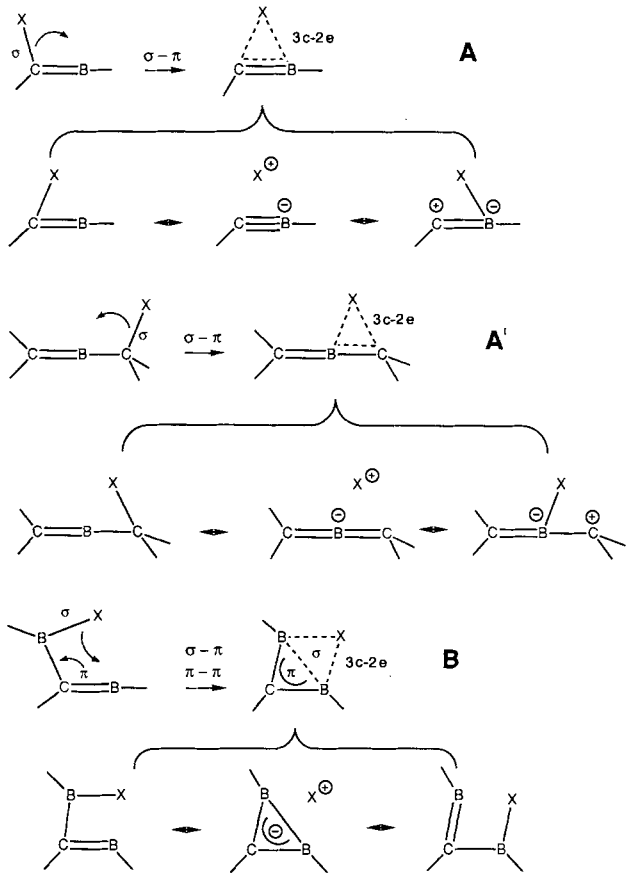
Scheme 6. Weak π–π delocalization in aryl(methylene)boranes.

1b[3d] and **50**.[58] Thus, the boron atom in **1d** is shielded by only $\Delta\delta = 7$ relative to that in **1b**, and the *ortho* and *para* carbon atoms in **1d** are deshielded by only $\Delta\delta = 8.7$ and 7.9 relative to the corresponding atoms in **50**. In contrast, with strong π–π delocalization as found in the vinyl cation **2b**,[32c] the *ortho* and *para* carbon atoms of the aryl substituents are much more strongly deshielded (see values given in the structural formulas). The electron-deficient center in **2b** is more shielded ($\Delta\delta \approx 168$) than the corresponding center in the vinyl cation **2c** ($\delta^{13}C$ from IGLO[69] calculations[32a]). Likewise, the rearrangements **12i** → **12j** (see Section 2.7) and **12b** → **12l** (see Section 2.8) can also be regarded as an indication of the small stabilization through π–π interactions of the type illustrated in Scheme 6. Here, the products in which the bis(trimethylsilyl)methyl groups reside on the dicoordinate boron atom are thermodynamically more stable than the reactants in which aryl groups are in this position.



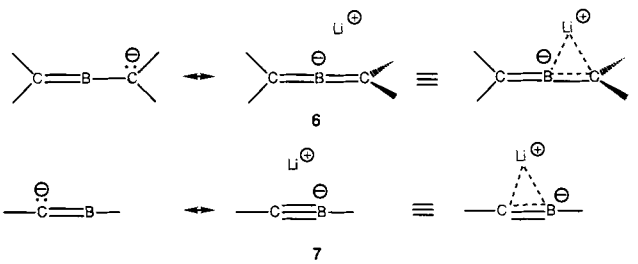
3.3. σ–π Delocalization in Nonclassical Methyleneboranes

The large bond angle distortions of up to 65° at the carbon atom of the C–B double bond, the greater NMR shielding of their boron atoms of up to $\Delta\delta = 65$ (see Section 3.3.1.1), and the decrease in the $^{13}C-^{117/119}Sn$ NMR coupling constants of down to 20% of the normal value (see Section 3.3.1.4), as well as additional smaller effects, can be explained by σ–π delocalization (Scheme 7) of α-agostic type (**A** or **A'**) and β-agostic type (**B**).



Scheme 7. α-Agostic (type **A**, **A'**) and β-agostic (type **B**) σ–π delocalizations.

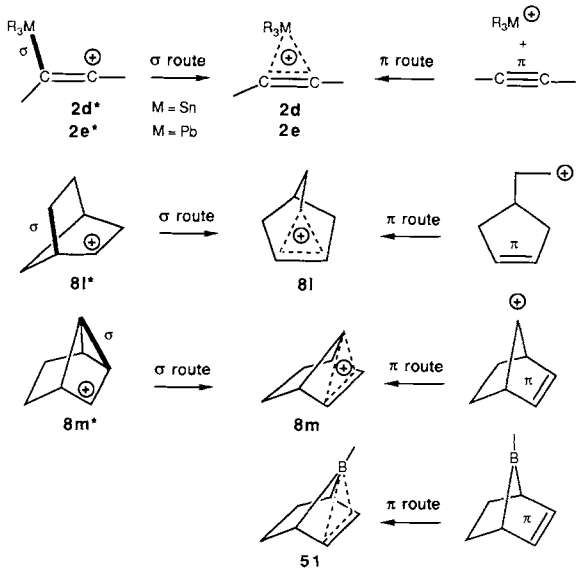
The resonance formulas of the 3c–2e bond in **A** and **A'** in which the positive charge is localized on the X atom are identical with those which result from π–π delocalization in the 2-borataallenes **6** and borataalkynes **7** when the counterions are taken into account (Scheme 8). Considered from



Scheme 8. Borderline cases of classical and nonclassical methyleneboranes; π complexes.

this point of view, π–π delocalization is a borderline case of σ–π delocalization with very electropositive X atoms: the bonding electron pair becomes the formally nonbonding electron pair. One can therefore expect that as the electropositive character of the X atom increases, the properties of methyleneboranes with strong σ–π interactions will approach the properties of systems with π–π delocalization.

Seen from the metal countercations, **6** and **7** are π complexes. Nonclassical carbocations have also been described as π complexes[70] (for example the recently reported bridged β-stannyl- and β-plumbyl-substituted vinyl cations of the types **2d**[71a] and **2e**;[72] see Section 3.3.1.6). Their formation from reactions of alkynes with electrophiles is reminiscent of the "π route" to the nonclassical carbocations. In addition to σ routes,[73] 3c–2e bonds can also form along π routes[74, 75] (the 2-norbornyl and 7-norbornenyl cations **8l** and **8m**, Scheme 9), and only the π route is known for the bishomoborirene **51**.[76, 77] The description "homoaromatic" for **8m** and nonclassical systems of type **51** emphasizes their similarity to 2π-electron aromatic systems having *classical* 3c–2e bonds.



Scheme 9. The σ and π routes to nonclassical 3c–2e bonds.

3.3.1. α-Agostic σ–π Interactions of Type A

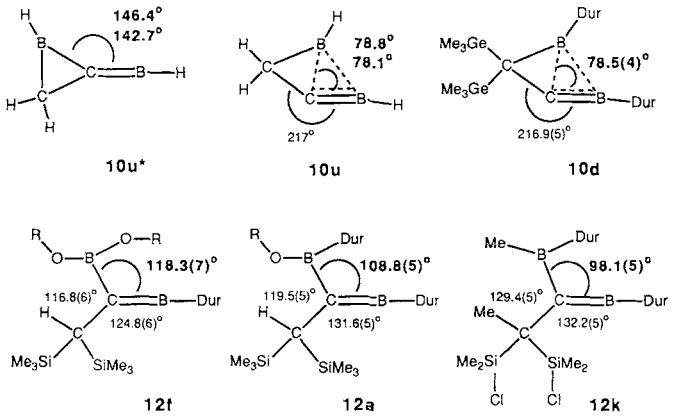
3.3.1.1. Nonclassical Bridging, Strong C–B Hyperconjugation and Its Reduction by Electronegative Substituents on the Boryl Groups in (Borylmethylene)boranes

Bond Angle Distortions

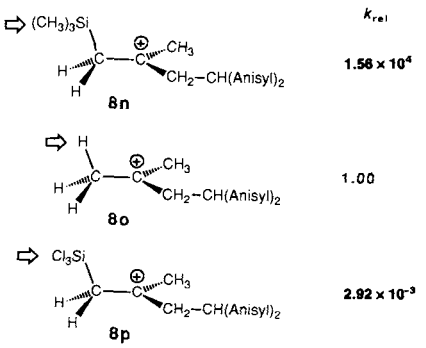
It was predicted in 1984 from ab initio calculations that the B–C=B bond angle in **10u** (78.8°[25a] or 78.1°[26]) is compressed by not less than 65° compared to that in the classical **10u*** (146.4°[25b] or 142.7°[26]). The coupled C–C=B angle at the tricoordinate carbon atom is accordingly widened to 217°! The crystal structure of **10d** was obtained in 1990 and revealed B–C=B and C–C=B bond angles of 78.5° and 216.8°,[1f, 57] in impressive agreement with the calculated angles.

The importance of ring strain to the distortion in **10** can be recognized when one compares **10d** to the (borylmethylene)borane **12k**,[1i] in which the boryl substituent is not part of the three-membered ring. Thus, the B–C=B bond angle of 98° in **12k** is approximately 20° larger than the corresponding angle in **10d**. Note that the electron-deficient center is =B–Dur in both cases. On the other hand, the

B–C=B bond angle in **12k** is still more than 20° smaller than the normal bond angle found at a tricoordinate carbon atom and is an indication of the strong C–B hyperconjugation caused by the electropositive nature of the boron atom at the position β to the electron-deficient center. In the (borylmethylene)boranes **12a** and **12f** the β boron atom carries, respectively, one and two substituents in which an electronegative oxygen replaces the carbon substituent in **12k**. These compounds have significantly larger B–C=B bond angles of 109° and 118°; the latter in **12f** is almost the normal size.



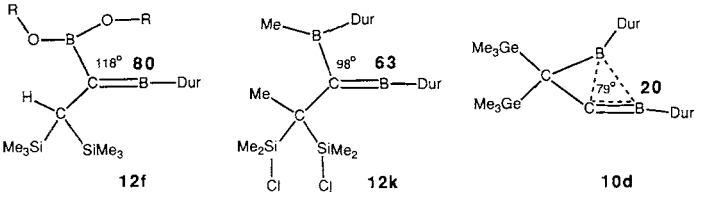
The inverse relationship between the degree of bond angle distortion and the number of electronegative substituents on the β boron atom indicates that the propensity of this boron atom to make the electrons of its bond to the carbon atom of the C–B double bond available for σ–π interactions with the dicoordinate boron atom greatly decreases the higher the number of the electronegative substituents. Thus, as the number of electronegative substituents increases, the electronegativity of the boryl boron atom increases, which leads to weaker σ–π interactions. Carbocations with β-E atoms (E = Si, Ge, Sn) form more slowly when electronegative substituents are introduced at the E atoms. For example, the cation **8n** with a β-$SiMe_3$ group is formed 15600 times faster than **8o**, and the cation **8p** with a β-$SiCl_3$ group is formed about 340 times slower than **8o** despite the presence of a silicon atom in the β position.[78] The rate of formation of carbocations is a generally accepted measure of its stabilization, in this case by C–Si hyperconjugation.



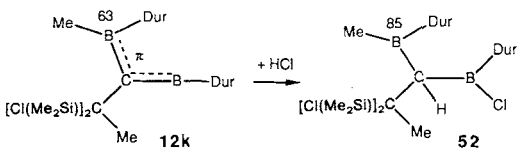
Unfortunately, we have not yet been able to prepare a methyleneborane whose only difference to **12a** is the substitution of an alkyl or an aryl group for the OAr group. The interfering steric requirements of the additional methyl group on the carbon atom carrying the two $SiMe_2Cl$ groups in **12k** primarily result in the widening of the B–C–C (129.4° compared to 119.5° in **12a**) and Me–B–C bond angles (127.5° compared to the 115.0° O–B–C angle) and prevent an even greater widening of the coupled C–C=B angle. C–B hyperconjugation in **12k** may be supported by this steric effect similar to the reinforcement of the β-agostic interactions by steric effects shown recently by Gleiter, Erker et al.[34b]

NMR Shielding of the Electron-Deficient Center

Of all the methyleneboranes with duryl groups at the dicoordinated boron atom, the (borylmethylene)boranes **12** displaying the least distorted B–C=B bond angles (118.3° in **12f**) have the most strongly *deshielded* dicoordinate boron atoms ($\delta^{11}B = 80$) and the nonclassical bridged boriranylideneboranes **10** displaying highly distorted B–C=B bond angles (78.5° in **10d**) have the most strongly *shielded* dicoordinate boron atoms ($\delta^{11}B = 18-20$). This is consistent with the results on carbocations that have strong σ–π interactions, as previously discussed in the Introduction. Bond-angle distortions and NMR shieldings of the electron-deficient centers are general consequences of strong σ–π interactions.[1f, 16, 18]

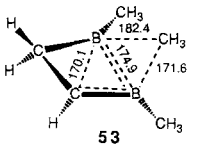


The chemical shift of the dicoordinate boron atom in **12a** ($\delta^{11}B = 79$) can hardly be differentiated from that in **12f**, although significant C–B hyperconjugation is indicated by the approximately 10° smaller B–C=B bond angle in **12a**. Likewise, the dicoordinate boron atom in **12k** is more deshielded ($\delta^{11}B = 63$) than would be expected from the intermediate value of its B–C=B bond angle (118°, 98°, 78.5° for **12f**, **12k**, **10d**). The reason for this deshielding can be seen from the chemical shift of the boron atom of the boryl substituent in **12k** ($\delta^{11}B = 63$) relative to that normally observed for a triorganoborane (e.g., $\delta^{11}B = 85$ in the HCl adduct **52**), which indicates π–π delocalization of the type illustrated in Scheme 3 (see Introduction).

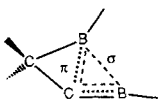


The shielding at the more negative tricoordinate boron atom should correspond to a deshielding at the more positive

dicoordinate boron atom and would explain the discrepancies described above. This π–π delocalization does not play an appreciable role in **12f**, since the electron requirements of the tricoordinate boron atom are already satisfied by the two OR substituents. The deshielding through π–π delocalization in **12a** is compensated for by the shielding through σ–π delocalization, as manifested by the small bond angle. Strong shielding through σ–π delocalization is diminished by the deshielding through significant π–π delocalization in **12k**. Such π–π delocalizations as illustrated in Scheme 3 appear in all (borylmethylene)boranes lacking strong π donors on the boryl boron atom and also in the nonclassical bridged **10**. This has been shown by analysis of the results from calculations[25, 26] and can also be clearly seen in the bond length between the boron atom of the three-membered ring and the carbon atom of the C–B double bond of 154.5 pm (calculated 152.7 and 153.9 pm), which is too short for a 3c–2e C–B bond. B–C bond lengths normally found in 3c–2e bonds are about 170 pm, as, for example, in the nonclassical bridged **53**,[1j] which can be considered as a derivative of **10** "saturated" at the C–B double bond. In the previous description of **10** π–π delocalization was not considered. Taking it into account leads to the more correct form above where the π–π delocalization is represented by the dotted lines.



53

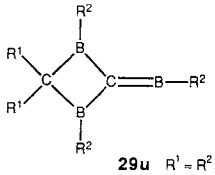


10

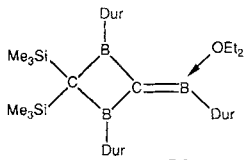
3.3.1.2. C–B Hyperconjugation in (Diborylmethylene)boranes

Considerable π–π delocalization in **29a,b**[1b] is indicated by the shielding at the boron atoms of the four-membered ring ($\delta^{11}B = 62$) when compared to that of the boron atoms in the 1,3-diboretanes **20a,b** (see Section 2.2, $\delta^{11}B = 81-82$) and **32a,b** (see Section 2.7, $\delta^{11}B = 76-77$). This, in turn, should lead to a distinct deshielding at the dicoordinate boron atom compared to that found in **12f** ($\delta^{11}B = 80$). The observed chemical shift of $\delta^{11}B = 71$ for the dicoordinate boron atoms in **29a,b** therefore indicates strong C–B hyperconjugation. This interpretation is supported by ab initio calculations (6-31G*) on the unsubstituted **29u** which gave π charges of −0.173 on the ring boron atoms, −0.159 on the carbon atom of the C–B double bond, + 0.504 on the exocyclic boron atom, and a π charge of −0.194 in its "empty" p orbital lying in the B_2CB plane.[1b] π charges of −0.18 and −0.22 on the carbon atom and + 0.18 and + 0.22 on the boron atom have been calculated for in $H_2C{=}B{-}H$.[63b, 26] Thus, the different electronegativities of boron (2.0) and carbon (2.5) alone lead to a considerably lower polarity in the π component of the C–B double bond.

C–B hyperconjugation is also responsible for the longer bond lengths between the tricoordinate carbon atom and the boron atoms of the four-membered ring in **29a** (155.7, 156.6 pm) compared to those in the ether adduct **54** (152.2, 150.7 pm). Adduct **54** exhibits π–π delocalization comparable to that in **29a** but *lacks* σ–π delocalization, since the electron hole on the former dicoordinate boron atom is intermolecularly filled by an electron pair from the diethyl ether. The C=B double bond of 137 pm is about the same length as that calculated for the unsubstituted methyleneborane $H_2C{=}BH$ (138 pm, 6-31G*[63]). The shortening caused by C–B hyperconjugation (additional partial 3c–2e bond) is compensated for by the elongation resulting from π–π delocalization (only partial C–B double bonding). A bond length increase resulting from π–π delocalization *not* compensated for by C–B hyperconjugation can be observed in **38a** (*d*(C=B) 142.5 pm, Section 3.3.3.4).[1h] The short 135.1 pm C=B bond length[1f] in **10d** shows that, in this case, the bond shortening effect through additional 3c–2e bonding is stronger than the bond lengthening effect of π–π delocalization.



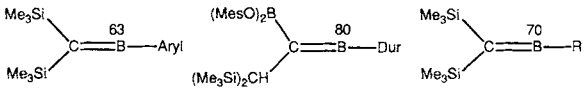
29u $R^1 = R^2 = H$
29a $R^1 = SiMe_3$, $R^2 = Dur$
29b $R^1 = SiMe_3$, $R^2 = Mes$



54

3.3.1.3. C–Si Hyperconjugation in (Silylmethylene)boranes

The difference of $\Delta\delta = 17$ between the shielding at the aryl-substituted dicoordinate boron atom in **1c,d** ($\delta^{11}B = 63$) and that in **12f** ($\delta^{11}B = 80$) is a result of strong C–Si hyperconjugation in (disilylmethylene)boranes. Similarly strong shieldings occur in the alkyl-substituted methyleneboranes **1a,b** if one takes into account the shielding ($\Delta\delta \approx 7$) at the dicoordinate boron atom caused by weak π–π delocalization of the π electrons of the aryl substituents in **12f** (see Section 3.2.2).

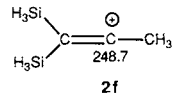


1c Aryl = Dur
1d Aryl = Mes

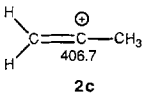
12f

1a R = CH_3
1b R = *t*Bu

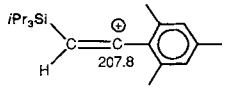
Both theoretical calculations[32a] and experimental measurements[32c] have shown that vinyl cations having β-silyl substituents on the sp^2 carbon atom exhibit increased shielding at the dicoordinate C^+ centers of $\Delta\delta = 158$ (**2f** compared to **2c**) and $\Delta\delta \approx 31$ (**2g** compared to **2b**) as a result of C–Si hyperconjugation.



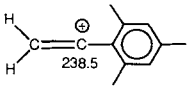
2f



2c



2g



2b

Bond-angle distortion caused by C–Si hyperconjugation effects can be seen in the crystal structure of **12r** (Fig. 1). The Si–C=B bond angle of 109.1(2)° is 9.6° smaller than the corresponding bond angle in **1b** (118.7(1)°[3d]), and the coupled angle B–C=B is widened to 125.3(3)°. The π–π delocalization characteristic for (borylmethylene)boranes, as reflected in the shielding at the tricoordinate boron atom ($\delta^{11}B = 67$), probably contributes to strong C–Si hyperconjugation by increasing the electron deficiency at the dicoordinate boron atom (see also Section 3.3.1.5).

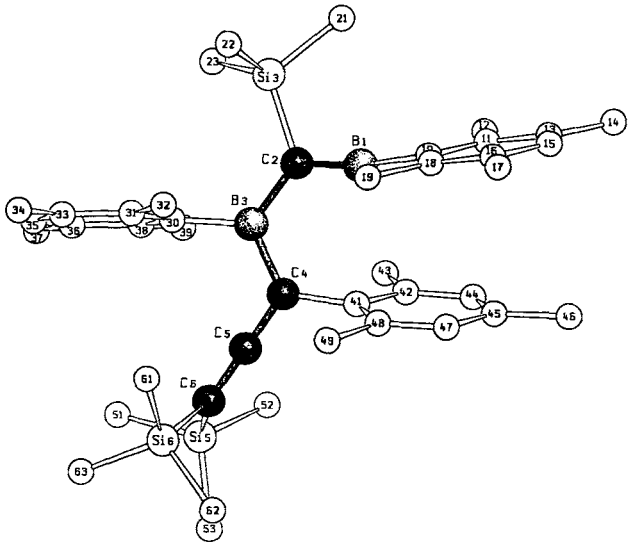


Fig. 1. Schakal representation of the crystal structure of **12r**.

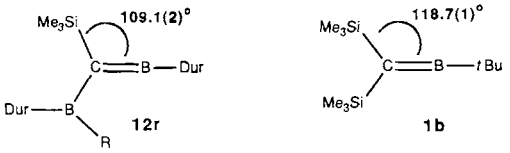
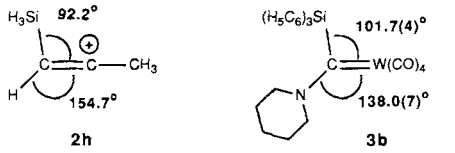
Calculations at the MP2/6-31G* level for the β-silyl-substituted vinyl cation **2h** gave a compressed Si–C=C$^{\oplus}$ bond angle of 92° and a widened H–C=C$^{\oplus}$ angle of 155°.[79]



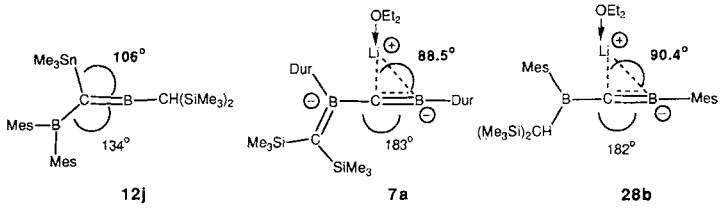
R = 1-mesityl-3,3-bis(trimethylsilyl)allenyl (=All)



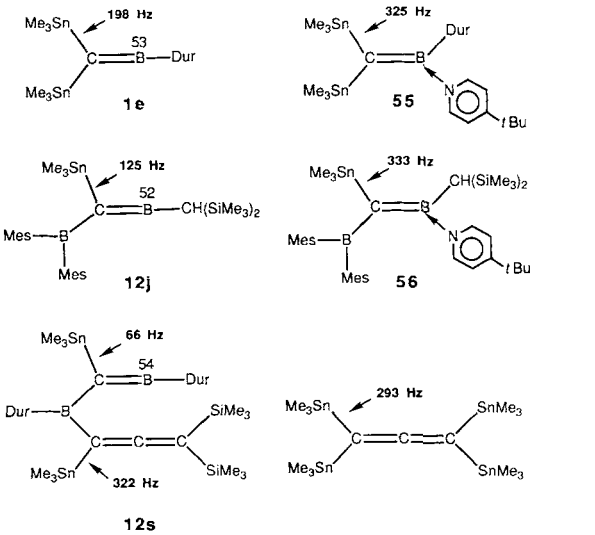
The small Si-C-W angle of 101.7(4)° and the coupled large angle N-C-W of 138.0(7)° in the 16-electron carbene complex **3b** of Schubert et al.[80a] can be plausibly understood as a consequence of an α-C–Si agostic effect.

3.3.1.4. C–Sn Hyperconjugation in (Stannylmethylene)boranes

Strong σ–π interactions in (stannylmethylene)boranes can be recognized from the small Sn–C=B bond angle of 106.0(4)° in **12j**, which approaches the Li–C–B bond angle in the borataalkynes **7a** and **28b** where an electropositive lithium replaces the alkyl tin group in **12j**. Parallel to the bond-angle distortion, strong shielding is observed at the dicoordinate boron atom in **12j** ($\delta^{11}B = 52$), in **1e** ($\delta^{11}B = 53$), and **12s** ($\delta^{11}B = 54$), relative to **12f** and **12l** ($\delta^{11}B = 80$ and 82). Moreover, greatly reduced ^{13}C–$^{117/119}Sn$ coupling constants are found for the carbon atoms

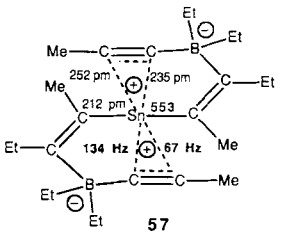


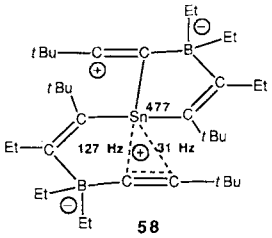
of the C–B double bond. The corresponding coupling constants are of normal magnitude (as in tetra(trimethylstannyl)-allene[80b] or in the allene part of **12s**) in the pyridine adducts **55** and **56**, in which the electron deficiency at the former dicoordinate boron atom is relieved *inter*molecularly. Smaller coupling constants indicate bond weakening, as for example in the C–H bonds of H-bridged carbocations,[81] in this case of the C–$SnMe_3$ bonds, caused by strong C–Sn hyperconjugation. The smaller coupling constant in **12j** relative to that of **1e** can be explained if we consider that the effect in **12j** is concentrated on only *one* C–Sn bond, whereas it is distributed over *two* equivalent σ bonds in **1e**. The even smaller coupling constant in **12s** (66 Hz) may originate from greater electron deficiency and lower steric hindrance at the dicoordinate boron atom in **12s**, which then promote stronger σ–π interactions than in **12j**. The lower stabilization afforded by aryl groups as compared to bis(trimethylsilyl)methyl groups has already been discussed (Section 3.2.2).



Small ^{13}C–$^{117/119}Sn$ coupling constants comparable to those in **12j** and **12s** have been observed in the compounds **57**[71a] and **58**.[71b] Originally considered as a π complex,[71a] **58** has recently been discussed as a vinyl cation stabilized by

C–Sn hyperconjugation.[71b] The upper portion of the structural formula **58** has been drawn to illustrate its description as a vinyl cation bearing a β-stannyl substituent.

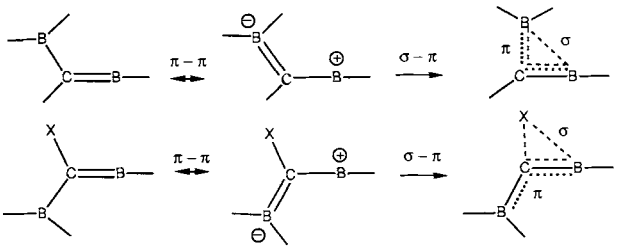




A comparison of the crystal structure data of **57** with that of **8c**[117] (see Introduction) suggests the description "unsymmetrically bridged vinyl cation" for **57**. The similarity between the ^{13}C–$^{117/119}Sn$ coupling constants for **12s** and **57** leads one to expect a strongly distorted Sn–C=B bond angle in **12s**.

3.3.1.5. Strengthening of the σ–π Interactions through π–π Delocalization in (Borylmethylene)boranes

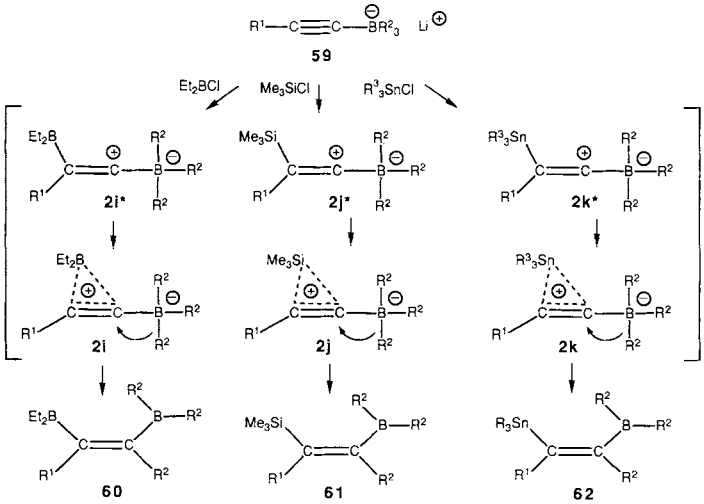
The π–π delocalization in (borylmethylene)boranes illustrated in Scheme 3 increases the electron deficiency at the dicoordinate boron atom and converts it into a better π acceptor (lower lying LUMO) for σ–π interactions. This π–π delocalization will supply additional electron density to the tricoordinate boron atom (Scheme 10) and increase its ability to make the electrons of its σ bond to the carbon atom of the B–C double bond available for σ–π interactions (compare the opposite effect caused by electronegative substituents in **12f** and **12a** in Section 3.3.1.1). Thus, π–π delocalization in the (borylmethylene)boranes leads to stronger σ–π interactions. The abundance of (borylmethylene)boranes **12**, to which over half the reported methyleneboranes belong, and their unexpected thermodynamic stability (see Section 2.7) can be reasonably explained by this synergic stabilization. In (borylmethylene)boranes such as **10**, **12a**, and **12k**, the boron atom of the boryl substituent acts as a π acceptor and its σ bond to the carbon atom of the C–B double bond as a σ donor. In (borylmethylene)boranes that carry a *second* electropositive atom on the carbon atom of the C–B double bond (Sn, Si, B; represented in general by X in Scheme 10), the C–X σ bond can take on the role of the σ donor. Examples in which X = Si or Sn include **12r** (Section 3.3.1.3) and **12j** (Section 3.3.1.4). In (diborylmethylene)boranes, one boryl group can act as the π acceptor, while the =C–B σ bond of the other becomes the σ donor. Such behavior should lead to distinctly different B–C=B bond angles as, in fact, found in the bond angles of 133.3(5) and 148.2(5)° in **29a** (Section 3.3.1.2). One can therefore conjecture that the different B–C=B bond angles observed in **45a** (Section 3.3.2.2, 107.2(7) and 128.2(7)°) are not only a result of the steric hindrance from the *tert*-butyl group on one of the boryl substituent but also, in part, of the above mentioned effect. Attempts to synthesize (diborylmethylene)boranes having identical boryl substituents have not yet been successful.



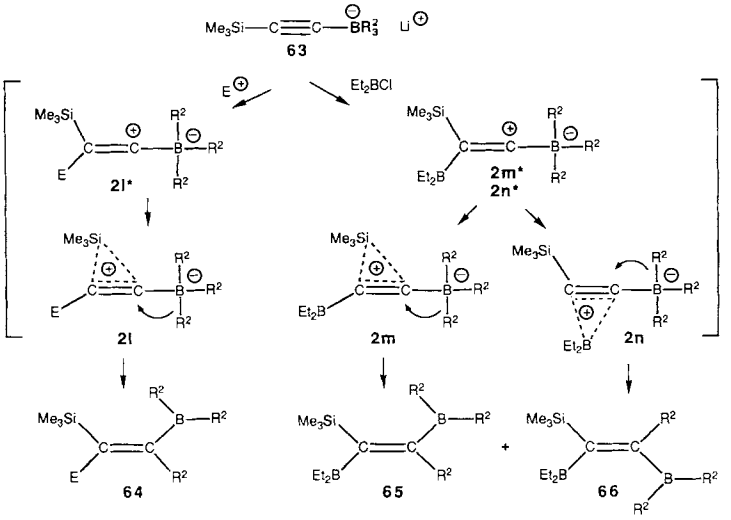
Scheme 10. Synergic strengthening of σ–π delocalization through π–π delocalization.

3.3.1.6. Boryl-, Silyl-, Germyl-, Stannyl-, and Plumbyl-Bridged Vinyl Cations as Reactive Intermediates

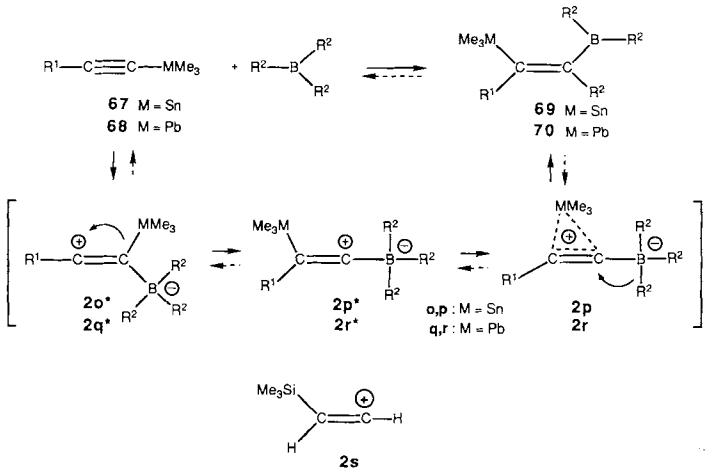
The following interpretation of the experimental results in terms of vinyl cations having electropositive bridging atoms at the position β to the electron-deficient center is equivalent to the interpretation by Wrackmeyer et al.[82] in terms of "π complexes of alkynes". The stereoselective formation of the alkenylboranes **60**–**62** with boryl, silyl, or stannyl substituents at the position *cis* to the boryl group, from reactions of the alkynylborates **59** with chlorodiethylborane, chlorotrimethylsilane (Köster[83, 84]), chlorotrimethylstannane (Mortimer[85]) or from reactions of the trimethylsilylalkynylborates **63** with electrophiles E which do *not* react stereoselectively with **59** (Köster[84]) can be explained as follows: In the initially formed vinyl cations **2i***, **2j***, **2k***, and **2l***, one side of the electron-deficient center will be blocked because of strong σ–π interactions (unsymmetrical bridging by BEt_2 in **2i**, $SiMe_3$ in **2j** and **2l**, and $SnMe_3$ in **2k**) with the result that the migrating R^2 fragment can only enter from the opposite side.



The low stereoselectivity seen in the formation of **65** and **66** from the reaction of **63** with chlorodiethylborane was attributed to the "competition of the trimethylsilyl and the

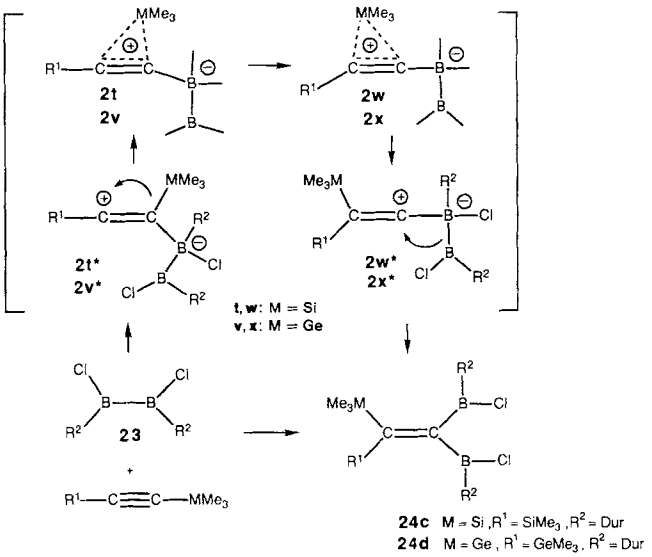


boryl groups",[84] which has to be supplemented by the qualification "in σ–π interactions in the intermediate **2m***,**2n***, which can lead to the bridged vinyl cations **2m** and **2n**". The stereoselectivity found in Wrackmeyer et al.'s syntheses of the alkenylboranes **69** and **70**,[82] with stannyl and plumbyl substituents in the position *cis* to the boryl group from reaction of stannyl- (**67**) or plumbylalkynes (**68**) with trialkylboranes, can be likewise explained with the relevant bridged vinyl cations **2p** and **2r**, these having been formed via **2o*** and **2q*** and their rearrangement products **2p*** and **2r***.



Similarly, the remarkably easy thermal cleavage of the $=C-C(R^2)$ bonds in the vinylboranes **69** and **70**, already at room temperature, to regenerate the trialkylboranes and stannyl- or plumbylalkynes[82] (reverse of the **69** and **70** formation reactions) probably is primarily a result of the considerable thermodynamic stabilization of the vinyl cations **2p** and **2r** through strong C–Sn and C–Pb hyperconjugation. Strong stabilization was recently determined for the β-trimethylsilyl-substituted vinyl cation **2s** by mass spectrometry (43.5 kcal mol^{-1} more stable than $H_2C{=}C^+H$, **2u**).[23c] Large stabilization energies are therefore to be expected for **2p** and **2r** because of the considerably greater stabilization energy of the β-stannyl-substituted ethyl cation **8k** over the β-silyl-substituted ethyl cation **8i** (see Introduction). Wrackmeyer et al. have already emphasized the significance of the weak =C–Sn and =C–Pb bonds and the weakening of the =C–C bond by C–C hyperconjugation with the boryl boron atom.[82]

Closely related to the synthesis of the alkenylboranes **69** and **70** from the reaction of stannyl- or plumbylalkynes with trialkylboranes is the formation of the 1,1-diborylalkenes **24** from reactions of trimethylsilyl- or trimethylgermylalkynes with the diboranes(4) **23** (see Section 2.3). In the first step of these reactions, the vinyl cations **2t*** or **2v*** are probably formed. These then rearrange by 1,2 migration into their respective vinyl cation isomers **2w*** and **2x***. These are small changes when one considers that both types of cations are highly distorted through strong C–Si or C–Ge hyperconjugation (unsymmetrical bridging, see **2t**, **2w** and **2v**, **2x**). The



rapid formation of 1,1-diborylalkenes having $GeMe_3$ groups in place of the $SiMe_3$ substituents—the reaction to form **24c** requires four weeks whereas the reaction to form **24d** only three days—is in agreement with the observation that carbocations are more strongly stabilized through C–Ge hyperconjugation (**8j**: 38.8 kcal mol^{-1} [22d]) than through C–Si hyperconjugation(**8i**: 29.1 kcal mol^{-1} [22d]). Stannylalkynes react with **23** with elimination of chlorotrimethylstannane to form borylborirenes.[86]

3.3.2. σ–π Interactions of the α-Agostic Type A'

3.3.2.1. A Methyleneborane with Type A' C–Sn Hyperconjugation

The crystal structure of the methyleneborane **49a**[58–60] is illustrated in Figure 2. Disorder appears in the region of the substituents at the dicoordinate boron atoms. The Sn 5 position has a 57% tin and a 43% silicon occupation; the occupancy of positions Si 6 and Si 7 are likewise 78% silicon and 22% tin.[60] The observed B–C–Sn bond angle of 103.4(2)° therefore reflects only a portion of the distortion due to C–Sn hyperconjugation. This angle approaches that of the

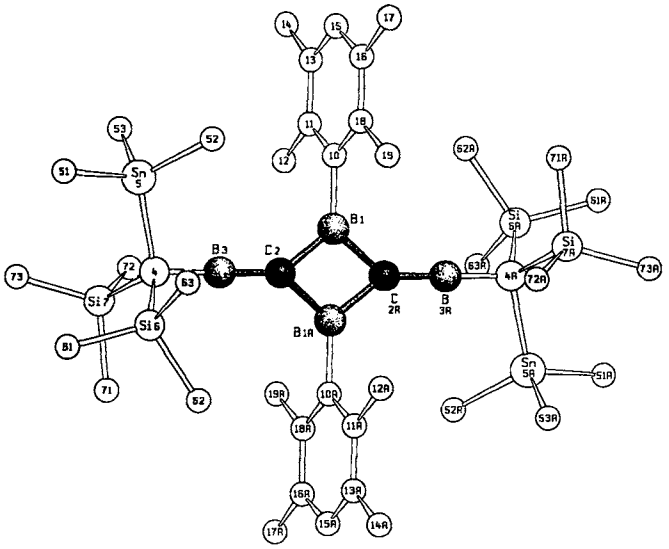


Fig. 2. Schakal representation of the crystal structure of **49a**.

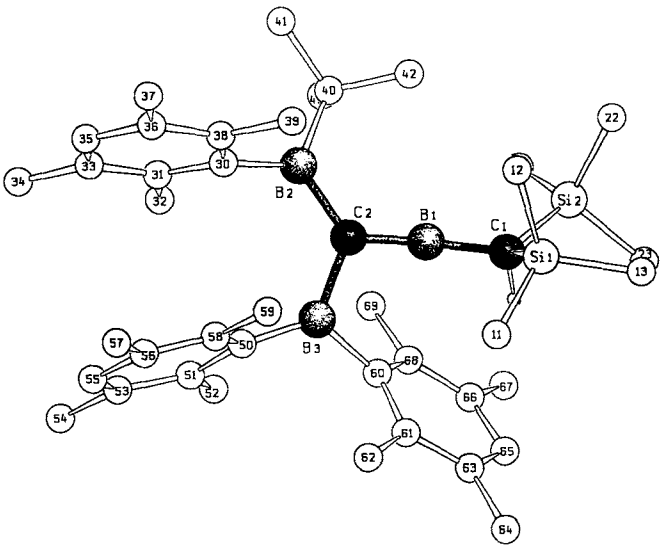

Fig. 3. Schakal representation of the crystal structure of **45a**

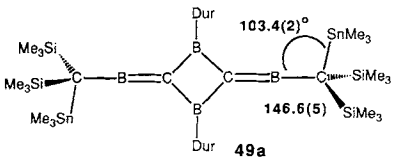
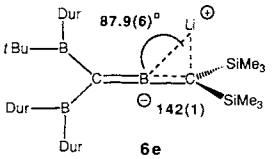
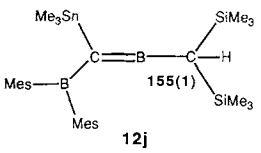
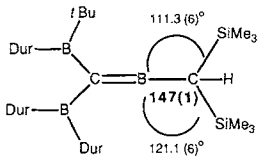
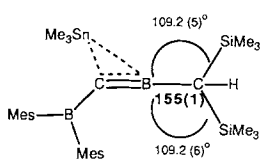
B–C–Li bond angle in the borataallene **6e**,[9a] in which an electropositive Li^+ takes up the position of the stannyl substituent in **49a**. The $B-CSi_2$ single bond in **49a** (146.6 pm) is considerably shorter than the corresponding bond in **12j** (155(1) pm) and approaches the length of the $B=CSi_2$ double bond (142(1) pm) observed in the 2-borataallene **6e**.

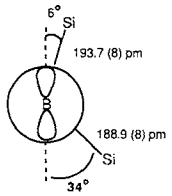


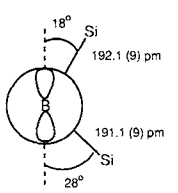












3.3.2.2. Preference for One of Two Equivalent σ Bonds in the Strong σ–π Interaction in a [Bis(trimethylsilyl)methyl]methyleneborane

Figure 3 shows the crystal structure of the methyleneborane **45a**.[56, 57a] Strong **A′** type C–Si hyperconjugation can be recognized in its short $B-CSi_2$ bond (147(1) pm compared to 155(1) pm in **12j**).

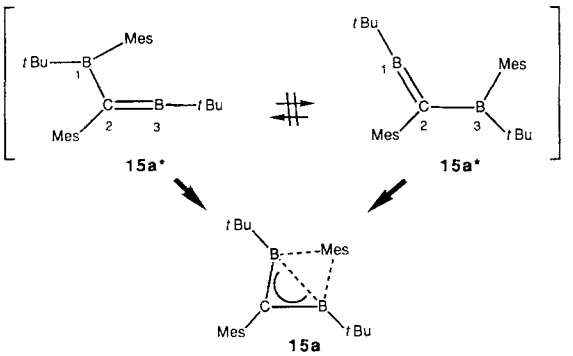
While the C–Si distances and the associated torsion angles (see Newman projections) of the two $C-SiMe_3$ bonds in **12j** are only slightly different from each other, in **45a** they differ substantially. The small 6° torsion angle in **45a** is associated with the long C–Si bond of 193.7(8) pm and the small B–C–Si bond angle of 111.3(6)°. The large 34° torsion angle corresponds to the considerably shorter 188.9(8) pm C–Si bond and the larger 121.1(6)° B–C–Si bond angle. These data show that one of the two equivalent $C-SiMe_3$ σ bonds in the bis(trimethylsilyl)methyl group is preferred for σ–π interaction with the electron-deficient dicoordinate boron atom. Preferences for one of two (or three) equivalent σ bonds in the interaction with electron-deficient centers are well-known in carbocations[87] and transition metal complexes exhibiting agostic interactions;[7, 34] typical examples are the vinyl cations **2a** and **2u** (see Introduction).

This effect results in diastereotopic trimethylsilyl groups of the $CH(SiMe_3)_2$ groups of the vinyl cation **2y**, as evident in its ^{13}C NMR spectrum.[32a] The 7.5 kcal mol^{-1} exchange barrier for these groups is a quantitative measure of the magnitude of this preference and is a characteristic consequence of strong nonclassical interactions with concomittant distortion towards 3c–2e bond formation. One-sided preferences are unknown for π–π interactions between an electron-deficient center and two equivalent π donors, for example in the divinylmethyl cation.

3.3.3. σ–π Interactions of the β-Agostic Type B

3.3.3.1. A Mesityl-Bridged (Borylmethylene)borane

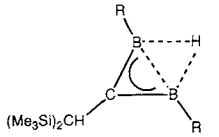
The 3c–2e bond in the mesityl-bridged (borylmethylene)-borane **15a** is apparent in the long bond lengths between the boron atoms and the *ipso* carbon atom of the mesityl group (174.8(9) and 176.9(8) pm) and in the short B–B interatomic distance (188.3(9) pm) between the two formally nonbonded boron atoms.[1g] Shielding of the boron atoms through bridging (that is, through an increase in the coordination number) and through symmetrical π–π delocalization—as opposed to the unsymmetrical π–π delocalization shown in Scheme 3 for nonbridged and cyclic methyleneboranes (Sections 3.3.3.3 and 4)—produces a chemical shift ($\delta^{11}B = 42$) that is incompatible with a rapid topomerization equilibrium of the classical methyleneborane **15a*** in solution.[1g]



The methyleneborane **12n**,[48] in which bis(trimethylsilyl)methyl groups replace the *tert*-butyl groups in **15a***/**15a**, is not bridged, and its NMR spectra show line broadening typical for a rapid exchange of the mesityl group between the two boron atoms. The transition state of the exchange reaction can be represented by the bridged structure **15d**, and the exchange barrier has been determined from NMR spectroscopy to be 10 kcal mol^{-1}. The energy difference between **15d** (the topomerization transition state of **12n**) and the ground-state bridged form of **15a** must therefore be considerably larger than 10 kcal mol^{-1}. This shows the large effect of the electron-deficient center's $CH(SiMe_3)_2$ substituents on the strength of the 3c–2e bond, which can be explained by a reduction of the electron deficiency at the dicoordinate boron atom through C–Si hyperconjugation (compare Section 3.3.2.2). Additional steric effects cannot be ruled out.

3.3.3.2. H-bridged (Borylmethylene)boranes

The 3c–2e bond in **15b**, which we described in 1985 as a B–H–B bridged 1,3-diboraallyl system,[35] corresponds qualitatively to that found in **15a**.[1g] The B–B interatomic distance of 170.9 pm calculated at the MP2/6-31G* level[66c] for the unsubstituted **15u**[66a, b] is considerably shorter than that in **15a** (188.3(9) pm) and is a clear indication of a stronger 3c–2e bond in **15u**. In order to check the calculated data against a crystal structure we have prepared **15c**[51] but, unfortunately, have not yet obtained a single crystal. The

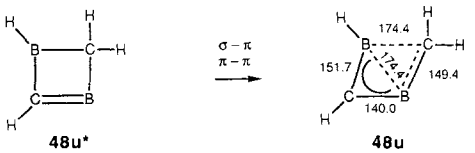


15b R = *t*Bu
15c R = Dur

bridge in **15b**, in contrast to that found in **15a**, can not be opened with either the Lewis base pyridine or *tert*-butyllithium,[35] which is a further indication that the 3c–2e bond in **15b** is stronger than that in **15a**. Additional evidence of the well-developed 3c–2e bonds in **15b,c** is the considerably greater shielding of the boron atoms in **15b** and **15c** ($\delta^{11}B = 27$ and 23) compared to that in **15a** ($\delta^{11}B = 42$), despite their comparable symmetrical π–π delocalization.

3.3.3.3. The Nonclassically Bridged, Cyclic (Borylmethylene)borane 3,4-Dihyro-1,3-diborete

Schleyer showed by ab initio calculations that the cyclic (borylmethylene)borane **48u***/**48u** is the lowest energy system of composition $C_2B_2H_4$, thus suggesting for the first time strong σ–π interactions of the β-agostic type **B** in methyleneboranes.[25b] In addition to unsymmetrical π–π delocalizations of the type observed in open-chain (borylmethylene)-boranes, **48u** exhibits a well-developed 3c–2e bond.



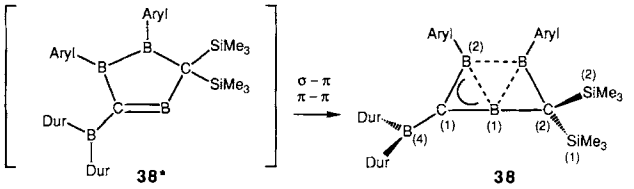
Our attempts to synthesize and isolate compounds of the type **48** have not yet been successful. Compounds **48a,b** may be reactive intermediates in the formation of the methyleneboranes **49** upon thermal elimination of arylstannanes from the 1,3-diboretanes **20a,b** (see Section 2.12).[58–60] We regard the thermodynamic stabilization of **48a,b** through σ–π delocalization to be the reason for the unusually facile 1,2 elimination of arylstannanes from **20a,b**.

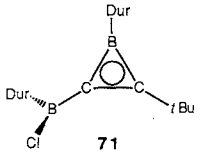
3.3.3.4. A Cyclic, Nonclassical (Diborylmethylene)borane Having a Trapezoidal Geometry as a Typical Example of Different Kinds of σ–π Interactions

Except for the boryl substituent, the cyclic methyleneboranes **38**[1h] can be considered as a homologue of **48** hav-

ing an additional B-aryl unit. The 3c–2e bond between three boron atoms with distinctly different B–B bond lengths in **38** replaces a 3c–2e bond between one carbon and two boron atoms in **48**. The formation of this nonclassical bond distorts the hypothetical, classical, five-membered ring **38*** into the trapezoidal form **38**.

As expected, the unsymmetrical π–π delocalization of the π electrons in the C–B double bond leads to a clear lengthening of this bond to 142.5 pm. The short C1–B4 bond (152.0(5) pm) suggests C–B hyperconjugation between the strained C1–B1 and C1–B2 σ bonds and the empty p orbital on the tricoordinate exocyclic boron atom B4. Likewise, this contributes to a lengthening of the C1–B1 bond of the ring. Similar distortions have been calculated for C-borylborirenes[25b] and observed in the C-borylborirene **71**.[86b]





Type **A′** C–Si hyperconjugation, in which σ–π interactions follow the characteristic preference for one of the two equivalent C–$SiMe_3$ σ bonds (compare Section 3.3.2.2), occurs with the boron atom of the C–B double bond whose positive charge is increased through π–π delocalization. The small 102° B1–C2–Si2 bond angle is associated with the long 191 pm C2–Si2 bond length and the small 15° torsion angle between the C2–Si2 bond and the p orbital on the boron. The large 124° B1–C2–Si1 bond angle correlates with the relatively short 188 pm C2–Si bond and the large 34° torsion angle.[1h, 54]

Strong and very strong **A′** and **B** type σ–π interactions (that is, C–B and C–Si hyperconjugation and nonclassical bridging) thus contribute to the structure of **38**. Additionally, the extreme forms of types **A** and **B** are also involved in the 1,2 and 1,3 rearrangements that lead to **38** (see Sections 2.7 and 2.8).

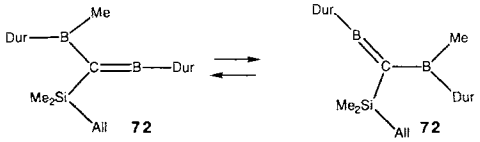
4. Reactions

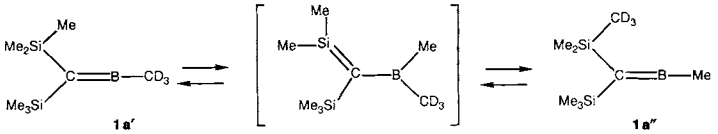
Numerous reactions typical of methyleneboranes have already been described in the syntheses (Section 2), and, for comparison, the adducts prepared by the addition of Lewis bases were taken into account in Section 3. A description of all the reactions known for methyleneboranes is outside the scope of this review. In the following, intramolecular reactions will be considered for which nonclassical 3c–2e bond formation in the transition state can explain low activation energies. These are α- and β-agostic interactions in rearrangement reactions involving 1,2 and 1,3 migration. C–H bond additions to the C–B double bond will be regarded as extreme forms of γ-, δ-, and ε-agostic interactions as illustrated in Scheme 5 of the Introduction.

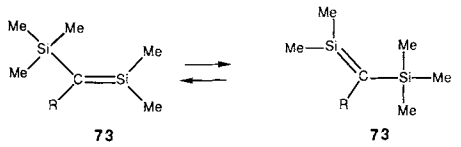
4.1. Topomerization Reactions

4.1.1. Topomerization Reactions Involving 1,3 Migrations

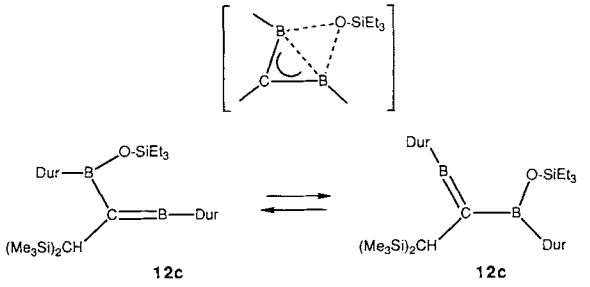
Topomerizations through the 1,3 migration of a residue R from the tri- to the dicoordinate boron atom are characteristic reactions of the (borylmethylene)boranes **12** (for **12n**, see Section 3.3.3.1), **12c**,[51] and **72**.[51] They correspond to the topomerization reactions of the (silylmethylene)silanes **73** (Wiberg et al.[39b]) in which methyl groups undergo a 1,3 migration from the tetra- to the tricoordinate silicon atom. The isotopomerization of the Paetzold group's (silylmethylene)borane **1a′** to **1a″** [3e] through a double 1,3 migration, first from the tetracoordinate silicon to the dicoordinate boron and then from the tricoordinate boron to the tricoordinate silicon atom, is to be classified between the topomerization reactions of **72** and **73**.







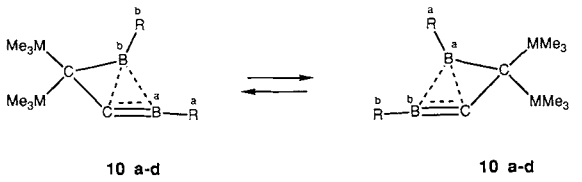
In addition to methyl group migrations (**72**: $\Delta G^{\neq}$ = 12 kcal mol^{-1}), both aryl groups (**12o**,[54] **12n**: $\Delta G^{\neq}$ = 10 kcal mol^{-1}; see Section 3.3.3.1) and $OSiEt_3$ groups (**12c**: $\Delta G^{\neq}$ = 15 kcal mol^{-1} [51]) have been observed to undergo migrations in (borylmethylene)boranes. The relatively low activation energies for these rearrangements in which B–C bonds, or even the B–O bond in **12c**, must be broken can be



explained quite easily by transition states **15** stabilized through σ–π and π–π delocalizations of the β-agostic type B.

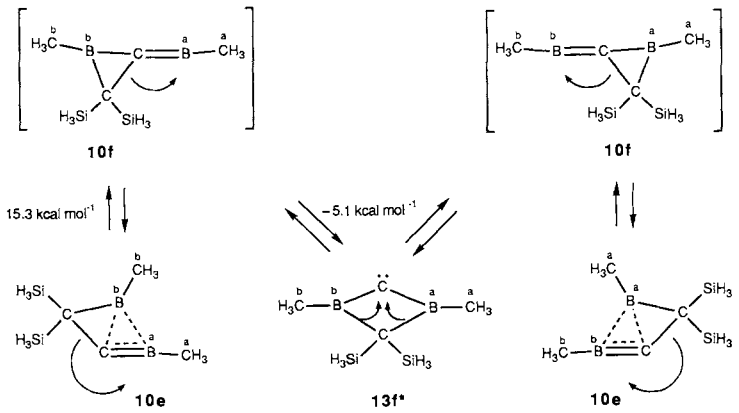
4.1.2. Topomerization Reactions Involving Double 1,2 Migrations

The boron atoms and their bound substituents R in the bridged boriranylideneboranes **10a–d** can be differentiated by NMR spectroscopy only below certain temperatures. Line broadening and coalescence indicate rapid topomerization reactions with exchange barriers of 11.4–12.5 kcal mol^{-1}.[1a, 88, 89]



10 a-d **10 a-d**

Schleyer[25b] showed by ab initio calculations on **10e** that this transformation proceeds via the transition state **10f** and the diborylcarbene intermediate **13f/13f***. π–π delocalization as found in other (borylmethylene)boranes (see Scheme 3) can be recognized in **10f** from the short =C–B bond length (146.1 pm). Strong C–C hyperconjugation be-

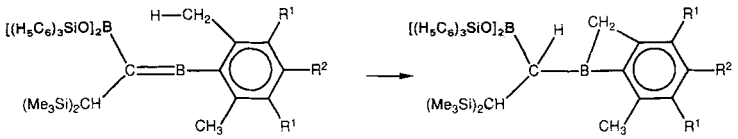


tween the strained C–C σ bond of the three-membered ring and the partially positively charged dicoordinate boron atom (partial charge caused by π–π delocalization) can be seen in the 29° contraction of the C–C=B bond angle to 124° compared to that in **10u***, in the large B–C–B angle of 177.1°, and in the long C–C bond of the three-membered ring (162.3 pm). Complete transfer of this C–C σ bond to the neighboring electron-deficient center provides, through an initial 1,2 migration, the diborylcarbene **13f/13f***, in which the boron atoms and also their bound groups are equivalent. As previously described for **13a** in the Introduction, the severe distortions caused by the σ–π interactions of the Si_2C–B σ bonds with the partially positively charged carbene carbon atom (charge results from π–π delocalization) set up the second 1,2 migration in which the C–B σ bond is transferred to the carbene carbon atom. After this migration, the boron atom B^b that was formerly part of the three-membered ring has now been transformed into the boron atom of the C–B double bond. Redevelopment of the strong σ–π interaction with the C–B σ bond of the three-membered ring, which initially had to be sacrificed, completes the topomerization.

4.2. Intramolecular Addition of C–H Bonds to the C–B Double Bond in Methyleneboranes

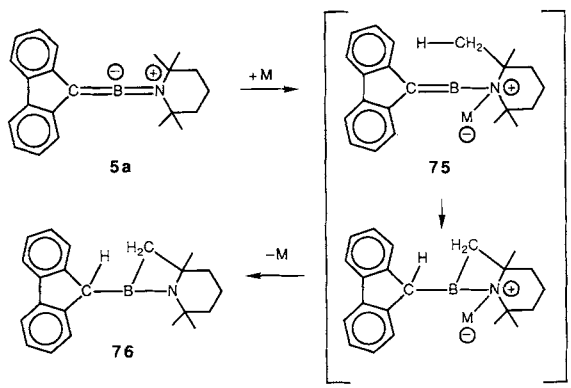
4.2.1. Formation of Boron Containing Four-Membered Rings

The methyleneboranes **12g,h** are transformed cleanly into the benzo-1,2-dihydroboretes **74a,b** on melting (166 and 135 °C).[51] Nöth et al. obtained product **76** from the attempt



12g $R^1 = CH_3$, $R^2 = H$ **74a** $R^1 = CH_3$, $R^2 = H$
12h $R^1 = H$, $R^2 = CH_3$ **74b** $R^1 = H$, $R^2 = CH_3$

to prepare π complexes by reaction of the amino(methylene)-borane **5a** with either $[\{(H_5C_6)_3P_2Pt(C_2H_4)\}]$ or $[Ni(cod)_2]$ (cod = cyclooctadiene).[2k] The formation of this product can be quite easily explained if one assumes that the metal accepts the lone pair of electrons on the nitrogen to form the methyleneborane **75**, which is no longer stabilized by π–π delocalization and reacts by intramolecular C–H bond addition to the highly reactive C–B double bond, as in the previous example.

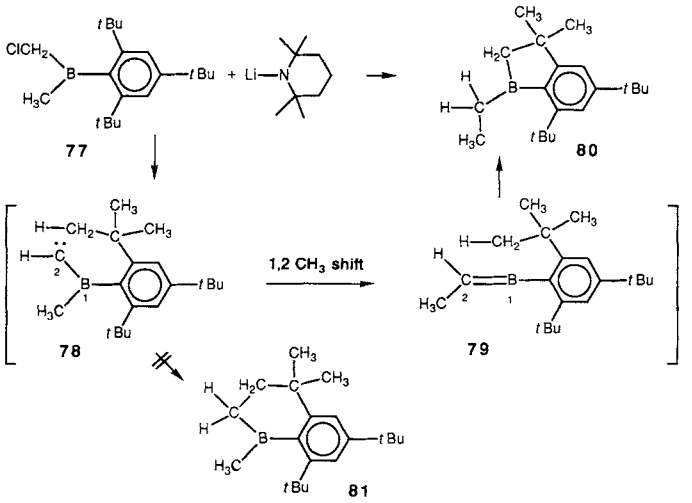


The C–H bond additions to double bonds involving dicoordinate boron atoms described here can be regarded as extreme forms of γ-agostic interactions.[7]

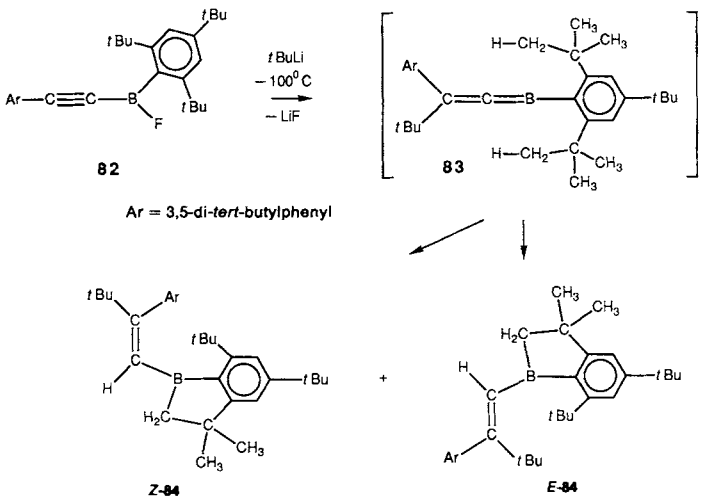
4.2.2. Formation of Boron Containing Five-Membered Rings

From our attempts to synthesize the methyleneborane **79** by reaction of the chloromethyl(methyl)borane **77**,[90] pre-

pared from 2,4,6-tri-*tert*-butylphenyldifluoroborane[90] with lithium tetramethylpiperidide in ether at −65 °C, through α elimination via the borylcarbene **78**, we obtained in good yield (90%) the boraindane **80**[90] in which an ethyl group is bonded to the boron atom. The formation of this compound can be quite easily explained by addition of a C−H bond of an ortho-*tert*-butyl group to the highly reactive C−B double bond in **79**. The direct insertion of the carbene carbon atom

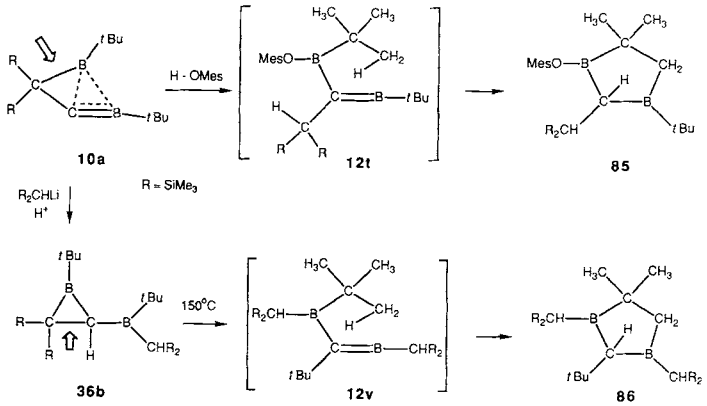


into a C−H bond, which would lead to the six-membered ring **81** in which a methyl group is bonded to the boron atom, occurs only to a minor extent, if at all. From the attempt to synthesize the boraallene **83** or its THF adduct from reaction of the alkynylfluoroborane **82** with *tert*-butyllithium at −120 °C in THF we obtained the vinylboraindane stereoisomers ***E*-84** and ***Z*-84**.[90]



These insertions correspond to those observed for compounds containing the 2,4,6-tri-*tert*-butylphenyl residue bonded to a center of high electron deficiency.[91] For kinetic stabilization of compounds with low-coordinate main group elements *lacking* electron-deficient centers,[93] the "supermesityl" (2,4,6-tri-*tert*-butylphenyl) residue—originally used by Yoshifuji[92] for compounds containing dicoordinate phosphorus—has proven outstanding.

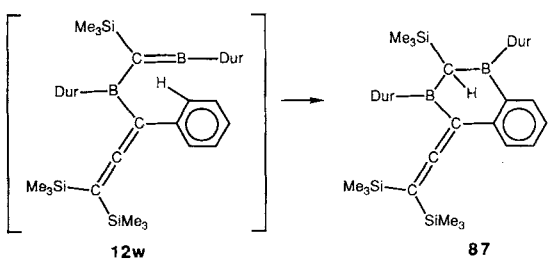
Our attempt to produce **12t** from the reaction of **10a** with 2,4,6-trimethylphenol, analogous to the formation of **12f** under cleavage of the three-membered ring in **10c** (see Section 2.4), yielded the diborolane **85** smoothly.[88] Instead of the expected methyleneborane **12v**, analogous to the formation of **5h** from the borirane **36a** (see Section 2.8), the diborolane **86** formed quantitatively upon melting of the borirane **36b** at 150°C.[94]



The absence of electronic stabilization and the presence of a favorable geometry for δ-agostic activation of their C−H bonds in the transition states (see Scheme 5) are probably responsible for the low temperatures at which the intramolecular addition reactions occur in the methyleneboranes **79**, **83**, and **12t**. Intermediate **12v** is stabilized by C−Si and C−B hyperconjugation, so C−H bond addition to the C−B double bond probably is caused by the high temperature necessary for the formation of **12v** (compare the reaction conditions for producing **74a,b**).

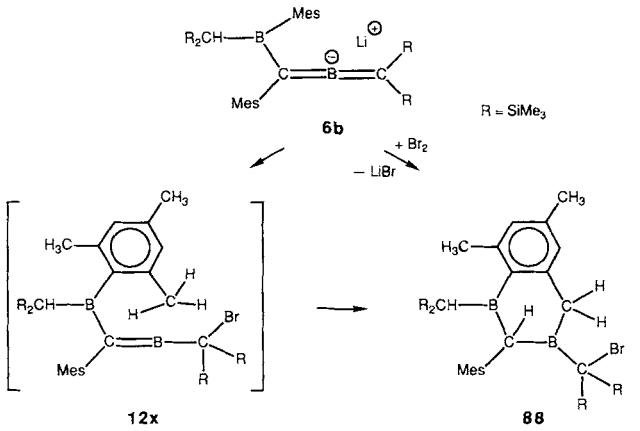
4.2.3. Formation of Boron Containing Six-Membered Rings

Analogous to the formation reaction of **12r** (see Section 2.13), we attempted to prepare the methyleneborane **12w** from the reaction of **10c** with phenyltrimethylsilylacetylene but instead obtained **87**.[51] Despite the stabiliza-



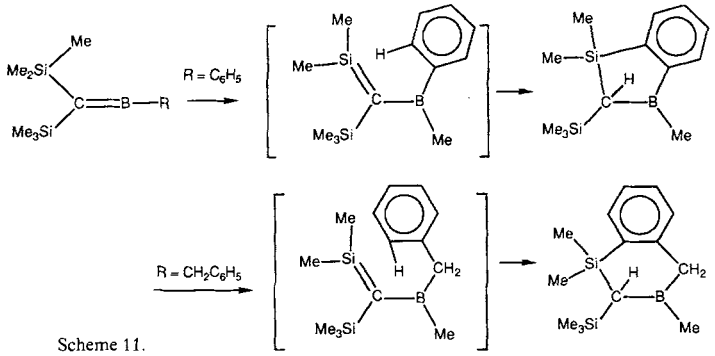
tion of **12w** by C−Si and C−B hyperconjugation, an intramolecular C−H bond addition to the C−B double bond took place already at room temperature, probably as a result of optimal geometry. The formation of **88**[48] from **6b** and

bromine can be explained with the corresponding extreme form of an ε-agostic interaction in intermediate **12x**.



6b **12x** **88**

Closely related to the C–H bond additions to the C–B double bond described here are the high-temperature (560 °C) reactions of (silylmethylene)boranes observed by Paetzold et al.[3e] Here, C–H bonds add intramolecularly to C–Si double bonds formed by the 1,3 migration of a methyl group from a tetracoordinate silicon atom to the dicoordinate boron atom (Scheme 11, compare Section 4.1.1).



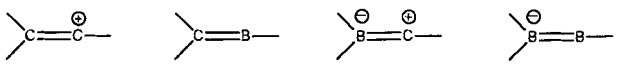
Scheme 11.

5. Summary

Methyleneboranes that are isoelectronic to vinyl cations augment the range of known electron-deficient compounds with members that allow, through spectroscopic and crystal structure analyses, the investigation of σ–π delocalization (hyperconjugation, nonclassical behavior, various degrees of three-center, two-electron bond formation) from σ bonds to electropositive atoms at the position β to an electron-deficient center. σ–π delocalization can be synergically strengthened in methyleneboranes that have tricoordinate boron atoms at the position β to the electron-deficient center by increasing the electron deficiency at the dicoordinate boron atom through concurrent π–π delocalization of the π electrons of its C–B double bond to the boron atom in the boryl substituents. Impressive consequences of strong σ–π delocalization of the α-agostic type include bond angle distortions of up to 65°, reductions in the NMR coupling constants of as much as 80% of their normal values, and NMR shielding at the electron-deficient center of up to $\Delta\delta = 65$. Increasing the electronegativity of the β boron atom with electronegative substituents leads to decreased σ–π delocalization and its associated consequences. Strong σ–π interactions of the β-agostic type are present in mesityl- and H-bridged (borylmethylene)boranes and in a cyclic methyleneborane with trapezoidal geometry. Low activation energies of rearrangement reactions with 1,3 migrations of substituents from tri- to dicoordinate boron atoms—which are characteristic for (borylmethylene)boranes—are explained by transition states stabilized by σ–π interaction of the β-agostic type. The results for methyleneboranes complement the current understanding of σ–π delocalization in an area that is not accessible through carbocations, or only in exceptional cases.

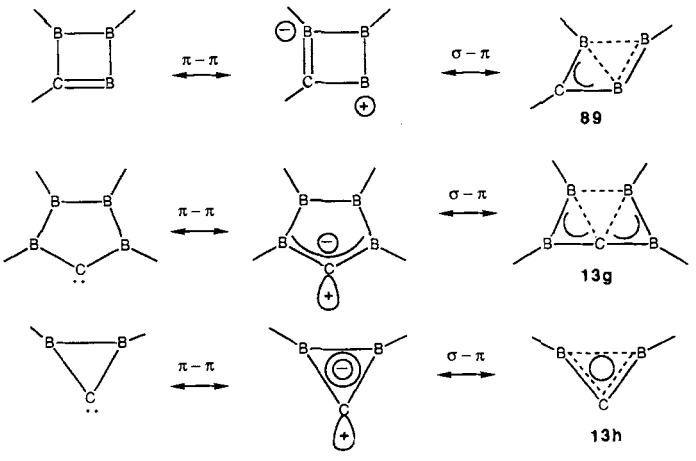
6. Outlook

Our studies on the chemistry of the methyleneboranes have for an essential part been developed not deliberately through planning but serendipitously (to quote G. Wittig[95] "not by intention, but by chance and surprise"). Further pleasant surprises will be welcome. There are several goals that we consider worthwhile, as, for example, the last isoster in the series depicted in Scheme 12, which has only been treated theoretically.[96]



Scheme 12. Isosteres of methyleneboranes.

A simple route to borylcarbenes and diborylcarbenes could open a general access to methyleneboranes and (borylmethylene)boranes. (Halomethylene)boranes would not only be interesting for comparing with β-halogen-substituted vinyl cations[97] but also as starting materials for the synthesis of simple borataalkynes R–C≡B$^{\ominus}$–Ar. These should enable the preparation of a variety of substituted methyleneboranes including the missing β-plumbyl-substituted species and reactants for the synthesis of four-mem-



89 **13g** **13h**

H–B≡C≡B–H

90

bered rings containing three boron atoms. With appropriate substituents, the nonclassical cyclic methyleneborane **48**,[25b] the related methyleneborane **89**, and the analogously stabilized diborylcarbene **13g** should be isolable.

The simplest cyclic diborylcarbenes, diboriranylidenes **13h**, which are 2π aromatic systems containing both a classical bond and a nonclassical 3c–2e bond, probably will be detectable only in a matrix. According to calculations by Schleyer et al.,[98] the parent compound (CB_2H_2) exhibits a long B–B bond (194.4 pm) and short C–B bonds (138.0 pm) and is about 1.2 kcal mol^{-1} lower in energy than the recently characterized (in argon matrix) 1,3-diboraallene **90**.[99]

For the results obtained in Marburg and presented in this review I thank the dedicated work of J. Allwohn, C. Balzereit, G. Baum, A. Höfner, R. Hunold, H. Klusik, C. Kybart, K. Kyritsis, U. Lippold, H. Lukasch, S. Mehle, H. Meyer, H. Michel, R.G. Müller, M. Pilz, C. Pues, G. Schmidt-Lukasch, M. Stadler, N. Stamatis, R. Wehrmann, C. Wieczorek, P. Willershausen, and B. Ziegler. I should also like to thank Prof. Dr. W. Massa, Marburg, for the determination of numerous crystal structures and for the instruction and support of to my coworkers, who have themselves performed X-ray structure analyses. Furthrmore I am grateful to Prof. Dr. S. Berger, Marburg, Prof. Dr. P. von R. Schleyer, Erlangen, Prof. Dr. H.-U. Siehl, Tübingen, Prof. Dr. Y. Apeloig, Haifa, and Prof. Dr. B. Wrackmeyer, Bayreuth, for good collaboration, Prof. Dr. B. Bogdanović, Max-Planck-Institute für Kohlenforschung, Mülheim, for information on the preparation of highly reactive magnesium, Prof. Dr. P. Paetzold, Aachen, for valuable suggestions for the organization of this review, and Ms. I. Bublys for her infinite patience during the preparation of the manuscipt. We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.

Syntheses of Polycyclic Natural Products Employing the Intramolecular Double Michael Reaction

New Synthetic Methods (91)

By Masataka Ihara* and Keiichiro Fukumoto*

The one-pot intramolecular double Michael reaction of compounds having two different α,β-unsaturated carbonyl groups to form polycyclic compounds can be carried out by three different methods: in the first the substrate is treated with lithium hexamethyldisilazide, in the second with chlorotrimethylsilane, triethylamine, and zinc chloride at an elevated temperature, and in the third with *tert*-butyldimethylsilyl trifluoromethanesulfonate and triethylamine. The reaction proceeds with complete regioselectivity and high stereoselectivity following a stepwise mechanism. Spiro-fused bicyclo[2.2.2]octane derivatives can be constructed with high stereoselectivity by the intramolecular double Michael reaction by using the first method. Enantiomerically pure atisine and the enantiomer of atisirene were synthesized stereoselectively by application of this methodology. The syntheses of steroids and angular triquinane-type sesquiterpenoids were possible with the second method. Heterocyclic compounds with a bridgehead nitrogen atom were obtained by the reaction of α,β-unsaturated amides following the second and third methods. The asymmetric synthesis of tylophorine with diastereofacial control was achieved by the intramolecular reaction according to the third method. The sulfur-mediated intramolecular double Michael reaction utilizing the third method produced *trans*-hydroindane derivatives. Furthermore, the intramolecular Michael–aldol reaction can be employed in synthesizing polycyclic systems with cyclobutane units by treatment with *tert*-butyldimethylsilyl trifluoromethanesulfonate in the presence of triethylamine. The intermolecular double Michael reaction and related reactions will also be described.

1. Introduction

Since new methods for C–C bond formation with regio- and stereocontrol are needed in synthetic organic chemistry, ring construction is a central theme. If functional group A acts as an electron donor to an electron-accepting group B, which is in the same molecule, and during the reaction the character of the functional groups change to electron-accepting and electron-donating, respectively, formation of a second bond would lead to a polycyclic ring system having a number of stereogenic centers. An example of such a sequence is provided by the intramolecular double Michael reaction shown in Figure 1.

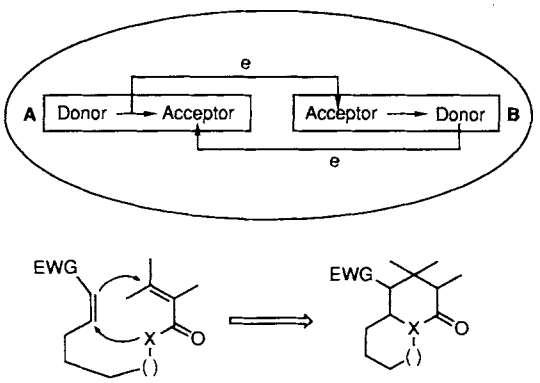

Fig. 1. Schematic representation of the intramolecular double Michael reaction. EWG = electron-withdrawing group; X = electron-donating group. The ellipse represents a molecule with functional groups A and B; the arrows labeled with e indicate intramolecular nucleophilic additions.

The Michael reaction of activated methylene groups with α,β-unsaturated esters or ketones is one of the most widely utilized approaches for C–C bond formation.[1] The strategy described consists of two sequential Michael reactions, but the reaction can be also regarded as an anion-assisted or a Lewis acid catalyzed Diels–Alder reaction. Although the determination of the reaction mechanism is difficult, many results support a stepwise mechanism.

The intramolecular double Michael reaction leads to the rapid construction of polycyclic compounds. Hence, it is potentially a powerful weapon for the synthesis of complex natural products.[1b] We would like to show here its usefulness in the field of chemical synthesis. For the purpose of comparison, we will first describe the intermolecular double Michael reaction and several applications.

2. Intermolecular Double Michael Reactions

Double Michael reactions can be carried out under either basic or acidic conditions.[2] In the case of the intermolecular reaction under acidic conditions, it is necessary to convert the first Michael donor into a cross-conjugated silyl enol ether prior to the reaction. In contrast, in the intramolecular variant the sequential conjugate additions directly occur without formation of silyl enol ethers (see Sections 3.1.1–3.1.3, 3.2.4–3.2.7).

2.1. Under Basic Conditions

Cross-conjugated dienolates can be generated from α,β-unsaturated ketones having no hydrogen atom at the γ position by treatment with sodium hydride or potassium *t*-bu-

toxide. The dienolate formed from **1** or **3** underwent double Michael reactions with electron-deficient olefins to give **2**[3] and **4**[4], respectively (Fig. 2).

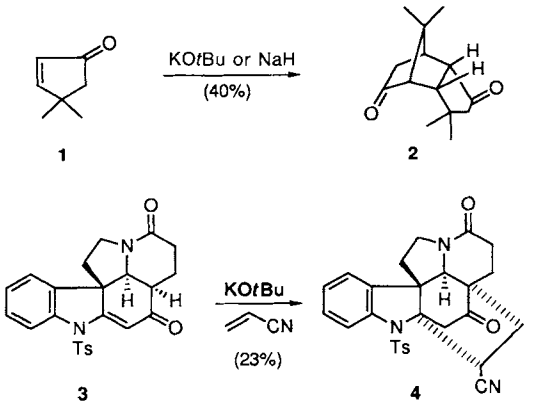

Fig. 2. Intermolecular double Michael reaction of α,β-unsaturated ketones having no γ-hydrogen atoms. Ts = toluenesulfonyl.

The intermolecular double Michael reaction of α,β-unsaturated ketones possessing an γ hydrogen atom was first reported by Lee.[5] Bicyclo[2.2.2]octane derivatives **6** were efficiently synthesized by the reaction of cyclohexenones **5** with methyl acrylate in the presence of lithium diisopropylamide (LDA) (Fig. 3, entries 1 and 2). White and Reusch added several more examples (entries 3–5). They also examined the double Michael reaction of dienolates with methyl vinyl ketone; bicyclic compounds **7** were obtained in good yield when free amine was removed from the reaction mixture (entries 6 and 7).[6] The distinct preference for products **6** and **7** having a *syn* relationship between the two carbonyl groups is noteworthy. These results indicate that the cation is chelated in the transition state by carbonyl groups of the donor and acceptor portions of the moleule.

Hagiwara and Uda also reported the intermolecular double Michael reaction of ethyl α-phenylthio- and α-

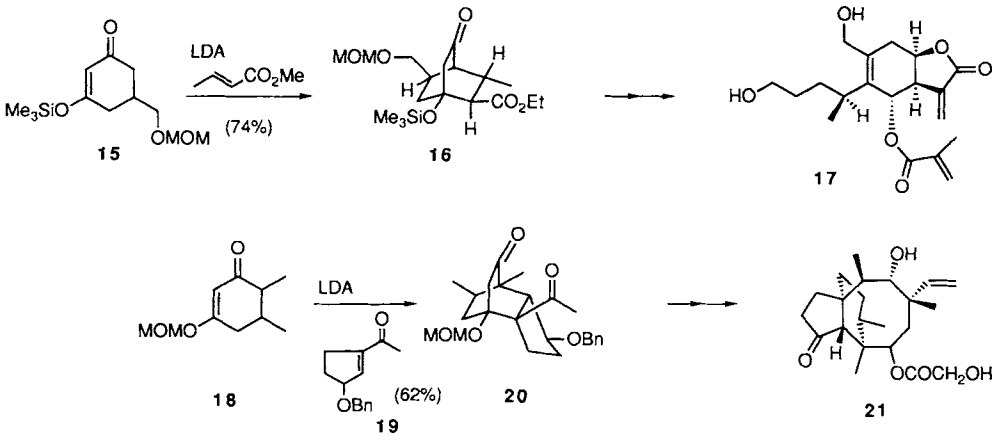
Masataka Ihara, born in 1942, was educated at the Pharmaceutical Institute, Tohoku University, and received his Ph.D. degree there in 1970. He has been Associate Professor of Organic Chemistry at the Pharmaceutical Institute, Tohoku University, since 1981. His current interests are the development of new synthetic methods and the syntheses of natural products. He received the Miyata Academic Prize in 1992.

Keiichiro Fukumoto was born in 1934, graduated from the Pharmaceutical Institute, Osaka University, and obtained his Ph.D. degree from Osaka University in 1964. He has been Professor of Organic Chemistry at Pharmaceutical Institute, Tohoku University, since 1981, and his research focuses on the syntheses of natural products. He received the Prize of the Pharmaceutical Society of Japan in 1976.



phenylsulfinylcrotonates giving **8** and **9**.[7] In the course of these investigations, several mono Michael adducts such as **10** and **11** were obtained. Failure of the second Michael addition was ascribed to the stability of the enolate anion formed in the first Michael reaction. Formation of adducts **10** and **11** is consistent with a stepwise mechanism. Similar strategies were used for the construction of bridged compounds,[8-14] and mono Michael adducts were detected by several researchers.[8-10]

The stepwise mechanism was clearly supported by the following experiment. Deprotonation of the vinylogous ester **12** with LDA at low temperature was followed by addition of methyl acrylate and in situ silylation to yield the mixed ketene acetal **13** as a rather stable compound. The second Michael addition of **13** proceeded smoothly upon treatment with silica gel to produce **14** (Fig. 4).[15]

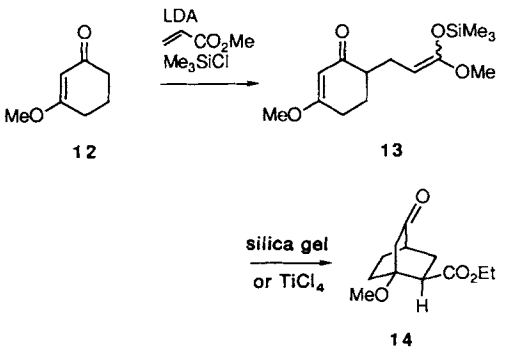


Fig. 4. Intermolecular double Michael reaction via a mixed ketene acetal.

This reaction was applied in the syntheses of many natural products (Fig. 5). Treatment of the dienolate derived from **15** with methyl crotonate gave the bicyclo[2.2.2]octane derivative **16**, which was converted into (±)-eriolanine (**17**).[16,17] Double Michael reaction of **18** with enone **19** provided the tricyclic compound **20**, which was transformed into (±)-pleuromutilin (**21**).[18,19] When the enolate of **22** generated under kinetic control was treated with ethyl sorbate, the synthetic intermediate **23** of (±)-sanadaol (**24**) was produced.[20,21] Double Michael reaction of the enolate of **22** with the (*Z*) ester **25** yielded the bridged product **26** as a single stereoisomer. In contrast, the reaction with the corre-

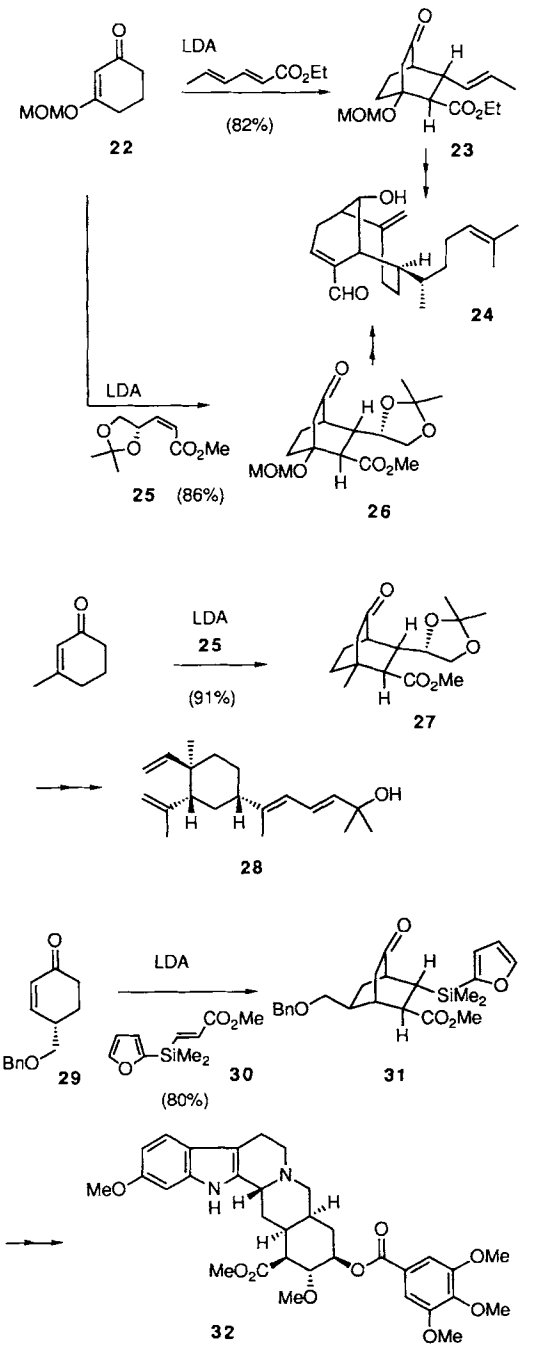

Fig. 5. Natural product syntheses utilizing the intermolecular double Michael reaction. MOM = methoxymethyl.

sponding (*E*) ester provided a mixture of two diastereoisomers. The ratio of the two products was reversed by the addition of HMPA.[22a] Product **26** was converted into (−)-sanadaol (**24**).[22b] The marine diterpene fuscol (**28**)[23] was synthesized via **27**, which was prepared by the double Michael reaction of 3-methyl-2-cyclohexenone with (*Z*) enoate **25**.[24] Stereoselective synthesis of reserpine (**32**)[25] was possible with intermediate **31**, which was obtained by the tandem reaction of **29** with the unsaturated ester **30**.[26]

Construction of bicyclic compounds by base-catalyzed double Michael reaction was devised by Deslongchamps et al.[27] As an example, the *cis*-decalin derivative **35** was prepared stereoselectively by the reaction of **33** with enone **34** in the presence of cesium carbonate (Fig. 6).[27a]

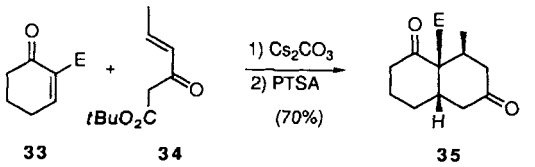

Fig. 6. Synthesis of the *cis*-decalin derivative **35**. E = CO_2Me; PTSA = *para*-toluenesulfonic acid.

2.2. Under Acidic Conditions

The double Michael reaction of cross-conjugated silyl enol ethers with α,β-unsaturated carbonyl compounds in the presence of a Lewis acid could be considered a Lewis acid catalyzed cycloaddition, and it is hard to distinguish between them. Interestingly, the *exo* adduct **38** was selectively formed by the reaction of siloxydiene **36** with enone **37** (Fig. 7).[28] In

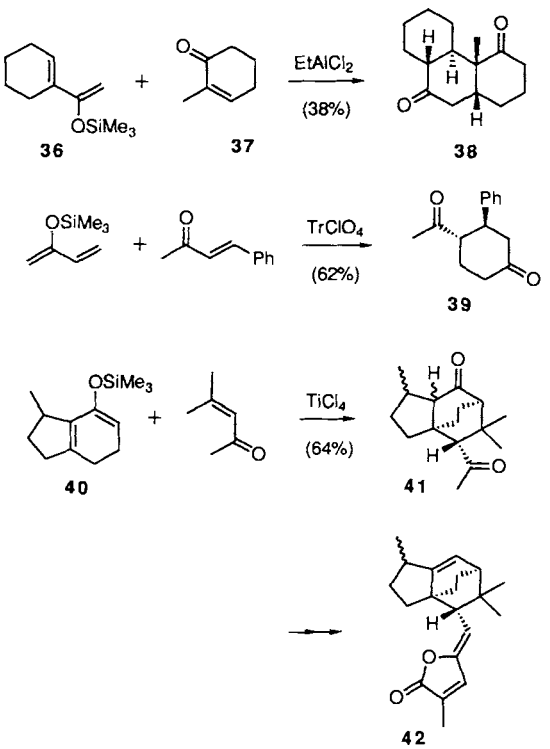

Fig. 7. Lewis acid catalyzed intermolecular double Michael reaction. Tr = trityl.

the presence of a catalytic amount of trityl perchlorate, the double Michael reaction effectively provided the cyclohexanone derivative **39** with selectivity.[29] The reaction of siloxydiene **40** with mesityl oxide in the presence of titanium(IV) chloride afforded a 1:2 mixture of tricyclic compounds **41**, which were transformed into (±)-eremolactone (**42**) (Fig. 7).[30, 31]

3. Intramolecular Double Michael Reactions

3.1. Construction of Polycyclic Ring Systems

3.1.1. Spiro-Fused Bicyclo[2.2.2]octane Derivatives

The bicyclo[2.2.2]octane framework is a partial structure for many natural products. A general method for the stereocontrolled construction of spiro-fused bicyclo[2.2.2]octanes should provide access to a number of interesting compounds. To this end, we studied intramolecular Diels–Alder reactions. But since only poor stereoselection was observed,[32] we were forced to investigate alternative approaches. It was anticipated that compounds having both an enone and an α,β-unsaturated ester group would undergo intramolecular double Michael reactions under either basic or acidic conditions. We also expected that the reaction would be diastereoselective if the ring closure proceeded via a metal-chelate intermediate.

We first examined the intramolecular double Michael reaction of **43** by using several bases (Fig. 8). Treatment with sodium hydride or potassium hydride gave none of the desired tricyclic compounds (entries 1 and 2); however, with LDA and lithium hexamethyldisilazide (LHMDS, $LiN(SiMe_3)_2$), the desired reaction occurred and **46** was produced single isomer (entries 3 and 4). The best results were obtained with LHMDS (entry 4). The stereoselective formation of the desired product **46** can be explained by the intramolecular conjugate addition via intermediate **52** in which the two oxygen atoms are coordinated to a metal cation. This hypothesis is supported by the observed absence of cyclization when NaH or KH was employed and the reduced yield from the reaction carried out in the presence of HMPA (entry 5).[33]

Treatment of the α,β-unsaturated ester **44**, which has hydrogen atoms at the γ position, with LHMDS in THF furnished **47** in poor yield (entry 6). The yield was considerably improved, however, when the reaction was carried out in hexane/ether (entry 7). This observation lends further support for the proposed intramolecular chelation.[34]

The tandem reaction of **45** was also examined with various lithium bases (entries 8–12). Although the racemic product **48** was a single isomer, the yields were dependent on the lithium base and the solvent used. The best results were obtained when **45** was treated with LHMDS in hexane/ether between −78 and 18 °C (2.5 h) and the reaction then quenched with silica gel (entry 10).[35]

The intramolecular tandem reaction of **45** under Lewis acidic conditions was also examined. Among the numerous conditions tested, only two procedures gave the annulation products although with poor stereoselectivity. Heating **45** together with an excess of chlorotrimethylsilane (TMSCl), triethylamine, and zinc chloride in toluene at 180 °C followed by an acidic workup provided **48** and **51** (entry 13).

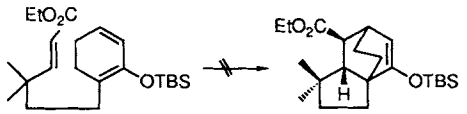
52



53 **54**

Fig. 8. Construction of spiro-fused bicyclo[2.2.2]octanes. TBS = *tert*-butyldimethylsilyl.

The same products were obtained by the reaction of **45** with *tert*-butyldimethylsilyl trifluoromethanesulfonate (TBSOTf) in the presence of Et_3N at 18 °C for 10 min followed by acidic workup (entry 14).[36] Thus, we found that the tandem reaction could be achieved under three sets of reaction conditions: 1) with LHMDS at a low temperature, 2) with TMSCl, Et_3N, and zinc chloride at elevated temperature, and 3) with TBSOTf in the presence of Et_3N at a low temperature. For the preparation of spiro-fused bicyclo[2.2.2]octane derivatives the first is the method of choice.

The other two methods[37–40] are frequently used in preparing silyl enol ethers. When **45** was treated with TBSOTf in the presence of trimethylamine at a low temperature, the cross-conjugated silyl dienol ether **53** was obtained. Treatment of **53** with TBSOTf and Et_3N at room temperature did not afford the tricyclic product **54**.[35] Thin-layer chromatograms of both reaction mixtures show that **45** gives rise to the cyclic ketones **48** and **51** directly, and these are gradually transformed into the corresponding epimeric silyl enol ethers **54**. This observation speaks against the intramolecuar Diels–Alder reaction of triene **53**.[41]

3.1.2. *Heterocycles with a Bridgehead Nitrogen Atom*

It was assumed that the construction of heterocyclic compounds with a nitrogen atom at the bridgehead position by an intramolecular double Michael reaction would be an efficient method for the synthesis of alkaloids. Treatment of the amide ester **55** under basic conditions with either LDA, LHMDS, potassium *tert*-butoxide, or sodium hydride in the presence of Et_3N led only to the mono Michael product **58** (Fig. 9). Apparently the α,β-unsaturated amide group does

58 **59** **60**

Fig. 9. Synthesis of indolizidines.

not function as a Michael acceptor under basic conditions. Various Lewis acids were then examined in order to accomplish the second Michael addition. The desired reaction giving a mixture of **56** and **57** was successfully achieved by treatment of **55** with TMSCl, Et_3N, and $ZnCl_2$ at an elevated temperature and, alternatively, with TBSOTf in the presence of Et_3N at low temperature. When the latter method was applied at −78 °C, **56** was obtained as a single isomer.[42] Formation of 1-azadiene **59** and silyl enol ether **60** was not detected during the reactions.[42] These findings provide further evidence for two sequential conjugate additions in the annulation reactions.

When **61** was subjected to either set of reaction conditions benzo[*a*]quinolizidine **62** was obtained as a single isomer (Fig. 10). Indolo[2,3-*a*]quinolizidine **64** was produced from

63 by heating with TMSCl, Et_3N, and $ZnCl_2$. Thus, the intramolecular double Michael reaction allows the efficient assembly of heterocyclic compounds with a bridgehead nitrogen atom under two sets of reaction conditions.[42, 43]

3.1.3. *Hydroindanes*

Since the *trans*-hydroindane framework with a methyl group at the angular position is a partial structure of steroids and various terpenoids, several methods for its construction have been devised.[44] We examined the synthesis of hydroindanes by the intramolecular double Michael reaction. All four geometrical isomers of **65** afforded the same main product, *trans*-fused **66**, upon treatment with TBSOTf in the presence of Et_3N. This procedure provides a useful methodology for the production of polyfunctionalized *trans*-hydroindanes, since **66** can be readily converted into the ketone **67** and the enone **68** (Fig. 11). Because there is no

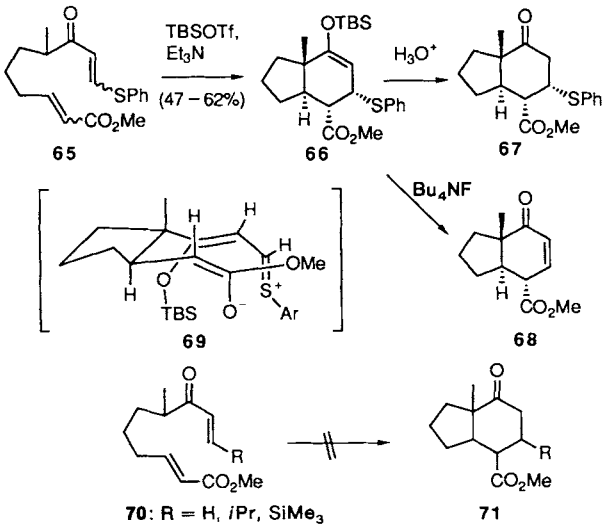

Fig. 11. Sulfur-mediated intramolecular double Michael reaction leading to *trans*-hydroindanes. Ar = aryl.

formation of bicyclic compounds **71** from enone esters **70** in the absence of the sulfenyl group, the sulfur-associated zwitterion **69** was proposed to be the common intermediate.[45] These results reconfirm the stepwise mechanism for the cyclization.

3.2. Syntheses of Natural Products

3.2.1. *Atisirene*

The optically active enone ester **72**, derived from the (+)-Wieland–Miescher ketone,[46] was treated with LHMDS and underwent an intramolecular double Michael reaction to afford the desired tetracyclic compound **74** in excellent yield (Fig. 12). The high stereoselectivity in the formation of **74** arises from the lithium-chelate intermediate **73**, which has no strong nonbonding interactions.[47] Keto ester **74** was converted by deformylation[48] into the synthetic precursor[49] of (+)-atisirene (**75**), the enantiomer of a diterpenoid isolated from *Erythroxylon monogynum*,[50] in order to remove the extra methoxycarbonyl group.[47] It is noteworthy that the corresponding *cis*-substituted substrate **76** produced the cyclized product **77** despite the crowded intermediate.[47a]

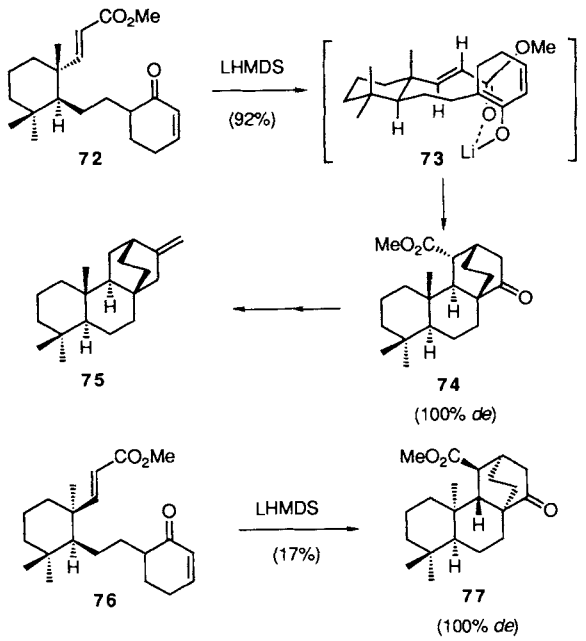

Fig. 12. Synthesis of the enantiomer (**75**) of atisirene.

3.2.2. *Aconitium Alkaloids*

The tricyclic compound **48**, which was mentioned in Section 3.1.1 as the product obtained form the highly stereoselective reaction of **45** with LHMDS, was transformed into the tetracyclic alcohol **78**. After mesylation the synthetic intermediate underwent a Wagner–Meerwein-type rearrangement[51] to give the tetracyclo[7.3.$0^{4,12}0^{5,13}$]tridecane derivative **79** as a single product; **79** corresponds to the CDF part of the *Aconitium* alkaloids **80** (Fig. 13).[35]

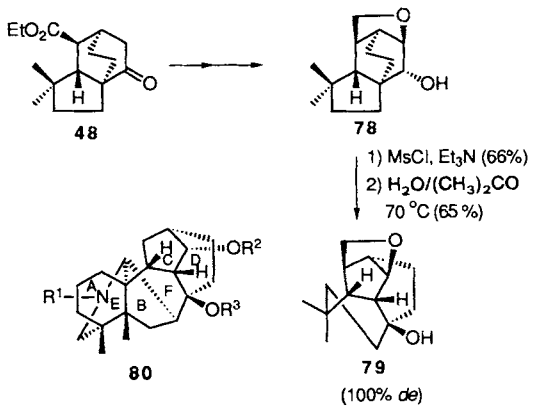

Fig. 13. Synthesis of the CDF part of the *Aconitium* alkaloids.

3.2.3. *Atisine*

Since the determination of the absolute configuration of atisine (**81**), a natural product found in *Aconitium heterophyllum*,[52] the alkaloid has attracted the attention of organic chemists as a target molecule. Three routes[53] were devised leading to Pelletier's synthetic intermediate,[54] but only racemates were obtained. We envisioned the construction of intermediate **82** by the intramolecular double Michael reaction of enone ester **83**.[55] It was further assumed that the substrate for the key step (**83**) could be accessible from the symmetrical azabicyclo[3.3.1]nonane **84** in optically active form (Fig. 14).[56]

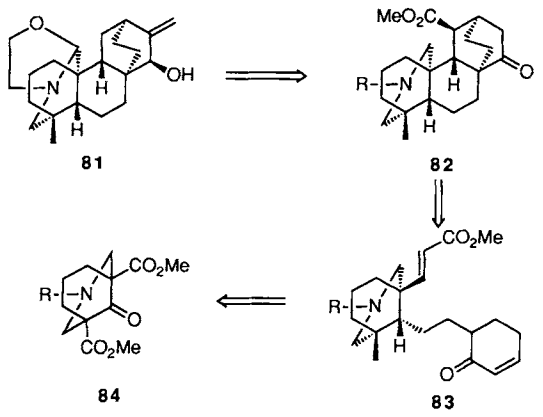

Fig. 14. Retrosynthesis of atisine (**81**).

Azabicyclononane **86**, corresponding to the AE part of atisine (**81**), was prepared quantitatively from diester **85** by a double Mannich reaction[57] (Fig. 15). The *meso* compound **86** is suited for enzyme-catalyzed, enantioselective transformation. After several attempts we were able to pro-

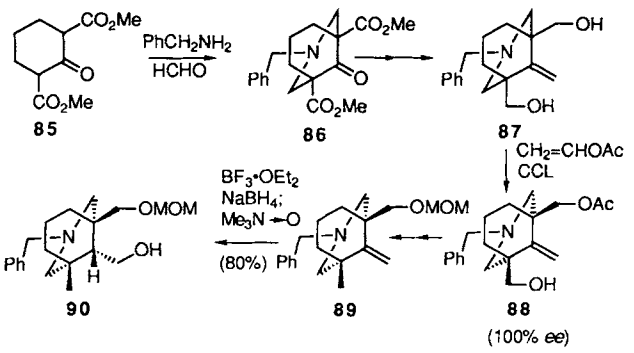

Fig. 15. Preparation of the chiral building block for the synthesis of actonitium alkaloids. CCL = *Candida cylindracea* lipase.

duce optically pure acetate **88** by lipase-catalyzed irreversible transesterification[58] of diol **87**. The absolute configuration was determined by X-ray analysis of the derivative after introduction of the (+)-camphorsulfonyl group with the known absolute configuration.[56] Monoacetate **88** was converted into olefin **89**; the latter could also be prepared from **86** by chemical means by utilizing a chiral auxiliary, however, the enantioselectivity was low.[59]

Stereoselective hydroboration of olefin **89** was not possible with standard borane reagents but was accomplished with sodium borohydride and boron trifluoride etherate, which generate borane in situ. Coordination of boron trifluoride to the amine blocks one side of the double bond, and the desired isomer **90** obtained stereoselectively.

The substrate required for the key step (**91**) was prepared in a straightforward manner from **90** and then subjected to the intramolecular double Michael reaction by treatment with LHMDS (Fig. 16). The highly stereoselective formation of the required pentacyclic compound **93** can be again accounted for by the lithium-chelate intermediate **92**. Removal of the unnecessary methoxycarbonyl group of **93** by Barton's procedure[60] followed by the one-step conversion of the carbamate into the acetamide[61] produced the key synthetic intermediate **94**[54] for atisine (**81**). This enantioselective total synthesis of atisine is the most efficient approach yet reported.[56]

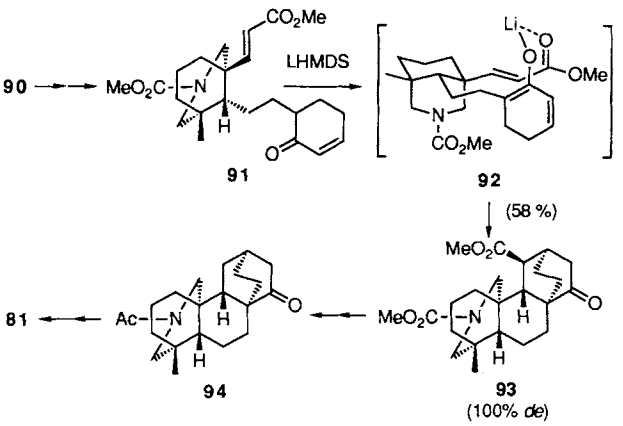

Fig. 16. Total synthesis of atisine (**81**).

The pentacyclic compound **96**, which has an oxygen functionality at the 6-position, was prepared by the intramolecular double Michael reaction of **95** under the same conditions as those above (Fig. 17).[62] It is expected that **96** should be a useful synthetic precursor for other *Aconitium* alkaloids.

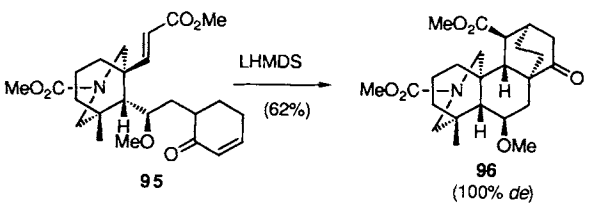

Fig. 17. Synthesis of an atisine derivative having an oxygen functionality at the 6-position.

3.2.4. *Steroids*

Steroids are attractive targets for synthetic work because of their medicinal importance and structural features.[63] We developed syntheses of androgens in which the AB rings are constructed by an intramolecular Diels–Alder reaction[64] and in which the B ring is formed by an intramolecular 1,3-dipolar cycloaddition of a nitrile oxide.[65] As an exten-

sion of this work we applied the intramolecular double Michael reaction to the construction of the AB ring system of estrane.[66] The substrate for the key step (**97**) was synthesized stereoselectively from a chiral indanone derivative.[67] The desired ring closure was achieved only by heating **97** with TMSCl, Et_3N, and $ZnCl_2$, since the vinyl ketone function was too reactive under the other two sets of reaction conditions. Three stereosiomers, **98A**, **98B**, and **99**, were obtained in a 2:1:1 ratio (Fig. 18).[66]

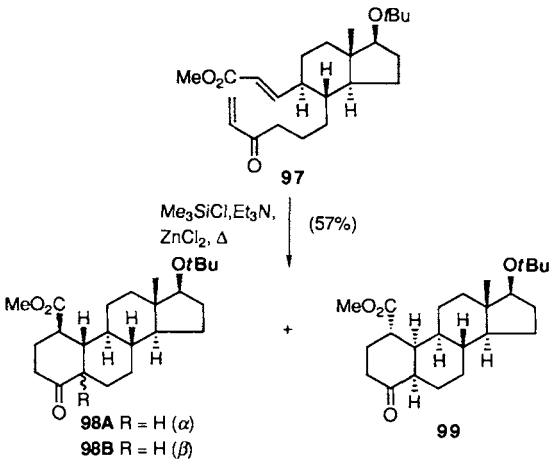

Fig. 18. Synthesis of estranes.

3.2.5. *Angular Triquinanes*

Angular triquinane-type sesquiterpenoids have recently received a great deal of attention from synthetic chemists because of their unique structures.[68] We synthesized the racemate of 3-oxosilphinene, a congener of silphinene, via a tricyclo[7.3.0.$0^{1,5}$]dodecane derivative prepared by an intramolecular Diels–Alder reaction.[69] We envisioned that a structurally related tricyclododecane suitable as a precursor for other triquinanes could be synthesized by the intramolecular double Michael reaction. Vinyl ketone **100** was synthesized in a straightforward manner starting from 5,5-dimethylcyclopent-2-en-1-one. Heating **100** with TMSCl, Et_3N, and $ZnCl_2$ produced two diastereoisomers, **101**, and **102** (Fig. 19). Both the yield and ratio of these products depended on the reaction temperature and solvent. The major product **101** could be transformed into (±)-pentalenic acid (**103**)[70] and (±)-pentalenene (**104**)[71] through ring contraction.[72]

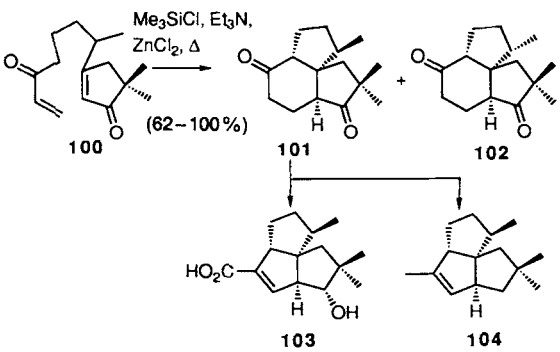

Fig. 19. Synthesis of (±)-pentalenic acid (**103**) and (±)-pentalenene (**104**).

3.2.6. *Epilupinine*

In order to demonstrate the usefulness of the intramolecular double Michael reaction for alkaloid synthesis, we chose epilupinine (**107**)[73] as the first target molecule (Fig. 20). Treatment of the amide ester **105** with TMSCl, Et_3N, and $ZnCl_2$ at an elevated temperature provided quinolizidine **106**. Better yields were possible when the reaction was conducted with TBSOTf *in* the presence of Et_3N at −78 °C. Reduction of **106** gave (±)-epilupinine (**107**).[42]

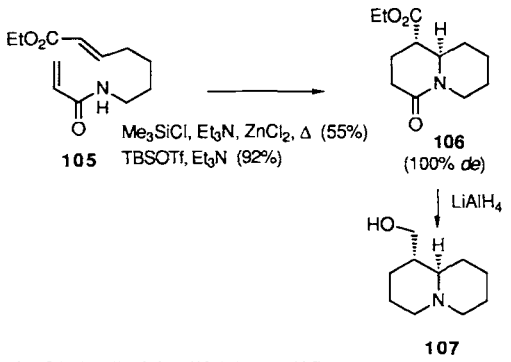

Fig. 20. Synthesis of (±)-epilupinine (**107**) (+ *ent*-**107**).

3.2.7. *Tylophorine*

The absolute configuration of (−)-tylophorine was tentatively assigned as the (*S*) form on the basis of degradation studies.[74] However, synthetic work[75] revealed that the absolute configuration of the natural (−) isomer corresponds to the (*R*) form (**111**). Since synthesis of optically active tylophorine had been carried out with (*S*)-amino acids as chiral precursors,[75] there was no report on the synthesis of the naturally occurring enantiomer. Preliminary experiments for the synthesis of the racemate[76] indicated that the construction of the indolizidine skeleton was possible with the intramolecular double Michael reaction by using TBSOTf in the presence of Et_3N at a low temperature. Therefore, we turned our attention to the asymmetric synthesis of the naturally occurring enantiomer **111**. Based on considerations of the conformation of the transition state, we expected that (−)-phenylmenthol or a secondary alcohol derived from glucose would be a suitable chiral auxiliary for the synthesis of the desired enantiomer. Two chiral amide esters, **108A** and **108B**, were prepared and then subjected to the tandem reaction. It was surprising that only the desired stereoisomers, **109A** and **109B**, respectively, were obtained in excellent yield (Fig. 21). Oxidation of **109A** with thallium(III) trifluoroacetate (TTFA) in the presence of boron trifluoride etherate[77] provided phenanthroindolizidine **110**. (−)-Tylophorine (**111**) was synthesized from both **109A** and **109B** by thermal decarboxylation.[78] These results support the expected transition state **112**, assuming that the conjugated double bond and the ester carbonyl bond of the α,β-unsatu-

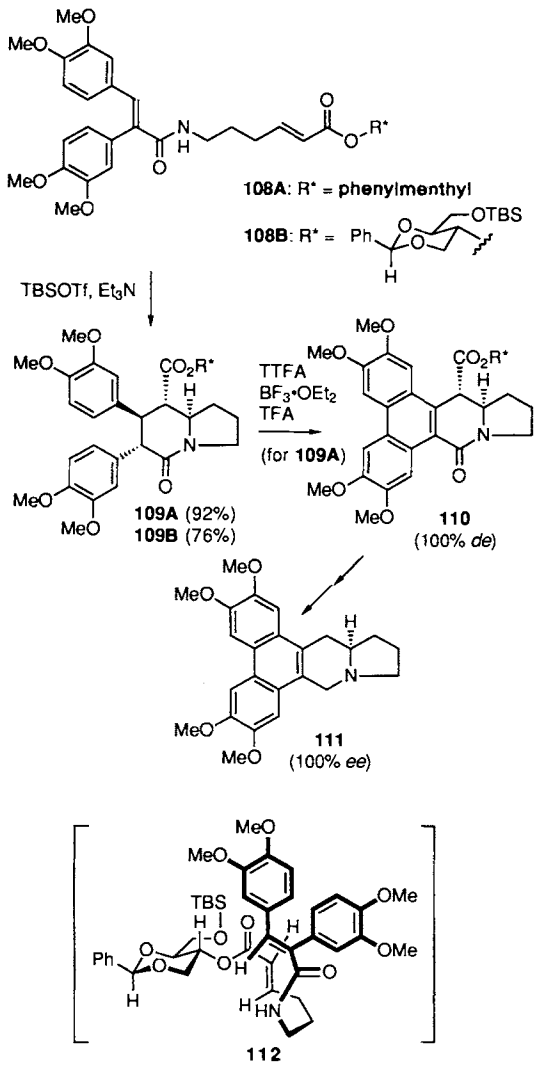

Fig. 21. Asymmetric synthesis of (−)-tylophorine (**111**).

rated ester have an antiplanar disposition and that the alkoxy α-hydrogen atom of the chiral auxiliary and the ester carbonyl oxygen atom have a synplanar arrangement.[44, 79]

4. Extension of Sequential Reactions

Sequential reactions, in which the intermediate in the Michael addition initiates a subsequent reaction, are potentially useful tools for the syntheses of cyclic and polycyclic compounds.

4.1. Other Types of Double Michael Reactions

Disubstituted pyrrolidine and piperidine frameworks were constructed by one-pot tandem Michael reactions, in which a molecule with an electrophilic double bond and a secondary benzylamine bearing an acceptor moiety trap the initially formed enolate.[80] (+)-α-Allokainic acid (**114**)[81] was synthesized by the base-catalyzed reaction of methyl vinyl ketone and the chiral amine **113** (Fig. 22).[80]

Lithium *N*-benzyltrimethylsilylamide (LSA) is an excellent nucleophile which only undergoes 1,4-addition to croton-

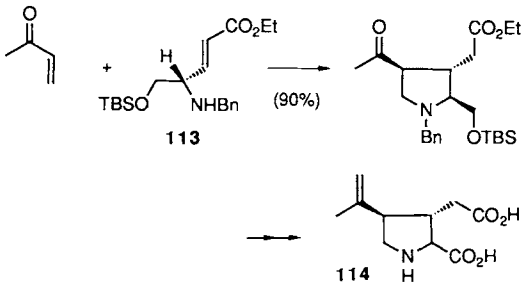

Fig. 22. Synthesis of (+)-α-allokainic acid (**114**).

ate derivatives. The reaction of the symmetrical diester **115** (R = Et) with LSA was followed by treatment with acetic acid to provide a 7:3 mixture of cyclopentane derivatives **116** (Fig. 23).[82] In contrast, treatment of **115** (R = Me) with silyl ketene acetal **117** in the presence of tetrabutylammonium *m*-chlorobenzoate afforded cyclopentane **118** as a single diastereoisomer.[83]

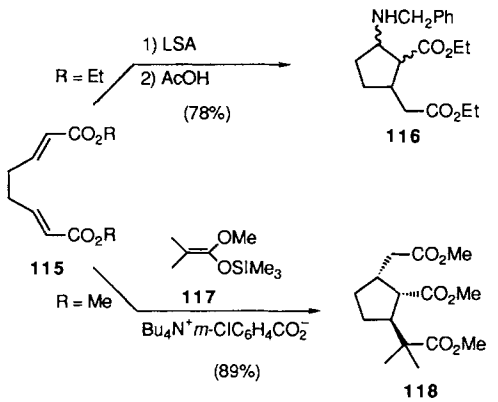

Fig. 23. Synthesis of cyclopentanes by tandem Michael reactions.

4.2. Triple Michael Reactions

Divinyl ketone and the trimethylsilyl enol ether **119** underwent Lewis acid assisted triple Michael reaction to yield tricycle **120**[84] as a single stereoisomer (Fig. 24);[85] **120** is a synthetic intermediate en route to (±)-seychellene (**121**).[86]

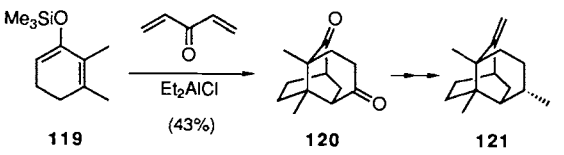

Fig. 24. Synthesis of (±)-seychellene (**121**) by a triple Michael reaction.

4.3. Michael–Michael–Substitution Reactions

If the cross-conjugated dienolate **122** reacts with a Michael acceptor in which the activating group is also a good leaving group, then the double Michael reaction may be followed by intramolecular substitution to generate a polycyclic ring system like **123** with a cyclopropane unit. This transformation was successfully carried out for Michael acceptors with

phosphonium bromide,[87] sulfone,[88] and nitro groups (Fig. 25).[89] For example, the dienolate derived from enone **124** reacted with vinylphosphonium bromide to produce the pentacyclic ketone **125** with high stereoselectivity.[90] A subsequent transformation provided the enantiomer of the diterpene *ent*-trachyloban-19-oic acid (**126**).[91]

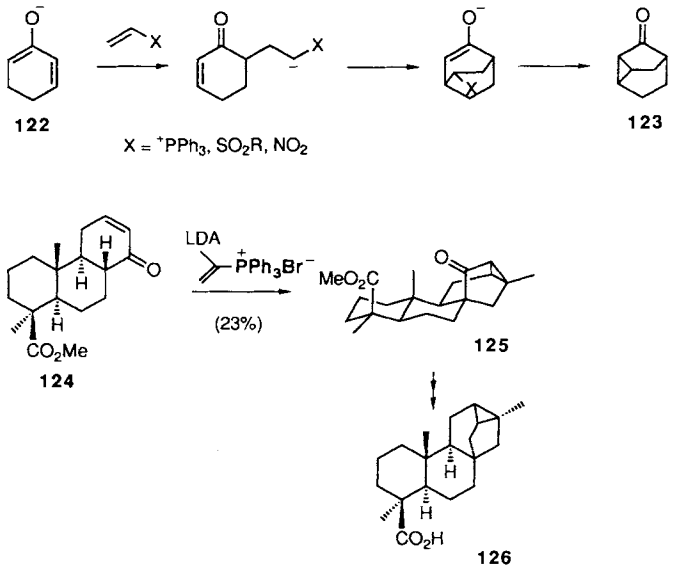

Fig. 25. Synthesis of *ent*-trachyloban-19-oic acid (**126**) by a Michael-Michael-substitution reaction.

Dienolates also undergo smooth Michael–Michael–substitution reactions with acrylic esters bearing a halogen atom at the 2-position.[92] The isolation of the mono Michael adduct as the intermediate supported the stepwise mechanism and ruled out the possibility that the Michael reaction is followed by a carbenoid reaction.[92e] Compound **128**, a precursor of (±)-ishwarane (**129**),[93] was prepared as the major product together with one diastereoisomer in the reaction of enone **127** with methyl α-bromoacrylate (Fig. 26).[92b] Reaction of the dienolate derived from enone **130** with ethyl α-bromocrotonate in the presence of HMPA produced a 4:1 mixture of tricyclic compounds **131** isomeric at the C7 position,[94] which were converted into (±)-helminthosporal (**132**).[95]

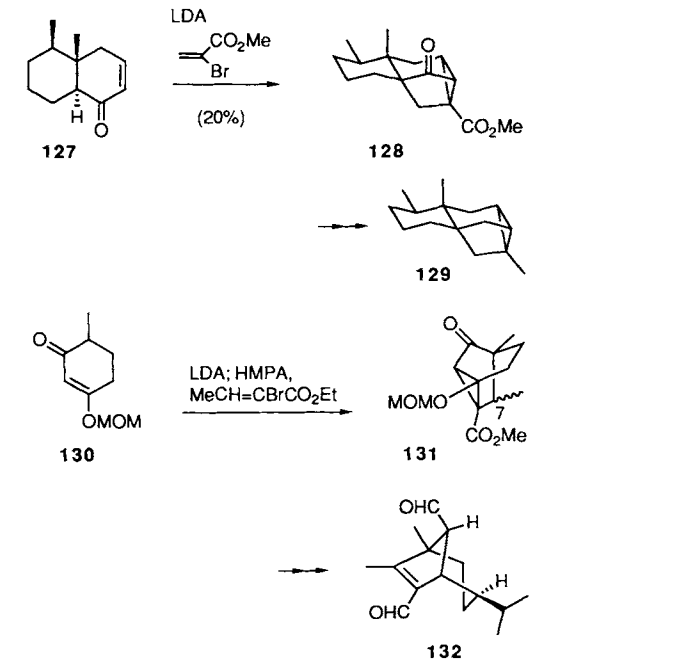

Fig. 26. Synthesis of (±)-ishwarane (**129**) and (±)-helminthosporal (**132**) by Michael-Michael-substitution reactions.

4.4. Michael–Michael–Aldol and Related Reactions

In the reaction shown in Figure 27 the external nucleophile underwent a Michael addition to the β carbon atom of the α-methylene ketone **133** which was then followed by intramolecular Michael addition. The enolate thus produced reacted with the isopropyl ketone part to complete the ring closure. A mixture of a bromohydrin **134** and two diastereoisomeric epoxides **135** was synthesized as a model experiment toward the synthesis of the indole alkaloid aflavinine (Fig. 27).[96]

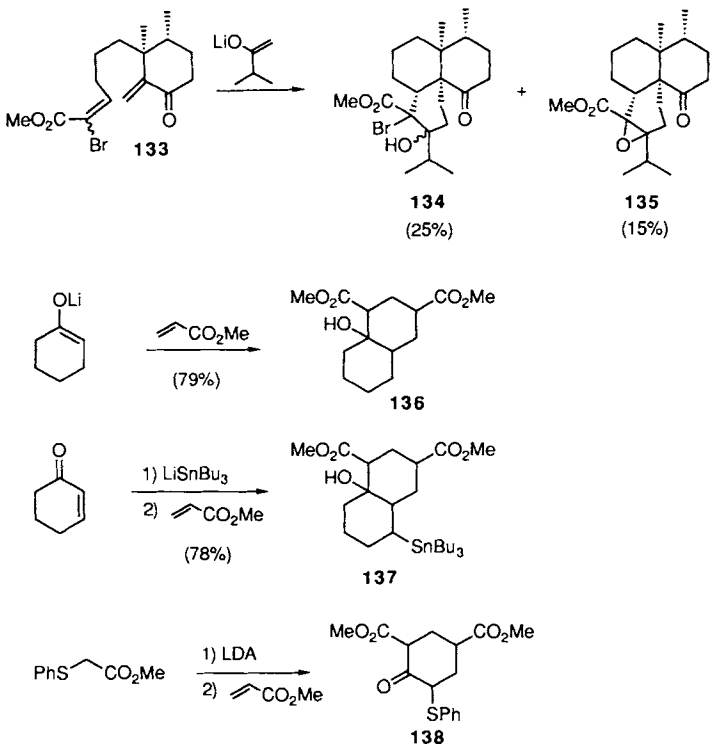

Fig. 27. Three Michael–Michael–aldol reactions (top) and one Michael–Michael–Dieckmann reaction (bottom). Two equivalents of methyl acrylate were used in each case.

Treatment of the lithium enolate from cyclohexanone with two equivalents of methyl acrylate resulted in Michael–Michael–aldol reaction to afford **136**.[97] Furthermore, the lithium enolate prepared by the treatment of 2-cyclohexenone with a trialkylstannyllithium reagent reacted with two equivalents of methyl acrylate to yield **137** (Fig. 27).[98] In contrast, when the lithium enolate of an acyclic or cyclic carboxylate ester was treated with two equivalents of methyl acrylate, a Michael–Michael–Dieckmann reaction afforded

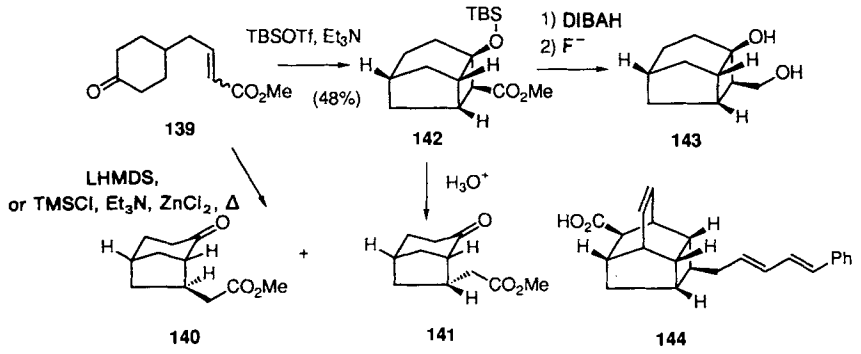

Fig. 28. Synthesis of the partial structure of endiandric acid C (**144**) by intramolecular Michael–aldol reaction.

a cyclohexanone product. In this manner **138** was synthesized in a one-pot procedure (Fig. 27).[99]

4.5. Intramolecular Tandem Michael–Aldol Reactions

A number of polycyclic natural products possessing a cyclobutane unit, for example, endiandric acid C (**144**), trihydroxydecipiadiene (**147**), and italicene (**150**), have been isolated. Although several methods are available for the synthesis of cyclobutane derivatives, [2 + 2] photocycloaddition is the most common.[100] We expected that polycyclic ring systems with cyclobutane units could be constructed by the tandem Michael–aldol reactions of α,β-unsaturated esters having a ketone function at an appropriate position.

When keto ester **139** was treated with LHMDS or TMSCl, Et_3N, and $ZnCl_2$, Michael adduct **140** was obtained as the major product together with diastereoisomer **141** (Fig. 28). In contrast, the reaction of **139** with TBSOTf in the presence of Et_3N resulted in sequential Michael–aldol reactions affording the cyclobutane derivative **142** as a single isomer. The same product **142** was obtained from both the (*E*) and (*Z*) isomers of the unsaturated ester **139**; this observation supports a stepwise mechanism. Acidic treatment of **142** gave the Michael adduct **141** as a single product. The silyl group of **142** was removed after reduction of the ester group leaving the cyclobutane ring intact to afford **143**. Thus, the partial structure of endiandric acid C (**144**)[101] was assembled by the sequential reactions.[102]

Treatment of **145** under the same conditions as above furnished the highly substituted product **146**, whose carbon framework is similar to that of trihydroxydecipiadiene (**147**) (Fig. 29).[103] Compound **149**, which has the framework of italicene (**150**),[104] was quantitatively constructed from **148** by treatment under the same reaction conditions at room temperature for 5 min. These examples demonstrate an effective route to a variety of polycyclic systems with cyclobutane units which is based on modification of the intramolecular double Michael reaction.[102] The intermolecular tandem reaction under the same reaction conditions was not successful.

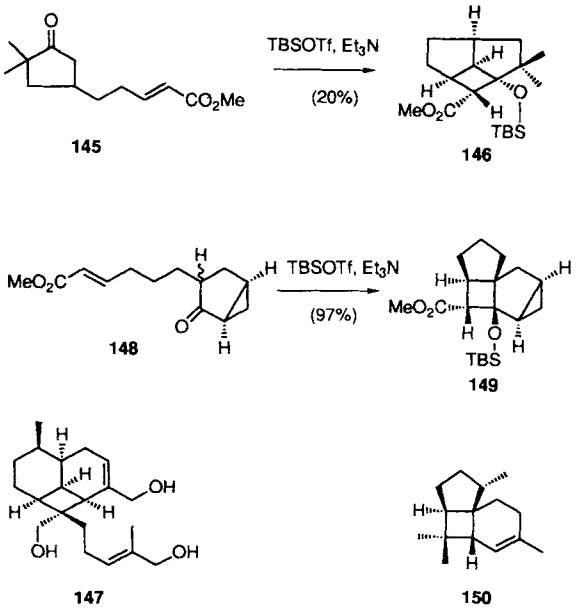

Fig. 29. Synthesis of the frameworks of trihydroxydecipiadiene (**147**) and italicene (**150**).

6. Summary and Outlook

The intramolecular double Michael reaction can be conducted under three sets of fundamentally different conditions—one basic and two acidic. Since a procedure suitable to the substrate can be selected from these, the intramolecular tandem reaction provides a versatile method for the production of polycyclic compounds. Furthermore, this reaction proceeds with complete regioselectivity and high stereoselectivity. Since many bonds are formed in one step, the method is economical. It is expected that this intramolecular sequential reaction will be further utilized as an effective approach to other target molecules.

It is a pleasure to acknowledge the fine efforts of both past and present group members, many of whose names appear in the references related to our work in the area of the intramolecular sequential reactions.

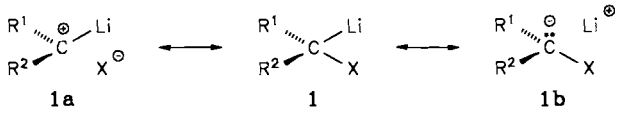
Successful X-Ray Structure Analysis of an Alkylidene Carbenoid—A Milestone in Carbenoid Research

By *Adalbert Maercker**

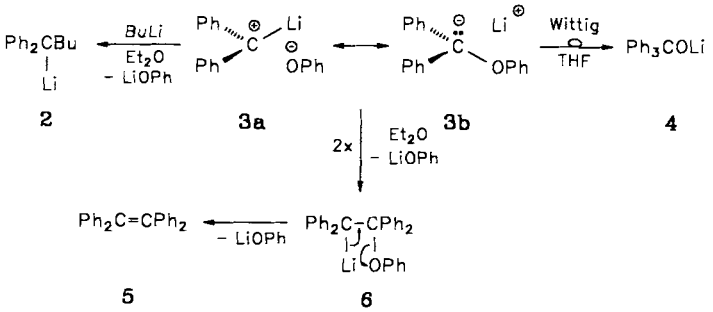
Since the pioneering work of G. Köbrich[1] (1929–1974), whose untimely death unfortunately cut short his work, the interest in carbenoids[2] has not diminished. In contrast to carbenes, the carbenoids show amphiphilic behavior, because a metal atom as well as a leaving group X is bound to a carbon atom. Halogen atoms and -OR or $-NR_2$ groups are possible X groups, but not heteroatoms of higher periods of the periodic system. If the metal is lithium the typical "carbenoid" character, that is, electrophilic properties on the one hand and nucleophilic, "carbanion-oid" properties on the other, is depicted in the two resonance forms of **1**.



1a **1** **1b**

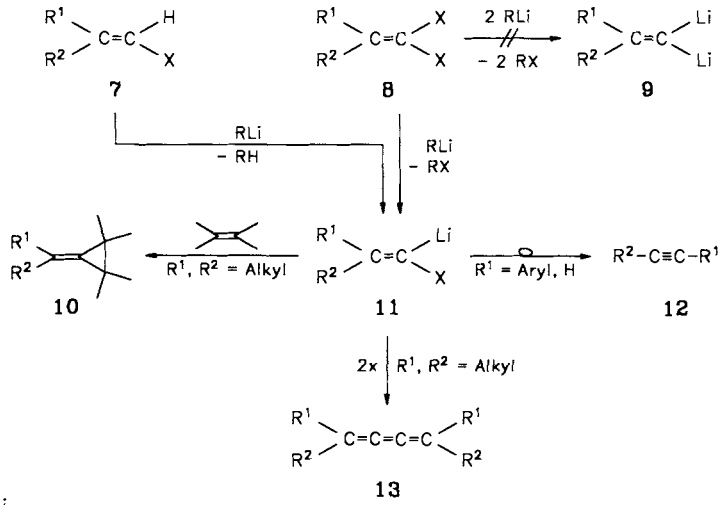
The lithiocarbenium structure **1a**, and therefore the electrophilic character of the carbenoid, is particularly pronounced only when the lithium atom is σ bound. As soon as an ion pair is present, that is, the ionic character of the C–Li bond is predominant or the negative charge is delocalized, the carbenoid properties disappear or can be observed only with strong nucleophilic partners like alkyllithium compounds. Whether a carbenoid behaves like a carbanion (**1b**) with typical nucleophilic properties depends not only on the substituents R^1 and R^2, but also on the solvent. Thus, the lithiated benzhydryl phenyl ether **3** reacts as a typical Li–OR carbenoid only in diethyl ether, for instance by dimerization to form **5** or by addition of butyllithium to form **2**. In THF, however, the classical carbanion character prevails, and the Wittig rearrangement is observed exclusively, and **4** is formed.[3]

In the dimerization to **6**, the amphiphilic nature of the carbenoid is particularly evident: one particle of **3** reacts as electrophile (**3a**) and one as nucleophile (**3b**).



2 **3a** **3b** **4** **5** **6**

The best method of determining whether the electrophilic character of a carbenoid is predominant (that is, it exists mainly as the resonance structure **1a**) is ^{13}C NMR spectroscopy. D. Seebach et al.[4] have studied a variety of typical carbenoids at low temperature and discovered that the carbenoid character (**1a**) can be recognized, amongst other factors, by the strong downfield shift of the ^{13}C NMR shift of the α-carbon atom. The extent of the shift $\Delta\delta$ is distinctly greater than that observed on replacement of a benzylic or vinylic H atom by lithium. Thus, on one hand for the metalated silyl ether analogous to **3** ($OSiMe_3$ instead of OPh),[5] the downfield shift ($\Delta\delta \approx 34.8$) is four units smaller than for the corresponding lithiated hydrocarbon, diphenylmethane ($\Delta\delta = 38.7$), which shows it to be no typical Li–OR carbenoid. On the other hand, this metalated silyl ether displays a distinctly elongated C–O bond, a finding that is likewise considered a criterion for the presence of a carbenoid. The downfield shift of the ^{13}C NMR signal of the α carbon atom should, however, be the more sensitive indicator of the existence of a carbenoid than the C–X distance, especially since according to calculations, the C–O distance for metalated ethers with carbanion character is also distinctly lengthened.[5]



7 **8** **9** **10** **11** **12** **13**

The reactions of the alkylidene carbenoids **11** in which the carbenoid C atom is part of an unsaturated π system are particularly diverse.[6] Because of the stronger C–X bond these carbenoids are more stable than aliphatic carbenoids, and their reactivity is very dependent on the groups R^1 and R^2. Alkylidene carbenoids with aryl groups in a β position can, for instance, no longer be trapped *intermolecularly*, such as by addition of an alkene to alkylidenecyclopropanes like **10** (dimerization to **13** also does not take place), because the intramolecular Fritsch–Buttenberg–Wiechell rearrangement[7] to afford **12** is substantially faster than the addition.

The same is valid for the hydride shift of β hydrogen atoms to yield 1-alkynes (**12**, $R^1 = H$).

The alkylidene carbenoids **11** can be prepared either by deprotonation of **7** or by halogen–metal exchange in **8**.[1] Interestingly, the halogen–lithium exchange is accelerated by large groups in a *cis* position,[8] whereas bulky R^1 groups hinder the deprotonation.[1] The report[9] of a double dehalogenation to form the geminal dilithio compound **9** (R^1 = Ph, R^2 = *i*PrO) was disproved.[10]

The first unambiguously characterized Li–Cl carbenoid was 1-chloro-1-lithio-2,2-diphenylethene (**11**, $R^1 = R^2$ = Ph; X = Cl); it was synthesized by G. Köbrich[1] by deprotonation of the appropriate vinyl chloride (**7**). The crystal structure (Fig. 1) of such a carbenoid containing *p*-chlorophenyl instead of phenyl substituents just published by Boche et al.[11] is without doubt a temporary peak in carbenoid research.

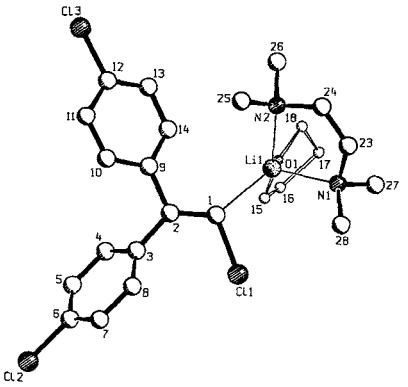

Fig. 1. Crystal structure of 1-chloro-2,2-bis(4-chlorophenyl)-1-lithioethene · TMEDA · 2THF omitting the second THF molecule that occupies a free lattice position and is not bound to Li1.

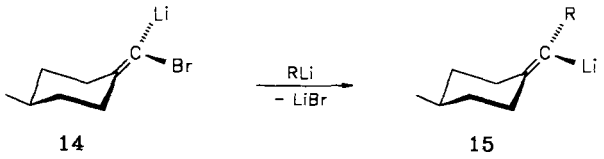
The pioneer G. Köbrich[1] predicted a rehybridization at the carbenoid carbon atom—he expected the s character of the C–Li bond and the p character of the C–X bond to increase. Exactly that has been shown in this spectacular X-ray structure analysis (at −115 °C!): The Li1-C1-C2 angle is widened from 120 to 137.1°, while the Cl1-C1-C2 angle is only 112.6°. Furthermore, the C1–Cl distance of 185.5 pm is distinctly elongated as anticipated and is about 12 pm longer than the average for C_{sp^2}–Cl bonds. This is consistent with ^{13}C NMR spectra[4] and calculations[12] on Li–halogen carbenoids. In contradiction to the calculations,[12] the lithium atom does *not* bridge the C1–Cl1 bond, presumably because of the solvation of Li1 by tetramethylethylenediamine (TMEDA) and THF.[11] Another feature of the structure is the bond angles at C2. Whereas the aryl group *cis* to Cl1 tilts away from the chlorine atom as expected (C1-C2-C3 129.5°), the *trans* aryl group bends slightly towards C1 (C1-C2-C9 = 116.5°), which seems to set up the Fritsch–Buttenberg–Wiechell rearrangement.[7] The finding that this aryl group is twisted less out of the olefinic plane (39°) than the group *cis* to the Cl atom (57°) is puzzling, as this should affect the overlap of the aromatic π system with the σ* orbital of the rupturing C1–Cl bond unfavorably. The stated cause and effect of the rehydridization at C2[11] could therefore possibly be exchanged—the steric interaction between the large chlorine atom and the aryl group *cis* to it could be the reason for the rehybridization.

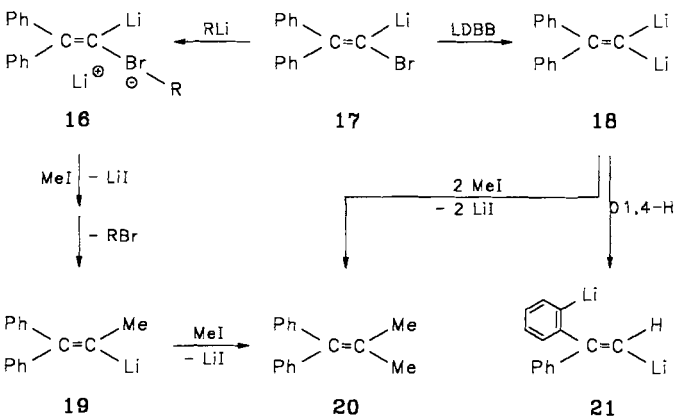
In this regard the reactivity of the alkylidene carbenoids towards alkyllithium compounds, which in turn depends strongly on the substituents R^1 and R^2, is interesting. Carbenoids bearing aliphatic substituents react particularly easily,[13] by metal-assisted nucleophilic substitution of the halogen atom (for instance **14** → **15**) accompanied by inversion.[14]



14 **15**

An analogous reaction with alkylidene carbenoids bearing aryl substituents has not yet been observed, even on treatment with *tert*-butyllithium.[10] Instead in this reaction a complex forms that possibly exists in the structure **16** and that in analogy to similar complexes[15] may be considered a Quasi Dianion Complex (QUADAC), especially because with electrophiles it leads to the same products—though in a stepwise mechanism—as the geminal dilithio compound **18**.[10]

1,1-Dilithio-2,2-diphenylethene (**18**) may be prepared from carbenoid **17** in a reaction with lithium-4,4'-di-*tert*-butylbiphenyl (LDBB),[16] a method that has already been used successfully for the synthesis of aliphatic, geminal dilithio compounds.[17] In contrast to the behavior of the QUADAC **16**, **18** rearranges at −70 °C to **21** through an *intra*molecular 1,4-proton shift.[10]



16 **17** **18**

19 **20** **21**

Li–OR carbenoids, and particularly Li–NR_2 carbenoids, have scarcely been studied. The future priority will probably also be the structure and reactivity of these compounds.

"Noncoordinating" Anions, II**

By *Konrad Seppelt**

The existence of an anion that has no capacity for coordination in the condensed phase is as impossible as that of a free proton or a naked fluoride ion. However, in the same way that it is possible in the two latter cases to achieve approximate states in which the chemical environment can be neglected, increasingly weaker coordinating anions can also be obtained.[1] This is a worthwhile goal: many compounds with elements with unusual bonding such as R_3Si^+, Fe(porphyrin)$^+$, and many kinds of coordinatively unsaturated metal ions could be prepared. Since cationic alkyl complexes of group 4 metals (Ti, Zr, Hf) function as single-component catalysts for olefin polymerization, these systems are also of great commercial interest.[2]

Each anion in solution competes with the solvent for coordination to the cation. Thus, an anion can, in certain systems, be classed as noncoordinating when it shows a weaker coordination than the solvent. However, the limiting cases of completely nonpolar solvents such as alkanes, perfluorinated alkanes, and even xenon show that we are still a long way from noncoordinating anions in these solvents. Furthermore, as long ago as 1975 complexes of the type $[M(CO)_5Xe]$ (M = Cr, Mo, W) with a dative Xe → M bond were detected.[3]

It is apparent that for a weakly coordinating anion the negative charge—apart from some special cases only singly charged anions are considered—should be distributed over a great number of ligand atoms. In addition, the peripheral atoms should be fluorine or hydrogen atoms, and not oxygen or chlorine atoms, which coordinate more strongly. The solubility of the salts containing weakly coordinating anions in nonpolar solvents is also an important prerequisite.

Telefax: Int. code + (30)838-2424

[**] First "highlight" on this topic see ref. [1a]

A further prerequisite is the kinetic stability towards ligand abstraction: the moderately strong coordinating anions such as BF_4^-, PF_6^-, and SbF_6^- are unstable towards electrophilic attack and lose F^-. Finally, the anions should be stable towards oxidative attack. This precludes, for example, the C_{60}^- anion from further consideration, especially when its ability to coordinate to metals through the six-membered ring-six-membered ring double bonds is taken into account.

$B(C_6H_5)_4^-$ and related anions: Tetraarylborates as ligands were only recently the subject of a highlight,[1a] and so we can limit ourselves here to a short addition.

In the series $ClO_4^- > BF_4^- > PF_6^- > B(C_6H_5)_4^-$, the ability to coordinate decreases. The aromatic ring system of the phenyl groups remains as a coordination site of the $B(C_6H_5)_4^-$ ion, and this ring system is mainly coordinated in an η^6 fashion to metal atoms. Coordination through the C–H bonds of the phenyl rings has, however, not yet been observed. The strength of the π interaction of a phenyl ring of $B(C_6H_5)_4^-$ with metals is similar to that of a neutral benzene ligand, if the metal–C bond lengths are regarded as a standard.[4] Since C_6F_6 is a far worse complex ligand than C_6H_6, $B(C_6F_5)_4^-$ or substituted and partially fluorinated tetraphenylborates have also been used. Salts of these anions are particularly soluble,[5] and so far no π-phenyl–metal interaction has been proven. A typical example is $[Zr\text{-}Cp_2^*R]^+[B(C_6F_5)_4]^-$ (R = alkyl, Cp* = η^5-C_5Me_5), which is stable towards aryl group transfer.[6] A recent example that shows the differing coordination abilities of phenyl and pentafluorophenyl groups is the ionic complex **1**.[7] The crystal structure analysis of **1** shows that only the benzyl group

$[Zr(CH_2C_6H_5)_3]^+[B(CH_2C_6H_5)(C_6F_5)_3]^-$ **1**

and not the C_6F_5 group functions as a η^6 ligand. The zirconium atom is bound to two benzyl ligands η^1, one η^2, and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1993 0570-0833/93/0707-1025 $ 10.00+.25/0

one η^6. Nevertheless, the preparation of triorgano-substituted silyl cations R_3Si^+ is not achieved with the $[B\{C_6H_3\text{-}3,5\text{-}(CF_3)_2\}_4]^-$ anion, because cations of the type $R_2(CH_3)SiOR'^+_2$ ($R = CH_3$, C_6H_5, C_4H_3S; $R' = C_2H_5$) are formed by addition of the ether solvent.[8] The current state of the debate regarding the existence or nonexistence of silyl cations has recently been summarized.[9] The substitution of the dimeric catecholate anion in $[Cp^*_2SiH]^+[C_6H_4O_2H_3O_2C_6H_4]^-$ by an extremely noncoordinating anion may help to obtain the postulated silyl cation[10] in crystalline form.

$CB_{11}H^-_{12}$: Starting from the BH^-_4 anion, which coordinates in many ways, one can proceed mentally by enlargement of this anion to polyhedral boranes and carboranes, of which the $CB_{11}H^-_{12}$ is weakly coordinating. The most hydridic hydrogen substituent H(12), that is the one opposite the C atom, forms metal$\cdots$H–B bridges,[11] as in $[FeCp(CO)_2]^+[HB_{11}CH_{11}]^-$. The ionic iron porphyrin complex **2**

$[Fe(tpp)]^+[CB_{11}H_{12}]^-$ **2**

(tpp = tetraphenylporphyrin) shows the hitherto weakest interaction between an iron porphyrin cation and any anion, the shortest Fe–N distances, and the smallest shift of the iron atom from the porphyrin plane[12, 13] (Fig. 1). Thus, one is already very close to a square planar surrounded Fe^{3+} ion in $Fe(tpp)^+$.

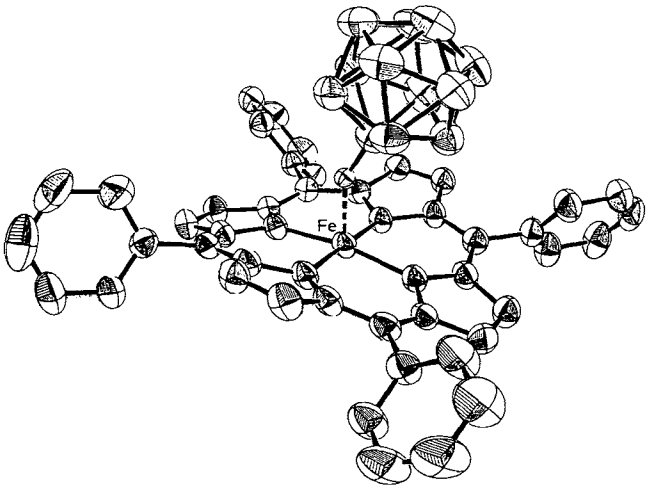

Fig. 1. Crystal structure of **2** [10]. The Fe–H distance is 182(4) pm.

$Nb(OTeF_5)^-_6$ and related anions: If the F^- anion is mentally enlarged to the $OTeF^-_5$ anion, the ability to coordinate is lost to a large degree, whereas the ability to stabilize high oxidation states ($\approx$electronegativity) is retained to a great extent.[14] $OTeF^-_5$ shows a coordinating effect through the oxygen atom. This is the reason why it is inferior to the isoelectronic SbF^-_6 ion and its homologues. Nevertheless, $Ag^+OTeF^-_5$, for example, is very soluble in CH_2Cl_2, in contrast to $Ag^+SbF^-_6$ and $Ag^+BF^-_4$.[15] Since, the $OTeF_5$ group has only one strong donor atom, the metal complexes remain coordinatively unsaturated. $Ag^+OTeF^-_5$ coordinates to, among other weak ligands, CH_2Cl_2 and carbon monoxide![16]

To further enhance these remarkable properties, complex anions of the type $A(OTeF_5)^{m-}_n$ with $m = 1$, 2, and $n = 4$, 6 were constructed. A can be varied in many ways, and the anions are prepared readily by metathesis reactions. $B(OTeF_5)^-_4$ is clearly unstable and readily loses an $OTeF^-_5$ group; however, with its help a dicarbonyl silver complex, the cation of **3**, was prepared for the first time. The spectro-

$[Ag(CO)_2]^+[B(OTeF_5)_4]^-$ **3**

scopic and structural investigation of this complex confirmed the principal weakness of the Ag–CO bond (Fig. 2).

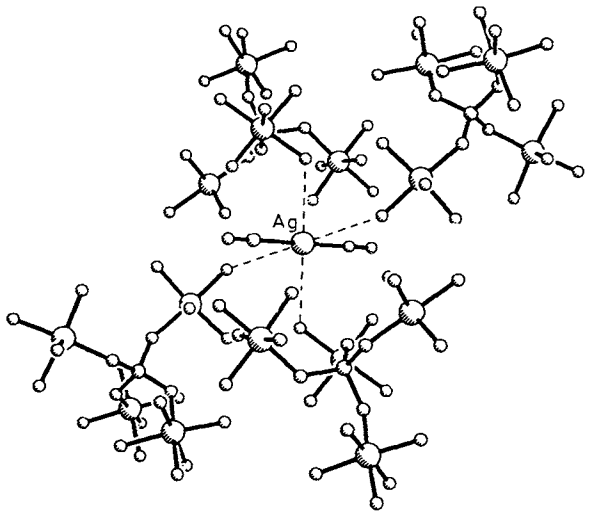

Fig. 2. The coordination sphere of the silver atom in **3** [17]. The Ag$\cdots$F distances to the nearest F atoms of the $OTeF_5$ group are 296(1) and 309(2) pm. Only the weakness of this coordination enables the existence of the carbonyl complexes.

Here, the principle can be explained: the hitherto unknown $[Ag(CO)_2]^+$ cation is formed, despite the weakness of the Ag–CO bond, because the coordination of Ag^+ by the anion is even weaker.[17] $Ti(OTeF_5)^{2-}_6$ and $Nb(OTeF_5)^-_6$ are known,[18, 19] and are particularly weakly coordinating anions.[20] They are extremely stable towards oxidation, towards the loss of a $OTeF^-_5$ group ($^{18}OTeF^-_5$ is not incorporated in $Nb(OTeF_5)^-_6$ in the presence of Ag^+), and like all anions that contain $OTeF^-_5$, these large anions are very stable towards loss of F^-.

$Ag^+_2Ti(OTeF_6)^{2-}_6$ is highly soluble in $C_2Cl_3F_3$ and CH_2Cl_2, and in the latter solvent it is so soluble that the quantitative determination of the solubility is difficult. It crystallizes as $[Ag^+(CH_2Cl_2)_3]_2Ti(OTeF_5)^{2-}_6$ with only two very weak Te–F$\cdots$Ag contacts, each of which is over 300 pm in length.[20] A great deal will probably be heard in the future about compounds with $Ti(OTeF_5)^{2-}_6$ and $Nb(OTeF_5)^-_6$ anions.

Outlook: Many other weakly coordinating anions have been investigated,[1b] for example heteropolyanions such as $PW_{12}O^{3-}_{40}$. So far, however, each of the given systems has its weaknesses. The use of fluorine in the outer sphere of ideally, large spherical anions is sufficient for solvents such as CH_2Cl_2 and chlorofluoro hydrocarbons. In hydrocarbons the weak ability of the fluorine atoms to coordinate will

probably be noticeable, and finally all fluoro compounds are thermodynamically unstable towards Lewis acids such as Fe^{3+}. Thus, the ideal noncoordinating anion should have a spherical hydrocarbon surface and carry the negative charge in the interior; here again a certain oxidation sensitivity will also play a role.

That the preparation of weakly coordinating anions has achieved unexpected significance is exemplified by the fact that the lithium salt of $HC(SO_2CF_3)_3$[21] is used in rechargeable lithium batteries, because it is particularly soluble in ethers and has a high ionic conductivity, and is extremely stable to oxidation.[22] This development could revolutionize present battery technology.

Biologically Active Linear Metabolites of Arachidonic Acid—The First Endogenous Ligand of the Cannabinoid Receptor

By *Wolf D. Lehmann** and *Gerhard Fürstenberger*

The cell membrane is an important site for storage of multiply unsaturated fatty acids. There, these particularly sensitive fatty acids are protected from radical-induced autoxidation by membrane antioxidants such as vitamin E. In addition, membrane fatty acids are esterified and therefore cannot be attacked by cellular enzymes such as lipoxygenases and prostaglandin H synthases, which preferentially accept free fatty acids as substrates. The most abundant multiply unsaturated fatty acids in nonmarine mammals are linoleic acid (9,12-octadecadienoic acid) and arachidonic acid (5,8,11,14-eicosatetraenoic acid) with two and four nonconjugated *cis* double bonds, respectively. As an example, the arachidonyl group is the preferred substituent at the C2 position of glycerol in phosphatidylcholine, an important membrane phospholipid. In unstimulated cells, cytosolic arachidonic acid occurs at a concentration on the order of 0.1 μM, a concentration below the typical K_m values of the main arachidonic acid metabolizing enzymes. Therefore, the release of arachidonic acid from the membrane pool of esterifed fatty acids by activation of phospholipase A_2, C, or D alone or in combination with diacylglycerol lipase or kinase is a key event in the regulation of all metabolic pathways of arachidonic acid. The pathways of archidonic acid release are displayed in the upper half of Figure 1.

Released free arachidonic acid is either reesterified or effectively metabolized into biologically active metabolites. *Cyclic metabolites* (prostaglandins, prostacyclines, thromboxanes) are generated by attack from a prostaglandin H synthase. The structure and function of these metabolites have been extensively studied since the early 1960s. Interest in the linear metabolic pathway of arachidonic acid was initiated by the discovery of mammalian lipoxygenases and their *linear metabolites* (HETEs, diHETEs, lipoxins, leukotrienes A_4 and B_4) as well as their *linear-branched metabolites* (cysteinyl leukotrienes). Since the early 1970s this area of arachidonic acid metabolism has been extensively investigated.[1] Linear metabolites may also be formed by attack of cytochrome P450 monooxygenase.

So far linear metabolites of arachidonic acid have been predominantly found in cells of the hematopoietic system and of the immune system. Recently, a new linear metabolite of arachidonic acid was isolated from brain and identified as an endogenous ligand of the cannabinoid receptor.[2] We will discuss this work here and describe some new linear metabolites of arachidonic acid with distinct biological activity. These arachidonic acid metabolites and the routes of their formation are given in the lower part of Figure 1.

Chemotaxis by 20-hydroxyleukotriene B_4: Leukotriene B_4 (LTB_4), (5*S*,12*R*)-dihydroxy-(6*Z*,8*E*,10*E*,14*Z*)-eicosatetraenoic acid, is strongly chemotactic for polymorphonuclear leukocytes (neutrophils), the typical defense cells of the immune system. The liver is the main catabolic site for

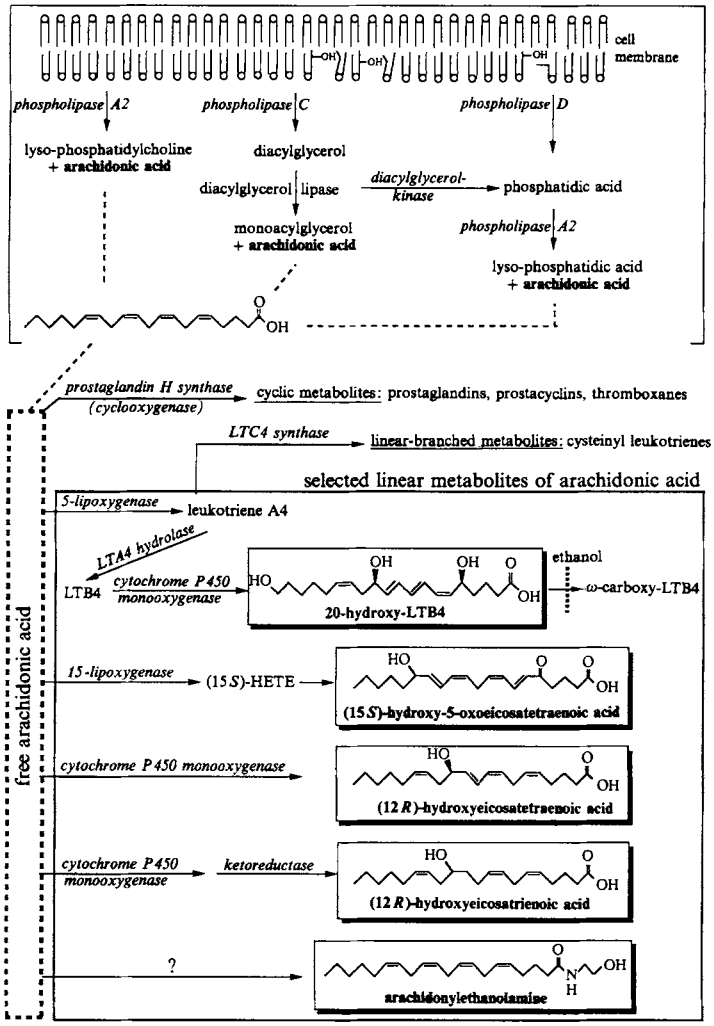

Fig. 1. Formation of free arachidonic acid from the membrane pool of esterified fatty acids and the metabolic pathways leading to the linear arachidonic acid metabolites discussed.

leukotrienes produced systemically, including leukotriene B_4. These are rapidly taken up by liver cells and catabolized by peroxisomal β-oxidation from the ω end. A characteristic feature of fibrotic and cirrhotic liver degeneration is the infiltration of leukocytes, and it is assumed that production of neutrophil-chemotactic metabolites by the liver promotes liver degeneration. One approach to understanding the role of ethanol in this complex pathogenesis is by investigation of the pathways of arachidonic acid metabolism in hepatocytes in vitro with and without the presence of ethanol. By using this approach it was recently shown that ethanol blocks the microsomal β-oxidation of LTB_4 from the ω end at the stage of ω-hydroxy-LTB_4.[3, 4] This intermediate in LTB_4 catabolism is observed only in the presence of ethanol and is an LTB_4 metabolite in which the chemotactic activity is retained. In the absence of ethanol, LTB_4 is rapidly metabolized to ω-carboxy-LTB_4, a chemotactically inactive metabolite. Another biological effect of ethanol that has been observed in the rat is the enhanced synthesis of LTB_4 in the mucus membranes of stomach and colon. Therefore, one factor in the pathogenetic mechanism of acute ethanol-induced hepatitis might be the enhanced systemic production of LTB_4 in combination with the blockage of the peroxisomal inactivation of LTB_4 in the liver.

Chemotaxis by 15-hydroxy-5-oxoeicosatetraenoic acid: A new metabolite with a pronounced chemotactic effect specific for eosinophils was observed following incubation of human peripheral eosinophils with arachidonic acid.[5] This lipid metabolite was identified as 15-hydroxy-5-oxo-6,8,11,13-eicosatetraenoic acid.[6] Moreover, this metabolite could be generated in vitro by incubation of arachidonic acid with soya lipoxygenase (a lipoxygenase with (15*S*)-specificity) in the presence of the heme protein cytochrome c. These investigations showed that in the presence of arachidonic acid, eosinophils can produce a self-specific chemotactic factor.

Chemotaxis and angiogenesis by (12R)-hydroxyeicosatetraenoic acid: By incubating bovine cornea microsomes with arachidonic acid, two new biologically active arachidonic acid metabolites were found.[7] Both metabolites are formed by a cytochrome P450 catalyzed reaction, as was shown by the use of specific inhibitors and by the observation that the formation of these metabolites was NADPH-dependent. The minor metabolite was identified as (12*R*)-hydroxy-(5*Z*,8*Z*,14*Z*)-eicosatrienoic acid [(12*R*)-HETrE].[8] Insight into the mechanism of formation of this metabolite was obtained by using deuterium-labeled arachidonic acid as substrate. Based on these experiments it was proposed that (12*R*)-HETrE is formed via a 12-oxo intermediate which is stereospecifically reduced to the (12*R*)-hydroxy metabolite by a ketoreductase. (12*R*)- and 12(*S*)-HETErE were prepared synthetically and their biological activity was tested separately in vivo in the rabbit eye.[8, 9] Application of 10 ng of the (12*R*) enantiomer caused a strong increase in the protein concentration of the aqueous humor indicating an impairment of the blood–aqueous barrier. Application of the same amount of the (12*S*) enantiomer had no effect. Additional biological effects in the rabbit eye exclusively observed for the physiologic (12*R*) enantiomer and not for the (12*S*) enantiomer were local vasodilation, leukocyte-specific chemotaxis, and angiogenesis (formation of new blood vessels). With a much higher dose of (12*S*)-HETrE, similar in vivo effects could be elicited, but it was suspected that this was actually caused by the contamination of 1–2% (*R*) enantiomer in the applied (12*S*)-HETrE. The effects observed after the application of small amounts of (12*R*)-HETrE are typical for the events observed following injury of the corneal epithelium. Therefore, these investigations support the hypothesis that (12*R*)-HETrE may be a physiologically important mediator of these processes.

Inhibition of an ion transport system by (12R)-hydroxyeicosatetraenoic acid: The main metabolite observed after incubation of corneal microsomes with arachidonic acid was identified as 12-hydroxyeicosatetraenoic acid (12-HETE). In the investigation of the biological effects of this metabolite, a pronounced inhibitory effect on bovine corneal (Na^+/K^+)ATPase was found. This ion transport system is widely distributed in cells and is responsible for maintaining the sodium and potassium concentration gradient across the cell membrane and for the transport of chloride ions out of the cell. These processes are directly connected with the formation of the membrane potential. (Na^+/K^+)ATPase in corneal epithelium probably has additional specialized func-

tions in maintaining transparency. Comparison of the inhibitory potency of the isolated metabolite with pure (12*R*)- and (12*S*)-HETE of synthetic origin showed that only the (12*R*) enantiomer was active. On this basis, the isolated metabolite was identified as (12*R*)-HETE. The inhibitory potency of (12*R*)-HETE towards (Na^+/K^+)ATPase was observed in various other rat and bovine tissues besides corneal epithelium.[10] Thus, (12*R*)-HETE might be a physiological inhibitor of this important ion transport system.

Arachidonylethanolamine as endogenous ligand of the cannabinoid receptor: It is known that fatty acid amides are present in brain tissue. Recently, an amide of arachidonic acid—arachidonylethanolamine—was isolated from porcine brain as the first natural ligand of the cannabinoid receptor.[2] A large number of chromatographically purified fractions obtained from porcine brain were incubated with rat brain synaptosomes, in which the cannabinoid receptor was loaded with a tritium-labeled cannabinol derivative of very high affinity (HU-243, K_D: 45 pM). The ability of the purified brain fractions to replace the specific tritium-labeled ligand at the cannabinoid receptor of the synaptosomes was tested, and it was observed that many lipophilic fractions could liberate the ligand partially by a nonspecific "emulgatory effect". Nevertheless, a compound with a specific affinity towards the cannabinoid receptor was also identified in this way. From 4.5 kg of porcine brain, 600 μg of this compound was isolated and subsequently identified as arachidonylethanolamine by using spectroscopic methods.[2] In addition, the isolated compound was found to be identical to arachidonylethanolamine of synthetic origin. The amino acid sequence of the rat[11] and human[12] cannabinoid receptor is known, and with this study the first endogenous ligand of the cannabinoid receptor could be identified. More than 20 other arachidonic acid metabolites have been tested for specific binding to the cannabinoid receptor, but all have yielded negative results up to now. The cannabinoid receptor plays a key role in the control of important biological functions such as the control of movement, nociception (the perception of pain), and emotional disposition.

The analytical and functional studies on linear arachidonic acid metabolites as described above highlight the important biological role of these fatty acid metabolites in spite of their relatively simple structural characteristics. Among these functions appear to be the regulation of elementary biological processes such as the immune response, the maintainance of membrane potential, and receptor-mediated signal transduction.

Concerning "An Evaluation of the Peer Review Process at *Angewandte Chemie*"

By *Paul F. Ross**

Research leading to improved practices in peer review in the sciences is badly needed. Daniel's work ("An evaluation of the peer review process at *Angewandte Chemie*"[1]) can contribute to understanding influences on decisions. My work[2] and the demonstration by Peters and Ceci[3] showing that current practices are seriously deficient are a decade old; yet few studies have been stimulated by our work. Daniel's work and *Angewandte Chemie*'s willingness to be examined are welcome.

Daniel's work addresses the validity, reliability, and biases of decisions and follows up on rejected work using a single sample of manuscripts, an approach essential to understanding outcomes of decisions by reviewers and editors. However, as presented, Daniel's work ascribes to scientific value outcomes that are actually caused by circumstances unrelated to scientific content. 1) Daniel's work assumes works published in German only have the same opportunity to be cited as works published in both German and English. That is like expecting the same monthly sales total for a $ 200 fashion item available only in Berlin and an equally fashionable $ 200 item available in both Berlin and New York. 2) Daniel's work assumes that the visibility of the journal in which an item appears has no influence on whether the item is cited. No executive deciding where to publish an advertisement would accept that premise. 3) Daniel's work assumes that the author's reputation, and the reputation of the author's employer, have no effect on the editor's decision to publish and 4) no effect on the citing author's decision to cite. Research shows otherwise (e.g., Peters and Ceci[3]). 5) Daniel's work counts citations for items published in *Angewandte Chemie* over a somewhat longer time period than for items rejected by *Angewandte Chemie* and published elsewhere, exaggerating the observed differences (see Daniel's Figure 1). Daniel's data need to be reexamined, controlling for these and other influences using the statistical method of factor analysis.

For these reasons, I strongly suspect Daniel's conclusion that the 1984 editorial decisions at *Angewandte Chemie* accepted for publication the manuscripts of highest value to scientists from among those it received is an incorrect conclusion.

Reply:

By *Hans-Dieter Daniel**

In his letter to the editor of *Angewandte Chemie* Ross[1] argues that my work[2] on the peer review process fails to control for the language in which the work was published, the visibility of the journal, the author's reputation, and the reputation of the author's employer, and that citations were not counted for equal-length post-publication periods for accepted and rejected-and-published-elsewhere communications.

To start with his last point: the analyses of covariance carried out to test for publication bias and validity of editorial decisions of course took into account the delay period from time of rejection by *Angewandte Chemie* to publication in another journal. The mean citation rates for accepted and rejected-but-published-elsewhere communications were compared, with number of months since publication of the manuscript held constant. It was not necessary to test for bias related to language in which the work was published, since very few of the rejected manuscripts subsequently published elsewhere appeared in German (cf. Table 4 in [2]). Prestige ratings of scientists, departments, and universities are very popular, and are published regularly in the United States. Unfortunately, there has been so far no analogous prestige rankings for most of the 21 different countries from which *Angewandte Chemie* received manuscripts during 1984. Therefore, it is not possible to test for bias related to prestige of author or employer. Moreover, how should one test the provocative thesis that the same paper published in *Angewandte Chemie* and in another journal will be cited more times from *Angewandte Chemie* than from the other journal?

To control for bias variables, Ross proposes a factor analysis with dummy variables. Factor analysis, however, as-

[*] Priv.-Doz. Dr. H.-D. Daniel
Das Rektorat der Universität
Postfach 103462, D-68131 Mannheim (FRG)

sumes interval levels of measurement. A factor analysis with mutually exclusive (i.e., orthogonal) dummy variables [e.g., paper about organometallic chemistry (1) or not (0), paper about physical organic chemistry (1) or not (0), etc.] does not make sense at all. Furthermore, it is unreasonable to expect that factor analysis will produce from a set of data unambiguous, self-evident insights into the validity of referees' recommendations or editor's decision. Factor analysis, in practice, remains highly subjective, as do several other multivariate data analysis techniques.

To provide the reader with more insight into the nature of the data upon which my conclusions on the reliability, fairness, and validity of the peer review process are based, a more detailed version of my study[3] will contain synoptic presentations of four sets of (anonymous) reviewer comments and recommendations, together with the corresponding observations of the editor. The four sets of data are derived from manuscripts differentiated as follows: accepted communications that were later subject to frequent citation, accepted communications that did not lead to citations, rejected communications published elsewhere and then cited relatively frequently, and rejected communications published elsewhere but not subject to citation. These synopses should lead to a clearer picture of the typical reactions of referees and editors.

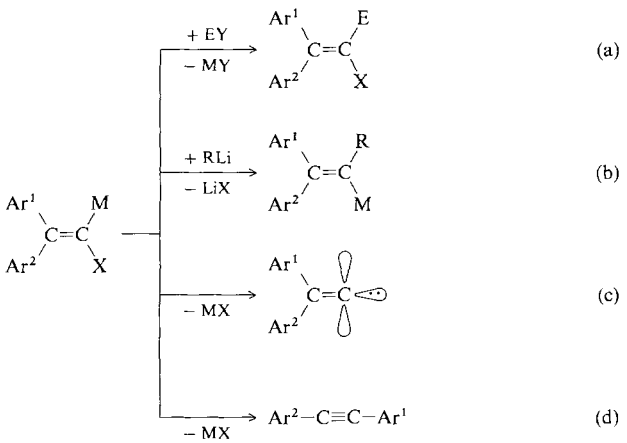
1-Chloro-2,2-bis(4-chlorophenyl)-1-lithioethene·TMEDA·2THF: Structure of a Li-Cl Carbenoid**

By *Gernot Boche,* Michael Marsch, Achim Müller,* and *Klaus Harms*

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

Carbenoids are exceptional compounds, because they react not only with electrophiles E–Y, as is usual for "anions", but also with nucleophiles such as RLi, eliminate M–X with the formation of carbenes, and—as in the present case of an aryl-substituted alkylidenecarbenoid—undergo the Fritsch–Buttenberg–Wiechell rearrangement to form alkynes (Scheme 1).[1]



Scheme 1. Reactions of aryl-substituted alkylidene carbenoids: a) reaction with electrophiles EY, b) reaction with nucleophiles RLi, c) α-elimination of MX, d) Fritsch–Buttenberg–Wiechell rearrangement. M = Li, Na, K, MgX; X = F, Cl, Br, I; Y = leaving group; Ar = aryl residue.

What are the structural prerequisites for reactions (b)–(d) in particular? Since carbenoids are thermally labile above about −60 °C, these compounds were previously studied mainly at low temperature by ^{13}C NMR spectroscopy (D. Seebach et al.[2]), or their structure was calculated (P. von R. Schleyer et al.[3]). We crystallized 1-chloro-2,2-bis(4-chlorophenyl)-1-lithioethene (**1**) in the presence of tetrahydrofuran (THF) and tetramethylethylenediamine (TMEDA) at −78 °C as **1**·TMEDA·2THF and determined its crystal structure at −115 °C. It is the first of the lithium halogen carbenoids[4] (Fig. 1).

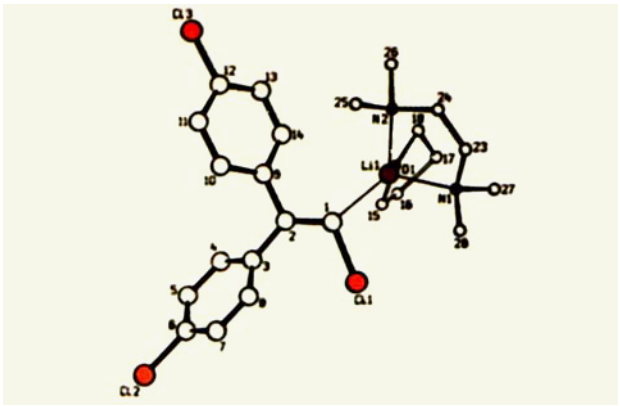


Fig. 1. Crystal structure of **1**·TMEDA·2THF without the second THF molecule, which is situated on a free lattice position and is not bound to the Li1 atom [5]. The carbon atoms are indicated by numbers only. Selected bond lengths [pm] and angles [°]: C1-Cl1 185.5(7), C1-Li1 214.5(14), C1-C2 134.4(10), Li1-O1 196.5(14), Li1-N1 213(2), Li1-N2 215.8(15); Cl1-C1-C2 112.6(5); Li1-C1-C2 137.1(6), Li1-C1-Cl1 108.7(5), C1-C2-C3 129.5(6), C1-C2-C9 116.5(6), C3-C2-C9 114.0(6); Cl1-C1-C2-C3 3(1), Cl1-C1-C2-C9 −175.7(5), C1-C2-C3-C8 57(1), C1-C2-C9-C14 39(1).

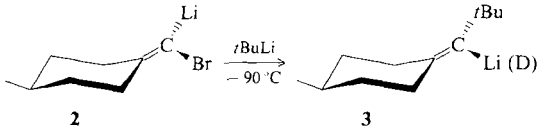
At first the distinctly extended C1–Cl1 bond in **1** (12 pm longer than that in the nonlithiated vinyl chlorides) is conspicuous: whereas the mean of 63 vinylic C_{sp^2}–Cl bond lengths lies at 172.9 pm,[9] the C1–Cl1 bond is 185.5(7) pm long. This bond lengthening distinguishes carbenoids from normal acceptor-substituted Li compounds in which the bond of the anionic C atom to the acceptor substituents (e.g., C(O)R, CN, SO_2R, SOR, SR, etc.) is always shortened.[10, 11] However, the elongation is consistent with the conclusions from ^{13}C NMR spectra of LiX carbenoids (X = halogen),[2] calculations on LiX or LiOR carbenoids,[3, 4] and crystal structure data of LiOR carbenoids.[4] The extended C1–Cl1 bond in **1**·TMEDA·2THF[12] is also consistent with the strikingly easy (−90 °C!) nucleophilic substitution of the alkylidenecarbenoid **2** by *tert*-butyllithium that yields **3** (Scheme 2), or after treatment of **3** with CH_3OD the corresponding deuterated compound (H. M. Walborsky et al.).[13]

Also remarkable are the bond angles at C1 and C2 of **1**·TMEDA·2THF. At the carbenoid C1 atom the Cl1-C1-C2 angle of 112.6(5)° is smaller than the 120° angle of a



2 **3**

Scheme 2. Stereochemistry of the reaction of the carbenoid **2** with *t*BuLi in Et_2O or THF. If **3** is treated with CH_3OD, the Li atom is exchanged for a deuterium atom (D).

sp^2-hybridized C atom, while the Li1-C1-C2 angle of 137.1(6)° is much larger. This finding is consistent with an α elimination of LiCl from **1**·TMEDA·2THF to form the corresponding singlet vinylidene,[14] in which the C1-Cl1 bond develops into the empty p orbital and the C1–Li1 bond into the sp orbital filled with two electrons on the carbene C1 atom (see Scheme 1, reaction (c)). The bond angles at C1 also explain the inversion[13] observed for the reaction **2** → **3**: as in **1**·TMEDA·2THF, the side opposite to the leaving group Br^- in the carbenoid **2** should be particularly accessible for the nucleophile *t*BuLi.

For the Fritsch–Buttenberg–Wiechell rearrangement in which it is always the aryl group *trans* to the leaving group X that migrates[15] (see Scheme 1, reaction (d)), the bond angles at the C2 atom are also significant. The chloro-substituted phenyl ring *trans* to the chlorine atom bends slightly towards the C1 atom to which this phenyl ring binds after LiCl elimination (C1–C2–C9 116.5(6)°), while the *cis* Cl-substituted phenyl ring tilts away from the C1 atom (C1–C2–C3 129.5(6)°).

According to calculations the most stable structure of a *nonsolvated* carbenoid is that in which the C–X bond is bridged by the Li atom.[3] This is in accord with formulations that propose easier rupture for the C–X bond when the Li atom assists by "pulling" at X.[1b, 13] As Figure 1 shows, the C1–Cl1 bond in **1**·TMEDA·2THF is, however, not bridged by the Li atom (Cl1–Li1 325.4(9) pm), probably because the Li1 atom is solvated by TMEDA and THF, which agrees with the long-known fact that carbenoids are more stable in THF than in diethyl ether. This stability is attributed to the better solvation of lithium by THF (G. Köbrich[1b]).

Experimental Procedure

1-Chloro-2,2-bis(4-chlorophenyl)ethene (150 mg, 0.53 mmol) was dissolved in a mixture of THF (1.65 mL), diethyl ether (1.1 mL), and *n*-hexane (0.55 mL) to which TMEDA (157 mg, 1.35 mmol) had been added. After cooling to −78 °C, deprotonation with *n*BuLi (0.36 mL, 0.58 mmol) in *n*-hexane ($c = 1.6$ mol L^{-1}) within 30 min with constant shaking formed an orange solution, from which after 10 days at −78 °C colorless crystals suitable for X-ray crystal analysis precipitated. Yield: 113 mg, 39%. The single crystal was mounted on a glass fiber with silicon grease in a stream of cold nitrogen (−90 °C), according to the method of M. Veith and H. Bärninghausen [16b] modified by E. Hahn [16a].

Formation of Molecular Strands by Hydrogen Bonds at the Gas–Water Interface: Molecular Recognition and Quantitative Hydrolysis of Barbituric Acid Lipids

By *Ramesh Ahuja, Pier-Lorenzo Caruso, Dietmar Möbius,* Wolfgang Paulus, Helmut Ringsdorf,** and *Gerald Wildburg*

Molecular recognition and organization are required for almost all processes at the cell membrane. Besides ionic and dipole–dipole interactions and steric effects, hydrogen bond formation plays a decisive role in molecular recognition and organization. In numerous studies these specific interactions have been examined in model systems, for example, with nucleolipids,[1], diaminotriazine lipids,[2] Kemp's acid,[3]

guanidinium lipids,[4] and amphiphilic azacrown compounds.[5] We report here on a model system, which in aqueous media forms molecular strands analogous to those described by Lehn et al.[6a] and Whitesides et al.[6b] in organic solvents by the formation of intermolecular hydrogen bonds. This model system undergoes a recognition- and orientation-induced reaction at the gas–water interface based on the formation of complementary hydrogen bonds between the barbituric acid lipids **1** and **2** and substrates like 2,4,6-triaminopyrimidine (TAP), melamine, and urea, as shown in Figure 1.

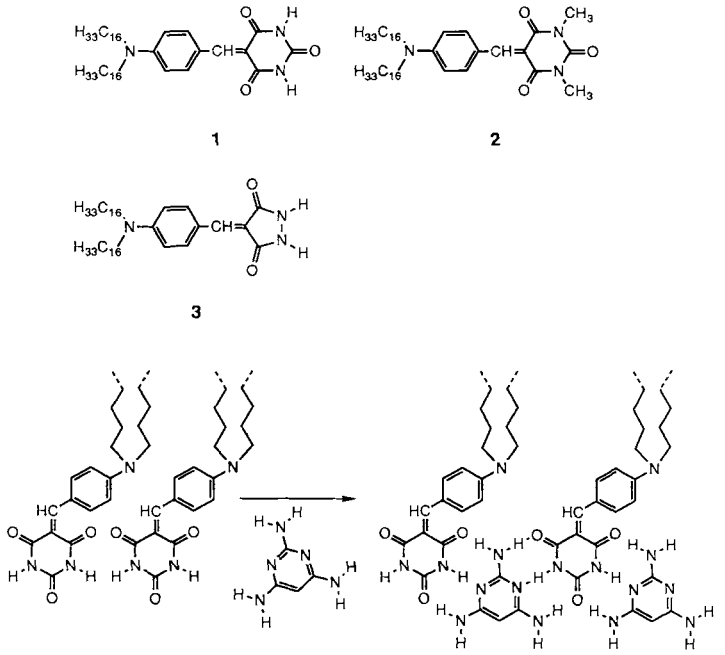

Fig. 1. Receptor lipids **1**–**3** and schematic representation of the formation of the molecular strands of barbituric acid lipid **1** with 2,4,6-triaminopyrimidine (TAP) at the gas–water interface.

The recognition reaction of the substrates and the barbituric acid lipids at the gas–water interface was investigated by measuring the surface pressure–surface area isotherms,[7] by Brewster angle microscopy,[7] and by UV/VIS reflection spectroscopy.[8] The latter method is especially suitable, as the detection of the recognition reaction relies on the disappearence of the aggregation band, which is a measure of the interaction of the lipid chromophore in the monolayer and does not occur in solution. The phase of the monolayer is important in the recognition reaction. The insertion of TAP into the lipid monolayer and formation of the strand structure occurs only when the lipid is in the fluid phase; for lipids **1**–**3** this is above 23 °C. Below this temperature, in the solid phase, the reflection spectra do not change, since TAP does not insert into the monolayer. All monolayer experiments whose results are discussed here were conducted at 25 °C with the same surface area per molecule and at the same pressure.

The reflection spectra of lipid **1** on pure water and 10^{-4} HCl subphases do not change, and the monolayer is stable for 17 h. In contrast, on subphases containing TAP at pH 3 the aggregation band at 430 nm disappears within 4 h (Fig. 2a). The corresponding insertion of TAP in the monolayer is a uniform and defined process, as is indicated by the three isosbestic points at 360, 486, and 544 nm. When the insertion of TAP in the monolayer of lipid **1** is monitored at pH 6.5, then an additional second process is evident—the hydrolytic cleavage of the C=C bond of the chromophore (Fig. 2b). This leads to the formation of the corresponding aldehyde (λ_{max} = 350 nm) and barbituric acid. Two isosbestic points at 298 and 384 nm occur, which again indicates that the reaction proceeds in a uniform and defined fashion. The barbituric acid head of the lipid is cleaved quantitatively after 4 h with formation of the aldehyde. It is quite remarkable that hydrolysis on a 10^{-4} M NaOH subphase (pH 10) is only in the initial stages after 4 h (Fig. 2c). Direct comparison shows that the TAP-catalyzed hydrolysis of the chromophore at pH 6.5 is 14 times faster than the addition of the hydroxide ion to the C=C bond at pH 10.

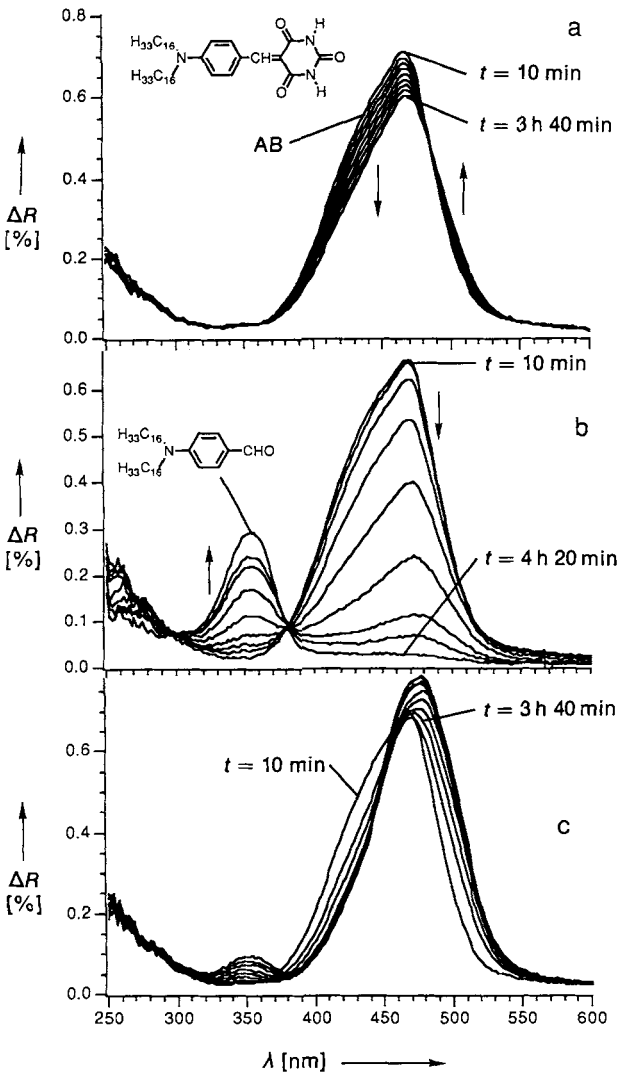

Fig. 2. UV/VIS reflection spectra of barbituric acid lipid **1** at the gas–water interface. R = reflection. a) On a 10^{-4} M TAP subphase at pH 3 containing HCl (disappearance of the aggregate bands (AB) at 430 nm, no hydrolysis); b) on a 10^{-4} M TAP subphase (pH 6.5), fast recognition-induced hydrolysis of barbituric acid lipid **1**; c) on a 10^{-4} M NaOH subphase (pH 10), slow basic hydrolysis of barbituric acid lipid **1**.

The first step of a reaction mechanism that would explain the dramatic increase in the rate of the cleavage of the double bond is shown schematically in Figure 3a and with a space-filling model in Figure 3b. The C—C double bond activated

by the formation of intermolecular hydrogen bonds between the chromophore and TAP is attacked by a water molecule. The high speed of the hydrolysis is not only due to this polarization of the double bond but also to an increase of the nucleophilicity of the water molecule, which is sitting in a hydrophobic pocket as shown schematically in Figure 3b.

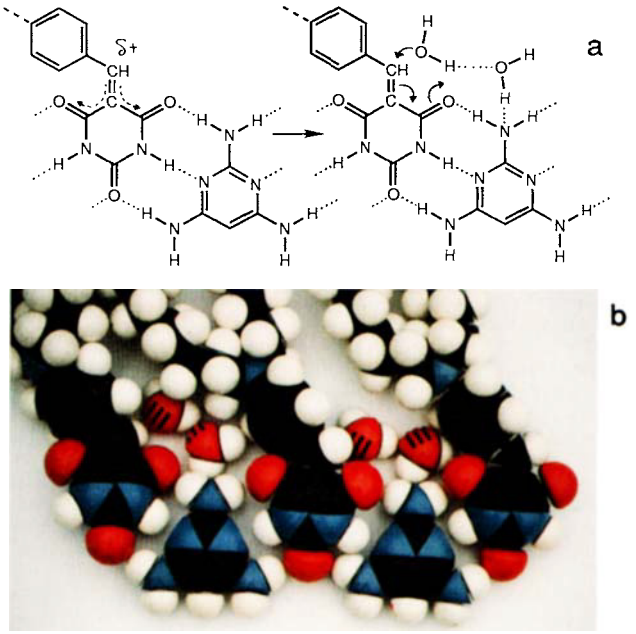

Fig. 3. Addition of water to the activated C=C bond of the chromophore of lipid **1**. a) Polarization of the double bond by hydrogen bonding and nucleophilic addition of water. b) Space-filling model of the molecular strands with water molecules in the hydrophobic environment between the lipids at the gas–water interface.

This proposed mechanism invoking recognition- and orientation-induced C=C cleavage (retro-Knoevenagel reaction) was supported by a series of further experiments. When melamine ($pK_B = 8.9$) was used as a substrate instead of TAP ($pK_B = 7.2$), the insertion was just as rapid (disappearance of the aggregation band), but the hydrolysis reaction was roughly nine times slower. This can be attributed to a weaker activation of the C=C bond, because the hydrogen bonds between the less basic melamine and the carbonyl groups adjacent to the double bond are not as strong. The importance of hydrogen bond formation and the consequent acceleration of the retro-Knoevenagel reaction can be demonstrated by the use of urea as substrate in the subphase.

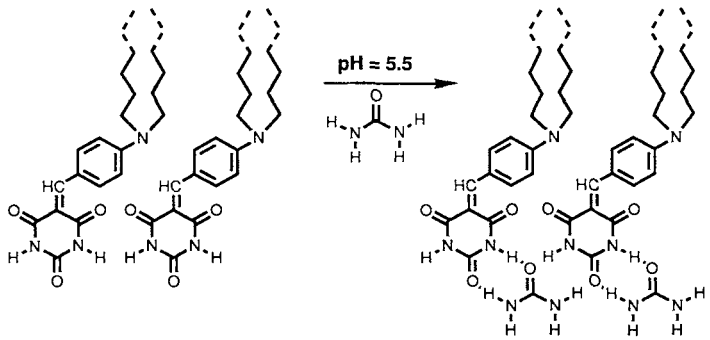

Fig. 4. Schematic representation of the insertion of urea into the monolayer of lipid **1** and formation of a molecular strand.

Figure 4 shows schematically the insertion of urea molecules into the monolayer forming molecular strands. The progress evident in the reflection spectra is analogous to that in Figure 2a, namely, the disappearance of the aggregation band (again three isosbestic points). In this experiment hydrolysis is not observed even at a pH value of 5.5, since the carbonyl groups adjacent to the double bond are not activated by hydrogen bonding.

Cospreading experiments[9] with mixtures of barbituric acid lipids and TAP in different ratios indicate that the insertion and cleavage reaction require the formation of molecular strands at the gas–water interface. The hydrolysis reaction for a 3:1 mixture is depicted at the top of Figure 5.

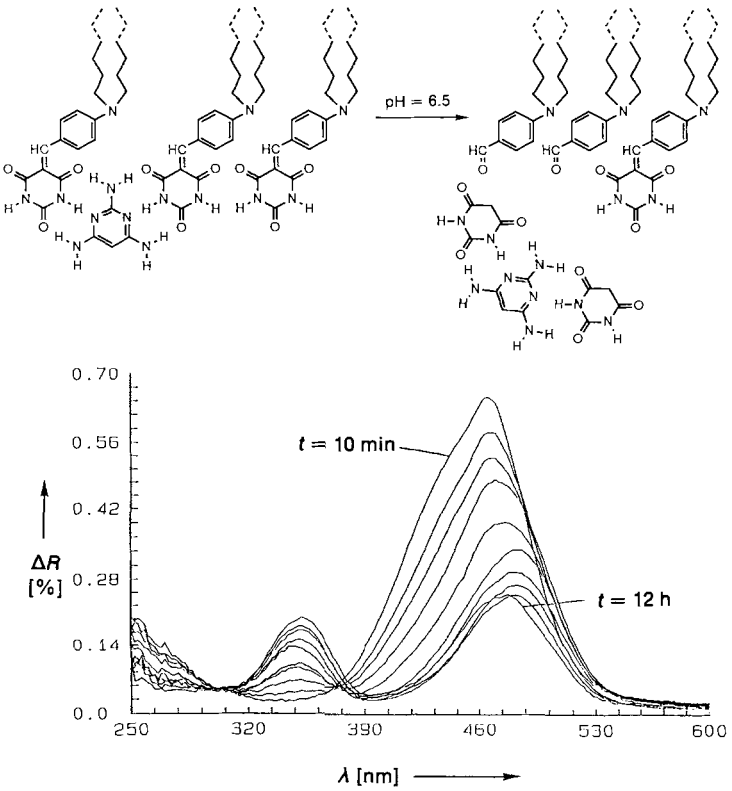

Fig. 5. UV/VIS reflection spectra recorded during the partial hydrolysis of a 3:1 mixture of lipid **1** and TAP, and schematic representation of a 2:1 complex of lipid **1** and TAP; reformation of the aggregation bands after the hydrolysis has ended (see Fig. 2a).

Three points should be noted: the hydrolysis is slower than for the 1:1 mixture (12 h instead of 3 h), the reaction comes to a halt after two-thirds of the lipid molecules are cleaved, and the aggregation band of the barbituric acid lipid reappears. Quantitative cleavage is observed for the 2:1 mixture of lipid **1** and TAP, but the reaction is also slower than for the 1:1 mixture. This implies that each TAP molecule forms hydrogen bonds to two lipid molecules (support for insertion), but only the molecular strand structure (1:1 mixture) leads to a fast reaction; the 2:1 complex (2:1 and 3:1 mixtures) reacts more slowly, since the double bond of the barbituric acid chromophore is activated from one side only. The reappearance of the aggregation band in the experiment with the 3:1 mixture after the reaction had stopped is a further indication that interruption of the lipid aggregates is caused only by the TAP insertion.

The importance of fit in the recognition reaction and the subsequent hydrolysis can be demonstrated by variation of the "receptor" of the barbituric acid (by methylation of the pyrimidine nitrogen atoms; lipid **2**). At pH 3, TAP is inserted into the monolayer of lipid **2** significantly more slowly than into that of lipid **1** (slow disappearance of the aggregation band) due to steric hindrance caused by the space-demanding methyl groups. The rate of the hydrolysis of lipid **2** on a TAP-containing subphase at pH 6.5 is linked to the rate of the insertion (Fig. 6). The aggregation band is observed until the hydrolysis is complete.

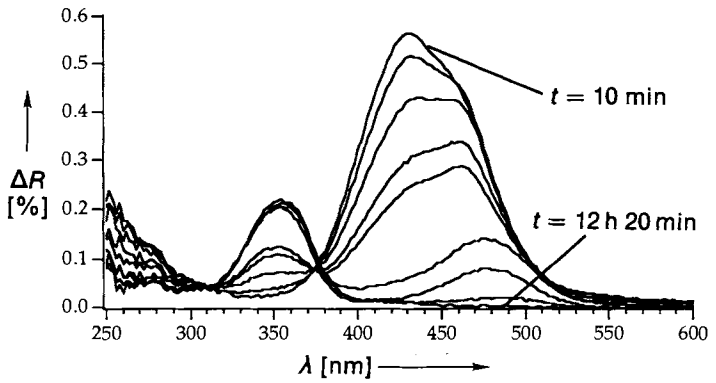

Fig. 6. UV/VIS reflection spectra of lipid **2** on a 10^{-4} M TAP subphase at pH 6.5. Slow insertion (slow disappearance of the aggregation band) followed by hydrolytic cleavage of the C=C bond (see Fig. 2b).

This experiment particularly emphasizes the importance of the organization of lipids at the gas-water interface. Although lipid **2** does not associate with TAP in $CDCl_3$ according to ^{1}H NMR spectra,[9] it does at the gas–water interface even though the solvent is changed from an aprotic to a protic one. The preorientation of the recognition structure by the lipid monolayer ensures that the complex, otherwise weak in solution, is stabilized by this arrangement. In this system the formation of the complex is the rate-determining step.

The importance of molecular recognition is underlined by the investigation of the interaction of the pyrazolidine-3,5-dione lipid **3** with TAP at the gas–water interface. In this case the aggregation band of the chromophore is not interrupted by TAP, because the five- and six-membered ring structures of lipid **3** and TAP do not fit together well enough. The monolayer of lipid **3** is stable on a TAP-containing subphase at pH 3 and pH 6.5 (no changes at all in the UV/VIS reflection spectra).

Preliminary experiments with subphases containing nucleobases indicate a defined interaction, for example, between cytosine and lipid **1**, which is only possible via the enol form of the base. In addition, the reverse systems—water-soluble barbituric acid derivatives and monolayers of amphiphilic triaminopyrimidine and melamine derivatives—are currently under investigation.

[7] The isotherms of lipid **1** show that the lipid has a collapse area of 0.46 nm^2 at a collapse pressure of 20 $mN\,m^{-1}$. The lipid has a liquid–solid coexistence region starting at 23 °C. At lower temperatures only gas- and solid-analogue phases are observed. Fluorescence microscopy shows that the lipids form anisotropic domains in the solid state. The isotherms of the lipid on the water and TAP subphases at pH 3 are almost identical but with slightly differing collapse pressures, which indicates a perfect fit, as shown schematically in Figure 1. The change in the surface potential of the monolayer during the measurements of the isotherms are also the same. The hydrolysis reaction can be followed just as well from the isotherms, since the resulting aldehyde does not form a solid phase at the gas–water interface. Thus the reduction in the collapse area of the barbituric acid lipid reflects the degree of hydrolysis of the monolayer. The same observations are made by Brewster angle micrscopy. Although the insertion does not lead to any noticeable change in the signal, the hydrolysis can be followed very easily.
[8] The UV/VIS reflection spectra were conducted on the monolayer at a subphase temperature of 25 °C and a surface pressure of approximately 5 mN^{-1}. A UV/VIS spectrometer adjusted on the surface of a Fromherz trough by glass fiber optics was used. The spectroscopy of a single monolayer was possible by comparison of the covered and uncovered surface. The experimental setup for the UV/VIS measurements is described in H. Grüniger, D. Möbius, H. Meyer, *J. Chem. Phys.* **1983**, *79*, 3701–3710.
[9] The ratios of the components for the cospreading experiments were determined by weight, and both components were dissolved in $CHCl_3$ as the spreading solvent. ^{1}H NMR spectra had previously established that the 1:1 complex forms in chloroform (quantitative shift of the signals of the amino and imide protons of TAP and barbituric acid by $\Delta\delta = 1.1$ and 2.25, respectively.

Hexakis(benzotriazolato)tetrakis-(2,4-pentanedionato)pentacopper(II): A Model for Corrosion Inhibition**

By *Jane Handley, David Collison, C. David Garner,* Madeleine Helliwell, Robert Docherty, John R. Lawson,* and *Peter A. Tasker**

The coordination chemistry of metal surfaces exposed to atmospheric attack is of considerable economic importance, especially with respect to effective corrosion inhibition. Empirically, specific ligands have been found to inhibit the corrosion of particular metals; benzotriazole (Hbta) is well established as a corrosion inhibitor for copper[1] and copper alloys,[2] performing well when applied in both aerated and deaerated conditions. The characterization of the nature of such ligation presents a significant challenge, not least because the surface to which the corrosion inhibitor is applied is rarely chemically pure or structurally defined. For the copper–benzotriazole interaction, it has been postulated that copper oxide films are prerequisites for successful corrosion inhibition.[2] The formation of polynuclear complexes, in

The importance of fit in the recognition reaction and the subsequent hydrolysis can be demonstrated by variation of the "receptor" of the barbituric acid (by methylation of the pyrimidine nitrogen atoms; lipid **2**). At pH 3, TAP is inserted into the monolayer of lipid **2** significantly more slowly than into that of lipid **1** (slow disappearance of the aggregation band) due to steric hindrance caused by the space-demanding methyl groups. The rate of the hydrolysis of lipid **2** on a TAP-containing subphase at pH 6.5 is linked to the rate of the insertion (Fig. 6). The aggregation band is observed until the hydrolysis is complete.

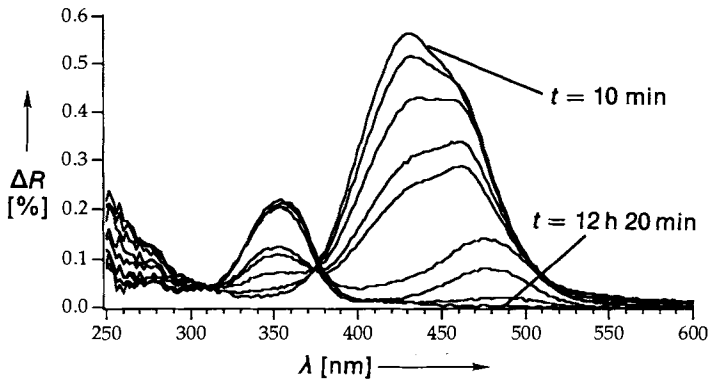

Fig. 6. UV/VIS reflection spectra of lipid **2** on a 10^{-4} M TAP subphase at pH 6.5. Slow insertion (slow disappearance of the aggregation band) followed by hydrolytic cleavage of the C=C bond (see Fig. 2b).

This experiment particularly emphasizes the importance of the organization of lipids at the gas-water interface. Although lipid **2** does not associate with TAP in $CDCl_3$ according to ^{1}H NMR spectra,[9] it does at the gas–water interface even though the solvent is changed from an aprotic to a protic one. The preorientation of the recognition structure by the lipid monolayer ensures that the complex, otherwise weak in solution, is stabilized by this arrangement. In this system the formation of the complex is the rate-determining step.

The importance of molecular recognition is underlined by the investigation of the interaction of the pyrazolidine-3,5-dione lipid **3** with TAP at the gas–water interface. In this case the aggregation band of the chromophore is not interrupted by TAP, because the five- and six-membered ring structures of lipid **3** and TAP do not fit together well enough. The monolayer of lipid **3** is stable on a TAP-containing subphase at pH 3 and pH 6.5 (no changes at all in the UV/VIS reflection spectra).

Preliminary experiments with subphases containing nucleobases indicate a defined interaction, for example, between cytosine and lipid **1**, which is only possible via the enol form of the base. In addition, the reverse systems—water-soluble barbituric acid derivatives and monolayers of amphiphilic triaminopyrimidine and melamine derivatives—are currently under investigation.

[7] The isotherms of lipid **1** show that the lipid has a collapse area of 0.46 nm^2 at a collapse pressure of 20 $mN\,m^{-1}$. The lipid has a liquid–solid coexistence region starting at 23 °C. At lower temperatures only gas- and solid-analogue phases are observed. Fluorescence microscopy shows that the lipids form anisotropic domains in the solid state. The isotherms of the lipid on the water and TAP subphases at pH 3 are almost identical but with slightly differing collapse pressures, which indicates a perfect fit, as shown schematically in Figure 1. The change in the surface potential of the monolayer during the measurements of the isotherms are also the same. The hydrolysis reaction can be followed just as well from the isotherms, since the resulting aldehyde does not form a solid phase at the gas–water interface. Thus the reduction in the collapse area of the barbituric acid lipid reflects the degree of hydrolysis of the monolayer. The same observations are made by Brewster angle micrscopy. Although the insertion does not lead to any noticeable change in the signal, the hydrolysis can be followed very easily.

which the Hbta uses its nitrogen atoms to bridge adjacent copper atoms, has been proposed.[3] Alternatively, the formation of a π complex between Hbta and surface copper(I) ions has been suggested.[4] As part of a programme to investigate the possible modes of bonding between copper surfaces and Hbta, a range of copper complexes with this and related ligands have been prepared, including the title compound, **1** (Hacac = 2,4-pentanedione).

$[Cu_5(bta)_6(acac)_4]$ **1**

X-ray structure analysis[5] of prismatic crystals of **1**, obtained from dichloromethane, revealed them to be composed of discrete $[Cu_5(bta)_6(acac)_4]$ molecules (Fig. 1).[6] The pentanuclear copper(II) assembly consists of a distorted tetrahedral arrangement of four copper atoms (Cu2–Cu5) centered on the fifth (Cu1); the cube which envelopes this arrangement is identified in Figure 1. Each of the six bta^- ligands

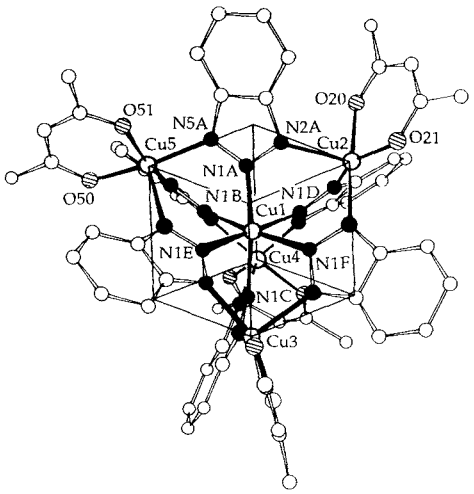

Fig. 1. The molecular structure of **1**; ○ Cu, o C, ● N, ◍ O. Cu1 is the central copper ion. Selected bond lengths [Å]: Cu1-N1A 2.030(9), Cu1-N1B 2.305(8), Cu1-N1C 2.058(9), Cu1-N1D 2.034(9), Cu1-N1E 2.063(9), Cu1-N1F 2.471(9), Cu2-O20 1.931(8), Cu2-O21 1.924(8), Cu2-N2A 2.036(9), Cu2-N2D 2.219(9), Cu2-N2F 1.984(9), Cu3-O30 1.952(7), Cu3-O31 1.929(8), Cu3-N3C 2.182(9), Cu3-N3E 2.026(8), Cu3-N3F 2.011(9), Cu4-O40 1.955(8), Cu4-O41 1.914(7), Cu4-N4B 2.181(9), Cu4-N4C 1.996(8), Cu4-N4D 2.026(9), Cu5-O50 1.920(8), Cu5-O51 1.936(8), Cu5-N5A 2.23(1), Cu5-N5B 1.978(9), Cu5-N5E 2.036(9); selected nonbonding distances [Å]: Cu1-Cu2 3.684(2), Cu1-Cu3 3.715(2), Cu1-Cu4 3.615(2), Cu1-Cu5 3.685(2), Cu2-Cu3 5.740(2), Cu2-Cu4 6.126(2), Cu2-Cu5 6.120(2), Cu3-Cu4 6.063(2), Cu3-Cu5 6.034(2), Cu4-Cu5 5.896(2); selected angles between copper atoms [°]: Cu2-Cu1-Cu3 101.75(5), Cu2-Cu1-Cu4 114.12(6), Cu2-Cu1-Cu5 112.29(6),Cu3-Cu1-Cu5 109.25(5), Cu3-Cu1-Cu4 111.61(5), Cu4-Cu1-Cu5 107.72(5).

spans an edge of the Cu_4 tetrahedron and is ligated to the central copper atom (Cu1) through its central nitrogen atom. Cu1 has a tetragonally distorted (4+2) octahedral coordination geometry. In contrast, each apical copper atom is in an approximately square-based pyramidal $(Cu(N_2O_2)_{eq}(N)_{ax})$ environment, bound to three benzotriazole nitrogen atoms and two oxygen atoms of a bidentate 2,4-pentanedionato group. The structure of **1** corresponds to that proposed by Marshall[7] for a compound he isolated with the same composition.

The arrangement of the $Cu_5(bta)_6$motif in **1** is a repeat of that observed[8] in the mixed-valence cluster **2**,[8] which involves a central Cu^{II} ion, ligated as in **1**, and four apical Cu^{I} ions, each possessing an essentially tetrahedral CuN_3C arrangement. The μ^3-bridging arrangement for bta^- has also been identified[9] in a thallium(I) compound.

$[Cu_5(bta)_6(t\mathrm{BuNC})_4]$ **2**

The mode of bonding of the bta^- ligands to Cu^{II} in **1** and to Cu^{I} and Cu^{II} in **2** could relate directly to the role of Hbta as a corrosion inhibitor of copper metal. Thus, bta^- could anchor to the oxidized metal by binding to two copper atoms in the surface layer and to a copper atom in the layer below. The copper atoms at an oxidized metal surface would be expected to be ligated to O^{2-}, OH^- and/or H_2O and, therefore, the inclusion of O-donor ligands in **1** is consistent with this.

These ideas have been developed further with molecular modeling packages,[11, 12] which have been used to examine the interaction of bta^- with the (110) faces of Cu_2O and CuO. These faces are considered to be the growth faces of these oxides. This is in agreement with classical morphological theory according to Bravais, Friedel, Donnay, and Harker which suggests that "allowing for space group symmetry, the most important growth forms will be those with the greatest interplanar spacings (d_{hkl})".[13, 14] A preliminary study has shown that the best structural match[15] corresponds to the bta^- unit binding to and penetrating the (110) face of Cu_2O, as shown in Figure 2. This arrangement involves the bta^- oriented perpendicular to the (110) face and allows an efficient packing of benzo substituents across the surface. The conclusion is consistent with the ideas of Fang et al.,[17] but contrasts with the idea that the bta^- moiety lies parallel to the surface[4] or is inclined at some intermediate orientation.[18] For CuO the best structural match was also obtained with the (110) face and with bta^- perpendicular to the surface, although the fit was not as good[15] as for the (110) face of Cu_2O. These calculations do not address the binding energies of bta^- to different copper oxide surfaces since an important feature to emerge from the molecular arrangement in **1** is that, even within such a relatively small polynuclear complex, there are significant structural variations which are tolerated within the Cu^{II}_3-bta^- moiety.

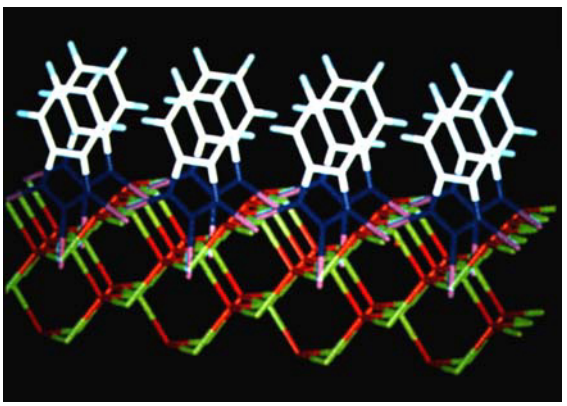

Fig. 2. Molecular modeling representation of binding of benzotriazolate ions to the (110) face of Cu_2O with a goodness of fit [16] of 0.24. The Cu–Cu distances within the unrelaxed triangular units bound by bta^- are 5.667, 3.270, and 3.270 Å; color coding: copper of oxidized surface is green, copper from benzotriazole structure is purple, oxygen is red, nitrogen is dark blue, carbon is white, and hydrogen is pale blue.

1) The inclinations of the bta^- units to the faces of the cube of Figure 1 vary considerably. The angle between a line joining the midpoints of the copper atoms on opposite faces of the cube and the plane of the bta^- penetrating these faces ranges from 1.18 to 27.38°.

2) The torsion angle between the nonadjacent nitrogen atoms of a bta$^-$ ligand and the two copper atoms to which they bind varies between 3.45 and 54.09°.

This versatility suggests that it is possible for benzotriazole to adapt to differences in the binding site geometry presented by various oxidized copper surfaces.

These studies lead to the suggestion that the interaction of benzotriazole with the surface of oxidized copper metal involves a near-normal approach; binding two copper atoms on the surface and one copper atom in the layer below. The flexibility possible with this mode of coordination would allow strong interaction with copper surfaces with varying degrees of oxidation and structure. Such binding of bta$^-$ utilizes its ligating ability to the maximum and would significantly inhibit the corrosion of the metal.

Experimental Procedure

1: A solution of bis(2,4-pentanedionato)copper(II) (3 mmol) in dichloromethane (150 cm^3) was treated with benzotriazole (15 mmol). This resulted in a deep green solution, from which green, prismatic crystals of **1** were isolated after approximately 21 days [5].

Why is Porphobilinogen the Biological Substrate for the Formation of Porphyrins? Calculations on the Conformation of Acyclic Tetrapyrroles and the Acid-Catalyzed Cyclization of Hydroxymethylpyrroles**

By *Lutz F. Tietze** and *Holger Geissler*

Dedicated to Professor Reinhard W. Hoffmann on the occasion of his 60th birthday

The biological evolution of the plant and animal kingdoms is intimately connected with chemical evolution, that is, with the diversification of those chemical substances required for the development of organisms. In addition to nucleic acids and peptides,[1] the tetrapyrroles—chlorins, porphyrins, and corrins—are important for evolution and absolutely essential for plant and animal life as cofactors in photosynthesis, respiration, and in the formation of methane as well as vitamins; all porphinoid cofactors are formed from uroporphyrinogen III (**6**).

The question raised here is why nature has chosen porphobilinogen (**1**)[2] as the monomer for the biosynthesis of uroporphyrinogen III (**6**) and not the unsubstituted or a monosubstituted 2-aminomethylpyrrole.[3] This cannot have been a problem of the biosynthesis, as a multitude of variously substituted pyrroles occur in nature. On the contrary, one must assume that the substitution pattern found in porphobilinogen (**1**) is critical for the formation of the cyclic tetramer. Franck and Wegner were able to show that even

	R^1	R^2	X
1	A	P	NH_2
2	H	H	OH
3	CH_3	CH_3	OH
4	H	CH_3	OH
5	CH_3	H	OH

P = $(CH_2)_2CO_2H$
A = CH_2CO_2H

	R^1	R^2
6	A	P
7	CH_3	CH_3
8	H	CH_3

sterically strained cyclic tetramers could be constructed very easily in vitro by the reaction of 3,4-disubstituted *N*-alkyl-2-aminomethylpyrroles.[4] Thus, the straightforward formation of the cyclic tetramers may be traced back to the conformational fixing of the acyclic tetramers,[5] formed in several steps, in a cyclic conformation as a result of 1,3-allylic strain.[6] To confirm this hypothesis we have investigated the acid-catalyzed cyclization of hydroxymethylpyrroles **2**–**5** and calculated[7] the lowest energy conformation of the substituted and unsubstituted acyclic tetrapyrroles **9** and **10** by using the semiempirical AM1 method.[8]

Since direct determination of the lowest energy conformation for **9** and **10** was not reasonable on account of the size

Why is Porphobilinogen the Biological Substrate for the Formation of Porphyrins? Calculations on the Conformation of Acyclic Tetrapyrroles and the Acid-Catalyzed Cyclization of Hydroxymethylpyrroles**

By *Lutz F. Tietze** and *Holger Geissler*

Dedicated to Professor Reinhard W. Hoffmann on the occasion of his 60th birthday

The biological evolution of the plant and animal kingdoms is intimately connected with chemical evolution, that is, with the diversification of those chemical substances required for the development of organisms. In addition to nucleic acids and peptides,[1] the tetrapyrroles—chlorins, porphyrins, and corrins—are important for evolution and absolutely essential for plant and animal life as cofactors in photosynthesis, respiration, and in the formation of methane as well as vitamins; all porphinoid cofactors are formed from uroporphyrinogen III (**6**).

The question raised here is why nature has chosen porphobilinogen (**1**)[2] as the monomer for the biosynthesis of uroporphyrinogen III (**6**) and not the unsubstituted or a monosubstituted 2-aminomethylpyrrole.[3] This cannot have been a problem of the biosynthesis, as a multitude of variously substituted pyrroles occur in nature. On the contrary, one must assume that the substitution pattern found in porphobilinogen (**1**) is critical for the formation of the cyclic tetramer. Franck and Wegner were able to show that even

	R^1	R^2	X
1	A	P	NH_2
2	H	H	OH
3	CH_3	CH_3	OH
4	H	CH_3	OH
5	CH_3	H	OH

P = $(CH_2)_2CO_2H$
A = CH_2CO_2H

	R^1	R^2
6	A	P
7	CH_3	CH_3
8	H	CH_3

sterically strained cyclic tetramers could be constructed very easily in vitro by the reaction of 3,4-disubstituted *N*-alkyl-2-aminomethylpyrroles.[4] Thus, the straightforward formation of the cyclic tetramers may be traced back to the conformational fixing of the acyclic tetramers,[5] formed in several steps, in a cyclic conformation as a result of 1,3-allylic strain.[6] To confirm this hypothesis we have investigated the acid-catalyzed cyclization of hydroxymethylpyrroles **2**–**5** and calculated[7] the lowest energy conformation of the substituted and unsubstituted acyclic tetrapyrroles **9** and **10** by using the semiempirical AM1 method.[8]

Since direct determination of the lowest energy conformation for **9** and **10** was not reasonable on account of the size

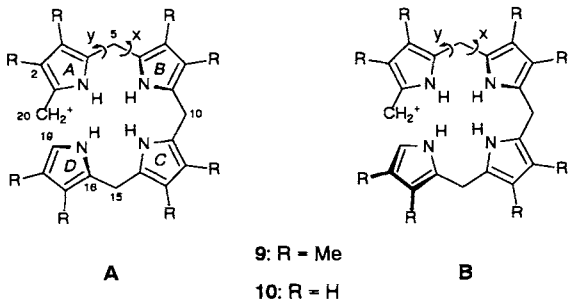
of the molecule, we proceeded in a stepwise fashion. First, the lowest energy conformation of the corresponding dipyrroles was calculated. A third pyrrole moiety was attached to give the tripyrroles, for which a potential energy surface with corresponding energy minima was obtained for the two new C–C bonds as a function of the torsion angle.[9] Further addition of a pyrrole unit gave the acyclic tetrapyrroles **9** and **10** with the conformations **A** and **B**. Once



again, the potential energy surfaces *H1* and *H2* for **9** (Fig. 1) and *H3* and *H4* for **10** (Fig. 2) were calculated by variation of the torsion angle[10] of the bonds x and y.

On comparison of the potential energy surfaces *H1* and *H2* with *H3* and *H4* the difference caused by the 1,3-allylic strain becomes immediately apparent. In comparison with *H1* and *H2* the potential energy surfaces *H3* and *H4* are relatively flat, and their minima are considerably less pronounced. In the ground state the cyclic conformation (minima *M1* and *M6*) of the acyclic tetrapyrroles is more favorable than the extended conformation (minima *M5* and *M10*; $\Delta H_f(M1,M5) = 4.53\ kJ\,mol^{-1}$, $\Delta H_f(M6,M10) = 3.34\ kJ\,mol^{-1}$). Although the minimum *M4* corresponds to the energetically lowest point on *H1* and *H2*, on conformational grounds it is only capable of undergoing cyclization via the minimum *M1* (Scheme 1).

Table 1. AM1/RHF energies (H_f) for the minima *M1–M10* for compounds **9** and **10** in $kJ\,mol^{-1}$.

9:	*M1*	*M2*	*M3*	*M4*	*M5*
	1043.0	1049.4	1056.2	1042.1	1047.6
10:	*M6*	*M7*	*M8*	*M9*	*M10*
	1320.9	1327.0	1331.6	1323.9	1324.3

The distance between C20 and C19 in **9** is 395 pm for *M1*; the cyclic tetramer should therefore be formed from this conformation very quickly and easily. The calculations also show that polymerization is anticipated for **10**, as the cyclic conformation is less strongly fixed and the activation energy for the electrophilic substitution is presumably greater than for **9** because of the lower electron density of the pyrrole.

The results of these calculations are in agreement with those of investigations on the acid-catalyzed cyclization of hydroxymethylpyrroles **2**–**5**. Solutions of **2**–**5** in 2-propanol

were treated with equal amounts of acetic acid under identical reaction conditions (20 °C, 2 h). The yields of the cyclic tetrapyrroles were determined by HPLC with 5,5,10,10,15,15,20,20-octamethylporphyrinogen as internal standard.[12] The reaction of **2** gave no identifiable products; **3** provided an 82% yield of the corresponding cyclic tetrapyrrole **7**.[13] Reaction of **4** and **5** led in each case to a mixture of **8** and the three possible isomeric tetrapyrroles in approximately 20% yield. The calculations and experimental results show unequivocally the importance of substitution at C3 and C4 in the pyrrole ring in the formation of cyclic tetrapyrroles.

[9] All calculations were carried out with the VAMP software package (T. Clark, Universität Erlangen-Nürnberg, unpublished) on an IBM 3090/300e from the Gesellschaft für wissenschaftliche Datenverarbeitung, Göttingen. VAMP is based on AMPAC 1.0 (QCPE no. 506) and MOPAC (QCPE no. 455).

[10] A point was calculated for the potential energy surface every 30°. In this way both torsion angles were fixed and the rest of the structure optimized.

[11] Rotation in a counterclockwise direction carries a positive sign.

[12] To an oxygen-free solution of hydroxymethylpyrroles **2**-**5** (6.00 μmol) in 1 mL of 2-propanol was added 2 μL of acetic acid with stirring at 20 °C under an argon atmosphere and with exclusion of light, and the resulting solution was stirred for another 2 h at 20 °C. After the addition of 4 μL of triethylamine, the solvent was removed by application of high vacuum for 1 h. Subsequently, 1 mL of a solution of 5,5,10,10,15,15,20,20-octamethylporphyrinogen (1 mg) in degassed acetonitrile (10 mL) was added, and quantitative HPLC analysis was conducted on a 5μ-C18 column with CH_3CN/H_2O (76:24, degassed) as solvent.

[13] In the reaction of **3** an acyclic hydroxymethyltetrapyrrole can be formulated as an intermediate corresponding to hydroxymethylbilan, which was demonstrated to be a biosynthetic precursor of uroporphyrinogen III (**6**).

Investigations in the Biosynthesis of the Pigments of Life: Calculations on the Formation of Uroporphyrinogen III from Hydroxymethylbilan and Description of a New Mechanism for the D-Ring Inversion**

By *Lutz F. Tietze** and *Holger Geissler*

Dedicated to Professor Wolfgang Steglich on the occasion of his 60th birthday

The cyclic tetrapyrrole uroporphyrinogen III (**2**) is the biosynthetic precursor for chlorophylls and bacteriochlorophylls, as well as of heme, siroheme, coenzyme F 430, and vitamin B_{12}, which have been described as the pigments of life. Uroporphyrinogen III is formed from porphobilinogen (PBG) by the action of the enzymes hydroxymethylbilan

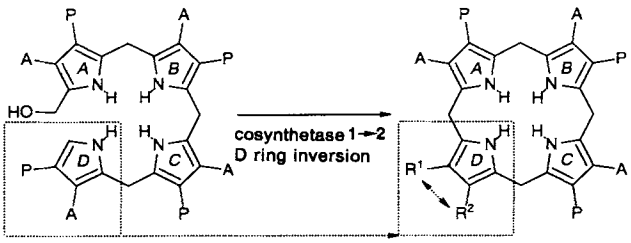
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

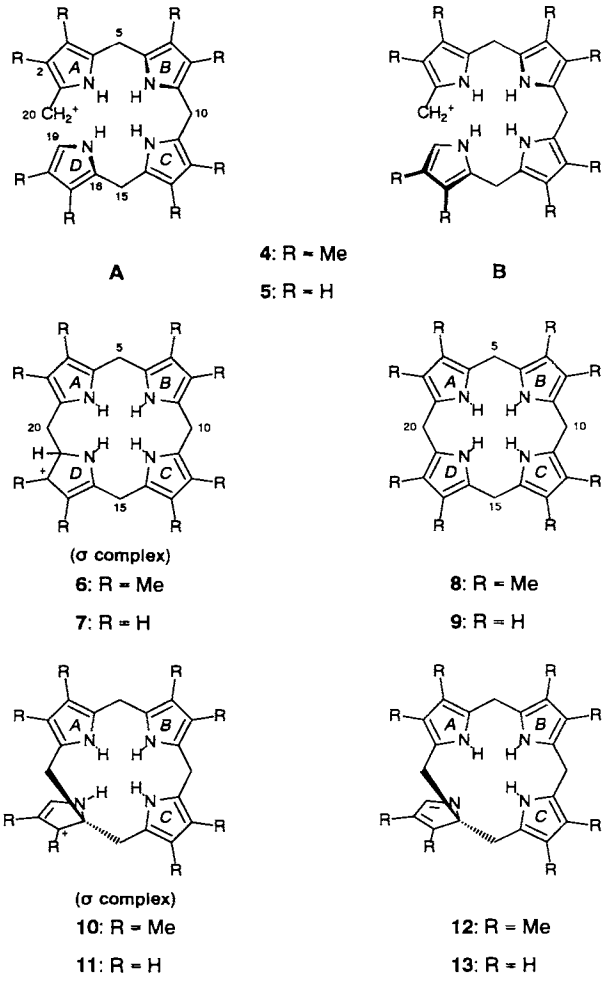
synthase (HMBS) and uroporphyrinogen III synthase (cosynthetase); hydroxymethylbilan (**1**) was shown to be a non-enzyme-bound intermediate.[1] A remarkable step in the biosynthesis of uroporphyrinogen III (**2**) is the inversion of ring D, which takes place only in the presence of cosynthetase.[2] In the absence of this enzyme only uroporphyrinogen I (**3**) is formed, which does not isomerize to give **2** even in the presence of cosynthetase.[3] Countless models (so far unverified), such as the formation of a spiro compound as intermediate,[4] the fragmentation–recombination mechanism,[1,5] [1,5] sigmatropic rearrangements[5b,c] and the intermediate formation of a lactone[6] have been used to explain this phenomenon. We describe here calculations on the formation of uroporphyrinogen III (**2**) from hydroxymethylbilan (**1**) using the model compounds **4** and **5**, and introduce a new mechanism for the inversion of the D ring.



1 A: CH_2CO_2H P: $(CH_2)_2CO_2H$ **2**: R^1=A, R^2=P **3**: R^1=P, R^2=A

In the preceding communication we were able to show, based on calculations, that the cyclic conformations **A** and **B** correspond to energy minima for the acyclic tetrapyrroles **4** and **5**.[7] To investigate the cyclization, we have now determined the transition states[8] and σ complexes involved in the formation of the cyclic tetramer **8** from **4** by attack of C19 at C20 and that of the spiro compound **12** from **4** by attack of C16 at C20 by using the semiempirical method AM1/RHF.[9] We have also conducted similar calculations for the formation of **9** and **13** from the unsubstituted acyclic tetrapyrrole **5**.

Four transition state structures (**TS-4a–d** and **TS-5a–d**) were found for the cyclization of **4** and **5**, respectively. The cyclization of **4** to give the cyclic tetrapyrrole **8** via **6** from the conformation **A** requires the least expenditure of energy (**TS-4a**: $\Delta H_f^{\neq} = 8.36\ kJ\,mol^{-1}$). This corresponds to the formation of uroporphyrinogen I (**3**) from **1** and is in agreement with the acid-catalyzed cyclization of porphobilinogen, which leads first to **3** in a kinetically controlled process; under equilibrating reaction conditions a mixture of uroporphyrinogens I, II, III, and IV in the molar ratio 1:1:4:2 is found.[10] In this context it is worth noting that an activation energy almost twice as great has been calculated for the cyclization of **5** to **9** via **7** (**TS-5a**: $\Delta H_f^{\neq} = 14.7\ kJ\,mol^{-1}$). The lower reactivity of the unsubstituted pyrrole certainly accounts for this figure; the tendency for polymerization[7] becomes understandable when the potential energy surface for the conformation of **5**, which shows only weakly pronounced minima, is considered. Interestingly, the cationic σ complexes **6** and **7**, formed as intermediates in the electrophilic substitution at the pyrrole ring D, and which lead to the tetrapyrroles **8** and **9**, respectively, are considerably more stable than the cationic substrates **4** and **5**; the calculated energy differences ΔH_f amount to $-91.3\ kJ\,mol^{-1}$ for **4** and $-87.3\ kJ\,mol^{-1}$ for **5**. These results could be an indication that a cationic intermediate of type **4** does not arise in the enzymatic cyclization of hydroxymethylbilan and that σ complexes of type **6** have comparatively long lifetimes.



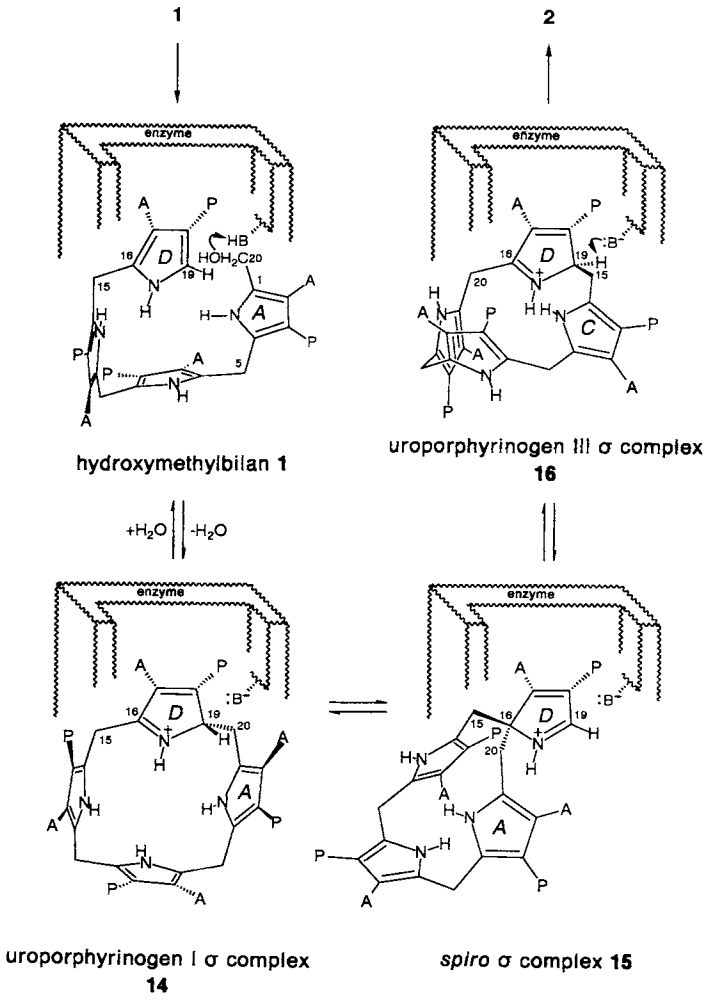
Of considerable importance for the elucidation of the ring inversion in the formation of uroporphyrinogen III (**2**) from **1** is the finding that the calculated activation energies for the formation of the spiro compounds **12** and **13** from **4** and **5** via **10** and **11**, respectively, are considerably higher than the values found for the cyclization to **8** and **9** (see above) (**TS-4b**: $\Delta H_f^{\neq} = 56.0$, **TS-5b**: $\Delta H_f^{\neq} = 54.0\ kJ\,mol^{-1}$). Thus, the difference in energy for the cyclization of **4** to provide the spiro compound **12** relative to that for the cyclization of **4** to **8** amounts to $47.6\ kJ\,mol^{-1}$.

Based on the calculated results, cyclization from conformation **B** can be neglected, as the transition states for both types of cyclization (C19 → C20 and C16 → C20 are higher in energy (**TS-4c**: $\Delta H_f^{\neq} = 35.7$, **TS-5c**: $\Delta H_f^{\neq} = 29.2$, **TS-4d**: $\Delta H_f^{\neq} = 74.5$, **TS-5d**: $\Delta H_f^{\neq} = 72.1\ kJ\,mol^{-1}$).

The calculations show that the direct formation of the spiro compound **12** or of the σ complex **10** from **4** is energetically much less favorable than the formation of **8** or **6** from **4**. Thus, we regard the postulated spirotetrapyrrole model for the formation of uroporphyrinogen III (**2**) from hydroxymethylbilan (**1**) as less likely and therefore suggest the mechanism outlined in Scheme 1 for the formation of **2** from **1**. This mechanism is in agreement with the results of the calculations performed and with the investigations on the biosynthesis of **2** conducted to date.

The first step is the protonation of the hydroxyl group in **1** by an acid moiety in a pocket of the enzyme cosynthetase, followed by formation of the uroporphyrinogen I σ complex

14. The initially formed oxonium ion is attacked from above by the pyrrole ring D to give **14** with a β-directed H atom on C19 (or vice versa). This step is followed by numerous reversible suprafacial [1,5] sigmatropic shifts to provide the spiro σ complex **15** and subsequently the uroporphyrinogen III σ complex **16**, in which the H atom on C19 is now in the α position (or vice versa). Abstraction of this proton by a suitably placed base in the enzymic cleft—presumably the anion of the acid that protonated **1** in the first step—leads to formation of uroporphyrinogen III (**2**) in an irreversible reaction.



Scheme 1. Postulated biosynthetic route to uroporphyrinogen III (**2**) from hydroxymethylbilan (**1**) (A: CH_2CO_2H, P: $(CH_2)_2CO_2H$).

In summary it can be said that nature had to find a way to improve the unselective synthesis of uroporphyrinogen III in the primordial broth. This was accomplished with the formation of the enzyme cosynthetase, which, as we assume, prohibits the abstraction of a proton of the initially formed uroporphyrinogen I σ complex to give uroporphyrinogen I, whilst the abstraction of a proton from the uroporphyrinogen III σ complex, which is formed in equilibrium, is enhanced giving uroporphyrinogen III. The differentiation of the protons in the σ complexes by the enzyme is possible as they have opposite orientations.

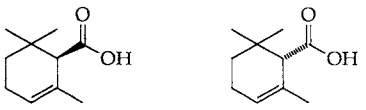
Highly Enantioselective Protonation of Thiol Ester Enolates

By *Charles Fehr,* Isabelle Stempf,* and *José Galindo*

Enantioselective protonation of achiral enolates using an efficient and synthetically useful chiral proton source has long been discussed and has great synthetic potential. Recent progress in this field[1–3] has led to enantioselectivities of up to 91 % *ee*.[2] From both preparative and mechanistic standpoints greater enantiofacial discrimination would be highly desirable. Our efforts have concentrated on the preparation of enantiomerically pure (*R*)- and (*S*)-α-cyclogeranic acid ((*R*)-**1** and (*S*)-**1**)[4] which are pivotal, versatile intermediates in the synthesis of fragences and in medicinal chemistry.[5]



We herein report the large-scale synthesis of thiol esters (*S*)-**4**, (*S*)-**5**, and (*R*)-**4** by an unprecedentedly efficient enantioselective protonation (99 % *ee*) of enolates **4**(Li) and **5**(Li) with readily accessible and easily recoverable (−)- and (+)-*N*-isopropylephedrine ((−)-**7** and (+)-**7**)[11] as the chiral proton source.

The transformations of (*R*)-**4** and (*S*)-**4** into (*R*)-**1** and (*S*)-**1** as well as the perfume components (*R*)- and (*S*)-methyl-α-cyclogeranate ((*R*)-**2** and (*S*)-**2**) and (*S*)-α-damascone ((*S*)-**11**)[11] under nonracemizing conditions (see below) demonstrate the importance of the new enantioselective protonation protocol.[6]

When racemic methyl α-cyclogeranate ((*R*, *S*)-**2**) was deprotonated with *n*BuLi and the resulting enolate **2**(Li)[7] (*Z*/

E=19:1)[8] protonated with (−)-7, (*S*)-**2** was obtained with 36% *ee*[9, 10] (Table 1, entry 1). This low enantiofacial discrimination may be due to an insufficient structural differentiation of the enolate substituents on C1 (OLi vs. OMe) for efficient enantiotopic recognition, and an overly rapid protonation of **2**(Li) due to the high pK_a of **2**. Therefore, phenyl ester **3** and the aryl thiol esters **4**,[7] **5**, and **6** were chosen as substrates.

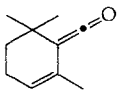
Table 1. Enantioselective protonation of enolates **2**(Li)–**6**(Li).

Entry	Substrate	Reaction conditions (equiv; T [°C] (t[min]))	*ee* [%]	Yield [c] [%]
1	**2**	1) *n*BuLi (2.0; −78 (240)) 2) (−)-**7** (2.6; −100 (60) → −10 (25))	36 (*S*)	–
2	**3**	1) *n*BuLi (3.0; −100 (180)) 2) (−)-**7** (4.0; −100 (60) → −10 (25))	77 (*S*)	–
3	**4**	1) *n*BuLi (1.5; −100 (120))[a], 2) (−)-**7** (2.0; −100 (60) → −10 (25))	**99** (*S*)	87
4	**4**	1) [b], 2) (+)-**7** (2.0; −100 (60) → −10 (25))	**99** (*R*)	87
5	**5**	1) [b], 2) (−)-**7** (2.0; −100 (60) → −10 (25))	**99** (*S*)	82
6	**6**	1) *n*BuLi (1.7; −100 (120)) 2) (−)-**7** (2.3; −100 (60) → −10 (25))	90 (*S*)	–

[a] Use of 1.1 equiv *n*BuLi gave 97% *ee*. [b] As in entry 3. [c] After distillation.

To ensure efficient deprotonation, the starting ester was deprotonated with 1.5–3 equiv *n*BuLi in THF/hexane at −100 °C (liquid N_2/Et_2O).[11] Protonation of **3**(Li) with (−)-**7** at −100 °C (1 h), followed by gradual warming to −10 °C (25 min) afforded (S)-**3** with 77% *ee*[12] (Table 1, entry 2). In line with our expectations, thiol esters **4**–**6** gave even better results (Table 1, entries 3–6): we were very gratified to find an exceptionally high enantioselectivity of more than 200:1[12] for the protonation of both phenyl thiol ester enolate **4**(Li)[13] and 2-naphthyl thiol ester enolate **5**(Li). In addition, when (−)-**7** and (+)-**7** were used, (*S*)-**4** and (*R*)-**4**, respectively, were obtained with 99% *ee* (Table 1, entries 3 and 4). These values are the highest enantioselectivities yet reported for enolate protonations.

The propensity of the thiol ester enolates to form ketenes by elimination of thiolate, and the fact that ketene **8** was detected by GC (≈ 10%) in all cases studied, led us to also consider an alternative mechanism involving elimination/

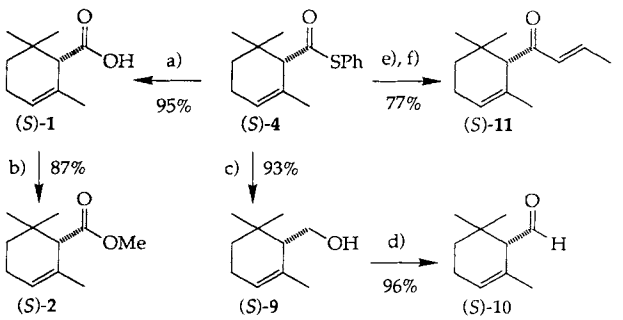


8

enantioselective addition. In order to test this possibility, thiol ester enolate **4**(Li) was treated with lithium 2-naphthyl thiolate prior to protonation with (−)-**7**. The same experiment was then repeated with thiol ester enolate **5**(Li) and lithium phenyl thiolate. In both cases the thiol ester corresponding to the original enolate was isolated with 99% *ee*. The absence of scrambling leads us to the conclusion that a free ketene is not involved. Nevertheless, the addition of lithium phenyl thiolate to **8** in the presence of (−)-**7** was also investigated and showed the same enantiofacial preference as enolate **4**(Li) when treated with (−)-**7**.[14]

A prerequisite for the exceptionally high enantioselectivities obtained in the protonation of aryl thiol ester enolates is the formation of a unique *Z* enolate possessing appropriately differentiated enolate substituents (OLi vs. SAr),[15] coupled with the strong coordination and chelation abilities of ephedrine derivatives.[16] Presumably, protonating agent (−)-**7** or (+)-**7** rapidly forms a 1:1 complex with the enolate leading to a chiral enol/enolate "hybrid" structure,[1a] followed by an irreversible, stereocontrolled C-protonation via an ordered, conformationally rigid transition state.[1a, 3a, 14]

The synthetic value of thiol esters (*R*)-**4** and (*S*)-**4** as versatile chiral building blocks is demonstrated by their ready conversion into (*R*)- and (*S*)-α-cyclogeranic acids ((*R*)-**1** and (*S*)-**1**)[4] (≥ 98% *ee*),[10] methyl esters (*R*)-**2** and (*S*)-**2** (≥ 98% *ee*), (*S*)-α-cyclocitral (**10**)[5a] ($[\alpha]_D^{20} = -743$ (c = 0.05 in $CHCl_3$), 98% *ee*)[10] and (*S*)-α-damascone (**11**)[11] (99% *ee*)[10] (Scheme 1). The saponification (*S*)-



Scheme 1. (*R*)-**4** and (*S*)-**4** as new chiral building blocks (only (*S*) enantiomers are represented). a) H_2O_2 (6.0 equiv), LiOH (3.0 equiv), aq EtOH, 80 °C, 90 min; b) K_2CO_3 (1.2 equiv), MeI (1.2 equiv), acetone, 60 °C, 90 min; c) $LiAlH_4$ (1.0 equiv), Et_2O, 20 °C, 1 h; d) $(COCl)_2$ (1.5 equiv), NEt_3 (5.0 equiv), dimethyl sulfoxide, (2.4 equiv), −70 → 0 °C, 15 min, (Swern oxidation); e) $H_2C{=}CHCH_2MgCl$ (1.70 equiv), LDA (1.05 equiv), THF, 35 °C, 1 h; f) TosOH (cat.), toluene, 20 °C, 15 h.

4 → (*S*)-**1** and the mono-Grignard reaction (*S*)-**4** → (*S*)-**11** merit special comments: the use of LiOOH for the hydrolysis of (*R*)- and (*S*)-**4** without racemization is new.[17, 18] It is not yet clear whether this reaction proceeds via an acyl sulfoxide, followed by O(S) to O(C) rearrangement and hydrolysis of the sulfinyl ester[19] or by normal $B_{AC}2$ (base-catalyzed acyl cleavage via a tetrahedral intermediate) nucleophilic substitution. Conversion of (*S*)-**4** to (*S*)-α-damascone ((*S*)-**11**)[11] with allylmagnesium chloride/LDA proceeds by regioselective deprotonation of the product ketone which favorably competes with nucleophilic attack of a second molecule of the Grignard compound.[20] The fact that no racemization is observed clearly demonstrates that thiol ester (*S*)-**4** is not deprotonated during this process, thus considerably enlarging the scope of possible transformations starting from (*R*)- and (*S*)-**4**.

Experimental Procedure

(*S*)-**4**: A solution of (*R*,*S*)-**4** (40.0 g, 153.8 mmol) in THF (450 mL) was cooled at −100 to −110 °C (Et_2O, liquid N_2) and treated with 1.92 M *n*BuLi in hexane (120.2 mL, 230.8 mmol) (40 min, $T \leq -100$ °C). The solution was stirred between −105 and −100 °C for 2 h. A solution of (−)-**7** (63.7 g, 307.7 mmol) in THF (100 mL) was then added over 50 min at −100 °C. The reaction mixture was cooled to between −102 and −100 °C for 1 h and than allowed to warm up to −10 °C over 25 min. The mixture was poured into vigorously stirred 5% aq. NaOH and extracted with Et_2O. The organic phase was washed successively with H_2O, 5% aq HCl, H_2O, saturated $NaHCO_3$, and saturated NaCl solution, dried over Na_2SO_4, and concentrated. Distillation (110 °C/0.02 Torr) afforded (*S*)-**4** (34.92 g, 87%, ≥ 97% by GC, 99% *ee*[12], $[\alpha]_D^{20} = -421$ ($CHCl_3$, c = 0.04). The combined acidic aqueous phases were basified (10% KOH), extracted (Et_2O), and distilled 90 °C/2 Torr) to afford recovered (−)-**7** (62.4 g, 98%). −(*S*)-**4**: ^{1}H NMR (360 MHz, $CDCl_3$, 25 °C): δ = 0.96 (s, 3 H); 1.05 (s, 3 H); 1.21 (m, 1 H), 1.79 (br. s, 3 H), 1.91 (m, 1 H), 1.98–2.18 (m, 2 H), 2.86 (br. s, 1 H), 5.64 (br. s, 1 H), 7.38 (s, 5 H). IR (neat): $\tilde{\nu}$ = 2970, 1705, 1480, 1440, 980 cm^{-1}. MS (70 eV): *m*/*z*(%): 151 (13), 123 (100), 109 (12), 107 (10), 91 (9), 81 (33).

(*R*)-**4** (≥ 97% pure by GC; 99% *ee*[12], $[\alpha]_D^{20} = +427$ ($CHCl_3$, *c* = 0.06)) was obtained accordingly when (+)-**7** was used.

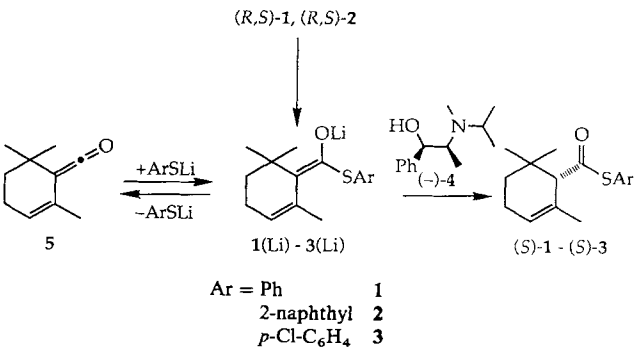
Enantioselective Addition of Aromatic Thiols to a Ketene

By *Charles Fehr*,* *Isabelle Stempf*, and *José Galindo*

In the preceding communication, we reported the enantioselective protonation of *Z* thiol ester enolates **1**(Li) and **2**(Li) with 99% *ee*, using (+)- or (−)-*N*-isopropylephedrine ((+)-**4** or (−)-**4**) as the chiral proton source.[1] A prerequisite for the success of this process is the highly stereoselective formation of a *Z* thiol ester enolate at low temperature, since above −80 °C enolates **1**(Li) and **2**(Li) eliminate lithium thiolate to give ketene **5**.

Both preparative and mechanistic considerations directed our interest to a hitherto unknown reaction, the enantioselective addition of a thiolate to a ketene (e.g. **5** → **1**(Li) → (−)-**1** or (+)-**1**) in the presence of a chiral proton donor.[2, 3] We now describe the successful realization of this procedure (up to 97% *ee*) and its extension to a catalytic version (up to 90% *ee* with 2–5 mol% chiral catalyst).



Scheme 1. Enantioselective addition of thiols to **5**. The deprotonation of racemic **1** and **2** is described in ref. [1].

Slow addition (3–4 h) of (−)-**4** to a solution of **5** and lithium thiophenoxide in THF at −55 °C afforded thiol ester (*S*)-**1** in 84% yield and 95% *ee* (Table 1, entry 1). Thiol ester (*S*)-**3** was obtained analogously in 83% yield and 97% *ee* from **5** and lithium *p*-chlorothiophenoxide (Table 1, entry 2). Since under these conditions the equilibrium between **5** and **1**(Li) (or **3**(Li)) lies on the side of **5**, the reaction rate is controlled by the addition of (−)-**4**. This allows rapid and irreversible C-protonation of the incipient enolate. In this

[+] Postdoctoral fellow at Firmenich SA (1990–1991).

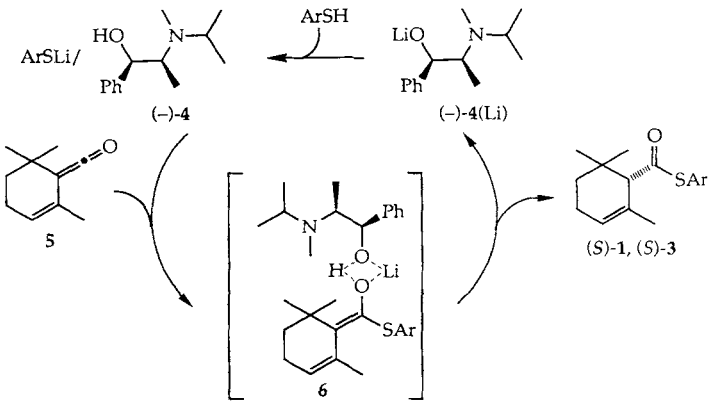
manner, the concentration of (−)-**4** in the reaction medium is kept low, thus minimizing the risk of proton exchange with the thiolate.[4]

Table 1. Results of the reactions following Scheme 1 (stoichiometric and catalytic).

Entry	Ar	Mol % (−)-**4**	T [°C]	Addition time [h]	Reaction time [h]	*ee* [%] [a]	Yield [%] [c]
1	Ph	100	−55	3	3.5	95 [b]	84
2	*p*-Cl-C_6H_4	100	−55	4	4.5	97	85
3	Ph	5	−27	3	3.5	89	86
4	Ph	2	−27	1	1.5	77	87
5	*p*-Cl-C_6H_4	5	−27	3	3.5	90	81
6	*p*-Cl-C_6H_4	2	−27	3	3.5	57	–

[a] For (*S*)-**1** or (*S*)-**3** the *ee* values and absolute configurations were determined by GC of the corresponding (2,6,6-trimethyl-2-cyclohexenyl)methyl acetate using permethylated β-cyclodextrin in OV-1701 as chiral stationary phase. [b] At −78°: 90% *ee* (72% yield); at −30°; 93% *ee* (83% yield). [c] After distillation.

We next tried to devise a catalytic process, in which the aromatic thiol ArSH serves as both nucleophile and proton source in the presence of a catalytic amount of (−)-**4**(Li). We reasoned that if the rate of introduction of ArSH to a solution of **5** and a catalytic amount of (−)-**4**(Li) in THF is maintained low enough to avoid accumulation of ArSH ([ArSH] ≤ [(−)-**4**(Li)]), and if the added thiol is selectively deprotonated by (−)-**4**(Li) and not by the intermediate thiol ester enolate, a catalytic cycle according to Scheme 2 might be possible. It was envisaged that the mixed reagent ArSLi/(−)-**4** would add in a possibly reversible step to ketene **5**; fast and irreversible C-protonation of enolate complex **6** would then liberate (−)-**4**(Li), which re-enters in the catalytic cycle.



Scheme 2. Catalytic enantioselective addition of aromatic thiols to **5**.

Indeed, this concept proved fruitful. Continuous slow addition of PhSH to a mixture containing 1 mol equiv ketene **5** and 5 mol% (−)-**4**(Li) at −27 °C furnished (−)-**1** (86% yield) with 89% *ee* (Table 1, entry 3). The temperature of −27 °C seems to be optimal: at lower temperature the reaction is too slow, and at 0 °C the enantioselectivity drops markedly (≈ 50% *ee*). This is largely due to the consumption of (−)-**4**(Li) by competing addition to **5** and the accumulation of PhSH. When 2 mol% (−)-**4**(Li) was used, the *ee* value of (−)-**1** decreased to 77% (entry 4). We next applied the catalytic conditions (5 mol% (−)-**4**(Li)) to the addition of *p*-chlorothiophenol (entry 5) and obtained thiol ester (*S*)-**3** with 90% *ee*. The slow addition of the thiols (3 h) turned out to be critical for inducing high enantioselectivities. When *p*-chlorothiophenol was added in 1 h, the *ee* value dropped to 53%. Lowering the amount of (−)-**4**(Li) to 2 mol% proved deleterious (57% *ee*, entry 6) and would presumably require even longer addition times.

Strikingly, the same enantioselectivity trends are observed regardless of whether the esters are generated from **5** or from the racemic esters by deprotonation/protonation.[1,4] Therefore, the mechanism for the chirality-inducing step is likely to be the same in both processes. Taking into consideration the successful catalytic process, in which more than 95% of the protons are supplied by an achiral aromatic thiol, we conclude that a tight transition-state-like complex of type **6** immediately precedes an irreversible stereocontrolled C-protonation.[5–7] Inspection of Table 1 and footnote 4 shows a striking parallel between the *ee* values and the pK_a value of the nucleophile. More acidic thiols such as *p*-chlorothiophenol may be more completely deprotonated to the thiolate;[8] in addition, the lower pK_a of aromatic thiol esters **1**–**3** would allow a slower and more selective protonation.

Experimental Procedure

a) (*S*)-**1** under stoichiometric conditions (1 mol equiv (−)-**4**, Table 1, entry 1): A solution of PhSH (1.47 g, 1.36 mL, 13.33 mmol) in THF (10 mL) containing one crystal of 1,10-phenanthroline was treated without cooling (35–40 °C) with 1.60 M BuLi (8.35 mL, 13.33 mmol) until the colorless solution turned bright violet. The solution was decolorized by addition of one drop of (−)-**4**, diluted with THF (40 mL), cooled to −55 °C, and treated with ketene **5** (2.00 g, 13.33 mmol). Over a period of 3 h, a solution of (−)-**4** (2.76 g, 13.33 mmol) in THF (5 mL) was added with a syringe pump (Bioblock Scientific) (temperature −55 °C). The mixture was stirred for 30 min, poured into vigorously stirred 5% aq NaOH, and extracted with Et_2O. The organic phase was washed successively with H_2O, 5% aq HCl, H_2O, saturated $HaHCO_3$, and saturated NaCl, dried (Na_2SO_4), evaporated, and distilled bulb-to-bulb (oven temperature 130 °C/0.05 Torr) to afford (*S*)-**1** (2.90 g, 84%; 95% *ee*) [1]. The combined acidic aqueous phases were basified (10% aq KOH), extracted (Et_2O), and distilled to afford recovered (−)-**4** (2.70 g, 98%).

b) (*S*)-**1** under catalytic conditions (5 mol% (−)-**4**, Table 1, entry 3): A solution of (−)-**4** (322 mg, 0.67 mmol) in THF (5 mL) containing one crystal of 1,10-phenanthroline was treated with 1.60 M BuLi (0.42 mL, 0.67 mmol) until the colorless solution turned bright violet. Upon addition of the first drop of PhSH (55 mg, 0.05 mL, 0.50 mmol) in THF (0.2 mL) the color faded. The solution was diluted with THF (35 mL), cooled to −27 °C (cryostat at −30 °C) and treated with ketene **5** (2.00 g, 13.33 mmol). Over a period of 3 h, a solution of PhSH (1.35 g, 1.25 mL, 12.30 mmol (total amount 12.80 mmol; 0.96 mol equiv)) in THF (5 mL) was added with a syringe pump (Bioblock Scientific) (temperature −27 °C). Stirring was continued for 30 min. Workup as above afforded (*S*)-**1** (2.98 g, 90% based on PhSH (86% based on **5**); 89% *ee*).

[3] For a thio Michael addition/enantioselective protonation, see: A. Kumar, R. V. Salunkhe, R. A. Rane, S. Y. Dike, *J. Chem. Soc. Chem. Commun.* **1991**, 485.

[4] Indeed, when **5** was stirred with an equimolar mixture of lithium thiolate and (−)-**4** in THF at −60 °C for 3 h, (*S*)-**1** or (*S*)-**3** were obtained with diminished enantioselectivities of 81 and 94% *ee*, respectively. Low enantiofacial discriminations (10–40% *ee*) resulted from the reactions of **5** with BnSH or BuSH at −70 °C and with PhOH, MeOH, or (−)-**4** at 20 °C.
[5] For an enantioselective protonation with intramolecular proton return, see: E. Vedejs, N. Lee, *J. Am. Chem. Soc.* **1991**, *113*, 5483.
[6] The postulated mechanism is in line with related nucleophilic additions to ketenes, see refs. [2a, c].
[7] For catalytic enantioselective additions of thiols to cycloalkenones, see: H. Hiemstra, H. Wynberg, *J. Am. Chem. Soc.* **1981**, *103*, 417.
[8] *p*-Chlorothiophenol: $pK_a = 6.96$, thiophenol: $pK_a = 7.76$; see: F. G. Bordwell, H. M. Andersen, *J. Am. Chem. Soc.* **1953**, *75*, 6019. Amine-catalyzed additions of thiols to maleic anhydride also necessitate prior dissociation of the thiol. Indeed, the rate of thiol addition has been found to be proportional to the acid strength of the thiol; *p*-chlorothiophenol reacts faster than *n*BuSH (pK_a 12.4), see: B. Dmuchovsky, B. D. Vineyard, F. B. Zienty, *J. Am. Chem. Soc.* **1964**, *86*, 2874.

Alternating Ferro- and Antiferromagnetic Interactions in a Chainlike Cu^{II} Coordination Polymer**

By *Giovanni De Munno, Miguel Julve,* Francesc Lloret, Juan Faus, Michel Verdaguer*, and *Andrea Caneschi*

One of the best known magneto-structural correlations in systems with magnetic exchange interactions concerns the di-μ-hydroxo-copper(II) complexes $[LCu(OH)_2CuL]^{2+}$.[1] Systematic studies of this family of complexes have established that the singlet–triplet energy gap J is directly proportional to the Cu-OH-Cu bridging angle θ, leading to a singlet ground state for $\theta > 97.5°$ and to a triplet ground state for $\theta < 97.5°$. The value of θ ist strongly influenced by the nature of the terminal ligand L. In this respect we have restricted ourselves to complexes that contain chelating N donor groups as terminal ligands, and for L = diamine[2] antiferromagnetic and for L = 2,2′-bipyridine[2b, 3] ferromagnetic coupling has been observed.

In a recent work, some of us investigated the complex formation between $[Cu(bpym)]^{2+}$ (bpym = 2,2′-bipyrimidine) and OH^- in aqueous solution.[4] The only hydroxo species whose formation was observed in solution is the di-μ-hydroxo $[Cu_2(bpym)_2(OH)_2]^{2+}$ complex. This complex was isolated in the solid state as a perchlorate salt, and displays a relatively strong intramolecular ferromagnetic coupling ($J = 147\ cm^{-1}$), as expected from the θ value (95.0°). Bpym can also act as a bischelating ligand towards transition metal ions,[5] and its ability to transmit antiferromagnetic coupling makes this dinuclear complex a suitable precursor of alternatingly bridged one-dimensional (1D) structures with alternating ferromagnetic (through the hydroxo bridge) and antiferromagnetic (through the bpym bridge) interactions. It should be noted that examples of alternating ferromagnetic/antiferromagnetic exchange in 1D chains are very rare.[6]

Our first attempts along this line led us to prepare the dinuclear precursor **1** and the related Cu^{2+} complex **2**. These

$[Cu_2(bpym)_2(H_2O)_2(OH)_2(NO_3)_2] \cdot 4H_2O$ **1**

$[Cu_2(bpym)(OH)_2(NO_3)_2] \cdot 2H_2O$ **2**

compounds were characterized by elemental analysis, IR spectroscopy, magnetic measurements, and X-ray structural analysis.[7]

The crystal structure of **1** consists of discrete, centrosymmetric di-μ-hydroxocopper(II) dimers with bpym as terminal ligand, weakly coordinated water molecules, and unidentate nitrate anions (bound through an O atom), and molecules of water of crystallization. The coordination geometry around each Cu^{II} ion is approximately octahedral with tetragonal distortion. The two bridging hydroxo groups and the two nitrogen atoms of the bpym ligand form the equatorial plane, and a water molecule and an oxygen atom of a nitrate anion occupy the axial positions (Fig. 1). The Cu–N and

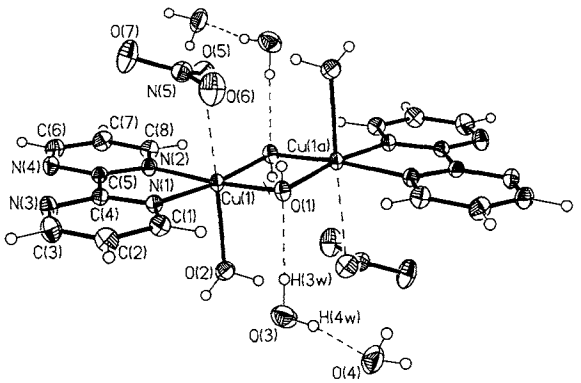

Fig. 1. Molecular structure of **1** (ellipsoids drawn at the 30% probability level). Selected distances [Å] and angles [°] (standard deviations in parentheses): Cu(1)-N(1) 2.014(2), Cu(1)-N(2) 2.018(2), Cu(1)-O(1) 1.944(2), Cu(1)-O(1a) 1.943(2), Cu(1)-O(2) 2.310(2), Cu(1)-O(5) 2.691(2); N(1)-Cu(1)-N(2) 80.7(1), N(1)-Cu(1)-O(1) 96.1(1), N(1)-Cu(1)-O(2) 97.1(1), N(1)-Cu(1)-O(5) 84.3(1), N(1)-Cu(1)-O(1a) 172.5(1), N(2)-Cu(1)-O(1a) 98.0(1), N(2)-Cu(1)-O(2) 91.0(1), N(2)-Cu(1)-O(5) 84.7(1), N(2)-Cu(1)-O(1) 172.7(1), O(1)-Cu(1)-O(1a) 84.3(1), O(1)-Cu(1)-O(2) 95.9(1), O(1)-Cu(1)-O(5) 88.4(1), O(2)-Cu(1)-O(5) 175.3(1), O(2)-Cu(1)-O(1a) 90.3(1) [11].

Cu–O (hydroxo bridge) distances in **1** are very close to those observed in the parent compound $[Cu_2(bpym)_2(H_2O)_4(OH)_2](ClO_4)_2 \cdot 2H_2O$.[4] The main difference between these two compounds is that the axial positions are occupied by two water molecules in the perchlorate species, whereas they are filled by a nitrate group and a water molecule in **1**. The four equatorial atoms are coplanar; no atom deviating from the least-squares plane by more than 0.006(2) Å. The copper atom is displaced by 0.122(1) Å from this plane towards the O(2) atom of the water molecule. Hydrogen bonds link coordinated and uncoordinated water molecules and nitrate anions (some of them are represented by broken lines in Fig. 1). The intramolecular Cu(1)···Cu(1a) separation is 2.881(1) Å; the Cu(1)-O(1)-Cu(1a) bridging angle θ is 95.7(1)°.

The crystal structure of **2** consists of chains of copper(II) ions alternatively bridged by bpym and two hydroxo groups, unidentate nitrate anions (bound through an O atom), and uncoordinated water molecules (Fig. 2). Each copper atom

has a distored square pyramidal coordination. Two nitrogen atoms of bpym and two oxygen hydroxo groups form the equatorial plane, whereas an oxygen atom of a nitrate ion occupies the axial position. The Cu(1) and Cu(2) copper atoms are not found in equivalent positions (small differences concerning bond lengths and angles of their surroundings are observed). The maximum deviations from the N(1)N(2)O(1)O(2) and N(3)N(4)O(1)O(2) mean planes are 0.076(5) and 0.006(5) Å, respectively. The copper atoms rise 0.221(1) [Cu(1)] and 0.227(1) Å [Cu(2)] from their mean basal planes in the direction of the nitrate groups. The dihedral angle between the two equatorial mean planes is 6.2(1)°, whereas the dihedral angle formed between Cu(1)O(1)O(2) and Cu(2)O(1)O(2) is 12.2(2)°. Compound **2** grows as a linear chain with the two nitrate ligands in a *cis* arrangement with respect to the (bpym)Cu(OH)$_2$Cu(bpym) plane. Adjacent pairs of nitrate anions are alternatively up and down along the chain. The nitrate-oxygen atoms of one chain point towards the copper atoms of the nearest one (Fig. 2, bottom) [Cu(1)···O(4) and Cu(2)···O(8) distances are 2.9 and 3.1 Å, respectively]. The Cu(1)···Cu(2) separation [2.886(1) Å] and the Cu-μ-OH-Cu angles [θ = 96.2(2) and 96.1(2)° for Cu(1)O(1)Cu(2) and Cu(1)O(2)Cu(2), respectively] are very close to those of **1**. The intrachain metal–metal distances between the metal atoms separated by bpym are 5.451(1) [Cu(1)···Cu(1b)] and 5.574(1) Å [Cu(2)···Cu(2a)], whereas the shortest interchain metal–metal distance is 7.040(1) Å.

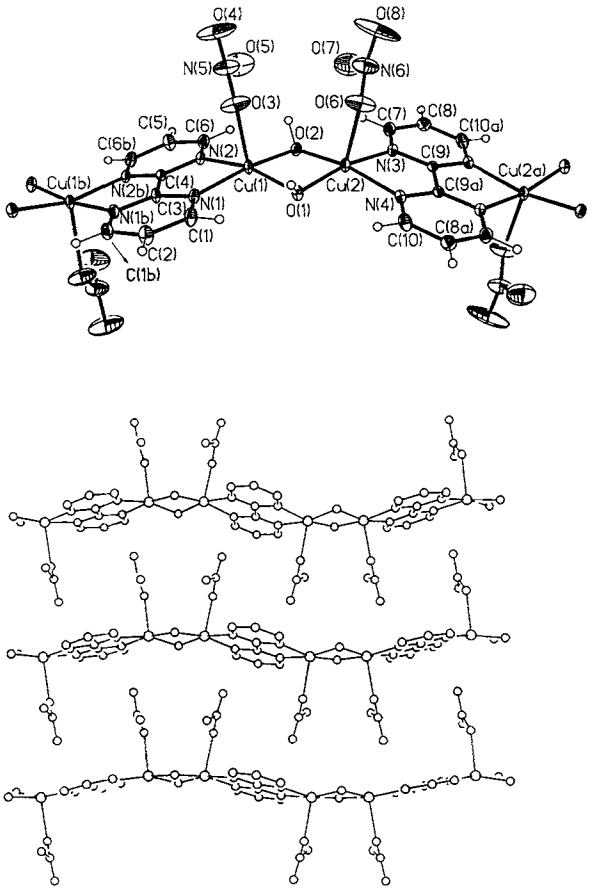

Fig. 2. Crystal structure of **2** (ellipsoids drawn at 30% probability level). Top: View of the alternating chain. Bottom: Arrangement of the chains in the *xz* plane (hydrogen atoms and water molecules have been omitted for clarity). Selected distances [Å] and angles [°] (standard deviations in parentheses): Cu(1)-N(1) 2.054(5), Cu(1)-N(2) 2.035(5), Cu(1)-O(1) 1.921(4), Cu(1)-O(2) 1.923(4), Cu(1)-O(3) 2.298(6), Cu(2)-N(3) 2.036(5), Cu(2)-N(4) 2.055(5), Cu(2)-O(1) 1.931(4), Cu(2)-O(2) 1.930(4), Cu(2)-O(6) 2.320(7); N(1)-Cu(1)-N(2) 81.8(2), N(1)-Cu(1)-O(1) 96.7(2), N(1)-Cu(1)-O(3) 84.1(2), N(1)-Cu(1)-O(2) 171.1(2), N(2)-Cu(1)-O(2) 95.6(2), N(2)-Cu(1)-O(3) 101.0(2), N(2)-Cu(1)-O(1) 163.3(2), O(1)-Cu(1)-O(2) 83.4(2), O(1)-Cu(1)-O(3) 95.4(2), O(2)-Cu(1)-O(3) 104.8(2), N(3)-Cu(2)-N(4) 81.7(2), N(3)-Cu(2)-O(2) 96.0(2), N(3)-Cu(2)-O(6) 96.6(2), N(4)-Cu(2)-O(1) 96.3(2), N(4)-Cu(2)-O(6) 85.2(2), N(4)-Cu(2)-O(2) 166.6(2), O(1)-Cu(2)-O(2) 82.9(2), O(1)-Cu(2)-O(6) 95.9(2), O(1)-Cu(2)-N(3) 167.2(2), O(2)-Cu(2)-O(6) 108.2(2) [12].

The magnetic behavior of **1** is characteristic of compounds with a ferromagnetic interaction with a triplet ground state. The value of $\chi_M T$ (χ_M is the magnetic susceptibility per two Cu^{II} ions) at room temperature is 0.96 cm^3 mol^{-1} K, a value somewhat larger than expected for two uncoupled Cu^{II} ions; $\chi_M T$ increases with decreasing temperature and reaches a plateau at 40 K with $\chi_M T$ = 1.13 cm^3 mol^{-1} K. This value remains constant until 4.2 K. Least-squares fitting through a simple Bleaney–Bowers expression leads to a J value of 114 cm^{-1} and a g value of 2.13.

The $\chi_M T$ value for **2** at room temperature is 0.71 cm^3 mol^{-1} K, a value much smaller than expected for two uncoupled Cu^{II} ions. This value decreases with decreasing temperature and vanishes at temperatures lower than 20 K. The susceptibility curve exhibits a rounded maximum at about 120 K. This compound should exhibit alternating ferromagnetic and antiferromagnetic interactions, since bridging bpym is able to mediate an antiferromagnetic interaction between paramagnetic centers, and the doubly hydroxo bridge with $\theta < 97.5°$, as in **1**, leads to a ferromagnetic coupling. Consequently, the magnetic susceptibility data of **2** were analyzed with a 14-spin ring approximation[13] by using the Hamiltonian $\hat{H} = -J\sum[\hat{S}_{2i}\hat{S}_{2i-1} - \alpha S_{2i}S_{2i+1}]$. This model resulted in an excellent fit to the data (Fig. 3); the best-fit parameters are $J_1 = -140$ cm^{-1}, $J_2 = 105$ cm^{-1}, and

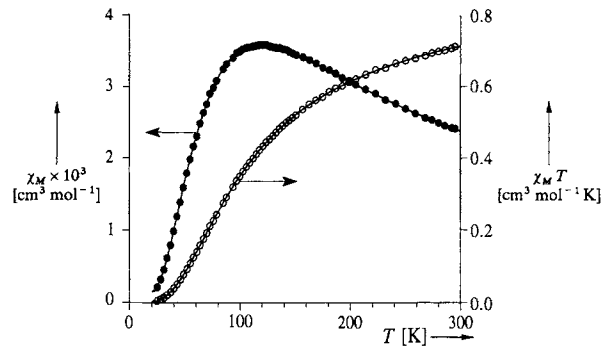

Fig. 3. Plot of $\chi_M T$ (○) and χ_M (●) of **2** versus T. Solid lines correspond to the best theoretical curves.

g = 2.02. The exchange coupling constants of −140 and +105 cm^{-1} are thus accociated with the μ-bpym[14] and di-μ-hydroxo fragments of the alternating chain **2**, respectively. The complex $[Cu_2(bpym)_2(OH)_2]^{2+}$ with its two peripheral potentially bridging ligands appears to be a suitable ferromagnetic building block for the design of new chains with alternating ferro- and antiferromagnetic exchange coupling.

Experimental procedure

1: Blue-green rhombohedral crystals were obtained in good yield by following the previously reported procedure for $[Cu_2(bpym)_2(H_2O)_4(OH)_2](ClO_4)_2 \cdot 2H_2O$ [4].

2: A mixture of **1** and green, chunky single crystals of **2** was obtained by slow evaporation of aqueous solutions containing copper(II) nitrate trihydrate, bpym, and sodium carbonate in a 2:1:1 molar ratio. The yield was low because of the initial precipitation of copper(II) hydroxide. Crystals of **2** were separated manually and studied by X-ray diffraction. The synthesis was repeated until 13 mg of **2** was obtained. This was then used for magnetic measurements. Both **1** and **2** provided correct elemental analysis (C, H, N, Cu).

[11] Bond lengths and angles in the bpym ligand are in agreement with those reported in the literature. The pyrimidyl rings of bpym are planar, but they form a dihedral angle of 1.4(1)°. The dihedral angle between the equatorial N(1)N(2)O(1)O(1a) and bpym mean planes is 5.5(1)°. The nitrate anion is planar as expected. The N–O bond lengths and the intraanion bond angles average 1.255 Å and 120°, respectively. The nitrate ion contributes to the packing by forming hydrogen bonds involving two of its three oxygen atoms.

[12] Bond lengths and angles of the bridging bpym ligands are close to those of the bpym ligands of **1**. Their pyrimidyl rings are planar. However, only the bpym that bridges the Cu(2) and Cu(2a) atoms is planar, whereas the N(1)C(1)C(2)C(1b)N(1b)C(3) and N(2)C(6)C(5)C(6b)N(2b)C(4) pyrimidyl rings form a dihedral angle of 3.4(2)°. Each water of crystallization is linked through hydrogen bonding to two hydroxo groups of different chains. Only one nitrate-oxygen atom [O(5)] contributes to the network of hydrogen bonds.

[14] The value of J_1 is of the same order of magnitude as previously reported values in bpym-bridged Cu^{II} complexes (see ref. [5d] and references therein), the mechanim of the interaction through bis(bidentate) bridges is now well documented.

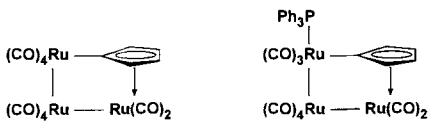
Insertion of a Cp Unit into a Metal–Metal Bond: $[Ru_3(CO)_{10}(C_5H_4)]$ and its PPh_3 Derivative**

By *Daniel Heineke* and *Heinrich Vahrenkamp**

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

The field of cyclopentadienylmetal complexes, the oldest and most developed in organotransition metal chemistry, is still fertile and of increasing utility. Recent examples of new compound types[1] and new applications[2] underline this. While only mononuclear cyclopentadienyl complexes have been of practical value, new compositions or structural types are more likely to be found in polynuclear compounds.[3] We demonstrate this here by describing the synthesis and structure of the new Ru_3 clusters **1** with μ_2-η^5:η^1-C_5H_4 units.

Compounds **1a**, **b** were found in the course of our systematic studies of reactions of $[Ru_3(CO)_{12}]$ with phosphorus ylides.[4] These mostly multistep reactions normally lead to organometallic products in which the initially ylidic P–C bond is maintained. An exception to this rule is the reaction between $[Ru_3(CO)_{12}]$ and $Ph_3P{=}C(CH)_4$. Heating the reagents under reflux in cyclohexane for 1 hour results in complete conversion, and after chromatography with hexane over silica gel, yellow **1a** (49%), red $[Ru_3(CO)_{11}PPh_3]$ (8%), and yellow **1b** (29%) are isolated. Thus, the two constituents of the phosphorus ylide are separated and incorporated in one (**1b**) or two (**1a** and $[Ru_3(CO)_{11}PPh_3]$) triruthenium clusters.



1a **1b**

The compositions of **1a**, **b** were ascertained by mass spectra and NMR data.[5] But only the structure determination of **1b**[6] revealed the new structural type with an open Ru_3 triangle held together by the μ_2-η^5:η^1-C_5H_4 unit (Fig. 1). This C_5H_4 unit is clearly bonded as a metalliocyclopentadienyl (uniform Ru1–C and C–C bond lengths, long Ru2–C1 bond) rather than a cyclopentadienylidene unit (which would bind as a carbene with Ru2 and as an olefin with

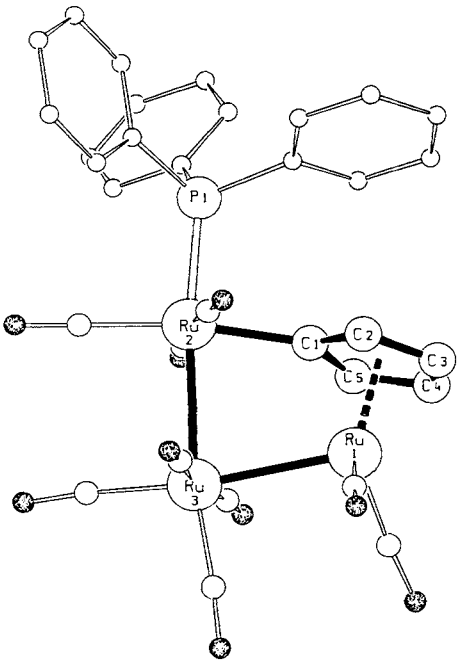

Fig. 1. Molecular structure of **1b**. Selected bond lengths [pm]: Ru2-C1 213.0(5), Ru1-C1 227.1(5), Ru1-C2 222.6(6), Ru1-C3 223.0(6), Ru1-C4 223.4(7), Ru1-C5 222.3(6), C1-C2 143.1(8), C2-C3 142.8(9), C3-C4 138.9(9), C4-C5 143.5(9), C5-C1 143.6(8).

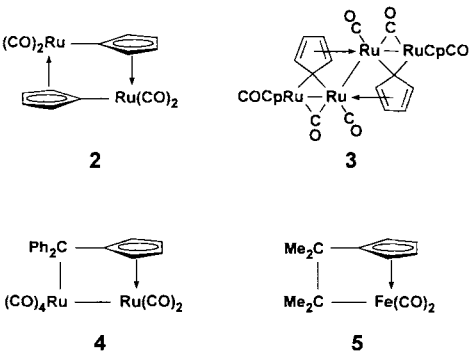
Ru1).[7] Both of these bonding types are known in the chemistry of ruthenium in, for example, **2**[8] and **3**,[9] but this structure in which the cluster geometry is fixed by insertion of a linking Cp unit into a metal–metal bond is, to our knowledge, unprecedented. Compound **4**[10] is, however, an isolobal analogue of **1**, and the mononuclear analogue **5**[11] completes this isoelectronic series of M_3, M_2, and M_1 metallacycles.



The reaction pathway leading to **1a, b** is as uncommon as their structure. Almost all coordination compounds of $Ph_3P{=}C(CH)_4$ contain this ylide as an intact ligand.[12] Its reactions with $[Os_3(CO)_{10}(MeCN)_2]$, for example, produce closed Os_3 clusters with doubly and triply bridging $Ph_3PC_5H_3$ units.[13] Although the cleavage of phosphorus ylides to generate carbene ligands is not unusual,[12] the separation of the oppositely charged Ph_3P and C_5H_4 fragments and insertion of the cyclopentadienylide fragment into one Ru–Ru bond of $[Ru_3(CO)_{12}]$ are remarkable. Clusters **1a, b** thus extend the long list of product types from reactions of $[Ru_3(CO)_{12}]$ and phosphorus ylides[4, 14] and underline once again the valuable balance of stability and reactivity in triruthenium clusters.

Cs_3AuO, the First Ternary Oxide with Anionic Gold**

By *Claus Feldmann* and *Martin Jansen**

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday.

Gold has the highest electron affinity among the metals, 222.73 kJ mol^{-1}, a value comparable to that of iodine (295.30 kJ mol^{-1}).[1] Accordingly, the unusual properties of CsAu, which crystallizes with the CsCl structure type, are attributed to ionic bonding and thus the existence of anionic gold (Au^-).[2] Because of this singular feature,[14] this compound has been intensively studied in recent years. It behaves as a semiconductor with a band gap of approximately 2.6 eV.[3] There is still considerable disagreement whether the cesium auride can be viewed as a purely ionic crystal Cs^+Au^-. Differing ionic contributions to chemical bonding have been discussed, and a value of roughly around 50% is

the most popular;[2b, 2e, 4] even covalency has been considered.[5] The picture of a pure ionic crystal is weakened by the amazingly high electronic conductivity observed[3b, 6] in comparison to that expected for an ionic model, and by the presence of disorder (Au on Cs positions and vice versa) on the order of 5%.[7, 8] To gain insight into the bonding in CsAu from its chemical behavior, we started conducting solid-state reactions with CsAu to determine whether Au^- ions are transported in solid state through diffusion. We have observed the interdiffusion of Cs_2O and CsAu and established that a new crystalline ternary compound, Cs_3AuO, is formed through transport in the solid. Crystals of higher quality are obtained when CsAu is introduced as the constituting elements in the presence of excess cesium. The rod-shaped ($0.15 \times 0.15 \times 0.38$ mm^3), red-brown, transparent crystals are extremely oxygen and moisture sensitive.

According to the results of X-ray powder diffraction, which were verified by a single-crystal structure determination,[9] Cs_3AuO crystallizes as a hexagonal perovskite with the anti-$CsNiCl_3$ structure type,[10] in which Au and O adopt the crystal-chemical function of Cs and Ni, respectively (Fig. 1). The OCs_6 structural unit is stretched along the threefold axis; the Cs–O distances correspond roughly to those in Cs_2O.[11] Each gold atom is surrounded by 12 cesium atoms in the form of a hexagonal cuboctahedron. The increase in the (averaged) Au–Cs distance (4.08 Å) from that in CsAu (3.69 Å)[2a] is the result of an increase in the coordination number from 8 to 12, and the extent of lengthening corresponds well to that expected. The strong distortion of the polyhedron around Au is striking: the distance between Au and the six Cs neighbors in the a/b level is 3.917(2) Å, and between Au and the 2×3 Cs atoms above and below this layer 4.242(3) Å.

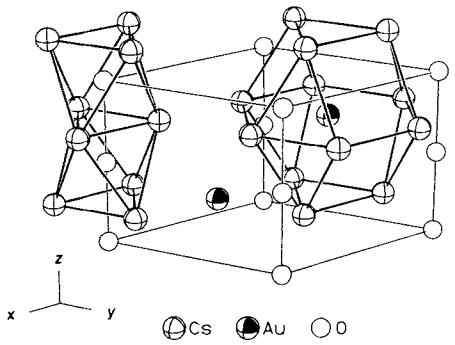

Fig. 1. Unit cell of Cs_3AuO; the polyhedra surrounding Au^- and O^{2-} are emphasized; d(O–Cs) = 2.796(2) Å (6×), d(Au–Cs) = 3.917(2) Å (6×), and 4.242(3) Å (6×).

Every formulation other than the corresponding ionic one, $(Cs^+)_3Au^-O^{2-}$, would require the existence of energetically very high-lying electronic states as well as electron delocalization, which can be excluded due the transparency of the crystals (even in thick layers). Thus, the ionic formulation must correctly describe the fundamental bonding situation. This interpretation is supported by a comparison of the gold L_3-XANES (XANES = X-ray Absorption Near-Edge Structure) spectra of Au_2O_3, $AuCl_3$, AuCN, AuCl, Au, CsAu, and Cs_3AuO (Fig. 2). The area of the prepeak at about 12 keV correlates with the number of unoccupied Au 5d states and is therefore a sensitive indicator for the valence state of gold. One can recognize that the density of free states in the region of the Au valence levels for Cs_3AuO is even lower than that for CsAu. We consider this to be evidence that Au in this compound has an even more distinct anionic character.[12]

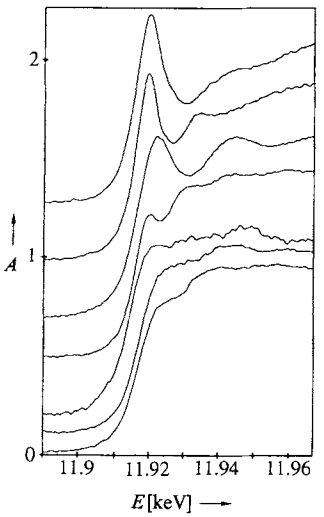

Fig. 2. Au L_3-XANES spectra of Au_2O_3, $AuCl_3$, AuCN, AuCl, Au, CsAu, and Cs_3AuO (from top to bottom).

Experimental Procedure

Cs_3AuO was synthesized by the interdiffusion of equal molar amounts of CsAu (0.601 g, 1.82 mmol) [8] and $CsO_{0.49}$ (0.513 g, 1.82 mmol) [11]. The intimately ground binary components Cs_2O and CsAu were annealled at 300 °C in a gold crucible under argon for 3 weeks. Only small, strongly intergrown crystals of Cs_3AuO were found in the resulting reaction product.

Large, rod-shaped, red-brown, transparent crystals were isolated according to the following method: Equal molar amounts of $CsO_{0.49}$ (0.986 g, 3.50 mmol) and fresh precipitated gold (0.690 g, 3.50 mmol) [13] were heated at 200 °C in a melt of distilled cesium (1.892 g, 14.20 mmol) in a Duran glass tube under argon for eight weeks. The excess cesium was then distilled off under high vacuum (0.01 Pa). To improve the crystal quality, the single-phase residue was annealled for an additional five days at 200 °C in a Duran glass ampule under argon and then cooled slowly (5 K h^{-1}).

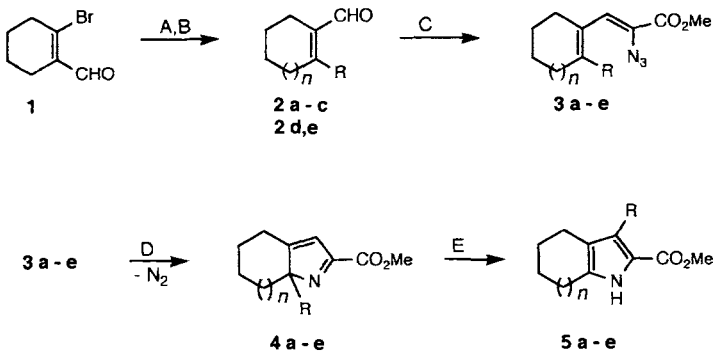
Cycloalkano-2*H*-pyrrole as a Stable Intermediate in the Conversion of β-Cycloalkenyl-α-azidoacrylates to Cycloalkano-1*H*-pyrroles**

By *Claus Vogel,* Bernd Schnippenkötter, Peter G. Jones,* and *Peter Bubenitschek*

The thermolysis of substituted vinyl azides in solution has been used to synthesize N-heterocycles such as 2*H*-azirines, 1*H*-pyrroles, indoles, isoquinolines, and benzazepines.[1, 2] In several cases, substituted 2*H*-pyrroles were formed by the thermolysis of 4,4-disubstituted 1-azidobutadienes although with poor yields and as a mixture with the corresponding 1*H*-pyrroles or pyridines.[3] We have found that the thermolysis of β-cycloalkenyl-α-azidoacrylates results in the quantitative formation of substituted cycloalkano-2*H*-pyrroles. In the thermolysis of α-azidocinnamates with *ortho*-alkenyl[2] or -1,3-butadienyl side chains,[4] the vinyl azides or the vinylnitrenes react almost exclusively with these side chains. In our studies of vinyl azides **3**, the vinyl azide unit is not attached to an aryl group but to a cycloalkene bridge in conjugation with a vinyl, phenyl, styryl, or 4-phenylbuta-1,3-dienyl side chain. This structure causes the thermolysis to proceed along a different reaction path.

The conjugated aldehydes **2a–c** were prepared from 2-bromocyclohex-1-ene-1-carbaldehyde (**1**)[5] by the following reaction sequence (Scheme 1): 1. Wittig or Wittig–Horner



a: R = CH=CH$_2$; *n* = 1; **b**: R = CH=CHPh; *n* = 1;
c: R = CH=CH-CH=CHPh; *n* = 1; **d**: R = Ph; *n* = 1; **e**: R = Ph; *n* = 0

Scheme 1. Synthesis of the substituted 2*H*- and 1*H*-pyrroles **4** and **5**, respectively. Reaction conditions: A: $(EtO)_2P(O)CH_2R^1$/NaH or $Ph_3P{=}CH_2$, THF, room temperature, 70–85%; B: 1.2 equiv *t*BuLi, THF, −78 °C, 2. DMF, −78 °C → room temperature, 80–85%; C: $N_3CH_2CO_2Me$, NaOMe, MeOH, 0 °C → room temperature, 40–60%; D: cyclohexane, xylene, or DMF, 80 °C, 40 min, quantitative; E: for **4a–c**: xylene (or DMF) at reflux, 140 °C, 4 h, 95%; for **4d, e**: tetralin, 200 °C, 2 h, 95%.

reaction (A) for the synthesis of the unsaturated side chain; 2. Br/Li exchange (B) with *tert*-butyllithium following the method of Seebach et al.[6] and subsequent formylation with dimethylformamide (DMF). The functionalized aldehydes **2d, e** were obtained from 1-phenylcyclohexene and 1-phenylcyclopentene, respectively, by Vilsmeier formylation with $POCl_3$/*N*-methylformanilide.[7] The methyl α-azidoacrylates **3a–e** were prepared by the condensation of **2a–e** with methylazidoacetate in the presence of sodium methoxide in methanol (C), according to the method of Knittel to recover methyl α-azidocinnamate.[8] This condensation does not occur if the substituent R in **2** can form a conjugated enolate from the starting aldehyde (e.g. R = methyl).

The thermolysis of vinyl azides **3** in solution at 80 °C (40 min in cyclohexane, xylene, or DMF) proceeded with cleavage of N_2 and gave the substituted cycloalkano-2*H*-pyrroles **4** in quantitative yield. The cyclization products **4a–c** are stable up to 130 °C, **4d, e** even up to 190 °C. Only when the products are heated in refluxing xylene (140 °C, 4 h; **4a–c**) or in tetralin (200 °C, 2 h; **4d, e**) does a slow rearrangement to the substituted 1*H*-pyrroles **5** occur (Scheme 1).

In the thermolysis of vinyl azides, cleavage of nitrogen leads to vinyl nitrenes as the reactive intermediates.[1–3] In the reaction described here, neither the vinyl azide nor the vinyl nitrene reacted with the unsaturated substituent R in **3a–c**, although this was to be expected based on the findings for α-azidocinnamates with unsaturated *ortho* side chains.[2, 4] The products of a 1,7-electrocyclization involving the alkenyl or the phenyl substituents could not be detected. The exclusive formation of the cyclization products **4** can be explained by the quantitative 1,5-electrocyclization of a dienyl nitrene. The cyclization to afford a five-membered ring system apparently proceeds considerably faster than the reaction with the unsaturated side chain. The converse is the case with the corresponding azidocinnamates, whose cyclization would lead to indoles.[1, 2]

The annelated 2*H*-pyrroles **4** rearrange only at high temperatures, presumably by a double 1,5 shift of the substituent R, to give the annelated 1*H*-pyrroles **5**. The first 1,5 shift should lead to the corresponding 3-substituted 3*H*-pyrroles. Then a second 1,5 shift of R and subsequent 1,3 H-migration and aromatization gives **5**. This could well explain the thermal stability of the product **4**.

In the ^1H NMR spectra (400 MHz) of **4a–d**, it is notable that a clearly resolved signal is found for each of the aliphatic ring protons. The structure deduced from the spectroscopic data of the rearranged products **5** was confirmed for **5b** by X-ray crystallography.[9]

Previously, 2*H*-pyrroles were difficult to synthesize. The quantitative synthesis of annelated 2*H*-pyrroles described here provides a good synthetic route to this class of compounds and to isomeric 1*H*-pyrroles.

Experimental Procedure

General thermolysis method: A 0.05 M solution of **3** or **4** was heated (for solvent, temperature, and time, see Scheme 1). After the solvent was distilled off under reduced pressure, the residue was purified by flash chromatography (silica gel, hexane/ethyl acetate 9:1 to 2:1). ^1H NMR data for **4a**: (400 MHz, $CDCl_3$, TMS): δ = 0.94 (dt, *J* = 3.9 Hz, 13.2 Hz, 1H); 1.11 (qt, *J* = 4.4 Hz, 13 Hz, 1H); 1.59 (qt, *J* = 3.5 Hz, 13.4 Hz, 1H); 1.80 (m, 1H); 2.06 (m, 1H); 2.33 (tdd, *J* = 1.7 Hz, 5.7 Hz, 13.1 Hz, 1H; 4-H); 2.68 (m, 1H); 2.84 (m, 1H); 3.92 (s, 3H; OCH_3); 5.00 (d, *J* = 17.5 Hz, 1H; *trans* H of vinyl-CH_2); 5.13 (d, *J* = 10.3 Hz, 1H; *cis* H of vinyl-CH_2); 5.91 (dd, *J* = 17.5 Hz, 10.3 Hz, 1H; vinyl-H); 6.49 (d, *J* = 1.7 Hz, 1H; 3-H).

Catalytic Hydrogenation with Rhodium Complexes Containing dipamp-pyrphos Hybrid Ligands**

By *Ulrich Nagel** and *Thomas Krink*

The hydrogenation of olefins with rhodium phosphane complexes as catalysts[2] under homogeneous conditions is well established, and chiral complexes and prochiral olefins[3] are known to give rise to mixtures of enantiomers with various compositions. In related work a series of catalysts has been developed for the hydrogenation of dehydroamino acids.[4] Among other empirically determined properties, efficient catalysts should have C_2 symmetry.[5] The development of P- and C-chiral bisphosphane ligands[6] with additional ether groups[7] allows a systematic investigation of the influence of the symmetry on the activity and enantioselectivity of the catalyst.

The introduction of one *ortho* substituent into one of each pair of phenyl groups of diop was described recently.[8] In parallel work we succeeded in synthesizing ligands that can be considered combinations of the two "classic" ligands employed successfully in hydrogenation, dipamp and pyrphos (Fig. 1).[9] In our case the similarity is quite profound, since both dipamp and pyrphos are 1,2-bisphosphanes.

Replacement of one phenyl group on each of the phosphorus atoms in pyrphos with an *ortho*-anisyl group leads to the mixture of diastereomers **1a–c**.[10] The synthesis of these ligands, their purification, and the preparation of the catalysts are described in ref.[1]; in this communication we report on the results in asymmetric hydrogenation.

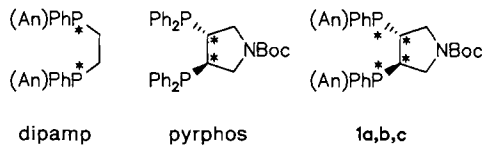

Fig. 1. The structures of dipamp and pyrphos, and their combination to give **1a**, **1b**, **1c**. The stars mark stereogenic centers. An = 2-methoxyphenyl (anisyl), Boc = *tert*-butoxycarbonyl.

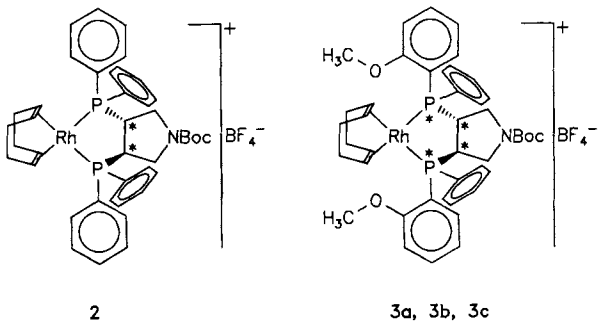

Fig. 2. The structures of catalysts **2**, **3a**, **3b**, and **3c**. The spatial arrangement of the aryl groups in **3a**, **3b**, and **3c** is shown in Figure 3.

Whereas **2** and **3a,b** have C_2 symmetry, **3c** is asymmetric (Fig. 3).[11] By comparing **2** with **3a,b**, it is possible to examine the influence of the additional ether groups while retaining the C_2 symmetry. The consequences of a reduction in symmetry are revealed by a comparison of the activity and enantioselectivity of **3c** with that of **2** and **3a,b**.

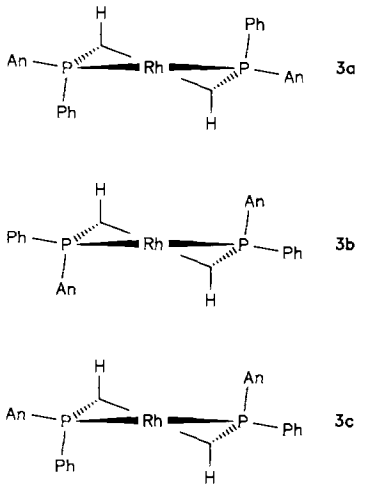

Fig. 3. The spatial arrangement of the aryl groups in **3a**, **3b**, and **3c**. Only the important portions of the molecules are shown (view along the C_2 axis in **3a** and **3b**).

Since both the enantioselectivity and the rate of the catalysis depend on many external parameters, we varied pressure and temperature. The results of these investigations are shown in Figures 4–7 for the hydrogenation of *Z*-α-acetamidocinnamic acid to (*S*)-acetylphenalanine with catalysts **2** and **3a–c**.

The introduction of the additional methoxy groups in catalyst **2** has rate-increasing (**3a** and **3c**) and rate-decreasing

[**] Enantioselective Catalysis, Part 10. This research was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie. We thank Priv.-Doz. Dr. B. Koppenhoefer, Tübingen, for valuable suggestions for the analysis of enantiomers and J. M. Briody, Maynooth, for the measurement of some of the enantiomeric excesses. – Part 9: [1].

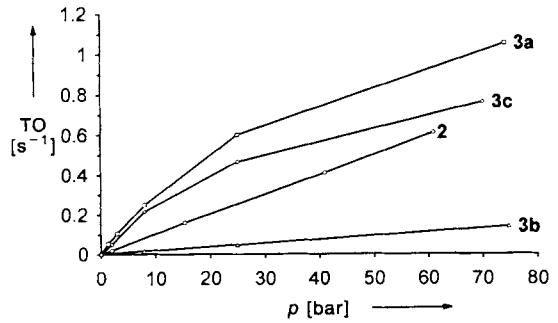

Fig. 4. Reaction rates for the hydrogenation of *Z*-α-acetamidocinnamic acid with catalysts **2**, **3a**, **3b**, and **3c** at 25 °C and at different H_2 pressures. TO = turnover.

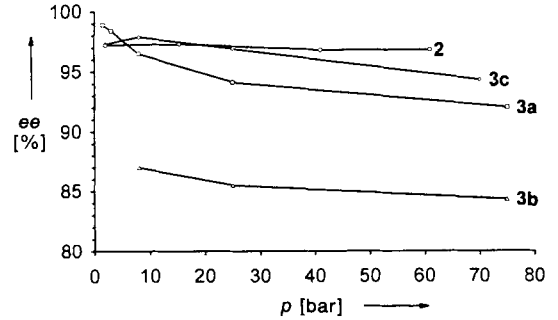

Fig. 5. *ee* Values of the (*S*)-*N*-acetylphenylalanine obtained with catalysts **2**, **3a**, **3b**, and **3c** at different H_2 pressures (reaction conducted at 25.0 °C).

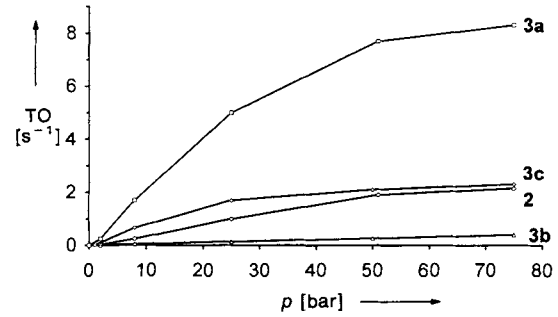

Fig. 6. Reaction rates for the hydrogenation of *Z*-α-acetamidocinnamic acid with catalysts **2**, **3a**, **3b**, and **3c** at 50 °C and at different H_2 pressures.

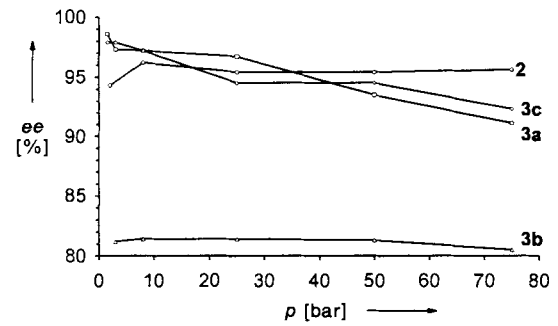

Fig. 7. *ee* Values of the (*S*)-*N*-acetylphenylalanine obtained with catalysts **2**, **3a**, **3b**, and **3c** at different H_2 pressures (reaction conducted at 50.0 °C).

effects (**3b**) because of the effect on ligand symmetry and the resulting relative position to rhodium. The enantiomeric excesses obtained for the hydrogenation of *Z*-α-acetamidocinnamic acid also depend on ligand symmetry. A direct comparison of C_2 symmetry with asymmetry (C_1 symmetry) is possible with compounds **3a**, **3b**, and **3c**, since these are stereoisomers with the same empirical formula. No comparisons of this type have been previously reported. Remarkably, the results from the reaction with asymmetric diastereomer **3c** are almost as good as, and in part even better than, those with **3a**.[12] At least in this case, C_2 symmetry is not essential for high enantiomeric excesses. Whereas the parent compound **2** provides constant enantiomeric excesses over the entire pressure range, the *ee* values obtained with the catalysts **3a**, **3b**, and **3c** decrease to different extents. At pressures over 40 bar **2** is the most selective catalyst; in the low-pressure range **3a** and **3c** are definitely superior to the parent compound **2**. The hybrid ligand in catalyst **3a** (matched pair) combines the partial structures *R*-pyrphos (which gives (*S*)-*N*-acetylphenylalanine in 97% *ee*) and *S*-dipamp (which give the *S* isomer in 95% *ee*) and provides the *S* isomer in up to 99% *ee*. The unsymmetric hybrid ligand in **3c** from *R*-pyrphos and *meso*-dipamp yields the *S* isomer in up to 98% *ee* but is remarkably superior to the matched pair **3a** at higher pressures. In each case the pyrphos structure element dominates the selectivity. In the optimization of a ligand the isoinversion principle[13] helps to only a limited extent. Our measurements show that the selectivities obtained at 25 °C are higher than those at 50 °C; however, the differences are not particularly distinct.

Experimental Procedure

The preparation of the catalysts **2**[6] and **3a–c**[1] were described previously. The hydrogenations were conducted in an autoclave with a stirrer with 5–10 μmol catalyst, 5–10 mmol substrate, and 50 mL methanol. The reaction mixture was initially under argon, which was removed by evacuation, and hydrogen was introduced. The hydrogenation started when stirring started. The H_2 consumption could be determined at any point in the reaction with a resolution of ±0.01 mmol. The hydrogenation reaction has three stages: 1) Saturation phase: when the stirrer is started hydrogen is stirred into the solution (ca. 3 min). 2) Induction phase: in low-pressure hydrogenations (up to 10 bar) the rate of the hydrogenation initially increases only slowly (probably until all of the cyclooctadiene (cod) of the catalyst is hydrogenated). 3) Hydrogenation phase: the rate of the hydrogenation is constant at the selected catalyst/substrate ratio. Workup: The solvent was removed by distillation, and the crude product was dissolved in aqueous NaOH solution and extracted three times with dichloromethane and diethyl ether. The aqueous phase was acidified to pH 3 with 2N HCl. The *N*-acetylphenylalanine formed was extracted with ethyl acetate. Analysis: A solution of *N*-acetylphenylalanine in methanol was converted to the corresponding methyl ester by treatment with HCl/methanol. Baseline separation of the enantiomers was achieved by gas chromatography (GC: Chrompack CP 9000 with a flame-ionization detector; integration: Chrompack integrator with the Mosaic program for data evaluation; capillary column coated with (*S*)-chirasil-Val, standards for calibration prepared from the racemate and a sample of (*S*)-*N*-acetylphenylalanine (99.95% *ee*)).

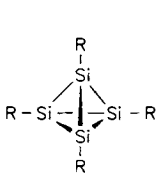
By using the isoinversion principle one can predict that for this type of catalysis a catalyst that has been optimally tailored to the substrates will provide the best *ee* values at 49 °C and 2.3 bar.

Tetrakis(tri-*tert*-butylsilyl)-*tetrahedro*-tetrasilane (tBu$_3$Si)$_4$Si$_4$: The First Molecular Silicon Compound with a Si$_4$ Tetrahedron**

By *Nils Wiberg,* Christian M. M. Finger,* and *Kurt Polborn*

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

In a recently published review on the cluster chemistry of the heavier elements in the fourth main group (Si, Ge, Sn), which is still in its infancy, S. Masamune et al. state in their concluding remarks that the syntheses of tetrasilatetrahedrane **1**, disilyne **2**, and 1,1,1-pentasilapropellane **3** are currently the greatest challenges for silicon chemists.[1] We report here on our achievement of one of these goals—the synthesis of a molecular silicon compound with a Si$_4$ tetrahedron (see note[14] with regard to the question of a disilyne).



1 (here R = SitBu$_3$)

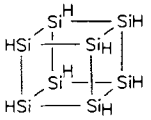
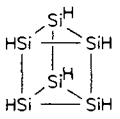
[**] Sterically Overloaded Silicon Compounds, Part 6, Silicon Compounds, Part 96. This research was supported by the Deutsche Forschungsgemeinschaft. We thank Dr. J. Evers (Institut für Anorganische Chemie der Universität München) for the measurement and interpretation of various rotating crystal and Weissenberg photographs, and Dr. O. Seligmann (Institut für Pharmazeutische Biologie der Universität München) for recording a FAB mass spectrum. – Part 5 and 95: J. Kovács, G. Baum, G. Fritz, D. Fenske, N. Wiberg, H. Schuster, K. Karaghiosoff, *Z. Anorg. Allg. Chem.* **1993**, *619*, 453.

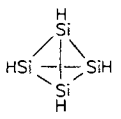
According to ab initio calculations, the strain energy of (SiH)$_n$ polyhedra increases with the number of three-membered rings in the polyhedron framework (see Scheme 1).[2, 3]



***hexahedro*-octasilane**
(391 kJ mol^{-1}; 239.6 pm)



***triprismo*-hexasilane**
(476 kJ mol^{-1}; 237.5 pm)



***tetrahedro*-tetrasilane**
(590 kJ mol^{-1}; 231.4 pm)

Scheme 1. (SiH)$_n$ Polyhedra; calculated strain energies and Si-Si distances in parentheses [2, 3].

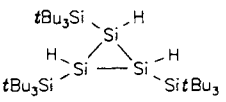
One expects the difficulty of the syntheses of these fascinating polyhedral compounds[4] to follow the same trend. Indeed, until now only *hexahedro*-octasilane derivatives (Si substituents: SiMe$_2$$tBu, CMe_2$CHMe$_2$, 2,6-Et$_2C_6H_3$) have been synthesized.[5] (For the heavier homologue germanium, a *triprismo*-hexagermane with CH(SiMe$_3$)$_2$ substituents on the germanium atoms has also been generated.[6]) Since compounds with a tetrahedral framework constructed of atoms of one element exist for most of the elements near silicon in the periodic table, boron,[7] aluminum,[8] gallium,[9] carbon,[10] phosphorus (P$_4$), and arsenic (As$_4$), it is especially puzzling that neither a *tetrahedro*-tetrasilane nor a *tetrahedro*-germane have been synthesized previously.

A *tetrahedro*-tetrasilane Si$_4$R$_4$ should be more stable than either a *hexahedro*-octasilane or a *triprismo*-hexasilane if it has sterically demanding R groups (see comment[3]). Thus we chose to synthesize the target tetrahedron molecule **1** with tri-*tert*-butylsilyl groups (R = SitBu$_3$, "supersilyl") (for more on the name supersilyl see comment[8]). Since Si_4^{4-} tetrahedra are anionic components in alkaline and alkaline earth silicides such as NaSi, KSi, and BaSi$_2$, it was reasonable to try to give these "molecular freedom" (e.g. $Si_4^{4-} + 4RX \rightarrow Si_4R_4 + 4X^-$). All attempts at derivatization have failed thus far (one reason for this is the high reducing ability of the silicides; see comment[11, 12]).

Another imaginable approach, the dehalogenation of the previously unknown tBu$_3$Si–SiCl$_3$ with sodium, did not provide access to **1**, although the analogous reaction of the less bulky tBuMe$_2$Si–SiBr$_3$ led to *hexahedro*-octasilane (Si substituents = SiMe$_2$$t$Bu).[5] Treatment of tBu$_3$Si–SiCl$_3$ with sodium in benzene at 80 °C did not give **1**; instead NaCl formation and hydrogen uptake led to a number of products including 1,2-bis(supersilyl)disilane **4**, which can be brominated easily to provide tetrabromobis(supersilyl)disilane **5**, and the very interesting tris(supersilyl)cyclotrisilane **6**.[13]

tBu$_3$Si–SiH$_2$–SiH$_2$–SitBu$_3$
4

tBu$_3$Si–SiBr$_2$–SiBr$_2$–SitBu$_3$
5



6

At this point we found that **1** (R = SitBu$_3$) can be obtained according to Equation (a) by the reaction of **5** with supersilylsodium tBu$_3$SiNa.[14] Compound **4**, the precursor

$$2\,\mathbf{5} + 4\,t\mathrm{Bu_3SiNa} \longrightarrow \mathbf{1}\ (\mathrm{R} = \mathrm{Si}t\mathrm{Bu_3}) + 4\,t\mathrm{Bu_3SiBr} + 4\,\mathrm{NaBr} \qquad \text{(a)}$$

of **5**, can be synthesized by treating supersilylchlorosilane tBu$_3$Si–SiH$_2$Cl, accessible from SiH$_2$Cl$_2$ and tBu$_3$SiNa, with sodium; the yields here are much better than by the previously mentioned approach.

Compound **1** forms intensely yellow-orange needles, which change color (to deep-red) reversibly upon heating and do not melt below 350 °C. The crystals display high thermo- and photostability and are stable to water and air. Compound **1** cannot be reduced by sodium in benzene in the presence of [18]crown-6 but reacts with oxidants like tetracyanoethylene and Br_2.

X-ray quality crystals of pure **1** have not yet been obtained; however, when a mixture of **1** and hexa-*tert*-butyldisilane tBu$_3$Si–SitBu$_3$ ("superdisilane") was recrystallized from hexadeuteriobenzene,[15] yellow-orange rectangular cubes formed with the composition $2(t\text{Bu}_3\text{Si})_4\text{Si}_4 \cdot (t\text{Bu}_3\text{Si})_2 \cdot \text{C}_6\text{D}_6$ **1a**, whose structure was established by X-ray crystallography.[16] The cubic unit cell (Fig. 1) contains two sets of four molecules of **1** (tetrahedra 1 and 1A), which are located in the eight cube quadrants, as well as four molecules of superdisilane (occupation of the middle of every edge and the center of the cube) and four molecules of hexadeuteriobenzene (occupation of all corners and middles of all the faces of the cube). All the molecules are positioned on threefold symmetry axes. The superdisilane molecules fill the large gaps between the almost sphere-shaped molecules of **1** and thereby apparently stabilize the structure of the crystal.

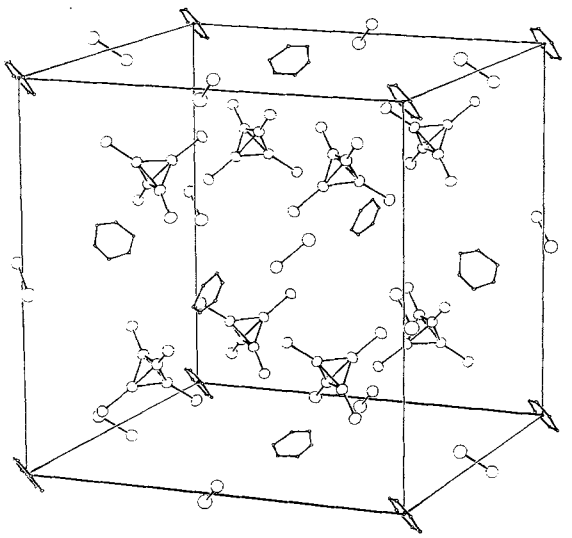


Fig. 1. Cubic unit cell of **1a** (all tBu groups were left out for clarity; the C atoms of C_6D_6 have effective radii; all molecules are found on threefold symmetry axes).

As expected, the units of **1** in crystal **1a** (Fig. 2) are constructed of Si_4 tetrahedra, which have two different Si–Si distances (tetrahedron 1: 233.0 and 231.5 pm; tetrahedron 1A: 232.6 and 234.1 pm) as a consequence of the crystal symmetry. These distances are somewhat longer than those calculated for unsubstituted *tetrahedro*-tetrasilane (231.4 pm; for comparison, in cyclotrisilanes: Si–Si distance in $[(t\text{BuCH}_2)_2\text{Si}]_3$ 239.1 pm, in $(t\text{Bu}_2\text{Si})_3$ 251.1 pm;[18] see also comment[19]). The exocyclic Si–Si separations are somewhat longer than normal Si–Si single bonds as a result of the bulk of the supersilyl groups (tetrahedron 1: 235.5 and 236.5 pm; tetrahedron 1A: 237.1 and 235.6 pm; for comparison[15] the Si–Si distance in Me$_3$Si–SiMe$_3$ 234.0 pm, in tBu$_3$Si–SitBu$_3$ 268.5 pm). The elongated Si–C bonds (range 191.2–197.0 pm) are rationalized in the same way.

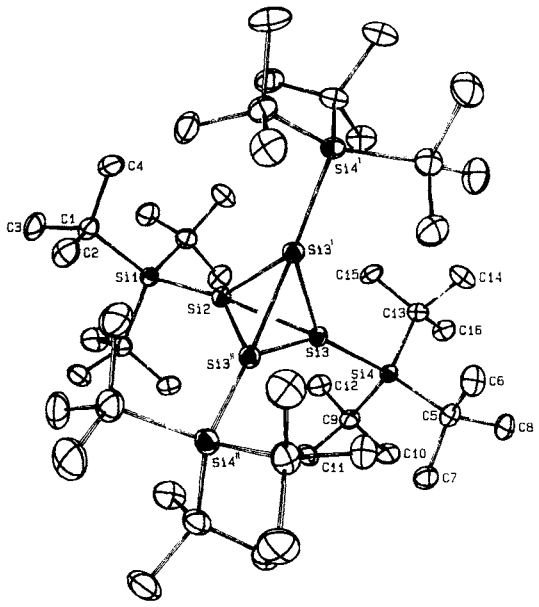

Fig. 2. Structure of **1** in the crystal of **1a** (ORTEP; Si atoms: thermal ellipsoids at the 50% level; C atoms with arbitrary radii for clarity; no H atoms). Selected bond lengths [pm] and angles [°]: Tetrahedron 1: Si1-Si2 235.5(2), Si3-Si4 236.5(2), Si2-Si3 232.0(2), Si3-Si3′ 231.5(2), Si1-C1 194.7(5), Si4-C5 194.0(5), Si4-C9 196.2(5), Si4-C13 191.7(5); Si1-Si2-Si3 144.8(1) (idealized value 144.75), Si2-Si3-Si4 144.9(1), Si4-Si2-Si3′ 59.9 (1) (idealized value 60), Si2-Si1-C1 106.1(1), Si3-Si4-C5 105.8(2), Si3-Si4-C9 106.0(2). Tetrahedron 1A: Si1A-Si2A 237.1(1), Si3A-Si4A 235.6(2), Si2A-Si3A 232.6(2), Si3A-Si3A′ 234.1(2), Si1A-C1A 194.1(5), Si4A-C5A 194.1(5),Si4A-C9A 191.2(5), Si4A-Si13A 197.0(5); Si1A-Si2A-Si3A 144.5(1), Si2A-Si3A-Si4A 144.9(1), Si3A-Si2A-Si3A′ 60.4(1), Si2A-Si1A-C1A 105.8(2), Si3A-Si4A-C5A 107.1(2),Si3A-Si4A-C9A 106.6(2) Si3A-Si4A-C13A 105.8(2).

The superdisilane molecules tBu$_3$Si–SitBu$_3$ in crystals **1a** display almost the same Si–Si distance (268.5 pm) as in crystals containing only superdisilane. As in the pure crystal of superdisilane,[20] in **1a** the two tBu$_3$Si halves are not staggered but twisted out of this symmetric position by 5.2°.

Experimental Procedure

To a solution of **5** (0.428 g, 0.553 mmol) in THF (50 mL) at −20 °C was added dropwise a 0.56 M solution of tBu$_3$SiNa (2.00 mL, 1.12 mmol). The reaction mixture was allowed to warm to room temperature, the THF removed under vacuum, the residue dissolved in pentane (70 mL), the precipitated NaBr filtered off, and the pentane removed by distillation. The crude product was recrystallized a number of times from tBuOMe to provide 0.144 g (0.158 mmol, 57%) pure, yellow-orange **1** (R = SitBu$_3$), m.p. > 350 °C. – ^{1}H NMR (C_6D_6): $\delta = 1.357$; ($CDCl_3$): $\delta = 1.185$; ^{29}Si{^{1}H} NMR (C_6D_6): $\delta = 38.89$ (Si_4), 53.07 (SitBu$_3$); ^{13}C{^{1}H} NMR (C_6D_6): $\delta = 24.68$ (CMe_3), 32.16 (CMe_3); MS (Kratos 80 RFA, Xe (7 kV, 10 W)): m/z (%) 908/909/910/911/912/913/914 (8.5/100/86.3/64.5/31.9/17.6/7.4) [M^+], 710/711/712/713/714 (51.9/47.4/24.5/14.3/7.2) [M^+ − SitBu$_3$]; UV/VIS (isooctane): λ_{max} = 210/235/310/451 nm (extinction 75870/70891/19867/3583). $Si_8C_{48}H_{108}$ (M_r = 908.7): calcd. C 63.33 H 11.97, found C 63.53 H. 12.28.

[14] The idea that the conversion of **5** into **1** could proceed by the dimerization of bis(superdisilyl)disilyne $tBu_3Si-Si\equiv Si-SiBu_3$ is quite fascinating: **5** + $tBu_3SiNa \rightarrow (tBu_3Si)BrSi=SiBr(SitBu_3) + tBu_3SiBr + NaBr$; $(tBu_3Si)BrSi=SiBr(SitBu_3) + tBu_3SiNa \rightarrow tBu_3Si-Si\equiv Si-SitBu_3 + tBu_3SiBr + NaBr$.

[16] X-ray analysis of **1a**: $2Si_8C_{48}H_{108}\cdot Si_2C_{24}H_{54}\cdot C_6D_6$, $M_r = 2303.15$, cubic, $P2_13$ (no. 198), $a = 2473.3(8)$ pm, $v = 15.1304$ nm^3, $Z = 4$(!), $\rho_{calcd} = 1.011$ Mg m^{-3}, $\mu = 0.185$ mm^{-1}, $T = 296$ K, data collection on a yellow-orange crystal with dimensions of $0.4 \times 0.53 \times 0.53$ mm. 16621 Reflections were collected on an Enraf-Nonius CAD4 diffractometer, of which 6761 were independent and observed, 5940 with ($F > 3\sigma F$). ω-Scan, scan width $0.50° + 0.35\tan\theta$, maximum measurement 180 s per reflection; range: $2° < 2\theta < 46°$. Complete measurement of $\pm h, k, l$ with $|h| \leq l$ and $k < l$; additional reflections without this restriction, i.e. ca. 78% of $\pm h, k, l$ ($R_i = 0.019$), then interruption because of decomposition. Correction for anisotropic disintegration (0.9949, 1.2071). Weissenberg photographs confirm the unit cell found and showed only weak reflections for $0kl$ when $k = 2n + 1$; the reflections h were extinguished when $h = 2n + 1$. The *t*Bu groups of the hexa-*tert*-butyldisilane molecules are more disordered and require geometric constraints; the C atoms of C_6D_6 were also quite disordered; in the final model the D atoms were not included. Solution: SHELX86, block refinement with SHELX76 [17]. Riding hydrogen atoms at geometrical positions, all non-hydrogen atoms refined anisotropically. $R = 0.057$, $R_w = 0.051$, $w = 1/\sigma^2(F_0)$. 433 Parameters. The ratio of reflections to refined parameters is 13.7:1. The absolute configuration was not determined. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57184, the names of the authors, and the journal citation.

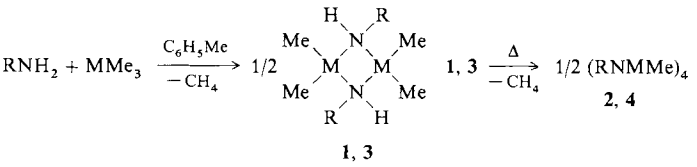
$(C_6F_5NGaMe)_4$ and $(C_6F_5NInMe)_4$: The First Gallium–Nitrogen and Indium–Nitrogen Compounds with Cubane Structures**

By *Thomas Belgardt, Herbert W. Roesky,* Mathias Noltemeyer*, and *Hans-Georg Schmidt*

Dedicated to Professor Hans Bock on the occasion of his 65th birthday

Compounds with heterocubane frameworks have been known for a long time for main group elements.[1] The first aluminum–nitrogen compound with cubane structure $(PhNAlPh)_4$ was prepared in 1962 and structurally characterized ten years later.[2] In the meantime several more compounds of this type have been described.[3] In contrast, there are no indications of analogous gallium–nitrogen and indium–nitrogen compounds. Starting materials for the synthesis of the aluminum–nitrogen compounds with a central cubic Al_4N_4 unit are the aminoalanes $(RNHAlR'_2)_n$, which form cubanes through intermolecular reactions. Power et al. have transferred these reactions to the corresponding aminogallanes and have thus observed that under C–H activation an intramolecular elimination of hydrocarbons takes place.[3b] Corresponding reactions of the aminoindanes are not known. In order to prevent a C–H activation, we have now treated $GaMe_3$ and $InMe_3$ each with pentafluoroaniline (Scheme 1).



Scheme 1. **1**, **2**: M = Ga; **3**, **4**: M = In. R = C_6F_5.

The aminometallanes **1** and **3** are obtained as intermediates, which precipitate in the form of needlelike crystals in high yield. The compounds **2** and **4**, the first gallium–nitrogen and indium–nitrogen compounds with cubane frameworks, respectively, can be prepared by heating the appropriate aminometallanes without solvent, and subsequent recrystallization of the products from *n*-hexane. Compound **2** belongs to the class of iminogallanes $(RNGaR')_n$, for which to our knowledge only one compound with a complex cage structure is known.[4] Compound **4** is the first structurally characterized iminoindane $(RNInR')_n$.

The crystal structure of **2** is shown in Figure 1.[5] The framework consists of fourfold coordinated Ga and N atoms, which together form a regular cube (angles at Ga and N lie between 85.9(2) and 94.0(2)°). However, the angles here deviate significantly from the 90° angle of a perfect cube, in contrast to $(PhAlNPh)_4$, for which angles of almost 90° are observed. The Ga–N bond lengths lie between 197.2 and 203.9 pm (mean 200.8(4) pm). Thus, they correspond to the atomic distances in aminogallanes, for example those of $(Me_2GaNHPh)_2$.[3b] As expected, the distances are somewhat longer than those for iminoalanes with cubane struc-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

ture (for $(PhAlNPh)_4$, these lie between 186(2) and 193(1) pm); for comparison we have also prepared the aluminum compound $(C_6F_5NAlMe)_4$ (Al–N bond lengths in the range of 190.5 to 196.7 pm) analogous to **2** and **4** in a similar way.[6] The mean Ga···Ga distance in **2** is 290 pm and the N···N distance 276 pm.

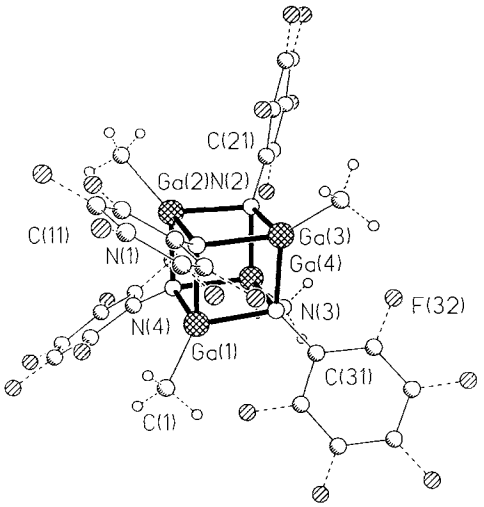

Fig. 1. Crystal structure of **2**. Selected bond lengths [pm] and angles [°]: Ga(1)–N(4) 199.5(4), Ga(2)-N(4) 201.7(4), Ga(1)-C(1) 192.6(6), Ga(4)-C(4) 193.3(5), N(2)-C(21) 142.1(6), N(4)-C(41) 140.1(7); N(3)-Ga(1)-N(4) 88.8(2), Ga(1)-N(1)-N(3) 91.5(2).

The crystal structure of **4** is shown in Figure 2.[7] It is a slightly distorted cube of alternating indium and nitrogen atoms (mean In-N-In angle 95.5(4)°, mean N-In-N angle 84.3(4)°). In this case the angles between the In and N atoms

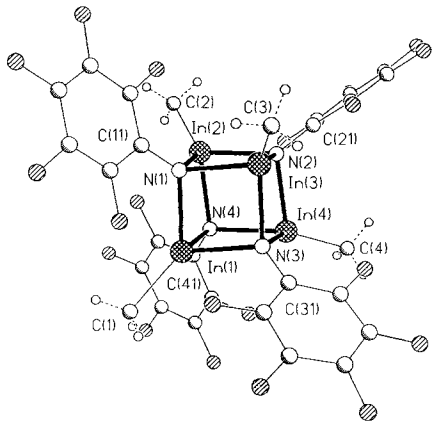

Fig. 2. Crystal structure of **4**. Selected bond lengths [pm] and angles [°]: In(1)-N(3) 220.2(9), In(3)-N(2) 216.7(10), In(4)-N(2) 222.7(10), In(1)-C(1) 211.5(12), In(4)-C(4) 209.9(14); N(1)-In(1)-N(3) 85.4(3), In(1)-N(1)-In(3) 94.9(4).

deviate even more from those of an ideal cube than in compound **2**. Thus, the heavier the participating metal atom is the greater the deviations. This tendency is on the one hand certainly to be attributed to the differences in size of the metals, and also to the fact that the degree of hybridization decreases with increasing atomic mass. In order to be able to make more accurate statements about the bonding, more compounds of this type must be prepared and be compared with **2** and **4**. The In–N distances are between 216.7 and 222.7 pm (mean 220 pm) and are thus significantly longer than those for the homologous aluminum and gallium compounds. The mean In···In distance is 326 pm and the mean N···N distance 296 pm. In the ^1H NMR spectrum of **2**, a septet is observed for the methyl group at gallium, which is attributed to the long-range couplings of the protons with the *ortho*-positioned fluorine atoms of three of the four pentafluorophenyl substituents. For compound **4** these long-range couplings are not observed. In the mass spectra of **2** and **4** the signals of the molecular ions appear with high relative intensities [for **4** 100%]. This indicates that the compounds are also stable in the gas phase.

In conclusion, it is possible to prevent an intramolecular reaction by the use of perfluorinated phenyl substituents and thus transfer the elimination reaction known for aminoalanes to gallium and indium. We will now investigate whether lanthanides behave in a similar fashion.

Experimental Procedure

1: $C_6F_5NH_2$ (4.03 g, 22 mmol) dissolved in freshly distilled toluene (20 mL) was slowly added dropwise to a solution of $GaMe_3$ (1.46M in toluene, 15 mL, 22 mmol) at room temperature and with the exclusion of air and moisture. The reaction mixture was heated for 12 h under reflux. Subsequently the toluene was removed under vacuum and the residual solid was crystallized from *n*-hexane. Yield of **1**: 5.39 g (87%); m.p. 145 °C. ^1H NMR (250.130 MHz, C_6D_6, TMS ext.): $\delta = 2.58$ (s, br, 2H; N-H), −0.22 (s, 12H; Ga-CH_3); ^{19}F NMR (75.39 MHz, C_6D_6, $CFCl_3$ ext.): $\delta = -164.1$ (m, 4F; *o*-F), −165.7 (m, 4F; *m*-F), −174.2 (m, 2F; *p*-F); IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 3327, 3304, 1513, 1351, 1310, 1260, 1241, 1221, 1211, 1134, 1062, 1018, 990, 887, 843, 788, 727, 694, 623, 591, 543. MS (70 eV): *m/z* (%) 563 (5) [M^+], 281 (40) [$M^+/2$], 183 (100) [$C_6F_5NH_2$]. Correct C,H,N analysis.

2: **1** (1.74 g, 3.1 mmol) was heated to 200 °C for 3 h; the methane formed was allowed to escape through a mercury-pressure manometer. Recrystallization of the residue from *n*-hexane led to colorless crystals of **2**. Yield **2**: 1.01 g (61.5%); m.p. 202 °C. 1.01 g (61.5%). ^1H NMR (400.130 MHz, C_6D_6, TMS ext.): $\delta = -0.25$ (sept. 12H; Ga-CH_3); ^{19}F NMR (376.498 MHz, C_6D_6, C_6F_6 ext.): $\delta = 10.82$ (m, 8F; *o*-F), 0.55 (m, 8F; *m*-F), −3.31 (m, 4F; *p*-F); IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 2434, 1512, 1499, 1465, 1452, 1302, 1258, 1218, 1150, 1133, 1020, 1001, 772, 756, 664. MS (70 eV): *m/z* (%) 1064 (59) [M^+], 532 (100) [$M^+/2$]. Correct C,H,N analysis.

3: $C_6F_5NH_2$ (3.66 g, 20 mmol) dissolved in toluene (20 mL) was slowly added dropwise to a solution of $InMe_3$ (3.2 g, 20 mmol) in toluene (20 mL) at room temperature. The reaction mixture was heated under reflux for 12 h. Subsequently the solvent was removed under vacuum and the colorless residue was recrystallized from *n*-hexane. Yield of **3**: 5.1 g (78%); m.p. 159 °C. ^1H NMR (250.130 MHz, C_6D_6, TMS ext.): $\delta = 2.78$ (s, br, 2H; N-H), −0.18 (s, 12H; In-CH_3); ^{19}F NMR (250.320 MHz, C_6D_6, $CFCl_3$ ext.): $\delta = -150.48$ (m, 4F; *o*-F), −161.95 (m, 4F; *m*-F), −164.00 (m, 2F; *p*-F); IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 3288, 1519, 1508, 1450, 1356, 1308, 1260, 1242, 1158, 1133, 1093, 1018, 992, 978, 823, 801, 727, 618, 521. MS (70 eV): *m/z* (%) 654 (4) [M^+], 639 (36) [$M^+ - CH_3$], 327 (25) [$M^+/2$], 145 (100) [$M^+/2 - C_6F_5$]. Correct C,H,N analysis.

4: **3** (2.1 g, 3.21 mmol) was heated to 220 °C for 1 h; the methane formed was allowed to escape and solid **4** was obtained. Crystals suitable for the crystal structure analysis were obtained by the crystallization from *n*-hexane. Yield of **4**: 1.57 g (78.6%); m.p. 225 °C (decomp). ^1H NMR (250.130 MHz, C_6D_6, TMS ext.): $\delta = 0.12$ (s, 12H; In-CH_3); ^{19}F NMR (75.39 MHz, C_6D_6,C_6F_6 ext.): $\delta = 8.50$ (m, 8F; *o*-F), −0.90 (m, 8F; *m*-F), −8.15 (m, 4F; *p*-F); IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 2430, 1646, 1640, 1506, 1437, 1293, 1251, 1140, 1127, 1011, 993, 738, 545. MS (70 eV): *m/z* (%) 1244 (100) [M^+], 622 (20) [$M^+/2$]. Correct C,H,N analysis.

A New Route to Water-Soluble Phosphanes with *para*-Sulfonated Phenyl Substituents. Crystal Structure of $P(C_6H_4\text{-}p\text{-}SO_3K)_3 \cdot KCl \cdot 0.5\,H_2O$**

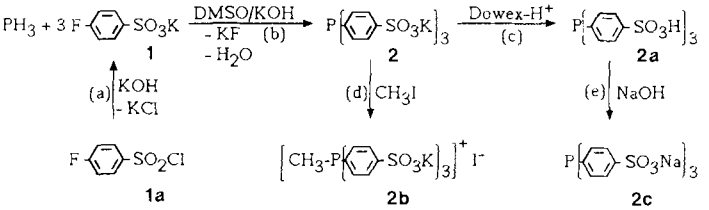
By *Oliver Herd, Klaus Peter Langhans, Othmar Stelzer,* Norbert Weferling,* and *William S. Sheldrick*

Dedicated to Professor Ulrich Wannagat on the occasion of his 70th birthday

Since the application of water-soluble Rh^I complexes of $P(C_6H_4\text{-}m\text{-}SO_3Na)_3$ (tppts) as catalysts for the industrial hydroformylation of propene in the two-phase system water/organic solvent by the Ruhrchemie/Rhône-Poulenc process, sulfonated triphenylphosphanes have become increasingly important.[1, 2] Because of its extremely good solubility in water the Rh catalyst $[HRh(CO)(tppts)_3]$ can be separated from the hydrophobic products quite simply and reintroduced into the process.

Water-soluble ligands like tppts can be prepared by the direct sulfonation of PPh_3 with fuming sulfuric acid. However, this reaction is not specific, and mixtures of *meta*-sulfonated phenylphosphanes with different degrees of sulfonation are obtained in addition to phosphanoxides and -sulfides. Time-consuming purification procedures are thus necessary for the preparation of uniform and pure products.[3, 4] The modified direct sulfonation of PPh_3 described recently by Larpent, Patin, Thilmont, and Valdor[5] provides the oxide of tppts in good yields, but its conversion into the phosphane requires several low-yielding steps.

We report here that the potassium salt **2** of 4,4′,4″-phosphanetriylbenzenesulfonic acid can be made simply and in high purity by the reaction of potassium *p*-fluorobenzenesulfonate (**1**) with PH_3 in the superbasic medium dimethylsulfoxide (DMSO)/KOH[6] [yield ca. 60%, reaction (b) in Scheme 1)]. Salt **1** was prepared by hydrolyzing *p*-fluorobenzenesulfonyl chloride (**1a**) with aqueous KOH and was used as a mixture with KCl formed in this reaction.[7]



Scheme 1.

Salt **2** is formed according to reaction (b) by stepwise nucleophilic aromatic substitution of the fluorine atom in **1** by the phosphide ions PH_2^-, $[PH(C_6H_4\text{-}p\text{-}SO_3K)]^-$, and $[P(C_6H_4\text{-}p\text{-}SO_3K)_2]^-$, which in the superbasic medium are in equilibrium with PH_3, $PH_2(C_6H_4\text{-}p\text{-}SO_3K)$, $PH(C_6H_4\text{-}p\text{-}SO_3K)_2$.

During the workup of the reaction mixture formed by treatment of PH_3 with a mixture of salt **1** and KCl, product **2** crystallized as a hydrate of a double salt with the composition $\mathbf{2} \cdot KCl \cdot 0.5\,H_2O$. For the preparation of KCl-free **2**, pure **1** was employed in reaction (b); the latter can be obtained by hydrolysis of **1a** with aqueous acetic acid and subsequent neutralization with K_2CO_3 (yield 85%). Salt **2** precipitated as the dihydrate; however, no crystals suitable for X-ray structural analysis could be obtained.

The unit cell of $\mathbf{2} \cdot KCl \cdot 0.5\,H_2O$ (space group $Fd3$)[8] contains 32 formula units, and the anion of **2** has crystallographic C_3 symmetry (Fig. 1). The P–C bonds (1.843(4) Å) are only slightly longer than those in PPh_3 (mean value 1.828(3)[9a] or 1.831(2) Å[9b]). The P-C-P angles in **2** (103.5(2)°) and in PPh_3 (mean value 103.0(8)°[9a] or 102.8(9)°[9b]) are almost identical. The arene substituents are all twisted in the same direction. The angle ω between the plane defined by the three *ipso* C atoms (C(1), C(1a), C(1b)) and the arene ring is 65.7°. The first coordination spheres of the potassium atoms are occupied by eight oxygen and nine chlorine atoms. Compound **2** is the first sulfonated triphenylphosphane whose structure has been determined by X-ray crystallography.

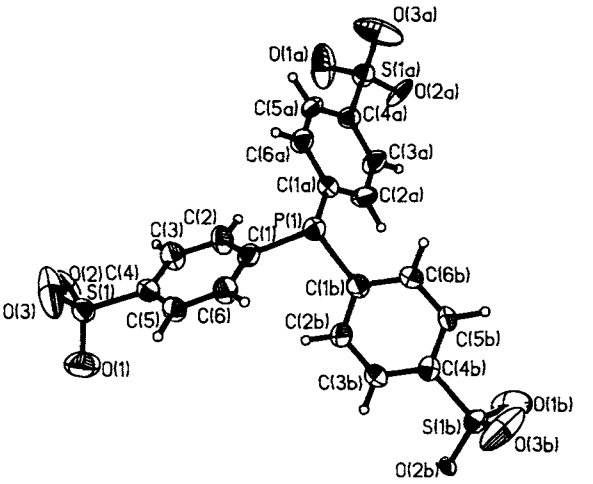


Fig. 1. Structure of the anion $P(C_6H_4\text{-}p\text{-}SO_3^-)_3$ in $\mathbf{2} \cdot KCl \cdot 0.5\,H_2O$. Bond lengths [Å] and angles [°]: P(1)-C(1) 1.843(4), S(1)-O(1) 1.413(4), S(1)-O(2) 1.406(4), S(1)-O(3) 1.440(5); C(1)-P(1)-C(1a, 1b, 1c) 103.5(2), O(1)-S(1)-O(2) 114.1(4), O(1)-S(1)-O(3) 109.5(4), O(2)-S(1)-O(3) 110.5(4).

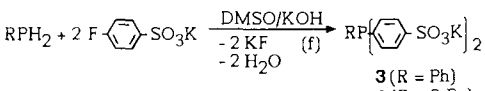
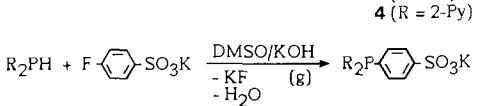
[**] Water-Soluble Phosphanes, Part 1. – This research was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The potassium salt **2** was converted into the sulfonic acid **2a** by treatment with the acidic form of an ion-exchange resin (Dowex-H^+) [reaction (c) in Scheme 1]. Salt **2** was quaternized with CH_3I in the two-phase system CH_2Cl_2/water to give the phosphonium salt **2b** [reaction (d) in Scheme 1]. Neutralization of **2a** with NaOH provided the Na salt **2c**.

In analogy to reactions of PH_3, primary and secondary phosphanes such as $PhPH_2$, 2-$PyPH_2$ (2-Py = 2-pyridyl)[10a], Ph_2PH, and 3-Py_2PH[10b] can be arylated with **1** in the superbasic medium to yield the tertiary phosphanes **3**, **4**, **5**, and **6** directly and with a defined degree of sulfonation [reactions (f) and (g) in Scheme 2].[11]



3 (R = Ph)
4 (R = 2-Py)



5 (R = Ph)
6 (R = 3-Py)

Scheme 2.

The chemical shifts $\delta^{31}P$ of the phosphanes $Ph_{3-n}P(C_6H_4\text{-}p\text{-}SO_3K)_n$ [**2** ($\delta = -8.9$), **3** (−13.2), **5** (−7.9)] show only a slight dependence on the degree of sulfonation n and the position of the SO_3M group in the arene ring [**2** ($\delta = -8.9$), tppts (−5.3)].[5] The solubility of the anionic phosphanes in water increases with the degree of sulfonation [**2** (0.8) kg L^{-1}), **3** (0.4), **5** (0.1)]. The solubility of **2** and **2c**, 0.8 and 0.9 kg L^{-1}, respectively, is only slightly less than that of the Na salt of tppts (ca. 1.1 kg L^{-1}).

Experimental Procedure

2: *p*-Fluorobenzenesulfonyl chloride (19.5 g, 0.1 mol) was added to 50 mL aqueous 2 N KOH, and the mixture was heated for 2 h at reflux. The solvent was removed at 40 °C (20 mbar), leaving a colorless powder consisting of **1** and KCl. This powder was added during the period of 1 h to a suspension of KOH (26.4 g, 0.4 mol, 85%) in 100 mL DMSO, which was saturated with PH_3. During the addition the PH_3 pressure was held constant at 1.1 bar. Upon addition of 50 mL water and 250 mL ethanol **2** was obtained as a colorless precipitate, which was filtered off and recrystallized twice from water. Correct C,H,P-analysis, 12.4 g (53%) yield. $^{31}P\{^1H\}$ NMR (32.2 MHz, D_2O): $\delta = -8.9$; $^{13}C\{^1H\}$ NMR (62.9 MHz, D_2O): $\delta = 140.1$ (11.0, C1), 135.1 (19.8, C2), 126.7 (7.3, C3), 144.5 (C4); ^1H NMR (250 MHz, D_2O); AA'BB'X spin system (A, A' = H_a, $H_{a'}$; B, B' = H_b, $H_{b'}$; X = ^{31}P): $\delta = 7.28$ [$^3J(PH_a) = 8.0$, $^3J(H_aH_b) = 8.4$, $^4J(H_aH_{a'}) = 1.8$, $^5J(H_aH_{b'}) \approx 0.1$ Hz; H_a], 7.61 [$^4J(PH_b) = 1.3$; $^4J(H_bH_{b'}) = 1.7$ Hz; H_b]. IR (KBr pellet): $\tilde{\nu} = 1205$, 1034 cm^{-1} ($\nu_{as}SO_3$, ν_sSO_3).

[{$(Et_2O)_2ClGa$}Ga{$GaCl_2(Et_2O)$}$_3$]: A Molecular Compound with a Tetrahedral Ga_5 unit**

By *Dagmar Loos, Hansgeorg Schnöckel,** and *Dieter Fenske*

In memory of Harald Schäfer

The chemistry of Group IIIA elements in low oxidation states has seen a renaissance during the past years within the realm of solid-state chemistry and, more recently, also in the field of molecular compounds.[1] For solid compounds of the heavier elements, halides with weak metal–metal interactions (such as In_7Cl_9[2]) are known, as well as halides with "true" electron-pair bonding. In_5Br_7,[3] Ga_2I_3,[4] and Ga_2Br_3,[5] in which isolated $M_2X_6^{2-}$ units occur,[6] are among the latter. We are not aware of analogous solvent-free chlorides with Ga–Ga bonds,[7] since Ga_2Cl_4,[9] easily obtainable and known for a long time, must be described as $Ga^+GaCl_4^-$[10] in the crystalline solid[11] and also in the melt.[12]

Ga_2Cl_4 has proven to be an ideal starting compound for the synthesis of lower valent molecular Ga compounds. Interesting Ga^I complexes[14] are formed by adding arenes, whereas stronger donors like dioxane lead to formally divalent gallium compounds with Ga–Ga bonds.[15, 16] [$Ga_2Cl_4(OC_4H_8O)_2$] was the first molecular compound of that kind, with a Ga–Ga distance of 240.6 pm.[17] Starting from this compound, W. Uhl et al. prepared the first solvent-free organometallic compound of Ga with Ga–Ga bonds (254 pm) some years ago: $R_2Ga\text{–}GaR_2$ (R = $CH(SiMe_3)_2$).[18]

Starting from [$Ga_2Br_4(OC_4H_8O)_2$], the same authors recently succeeded in synthesizing the first Ga^I compound stable at room temperature, [Ga_4{$C(SiMe_3)_3$}$_4$],[19] which contains tetrahedral Ga_4 cluster units (d(Ga-Ga) =

268.8 pm). In concurrent studies we showed that Ga^{I} compounds with suitable ligands such as cyclopentadienyl can also be obtained as monomers in solution and in the gas phase (even at approximately $-70\,^{\circ}C$).[20] Crucial to the synthesis of [GaCp] from GaCl and [$MgCp_2$] or [LiCp] was the cryochemical preparation of GaCl.[21] By co-condensing GaCl and a mixture of toluene/diethyl ether (4:1) around $-196\,^{\circ}C$, GaCl, which is metastable at room temperature, was obtained in solution. The structure of this solution species was hitherto unknown. By employing an appropriate crystallization procedure[22] we have now been able to isolate yellow, air- and temperature-sensitive crystals of **1** and have solved the structure by X-ray methods.[23]

$[\{(Et_2O)_2ClGa\}Ga\{GaCl_2(Et_2O)\}_3]$ **1**

Figure 1 shows the result of the X-ray structure analysis. A central atom (Ga1) is tetrahedrally surrounded by another four Ga atoms (Ga2–Ga5). Each of these is likewise coordinated tetrahedrally; two Cl atoms and one ether molecule bind to Ga3, Ga4, and Ga5, while Ga2 is bound to only one Cl atom and two ether molecules. Consequently, the following oxidation states are derived for the Ga atoms: 0 for Ga1, +1 for Ga2, and +2 for Ga3–Ga5. Nevertheless, the Ga–Ga distances vary only little between 241.7(2) and 245.0(2) pm; the longest distance observed is between Ga1 and Ga2. This seems plausible from the individual oxidation states of the respective Ga atoms and their corresponding sizes. In comparison with the distances in the metal, the Ga–Ga bond lengths in **1** also make sense. In Ga metal, a short bond of 244 pm is observed in addition to six longer bonds from 270 to 279 pm.[24] The Ga–Cl bond lengths with distances between 220.8(2) and 222.4(3) pm fall into the expected range, since in $[Ga_2Cl_4(OC_4H_8O)_2]$ the length of the Ga–Cl bond is 217 pm.[17] A shortening of the bond with respect to **1** is plausible, since larger radii of the Ga atoms are expected in **1** due to the lower averaged oxidation number. Therefore, dimeric $GaCl_3$ (containing tetrahedrally coordinated Ga atoms like in **1**) exhibits an unusually short terminal Ga–Cl distance of 206 pm as a consequence of the higher oxidation number for gallium.[25]

The angles measured within the Ga_5 tetrahedron can be explained by repulsive electrostatic interactions. Thus, angles that involve two Ga^{II} ions are wider than the tetrahedral angle. For angles engaging Ga^{I} (e.g. Ga5–Ga1–Ga2) we find smaller values, resulting from less repulsion.[26]

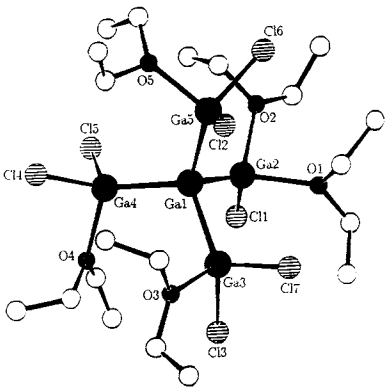

Fig. 1. Crystal structure of **1**. Selected distances [pm] and angles [°] (standard deviations in parentheses): Ga1–Ga2 245.0(2), Ga1–Ga3 242.6(2), Ga1–Ga4 241.7(2), Ga1–Ga5 242.6(2), $d_{max}/d_{min}/\bar{d}$: Ga–Cl 222.4(3)/220.8(3)/221.7, Ga–O 205.8(7)/203.2(7)/205.0; Ga2–Ga1–Ga3 101.27(5), Ga2–Ga1–Ga4 102.45(5), Ga2–Ga1–Ga5 109.01(5), Ga3–Ga1–Ga4 113.05(5), Ga3–Ga1–Ga5 112.44(5), Ga4–Ga1–Ga5 116.81(5).

Compound **1**, in which the Ga atoms are found in different oxidation states, forms in a solution of GaCl, which from the conditions of preparation invariably contains small amounts of $GaCl_3$ (maximum 5%). Formation of **1** therefore must entail disproportionation reactions ($2\,Ga^{I} \rightarrow Ga^{0} + Ga^{II}$), and possibly comproportionation reactions ($Ga^{III} + Ga^{I} \rightarrow 2\,Ga^{II}$) as well. Most likely the mechanism on which such reactions are based is very similar to that of the halogen transfer discussed for analogous reactions of indium compounds.[15]

In this isolation of **1**, an intermediate in the disproportionation of GaCl was successfully trapped and characterized for the first time. Besides their importance for the evaluation of unusual structural relationships, complex **1** and similar compounds may be suitable starting materials for new solid compounds not accessible by the standard high-temperature methods of solid-state chemistry.

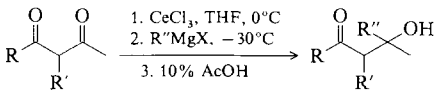
[26] That is why the nonbonding distances between, for example, Ga3 and Ga1 (approximately 377 pm) are also smaller than those between Ga3 and Ga4 (approximately 404 pm).

$CeCl_3$-Mediated Addition of Grignard Reagents to 1,3-Diketones**

By *Giuseppe Bartoli,* Enrico Marcantoni,* and *Marino Petrini*

1,3-Diketones have been always perceived as a practical source of stabilized carbanions owing to the enhanced acidity of the active methylene hydrogen atoms.[1] The alkylation of 1,3-diketones can be carried out with almost complete regio- and stereocontrol of the products.[2] Every attempt at attacking the carbonyl group with organometallic species led to unsatisfactory results, since these nucleophilic reagents are basic enough to promptly deprotonate the active methylene hydrogen atoms. The resulting enolate anion has an extremely stable cyclic structure with pseudoaromatic character and hence it is completely inert towards nucleophilic attack.[3]

We report here that Grignard reagents can be directly added to 1,3-diketones in the presence of dry $CeCl_3$ (Scheme 1). Through the addition of the diketone to a suspension of dry $CeCl_3$ in THF at 0 °C, a 1:1 complex is probably formed.[4] This complex formation enhances the electrophilicity of the carbonyl groups, and the subsequent addition of the organomagnesium reagent at −30 °C proceeds with the attack of the Grignard species at the carbonyl functionality. The usual workup gives β-hydroxy ketones in good yields (Tables 1 and 2).



1 a–c **2 a–h**

Scheme 1. Synthesis of β-hydroxyketones **2a–h**. **1a**: R = CH_3, R′ = H; **1b**: R = Ph, R′ = H; **1c**: R + R′ = $-(CH_2)_4-$. R″ = Me, Ph, *n*Pr, H_2C=CH, H_2C=CH–CH_2.

Table 1. Reaction of 1,3-diketones with Grignard reagents in the presence of $CeCl_3$ in THF at −30 °C.

1c	*n*PrMgCl	**2h**	85

[a] Isolated yields.

The amazing reactivity of the 1,3-diketones was initially attributed to the formation of organocerium intermediates which are known to efficiently add to easily enolizable substrates.[5] However, preformed organocerium reagents[6] are unable to furnish the same products **2**. The starting material is usually recovered in these experiments.[7]

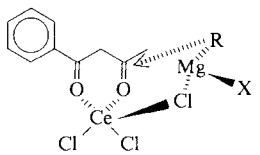
2g: Oil, ^{1}H NMR: δ = 1.32 (s, 3H, CH_3), 2.44 (d, ^3J(H,H) = 7.3 Hz, 2H, CH_2 (allyl)), 3.05 (d, ^2J(H,H) = 17.4 Hz, 1H, CH_2), 3.20 (d, ^2J(H,H) = 17.4 Hz, 1H, CH_2), 4.20 (s, 1H, OH), 5.05–5.20 (m, 2H, =CH_2), 5.85–6.00 (m, 1H, CH=), 7.30–7.60 (m, 3H, Ph), 7.90–8.00 (m, 2H, Ph); IR (film): $\tilde{\nu}$[cm^{-1}] = 3440 (OH), 1655 (C=O); MS (70 eV): *m/z* (%) 186 ($M^+ - H_2O$, 0.5), 163 (29), 105 (100), 77 (35), 51 (9), 43 (18), 39 (6).

2h: Oil, ^{1}H NMR: δ = 0.90 (t, ^3J(H,H) = 6.4 Hz, 3H, CH_3), 1.15 (s, 3H, CH_3, diastereomer a), 1.18 (s, 3H, CH_3, diastereomer b), 1.30–2.40 (m, 14H); IR (film): $\tilde{\nu}$[cm^{-1}]: 3490 (OH), 1670 (C=O); MS (70 eV): *m/z* (%) 166 ($M^+ - H_2O$, 84), 151 (100), 137 (35), 123 (31), 109 (50), 95 (35), 81 (37), 67 (57), 55 (30).

We believe that a six-membered ring transition state, favored by the presence of the chelating $CeCl_3$ (Scheme 2), forms in which the Grignard reagent approaches the less hindered carbonyl group. Steric factors should strongly influence the reactivity of the carbonyl groups, since only the less hindered carbonyl group is reactive under our reaction conditions. Furthermore, secondary and tertiary Grignard reagents cannot be introduced even by adopting prolonged reaction times or more elevated temperatures.[8]



Scheme 2. Proposed transition state for the formation of **2**.

The organomagnesium reagent is added in 0.5 molar excess, and it is worth noting that even when using a larger amount of the reagent no traces of 1,3-dihydroxy compounds, derived from nucleophilic attack at both carbonyl groups, have been found. The present procedure can be used to introduce a large variety of carbon frameworks, including aryl, vinyl, and allyl groups, but it only seems to function with Grignard reagents.[9]

In conclusion, 1,3-ketones in the presence of $CeCl_3$ are extremely reactive towards Grignard reagents. This reaction is considerably chemoselective and allows the straightforward preparation of functionalized β-hydroxy ketones. A study of the synthetic potential of this procedure is currently in progress.

Experimental Procedure

Finely ground $CeCl_3 \cdot 7H_2O$ (0.93 g, 2.5 mmol) was dried by heating at 140 °C/0.1 Torr for 2 h. Dry THF (35 mL) was then added at 0 °C, and the milky suspension was stirred for about 15 h under N_2 at room temperature. The 1,3-diketone (1.66 mmol) was then added at 0 °C, and the mixture was stirred for 1 h at the same temperature. The appropriate Grignard reagent (2.5 mmol) was then added dropwise at −30 °C, and the mixture was stirred at this temperature for a further 30 min. Subsequently 10% acetic acid (45 mL) was poured into the mixture. After extraction with ether (3 × 30 mL), the organic phase was washed with saturated $NaHCO_3$ (10 mL) and saturated NaCl (10 mL), and dried ($MgSO_4$). Flash chromatography (SiO_2, hexane/ethyl acetate 7:3) afforded the pure product.

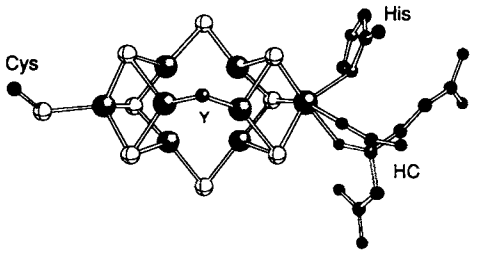
How N_2 Might Be Activated by the FeMo-Cofactor in Nitrogenase**

By *Haibin Deng* and *Roald Hoffmann**

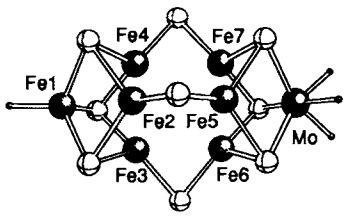
We finally have a structural model for the nitrogenase FeMo-cofactor, based on 2.7 Å resolution crystal structure of the *Azotobacter vinelandii* MoFe-protein by J. Kim and D. C. Rees.[1] Here we examine the electronic structure of this model, and its possible N_2 binding modes.

The FeMo-cofactor (**1**) contains two clusters of composition 4Fe:3S and 1Mo:3Fe:3S, bridged by three non-protein ligands. The cofactor is linked to the protein through the Fe1 and Mo metal atoms (see **2**). The sulfur atom of the $Cys^{\alpha 275}$ residue coordinates Fe1, whereas the Mo atom is ligated by the imidazole group of the $His^{\alpha 442}$ residue, as well as a homocitrate HC through hydroxyl and carboxyl oxygen atoms.[1] The 4Fe:3S and 1Mo:3Fe:3S clusters may be structurally related to common 4Fe:4S cubane clusters by



1

removing one of the S atoms of the latter. The six inner iron atoms of the cofactor (Fe2–Fe7 see **2**) form an approximate trigonal prism. The coordination environment around Mo is approximately octahedral and that around Fe1 tetrahedral. Fe2–Fe7 have quite distorted trigonal-planar coordination. Two of the three bridging ligands between the two clusters are sulfide ions S^{2-}, while the third ligand Y is probably a nitrogen or oxygen atom, or a less ordered sulfur.[1]



2

We first examine the electronic structure and the bonding in the cofactor model.[2] To simplify the analysis and yet not lose essential chemical information we have replaced the uncertain Y atom with S^{2-}, the ligating atoms from the cysteine, histidine, and homocitrate with the simplest ligands, H^-. Finally we symmetrize the structure to C_{3v} point symmetry.[3] The bond lengths are set at 2.75 (Fe–Fe (all)), 2.85 (Fe–Mo), 2.3 (Fe–S), 2.35 (Mo–S), 1.6 (Fe–H), 1.70 Å (Mo–H). In much previous work we have found it useful to set distances equal and then allow the overlap populations (OPs) to tell us which bonds are stronger. This is why we have equalized the Fe–Fe separations in **2**.

What about the oxidation states of the metal centers in **1**? Mo ENDOR and EXAFS studies indicate that the most likely formal oxidation state for Mo is +4;[4] and Mössbauer investigations show that Mo does not seem to change oxidation state when the MoFe-protein is reduced.[5] We assign the four iron atoms in the 4Fe:3S cluster together a +10 charge, as in the cubane clusters $[Fe_4S_4(SR)_4]^{2-}$.[6] The three iron atoms in the 1Mo:3Fe:3S cluster are given a total +7 charge, to be in line with the spin state of the FeMo-cofactor ($S = 3/2$).[4] Thus the actual molecule calculated, a model of a model, is $[HFe_4S_3(\mu\text{-}S)_3Fe_3S_3MoH_3]^-$ (**2**).

The given charge assignment is by no means unique, or even correct. But we must start somewhere. Thorneley–Lowe kinetic models[7] for dinitrogen reduction indicate that dinitrogen binds to more reduced forms of the cofactor. Thus we will also examine the consequence of adding up to three electrons to the cofactor model **2** (i.e., the reduction of all Fe atoms to Fe^{II}).

An energy level diagram for **2** is shown in Figure 1a. The HOMO is a singly occupied orbital. There is another orbital only 0.03 eV above it; in fact there are nine orbitals within half an eV around the HOMO. Thus the system should be a high-spin one. The electron coupling in the cofactor **1** is

[**] We are grateful to the National Science Foundation for its support of this work through CHE 8912070. Dr. Douglas Rees was kind enough to transmit to us his refinement of the MoFe-protein structure. We are also grateful to him for discussions of the N_2 binding.

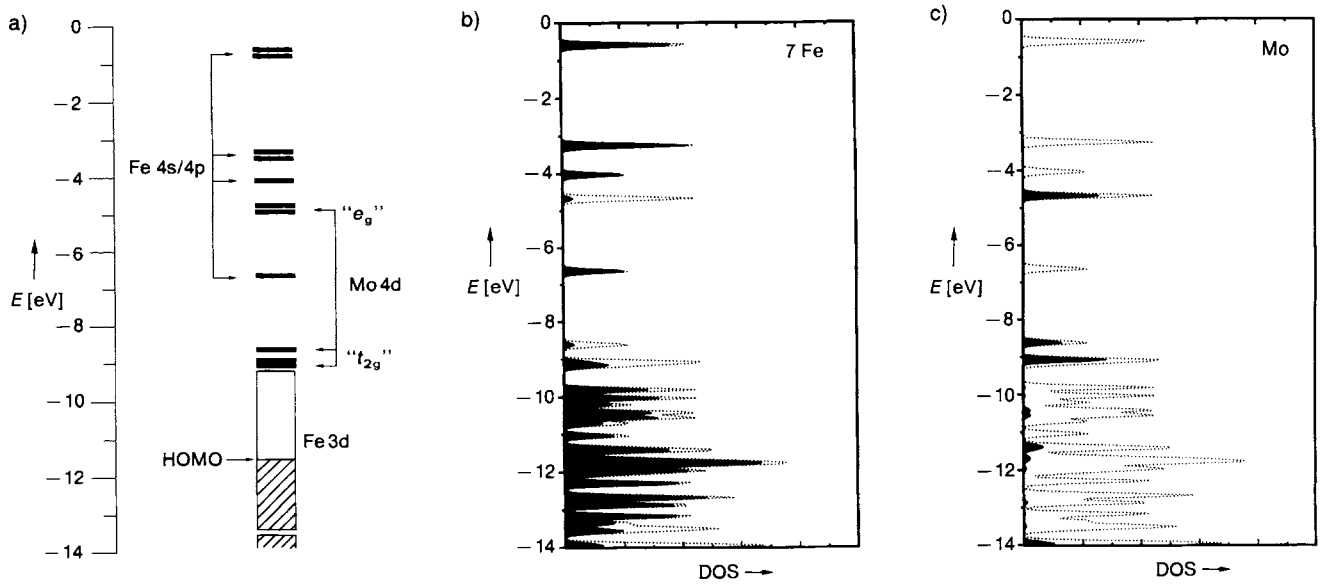

Fig. 1. a) Energy level diagram for **2**. Fe 4s/4p stands for hybrid orbitals, the striped block at the bottom represents ligand-based (S, H) orbitals. b) and c) "Density of states" (DOS) diagrams for **2**; the dotted line is the total DOS of **2**, and the contributions of seven Fe atoms and the Mo atom to the total DOS are shown by the shaded areas in b) and c), respectively.

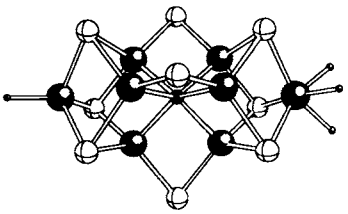
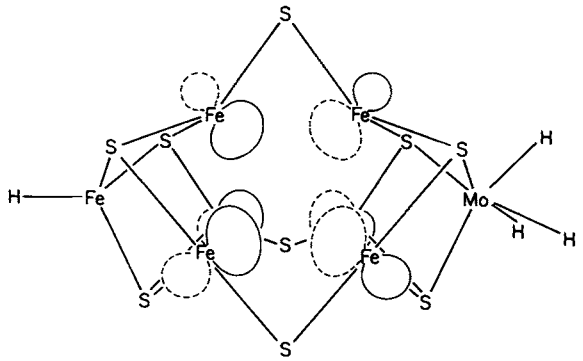
likely to be complicated, so our results on **2** are not inconsistent with $S = 3/2$ for **1**. We can also show the energy levels in a "density of states" (DOS) fashion,[8] as in Figures 1b and 1c. This is convenient when the contributions of individual atomic orbitals or fragment molecular orbitals are desired. Figures 1b and 1c illustrate such contributions from the Fe and Mo atoms, respectively.

We can analyze these orbitals in some detail. The orbitals below -13.5 eV are mainly ligand-based (S and H) orbitals, which are metal–ligand bonding. A block of 35 levels, mainly Fe 3d orbitals, is concentrated between -13.5 and -9 eV. The bottom of this block is Fe–Fe bonding, while the top part is Fe–Fe antibonding. The HOMO is at about the center of the Fe 3d block. The Mo 4d orbitals are higher in energy than Fe 3d orbitals; the Mo 4d orbitals split into "e_g" and "t_{2g}" sets, typical for an octahedral transition metal complex.[9] The six empty levels (above -7 eV) are composed mainly of combinations of 4s and 4p orbitals on three-coordinate Fe atoms. The resulting hybrids are approximately perpendicular to the local coordination planes of these Fe atoms. One such MO is drawn in Scheme 1. In these orbitals resides the coordinative "unsaturation" of these Fe atoms and their reactivity toward bases. The presence of these acceptor orbitals and the "open" cavity in the trigonal prism formed by Fe2–Fe7 have made people think about occupation of the cavity, even though there is *no* structural evidence for such a species. The model **3** has the geometry in question; when one does a calculation with a main group element in the center, for example, O^{2-} (Fe–O = 2.1 Å), four of the six Fe acceptor orbitals are indeed pushed up. Thus, there is nothing wrong electronically with a central atom in **2**.



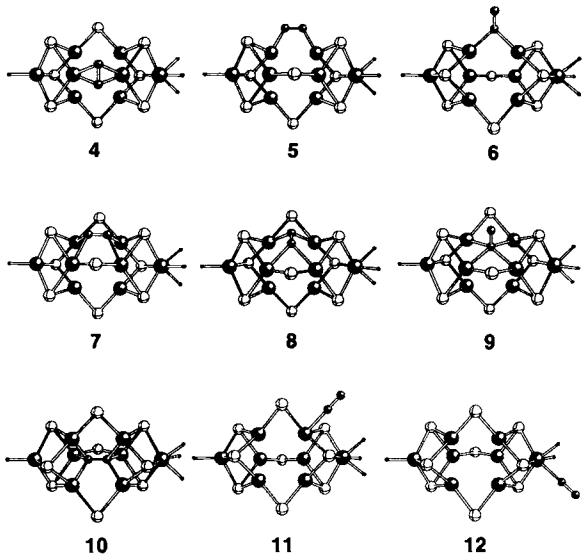
3



Scheme 1. One of the 4s/4p hybrid orbitals of **2**.

If we now return to the symmetrized cofactor model **2**, the overlap populations (OPs) between three-coordinate Fe atoms (e.g., Fe2–Fe3, Fe2–Fe5, Fe5–Fe6) are substantial (0.14–0.15). This is actually equivalent to something like a single bond. For instance, unbridged $[Fe_2(CO)_8]^{2-}$ at the same Fe–Fe distance has an Fe–Fe OP of 0.21. There definitely is metal–metal bonding everywhere in **2**, and across the trigonal prismatic cavity in particular.[10] This is reflected by the shorter Fe2–Fe5, Fe3–Fe6, and Fe4–Fe7 distances (2.5–2.6 Å) in the structurally refined cofactor model.

We assume that the first step in nitrogen fixation is the binding of N_2 to the FeMo-cofactor.[11] Various models with different N_2 binding sites are shown in Scheme 2. Model **4** has also been suggested by Orme-Johnson.[12] We set all the Fe–N or Mo–N distances at 2.0 Å, and the N–N distance at 1.1 Å, the value in free dinitrogen. We then compared the overlap populations for the N–N bonds and the net charges on the N atoms (Table 1) for various binding modes and for two different redox states of the cofactor (the "reduced" state has three more electrons than the "native" state). As the N–N bond has to be weakened and protonation at N has to occur before the coordinated N_2 can be reduced to NH_3,



Scheme 2. Theoretically studied complexes from N_2 and **2**.

a small value of N–N OP and a net negative charge on the N atoms should activate an N_2 molecule for reduction.

In models **4**–**6** the Y ligand is replaced by dinitrogen, while in **7**–**9** dinitrogen approaches the cofactor at a face of the Fe_6 trigonal prism. Models **7**–**9** give too close N–S contacts; we would like to reject them for that reason, but hesitate because the cofactor may expand its dimension upon reduction or N_2 binding. In **10**, the simple insertion of N_2 into the Fe_6 trigonal prism gives rise to very short Fe–N distances (ca. 1.8 Å). To obtain an Fe–N separation of 2 Å, a more reasonable value, the Fe_6 trigonal prism has to be expanded until the Fe–Fe distances, originally 2.75 Å, reach 3 Å. Table 1 includes data for both geometries of **10**. Two models involving end-on binding of N_2 are considered in **11** and **12**. One of the ligands on Mo has to be dissociated in order for Mo to bind N_2 in **12**.

Table 1. Overlap populations (OPs) of N–N bonds and net atomic charges on the N atoms for the N_2–FeMo-cofactor models shown in Scheme 2.

	"Native" State		"Reduced" State (three more electrons)	
	OP(N–N)	Charge on N [a]	OP(N–N)	Charge on N [a]
Free N_2	1.73	0		
4	1.47	−0.12	1.47	−0.18
5	1.61	0.11, 0.09	1.60	0.08, 0.06
6	1.58	0.49, −0.37	1.56	0.46, −0.43
7	1.45	0.28, 0.35	1.45	0.26, 0.32
8	1.51	0.20	1.49	0.16
9	1.52	0.58, −0.34	1.52	0.57, −0.39
10 [b]	1.23	0.43, 0.42	1.27	0.41, 0.28
10 [c]	1.35	0.34, 0.33	1.43	0.24, 0.16
11	1.70	0.62, −0.16	1.70	0.62, −0.17
12	1.72	0.45, −0.12	1.71	0.44, −0.14

[a] When two N atoms are not equivalent, the first value is for the "left" (or the bound) nitrogen atom in the structures in Scheme 2. [b] Fe–N = 1.79, Fe–Fe = 2.75 Å (for all edges of the Fe_6 trigonal prism). [c] Fe–N = 2.0, Fe–Fe = 3.03 Å (for all edges of the Fe_6 trigonal prism).

As shown in Table 1, centered **10** gives the smallest OP for the N–N bond; however, the net charges on N are quite positive, which is undesirable for protonation. Model **4** seems to be the best compromise—it has two ingredients important for N_2 reduction: a lowered N–N OP, and negative net charge on N. The reduced OP is primarily a consequence of the occupation of π_g^* orbitals of N_2. The contribution of this fragment MO to all the composite orbitals of **4** is shown in Figure 2. The π_g^* orbital is occupied to the extent of 20%. The models **6** and **9** are also possible binding modes, as the N–N bond is highly polarized and the terminal N atom carries a substantial net negative charge.

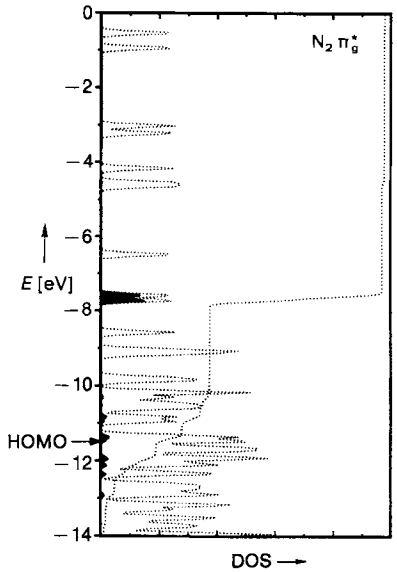


Fig. 2. The contribution of the N_2 π_g^* fragment MO (shaded area) to the total DOS of **4** (dotted line). The integration line indicates the percentage of π_g^* filled, on a scale from 0 to 100%.

The "reduced" state (with three more electrons) gives OPs for the N–N bond and net charges on the N atoms comparable to the "native" state. This is because the three additional electrons enter one or two levels immediately above the HOMO in the Fe 3d block, where there is relatively little N_2 orbital contribution. The net charges on the Fe or Mo atoms that bind N_2 do become more negative.[13]

In conclusion, our initial study finds that metal–metal bonding in the FeMo-cofactor model of nitrogenase is important; the Fe–Fe bonds are especially strong among three-coordinate iron atoms. N_2 coordinated models **4**, and possibly **6** and **9** are, we think, best activated for reduction.

[9] When the Mo 4d orbitals are put in with an energy of the Fe 3d (see end of ref. [2]), the Mo "t_{2g}" set is filled and the Mo reduced. The results of the N_2 binding are not affected.
[10] In a hypothetical model **3** with a central O atom, all the Fe–Fe (and Fe–Mo) interactions are weak, but definitely bonding (OPs range from 0.04 to 0.09), similar to those in a cubane cluster $[Fe_4S_4(SR)_4]^{2-}$ (OP = 0.07). In addition there is reasonable Fe–O bonding.
[11] One or two protons may also be bound to the MoFe-protein [7]. The protons may not necessarily bind to the cofactor; but if they do they would interact with the donor levels of the cofactor (e.g., the lone pairs of sulfide ions, or the filled Fe 3d orbitals), and should have little effect on the chemical bonding and the N_2-binding properties of the cofactor. We confirmed this by repeating the N_2-Binding studies with two protons bound to two bridging sulfide ions, and to Fe2 and Fe5 along the perpendicular direction of the coordination planes, respectively.
[12] W. H. Orme-Johnson, *Science*, **1992**, *257*, 1639–1640.
[13] We also performed calculations on N_2 binding with the O^{2-}-centered model **3**, but do not present details here. Binding modes **7**–**9** give unreasonably short N–O distances. For **5**, **6**, **11**, **12**, the central O^{2-} has little influence on the OP of the N–N bond. Only for **4** are both the OP for the N–N bond and the net atomic charge on the N atom substantially reduced, to values of 1.39 and −0.32, respectively. This is because the energy levels within half an eV above the HOMO have some contributions from the π^* state of the N_2 fragment, and they are filled when the central O^{2-} raises the energy of the HOMO by 0.4 eV. Of course, **10** is impossible in this case.

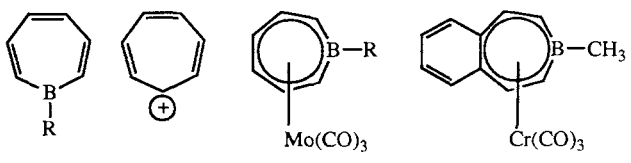
Structural Evidence of the Aromaticity of Borepins: A Comparison of 1-Chloroborepin and Tricarbonyl(1-chloroborepin)molybdenum **

By *Arthur J. Ashe, III,* Jeff W. Kampf, Wolfram Klein,* and *Roger Rousseau*

Dedicated to Professor Hans Bock on the occasion of his 65th birthday

Borepins **1** have been intensely investigated since they are the neutral isoelectronic analogues of tropylium **2**.[1–9] However, theoretical work has suggested that the aromaticity of 1 *H*-borepin (**1a**) is more limited than that of **2**.[10] The ready availability of minimally substituted borepins offers the opportunity to obtain experimental data on borepin aromaticity.[8, 9] We report here on the structures of 1-chloroborepin (**1b**) and tricarbonyl(1-chloroborepin)molybdenum (**3b**).[11]

At room temperature **1b** is a moisture- and air-sensitive liquid (m.p. −37 °C). We have determined the X-ray crystal structure of **1b** by using crystals grown from the neat liquid and sealed in capillaries. Selected bond lengths are listed in Table 1, while Figure 1 illustrates the structure, showing a completely planar borepin ring as had been anticipated from theoretical work.[10] The B–C bond length (1.51 Å) is distinctly shorter than those which have been found for nonconjugated B–C bonds (typical range 1.55–1.59 Å),[12] indicating π bonding in the borepin ring. The ring C–C bond lengths range from 1.37 to 1.42 Å; the formal single bonds are somewhat longer than the formal double bonds. However, this range of bond lengths (± 0.058 Å) is considerably smaller than that found for cycloheptatrienes (1.33–1.46 Å)[13] and other cyclic polyenes. Indeed, the range of C–C bond lengths of **1b** is comparable with that of napthalene (1.36–1.42 Å), and is consistent with an aromatic ring.[14]



1a, R = H **1b**, R = Cl **2** **3a**, R = H **3b**, R = Cl **3c**, R = C_6H_5 **4**

Table 1. Selected bond lengths [Å] of the borepins **1b** and **3b**.

Bond	**1b** (exp.)	**1b** (6-31G*)	**3b** (exp.)

C3-C3a	1.366(1)	1.346	1.413(3)
C-C range	±0.058	±0.093	±0.023
Mo-B1	–	–	2.486(4)
Mo-C1	–	–	2.417(2)
Mo-C2	–	–	2.362(2)
Mo-C3	–	–	2.325(2)

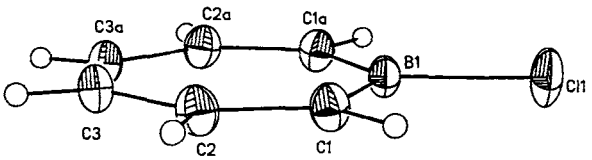

Fig. 1. Crystal structure of **1b** (ORTEP). Bond angles [°]: Cl1-B1-C1 116.76(6), C1-B1-C1a 126.5, B1-C1-C2 127.42(9), C1-C2-C3 128.96(9), C2-C3-C3a 130.4(1).

For purposes of comparison we have performed a Hartree Fock level ab initio MO calculation of **1b** with the 6-31G* basis set.[15] The optimized structural parameters listed in Table 1 do not differ significantly from those reported for **1a** calculated at the same level.[10] While the calculated and experimental structure for **1b** are in reasonable agreement (corresponding bond lengths are ± 0.02 Å), the calculated structure has a larger range of C–C interatomic distances (± 0.093 Å); thus the bond alternation is overestimated.

The reaction of **1b** with tricarbonyltris(pyridine)molybdenum and $BF_3 \cdot OEt_2$ gave the complex **3b**, which serves as a useful precursor for a variety of borepin complexes. The reduction of **3b** with lithium triethylborate afforded 1 *H*-borepin(tricarbonyl)molybdenum (**3a**) as stable crystals. This complex cannot be prepared directly from the very labile free 1 *H*-borepin.

It was of particular interest to obtain a crystal structure of **3b** and to compare it with that of **1b**. Structural data are known for **3c**[9] and **4**[12c] but not for the corresponding free ligands. The structure of **3b** (Fig. 2) consists of a nearly planar chloroborepin ring that is η^7-bound to the $Mo(CO)_3$ unit. The B–Mo distance (Table 1) is slightly longer than the

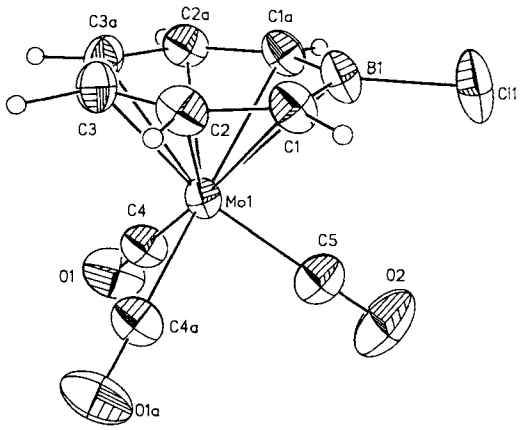

Fig. 2. Crystal structure of **3b** (ORTEP). Ring bond angles: [°]: Cl1-B1-C1 117.3(2), C1-B1-C1a 124.9(3), B1-C1-C2 128.5(2), C1-C2-C3 129.4(2), C2-C3-C3a 129.6(2).

C–Mo distances, and the boron atom is displaced out of the ring plane away from Mo by 0.05 Å. Thus, complexation causes this distortion of the planar free ligand. Similar distortions are found in the structures of **3c** and **4** and indeed in most other complexed boron heterocycles.[16, 17]

In addition, the formal double bonds (C1–C2, C3–C3a) lengthen on complexation, while the formal single bonds (B1–C1, C2–C3) remain unchanged. This suggests that the Mo atom removes electron density primarily from the electron-rich regions of the borepin ring which are *trans* to the CO ligands. The B–Cl unit is thereby eclipsed by one CO ligand. The conformational preferences of similar complexes have been discussed in detail by using an EH-MO model.[18] The effect of complexation is to reduce the C–C bond alternation from ± 0.058 Å in **1b** to ± 0.023 Å in **3b**. Therefore the delocalized π bonding is enhanced in **3b**.

Experimental Procedure

3b: A solution of **1b** (140 mg, 1.1 mmol) in pentane (2 mL) was added to a suspension of $[(C_5H_5N)_3Mo(CO)_3]$ (480 mg, 1.1 mmol) in ether (20 mL) at 25 °C. Then $BF_3 \cdot OEt_2$ (0.84 mL, 6.8 mmol) was added dropwise with stirring over 2 mins. After 3 h the solvent was removed under vacuum, and the residue was extracted with hexane. Crystallization at −20 °C afforded 220 mg (0.7 mmol) of crude crystals. Recrystallization from hexane gave orange cubes, M.p. 132–135 °C. High-resolution EI-MS: calcd. for $C_9H_6{}^{11}B^{35}Cl^{98}MoO_3$: 305.9153; found: 305.9146. IR (hexane): $\tilde{\nu}$ = 2024, 1974, 1947 cm^{-1} (vs, CO); ^1H NMR (360 MHz, C_6D_6): δ = 4.84 (br d, H_β), 4.45 (d, $J_{\alpha\beta}$ = 11.4 Hz, H_α), 4.26 (m, $J_{\beta\gamma}$ = 7.8 Hz, H_γ); ^{11}B NMR (115.5 MHz, C_6D_6): δ = 30.5 (br); ^{13}C NMR (90.6 MHz, C_6D_6): δ = 213.9 (CO), 109.4 (C_β), 95.9 (C_γ), 92.0 (br, C_α).

3a: To a solution of **3b** (40 mg, 0.1 mmol) in toluene (6 mL) at −60 °C was added with stirring 0.32 mL of a 1.0 M solution of $Li[BEt_3H]$ in THF. After the solution had been warmed to 25 °C, the solvent was removed under vacuum. A brown residue remained which was extracted with hexane. Removal of the solvent under vacuum left an orange oil which crystallized at 25 °C. Recrystallization from hexane gave bright orange crystals, M.p. 165 °C (decomp). High-resolution EI-MS: calcd. for $C_9H_7{}^{11}B^{98}MoO_3$: 271.9542; found: 271.9546. IR (hexane): $\tilde{\nu}$ = 2018, 1966, 1943 (vs, CO), 2512 cm^{-1} (w, BH); ^1H NMR (360 MHz, C_6D_6): δ = 5.16 (br d, H_β), 4.62 (dd, $J_{\alpha\beta}$ = 11.4, $^3J_{H\ BH}$ = 6 Hz, H_α), 4.42 (m, $J_{\beta\gamma}$ = 7.8 Hz, H_γ), BH (not observed); ^{11}B NMR (115.5 MHz, C_6D_6): δ = 23.1 (br d, J_{BH} = 94 Hz); ^{13}C NMR (90.6 MHz, C_6D_6): δ = 214.0 (CO), 112.8 (C_β), 97.4 (C_γ) C_α (not observed).

First Structure of a Mixed Organosodium/Lithium Alkoxide Compound: Model for a Superbase**

By *Sjoerd Harder* and *Andrew Streitwieser**

Mixtures of organolithium compounds and alkali metal alkoxides ROM (M = Na, K, Rb, Cs), such as BuLi/KO*t*Bu, are known as "superbases" and widely used in modern organic synthesis.[1] The development and application of these superbase systems have been subjects of chemical research for nearly three decades, yet the molecular structures of such systems are still a matter of controversy. The topic has been reviewed recently.[2] It is generally believed that the high reactivity of RLi/R′OM (M = Na, K, Rb, Cs) mixtures is

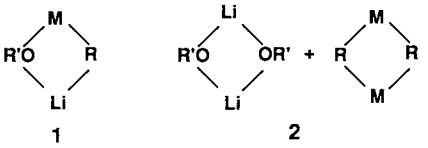
[**] S. H. thanks the NWO for a fellowship. This research was supported in part by the National Science Foundation (grant no. CHE87-21134).

caused by metal exchange, forming RM/R'OLi. The interaction of the smaller Li cation with the smaller O anion is favored electrostatically.[3] Organoalkali metal species, however, are commonly aggregated in the solid state and in solution.[4] The superbase mixture may well exist as mixed aggregates of RM and R'OLi monomers (**1**) or may be present as separate aggregates of RM and R'OLi (**2**).



1 **2**

Ab initio calculations on Li/Na dimer systems[5] have shown the importance of Li–O bond formation in the metal-exchange reaction [Eq. (a)]. The number of O–Li bonds is

$$(MeLi)_2 + (NaOH)_2 \longrightarrow (MeNa)_2 + (LiOH)_2 \quad \Delta E = -8.2\ kcal\,mol^{-1} \quad (a)$$

maximized in this reaction. There is, however, only a small energy difference between the separate MeNa and LiOH dimers and a mixed aggregate [Eq. (b)].

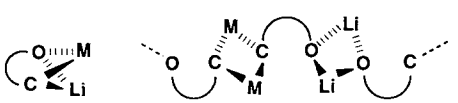
$$(MeNa)_2 + (LiOH)_2 \longrightarrow 2(MeNa/LiOH) \quad \Delta E = +1.3\ kcal\,mol^{-1} \quad (b)$$

This result suggests equilibria between **1** and **2** or at least the possible existence of short-lived mixed aggregates.

Because of the extreme reactivity of the superbase metalating reagents, the only report on the molecular structure of these compounds has been an NMR study of the model system cesium triphenylmethane/lithium 3-ethyl-3-heptoxide.[3] The authors could not detect mixed aggregates in this study.

All efforts so far to make crystals of superbase mixtures for X-ray diffraction studies have failed. The mixing of several organolithium compounds with several sodium or potassium alkoxides has resulted in microcrystalline precipitates of the pure organosodium or -potassium compounds.[6] This observation does not rule out the existence of mixed aggregates in solution since the precipitate only represents the least soluble species.

An alternative approach to the study of the structural properties of RM/R'OLi mixtures (M = Na, K, Rb, Cs) is the synthesis, crystallization, and X-ray diffraction analysis of compounds that contain both functionalities (C–M and O–Li) in one molecule. This approach in one sense circumvents the problem but could provide information on bonding and coordination patterns in mixed aggregates. For example, such compounds may form structures in which Li and M are doubly bridging between the anionic centers (**3**), a structure type common for dilithiated species,[4a] or they may form polymeric structures in which distinct C–M and O–Li interactions can be recognized (**4**).



3 **4**

A compound with both functionalities (C–M and O–Li) was obtained by treating sodium 2,4,6-trimethylphenoxide (**5**) with butyllithium in hexane to yield lithium 4,6-dimethyl-2-sodiomethylphenoxide (**6**).[7] Single-crystal X-ray structure analysis[8] of **6** · tmeda (tmeda = tetramethylethylenediamine) reveals a tetrameric aggregate with approximate, noncrystallographic S_4 symmetry (Fig. 1).

5 **6**

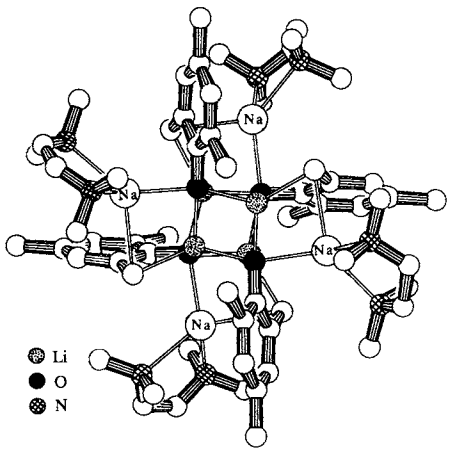


Fig. 1. Crystal structure of **6** · tmeda (hydrogen atoms omitted). The tetrameric aggregate has approximate S_4 symmetry. Average bond lengths [Å] and angles [°]: C-Li 2.17(2), O-Li 1.97(2), C-Na 2.671(9), O-Na 2.410(6), N-Na 2.496(9); Li-O-Li 82.0(7), O-Li-O 97.4(8), N-Na-N 72.6(3).

The core of the structure is a distorted cube made up of O and Li atoms, whose edges are formed by eight O–Li bonds 1.97(2)–2.06(2) Å in length and four significantly shorter O–Li bonds 1.88(2)–1.91(2) Å in length. The four shorter bonds are nearly colinear with the four C_{aryl}–O bonds (C-O-Li angles vary from 165.1(7)° to 171.3(7)°). The Li–O distances are similar to those in a tetrameric Li alkoxide (*O*-lithio-*N*-methylpseudoephedrin, 1.87–1.99 Å)[9] and a tetrameric lithium ester enolate (1.90–2.04 Å).[10]

Each of the Li bridges between the anionic carbon and oxygen centers is part of a puckered five-membered Li-C-C-C-O ring. This type of benzyl–Li interaction is novel for benzyl alkali metal compounds in which the metal atom is usually bonded to an α-benzyl carbon atom and approximately perpendicular to the benzyl plane. The C–Li distances range from 2.14(2) to 2.21(2) Å and are somewhat shorter than those in benzyllithium which range from 2.189(8) to 2.229(8) Å).[11]

The Na atoms are coordinated perpendicular to the plane of the benzyl group with an average distance of 2.671(9) Å to the carbanion center; this is comparable to the average CH_2–Na distance of 2.68 Å in tetrameric benzylsodium · tmeda.[12] Short distances to atoms in the ring system are shown in Figure 2. The Na–O contact (3.75 Å) is quite long, but there is a shorter contact of 2.410(6) Å between the Na atom and another O atom in the LiO cube. This is somewhat longer than the Na–O distances in dimeric sodium 2,4,6-tris(trifluoromethyl)phenoxide, which range from 2.231 to 2.313 Å.[13] The coordination sphere around Na in **6** is completed by chelation to tmeda; the Na–N distances are in the normal range of 2.445(8)–2.528(9) Å. The coordina-

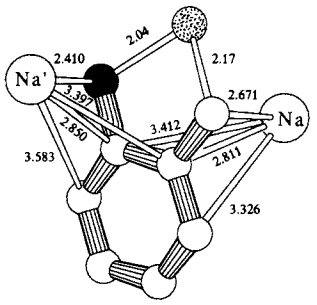

Fig. 2. Metal coordination around each aryl ring in **6** with average distances [Å].

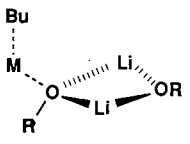
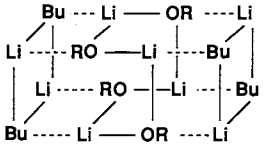
tion sphere of the oxygen atom in this aggregate deviates from the commonly observed trigonal (in ROLi dimers) and tetrahedral (ROLi tetramers/hexamers), and can be described best as tetragonal-pyramidal.

The structure of **6** · tmeda is the first of a "mixed" organosodium/lithium alkoxide aggregate. The structure is dictated by O–Li bonding. The observed cube structure results from the formation of the maximum number of O–Li bonds; Na–O coordination is of minor importance in the coordination sphere of the five-coordinate oxygen atom. The structure of **6** indicates that lithium alkoxides also have a dominating role in superbases in solution and suggests that analogous interactions occur between RM (M = Na, K, Rb, Cs) and R'OLi aggregates. That is, lithium alkoxide dimers or tetramers can be distorted to extend the coordination sphere around the O atom for interaction with the alkali metal (**7**). The resulting reduced coordination of the carban-



7



8

ion then effectively increases its basicity; such structural effects thereby contribute to the superbasicity of such mixtures. For comparison, the solid-state structure of (*n*BuLi · LiO*t*Bu)$_4$ may be viewed as a distorted cube made up of a LiO*t*Bu tetramer which is opened on two sides to interact with two BuLi dimers (**8**).[14]

[3] This preference for Li–O bonding is shown clearly by replacing anionic and cationic centers in these highly ionic compounds by simple unit negative and positive point charges, and calculating the potential energies. If R is the covalent radius of a nucleus, and $R_M > R_{Li}$ and $R_C > R_O$, then $1/(R_C + R_M) + 1/(R_{Li} + R_O)$ is always larger than $1/(R_C + R_{Li}) + 1/(R_M + R_O)$, no matter what the exact values of R are.

[7] Compound **6** was synthesized by treating a white suspension of **5** (1.0 g, 6.3 mmol) in 10 mL of hexane with BuLi/hexane (2.0 M, 6.6 mmol) under nitrogen at reflux. The resulting yellow powder (quantitative yield) underwent complete monodeuteration at the benzylic carbon when treated with D_2O.

[8] Crystal structure data of **6** · tmeda, orthorhombic, $a = 19.220(3)$, $b = 18.032(4)$, $c = 39.806(8)$ Å, $V = 13796(5)$ Å^3, space group *Pbca*, formula $\{(C_9H_{10}OLiNa) \cdot (C_6H_{16}N_2)\}_4$, $M = 1121.26$, $Z = 8$, $\rho_{calcd} = 1.080$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.8$ cm^{-1}; 9837 unique reflections were measured on a Enraf-Nonius CAD4 diffractometer ($Mo_{K\alpha}$ radiation, graphite monochromator, $T = -95$ °C) and 3704 reflections with $F^2 > 2.5\sigma(F^2)$ were considered observed. Solution by direct methods with SHELXS-86 [15], refinement by minimalization of $\sum w(F_o - F_c)^2$ to $R = 0.077$ and $wR = 0.069$ with $w = 1/\sigma^2(F_o)$, non-hydrogen atoms anisotropic; H atoms were assigned idealized locations and isotropic thermal parameters approximately 1.3 times that of the atoms to which they are attached. Two of the four tmeda molecules show disordering which is common for tmeda and well described in literature [16]. Disorder in the structure of **6** · tmeda was described best with large anisotropic parameters on the disordered atoms. Unfortunately, benzylic hydrogen atoms could not be detected in the difference Fourier map, and the hybridization at the benzylic carbon atom remains unknown. Plots were made with the EUCLID package [17]. Further details of the crystal structure investigation are available from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

Rapid Carboalumination of Alkynes in the Presence of Water**

By *Peter Wipf** and *Sungtaek Lim*

The carboalumination of alkynes is one of the most versatile routes for the preparation of olefins with defined configurations.[1] Recent applications of this methodology in natural products synthesis include the preparation of segments for lophotoxin,[2] macbecin,[3] and FK-506.[4] Whereas the uncatalyzed carboalumination of nonfunctionalized alkynes is slow even at elevated temperatures, the zirconium-catalyzed variant[5] occurs under mild conditions. Methylalumination of 1-octyne (**1**) in the presence of 1 equiv of [Cp_2ZrCl_2], for example, yields 2-methyl-1-octene (**2**) and 2-nonene (**3**) in a 95:5 ratio after 3 h at 22 °C.[6]

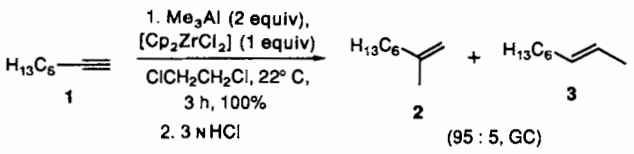
[**] This work was supported by the University of Pittsburgh. We thank Prof. H. Yamamoto for stimulating discussions.



In the course of our studies of transmetalation of alkenylalanes,[7] we discovered that the addition of 1–2 equiv of *water* to the carboalumination reaction mixture led to a considerable increase in the rate of this process. *In fact, even at −70 °C methylalumination of 1-hexyne* (**4**) *was essentially complete in 10 min in the presence of 1.5 equiv of* H_2O*!*

Table 1 summarizes the scope of this novel water effect in carboaluminations.[8] A solution of Me_3Al in hexane or toluene was treated with $[Cp_2ZrCl_2]$ and H_2O, and then alkyne **4**. The vinylalane intermediate formed in 10 min at −23 °C and was trapped with iodine to afford 1-iodo-2-methyl-1-hexene (**7**) and 3-iodo-2-heptene (**8**) (ratio 98:2) in 89% yield after chromatographic purification (entry 1). Trapping with propene oxide (**12**) provided the homoallylic alcohol **13** in 80% yield (entry 3).[9] These results compare very favorably with those from the standard protocols for methylalumination, exemplified in entries 2 and 4, which require reaction times of 4–12 h at room temperature for completion.

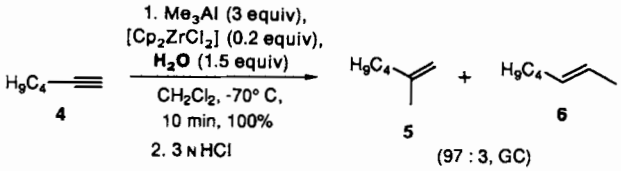


Table 1. Comparison of water-accelerated (methods A and B) and standard (method C) carboalumininations of alkynes.

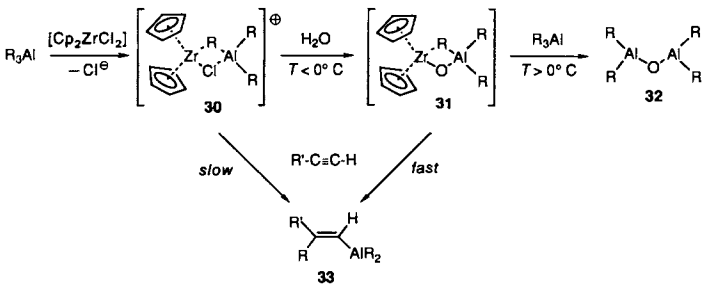
[a] Yields refer to chromatographically purified products and are based on the alkyne. [b] 8% Regioisomer was present according to the ^1H NMR spectrum. [c] Carboalumination in the presence of 1 equiv of $[Cp_2ZrCl_2]$ for 2 h at $-23 \rightarrow 20$ °C. [d] Carboalumination in the presence of 1 equiv of $[Cp_2ZrCl_2]$ for 18 h at −23 °C. [e] The alcohol was pretreated with 0.33 equiv of Me_3Al; carboalumination for 1 h at $-23 \rightarrow 20$ °C.

The presence of remote functional groups such as silyl ethers[10] or hydroxyl groups does not interfere with the H_2O effect. Thus, methylalumination of **16** was complete after less than 10 min at −23 °C (entry 6). For propargylic and homopropargylic alcohols, however, higher temperatures or longer reaction times were necessary. Methylalumination of **18** followed by trapping with ethyl chloroformate provided ester **19** in 52% yield after 2 h at −23 → 20 °C, and **20** was converted to the silylated methallyl alcohol **21** in 61% yield after 18 h at −23 °C (entries 7 and 8). Treatment of alcohol **22** with 0.33 equiv of Me_3Al, followed by water-accelerated carboalumination at −23 → 20 °C for 1 h and trapping with I_2 led to vinyl iodide **23** in 85% yield (entry 9). In the absence of water, conversion of **22** to the iodide **23** required 12 h reaction time at room temperature for the carboalumination step,[5a] and provided a significantly lower yield of the trapping product (entry 10).

The standard methylalumination with Me_3Al in the presence of $[Cp_2ZrCl_2]$ generally provides quite satisfactory regioselectivities.[5] However, very slow reactions and much inferior regioselectivities are observed in carboaluminations with higher alkylaluminums such as Et_3Al. We therefore investigated the effect of H_2O in the ethylalumination of alkyne **4**. As expected, the turnover number was greatly increased: after 30 min at −23 °C, trapping of the alkenylalane with I_2 provided vinyl iodides **24** and **25** (ratio 73:27) in 74% yield (entry 11). In contrast, hydrolysis of the alkenylalane of **26**, prepared in the absence of H_2O after 24 h reaction time at 20 °C, provided regioisomers **27** and **28** (61:39 ratio) in only 31% yield (entry 12). A more efficient protocol was recently reported by Inoue et al. With Zr^{IV} complexes of tetraphenylporphyrin (TPP) $[(TPP)ZrCl_2]$ in place of $[Cp_2ZrCl_2]$, the turnover of **26** with Et_3Al was slightly improved and led to the ethylalumination products **27** and **28** (ratio 88:12) in 52% yield after 24 h reaction time in benzene (entry 13). Compared to this modified procedure, our water-accelerated ethylalumination provides a lower regioselectivity but still a greatly increased reaction rate and a higher yield. Trapping of the intermediate alane from the low-temperature ethylalumination of 1-hexyne with propene oxide, for example, led to pure homoallylic alcohol **29** in 53% yield after chromatographic separation from the minor regioisomer present in 20% yield (entry 14).

The rate-enhancing effect in Zr-catalyzed carboaluminations seems to be unique to H_2O. We have also used H_2S, alcohols, silanols, diphenylborinic acid (Ph_2BOH), and bis(diisobutylaluminum)oxide, but all of these additives failed to reproduce the effects of water. Zirconocene dichloride is necessary as a cocatalyst, and the rate-enhancing effect is not due to the formation of methylalumoxane ($(AlMeO)_x$, MAO), which is a well-known and highly active cocatalyst for the polymerization of α-olefins.[13, 14] Independently prepared methylalumoxane failed to show any accelerating effects in carboaluminations at low temperatures. Indeed, when the yellowish reaction mixture obtained after addition of $[Cp_2ZrCl_2]$ and H_2O to trialkylalane was warmed from −23 °C to room temperature, which presumably causes the formation of alkylalumoxanes **32**, the resulting medium had greatly reduced catalytic activity for carboalumination. Therefore, we propose that a thermodynamically labile, but catalytically highly active oxo-bridged dimer **31** forms in mixtures of trialkylalane, zirconocene dichloride, and water at temperatures below 0 °C (Scheme 1).

In conclusion, we have demonstrated a novel rate-acceleration by H_2O in the low-temperature carboalumination of alkynes. Alkenylalanes are thus generated within minutes at −23 °C and serve as starting materials for the stereoselective



Scheme 1. Proposed mechanism for the formation of a highly active species in the water-accelerated zirconium-catalyzed carboalumination of alkynes.

preparation of functionalized trisubstituted alkenes. This is another example for the unique and yet still basically unexplored effects of water in reactions with organometallic compounds.[15]

Experimental Procedure

Method A: **7**: To a solution of 5 mL (10 mmol) of a 2 M solution of trimethylalane in hexane and 208 mg (0.71 mmol) of $[Cp_2ZrCl_2]$ in 12 mL of CH_2Cl_2 was slowly added 90 μL (5 mmol) of water at −23 °C under vigorous stirring. **Caution: Exothermic reaction!** After 10 min, a solution of 265.8 mg (3.23 mmol) of 1-hexyne in 5 mL of CH_2Cl_2 was added. The reaction mixture was stirred for another 10 min at −23 °C before a solution of 983 mg (3.88 mmol) of iodine in 5 mL of THF was added dropwise. After 10 min, the mixture was allowed to warm to room temperature, and 1 mL of a saturated K_2CO_3 solution was added slowly with vigorous stirring. After 15 min, 2 g of anhydrous $MgSO_4$ was added and the mixture was filtered and extracted with Et_2O. The combined organic layers were concentrated under reduced pressure, and the residue was chromatographed on silica gel (pet. ether) to afford 641.9 mg (89%) of **7** as a colorless oil: ^1H NMR (300 MHz, $CDCl_3$, 22 °C): $\delta = 5.85$ (s, 1H; CH), 2.20 (t, $^3J(H,H) = 7.2$ Hz, 2H; CH_2), 1.82 (s, 3H, CH_3), 1.44–1.37 (m, 2H; CH_2), 1.33–1.22 (m, 2H; CH_2), 0.89 (t, $^3J(H,H) = 7.3$ Hz, 3H; CH_3); ^{13}C NMR (75 MHz, $CDCl_3$, 22 °C): $\delta = 148.4$, 74.4, 39.4, 29.9, 23.8, 22.2, 13.9; IR (neat): $\tilde{\nu} = 2957$, 2930, 2870, 2859, 1617, 1456, 1377, 1267, 1142, 764, 668 cm^{-1}; MS (70 eV): *m/z* 224 (20%) [M^+], 182 (18), 168 (4), 97 (15), 84 (10), 55 (100).

Method B: **24**: To a solution of 3 mL (5.7 mmol) of a 1.9 M solution of triethylalane in toluene and 122 mg (0.42 mmol) of $[Cp_2ZrCl_2]$ in 12 mL of CH_2Cl_2 was slowly added 56 μL (3.1 mmol) of water at −23 °C under vigorous stirring. **Caution: Exothermic reaction!** After 30 min, a solution of 155 mg (1.89 mmol) of 1-hexyne in 3 mL of CH_2Cl_2 was added. After stirring for another 30 min at −23 °C, a solution of 575 mg (2.26 mmol) of iodine in 4 mL of THF was added dropwise. After 10 min the mixture was allowed to warm to room temperature, and 1 mL of a saturated K_2CO_3 solution was added slowly with vigorous stirring. Workup as described for method A afforded 332.3 mg (74%) of a 73:27 mixture of **24** and **25** as a colorless oil. **24**: ^1H NMR: $\delta = 5.80$ (s, 1H; CH), 2.17 (m, 4H; $2CH_2$), 1.44–1.25 (m, 4H; $2CH_2$), 1.00 (t, $^3J(H,H) = 7.6$ Hz, 3H, CH_3), 0.90 (t, $^3J(H,H) = 7.1$ Hz, 3H; CH_3); ^{13}C NMR: $\delta = 153.1$, 73.6, 36.5, 30.5, 30.0, 22.3, 13.9, 11.8; IR (neat): $\nu = 2961$, 2930, 2872, 1462, 1377, 1244, 1142, 762, 668 cm^{-1}; MS (70 eV): *m/z*: 238 (25%) [M^+], 196 (15), 167 (10), 84 (8), 69 (100), 55 (40).

[8] Carboaluminations were generally performed at −23 °C in a dry ice/CCl_4 bath. Problems with the rapid freezing of the added H_2O at temperatures below −30 °C were thus avoided. All products were characterized by ^1H NMR, ^{13}C NMR, IR and mass specta.

[9] As the yields of the trapping reactions show, the intermediate vinylalane is not hydrolyzed by any residual water present in the reaction mixture. In a control experiment, 1.5 equiv of D_2O were used in place of H_2O in the accelerated methylalumination of alkyne **18**. After addition of the alkyne at $-23\,^{\circ}C$, the reaction mixture was stirred for 3 h at $0\,^{\circ}C$ before the trapping reagent (I_2) was added. Only 3.4% of the deuterated species **i** besides 66% of the iodide **ii** was detected by ^1H NMR.

Stereochemistry of the C–S Bond Cleavage in 1-Phenylethyl Phenyl Sulfide Radical Cation: Evidence for a Unimolecular Pathway**

By *Enrico Baciocchi,* Elisabetta Fasella, Osvaldo Lanzalunga*, and *Mario Mattioli*

Aromatic radical cations are key intermediates in a large number of chemical and biochemical processes.[1] The reactions of these radical cations have therefore attracted continuous attention, particularly the ones involving the cleavage of a σ bond [Eq. (a)].[2] These reactions have a wide scope

$$[Ar-a-b]^{\bullet+} + Nu^- \longrightarrow [Ar-a]^{\bullet} + bNu \qquad (a)$$

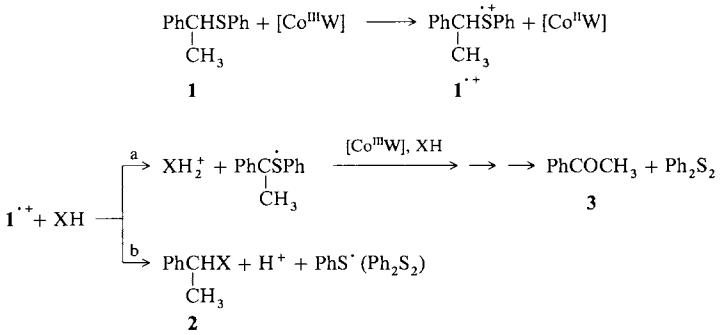
and moreover, they exhibit features of theoretical interest, since they represent a new class of nucleophilic displacements in which a free radical is the leaving group. Thus, for these reactions, either a bimolecular, concerted mechanism (S_N2) or a stepwise unimolecular mechanism (S_N1) can be envisaged; interestingly, in the former case, both inversion and retention of configuration are in principle possible, since the radical cation is an open-shell system and either its SOMO or its LUMO may interact with the HOMO of the nucleophile.

Surprisingly, very little information on the mechanisms of these processes is presently available. Unimolecular C–C bond cleavage has been observed for bicumyl[3a] and benzyl acetal radical cations,[3b] whereas clear evidence for a bimolecular mechanism has been provided for ring opening C–C bond cleavage in phenylcyclopropane radical cations[4] as well as for the breaking of the C–Si bond in benzyltrimethylsilane radical cations.[5]

For phenylcyclopropane radical cations, the reaction occurs with complete inversion of configuration, therefore indicating that the LUMO–HOMO interaction is decisive. This has been justified on the basis of theoretical considerations.[6]

Since the nature of the bond to be broken plays a crucial role in the mechanism, we decided to study the C–S bond cleavage in benzyl phenyl sulfide radical cations. We chose the reaction of 1-phenylethyl phenyl sulfide (**1**) promoted by $K_5[Co^{III}W_{12}O_{40}]$, (abbreviated as $[Co^{III}W]$) a "bona fide" outer sphere one-electron oxidant,[7] in $AcOH/H_2O$ (70/30) at $50\,^{\circ}C$. This reaction leads, with an excellent mass balance, to 1-phenylethyl acetate (**2**, X = OAc), 1-phenylethanol (**2**, X = OH), and acetophenone **3**, in a 1.2:2.1:1 molar ratio.

Among the products, diphenyl disulfide and small amounts of styrene are also observed. The oxidation of **1** occurs via the radical cation $\mathbf{1}^{\bullet+}$, which, as shown in Scheme 1, undergoes C–S and C–H bond cleavage, leading to **2** (path b) and **3** (path a), respectively. As expected,[9] when the reaction was carried out in the presence of AcOK (0.25 M), deprotonation becomes more important and acetophenone **3** is the major product: the molar ratio **2**, X = OAc to **2**, X = OH to **3** is 0.65:0.65:1.



Scheme 1. Possible reaction mechanism for the oxidation of **1** with $[Co^{III}W]$. X = OH, OAc.

When the same reaction was carried out starting from enantiomerically pure (*R*)-(+)-**1**, we observed that the formation of the products **2** took place with racemization, accompanied to some extent (16%) by inversion: The (*S*):(*R*) ratio is 1.4:1 for both products. In the presence of AcOK, the (*S*):(*R*) ratios increase slightly to 1.55:1 (0.25 M AcOK) and 1.8:1 (0.5 M). Again, the (*S*):(*R*) ratio is the same, within the experimental error, for **2**, X = OH and **2**, X = OAc.

These results clearly indicate that the cleavage of the C–S bond in $\mathbf{1}^{\bullet+}$ takes place by two pathways, one leading to racemized **2**, the other to inverted **2**. For the former, there is little doubt that we are dealing with an S_N1 mechanism. This involves the formation of the 1-methylbenzyl carbocation which reacts with the mixed solvent to produce racemic **2** (Scheme 2, path a), or is deprotonated to styrene.

For the pathway with inversion, the situation is less straightforward and two possibilities can be considered. The first is an S_N2 mechanism, occurring with inversion of configuration, as already observed for the C–C bond cleavage in phenylcyclopropane radical cations.[4] The role of this mechanism could become more important in the presence of AcOK, since AcO^- is certainly a much stronger nucleophile than both H_2O and AcOH.

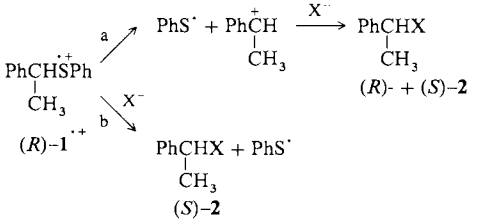
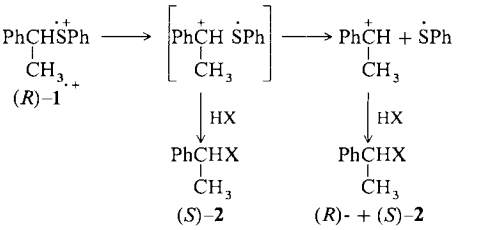


Scheme 2. Competition between unimolecular (path a) and bimolecular mechanisms (path b) for the C–S bond cleavage in $\mathbf{1}^{\bullet+}$.

The second possibility is that the S_N1 mechanism is more complex than indicated in Scheme 2, the unassisted cleavage of the C–S bond first leading to a contact radical–cation pair[10] and then to a solvent-separated radical–cation pair (Scheme 3). Nucleophilic attack on the contact radical–cation pair should lead to the inverted products.



Scheme 3. Possible mechanism for the unimolecular C–S bond cleavage in $\mathbf{1}^{\bullet+}$.

We suggest that the latter hypothesis is the more likely. First, because the effect of AcOK on the (*S*):(*R*) ratio seems too small to be compatible with an S_N1–S_N2 competition. Since some inversion is already present in $AcOH/H_2O$, we would expect a larger effect of AcOK on the (*S*):(*R*) ratio than the one observed. Indeed, this effect is very modest, the percent of inversion changing from 16%, in the absence of AcOK, to 28%, in the presence of AcOK (0.5 M). Such a small increment seems to be more consistent with the mechanism in Scheme 3, where it can be justified by suggesting that, in the presence of AcOK, a larger fraction of the contact radical–cation pairs reacts with the nucleophile before dissociation. Second, a significant contribution of an S_N2 mechanism for the formation of **2** is not in line with the results of preliminary kinetic experiments which indicate that the overall oxidation rate is increased by only 35% in the presence of 0.2 M AcOK. Such an increase is almost exclusively due to the enhanced rate of the deprotonation reaction leading to acetophenone **3**, a process which is certainly base catalyzed.[9] Finally, another argument is the observation that the (*S*):(*R*) ratio is the same for **2**, X = OH and **2**, X = OAc even in the presence of AcOK. This requires that both compounds form in an almost identical ratio in the path leading to inversion and in that leading to racemization. This possibility is very unlikely for the structurally unrelated S_N1 and S_N2 pathways, whereas it is very reasonable if the two reaction channels, as in Scheme 3, involve extremely similar intermediates, namely a solvent-separated and a contact radical–cation pair.

Interestingly, if this hypothesis is correct, the solvolysis of $\mathbf{1}^{\bullet+}$ would closely resemble that of the corresponding closed-shell systems (1-phenylethyl halides) which also exhibit racemization accompanied by some inversion, and have similarly been interpreted on the basis of ion pair formation.[11]

Since the C–S bond dissociation energy in $\mathbf{1}^{\bullet+}$ is about 16 kcal mol^{-1},[12] a value close to that estimated for the C–C bond breaking in the phenylcyclopropane radical cation (ca. 15 kcal mol^{-1}[4]), it is surprising that in $\mathbf{1}^{\bullet+}$ the C–S bond cleavage utilizes an unassisted pathway (unimolecular), whereas the C–C bond cleavage in the phenyl cyclopropane radical cation exclusively occurs by a bimolecular mechanism and is very fast. We suggest that this difference in behavior can be attributed to the fact that small rings, particularly the three-membered ones, exhibit a reactivity in S_N2 ring opening reactions which is many orders of magnitude higher than that expected on the basis of steric strain.[13] However, it should also be considered that phenylcyclopropane radical cations are of π character, whereas $\mathbf{1}^{\bullet+}$ has presumably *n* character.[15]

Experimental Procedure

1: The corresponding ditosylamide was prepared from (*S*)-(1)-phenylethylamine (Aldrich) [14] and this was converted to (*R*)-**1** by reaction with thiophenol in acetone containing potassium carbonate [8]. When treated with H_2O_2 in AcOH, (*R*)-**1** gave the corresponding sulfone, m.p. 120–121 °C (115–116 °C [14]), $[\alpha]_{25}^{D} = 106$ (103 [14]) ($c = 1.5$ g L^{-1}; MeOH). For the oxidation experiments the concentration of **1** was 0.02–0.04 M, and that of [$Co^{III}W$] 0.02–0.08 M. In a typical experiment, 0.23 mmol of substrate was treated with 0.23 mmol of [$Co^{III}W$] in 10 mL of 0.25 M AcOK. After 3 h, 20% of the [$Co^{III}W$] had been consumed, which afforded **3** (0.015 mmol), **2**, X = OH (0.01 mmol), **2**, X = OAc (0.01 mmol), Ph_2S_2 (0.017 mmol), styrene (0.002 mmol), and 0.19 mmol of unreacted **1**. No reaction took place in the absence of [$Co^{III}W$]. In some experiments unreacted (*R*)-**1** was recovered from the reaction mixture and converted into the sulfone which showed no loss of optical activity. Thus, (*R*)-**1** was configurationally stable under the reaction conditions. The products were analyzed by GLC and GC-MS (comparison with authentic specimens) by using two internal standards (anisaldehyde and octadecane). The (*S*)-**2**/(*R*)-**2** ratios were determined by GLC with a Varian Model 3400 flame-ionization gas chromatograph equipped with a chiral capillary column (cyclodex-B, 30 m × 0.25 mm, from J & W Scientific) and He as carrier gas (1.8 atm). Under isothermal conditions (90 °C), the following retention times were obtained for the optically active products **2**: (*R*)-**2**, X = OH: 15.54; (*S*)-**2**, X = OH: 16.16; (*S*)-**2**, X = OAc: 18.91; (*R*)-**2**, X = OAc: 19.57 min. In the experiments in the presence of AcOK, the (*S*):(*R*) ratios showed no change during the course of the reaction, for those in the absence of AcOK, a slight decrease in these ratios was observed at high percent of conversion. This was probably due to some racemization of **2** promoted by the acid which forms during the reaction.

[12] a) By a thermochemical cycle, the C–S bond dissociation energy (BDE) in $1^{\bullet+}$ is given by $BDE(1^{\bullet+}) = BDE(1) + I_p(rad) - I_p(1)$, where BDE(1) and $I_p(1)$ are the C–S bond dissociation energy and the ionization potential of 1, respectively, and $I_p(rad)$ is the ionization potential of the 1-phenylethyl radical. BDE(1) was estimated to be about 50 kcal mol^{-1} by subtracting the difference between the C–H BDE values of $PhCH_2$–H (88 kcal mol^{-1}) [12b] and $PhCH(CH_3)$–H (85.4 kcal mol^{-1}) [12c] from the C–S BDE of $PhCH_2$–SPh (52.6 kcal mol^{-1})] [12c]. The latter value is given by the C–S BDE of $PhCH_2$–SH (58.8 kcal mol^{-1}) [12c] minus the difference between the C–S BDE values of CH_3–SH (73.9 kcal mol^{-1}) [12c] and CH_3–SPh (67.7 kcal mol^{-1}) [12c]. $I_p(rad)$ is 6.9 eV [12d] and $I_p(1)$ is taken to be equal to that of benzyl phenyl sulfide (8.36 eV [12e]). The value of BDE($1^{\bullet+}$) obtained in this way refers to the gas phase. However, gas phase bond dissociation energies of radical cations are often similar to those in solution [12f]. b) D. F. [15] An *n* character has been shown for the structurally similar benzyl phenyl sulfide radical cation [9]. We thank a referee for having called our attention to this point.

Structure and Reactivity of $[HFe(CO)_3(\eta^3\text{-}C_3H_5)]$**

By *Terence M. Barnhart, James De Felippis,* and *Robert J. McMahon**

Transition metal η^3-allyl hydrido complexes were first proposed in 1962 by Pettit et al.[1] and Manuel[2] as key intermediates in the $Fe(CO)_5$-catalyzed isomerization of alkenes. Despite continuing interest in the mechanism of this important process,[3] the extremely high reactivity of first-row η^3-allyl hydrido complexes has precluded direct characterization of catalytically important species in solution.[4] We report here the characterization of a highly reactive iron η^3-allyl hydrido complex, $[HFe(CO)_3(\eta^3\text{-}CH_2CHCH_2)]$ (**2**), by ^1H and ^{13}C NMR spectroscopy in $[D_{14}]$methylcyclohexane at 160 K. This is the first observation of a catalytically significant η^3-allyl hydrido complex in solution, and thus paves the way for further detailed studies concerning the mechanism of alkene isomerization.

Photolysis ($\lambda > 280$ nm) of **1** in a $[D_{14}]$methylcyclohexane glass produces **2**,[5] which persists upon warming the glass above its melting point (ca. 140 K). At 160 K, the photolyzed sample displays four new resonances ($\delta = 5.19$, 2.56, 1.80, −12.20, integrated intensities 1:2:2:1) and a fifth, very minor resonance (−12.0) (Fig. 1). We attribute the four major

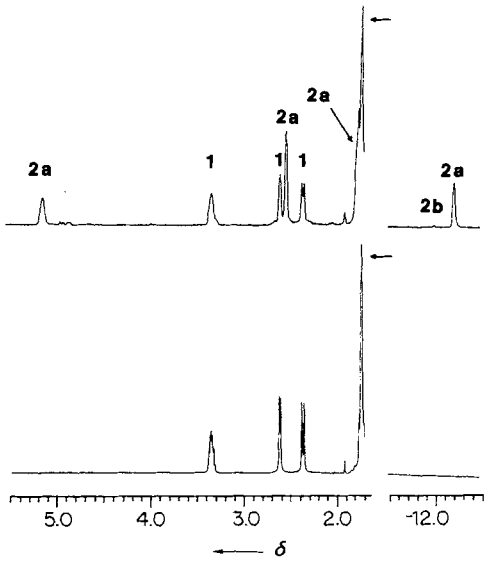

Fig. 1. Bottom: ^1H NMR spectrum **1** in $[D_{14}]$methylcyclohexane at 160 K prior to irradiation. Top: ^1H NMR spectrum of **2a** obtained upon photolysis of **1** ($\lambda > 280$ nm, 1 h). The weak signals near $\delta = 5.0$ are assigned to free propene, and the strong signals marked with arrows are assigned to $[D_{14}]$methylcyclohexane.

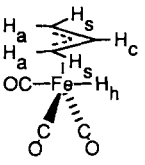
resonances to a pseudo-octahedral π-allyl hydrido complex (either **2a** or **2b**), drawing on analogy with π-allyl complexes of iron[6] and with other, less reactive π-allyl hydrides.[4] The high-field resonance ($\delta = -12.2$) is characteristic of a terminal hydrido ligand H_h. The remaining resonances display chemical shifts, coupling constants, and integration consistent with a symmetrical η^3-allyl ligand.[6–8] The signal of the central proton H_c of the allyl ligand ($\delta = 5.19$, m, 1H) exhibits the largest chemical shift, and appears as a broadened multiplet due to coupling with the *syn*-H_s and *anti*-H_a protons. The *syn* protons H_s ($\delta = 2.56$, d, 2H, $J = 5$ Hz) appear



2a, *exo*

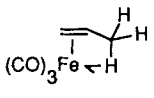
upfield of H_c and display the expected small *cis* coupling constant J_{H_c,H_s}. The *anti* protons H_a ($\delta = 1.8$, 2H) appear even further upfield of H_c.[9] The COSY spectrum reveals small coupling constants ($J < 5$ Hz) for the coupling between the hydrido ligand H_h and each of the allyl protons.[4] We could not resolve this coupling in the one-dimensional ^1H NMR spectrum.[7] The observation of two distinct carbonyl resonances in the ^{13}C NMR spectrum of **2** implies that

the CO ligand *trans* to the hydride ($\delta = 212.2$, $^2J_{C,H} = 18$ Hz) and the CO ligands *cis* to the hydride ($\delta = 210.7$, $^2J_{C,H} = 12$ Hz) do not exchange rapidly on the NMR timescale.

Pseudo-octahedral π-allyl halide complexes analogous to **2** exhibit geometric isomerism; the isomers differ in the relative orientation of the allyl ligand with respect to the M–X bond.[6] The isomers interconvert by allyl ligand rotation, but this process is slow on the NMR timescale at 298 K.[6] Thus, the geometric isomers are readily distinguished by ^{1}H NMR spectroscopy. We fully expect to resolve geometric isomers of **2** at 160 K. We tentatively ascribe the additional resonance at $\delta = -12.0$ to the isomer **2b**, although we cannot identify the resonances of the allyl ligand. The integrated ratio of the H_h resonances at $\delta = -12.0$ and -12.2 is $1 : > 20$. We do not know whether this ratio reflects the thermodynamic equilibrium.

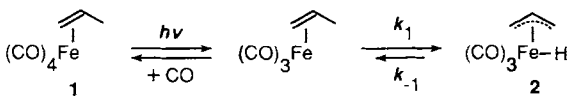
We assigned the geometry of the major isomer of **2** on the basis of ^{1}H–^{1}H NOE effects. We used Landis' method to predict the NOE intensities for both *exo* and *endo* isomers.[10] In the *exo* isomer, the NOE intensities for the interactions between H_h and each of the allyl protons are calculated to be roughly comparable. In the *endo* isomer, the NOE intensity for the interaction between H_h and H_a is calculated to be one order of magnitude larger than the NOE intensities for the interactions between H_h and either H_c or H_s. The measured ^{1}H–^{1}H NOESY spectrum shows cross peaks of similar intensity between H_h and each of the allyl protons. The calculations therefore enable us to assign the major product of the photolysis as *exo*-**2a**.[11]

^{1}H and ^{13}C NMR data are inconsistent with various structures involving agostic interactions.[12] An agostic structure such as **3**, in which the methyl group is either static or rotating, would display a 1:1:1 ratio of olefinic resonances in the ^{1}H NMR spectrum. We therefore rule out these structures based on the observation of a 1:2:2 ratio of olefinic resonances. Rapid, reversible 1,3-hydrogen migration in **3**, with accompanying C–C bond rotation, would render all five terminal hydrogen atoms equivalent. This scenario is inconsistent with the observed ^{1}H NMR spectrum. Rapid, reversible 1,3-hydrogen migration in **3**, without accompanying C–C bond rotation, would be consistent with the observed ^{1}H NMR spectrum. In this case, the coupled ^{13}C NMR spectrum should reveal a small $^1J_{C,H}$ coupling of 60–90 Hz.[12] The actual coupled ^{13}C NMR spectrum shows a normal olefinic $^1J_{C,H}$ coupling (170 Hz) and no observable $^2J_{C,H}$ coupling. These observations are inconsistent with a fluxional agostic structure, and consistent with an η^3-allyl hydride structure.



3

The hydrido complex **2** is exceedingly reactive. Warming samples of **2** to temperatures above 170 K results in the back-reaction of **2a** with CO to regenerate the propene complex **1** ($t_{1/2} = 25$ min at 169 K). If CO is removed by freeze-pump-thaw degassing, **2a** persists at temperatures up to 185 K. Above 185 K, **2a** reacts to give an unidentified product. The CO trapping experiment suggests a lower limit on k_{-1} of 6.7×10^{-4} s^{-1} at 169 K. The lack of line broadening in the NMR spectrum at 185 K provides an upper limit on k_{-1} of approximately 10 s^{-1}. These limiting values establish that the Gibbs free energy of activation, $\Delta G^{\neq}$, for hydride migration must be 9–12 kcal mol^{-1}.



1 **2**

Experimental Procedure

A degassed solution of **1** [13] (ca. 20 mM in [D_{14}]methylcyclohexane) in a sealed 5 mm NMR tube was immersed in liquid nitrogen in a Pyrex dewar, photolyzed ($\lambda > 280$ nm, 1 h, 300 W Xe arc lamp), and transferred to the precooled probe (160 K) of a Bruker AM-500 NMR spectrometer. Data acquisition commenced upon thermal equilibration at 160 K. (Note: it is important to photolyze **1** in a glass; extended photolysis of **1** in solution leads to dimeric products.)

[7] We attribute our inability to observe small coupling constants to the presence of small amounts of paramagnetic impurities, such as [$Fe(CO)_3(\eta^3$-$CH_2CHCH_2)$].
[8] We exclude the *mer* isomer of **2** as a possible structure, because it would display five nonequivalent allyl protons in the ^{1}H NMR spectrum. We exclude [$Fe(CO)_4(H)(\eta^1$-$CH_2CH{=}CH_2)$] as a possible structure, based on the dissimilarity of the observed ^{1}H NMR spectrum with that of the known [$(\eta^5$-$C_5Me_5)Ir(PMe_3)(H)(\eta^1$-$CH_2CH{=}CH_2)$] [4].
[9] Although this resonance occurs as a shoulder on a large solvent resonance, we can confidently assign it to H_a on the basis of both 1-D and 2-D (COSY and NOESY) spectra. The relative intensity of H_a was determined by integrating the subtracted spectra.

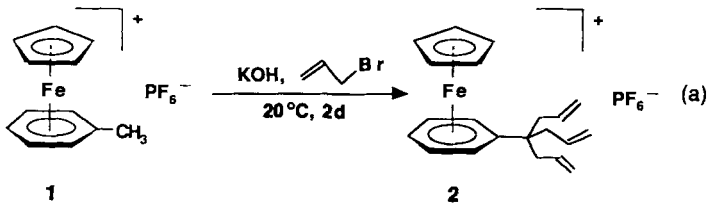
Organometallic Molecular Trees as Multielectron and Multiproton Reservoirs: $CpFe^+$-Induced Nonaallylation of Mesitylene and Phase-Transfer-Catalyzed Synthesis of a Redox-Active Nonairon Complex**

By *Françoise Moulines, Laurent Djakovitch, Roland Boese, Bruno Gloaguen, Werner Thiel, Jean-Luc Fillaut, Marie-Hélène Delville,* and *Didier Astruc**

Dedicated to Professor Hans Bock on the occasion of his 65th birthday

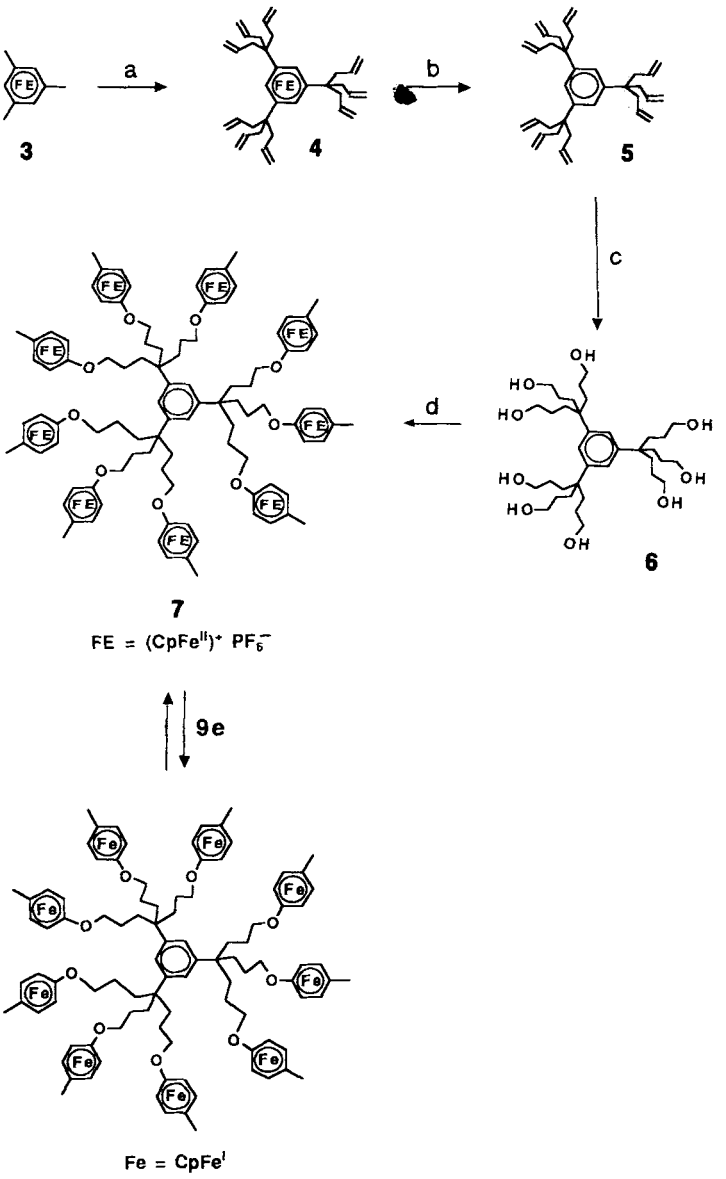
The theory[1] and organic syntheses[2] of multibranched compounds have recently encountered a renewed interest.[3] One especially challenging target is the functionalization of the branches (side chains) with redox systems; in this way molecular electronics devices and multielectron redox catalysis should be accessible.[4] We now present an organometallic strategy for the construction of molecular trees of novel topology. This method uses a one-pot nonafunctionalization of mesitylene and the synthesis of a nonairon complex in which the iron centers are quasi-equivalent reversible Fe^{II}/Fe^{I} redox systems.

Activation of arenes by π complexation to 12-electron transition metal fragments facilitates these nucleophilic reactions.[5-7] Deprotonation of an alkyl side chain followed by electrophilic attack was first shown by Trahanovsky and Card and used with $Cr(CO)_3$,[5a, b, 8] $Mn(CO)_3^+$,[5f, 9] $FeCp^+$ [Cp = (η^5-C_5H_5)][6, 7, 9] and Fe(η^6-arene)$^{2+}$[7c] fragments. We already know that the one-pot reaction of [FeCp(η^6-C_6Me_6)]PF_6 with alkyl, allyl, and benzyl halides in the presence of KOR (R = H, *t*Bu) yields discoid-shaped hexafunctional "tentacled sandwich" complexes.[7b, 9] So far only single[9c, e] and double[9d] branching functionalization of polymethyl arenes (i.e., polymethyl arenes in which each methyl substituent has been converted into a substituent with one or two functionalized branches, respectively) have been disclosed. We now report triple branching functionalization (i.e., each methyl substituent is converted into a substituent with three functionalized branches). The complex **1** (2 g, 5.58 mmol) was treated with KOH (12.54 g, 223 mmol) in allylbromide (20 mL, 223 mmol) for two days at room temperature. After chromatography on alumina the yellow resinous solid **2** (1.59 g, 134 mmol; 60%) with three allyl branches can be isolated [Eq. (a)].



1 **2**

Triple branching functionalization could also be achieved under the same conditions on polymethylarene iron complexes in which the methyl groups have no methyl neighbor (*m*- and *p*-xylene, mesitylene). The reaction of [FeCp(η^6-mesitylene)]PF_6 (**3**) with benzyl bromide does not lead to the replacement of all nine acidic methyl hydrogen atoms because of steric hindrance (maximum: seven or eight branches under forcing conditions). In contrast, we find that with allylbromide and KOH in DME (dimethoxyethane) (Scheme 1), one-pot nonaallylation of **3** proceeds at 20 °C within nine days. The nonaolefin **4**[10b] thus formed was obtained in 68% yield along with the demetalated arene **5** in 30% yield. The cleanest way to demetalate complex **4** is visible-light photolysis in MeCN in the presence of one equivalent of PPh_3[11] (the moderately air-stable complex [FeCp($NCMe)_2(PPh_3)$]PF_6[11b] was filtered off). The compound **5** was recrystallized in pentane (m.p. 35.5 °C, 90% yield). The result of an X-ray structure analysis of **5**[12] is shown in Figure 1. The anisotropic thermal parameters, disorder, and



Scheme 1. Synthesis of the nonacation **7**. a) CH_2CHCH_2Br, KOH, DME, 20 °C, 9 days; b) MeCN, PPh_3 (1 equiv), visible light, 7 h, 25 °C; c) Disiamylborane ($Me_2CHCHMe)_2BH$, THF, 20 °C, 1 day, 30% H_2O_2, 3 M NaOH, 50 °C, 1 h; d) [Fe(Cp)(η^6-*p*-MeC_6H_4F)]PF_6, K_2CO_3, $(Bu_4)NBr$, THF/DMSO (80:20), 20 °C, 3 days.

[**] This work was partly supported by the Centre National de la Recherche Scientifique (CNRS), the Université Bordeaux I, and the Région Aquitaine. We also thank Rhône-Poulenc (L. D.) and the Alexander von Humboldt Foundation (W. T.) for grants.

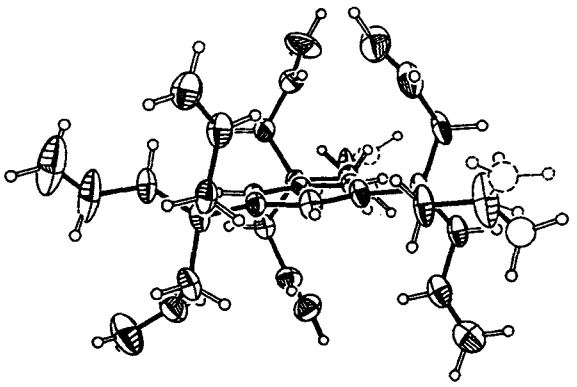

Fig. 1. Crystal structure of **5** (thermal ellipsoids 50% level); view along the plane of the benzene ring. Important distances [Å] (mean values for chemically equivalent bonds) C–C (aromat.) 1.391(3), C(benzene)–C(α) 1.534(3), C(α)–C(β) 1.546(2), C(β)–C(γ) 1.491(2), C(γ)–C(δ) 1.235(17) (this value is strongly affected by thermal movements and disorder).

different orientations of the allyl groups indicate their high flexibility, even in the solid state. The nonaolefin **5**[10c] was regiospecifically hydroborated with disiamylborane, and subsequent alkaline oxidation[9c, 13] gave the very hygroscopic nonaol **6**[10d] (Scheme 1).

The arborol strategy then requires iteration, namely, branching with $[FeCp(arene)]^+$ units in which the arene ligand in the complex fragment bears a methyl group suitable for further starburst reactions such as in Equation (a). Nonaarylmetalation[14] of **6** is activated by the cationic charge of $[FeCp(\eta^6\text{-}p\text{-}MeC_6H_4F)]PF_6$ and also proceeds smoothly at 20 °C with K_2CO_3 and 10% $(Bu_4N)Br$ in THF/DMSO to give the yellow resinous nonairon sandwich **7**.[10e] Phase-transfer catalysis had not yet been used for this type of reaction, but these conditions are indispensable for the sake of the required efficiency. After purification by chromatography on alumina (eluent: CH_2Cl_2/MeCN), the yield of purified **7** was 20% from which satisfactory elemental and spectroscopic analyses were obtained. Note that **7** (like **3**) is fairly soluble in moderately polar solvents in spite of the +9 charge.

The cyclic voltammograms of **7** show a reversible reduction wave[15] (Fig. 2) for Fe^{II} (18e) $\rightleftarrows$ Fe^{I} (19e) at −1.37 V [versus saturated calomel electrode (SCE)] in DMF/0.1 M $(Bu_4N)BF_4$; $\Delta E_p = 100$ mV and remains constant upon variation of scan rates, $I_a/I_c = 0.8$, −30 °C, 0.8 Vs^{-1}, diffusion control [I vs. scan rate was a straight line]. Thus **7** is a reservoir of nine electrons and 27 benzylic protons (the second wave at $E_p = -2.3$ V vs. SCE[15] is irreversible). This aspect of electron transfer (ET) in such large molecules compares with the ET in proteins.[16] Heterogeneous ET from the cathode to the closest redox centers should be faster than to those which are remote. However, the kinetics observed indicates that the rate constants for the ET are so similar that no distinction is made on the electrochemical time scale. From the intensity of the wave in the cyclic voltammogram the number of electrons transferred was calculated to be $n_p = 8 \pm 1$.[17] Using two different equations[18] the diffusion coefficient of **7** was found to be $D_p = 4 \pm 10^{-7}$ $cm^2 s^{-1}$.

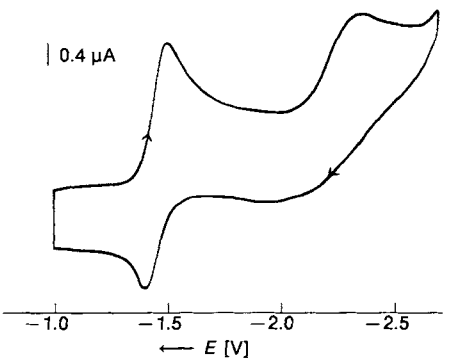

Fig. 2. Cyclic voltammogram of **7** in DMF, 0.1 M $(nBu_4N)BF_4$, Hg electrode, −30 °C, scan rate: 0.4 Vs^{-1} (internal reference: $FeCp_2/FeCp_2^+$).

In conclusion, the one-pot nonafunctionalization of mesitylene reported here has allowed us to design an iterative organometallic strategy for the construction of the molecular tree **7** with quasi-equivalent redox centers, by a very efficient phase-transfer-catalyzed arylmetalation reaction.

Novel Alkynylcopper(I) Complexes and Lithium Alkynyl Cuprates**

By *Falk Olbrich, Jürgen Kopf,* and *Erwin Weiss**

Alkynylcopper(I) compounds[1, 2] can exist free of base, stabilized by bases such as neutral amine or phosphane ligands, or as alkynyl cuprates like $[\{Li(OEt_2)(CuPh_2)\}_2]$.[3] Polymeric phenylethynylcopper(I) $[CuC{\equiv}CPh]_n$,[4] stabilized compounds like $[\{CuC{\equiv}CPh(PR_3)\}_4]$, and the adducts with 3,3,6,6-tetramethyl-1-thia-4-cycloheptyne (TMTCH) $[(CuC{\equiv}CtBu)_4(\eta^2\text{-tmtch})_2]$ and $[\{(CuC{\equiv}CPh)(\eta^2\text{-tmtch})\}_2]$[5] that we studied recently have been structurally characterized. No structural data of alkali metal alkynyl cuprates was previously reported.

We report on the unusual stacking structure of the *tert*-butylethynylcopper(I) complex **1** that consists of 24 units, on the tetramer stabilized by triphenylphosphane (**2**), and on the first investigations on the lithium alkynyl cuprates **3** and **4**. X-ray structures illustrate the diverse modes of coordination of the alkynyl ligands.

$[(CuC{\equiv}CtBu)_{24}] \cdot 2C_6H_{14}$ **1**

$[\{CuC{\equiv}CtBu(PPh_3)\}_4] \cdot 2Et_2O$ **2**

$[Li_6(Et_2O)_3Cu_4(C{\equiv}CPh)_{10}]$ **3**

$[Li_6(Et_2O)_3Cu_3(C{\equiv}CPh)_9]$ **4**

The synthesis of the Cu^I complex **1** (18% yield) was adapted from known procedures[6] from copper(I) bromide dimethylsulfide [7] (dms = dimethylsulfide) and $LiC{\equiv}CtBu$ according to Equation (a).

$$[CuBr(dms)]_n + LiC{\equiv}CtBu \xrightarrow[2.\ n\text{-hexane}]{1.\ Et_2O} \underset{\mathbf{1}}{[CuC{\equiv}CtBu]_{24} \cdot 2C_6H_{14}} \quad (a)$$

A crystal structure analysis of **1**[8, 9] revealed a stacking structure unusual for Cu complexes, which consists of an aggregate of 24 $CuC{\equiv}CtBu$ units (Fig. 1). On two sides of a

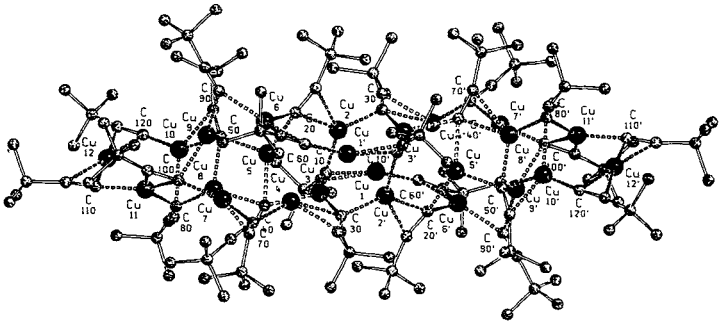

Fig. 1. SCHAKAL representation of the crystal structure of **1**, omitting H atoms and solvent molecules. Important distances [pm]: μ_4–η^2: Cu5–Cu50 215.3(4), Cu8–C50 206.6(4), Cu9–C50 220.5(5), Cu10–C50 209.0(4), Cu10–C51 208.9(4).

distorted central Cu_6 octahedron (Cu1–Cu3 and Cu1′–Cu3′, inversion center in the middle) lie $CuC{\equiv}CtBu$ molecules. The copper atoms Cu12 and Cu12′ situated at the outermost edge of the aggregate are bound in a linear arrangement to two η^2-$C{\equiv}CtBu$ ligands. All other $C{\equiv}CtBu$ ligands are bridging and display a variety of coordination types: μ_2–η^1, μ_2–η^2, μ_3–η^1, and μ_3–η^2. Moreover, a novel mode of coordination, μ_4–η^2, is observed: the alkynyl anion C50–C55 is coordinated through C50 to four different Cu atoms (Cu–C50 distances 207–220 pm), and in addition one of the Cu atoms interacts with the C_β atom of the ligand (C51). The Cu–Cu distances vary widely from 247 to 342 pm. The Cu–C bonds are 190–257 pm long (compare $[CuC{\equiv}CPh]_n$: Cu···Cu 242–247, Cu–C 198–213 pm). Similar stacked structures with different degrees of association were observed for $[Li_{12}(C{\equiv}CtBu)_{12}(thf)_4]$,[10] $[Na_{10}(NMe_2)_{10}(tmeda)_4]$, and $[Na_{12}(NMe)_{12}(tmeda)_4]$ (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine).[11]

The known compound **2**[12] was obtained in 4% yield from a new synthesis method according to Equation (b).

$$[CuBr(dms)]_n + LiC{\equiv}CtBu + PPh_3 \xrightarrow{Et_2O} \underset{\mathbf{2}}{[CuC{\equiv}CtBu(PPh_3)]_4 \cdot 2Et_2O} \quad (b)$$

[*] Prof. Dr. E. Weiss, Dr. F. Olbrich, Priv. Doz. Dr. J. Kopf

[**] On Metal–Alkyl and Metal–Aryl Complexes, Part 48. This work was supported by the Fonds der Chemischen Industrie. Part 47: S. Corbelin, N. P. Lorenzen, J. Kopf, E. Weiss, *J. Organomet. Chem.* **1991**, *415*, 293.

According to the X-ray crystal structure analysis of **2**,[13] the four Cu atoms form an almost regular tetrahedron (C···Cu 260–265 pm). The μ_3-coordinated C≡C*t*Bu ligands cap the Cu_3 faces (Cu1–C10 215.1(10) pm; Fig. 2). Furthermore each Cu atom binds a PPh_3 ligand (Cu–P 223–224 pm). Similar interatomic distances are observed in the isostructural complexes $[\{CuC{\equiv}CPh(PPh_3)\}_4]$[14] and $[\{CuC{\equiv}CPh(PPh_2py)\}_4]$.[15]

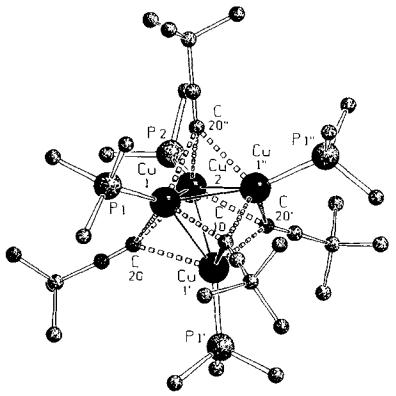

Fig. 2. SCHAKAL representation of the crystal structure of **2**, omitting H atoms and solvent molecules. The phenyl rings are indicated by C atoms.

Organocuprates are known to belong to the most important building blocks of organic synthesis. Apart from the simple organocuprates like R_2CuLi and $[\{Li(OEt_2)(CuPh_2)\}_2]$[3] (Gilman cuprates, low-order (LO) organocuprates), the higher order organocuprates (HO organocuprates) are gaining in importance.[16] Their structures[17] are still subject of a lively and sometimes controversial debate,[18] which includes the point of view, supported by NMR studies, that the HO cuprates do not exist in solution but degrade into LO cuprates that are in equilibrium with one another.[18a]

We have now synthesized the first lithium alkynyl cuprates **3** and **4** according to Equation (c) from $[CuBr(dms)]_n$ and an excess of phenylethynyllithium. The formation of yellow,

$$[CuBr(dms)]_n + LiC{\equiv}CPh \longrightarrow [Li_6(Et_2O)_3Cu_4(C{\equiv}CPh)_{10}]\,\mathbf{3}/[Li_6(Et_2O)_3Cu_3(C{\equiv}CPh)_9]\,\mathbf{4} \quad (c)$$

extremely air- and moisture-sensitive products depend of the reaction conditions.

The solid-state structure of tetracuprate **3** was determined (Fig. 3);[19] it is one of the few structurally characterized organocuprates of higher order[16] and comprises two linked structural units **A** and **B**. Unit **A** is a $[CuC{\equiv}CPh)_4]^{3-}$ anion in which the Cu atom is tetrahedrally surrounded by four C_α atoms of the Cα≡CβPh ligands (C-Cu-C 108–111°,Cu–C 197–202 pm). This structural unit is new for organocopper compounds and resembles the tetraphenyllithate(3−) found in $[\{Na(tmeda)\}_3][LiPh_4]$.[20] The large excess charge at the Cu atom is remarkable and might result in increased nucleophilicity for this unit. The base of the CuC_4 tetrahedron is formed by the C_α atoms C80, C90, and C100, and the apex by C70. Beneath the base lie three solvated Li atoms (Li7–Li9), which are also tetrahedrally coordinated by the oxygen atom of the ether molecule, two C_α atoms of the $C_\alpha{\equiv}C_\beta Ph$ ligand from the structural unit **A** (Li–C 230–236 pm), and another C_α atom from **B**.

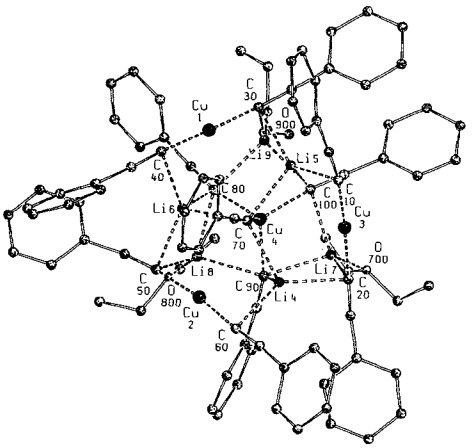

Fig. 3. SCHAKAL representation of the crystal structure of **3**, omitting the H atoms.

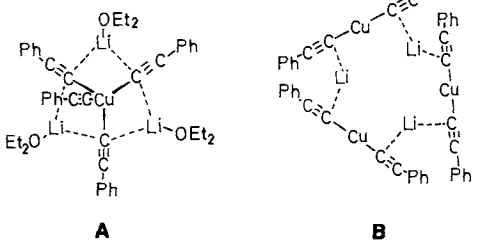

The structural component **B** is set on the threefold axis of the tetrahedral unit **A** like a crown. Unit **B** contains a slightly puckered Cu_3Li_3 six-membered ring (Cu1–Cu3, Li4–Li6; maximum deviation of the atoms from the best plane 13 pm). This plane lies 162 pm above the Cu4 atom. The Cu and Li atoms are bridged by phenylethynyl ligands.

All ten C_α atoms of the phenylethynyl ligands are links between components **A** and **B**. Thus, the Li atoms in the Cu_3Li_3 six-membered ring are also tetrahedrally surrounded by four C atoms. As in $[\{Li(OEt_2)(CuPh_2)\}_2]$,[3] linear cuprate anions $[Cu(C{\equiv}CPh)_2]^-$ are situated within the crown (C-Cu-C 170–173°, Cu–C 183–189 pm.

Experimental Procedure

1: A solution of LiC≡C*t*Bu (0.72 g, 8.2 mmol) in ether (75 mL) was added dropwise at room temperature within 90 min to a suspension of [CuBr(dms)] [7] (0.84 g, 4.1 mmol) in Et_2O (40 mL). The mixture was stirred for 20 h, evaporated almost to dryness (oil pump vacuum), and extracted with *n*-hexane (50 mL) at 50 °C for 2 h. The solution was concentrated to 1/3 of its volume, upon which **1** crystallized at 7 °C as square, yellow plates. Yield 18%; m.p. 104 °C (decomp.); readily soluble in *n*-hexane, Et_2O, and THF. The stoichiometries of **1** determined by X-ray structure analysis and elemental analysis do not agree. Fifteen percent of two *t*BuC≡C ligands are occupied by bromide to yield in the analysis $[Cu_{24}(C{\equiv}C\mathit{t}Bu)_{23.7}Br_{0.3}]\cdot 2C_6H_{14}$.

2: A solution of LiC≡C*t*Bu (0.32 g, 3.6 mmol) in ether (30 mL) was added dropwise at room temperature within 45 min to a suspension of [CuBr(dms)] (0.75 g, 3.7 mmol) in Et_2O (30 mL). After the mixture had been stirred for 30 min, PPh_3 (0.96 g, 3.7 mmol) was added. The mixture was stirred for a further 60 min, the solvent removed under vacuum (oil pump), and the solid extracted at room temperature with *n*-pentane (100 mL) for 15 h. After filtration, yellow crystals of **2** precipitated at 7 °C. Yield: 65 mg (4%); readily soluble in Et_2O and THF, soluble in *n*-hexane. The stoichiometries of **2** determined by X-ray structure analysis and elemental analysis do not agree. Twenty-five percent of three *t*BuC≡C ligands are occupied by bromide to yield in the analysis $[Cu_4(C{\equiv}C\mathit{t}Bu)_{3.25}Br_{0.75}(PPh_3)_4]$.

3: A solution of LiC≡CPh (0.47 g, 4.4 mmol) in ether (60 mL) was added dropwise within 90 min to a suspension of [CuBr(dms)] (0.48 g, 2.3 mmol) in

Et_2O (30 mL). The mixture was stirred for 5 h, filtered, evaporated to dryness, and the residue extracted with benzene (100 mL, 15 h), and filtered again. A small amount of yellow crystals of **3** precipitated from the solution at 7 °C. Decomposition above 206 °C, readily soluble in THF and Et_2O, soluble in benzene, almost insoluble in *n*-hexane.

4: A solution of LiC≡CPh (1.3 g, 12 mmol) in ether (30 mL) was added to a suspension of [CuBr(dms)] (0.56 g, 2.7 mmol) in Et_2O (50 mL) and heated under reflux for 2 h. The solvent was distilled off, the residue extracted with benzene (60 mL) for 24 h under reflux, the resulting solution filtered and evaporated to dryness, and the residue taken up in Et_2O (10 mL) and cooled to −55 °C. The yellow oil that separated was decanted off and dried under reduced pressure; it then appeared finely crystalline and colorless. Decomp. above 80 °C; extremely air-sensitive; readily soluble in THF and Et_2O, soluble in benzene. Correct elemental analysis; ^1H NMR (80 MHz, C_6D_6): δ = 7.69–7.34 (m, 17H; C_6H_5), 7.09–6.87 (m, 30H; C_6H_6), 3.40 (q, 12H; OCH_2), 1.07 (t, 18H; CH_3).

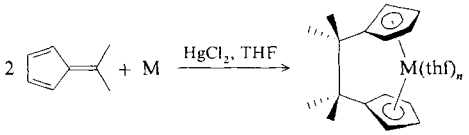
ansa-Metallocenes of Calcium and Strontium: One-Pot Synthesis of Organometallic Complexes of the Heavier Alkaline Earth Metals**

By *Melanie Rieckhoff, Ursula Pieper, Dietmar Stalke,* and *Frank T. Edelmann**

Dedicated to Professor Adolf Knappwost on the occasion of his 80th birthday

Although [Cp_2Ca] (Cp = η^5-C_5H_5) has been known since 1956,[1] the organometallic chemistry of the heavier alkaline earth metals slipped into obscurity for a long time. This field gained new momentum only after the discovery of the high-temperature superconductors of the type $YBa_2Cu_3O_{7-x}$.[2] In particular, the recent pioneering work of Hanusa et al.[3] has shown impressively that the organometallic chemistry of the heavier alkaline earth metals is extremely interesting. However, soluble organometallic compounds of these metals are still very rare; the decamethylmetallocenes [Cp^*_2M] (M = Ca, Sr, Ba; Cp* = η^5-C_5Me_5) and their adducts with Lewis bases are among the most thoroughly studied examples.[4–7] We now report an unusually simple, new route to cyclopentadienylcalcium and -strontium compounds as well as the first X-ray structure determination of an *ansa*-metallocene derivative of calcium.

On addition of 6,6-dimethylfulvene to a suspension of calcium granules (activated by a small amount of $HgCl_2$) in THF, the colorless *ansa*-metallocene complex **1** is formed in 74% yield in a smooth reaction.



1: M = Ca, $n = 0$
2: M = Sr, $n = 2$

Nonsolvated **1** forms extremely air-sensitive crystals that are readily soluble in toluene and THF. Activated strontium

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

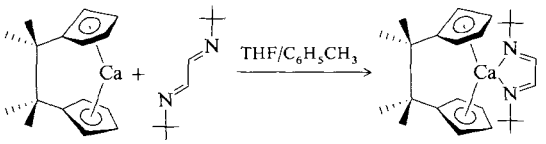
powder reacts analogously with 6,6-dimethylfulvene to form the likewise colorless bis(tetrahydrofuran) adduct **2** (38%). Finely divided barium does not react under similar reaction conditions with fulvenes. The colorless complex **3** forms on

$[\{Me_2Et_2C_2(C_5H_4)_2\}Ca]$ **3**

treatment of activated calcium with two equivalents of 6-ethyl-6-methylfulvene. This product, however, crystallizes as a nonseparable mixture of isomers, so the use of unsymmetrically substituted fulvenes does not offer any preparative advantages.

The reductive dimerization of fulvenes was recently reported for the lanthanide elements samarium and ytterbium, too.[8] In fact, this is a good example of the known analogy between the heavier alkaline earth metals and divalent lanthanides.[9] The IR spectrum of **1** is almost superimposable on that of the analogous ytterbium(II) compound $[\{Me_4C_2(C_5H_4)_2\}Yb]$.[8] This phenomenon has already been discussed in detail for the complex pair $[(MeC_5H_4)_2M(dme)]$ (M = Ca, Yb; dme = dimethoxyethane).[10]

The example of the adduct formation of **1** and **3** with 1,4-diazadienes shows that the *ansa*-metallocenes described here can also undergo interesting reactions. Treatment of **1** with *N*,*N*′-di(*tert*-butyl)glyoxaldialdimine in THF/toluene yields an air-sensitive, bright red 1:1 adduct **4**.



1 **4**

Similarly, **3** reacts with *N*,*N*′-di(*tert*-butyl)glyoxaldialdimine to afford the red, crystalline complex **5**, as a mix-

$[\{Me_2Et_2C_2(C_5H_4)_2\}Ca(tBuN{=}CHCH{=}NtBu)]$ **5**

ture of isomers. Crystallization from toluene/hexane provided single crystals of **4** that were suitable for an X-ray structure analysis.[11] Adduct **4** is monomeric in the solid state (Fig. 1). The reductive dimerization of 6,6-dimethylfulvene leads to the formation of the difunctional cyclopentadienyl ligand $[Me_4C_2(C_5H_4)_2]^{2-}$. The average distance between the

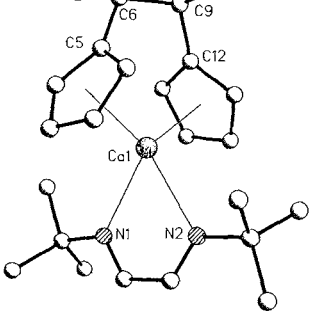


Fig. 1. Structure of **4** in the crystal (one of two crystallographically independent molecules). Selected distances [pm] and angles [°]: Ca1-N1 250.3(6), Ca1-N2 256.4(6), Ca1-X1a 239.6(3), Ca1-X1b 239.1(3), C5-C6 152.9(10), C6-C9 159.1(11), C9-C12 152.8(10); N1-Ca1-N2 68.7(2), (X1a, X1b = centers of Cp rings).

centers of the rings and the calcium atom is 239.4 pm and is thus comparable with the corresponding bond length in the complex $[(MeC_5H_4)_2Ca(dme)]$ (239.9 pm).[10] The diazadiene is coordinated to the central atom in the *cis* form as a chelating ligand. As a result the calcium atom has a distorted pseudo-tetrahedral coordination geometry. The angle between the calcium atom and the center of the rings is 119.0(5)°. However, the N-Ca-N angle of 68.7(2)° is substantially smaller than the tetrahedral angle.

The reductive dimerization of 6,6-dialkylfulvenes by elemental calcium and strontium described here is probably the simplest access to organometallic complexes of these elements. Furthermore, the compounds **1**–**5** are the first *ansa*-metallocene derivatives of the heavier alkaline earth metals.

Experimental Procedure

1: Granulated Ca (2.00 g, 49.9 mmol) was suspended in THF (200 mL) under an inert atmosphere (N_2) and activated by addition of $HgCl_2$ (200 mg; without stirring for 12 h followed by stirring for 1 h). While stirring and cooling (ice/salt mixture) 6,6-dimethylfulvene (5.30 g, 49.9 mmol) [12] was added, and the mixture was allowed to warm slowly to room temperature. After 24 h stirring the excess metal was filtered off, and the colorless filtrate was evaporated to dryness. The residue was dried for 2 h at 100 °C under vacuum and subsequently washed with two 150 mL portions of hexane. Drying under vacuum (2 h, 100 °C) yielded a colorless, very air-sensitive solid (4.66 g, 74%) that decomposed above 163 °C. Correct C,H analysis. IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 3075 s, 1613 m, 1302 m, 1259 m, 1128 m, 1099 m, 1029 vs, 879 m, 848 m, 724 vs, 697 m; ^{1}H NMR (250 MHz, [D$_8$]THF): δ = 6.06–5.97 (m, 4H, C_5H_4), 4.93 (m, 2H, C_5H_4), 4.48–4.42 (m, 2H, C_5H_4), 2.04 (m, 6H, Me), 1.21–1.15 (m, 6H, Me); EI-MS: *m*/*z* (%) 252 (16, M^+), 147 (96, $Me_2CH(C_5H_4)Ca^+$), 107 (53, $Me_2CH(C_5H_4)^+$), 91 (100, $MeC(C_5H_4)^+$).

3: Analogously the reaction of Ca (2.00 g, 49.9 mmol) and 6-ethyl-6-methylfulvene (6.00 g, 49.9 mmol) yields a colorless, very air-sensitive solid (3.61 g, 52%). M.p. 170 °C (decomp.); correct C,H analysis; IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 3074 m, 1610 m, 1260 m, 1096 m, 1029 w, 808 m, 724 vs; EI-MS: *m*/*z* (%) 280 (22, M^+), 161 (100, $MeEtCH(C_5H_4)Ca^+$), 131 (18, $EtCH_2C_2(C_5H_4)^+$), 105 (18, $EtC(C_5H_4)^+$), 93 (26, $MeH_2C(C_5H_4)^+$). The very complex ^{1}H NMR spectrum indicates the presence of a mixture of isomers.

3: Activated strontium powder (1.41 g, 16.0 mmol) and 6,6-dimethylfulvene (1.70 g, 16.0 mmol) were allowed to react for 48 h in THF (50 mL). The suspension was filtered through a thin layer of Celite, the filtrate was evaporated to dryness, and the residue washed with hexane (50 mL). Thorough drying under vacuum afforded a colorless, extremely air-sensitive solid (1.33 g, 38%) that decomposed above 181 °C. Correct C,H analysis. IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 3068 m, 1669 m, 1616 m, 1261 s, 1097 vs, 1039 vs, 800 s, 748 vs, 723 vs; ^{1}H-NMR (250 MHz, C_6D_6/[D$_8$]THF): δ = 5.75 (m, 4H, C_5H_4), 5.14 (m, 2H, C_5H_4), 4.63 (m, 2H, C_5H_4), 3.56–3.44 (m, 4H, THF), 2.15 (m, 6H, Me), 1.70 (m, 6H, Me), 1.52–1.45 (m, 4H, THF); EI-MS: *m*/*z* (%) 429 (14, $M^+ - CH_3$), 91 (100, $MeC(C_5H_4)^+$).

4: A solution of **1** (2.00 g, 7.8 mmol) and $(tBuN)_2C_2H_2$ (1.32 g, 7.8 mmol) [13] was stirred in THF (60 mL) for 2 h at room temperature. After addition of toluene (40 mL), the THF was slowly removed under vacuum at 30 °C. The color changed from yellow to dark red. The solution was filtered, concentrated to about 20 mL, and diluted with hexane (5 mL). Cooling to −25 °C afforded red crystals (2.73 g, 83%). M.p. 157 °C; correct C,H,N analysis; IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 3071 vs, 1650 m, 1613 m, 1601 m, 1590 m, 1385 vs, 1366 vs, 1238 s, 1226 s, 1202 s, 1127 s, 1116 s, 1099 s, 1052 s, 1039 vs, 971 vs, 927 m, 797 vs, 696 s, 466 m; ^{1}H NMR (250 MHz, C_6D_6): δ = 7.11–7.00 (m, 2H, N = CH), 6.31–6.15 (m, 4H, C_5H_4), 5.22–5.07 (m, 2H, C_5H_4), 4.80–4.68 (m, 2H, C_5H_4), 2.19–2.03 (m, 3H, Me), 1.88 (m, 3H, Me), 1.50–1.42 (m, 6H, Me), 1.07 (s, 18H, *t*Bu); EI-MS: *m*/*z* (%) 212 (1, $Me_4C_2(C_5H_4)_2^+$), 197 (3, $Me_3C_2(C_5H_4)_2^+$), 153 (18, $C_4H_9N(CH)_2NC_3H_6^+$), 141 (24, $C_4H_9NH(CH)_2NCH_2CH_3^+$), 112 (23, $C_4H_9N(CH)_2NH^+$), 97 (28, $C_4H_9N(CH)_2^+$), 57 (100, $C_4H_9^+$).

5 is prepared analogously from **3** (2.00 g, 7.0 mmol) and $(tBuN)_2C_2H_2$ (1.20 g, 7.0 mmol) to give 2.35 g of red crystals (75%). M.p. 166 °C; correct C,H,N analysis; IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 3075 s, 1651 m, 1611 m, 1590 m, 1580 m, 1345 m, 1304 m, 1240 m, 1220 m, 1200 m, 1097 m, 1056 s, 1029 s, 972 s, 803 s, 730 s; ^{1}H NMR (250 MHz, C_6D_6): δ = 7.07 (m, 2H, N = CH), 6.30–6.17 (m, 4H, C_5H_4), 5.20–5.08 (m, 2H, C_5H_4), 4.75 (m, 2H, C_5H_4), 1.88 (m, 3H, CH_2CH_3), 1.76 (m, 3H, CH_2CH_3), 1.50–1.41 (m, 6H, Me), 1.40–1.29 (m, 2H, CH_2CH_3), 1.05 (s, 18H, *t*Bu), 0.90–0.81 (m, 2H, CH_2CH_3); EI-MS: *m*/*z* (%) 329 (26, $[Me_2C_2H_3(C_5H_4)]Ca(C_4H_9NCH)_2^+$), 280 (10, $Me_2Et_2C_2(C_5H_4)Ca^+$), 161 (90, $MeEt_2C_2(C_5H_4)^+$), 57 (100, $C_4H_9^+$).

A Versatile and Efficient Synthesis of Annulated Cyclopentanes by Stereoselective [3+2] Cycloaddition of Allylsilanes and Cycloalkenyl Methyl Ketones**

By *Hans-Joachim Knölker,* Norbert Foitzik, Helmut Goesmann*, and *Regina Graf*

We recently reported[1, 2] that the "silyl-group-containing by-products" of the Sakurai reaction,[3] originally considered silylmethylcyclobutanes,[4] are in fact silylcyclopentanes. This novel cylcopentane annulation involves a cationic 1,2-silyl shift,[5] which proceeds stereospecifically, thus generating three stereogenic centers. While the cyclization to a silylcyclopentane in the course of the Sakurai reaction was previously unprecedented, the formation of trimethylsilylcyclopentenes has been described for the reaction of trimethylsilylallenes with enones.[6] Following our first communication,[1] more examples of silylcyclopentane formation along with Sakurai reaction products have been reported,[7] and many of the products previously described as silylmethylcyclobutanes have been reassigned as silylcyclopentanes.[8] Related reactions of allylstannanes with α,β-unsaturated acyliron complexes[9] and with aldehydes[10] have also been described. Currently we are investigating metal-mediated processes for the construction of five-membered ring systems.[11] We report here on an elaboration of the silylcyclopentane annulation, a novel [3+2] cycloaddition, which provides a versatile and useful method with broad potential for the synthesis of cyclopentanoid natural products.

In our mechanistic proposal[1] we suggested that a bridged nonclassical pentavalent silicon cation[12] is the crucial intermediate in this novel cycloaddition. A stereospecific cyclization by intramolecular nucleophilic attack of the titanium enolate at the carbon atom of the siliranium ion leads to the product. Thus, the overall process may be regarded as a sila-Wagner–Meerwein rearrangement. The same mechanism has been used to explain more recent examples.[7] We thought that variation of the alkyl substituents at the silicon atom of the allylsilane would allow us to suppress nucleophilic attack at the silicon atom of the pentavalent silicon cation and thus prevent the formation of the Sakurai product.

The allylsilanes that are not commercially available are easily prepared by treatment of allylmagnesium chloride with the appropriate trialkylchlorosilane (Scheme 1).[13] The results of the reactions of cyclohexenyl methyl ketone with a variety of allylsilanes **1** are presented in Table 1. Structural assignments for the bicyclo[4.3.0]nonanes **2** are based on X-ray crystal structure determinations for compound **2d**[8] and the 2,4-dinitrophenylhydrazone derivative of **2a**[1] as well as complete characterization by ^1H and ^{13}C NMR spectroscopy. In every example examined for the cyclopentane annulation onto the six-membered ring (**2a** to **2i**) under op-

[**] [3+2] Cycloadditions of Allylsilanes, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft (Gerhard-Hess-Förderpreis) and the Fonds der Chemischen Industrie.—Part 1: [1].

timized reaction conditions (see Experimental Procedure), only the stereoisomer with the silyl group in the position *anti* to the acetyl group could be isolated. The yield of the cycloadduct depends on the steric demand of the alkyl substituents at the silicon atom of the allylsilane moiety. Generally, when bulkier alkyl groups were employed, the cycloadduct was obtained in better yields. This outcome is explained by the inhibition of nucleophilic attack on the silicon at the stage of the intermediate pentavalent silicon cation. A similar observation has been made recently by Mayr et al. in their study on the Lewis acid promoted reaction of diarylmethyl chlorides with allylsilanes.[14]

We next investigated the [3+2] cycloaddition of allylsilanes with cycloalkenyl methyl ketones with different ring sizes (five- to seven-membered rings) by using allyltriphenylsilane **1d** and allyltriisopropylsilane **1i** (Scheme 2, Table 2). Of special interest to us was whether the same mode of stereospecificity would be observed with cyclopentenyl methyl ketone **4a** and cycloheptenyl methyl ketone **4c** as in the cycloaddition of cyclohexenyl methyl ketone **4b**. The

[a] 3:1 Mixture of the *anti*/*syn* stereoisomers (*anti* and *syn* give the position of $SiiPr_3$ group relative to the acetyl group).

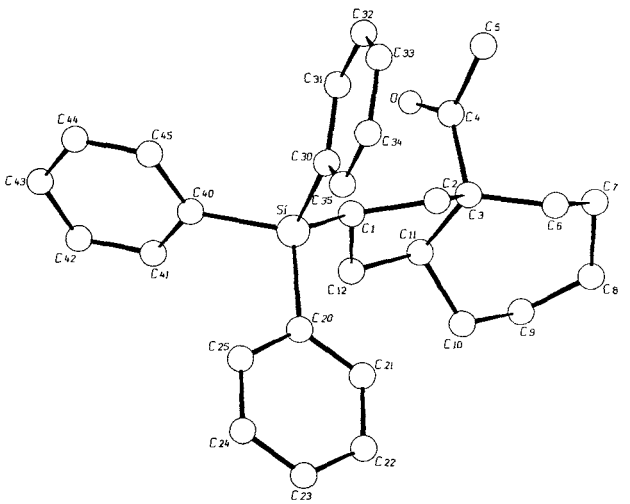

Fig. 1. Molecular structure of **5c** in the crystal. Selected bond lengths [Å]: C1-C2 1.528(5), C2-C3 1.543(5), C3-C11 1.557(5), C11-C12 1.546(4), C1-C12 1.534(6), Si-C1 1.879(4), Si-C20 1.878(3), Si-C30 1.884(4), Si-C40 1.876(3).

cycloaddition of allyltriisopropylsilane **1i** to **4a** gives only a 3:1 selectivity in favor of the product with the bulky triisopropylsilyl group in the *endo* position of the bicyclo[3.3.0]octane ring. Steric effects account for this lack of selectivity. For all other cycloaddition products an *anti* arrangement of the silyl substituent and the angular acetyl group was established. The stereochemical assignments are based on X-ray analyses of the perhydrindane **5b** (= **2d**)[8] and the perhydroazulene derivative **5c** (Fig. 1)[15] and are supported by the ^{13}C NMR data (Table 3).

Table 3. ^{13}C NMR data (δ values) and results of the DEPT experiments (100 MHz, $CDCl_3$) of selected annulated cyclopentanes.

10b: 17.1 (CH), 20.3 (CH_2), 26.5 (CH_2), 35.0 (CH_2), 67.1 (C), 127.9 (CH), 129.5 (CH), 134.6 (C), 135.9 (CH).

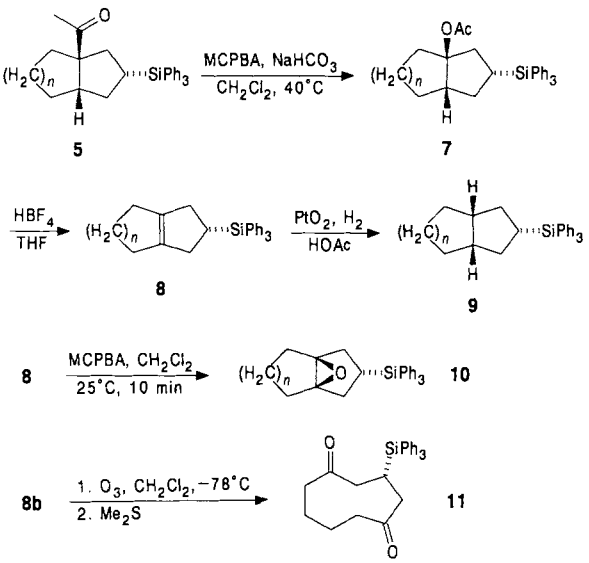
11: 19.9 (CH), 23.8 (CH_2), 40.9 (CH_2), 43.4 (CH_2), 128.2 (CH), 129.9 (CH), 132.8 (C), 136.0 (CH), 215.3 (C=O).

The bicyclic products exhibit a useful reactivity for further transformations directed towards the synthesis of cyclopentanoid terpenes. This has been demonstrated for the bicyclo[3.3.0]octane **5a** and the bicyclo[4.3.0]nonane **5b** (= **2d**) (Scheme 3, Table 4).

Table 4. Transformation of the annulated triphenylsilylcyclopentanes **5a** and **5b** (= **2d**) into **7**–**10**.

		Yield [%]			
	n	**7**	**8**	**9**	**10**
a	1	81	87	100	100
b	2	87	97	100	100

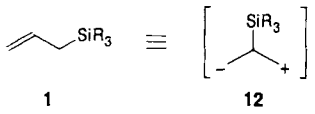
The Baeyer–Villiger oxidation to give the acetoxy derivatives **7** is followed by tetrafluoroboric acid promoted elimination of acetic acid to provide the symmetrical bicycloolefins **8** in high yields. In further transformations of the *meso* olefins **8** the triphenylsilyl substituent acts as a stereodirecting group and enforces an approach of the reagent from the opposite face. Thus, hydrogenation with Adam's catalyst affords the saturated bicyclic derivatives **9** stereoselectively. The utility of the bicycloolefins **8** for the synthesis



Scheme 3. **a**: $n = 1$, **b**: $n = 2$.

of propellane ring systems has been demonstrated by the stereospecific epoxidations to oxa[3.3.1]propellane **10a** and oxa[4.3.1]propellane **10b**, which proceed quantitatively. Moreover, ozonolysis of bicycloolefin **8b** to afford cyclononadione **11** (46% yield) emphasizes the potential of these intermediates as precursors for compounds with medium-sized rings.

In conclusion we have found a versatile, stereospecific method for the annulation of silylcyclopentanes by cycloaddition of an allylsilane **1** as the synthetic equivalent of the 2-silyl-substituted 1,3-dipole **12**. The stereoselective synthe-



ses and further synthetic transformations of the products emphasize the potential of this method for the synthesis of cyclopentanoid natural products. The oxidative cleavage of the carbon–silicon bond should occur with retention of configuration[16] and is currently under investigation. Preliminary results indicate that asymmetric syntheses of cyclopentanes are feasible by using chiral allylsilanes, and that cyclopentanes with five stereogenic centers can be generated stereospecifically by employing 1,3-disubstituted allylsilanes. The present method thus opens the way for the enantioselective synthesis of highly substituted cyclopentanes.

Experimental Procedure

6b: A solution of **4b** (500 mg, 4.03 mmol) in dry dichloromethane (2 mL) was added to a stirred solution of titanium tetrachloride (840 mg, 4.43 mmol) in dry dichloromethane (5 mL) at −20 °C. The formation of the Lewis acid/enone complex was indicated by the intense yellow color of the resulting suspension. The reaction mixture was cooled to −78 °C, and a solution of allyltriisopropylsilane **1i** (1.2 g, 6.04 mmol) in dry dichloromethane (6 mL) was added. The reaction temperature was raised to −20 °C, during which the color changed to an intense red-violet. The reaction mixture was stirred for 19 h at this temperature then quenched by addition of an aqueous ammonium chloride solution. The organic layer was separated, the aqueous layer was extracted three times with cold dichloromethane, and the combined organic layers were dried over magnesium sulfate. Removal of the solvent and flash chromatography (pentane/ether 20:1) of the residue on silica gel provided bicyclo[4.3.0]nonane **6b** (1.12 g, 86%) as a colorless oil along with the allyl derivative **3** (16 mg, 2%).

Structure and Reactivity of a Highly Twisted Amide**

By *Shinji Yamada**

The preparation and unusual properties of twisted amides have received considerable attention,[1] and a number of such compounds have been synthesized.[2] However, no amides have been reported that have twist angles[2a] about the C(O)–N bonds larger than about 40°. Recently we found

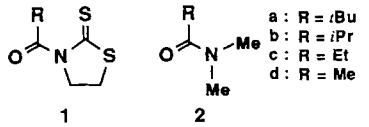
[**] The author thanks Noriko Kasuga at Kanagawa University for her helpful suggestions about X-ray crystallography.

that 3-pivaloyl-1,3-thiazolidine-2-thione (**1a**), which contains an amide unit, is extremely reactive, and reacts with alcohols to give the corresponding pivalates even at pH $\approx$ 7.[3] These observations prompted us to investigate the relationship between the structure and the reactivities of **1a**. We now report that the C(O)–N bond of **1a** is extremely twisted and that the reactivity is, surprisingly, greater than its analogues **1b–d**.



The compounds **1** were synthesized according to the reported method.[4] The rate constants of the reactions of **1a–d** with ethanol[5] at 75 °C were measured at pH $\approx$ 7 to elucidate their reactivities. Although **1a** has the largest substituent group R at the carbon atom of the carbonyl group, the rate constant was 100–1000 greater than those of the other compounds.

Table 1 gives the IR and UV spectral data of **1a–d**, and the ^{13}C NMR chemical shifts of **1** and **2**. The absorption band

Table 1. IR and UV spectroscopic data of **1a–d** and ^{13}C NMR spectroscopic data [a] of **1** and **2**.

	$\tilde{\nu}$(C=O) [cm^{-1}]	λ_{max} [b] [nm]	ε	δ (^{13}C = O)		$\Delta\delta$(^{13}C=O)
1a (**2a**)	1726 [c]	280	8750	187.8	(177.5)	10.3
1b (**2b**)	1701 [d]	309	10870	178.7	(177.0)	1.7
1c (**2c**)	1702 [d]	306	11730	175.6	(173.8)	1.8
1d (**2d**)	1697 [c]	306	11950	171.3	(170.6)	0.7

[a] 400 MHz in $CDCl_3$. [b] In $CHCl_3$. [c] KBr disc. [d] Neat liquid.

of the carbonyl group of **1a** in the IR spectrum appears at 1726 cm^{-1}, those of **1b–d** lie in the range 1697–1702 cm^{-1}. In the UV spectra, the λ value of the longest wavelength band of **1a** is significantly different from those of compounds **1b–d**; however, it is almost identical with that of thiazolidine-2-thione[6] which is the framework structure of the amides. In addition, the absorption coefficient of **1a** is much smaller than those of the compounds **1b–d**. A similar tendency is also seen for the chemical shifts in the ^{13}C NMR spectra. The $\Delta\delta^{13}C$ values listed in Table 1 correspond to the difference in the $\delta(^{13}C)$ value of δ(CO) of the compounds **1** and δ(CO) of the corresponding dimethyl amides. From these results, it is clear that the $\Delta\delta^{13}C$ value of **1a** is higher than those of the other compounds. These results suggest that the C(O)–N bond in the amide **1a** is significantly more twisted than those of the other compounds.

The structural distinction between **1a** and **1b–d** was confirmed by X-ray crystallographic analysis of **1a** and **1d**.[7] The ORTEP representations of **1a** and **1d** are shown in Figure 1, and a projection of the amide groups down the C–N bond of the two thiones is given in Figure 2. As expected, a remarkable difference between **1a** and **1d** exists with respect to their C(O)–N bond. Thus, the twist angle τ[8] of **1d** is 20.1 °, whereas that of **1a** is 74.3 °, which is the highest τ value known to date. Furthermore, the C(O)–N bond length of **1a** is longer than that of **1d** (1.448 Å and 1.413 Å,

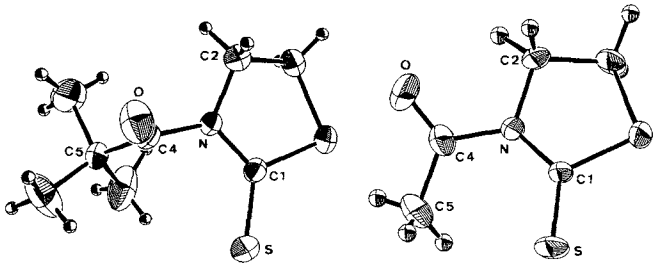


Fig. 1. The molecular structures of **1a** (left) and **1d** (right) (thermal ellipsoids draw at the 35% and 50% probability level, respectively). respectively). As a result, the 1,3-thiazolidine-2-thione ring and the carbonyl group of **1a** are nearly orthogonal, while those of **1d** are nearly planar.

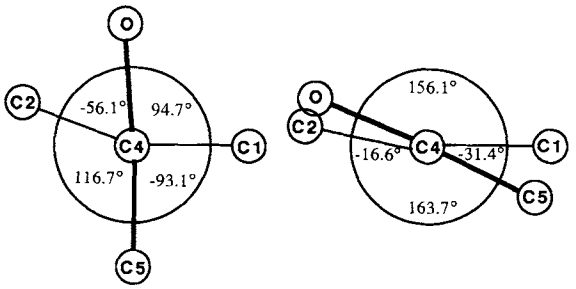

Fig. 2. Projection of the amide groups of **1a** (left) and **1d** (right), down the C–N bond.

From these results, it is apparent that the high reactivity of **1a** is attributed to the significant torsional strain of the C(O)–N bond which seems to arise from the steric repulsion between the bulky *tert*-butyl group and the thione group. Thus, the large rotation about the C(O)–N bond hinders the delocalization of the electrons in the amide unit, and thus causes an increase in the electrophilicity of the carbonyl group and the lengthening of the C(O)–N bond. Consequently, the amide **1a** is the most reactive toward alcohols even at pH $\approx$ 7.

[6] The longest wavelength absorption band of thiazolidine-2-thione appears at 280 nm, and the absorption coefficient is 13200.

[7] Crystal data for **1a** at 296K: $C_8H_{13}NOS_2$, $M = 203.32$, monoclinic, space group $C2/c$, $a = 33.524(3)$, $b = 6.258(2)$, $c = 10.459(3)$ Å, $\beta = 106.71(1)°$, $V = 2101.5(9)$ Å^3, $Z = 4$, $\rho_{calcd} = 0.642$ g cm^{-3}. Anisotropic refinement of all non-hydrogen atoms using 1271 reflections with $I > 3\sigma(I)$, from 1725 unique data collected, gave $R = 0.048$ and $Rw = 0.064$. Crystal data for **1d** at 296K: $C_5H_7NOS_2$, $M = 161.24$, monoclinic, space group $P2_1/n$, $a = 7.3517(8)$, $b = 13.9516(6)$, $c = 7.3806(6)$ Å, $\beta = 104.320(7)°$, $V = 733.5(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.406$ g cm^{-3}. Anisotropic refinement of all non-hydrogen atoms using 996 reflections with $I > 3\sigma(I)$, from 1154 unique data collected, gave $R = 0.083$ and $Rw = 0.119$. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ(UK), on quoting the full journal citation.

[8] Twist angle τ is defined by F. K. Winkler and J. D. Dunitz (see ref. [2a]) as follows: $\tau = 1/2\,(\omega_1 + \omega_2)$, where ω_1 and ω_2 are torsion angles O-C4-N-C1 and C2-N-C4-C5, respectively. According to their definition, the value of the twist angle τ lies in the range $-180°$ to $180°$. However, the larger the distortion, the nearer the value lies to $90°$ or $-90°$, on the other hand, the smaller the distortion, the nearer the value lies to 0°, 180°, or $-180°$. Therefore, in order to avoid confusion about the magnitude of τ, we represented twist angle as $|\tau|$ (for $0 \leq |\tau| \leq 90°$) or $|180 - |\tau||$ (for $90° \leq |\tau|$).

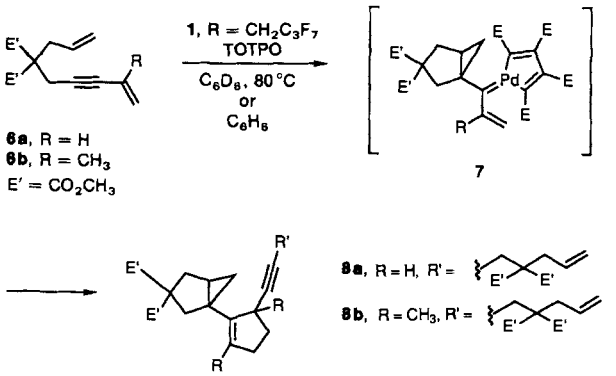
On the Mechanism of the TCPC^{HFB}-Catalyzed Metathesis of 1,6-Enyne: Evidence for Alkylidenepalladium Intermediates**

By *Barry M. Trost** and *A. Stephen K. Hashmi*

Pd^{IV} chemistry is emerging as an exciting new dimension to the organic chemistry of Pd.[1, 2] Pd^{IV} intermediates, for example **2**, are implicated in the metathesis of 1,6- and 1,7-enynes. These reactions are catalyzed by the esters of palladacyclopentadienetetracarboxylic acid (tetrakis(hydroxycarbonyl)palladacyclopentadiene, methyl ester = TCPC) **1**.[3] Labeling studies suggested two paths by which the reaction with terminal acetylenes could proceed, but only one path for the reaction with disubstituted acetylenes (Scheme 1).[4] To account for the labeling patterns, we suggested the intermediacy of the cyclobutene **3** and either cyclopropyl complex **4** or **5** in which we favored **4**. Recent work in which cyclobutenes have now been isolated in good yields validates path a.[5] Studies of the effects of substituents on the metathesis led to a new type of product whose structure strongly implicates the cyclopropylalkylidene complex **5** as a reactive intermediate (in contrast to our earlier preference). This intermediate then undergoes a most unusual further cycloaddition.

Since an ester group on the terminal acetylenic carbon atom promotes the "normal" metathesis,[3] we explored the effect of a nonpolarized sp^2 substituent, a vinyl group (as in **6**). Heating enyne **6** with 5% TCPC^{HFB} (**1**, R = $CH_2C_3F_7$)[3b] and 5% tri-*o*-tolyl phosphite (TOTPO) in the presence of dimethyl acetylenedicarboxylate (DMAD) produced the expected [2+2+2] adduct[3a] from the trapping of the palladacyclopentene (cf. **2**) and a structurally homogenous dimer, which became the exclusive product in the absence of DMAD in 70% yield (Scheme 2). With as little as



Scheme 2. TOTPO: see text.

0.1 mol% TCPC^{HFB} the yield of dimer was 87%. Since the reactions proceed as well with or without phosphite, in most cases, the phosphite was not added. Extensive ^1H and ^{13}C NMR spectroscopic investigations (see Table 1) (including DEPT, HOM2DJ, COSY, NOESY, and HETCOR), mass spectrometry, and combustion analysis clearly establish **8a**[6] as the structure of the dimer. The methylated starting material **6b** gave a 66% yield of the corresponding dimer **8b**.[6] In both cases, only a single stereoisomer was detected.

We rationalized the formation of the dimer as the trapping of a vinylalkylidene complex **7**[7] with the olefin of the starting enyne, and attempted to intercept this proposed intermediate with strained olefins (e.g. norbornene or norbornadiene), activated olefins (e.g. styrene, methyl acrylate, butoxyethene), and an isolated acetylene (5-decyne) unfortunately without success. In contrast the addition of 2.5 equivalents of 1-nonen-2-yne gave a 65% yield of the cross adduct **10a**[6] in addition to 24% of the homo dimer **8a** (Scheme 3). Strikingly, the addition of as little as one equivalent of methyl (*E*)-2,4-pentadienoate (**11**) led to complete trapping with the formation of the adduct **10b**[6] in 80–86% yield. The adduct from enyne **9** and dienoate **11**, namely **10c**,[6] obtained in 90% yield allows the assignment of all ^1H NMR signals. Examination of all NOEs of nonvicinal hydrogen atoms for **10c** combined with the coupling constants allows assignment of the configuration as depicted in Scheme 3. The formation of such products is best interpreted

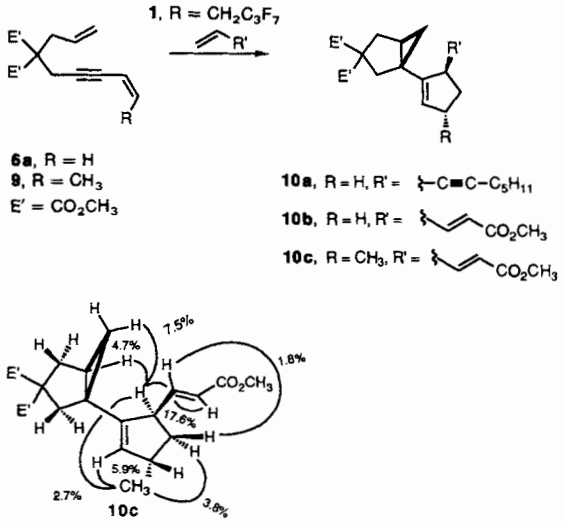
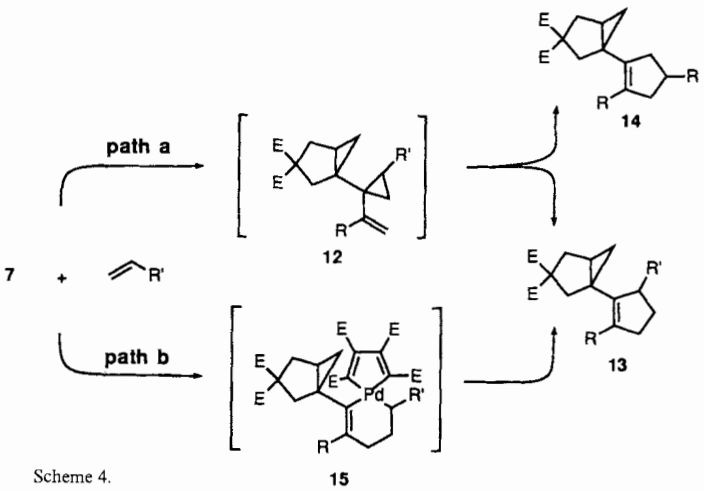


Scheme 3. Synthesis of **10a–c** and NOE effects for **10c** (below).

as arising from intermediates like **7** (Scheme 2). Such an intermediate might be expected to undergo cyclopropanation[8, 9] (Scheme 4, path a) rather than cyclopentannelation via the palladacyclohexene **15** (Scheme 4, path b). However, a vinylcyclopropane–cyclopentene rearrangement of **12** may produce two cyclopentenes **13** and **14**, in which the latter would be anticipated to dominate.[10] On the other hand, a [4+2] cycloaddition of a palladacyclopentadiene followed by reductive elimination nicely accounts for our observations. While such a cycloaddition appears unprecedented,[11] the failure to detect vinylcyclopropanes, the failure to trap **7** with nonconjugated olefins of any kind, and the regioselectivity of the reaction favor path b (Scheme 4). The unusual



Scheme 4.

structural features required in the trapping agents may be a combination of both electronic and coordinating effects necessary for the metalla-Diels–Alder reaction. Further studies are necessary to understand these requirements. Thus, this transformation involves two novel steps—a metallacyclopentene–metallavinylcyclopropane (cyclopropylalkylidene metal complex[12]) rearrangement and a [4+2] cycloaddition of metalladienes (vinylidene metal complex). These processes appear to be facilitated by Pd^{IV} intermediates, and they support path b of Scheme 1 as the likely major pathway for the metathesis of the terminal acetylenes. The introduction of a vinyl group on the alkylidene carbon atom stabilizes the intermediate and diverts the initial cyclopentene via path b (Scheme 1), whereas an acetylenic ester promotes reductive elimination by path a (Scheme 1). This new process appears to be widely applicable in synthesis.

[11] Vinylalkylidene metal complexes are reported to serve as dienophiles in [4+2] cycloadditions and not as the diene unit. For an excellent leading reference to this type of behavior, see W. D. Wulff, W. E. Bauta, R. W. Kaesler, P. J. Lankford, R. A. Miller, C. K. Murray, D. C. Yang, *J. Am. Chem. Soc.* **1990**, *112*, 3642. While this report deals with Fischer-type carbene complexes, and there are notable effects of the alkoxy group and metal ligands on the behavior of the carbene complex, this type of complex is the only current analogy. Clearly, the contrasting behavior, if any, of less stabilized vinylalkylidene metal complexes is an exciting topic for future endeavors.

Haematopodin, an Unusual Pyrroloquinoline Derivative Isolated from the Fungus *Mycena haematopus*, Agaricales**

By *Carsten Baumann, Martin Bröckelmann, Burkhard Fugmann, Bert Steffan, Wolfgang Steglich,** and *William S. Sheldrick*

Dedicated to Professor Meinhart H. Zenk on the occasion of his 60th birthday

Fruiting bodies of the toadstool *Mycena haematopus* (Pers. ex Fr.) Kummer, contain a red-brown sap which up until now has not been the subject of detailed chemical analysis. We have isolated a pigment from this fungus for which we propose the name haematopodin.

The fruiting bodies were placed in methanol immediately after collection and turned the solvent red-violet. The methanol was removed in vacuum leaving a red-brown, watery residue which was then subjected to chromatography on Sephadex LH-20, eluting with methanol. The haematopodin fraction can be distinguished from the red-violet main fraction as a slower moving rose-colored band. Every time the main fraction was rechromatographed, the haematopodin band reformed, allowing the isolation of the haematopodin in sufficient quantities for further investigations. Final purification by flash chromatography (silica gel, $CHCl_3$/CH_3OH 10/1) yielded pure haematopodin, which crystallized as a monohydrate from dichloromethane/methanol.[1]

The compound is optically active ($[\alpha]_D^{23}$ + 571, c = 0.14 in CH_3OH) and shows absorption maxima in the UV/VIS spectrum (measured in CH_3OH) at 208 (log ε 3.99), 242 (4.27), 344 (4.03), and 514 nm (2.95, broad absorption). The results of high-resolution EI mass spectroscopy indicate an empirical formula of $C_{13}H_{12}N_2O_3$, which was confirmed by the FAB^+ mass spectrum. An intense (M^+ + 2H) peak and the loss of CO from the molecular ion are indicative of the presence of an quinoid structural element.

The aliphatic region of the ^{1}H NMR spectrum (Table 1) shows signals corresponding to the structural elements $OCH_2CH_2CH_2N$ and $CH_2CH(N,O)$, singlets at δ = 5.37 and 7.12 characteristic of arene protons, and a broad NH signal at δ = 12.5. The analysis of the arene and carbonyl signals in the ^{1}H-coupled ^{13}C NMR spectrum (Table 1) indicates the presence of an indole-6,7-quinone chromophore. The fact that the singlet at δ = 180.28 exhibits no H,C coupling indicates that this signal is due to the 6-carbonyl group, whereas the signal due to the 7-carbonyl group at δ = 169.50 (in $CDCl_3$/CD_3OD (1/1)) is split into a doublet by spin–spin coupling with the proton at C-5 (^3J = 5.5 Hz). Selective decoupling experiments in [D_6]DMSO showed the proton at C-5 to have an additional ^3J coupling of 1.5 Hz with the indole-NH. COLOC experiments[2] allow the structural elements to be pieced together showing that haematopodin is identical with the structure 6,6a,9,10-tetrahydro-4*H*,8*H*-[1,3]oxazinol[3,2-*a*]pyrrolo[4,3,2-*de*]quinoline-2,3-dione (**1**).

Table 1. ^{1}H and ^{13}C Data for haematopodin (**1**) (400 and 100.6 MHz, respectively, in [D_6]DMSO, TMS).

^{1}H NMR [a]: δ = 1.53 (m, 9b-H), 1.91 (ddddd, 9α-H), 2.78 (dd, 6β-H), 3.10 (dd, 6α-H), 3.40 (ddd, 10β-H), 3.86 (ddd, 8β-H), 3.95 (m, 10α-H), 3.96 (m, 8α-H), 5.10 (dd, 6α-H), 5.37 (s, 1-H), 7.12 (s, 5-H), 12.5 (br. s, NH).

^{13}C NMR [b]: δ = 24.76 (t, J = 130 Hz, C-9), 26.13 (t, J = 132 Hz, C-6), 46.24 tm, J = 142 Hz, C-10), 67.58 (tm, J = 145, 7 Hz, C-8), 87.88 (dq, J = 161, 7 Hz, C-6a), 94.87 (d, J = 162 Hz, C-1), 114.06 (m, C-5a [c]), 123.11 (m, C-11b [c]), 124.64 (d, J = 8 Hz, C-3a), 124.88 (d, J = 188 Hz, C-5), 151.43 (br. s, C-11a), 169.50 (d [d], J = 5.5 Hz, C-3), 180.28 (s, C-2).

[a] J values [Hz]: $J_{6\alpha,6\beta}$ = 17 Hz, $J_{6\alpha,6a}$ = 6, $J_{6\beta,6a}$ = 3.5, $J_{8\alpha,8\beta}$ = 11.5, $J_{8\alpha,9a}$ = 5, $J_{8\beta,9a}$ = 12, $J_{9\beta,9\beta}$ = 2.5, $J_{9a,9\beta}$ = 13, $J_{9a,10\alpha}$ = 5, $J_{9a,10\beta}$ = 13.2, $J_{9\beta,10\beta}$ = 3.2, $J_{10\alpha,10\beta}$ = 13.5. [b] ^2J and ^3J relationships in 2D COLOC spectrum: C-3: 1-H; C-3a: 5-H; C-5: 6β-H; C-5a: 5-H, 6α-H, 6β-H; C-6a: 6β-H, 8α-H, 8β-H, 10α-H; C-8: 10α-H; C-9: 10α-H, 10β-H; C-11a: 10α-H, 10β-H; C-11b: 1-H, 5-H, 6β-H. [c] Signals could not be assigned unequivocally. [d] In $CDCl_3$/CD_3OD (1/1).

[**] Pigments of Fungi, Part 62. This work was supported by the Bundesministerium für Wissenschaft und Technologie and by the Fonds der Chemischen Industrie. – Part 61: H. Besl, A. Bresinsky, G. Geigenmüller, R. Herrmann, C. Kilpert, W. Steglich, *Liebigs Ann. Chem.* **1989**, 803.

The structural formula of haematopodin (**1**) was confirmed by X-ray crystallography (Fig. 1).[3] The asymmetric unit (space group $P2_1$) was found to contain two molecules of water in addition to two independent molecules of haematopodin. The molecules of **1** are linked together by N–H···O(water) and O2···H–O(water) hydrogen bonds and in this manner form a 3-D structure. The results of the X-ray crystallographic studies indicate that both molecules of **1** have a 6a-(*R*) configuration.[3]

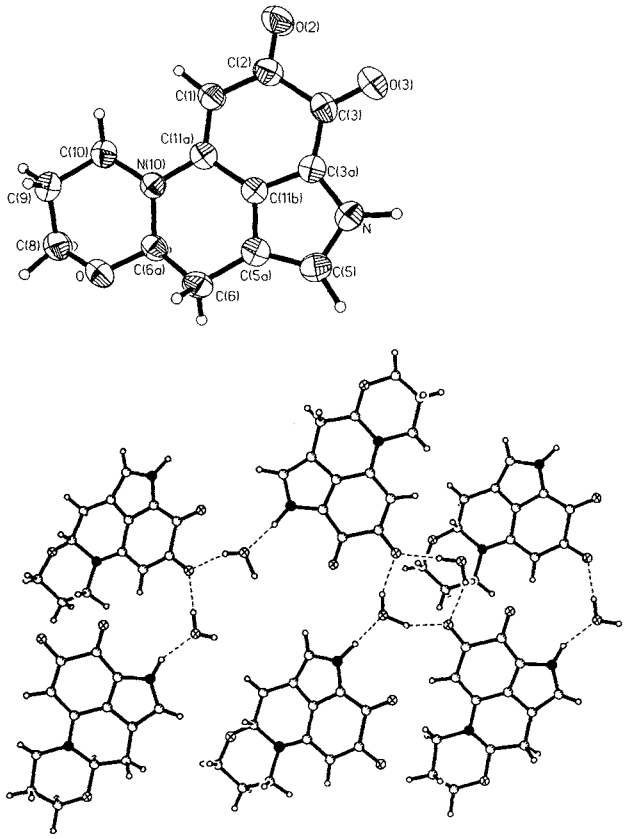

Fig. 1. Top: The structure of the first independent molecule of **1** in the unit cell (projection in accordance with IUPAC guidelines). Bottom: Linkage of the molecules of **1** by hydrogen bonds.

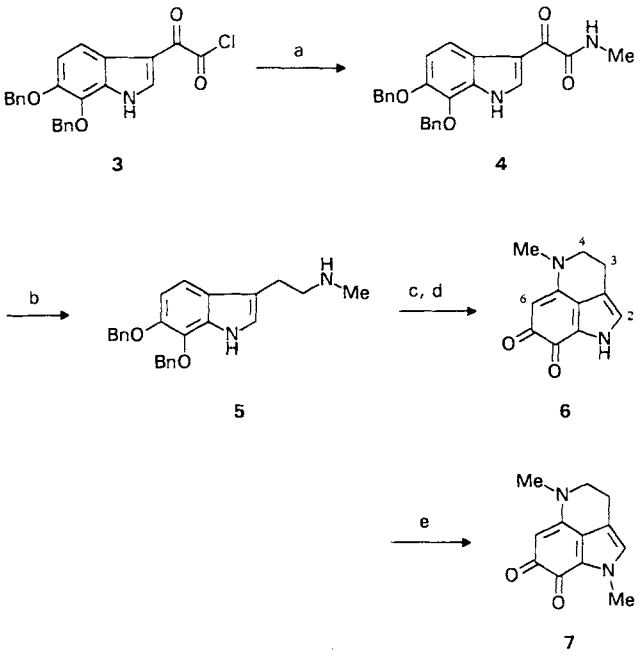
As mentioned in the introduction, haematopodin occurs, when at all, only in trace amounts in fresh fruiting bodies. It is formed by the breakdown of a very sensitive native pigment, which we have not yet been able to isolate in pure form.[4] For example, if a fungal extract is left in methanol in a sealed flask exposed to light for a few weeks, only haematopodin can be detected.

Related 1,3,4,5-tetrahydropyrrolo[4,3,2-*de*]quinoline pigments such as batzellins[5] and damirones[6] have been isolated from sea sponges. It is assumed that for these compounds the key step in the biosynthesis is the intramolecular cyclization of a tryptamine-6,7-quinone. In the case of haematopodin, the open chain compound **2** may be formed first which then undergoes oxidative cyclization to yield the oxazine derivative **1**.

A simple biomimetic synthesis along these lines starting from damirone B (**6**) and compound **2** is possible (Scheme 1, Table 2). The reaction sequence starts from the known compound 6,7-dibenzyloxyindolyl-3-glyoxylic acid chloride (**3**)[7] which in the case of **6** is converted to amide **4** by reaction with methylamine. After reduction to yield amine **5**, the



Scheme 1. Synthesis of damirone B (**6**) and damirone A (**7**). Reagents and reaction conditions: a) 1 equiv **3**, 2.0 equiv $MeNH_2 \times HCl$, 4.0 equiv Et_3N, CH_2Cl_2, room temperature (RT), 0.5 h (91%). b) 10 equiv $LiAlH_4$, THF, reflux, 4 h (51%). c) H_2, 10% Pd/$BaSO_4$, MeOH, RT, 1.5 h. d) O_2 from the air, Et_3N, MeOH, RT, 1 h (76%, 2 steps). e) 1.0 equiv **6**, 1 equiv K_2CO_3, 3 equiv CH_3I, EtOH, reflux, 1.5 h (89%).

benzyl protecting groups are removed by hydrogenolysis. The resulting dihydroxyindole derivative is stirred in methanol and triethylamine under air and cyclizes to provide damirone B (**6**). According to spectroscopic data, the synthetic product is identical to the naturally occurring compound.[6] Methylation with methyl iodide and addition of potassium carbonate yielded damirone A (**7**). In an

J = 6.8 Hz, 2H), 2.80 (t, J = 6.8 Hz, 2H), 3.45 (t, J = 6.8 Hz, 2H), 3.49(t, J = 6.8 Hz, 2H), 3.63 (t, J = 6.8 Hz, 2H), 4.63 (s, 1H, OH), 5.20 (s, 1H), 7.08 (s, 1H), 12.36 (s, 1H, indole-NH); ^{13}C NMR (100.6 MHz, [D$_6$]DMSO): δ = 19.7, 29.7, 47.5, 49.4, 58.0, 92.0, 116.4, 123.8, 124.5, 125.0, 152.6, 170.5, 178.4; IR (KBr): $\tilde{\nu}_{max}$ = 3423, 3117, 2934, 2866, 1670, 1608, 1587, 1543, 1432, 1417, 1323, 1241, 1078, 762, 745 cm^{-1}; EI-MS (70 eV): m/z 248 (68%, M^+ + 2H), 247 (44, M^+ + H), 246.1006 (42, M^+), calcd. ($C_{13}H_{14}N_2O_3$) 246.1004, 232 (26), 203 (100), 202 (88), 187(54), 174 (50), 146 (79); UV/VIS: λ_{max} (CH_3OH) = 207, 245, 349, 521 nm.

analogous manner the hypothetical precursor of haematopodin, **2**, was synthesized starting from acid chloride **3** and 3-aminopropanol. However, attempts to oxidatively cyclize this compound to yield **1** by using $Hg(OAc)_2$ or other reagents have not been successful up until now.

These syntheses demonstrate that 6,7-dihydroxytryptamine derivatives are easily converted by oxygen to pyrroloquinolines. Further studies on the chemistry of the *Mycena* pigments and the chemical synthesis of haematopodin are being carried out at the present time.

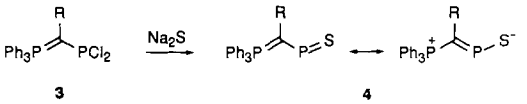
Ylide-Substituted Thioxophosphanes and Dithioxophosphoranes**

By *Georg Jochem, Heinrich Nöth* and *Alfred Schmidpeter**

Chalcogenophosphanes RP=Y (Y = O, S, Se) are extremely reactive, and so far no compound of this type is known that is stable at room temperature.[1b, 2c, 3] Halothioxophosphanes **1** (R = F, Cl, Br) were detected and studied in the gas phase and in argon matrices.[1b] Other thioxophosphanes with R = Me, Et, *n*Bu, Ph, NMe_2, OCH_2CCl_3, OPh, for example, could be generated but were detected only indirectly as adducts and cycloadducts as well as coordinated to metal complexes fragments.[1b] Four (!) independent experiments for the preparation of thioxophosphane **1** with 2,4,6-tri-*tert*-butylphenyl as the substituent R are found in the literature. This substituent was used successfully for the kinetic stabilization of lower coordinated main group elements in many cases before. In the attempted synthesis of **1**, R = 2,4,6-tri-*tert*-butylphenyl, however, only the cyclic trimer **2** and products of disproportionation were found.[2] We have now succeeded in stabilizing thioxophosphanes with an ylide substituent R and isolating them as stable compounds.

1 **2**

Dichloro[organo(triphenylphosphonio)methanidyl]phosphanes **3**, R = Me, Et[4] react smoothly with sodium sulfide in THF to form the ylide-substituted thioxophosphanes **4a, b** which can be isolated as orange-red crystals (Scheme 1). The aryl derivatives **4c, d** are prepared in the same manner but are not stable in solution. Here the reaction does not proceed uniformly. The selenoxophosphanes RP=Se can be prepared analogously from **3** and Na_2Se.[5] Thioxophosphanes **4** were characterized unequivocally by their ^{31}P NMR spectra (Scheme 1), particularly by the low-field signal of the two-coordinate phosphorus. Here the ^{31}P



3 **4**

	R	$\delta^{31}PPh_3$	$\delta^{31}PS$	$^2J(P,P)$ in THF
4a	Me	28.9	485.0	116.0 Hz
4b	Et	27.9	488.2	116.0 Hz
4c	Ph	25.0	495.9	107.8 Hz
4d	3-MeC_6H_4	25.3	493.8	107.8 Hz

Scheme 1.

nucleus remains much more strongly shielded, though, than would be expected from extrapolation from $RP=SiR_2$ and $RP=PR$[1f, 6] to RP=S. In keeping with this, the signal of the ylide carbon atom of **4** (**4b**: $\delta^{13}C = 137.2$) is at lower field than those of other ylides, even α-acyl-substituted triphenylphosphonium ylides.[7] Both features point to a considerable contribution of the dipolar resonance formula, in which **4** is depicted as a phosphalkene. The relatively strong P–P coupling indicates that the sulfur atom and the phosphonio group are *trans* to each other[8] as is also found in the crystal structure (see below); the polarity of the solvent (benzene/THF) does not have a discernible influence on the coupling.

Thioxophosphanes **4** prove to be ambident nucleophiles. Compound **4b** reacts with benzyl bromide by S-alkylation forming **5b** (in THF: $\delta^{31}PPh_3 = 25.9$, $\delta^{31}PS = 245.1$, $^2J(P,P) = 173.9$ Hz[9]), but by P-oxidation with sulfur giving **6b**. The latter is also directly accessible from **3** and Na_2S_2 like other dithioxophosphoranes $Ph_3P=Cr-PS_2$ **6**.[10] Oxi-

dation from **4** to **6** shifts not only the NMR signal of the affected phosphorus atom to higher field ($\Delta\delta^{31}P \approx -250$[10]) but also the NMR signals of the C and P atoms of the ylide substituent ($\Delta\delta^{13}C \approx -50$, $\Delta\delta^{31}P \approx -5$[10]). At the same time $^2J(P,P)$ decreases to less than half its original value.

That the thioxophosphanes **4** are monomeric and nucleophilic at sulfur seems a consequence of their polar nature, as reflected by the second resonance formula; the ^{31}P and ^{13}C NMR shifts are also compatible with this. The contribution of the dipolar resonance formula should be evident in a structure elucidation. The comparison of the structure of **4** to that of a dithioxophosphorane **6** must show, in addition, how the oxidation of the phosphorus affects its bond to the ylide group. Besides the ylide-substituted compounds **6**, three dithioxophosphoranes with bulky aryl substituents are known and their structures have been determined.[1e, 11] In these molecules the aryl and the CPS_2 planes are almost perpendicular to each other. Figure 1 and Table 1 show the results of the structure investigation[12] for single crystals of **4b** and **6c**. In both cases there are discrete molecules with no detectable intermolecular contacts between the S and/or P atoms.

As expected, the ylide carbon atom is surrounded in a planar manner and all sulfur atoms are found in this plane, too. In **4b** the sulfur atom is *trans* to the phophonio group.

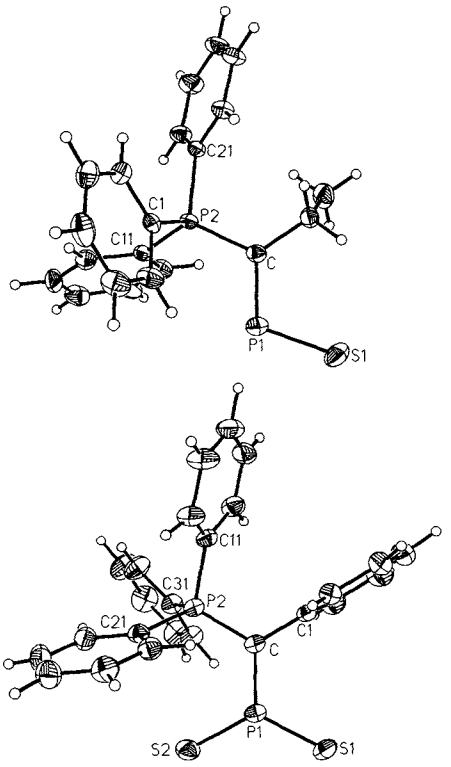

Fig. 1. Crystal structures of **4b** (top) and **6c** (bottom) (thermal ellipsoids at the 25% probability level).

Table 1. Structure parameters [a] of **4b** and **6c**.

Cmpd.	Bond lengths [Å]			Bond angles [°]	
	C-PPh$_3$	C-PS	P-S	C-P-S	S-P-S
4b	1.759(4)	1.704(5)	1.981(2)	109.9(2)	
6c (S1)	1.758(3)	1.689(2)	1.923(1)	117.3(1)	124.3(1)
(S2)			1.929(1)	118.4(1)	

[a] Standard deviations in parentheses.

In **6c** the P–S bonds *cis* and *trans* to the phosphonio groups are of almost equal length. As expected, the C-P-S angle opens on oxidation (**6c** compared to **4b**). Since the planes of the trigonal-planar coordinated C and P atoms in **6c** coincide, the structure of this compound forms a counterpart to the structure of the previously mentioned dithioxophosphoranes, which are stabilized by the steric shielding of the phosphorus.

The Ph_3P–C bond in **4b** and **6c** is longer than the bond in the ylide with an unsubstituted C atom (1.69 Å)[13a] and as long as the bond in α-acyl-substituted ylides (1.70–1.75 Å).[13b] On the other hand, the P–C bond with the two- or three-coordinate phosphorus is far shorter than a single bond (1.84 Å) and corresponds to a relatively long double bond in a phosphaalkene (1.61–1.71 Å).[1c] When **4** is sulfurized to give **6**, the bond is slightly but significantly shortened as is generally observed in the oxidation of a phosphaalkene to a methylenephosphorane.[1d, 14]

The lengths of the P–C bonds of **4b** and **6c** therefore signalize a predominating dipolar resonance formula. This can be seen less clearly in the lengths of the P–S bonds. In **4b** the P–S distance is intermediate to the length of a terminal P=S bond (at the tetrahedral or trigonal-planar surrounded phosphorus, 1.93 Å) and the length of a P–S single bond (2.12 Å; this value relates to a two-coordinate sulfur, however). In **6c**, where the negative charge is distributed between two sulfur atoms, the bond is just as short as the above-mentioned "normal" P=S bond. In other thioxophosphoranes these P–S bonds are also of the same length.[1e, 14]

The calculated angles for ClPS[1b] and for $ClPS_2$[1e] (Cl-P-S: 110° and 117°, respectively, S-P-S: 126°) are identical to those found in **4b** and **6c**. The P=S bond lengths resulting from the MNDO calculations (1.86 and 1.82 Å) are too short, however, as expected. A good comparison is given by the length of the P–S bond in PS_3^-, 1.96 Å, determined by ab initio calculations.[15]

Experimental Procedure

4b: A suspension of **3b** (2.18 g, 5.4 mmol) and Na_2S (0.47 g, 5.4 mmol) in THF (20 mL) was stirred for 15 h at room temperature. After separation of the insoluble products using a reverse frit and concentration of the light-red filtrate to one-third of the original volume, **4b** crystallized. A second fraction was obtained from the concentrated mother liquor to which benzene (5 mL) was added. Yield 1.34 g (68%) orange crystals, m.p. 146–150 °C. Crystals suitable for structural analysis were obtained at room temperature from a saturated solution (1:1 dichloromethane/benzene mixture) after a few mL of pentane was added.

6c: A suspension of **3c** (1.63 g, 3.6 mmol) and Na_2S_2 (0.40 g, 3.6 mmol) in THF (15 mL) was stirred for 15 h at room temperature. After separation of the insoluble products using a reverse frit, concentration of the orange-red filtrate to two-thirds of the original volume, and addition of benzene (8 mL), **6c** · 0.5 C_6H_6 crystallized within 24 h. Yield 1.16 g (66%) yellow crystals, softening >130 °C and decomposing >160 °C.

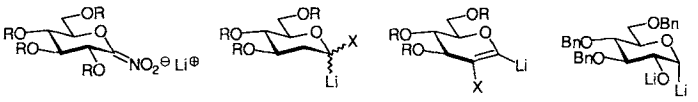
Stereoselective Synthesis of C-Glycosides with a Glycosyl Dianion**

By *Valentin Wittman* and *Horst Kessler**

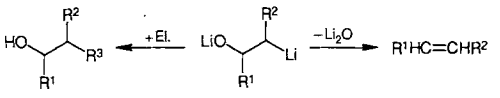
During the past few years the interest in the synthesis of C-glycosides[1] has greatly increased. This is chiefly due to the discovery of C-glycosidic or analogue structures in many natural products,[2] and their potential use as antimetabolites.[3] As with the synthesis of O-glycosides, the traditional approach to C-glycosides is based upon the addition of a suitable C-nucleophile to the electrophilic anomeric center of a 1-activated carbohydrate. The use of glycosyl radicals[1,4] and glycosylidene carbenes[5] has also been described. Direct 1-C-lithiation of sugars generally leads to the elimination of functional groups in the 2-position.[6] Paulsen et al. first reported the C-elongation of open-chain carbohydrates by polarity inversion (umpolung) at the anomeric center via dianions of hydroxy-1,3-dithianes.[7] However, in the case of pyranoses the concept of umpolung has been limited so far to 1-nitrosugars **1**,[8] 2-deoxysugars **2** (X = H,[6a,9] SO_2PH,[10] $^{\oplus}PPh_3$,[11] CO_2R[12]), and glycals **3** (X = H,[9d,13] SOPh,[14] SPh,[15] OBn[15]). Chain elongation of nitrosugars **1** followed by substitution of the nitro group by a hydroxy group leads to higher ketopyranoses with the added residue in the equatorial position. Glycals **3** offer the possibility of subsequent introduction of the missing hydroxy group and therefore access to β-C-glycosides.



1 **2** **3** **4**

In this communication we present the application of the dilithio compound **4** in the synthesis of C-glucosides. Simple lithiation of the 2-hydroxy group functions both as a means of protection, and efficiently prevents β elimination. Subsequent reaction with electrophiles directly produces 2-hydroxy-substituted C-glucopyranosides, exclusively with α-configuration (see Scheme 1).

Dianions of the general type **5** may be obtained from β-hydroxy organomercury compounds,[16] chlorohydrins,[17] epoxides,[18] carbonyl compounds,[10a,19] or hydroxy-1,3-dithianes,[7] and were used either as carbanions for C–C-coupling reactions (**5** → **6**, El. = electrophile)[7,16–18,19a] or in the synthesis of olefins by Li_2O elimination (**5** → **7**).[19,20]



6 **5** **7**

The suitability of **4** for chain elongation reactions at the anomeric center or its tendency to eliminate to give the glucal were not readily predictable. It was reported,[17] for example, that compounds **5** in which lithium is located at a primary carbon (R^2 = H) are stable up to – 60 °C. On the other hand in the case of R^2 = alkyl, they decompose spontaneously even at – 100 °C to the olefin by β elimination. Only compounds **5** with stabilizing substituents like R^2 = Ph or CO_2Et, or cyclic β-lithiocyclohexanolate (R^1,[10] R^2 = $-(CH_2)_4-$) can be converted into the corresponding deuterated alcohols **6** (R^3 = D). Beau and Sinaÿ have postulated[10] the presence of the dilithio derivative **8** and demonstrated that protonation without β elimination is possible.

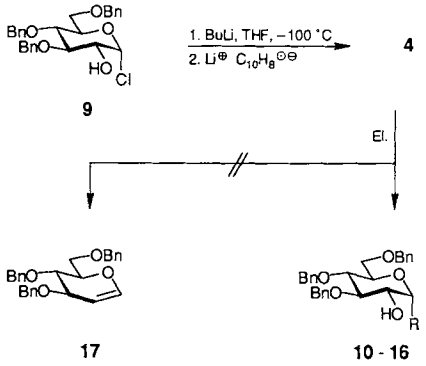
[**] This work was supported by the Fonds der Chemischen Industrie (doctoral fellowship for V. W.) and the Deutsche Forschungsgemeinschaft.

In a first experiment we treated 3,4,6-tri-O-benzyl-α-D-glucopyranosyl chloride **9**[21] in THF at − 78 °C dropwise with 1.1 equivalents of *n*-butyllithium (to generate the alcoholate), and after 15 minutes with 2.2 equivalents of lithium naphthalenide. After a further 15 minutes, quenching with MeOD, work up under acidic conditions, and chromatography on silica gel yielded a mixture of deuterated sugar **10** (66%), the corresponding β-configurated compound (3.1%), and the protonated compound **11** (17%) (Scheme 1). These products suggest that the dilithio compound **4** was formed intermediately during the reaction. The axial configuration of deuterium in **10** is based on the ^{1}H NMR spectrum (250 MHz, $CDCl_3$, $^3J_{H1,H2}$ = 5.3 Hz). The *a*/β ratio of 21 : 1 was determined by deuterium NMR spectroscopy. Obviously no Li_2O elimination leading to 3,4,6-tri-O-benzyl-D-glucal **17** takes place under these conditions.



Scheme 1. Synthesis of the α-C-glucosides **10**–**16** (cf. Table 1). Bn = CH_2Ph, El. = electrophile.

Table 1. Results of the C-glucoside synthesis according to Scheme 1.

Electrophile	Product [a]	R	Yield [%] [b]
MeOD	**10**	D	75
MeOH	**11**	H	82
MeCHO	**12a/b**	CH(OH)Me	62
PhCHO	**13a/b**	CH(OH)Ph	70
*i*PrCHO	**14a/b**	CH(OH)*i*Pr	59
HCHO	**15** [23]	CH_2OH	17
MeI [c]	**16**	Me	72

[a] Products were characterized by ^{1}H and ^{13}C NMR spectroscopy (see Table 2) and FAB-MS. [b] Yields of α-anomers after chromatography on silica gel. [c] Addition of 10% CuI.

The best yields were obtained by *quick* addition of the lithium naphthalenide solution. To avoid undue increase of reaction temperature, a precooled lithium naphthalenide solution (−78 °C) is recommended. However, since the solubility of lithium naphthalenide in THF is greatly reduced at this temperature, it is better to work at − 100 °C and add the reagent uncooled. The results presented in Table 1 were obtained by using the latter method.

We next turned our attention to the possibility of using the lithiated sugar **4** in the synthesis of α-C-glucosides. The reaction of **4** with acetaldehyde affords a mixture of diastereomers **12a/b**[22] (ratio 1.4 : 1) in 62% yield. In the same manner benzaldehyde and isobutyraldehyde produced **13a/b** (1 : 1, 70%) and **14a/b** (1 : 1, 59%), respectively. In all cases axial configurated C-glucosides were produced with high stereoselectivity ($\alpha/\beta \geq 20:1$). The use of gaseous formaldehyde gave the desired hydroxymethyl C-glucoside **15** in an unsatisfactory 17% yield; in this case large quantities of polyoxymethylene were formed. However, alkylation of the dianion **4** with MeI proceeded without complications to give α-methyl-C-glucoside **16** in 58% yield. An improved yield of 72% could be obtained by addition of 10% of CuI before addition of the electrophile.

Table 2. Selected ^{1}H and ^{13}C NMR chemical shifts (δ values) and coupling constants *J* [Hz] of **10**–**16** [a,b]. ax = axial, eq = equatorial, n.d. = not determinable.

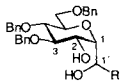
[a] NMR spectra in $CDCl_3$ at 300 K, internal standard TMS. ^{1}H: 500 MHz, ^{13}C: 125 MHz. [b] To facilitate comparison, atoms are numbered following that used for the starting sugar **9**.



[c] Identical chemical shifts of H1 and H2.

It is remarkable that the formation of tribenzylglucal **17** was not observed under any circumstances. Thus, the dilithio compound **4** proves to be a species which is stable at − 78 °C and reacts with electrophiles with *retention* of configuration at the anomeric center to give a variety of 2-hydroxy-α-C-glucosides. The precursor **9** is crystalline and stable at − 20 °C,[21] and is easily obtained from acetobromoglucose in a four-step synthesis in an overall yield of approximately 55%.

Experimental Procedure

Under argon a 0.15 M solution of **9** in dry THF at − 100 °C was treated with 1.1 equivalents of *n*BuLi (1.6 M in THF), followed by quick addition of 2.2 equivalents of lithium naphthalenide (1 M in THF). After 15 minutes, 1.5 equivalents of aldehyde or MeI were added, and the mixture was stirred for 1 h at − 100 °C and then allowed to warm up to room temperature. A saturated aqueous solution of NH_4Cl was added and the mixture extracted with dichloromethane. After the organic layer had been dried over $MgSO_4$, the product was purified by chromatography on silica gel (eluent: toluene/ethyl acetate or hexane/ethyl acetate).

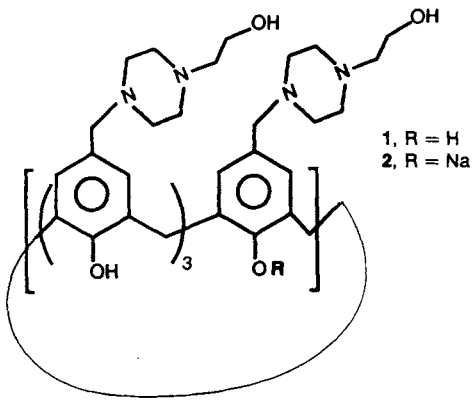
Supramolecular Complexes of Flexible, Extended Cavity Calix[4]arenes—Structural Characterization of a Molecular Venus Flytrap**

By *Jerry L. Atwood,* G. William Orr, Simon G. Bott,* and *Kerry D. Robinson*

The ability of calix[4]arenes to form supramolecular complexes has been responsible for much of the current interest in these macrocycles.[1, 2] While *p*-sulfonatocalix[4]arene has been shown to bind to a range of small molecules and ions,[3–9] there exists a need for calix[4]arenes with larger cavities possessing more binding possibilities. In search of deep-cavity calix[4]arenes, Gutsche and Nam reported[10] in 1988 that calix[4]arene undergoes acetic acid-catalyzed aminomethylation in the presence of formaldehyde and dimethylamine in THF. We have now expanded on this Mannich reaction[11] to synthesize a wide range of aminomethylcalix[4]arenes. One of these, *p*-[4-(2-hydroxyethyl)-piperidinomethyl]calix[4]arene (**1**), possesses a flexible binding capability reminescent of the capture of insects by the Venus flytrap.

In the original synthesis of **1** unidentified resonances appeared in both the ^{1}H and ^{13}C NMR spectra, and efforts to remove the compound causing these signals were unsuccessful. Subsequently, a single-crystal X-ray diffraction study[12] revealed the presence of a guest in the cavity (Fig. 1). This molecule appears to be unreacted, excess 1-(2-hydroxyethyl)piperazine that has been methylated at the position of the secondary nitrogen. Although the hydroxyethyl chain of this molecule is badly disordered (and thus not shown in Fig. 1), the remainder of the atoms are better defined. The ^{1}H and ^{13}C NMR spectra are also consistent with the presence of two different hydroxyethylpiperazine moieites.[13] As Figure 1 reveals, the arms of the calix[4]arene are spread wide to provide a shallow cavity similar to that found in *p*-sulfonatocalix[4]arene.[3–9]



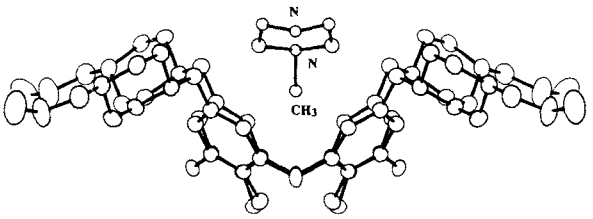


Fig. 1. Structure of *p*-[4-(2-hydroxyethyl)piperazinomethyl]calix[4]arene with the guest $CH_3N(CH_2CH_2)_2NCH_2CH_2OH$. The $-CH_2CH_2OH$ portion of the guest molecule was badly disordered and is not shown.

Preparation of **1** and subsequent neutralization with 10% Na_2CO_3 solution to pH 9 leads to the removal of one of the phenolic protons resulting in the complex **2**. Following crystallization from ethyl acetate, **2** was dried under vacuum for 48 h at 120 °C. The ^{1}H NMR spectrum revealed that even

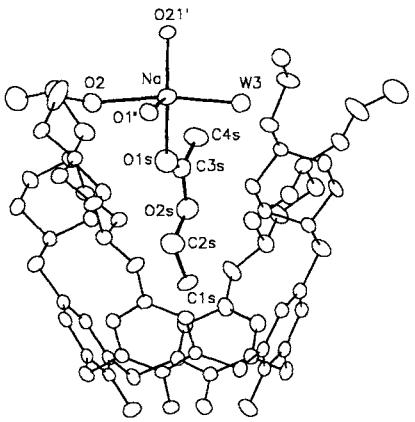

Fig. 2. Structure of Na[*p*-[4-(2-hydroxyethyl)piperazinomethyl]calix[4]-arene] · $CH_3COOCH_2CH_3$.

Tuscaloosa, AL 35487 (USA)

[**] This work was supported by the U. S. National Science Foundation.

under these extreme conditions one ethyl acetate molecule was retained. X-ray diffraction quality crystals of this compound afforded the structure[14] shown in Figure 2. In this complex the arms are directed up from the rim of the calix[4]arene to produce a cavity so deep that the ethyl acetate guest molecule is completely enshrouded. The guest is further bound by an electrostatic interaction with the Na^+ ion to the carbonyl oxygen atom. The Na^+ ion further ties the guest to the host by an electrostatic bond to one of the hydroxyl oxygen atoms of the calix[4]arene.[15]

Comparison of Figures 1 and 2 shows that *p*-[4-(2-hydroxyethyl)piperidinomethyl]calix[4]arene under different circumstances can deliver either a shallow or a deep cavity. Ethyl acetate is the largest guest thus far characterized as completely enshrouded by a calix[4]arene.

Experimental Procedure

1: Calix[4]arene (1.00 g, 2.36 mmol), 1-(2-hydroxyethyl)piperazine (1.84 g, 14.2 mmol), and 37% aqueous formaldehyde solution (1.05 mL, 14.2 mmol) were dissolved in 1,2-dimethoxyethane (50 mL). A solution of CF_3COOH (100 mL) in 1,2-dimethoxyethane (20 mL) was added dropwise to the unstirred solution over a period of 1 h. The resulting solution was allowed to stand at room temperature for 1.5 h at which time the solution was pale yellow. The reaction was allowed to continue for a total of 12 h after which time the volatile components were removed under vacuum at 40 °C. The resulting solid was dissolved in MeOH, stirred vigorously for 1 h over solid Na_2CO_3 (0.5 g), and filtered through a fluted filter paper. The filtrate was evaporated to dryness, and crystallization was effected by the addition of hot ethyl acetate to a boiling solution in MeOH, followed by cooling in an ice bath. The solid was collected on a fritted funnel, washed with ice-cold ethyl acetate, and dried under vacuum at 40 °C for 48 h to produce 1.3 g of **1** (50%).

2: Calix[4]arene (1.00 g, 2.36 mmol) and 1-(2-hydroxyethyl)piperazine (1.53 g, 11.8 mmol) were dissolved in THF (25 mL) and glacial acetic acid (2.7 mL). To the resulting colorless solution was added 37% aqueous formaldehyde solution (0.88 mL), and the contents were stirred in a sealed flask at room temperature for 28 h, after which the volatile components were removed under vacuum at 40 °C. The yellow-orange residue was dissolved in distilled water (25 mL) and neutralized to pH 9 with 10% Na_2CO_3 solution. The solution was then subjected to three freeze-pump-thaw cycles at −78 °C to remove traces of CO_2. The solution was then evaporated to dryness, and the residue was dissolved in methanol and filtered. Ethyl acetate was added, followed by cooling in an ice bath to produce the crystalline product. The reaction produced 0.4 g of **2** (17%).

[12] The pale yellow crystals of **1** · $[MeN(CH_2CH_2)_2NCH_2CH_2OH] \cdot 7H_2O$ belong to the orthorhombic space group *Pnma* with $a = 11.249(1)$, $b = 33.628(5)$, $c = 19.075(3)$ Å, and $\varrho_{calcd} = 1.17\ g\,cm^{-3}$ for $Z = 4$. Refinement based on 2922 observed reflections led to a final $R = 0.10$. See also [14b].
[13] The CH_2OH and NCH_2 resonances from the calixarene substituent appear as a pair of triplets at $\delta = 3.58$ and 2.44, respectively, corresponding to a total of sixteen protons. The CH_2OH and NCH_2 resonances of the substrate (guest) appear as triplets at $\delta = 3.64$ and 2.52, respectively, corresponding to a total of four protons. The NCH_2CH_2N resonances from the calixarene substituents appear as a very broad multiplet centered at about $\delta = 2.4$. The NCH_2CH_2N resonances of the substrate appear as a pair of broad triplets at $\delta = 2.95$ and 2.58. The ^{13}C resonances of the calixarene substituents appear at $\delta = 64.1$, 61.0, and 54.5 and 54.0 for CH_2OH, NCH_2, and NCH_2CH_2N, respectively. The corresponding substrate resonances appear at $\delta = 62.6$, 59.3, and 55.6 and 55.0, respectively. The CH_3N resonance appears as a singlet at $\delta = 3.35$ (^1H NMR) and $\delta = 42.9$ (^{13}C NMR). The origin of the signal from a CH_3 group was discerned from a DEPT experiment.
[14] a) The compound, Na[4-(2-hydroxyethyl)piperazinomethyl)calix[4]-arene] · $CH_3COOCH_2CH_3 \cdot 3H_2O$, crystallizes in the triclinic space group $P\bar{1}$ with $a = 12.139(1)$, $b = 15.628(2)$, $c = 16.248(1)$ Å, $\alpha = 87.93(1)$, $\beta = 85.76(1)$, $\gamma = 85.75(1)°$, and $\varrho_{calcd} = 1.26\ g\,cm^{-3}$ for $Z = 2$. Refinement based on 4785 observed reflections led to a final $R = 0.065$. b) Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge, CB21EZ (UK), on quoting the full journal citation.
[15] The sodium ion which resides at the mouth of the calix[4]arene cavity is found in a roughly trigonal bipyramidal ligand geometry. The bond lengths are Na–O1s = 2.300(7) Å, Na–O2 = 2.414(6) Å, Na–W3 (water oxygen atom) = 2.376(6) Å, Na–O1″ (from a hydroxyethyl group on a neighboring calixarene) = 2.308(6) Å and Na–O21′ (from the phenolic portion of a neighboring calixarene) = 2.397(6) Å.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Book Reviews

Survey of Industrial Chemistry. 2nd Revised Edition. By *P. J. Chenier*. VCH Publishers, New York, 1992. XV, 527 pp., hardcover \$ 95.00, softcover \$ 45.00.—ISBN 1-56081-082-3/1-56081-622-8

A common complaint in the chemical community is that, even though most chemists work in industry, chemistry is taught as though all graduate chemists would pursue academic careers. Philip Chenier has undertaken to do something about this situation. He has written an advanced undergraduate text that broadly surveys the American chemical industry. The book contains a substantial business perspective in addition to describing how most major industrial chemicals are made and used. The primary intended audience is the chemist who will move into business-orientated employment such as sales or technical service rather than getting an advanced degree. Simultaneously, though, it can provide a useful introduction to industry even for someone anticipating an academic career.

This *Survey of Industrial Chemistry* presents an enormous mass of information. It contains not just a compendium of chemical process technology, but also statistics on the size and scope of the chemical industry, salaries of U. S. chemists, and the sales of the top fifty chemical companies. Chenier has made a significant and largely successful effort to present current data and perspectives on the industry. The information seems to be current through 1990.

The process of packing so much information into a volume affordable by a student has led to a terse writing style. The body of the volume tends to present the facts without the many little anecdotes that might enliven the presentation. Nevertheless it is moderately readable and presents useful perspective not just on how a chemical is made but also on how it is used and what its economic prospects may be. The discussion of manufacturing technology contains many photographs of production facilities and laboratories. The process discussions are clarified with abundant chemical equations and formulas. There are a number of typographical errors in the equations, but they do not usually cause problems for the reader.

The subject matter of the book spans the whole chemical industry, including fields as diverse as pharmaceuticals, plastics, elastomers, mineral products, wood products, and detergents. The greatest attention is given to the fifty largest volume chemicals, but the selection seems repesentative of the industry as a whole. There is a timely and useful section on current environmental and health issues facing the chemical community. Throughout, the author presents a positive but realistic view of the chemical industry.

The survey of individual chemical products, which makes up the greatest part of the book, employs a standard format for each major chemical. For each, there is a discussion of both historic and current manufacturing processes with some perspective on technology trends. For example, the section on acetic acid includes discussion of the obsolescent ethylene-based Wacker process, the oxidation of butane to acetic acid, and the now preferred methanol carbonylation. For each process, the author presents a summary equation, the usual process conditions, and the separation and purification technology. For major processes such as the catalytic carbonylation of methanol there are also sketches of what is known about the reaction mechanism. The process descriptions are followed by summaries of the uses of the compounds together with key physical properties. The book also lists the production volumes and approximate prices for major chemicals.

The *Survey of Industrial Chemistry* is in many respects a mini-encyclopedia of the chemical industry. It meets its goal as a tool for the teacher of a business-orientated chemistry course, but it is also a useful reference source for anyone with a broad interest in the practice of industrial chemistry. The level of detail is not great, but it provides leading references to up-to-date chemical encyclopedias and review articles. After almost forty years in industrial chemistry, I found that I had much to learn from this book. I expect to use it extensively as a general reference source in the near future.

Volume 1

Volume 1 of *Comprehensive Organic Synthesis* is essentially concerned with the chemistry of carbanions. This volume is divided into three different sections: "Nonstabilized Car-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1993 0570-0833/93/0707-1095 \$ 10.00+.25/0

banion Equivalents," "Heteroatom-stabilized Carbanion Equivalents," and "Transformation of the Carbonyl Group into Nonhydroxylic Groups". These three sections are composed of various chapters authored for the most part by internationally recognized experts.

The first sections contains 13 chapters describing the chemistry of non-stabilized carbanions. A brief introduction to the structure of organometallic compounds is followed by chapters of about 30 pages each, which treat in detail the synthesis and reactions of organometallic compounds of alkali and alkaline earth metals, aluminum, copper, titanium, zirconium, chromium, zinc, cadmium, mercury, and lanthanoids. Special attention is given to the chemo-, regio-, and stereospecificity of the reactions, an essential aspect for any up-to-date compendium of this kind. In the chapter on the chemistry of organocopper compounds the discussion is limited to 1,2 additions of such compounds to carbonyl compounds and their hetero-analogues; 1,4 additions are treated in Volume 4 of the series. The last four chapters of this section describe the Lewis acid mediated reactions of organometallic compounds with carbonyl compounds, epoxides, and acetals, and additions of organometallic compounds to imines and carboxylic acid derivatives. Especially noteworthy here is the description in Chapter 1.10 of studies on asymmetric catalysis, currently a very hot topic.

The second section consists of six chapters dealing with the chemistry of heteroatom-stabilized carbanions. Important topics treated here include the deprotonation of arenes which is mediated by chelating agents, and the deprotonation of compounds in which the CH acidity is increased by –I substituents. As well as carbanions stabilized by nitrogen, boron, sulfur, and silicon, considerable space is devoted to the benzoin reaction and selenium chemistry.

The third section, which consists of about 200 pages divided into only three chapters, deals with the conversion of carbonyl compounds to olefins and epoxides and with ring-enlargement reactions of carbonyl compounds. Although the subject matter of this section does not fit in comfortably with the previous two, some of the methods described are extremely important, for example the olefin-forming reactions just mentioned. The chapter on this topic is 80 pages long, and treats not only the well-known named reactions such as the Wittig, Wittig–Horner, Peterson, Johnson, Tebbe, and Julia reactions, but also modern variants such as modified Tebbe reactions and samarium-induced reactions. The discussion of the advantages and disadvantages of the different reactions is especially useful, enabling the reader to quickly form a view as to which reaction offers the best solution to a specific problem. Under the heading of epoxidation of olefins one is likely to think immediately of the Sharpless epoxidation, but this highly important and elegant method is reserved for Volume 7. The short second chapter describes the preparation of epoxides by addition of heteroatom-stabilized carbanions to carbonyl compounds, which is followed by an intramolecular S_N2 cyclization. The third chapter is concerned mainly with the ring enlargement of cycloalkanones. In addition to the Arndt–Eistert method a number of more modern methods, involving a wide variety of mechanisms, are described.

The bibliographies attached to each of the chapters are a mine of information, citing over 3400 original publications extending up to the beginning of 1990. The detailed subject and author indexes also facilitate quick access to the primary literature. Most, but regrettably not all, chapters include clearly arranged tables from which the reader can obtain a quick overview of the capabilities and range of applicability of the methods described. Also the usefulness of many of the methods is illustrated by numerous examples of natural products syntheses.

Ulrich Groth
Institut für Organische Chemie
der Universität Göttingen (FRG)

Volume 2

Volume 2 consists of four parts as follows: "Uncatalyzed Additions of Nucleophilic Alkenes to C = X" (17 chapters, 526 pp.); "Catalyzed Additions of Nucleophilic Alkenes to C = X" (5 chapters, 134 pp.); "Addition–Elimination Reactions (Acylations)" (7 chapters, 158 pp.); "Additions of Nucleophilic Alkenes to C = NR and C = NR_2^+" (6 chapters, 219 pp.). An 88-page author index and a 61-page subject index are also included.

Nearly all the chapters are very useful reviews of recent developments in the areas covered, written by recognized experts. The topics treated in the first two parts range from "Allyl Organometallics" (W. R. Roush) through "Propargyl and Allenyl Organometallics" (H. Yamamoto) to "Allylsilanes, Allylstannanes and Related Systems" (I. Fleming), "Formation and Addition Reactions of Enol Ethers" (T. H. Chan), "Asymmetric Synthesis with Enol Ethers" (C. Gennari), and "Reactions of Activated Dienes with Aldehydes" (M. D. Bednarski and J. P. Lyssikatos). Between these comes a treatment of the formation and reactions of enolates with a wide variety of counterions. As well as Clayton Heathcock, the undisputed leading expert on the aldol reaction, there are contributions from G. Rosini on the nitroaldol (Henry) reaction, from L. F. Tietze and U. Beifuss on the Knoevenagel reaction, and by T. Rosen on the Perkin reaction. The Darzens condensation is not neglected, nor are metal homoenolates (treated by I. Kuwajima and E. Nakamura). Lastly there are chapters on metalloenamines (S. F. Martin), hydrazone anions (D. E. Bergbreiter and M. Momongan), and the Prins and carbonyl ene reactions (B. B. Snider). One could hardly ask for more from this part of the book. Here the reader will find information on the very latest developments in each of the reactions described.

The contents of the third part come as a slight surprise, but follow quite logically within the subject organization that has been adopted. There are chapters on "Aliphatic Friedel–Crafts Acylations" (S. C. Eyley), "Aromatic Friedel–Crafts Reactions" (H. Heaney), "The Vilsmeier–Haack Reaction" (O. Meth-Cohn and S. P. Stanforth), "Acylation of Esters, Ketones and Nitriles" (W. R. Davies and P. J. Garratt), and "The Eschenmoser Coupling Reaction" (K. Shiosaki).

In some cases it is not obvious why the topic was thought to deserve a separate chapter. For example, it is surprising to find that the Reimer–Tiemann reaction is given a separate chapter of only six pages with 29 references. Other reactions that one would expect to be grouped together in the same part of the book on the grounds of sharing a common mechanism, at least under the arrangement used here, appear elsewhere or are completely absent. For this volume at least the word "comprehensive" in the title should be interpreted as meaning "detailed"; the reader hoping for an exhaustive coverage will be disappointed. A few random checks soon reveal that some chapters have omitted quite important developments, while including others of relatively minor significance. However, this does not detract greatly from the work as a whole, as one can learn about other useful applications from the review articles cited. On the other hand, it is annoying to find that many of the examples mentioned in the text are not backed up by formula schemes that one could take in at a glance; presumably they were left out to save space. This

is a pity, as the chemist can assimilate information so much faster from formula diagrams than from text!

As the series editors point out in the preface, the assignment of subject areas to particular volumes is to some extent arbitrary. The same certainly applies also to the assignment to individual chapters within the volumes. Nevertheless, it can be disconcerting when a long-familiar reaction appears in an unusual context. Examples of this are the Eschenmoser coupling reaction in Chapter 3.7, and to some extent the three sections on different aspects of the Mannich reaction (bimolecular aliphatic, by E. F. Kleinman, bimolecular aromatic, by H. Heaney, and intramolecular, by L. E. Overman and D. J. Ricca) when compared with the chapters on "Reactions of Allyl and Propargyl/Allenyl Organometallic Compounds with Imines and Iminium Ions" (E. F. Kleinman and A. Volkmann) and "Additions to *N*-Acyliminium Ions" (H. Hiemstra and W. N. Speckamp). Several of these chapters are real mines of information for the reader seeking solutions to synthetic problems in heterocyclic chemistry. Here, as elsewhere in this volume, the regio-, stereo-, and enantioselectivity aspects are treated in detail. Also of interest in this context is Chapter 4.6 on "The Passerini and Ugi Reactions" (I. Ugi, S. Lohberger, and R. Karl).

The author index is sensibly planned, giving not only the page number in the present volume but also the number of the reference on the page concerned. In contrast the subject index is totally inadequate: many of the topics are found at best only by chance, as the choice of keywords under which particular topics are entered is rather arbitrary. For example, starting with the keyword "Fenestranes", then moving to the sub-heading "synthesis" (which has no page reference), we eventually find "Dieckmann reaction, p. 829)". But then, under the keyword "Dieckmann reaction", the same page references does not appear. Any number of further examples of this sort could be listed. Under "Dialdehydes" we find just three entries, the first under the sub-heading "Henry reaction", the second under "intramolecular aldol reaction", and the third under "Knoevenagel reaction", with three page numbers altogether. One can hardly believe that only three pages of this hefty volume contain any mention of dialdehydes.

Whoever was responsible for compiling this "Subject Index" may have had a plan in mind, but it is not apparent to the reader. However, perhaps its main purpose is to stimulate thought, which cannot be a bad thing.

Armin de Meijere
Institut für Organische Chemie
der Universität Göttingen (FRG)

Volume 3

The third volume of this series covers the formation of C–C σ-bonds, and is in four parts with a total of 32 chapters. The first part is concerned with alkylations at a carbon atom. Chapter 1.1 by D. Caine is well worth reading, and deals with alkylations of the enol and enolate forms of carbonyl compounds and their nitrogen derivatives. In Chapter 1.2 R. E. Gawley and K. Rein deal with the alkylation of nitrogen-stabilized carbanions, and this is followed by A. Krief's monumental review of the alkylation of sulfur- and selenium-containing carbanions (Ch. 1.3), which could hardly be bettered. Alkylations of carbanions stabilized by other heteroatoms are treated very briefly in Chapter 1.4 by D. R. Cheshire, then in Chapter 1.5 J. M. Klunder and G. H. Posner discuss the corresponding reactions of non-stabilized carbanions. Chapter 1.6 (D. W. Knight) and 1.7 (P. J. Garratt) contain interesting descriptions of alkylations of vinyl and alkynyl anions, respectively. In Chapter 1.8 G. A. Olah, R. Krishnamurti, and G. K. S. Prakash discuss another important type of reaction, Friedel–Crafts alkylations. In Chapter 1.9 J. K. Sutherland shows how polyene cyclizations can be used to synthesize a wide variety of cyclic compounds; however, the title of this chapter is slightly misleading, since the subject matter is not limited solely to rearrangements of polyenes. D. C. Harrowven and the volume editor G. Pattenden conclude this first part with a review of transannular electrophilic cyclizations (Ch. 1.10).

Part 2 is devoted to coupling reactions. The first five chapters are mainly concerned with transition metal catalyzed syntheses. In Chapter 2.1 D. C. Billington describes reactions in which a bond is formed between two sp^3 carbon atoms, then in Chapter 2.2 K. Tamao deals with couplings between sp^2 and sp^3 carbon atoms, and in Chapter 2.3 D. W. Knight describes couplings between two sp^2 carbon atoms. K. Sonogashira completes the picture by reviewing, in Chapters 2.4 and 2.5, couplings between an sp^2 and an sp carbon, and between two sp carbons. Next we come to reductive C–C coupling reactions: Chapter 2.6 (G. M. Robertson) deals with reactions of the pinacol type, and Chapter 2.7 (R. Brettle) with those of the acyloin type. Electrochemical methods are now increasingly important, as is convincingly illustrated in Chapter 2.8 on Kolbe reactions (H. J. Schäfer). In Chapter 2.9 D. A. Whitting concludes this part with a review of the current state of knowledge on the oxidative coupling of phenols and phenol ethers, a topic that continues to attract interest.

Part 3 is devoted to rearrangement reactions, beginning in Chapter 3.1 with an article by J. R. Hanson on the Wagner–Meerwein rearrangement. Next B. Rickborn reports briefly in Chapter 3.2 on the pinacol rearrangement, then in greater detail in Chapter 3.3 on acid-catalyzed rearrangements of epoxides. There follow contributions by D. J. Coveney on the semipinacol rearrangement (Ch. 3.4) and by D. A. Whiting on the dienone–phenol rearrangement (Ch. 3.5). Next come chapters on rearrangements performed under basic conditions: Chapter 3.6, by G. B. Gill, discusses the benzil–benzilic acid rearrangement, then in Chapter 3.7 J. Mann deals with the Favorskii rearrangement and in Chapter 3.8 J. M. Clough with the Ramberg–Bäcklund rearrangement. These are followed by the Wolff rearrangement (G. B. Gill, Ch. 3.9) and an excellent review of ylide rearrangement reactions by I. E. Markó in Chapter 3.10. This part ends with an article by J. A. Marshall (Ch. 3.11) on the Wittig rearrangement. Some of the reactions treated in this part could instead have been assigned to Volume 5 under the heading "sigmatropic processes", and conversely some rearrangements, such as the Fritsch–Buttenberg–Wiechell rearrangement, are not included, but on the whole this is a good representative survey of the present importance of rearrangement reactions in organic synthesis.

Under the rather uninformative title "Other Carbon–Carbon Bond Forming Reactions", Part 4 contains two very interesting articles. The first, by D. J. Thompson (Ch. 4.1), discusses carbonylation and decarbonylation reactions, and the second, by D. F. Taber (Ch. 4.2), is concerned with the formation of C–C bonds by C–H insertion.

The synthetic chemist will find that this volume covers all important aspects of alkylations at carbon atoms, coupling reactions, and rearrangements. Although it has not been possible to describe all the interesting developments in detail, appropriate references to the original literature are given throughout. In nearly all the articles the literature coverage extends up to 1989, and in some cases to 1990. Access to the older literature, where not cited in the original publications, is provided through references to older reviews. Naturally,

one cannot expect a book with this type of format to be completely free of errors, but my impression is that the authors and publisher have taken great care in the preparation of this volume. It is worth pointing out that this is not a comprehensive textbook but a collection of excellent review articles. Its usefulness could have been even further improved by more frequent cross-references to discussions in other chapters. However, the overall verdict is that this book has no rival of its kind, and it can be recommended unreservedly to everyone with an interest in organic synthesis.

Uwe Beifuss
Institut für Organische Chemie
der Universität Göttingen (FRG)

Volume 4

The very generally worded title of Volume 4, "Additions to and Substitutions at C–C π-Bonds", suggests right at the start that here space has had to be provided between the covers of one volume for a whole potpourri of reactions. The contributions by 31 eminent authors are grouped into four lengthy parts, three of which are devoted to the addition and substitution reactions of olefins, allenes, and alkynes, which are so useful to the synthetic chemist. In this otherwise coherent group of topics, Part 2, on nucleophilic substitutions of arenes, seems slightly out of place. This part treats not only classical methods such as the S_NAr reaction, the addition of nucleophiles to arynes, and the $S_{RN}1$ reaction, but also the reactions of nucleophiles with arene–metal complexes, and meets the needs of readers who wish to learn something about the mechanistic fundamentals of such reactions as well as those seeking a solution to a particular synthetic problem.

In the first six chapters of Part 1 the main emphasis is on the formation of C–C bonds by the addition of groups with a nucleophilic carbon atom at electron-deficient double and triple bonds. Not surprisingly, special attention is devoted to the Michael addition which, although quite old, is still an active research topic. The authors cover the whole range of nucleophiles, starting with the classical mesomerically-stabilized carbanions and continuing through lithium compounds and cuprates to boranes and silanes. A recurring theme throughout all the articles is the selectivity of the reactions; there is even a separate chapter devoted to ways of achieving diastereo- and enantioselective reactions. Next come three chapters on electrophilic additions to systems with multiple bonds, although these fit less appropriately under the title of this part ("Polar Additions to Activated Alkenes and Alkynes"). Here, as one would expect, the formation of carbon–heteroatom bonds features prominently.

The excursion into arene chemistry in Part 2, already discussed above, is followed by Part 3 with the rather misleading title "Polar Additions to Alkenes and Alkynes". This is definitely not concerned with "normal" olefins and alkynes; instead the common feature of all five chapters of Part 3 is that the unsaturated system undergoes complexation with fragments of transition metal compounds, making it vulnerable to attack by polar reagents. Three of the chapters describe palladium-induced additions of groups with a nucleophilic carbon atom or heteroatom to alkenes, alkynes, and allylic systems. The noble metal palladium is not essential in every case, as is shown in the two remaining articles. The iron tricarbonyl fragment can form complexes with dienes and polyenes and thereby activate them for attack by electrophiles; alternatively, its cationic pentadienyl complexes can be reacted with nucleophiles to yield a wide variety of substituted dienes.

Part 4 begins with two articles on the addition of free radicals at C–C π-bonds, which are well worth reading. As well as describing how such reactions can be used for synthetic purposes, these chapters equip the reader with much valuable basic knowledge about free radicals and their properties. The next two chapters deal with palladium-catalyzed vinyl substitutions and with the addition of organometallic compounds at carbon–carbon multiple bonds; however, it is a little surprising that they should appear in this part under the overall title "Nonpolar Additions to Alkenes and Alkynes". A further chapter is devoted to hydroformylation, the importance of which is not confined to industrial processes, as it enables one to form a C–C bond with the simultaneous introduction of a carbonyl group, thereby making possible a great variety of further transformations. The closing chapters take one into the broad field of cycloadditions. Two contributions describe the preparation of alkylidene- and keto-carbenes and their addition at carbon–carbon multiple bonds. A third article is concerned with the generation of dihalogen-carbenes, and discusses the impressive synthetic potential of the geminal dihalogen-cyclopropanes obtainable by this route. The volume ends with two articles on inter- and intramolecular 1,3-dipolar cycloadditions.

To summarize, Volume 4 of the series covers many different types of synthetically important reactions of C–C π-bonds in great detail. It is an excellent source of information for the synthetic chemist seeking help. Leaving aside the sometimes rather misleading titles, the presentation of this wealth of information has been carefully thought out, and in combination with a detailed subject index it gives rapid access to the relevant primary literature published up to 1989. Moreover, the needs of newcomers to the field have not been neglected, since most of the articles contain an introductory historical survey with many references to review articles for further reading.

Johannes Belzner
Institut für Organische Chemie
der Universität Göttingen (FRG)

Volume 5

Volume 5 deals with the combining of C–C π-bonds by pericyclic and related reactions. Those discussed include the ene reaction, thermally and photochemically induced [2 + 2]-cycloadditions of alkenes and carbonyl compounds, [3 + 2]- and [4 + 2]-cycloadditions and cycloadditions of higher order, electrocyclic processes, and sigmatropic rearrangements. To complete the volume there are contributions on rearrangements of small rings and reactions involving transition metals.

In the chapter on ene reactions B. B. Snider first describes reactions in which an alkene serves as the enophile (27 pp.), then W. Oppolzer discusses metallo-ene reactions (32 pp.). The carbonyl ene reaction is treated in Volume 2, fortunately indicated by a cross-reference in the introduction to this chapter. Elsewhere, however, such cross-references are rare; on the other hand, this should not be taken as a very serious criticism, since the work as a whole has a good (though not exhaustive) index.

Under [2 + 2]-cycloadditions J. E. Baldwin describes the thermally induced formation of cyclobutane (21 pp.), L. Ghosez and J. Marchand-Brynaert the preparation of four-membered heterocycles (37 pp.), M. T. Crimmins the photochemical cycloaddition of alkenes (27 pp.), J. A. Porco and S. L. Schreiber the Paternò–Büchi reaction (41 pp.), and O. De Lucchi, W. Adam, and M. Demuth di-π-methane photoisomerizations (44 pp.).

[3 + 2]-Cycloadditions are subdivided into those that are thermally induced (31 pp., by R. D. Little) and those cata-

lyzed by transition metals (43 pp., D. M. T. Chan). Almost 300 pages are devoted to the Diels–Alder reaction, underlining yet again the importance of this method, first reported in its general form in 1928. The treatment is divided into separate chapters dealing with the intermolecular Diels–Alder reaction, cycloadditions using heterodienophiles and heterodienes, the intramolecular Diels–Alder reaction, and the retro-Diels–Alder reaction; the authors are W. Oppolzer, S. M. Weinreb, D. L. Boger, W. R. Roush, R. W. Sweger, and A. W. Czarnik.

Coming to the higher-order cycloadditions, A. Hosomi and Y. Tominaga cover the [4 + 3]-cycloadditions (22 pp.), J. H. Rigby the [4 + 4]- and [6 + 4]-cycloadditions (26 pp.), and P. Wender, L. Siggel, and J. M. Nuss the interesting photochemical addition reactions of arenes (28 pp.). After the cycloaddition reactions, electrocyclic processes for the ring-opening of cyclobutenes to give 1,3-dienes (22 pp., by T. Durst and L. Breau) and for the formation of 1,3-cyclohexadienes (51 pp., by W. H. Okamura and A. R. DeLera) are described, as well as the Nazarov reaction, in which divinyl ketones are stereoselectively transformed into cyclopentenones through the influence of acids (33 pp., by S. E. Denmark). Altogether 123 pages are devoted to sigmatropic reactions with their wide variety of synthetic uses: the Cope and oxy-Cope rearrangements (R. K. Hill) and the Claisen rearrangements (P. Wipf). Also in this section, F. E. Ziegler describes the interesting sequential transformations in which two or more sigmatropic processes follow one after another.

The topics covered in the last 300 pages of this volume are: rearrangements of vinylcyclopropanes (T. Hudlicky and J. W. Reed, 71 pp.) and of divinylcyclopropanes (E. Piers, 27 pp.), charge-controlled rearrangements (J. J. Bronson and R. L. Danheiser, 37 pp.), and other transition-metal induced reactions, namely the Pauson–Khand reaction (Co-induced cycloaddition of alkynes with alkenes and CO to yield cyclopentenones, described here by N. E. Schore), the metal–carbene cyclization (W. D. Wulff), the alkene metathesis reaction and the interesting Co-induced [2 + 2 + 2]-cycloadditions of alkynes to arenes (R. H. Grubbs and S. H. Pine), the Zr-induced bicyclization of enynes (E. Negishi), and the metal-catalyzed cycloaddition of small rings (T. Ohta and H. Takaya).

All the articles are written by outstanding experts. A clear arrangement of the subject matter is always indicated at the beginning, and a useful summary is provided in nearly every case. There are, of course, differences in style and in care of presentation between the authors, and some chapters show a higher frequency of errors than others. However, all the articles are of a high quality, and the examples are well chosen in most cases, not only explaining the principles of the synthetic methods but also showing their potency for the synthesis of complex natural products. A small criticism is that some chapters do not devote enough space to the theoretical and mechanistic aspects and to explaining the individual steps in the syntheses. The literature has been carefully and critically reviewed, though it is, of course, unfortunate that two years elapsed between the completion of the articles and the volume's publication.

To summarize, this fifth volume offers a competently prepared, clearly arranged, and critical overview of modern methods for combining C–C π-bonds, and the wealth of interesting and topical examples makes it a rich source of information for scientists and students.

Lutz F. Tietze
Institut für Organische Chemie
der Universität Göttingen (FRG)

Volume 6

The sixth volume is devoted to heteroatom manipulations. In a total of 1194 pages under this main heading the volume covers substitution reactions, acylation type reactions, protecting groups, transformations of functional groups, and elimination reactions. The enormous amount of information is subdivided into individual articles of typically about 30 pages, each with between 100 and 200 literature references. The arrangement is well thought out, but it should be noted that topics have been assigned to chapters and larger sections (and to volumes) not so much on the basis of reaction mechanisms as by certain formal criteria and, so far as possible, classes of compounds. Nevertheless, this meets the needs of the preparative organic chemist very well and makes it easy to find individual topics. The editor, E. Winterfeldt, has in every case recruited expert authors to write the chapters, often those recognized as the leading proponents of their specialist fields.

Part 1 covers methods for synthesizing classes of compounds that are formally derived by substitutions: alcohols and ethers (O. Mitsunobu); glycosides, by all the usual glycosidation methods (R. R. Schmidt); amines and ammonium salts (O. Mitsunobu); nitro and nitroso compounds, hydroxylamines, hydrazines, diazoalkanes, diazoketones, and diazoesters (R. Askani and D. F. Taber); sulfides, thioacetals, sulfoxides, and sulfones (G. Solladié); phosphonium ylides of the alkylidene- and vinylidenephosphorane types, and carbodiphosphoranes (H. J. Bestmann and R. Zimmermann); halides (R. Bohlmann); and nitriles, isonitriles, cyanates, and azides (R. Grashey). Inter- and intramolecular Ritter reactions are also treated (R. Bishop).

Part 2 contains reviews of syntheses of compounds formed by acylation or related reactions: acyl halides, anhydrides, and α-ketonitriles (R. Sustmann); esters, activated esters, and lactones (R. Mulzer); amides, lactams, and imides (G. Benz); thioamides and thiolactams (E. Schaumann); thioesters and thiolactones with –(C=O)S–, –(C=S)O–, and –(C=S)S– groups (J. Voss); selenoesters with –(C=O)Se– and –(C=Se)O– groups, together with selenoamides (A. Ogawa and N. Sonada); iminium salts, orthoesters, and related compounds (W. Kantlehner, 115 pp. with 996 literature references!); and phosphate and phosphite derivatives commonly encountered in nucleotide chemistry (Y. Hayakawa).

Part 3, on protecting groups (70 pp., 409 references), is entirely the work of H. Kunz and H. Waldmann. As well as explaining the general requirements for the blocking of functional groups, the authors discuss specific protecting groups for hydroxy, amino, mercapto, carboxy, and carbonyl groups.

Part 4 discusses methods for the transformation of functional groups, beginning with carbonyl compounds and their derivatives. These chapters describe the conversion of carbonyl compounds into enamines, imines, hydrazones, oximes, and the carbanions derived from these (G. M. Whitesell), methods for synthesizing heterocycles from carbonyl derivatives using nucleophilic, electrophilic, free radical ring-closing, and hetero-Diels–Alder reactions (G. Bringmann, C. L. J. Ewers, and R. Walter), and the conversion of carbonyl derivatives by Beckmann, Neber, and Amadori rearrangements and by Bamford–Stevens and Shapiro reactions (K. Maruoka and H. Yamamoto). A further two chapters are devoted to stereoselective transformations of allylic systems, reactions of the S_N', S_E', and Claisen types being treated by H.-J. Altenbach, while 2,3-sigmatropic rearrangements are treated by R. Brückner. Part 4 also covers the breakdown of carboxylic acid derivatives by means of Hoffmann, Curtius, Schmidt, and Lossen reactions (T. Shiori),

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1993 0570-0833/93/0707-1099 $ 10.00+.25/0

and transformations based on the Polonovski, Pummerer, and Nef reactions.

Part 5 describes the synthesis of alkenes, allenes, and alkynes by E_1, E_1cB, and E_2 elimination reactions (A. Krebs and J. Swienty-Busch), reductive eliminations, vicinal deoxygenations and vicinal desilylations (P. Kocienski), Cope, sulfoxide, and selenoxide eliminations and related reactions (P. C. Astles, S. V. Mortlock, and E. J. Thomas), and lastly fragmentation reactions of the Grob and Beckmann types (P. Weyerstahl and H. Marschall). The volume is completed by a useful author index (73 pp.) and a rather less useful subject index (49 pp.).

In a multiauthor work of this kind it is inevitable that some reactions are described more than once (for example, transformations of allylic systems also appear in Chapters 1.1–1.3 of Volume 1 and in Chapter 7 of Volume 5). However, this should not be taken as a criticism, as the different viewpoints of the authors result in a more balanced overall picture. On the other hand, a few compound classes that would have fitted very appropriately into Volume 6 are unfortunately omitted or mentioned only briefly. For example, it would certainly not have been out of place in Part 2 to include short chapters on the synthesis of sulfates, sulfonates, sulfonamides, borates, boronates, borinates, and similar compounds, in view of their synthetic importance. Nevertheless, the team of authors and the volume editor have very successfully negotiated the tightrope between too much compression and too much detail, between too much and too little overlapping, and between generality and specificity. It would have been very useful, however, to be able to select information on reactions and on the associated literature with the help of computerized searching. This could be achieved by producing a data bank of reactions in the form of a CD-ROM, which the publishers could offer as a supplement to the set of volumes. CD updates could also be issued at intervals to accommodate the rapid developments occurring in many areas, thus keeping the total work up-to-date for many years to come. Leaving that aside, this is a first-class reference source which no chemical library should be without, and the reasonable price makes it affordable even for some people's private bookshelves.

Günter von Kiedrowski
Institut für Organische Chemie
der Universität Göttingen (FRG)

Volume 7

The seventh volume is devoted entirely to oxidation reactions. The seven parts, each subdivided into several chapters, cover almost every known oxidation method published up to about 1989. Care has been taken to select the methods that are most useful for synthetic purposes, and the many examples enable the reader to quickly review the possibilities and choose the most promising methods for a given problem. The authors of the individual chapters are all recognized experts in their fields, and in many cases the doyen of a particular method has been persuaded to write the contribution; thus one can be confident that the topics are treated expertly.

The division of subject matter between the chapters takes a little getting used to, but in view of the very large number of reactions that can be classified as oxidations it is a quite logical arrangement, enabling one to find a particular topic without difficulty. In this respect the well planned author index turns out to be very useful in cases where one can already associate a name with the reaction in question. Regrettably though, the subject index is much too scanty to give adequate help in finding one's way through the vast amount of information. In the age of computer-aided index compilation the appropriate maxim here should certainly have been: more would mean more!

Part 1 (82 pp.) deals with oxidations of non-activated C–H bonds. The four chapters describe how such oxidations can be performed not only by conventional chemical or biochemical methods but also by nitrene insertion reactions or by suitable intramolecular functionalizations.

Part 2, consisting of about 260 pages divided into eleven chapters, is concerned with oxidations of activated C–H bonds. Here there emerges a clear trend which helps one to quickly decide on the most suitable synthetic approach: methods for oxidations of C–H bonds adjacent to C=C or C=X bonds are contrasted to those for C–H bonds adjacent to sulfur, nitrogen, or oxygen. This part ends with oxidations of vinyl and aryl C–H bonds and the synthesis of quinones.

Part 3 (235 pp.) deals with the oxidation of C=C bonds. Here, as expected, special attention is devoted to asymmetric methods of epoxidation and hydroxylation. The authors have succeeded well in presenting the numerous methods that have been developed, with their respective advantages and disadvantages, in a logical framework. However, the speed of developments in this area is such that the advances made in the last two years, some of which are highly innovative, could not be included in these chapters. As well as a detailed treatment of addition reactions that involve the formation of C–O bonds, we find here methods for functionalizing C=C bonds by the introduction of nitrogen, sulfur, selenium, or halogens using appropriate reagents. Last but not least comes a discussion of the oxidative cleavage of C=C bonds.

In Part 4 (77 pp.) we come to the oxidation of carbon-heteroatom bonds. Methods for oxidizing carbon–metal bonds are treated especially thoroughly, with tin, palladium, and mercury as some of the more important metal atoms. Separate chapters are also devoted to the important topics of oxidations of carbon–boron, carbon–silicon, and carbon–halogen bonds.

Part 5 (63 pp.) is concerned with the oxidation of C–C bonds. Starting from the basis of the Baeyer–Villiger, Beckmann, and Hunsdiecker reactions, and the cleavage of glycols, the various possibilities in this area are described.

Part 6 (53 pp.) provides ample evidence of the interest in the oxidation of heteroatoms. In addition to nitrogen, phosphorus, and sulfur, which have traditionally received most attention as heteroatoms in this context, an appropriate amount of space is devoted to selenium and tellurium in view of their growing importance.

Any readers who have not up to this point found the ideal oxidation reaction for their purpose might usefully take a look at Part 7 (99 pp.), which deals with special methods. As well as electrochemical variants and oxidations using solid-phase reagents, this includes oxidative rearrangements and electron transfer reactions.

While it contains a great wealth of information on oxidation reactions, this book is more than just a survey of the literature. The clearly arranged tables give reliable information about the nature of each reaction, anticipated yields, and relevant review articles. Also it is pleasing to note that in some cases the tables include comments on the general advantages and disadvantages of each method. More information of this sort would certainly have been welcomed, as also would a more user-friendly form of presentation of the various methods: for example, a list identifying compatible and incompatible functionalities for each oxidation method would be very useful.

Despite these minor criticisms, I can recommend chemists to buy this book (and, indeed, the whole work). The defects mentioned above are comparatively trivial when one takes into account the affordable price and the expertly prepared contents.

Oliver Reiser
Institut für Organische Chemie
der Universität Göttingen (FRG)

Volume 8

Volume 8, "Reduction", consists of four parts with the following titles: "Reduction of C=X Bonds" (14 chapters, 356 pp.), "Reduction of X=Y Bonds" (3 chapters, 52 pp.), "Reduction of C=C and C≡C Bonds" (12 chapters, 369 pp.), and "Reduction of C–X to C–H" (8 chapters, 197 pp.). Like the other volumes in the series it also contains an author index (79 pp.) and a subject index (61 pp.).

Part 1 contains the following chapters: "Reduction of C=O to CH(OH) by Metal Hydrides" (N. Greeves, 24 pp., 147 references), "Reduction of C=N to CN(NH) by Metal Hydrides (R. O. Hutchins, 54 pp., 251 references), "Reduction of C=X to CH(XH) by Hydride Delivery from Carbon" (R. M. Kellogg, 28 pp., 131 references), "Reduction of C=X to CH(XH) by Dissolving Metals and Related Methods (J. W. Huffman, 21 pp., 95 references), "Reduction of C=X to CH(XH) Electrolytically" (L. Moëns, 10 pp., 60 references), "Reduction of C=X to CH(XH) by Catalytic Hydrogenation" (K. Harada and T. Munegumi, 20 pp., 203 references), "Reduction of C=X to CH(XH) by Chirally Modified Hydride Reagents" (M. Nishizawa and R. Noyori, 24 pp., 137 references), "Reduction of C=X to CH(XH) Using Enzymes and Microorganisms" (J. B. Jones, 27 pp., 173 references), "Reduction of Acetals, Azaacetals and Thioacetals to Ethers" (J. H. Brewster, 24 pp., 148 references; it is unfortunate, of course, that this chapter went to press before the publication of Nicolaous's imaginative use of the reduction of O,S-acetals as an approach to the synthesis of brevetoxin), "Reduction of Carboxylic Acid Derivatives to Alcohols, Ethers and Amines" (A. G. M. Barrett, 23 pp., 127 references), "Reduction of Carboxylic Acids to Aldehydes by Metal Hydrides" (R. A. W. Johnstone, 23 pp., 158 references), "Reduction of Carboxylic Acids to Aldehydes by Other Methods" (A. P. Davis, 23 pp., 102 references; contrary to what their titles suggest, this and the previous chapter also include reductions of all kinds of carboxylic acid derivatives, but they are much too short to cover these adequately), "Reduction of C=X to CH_2 by Dissolving Metals and Related Methods" (S. Yamamura and S. Nishiyama, 19 pp., 117 references), and "Reduction of C=X to CH_2 by Wolff–Kishner and Other Hydrazone Methods" (R. O. Hutchins, 36 pp., 204 references).

Part 2, covering the reduction of X=Y bonds, consists of three chapters: "Reduction of Nitro and Nitroso Compounds" (G. W. Kabalka and R. S. Varma, 17 pp., 168 references), "Reduction of N=N, N–N, N–O and O–O Bonds" (T. L. Gilchrist, 22 pp., 148 references) and "Reduction of S=O and SO_2 to S, of P=O to P, and of S–X to S–H" (I. W. J. Still, 13 pp., 135 references).

In Part 3 reductions of C=C and C≡C Bonds are covered by the following chapters: "Heterogeneous Catalytic Hydrogenation of C=C and C≡C" (S. Siegel, 26 pp., 85 references), "Homogeneous Catalytic Hydrogenation of C=C and C≡C" (H. Takaya and R. Noyori, 27 pp., 270 references), "Reduction of C=C and C≡C by Noncatalytic Chemical Methods" (D. J. Pasto, 18 pp., 67 references; here the section on reductions of C≡C bonds to olefins by metal hydrides unfortunately does not discuss the questions of *cis* versus *trans* selectivity nor the effects of substituents and reaction media), "Partial Reduction of Aromatic Rings by Dissolving Metals and Other Methods" (by L. N. Mander, the leading expert in this area, 33 pp., 133 references), "Partial Reduction of Enones, Styrenes and Related Systems" (E. Keinan and N. Greenspoon, 54 pp., 486 references), "Partial and Complete Reduction of Pyridines and their Benzo Analogs" (J. G. Keay, 24 pp., 107 references), "Partial and Complete Reduction of Pyrroles, Furans, Thiophenes and their Benzo Analogs" (G. W. Gribble, 31 pp., 188 references), and "Partial and Complete Reduction of Heterocycles Containing more than One Heteroatom" (M. Sainsbury, 32 pp., 123 references). There are four further chapters: "Hydrozirconation of C=C and C≡C and Hydrometalation by Other Metals" (J. A. Labinger, 36 pp., 150 references; but "other metals" here does not include free radical, cuprate-induced, or palladium-catalyzed hydrostannylations), "Hydroboration of C=C and C≡C" (K. Smith and A. Pelter, 29 pp., 199 references), "Hydroalumination of C=C and C≡C" (J. J. Eisch, 29 pp., 171 references), and "Hydrosilylation of C=C and C≡C" (T. Hiyama and T. Kusumoto, 30 pp., 123 references). The inclusion here of these four is surprising, as one thinks of these reactions as additions to carbon–carbon multiple bonds rather than reductions. Moreover, only in a tiny minority of the examples given do the organometallic products undergo a subsequent protonolysis, which might justify their inclusion in this context.

Part 4 treats reductions of C–X to C–H under the following headings: "Reduction of Saturated Alkyl Halides to Alkanes" (T. Imamoto, 17 pp., 129 references), "Reduction of Saturated Alcohols and Amines to Alkanes" (S. W. McCombie, 23 pp., 92 references), "Reduction of Sulfur–Carbon Bonds and Other Heteroatoms Bonded to Tetrahedral Carbon" (P. Caubère and P. Coutrot, 36 pp., 249 references), "Reduction of Epoxides" (S. Murai, T. Murai, and S. Kato, 19 pp., 149 references), "Reduction of Vinyl Halides to Alkenes, and of Aryl Halides and Related Compounds to Arenes" (M. Hudlicky, 28 pp., 121 references), "Reduction of Ketones to Alkenes" (A. R. Chamberlin and D. J. Sall, 32 pp., 177 references), "Hydrogenolysis of Allyl and Benzyl Halides and Related Compounds" (I. D. Entwistle and W. W. Wood, 27 pp., 149 references; the title of this chapter is misleading, since in addition to hydrogenolyses, i.e. bond cleavages by hydrogen, it includes the cleavage of C–X bonds by complex hydrides or by non-noble metals in ammonia, etc., and there are considerably more examples where X is O than where it is a halogen), and lastly "Reduction of α-Substituted Carbonyl Compounds –CX–C(=O)– to Carbonyl Compounds –CH–C(=O)–" (A. J. Fry, 15 pp., 72 references).

This volume, like the rest of the work, contains a wealth of information that no preparative organic chemist can afford to be without. In the examples chosen to illustrate the reactions the opportunity has been taken wherever possible to include interesting stereochemical aspects and/or noteworthy chemoselectivity effects. It has turned out that some reactions are treated in more than one chapter, but this is inevitable in view of the complexity of the subject and the degree of ambiguity in its subdivision. Moreover, to find several treatments of the same topic from different points of view can sometimes be an advantage rather than an annoying repetition. "Sins of omission", where one fails to find topics that should have been included, are far more serious. It is much to the credit of the team of editors (and others) that there is little to complain about in this respect. However, one topic that has been entirely overlooked is reductions of

glycols and their derivatives (halogen hydrins and the ethers or esters derived from them, *vic*-dihalides) to olefins, and also ring-opening reactions of cyclopropanes would perhaps have been of interest to some readers. The aromatic radical anions such as lithium naphthalide, lithium 4,4′-di-*tert*-butylbiphenylide, and lithium-1-(dimethylamino)naphthalenide (LDMAN), which have been used increasingly in recent years as reducing agents, also seem to have been overlooked. It is also regrettable, though understandable in view of the work involved, that the editor has not been able to persuade anyone to compile a table listing the reactivities and selectivities of different reducing agents. There can hardly be a single user of the book who would not welcome a table showing which transformations can be performed in the presence of which other functionalities without the latter being attacked.

In a work as substantial as this, in which the arrangement of the subject matter can never be ideal in *all* respects, it is essential to provide a well planned subject index which covers the contents as fully as possible and offers the reader a high probability of finding the required answer. Unfortunately the 61-page index is a total failure by these criteria. On the one hand the reader finds reducing agents listed with indications of the substrates that they are capable of reducing, and conversely he can look up a given substrate to locate information on its reactions with different reducing agents. However, the information given by the index is neither well organized nor complete. Suppose, for example, that we want to know how lactones can be reduced: under "Lactones" we find two page references, one with the (self-evident) sub-heading "reduction" and the other with the sub-heading "metal hydrides". But then under "Aldonolactones", if it occurs to us to look up this keyword, we find two different page references corresponding to "electrochemical reduction" and "formation of aldoses", respectively. Finally, under "γ-Butyrolactone" we find yet another (different) page reference with the sub-heading "hydrogenation".

Another type of question that the synthetic chemist may want to ask is "How can I obtain my target molecule via a reduction?" Here it is very unlikely that the subject index could yield an answer. An example will illustrate this: if one wishes to know how allyl alcohols can be obtained reductively, and to compare the possibilities of preparing these by reduction of the corresponding malonic ester, enone, propargyl alcohol, vinyl epoxide, or α,β-epoxyalcohol, the subject index does not yield a single page reference that could help. Even when we look under "Alcohols" for reductive methods of preparation we find only six references (under "via carboxylic acids", "via enantiomeric (!) reduction of carbonyl compounds", "via epoxide reduction", "via hydrogen transfer", "via metal hydride reduction", and "via reduction of hydroperoxides"). Examples of this kind could be continued at will; thus, for reductive routes to alkanes the index lists only three possibilities: "via alcohols and amines", "via alkyl halide reduction", and "via enzyme reduction of alkenes"; no references whatever are given to whole chapters that relate to this problem, nor to the heterogeneously or homogeneously catalyzed hydrogenation of carbon–carbon multiple bonds, nor to the Wolff–Kishner reduction! These inadequacies prompt one to ask whether chemists were really involved in the preparation of the subject index, and to doubt whether one should recommend buying this otherwise really excellent work (!!) until the publishers have replaced the present "Cumulative Indexes" volume by a revised version.

Reinhard Brückner
Institut für Organische Chemie
der Universität Göttingen (FRG)

A Semiempirical Life. (Series: Profiles, Pathways, and Dreams. Series editor: *J. I. Seeman.*) By *M. J. S. Dewar.* American Chemical Society, Washington, DC, 1992. XXIII, 215 pp., hardcover $ 24.95—ISBN 0-8412-1771-8

The title of this lively and informative scientific and personal autobiography derives from Professor Dewar's parametric ("semiempirical") method of determining reaction mechanisms based on an all-valence-electron SCF (self-consistent field) MO (molecular orbital) treatment, in contrast to the "ab initio" SCF approach—an approximation to the Hartree–Fock (HF) SCF MO method involving the linear combination of atomic orbitals (LCAO), introduced independently by C. C. Roothaan and G. G. Hall. Unlike many theoreticians, Dewar recalls that his interest in theory was "purely practical" from the beginning; his own experimental results had made him extremely skeptical of the reaction mechanisms that are "stated so confidently in organic texts." He maintains that reaction mechanisms cannot be observed directly because reactions take place too rapidly and because of the restrictions imposed by the uncertainty principle.

Although Dewar's prediction that most ab initio methods would fail to produce reliable results was confirmed, and although—or because—his treatments based on PNDDO, the various versions of MINDO, and later MNDO and AM1, required a thousand times less computing time than ab initio treatments, "every effort was made to suppress publication of [his] papers and papers by others reporting calculations that used [his] procedures, using every dirty trick in the book."

However, one of Dewar's traits is persistence: "Nothing ever works the first time in organic chemistry, but almost everything does eventually if you try hard enough" (p. 52). Undeterred by criticism, he went on to apply his theoretical-experimental approach to π-complexes, nonclassical carbocations, biomimetic cyclizations, pericyclic reactions (e.g., Diels–Alder reactions and the Cope, Claisen, and benzidine rearrangements), nucleophilic substitutions, enzyme reactions, elimination reactions, singlet oxygen, a refutation of frontier orbital theory, and dozens of other reactions. Dewar has made all his programs freely available rather than commercializing them, and he claims that "My group alone has studied more reactions than all the ab initioists put together with far more chemical effect and at a tiny fraction of the cost" (p. 167).

"Chemistry is, or should be, fun" Dewar proclaims (p. 184). His pursuit of this goal has led him in one direction after another in a long, distinguished multifaceted career that has not prevented him from also pursuing such hobbies as classical music, bridge, chess, running, ice skating, and rock climbing. He has even made original contributions to astronomy and geology.

In this book Michael James Steuart Dewar describes his life from his birth on September 24, 1918 in Ahmednagar, India, where his father, Francis, was a member of the Indian Civil Service, to his current activity as Research Professor of Chemistry at the University of Florida at Gainesville, where he is attempting to develop an effective theoretical treatment for transition metals, a major goal of his for the past decade and a half. In the course of his engrossing tale he discusses his education at a boarding school in England and at Winchester College, one of the leading English public (private) schools (1931–1936), where he taught himself science in general and chemistry in particular by reading books. ("If my thoughts about chemistry have often been unorthodox, this is probably the reason," p. 14). He then attended Balliol College, Oxford University (1936–1945). Here he supported

himself by means of two scholarships, was influenced by R. P. (Ronnie) Bell and Sir Robert Robinson, and received his B. A. (1940), D. Phil. (1942), and M. A. (1943). In addition to discussing his research on alkaloids (yohimbine) and his wartime work on explosives, sulfa drugs, antimalarials, and penicillin (the last two as a postdoctoral fellow with Sir Robert Robinson at Oxford's Dyson Perrins Laboratory), he relates "the most important event of my life," his meeting with "someone who was more than my equal," Mary Williamson, whom he wed on June 3, 1944, three days before D-Day. Because Mary was a historian, scholar, and author rather than a scientist, their relationship has been a mutually beneficial one ("we tend to look at things from different viewpoints"). Their almost half-century marriage has been a very close and happy one, resulting in two sons, Robert and Steuart, both of whom now work with computers.

From 1945 to 1951 Dewar was a "physical chemist" at the new laboratory set up by Courtaulds, Ltd. (the rayon and acetate fibers manufacturer) at Maidenhead near London, where he carried out basic research on polymerization and other problems, while teaching himself physical chemistry and writing his first book, *The Electronic Theory of Organic Chemistry* (1949), "the first general account of organic chemistry in terms of MO theory." Although a move from an industrial position to an academic position is unusual (another exception to the rule was Carl Djerassi's move from Syntex to Wayne State University, related in *Steroids Made It Possible*, an earlier volume in the *Profiles* series), in 1951 Dewar was offered the position of Professor of Chemistry and Department Head at Queen Mary College, University of London, the youngest person (age 33) to be appointed to a chair in London except for one or two mathematicians. At QMC, where Mary belatedly obtained her Ph.D., Dewar carried out research on resonance theory, bond localization, molecular orbital (PMO) theory, structures of phosphonitrile chlorides, condensation of steam on metal surfaces, liquid crystals, and NMR, ESR, and NQR spectroscopy.

In 1959 Dewar was appointed to the late Morris S. Kharasch's chair at the University of Chicago, the first full professor to defect in the "brain drain". Here he continued his work on borazaromatic compounds and "one-off" projects--relatively short-term projects designed to answer a specific question and providing ideal training for graduate students. He also began his current theoretical program described at the beginning of this review, which he developed fully during his tenure as Robert A. Welch Professor of Chemistry at the University of Texas at Austin (1963–1990). In the course of his account he discusses with praise or sometimes with scorn the contributions of others, and the book reads like a "Who's Who" of organic chemistry. He champions the contributions of chemists such as Christopher Longuet-Higgins and M. G. Evans, whose work he thinks has not been sufficiently appreciated.

This picture of Dewar that emerges from these pages is one of a complex, brilliant, no-nonsense scientist and devoted husband and father. Insight into his character is best conveyed in his own words. Being scrupulously realistic in evaluating his own abilities and shortcomings and those of others, he expresses himself with a refreshing frankness and matter-of-fact candor that sometimes appears brash or controversial: "Because I have ... never been a respecter of persons, let alone of 'experts', my contributions have ... not always been expressed too tactfully" (p. 183). Being secure and comfortable with who he is, he can make statements that might be considered boastful if uttered by others: "My arrival in Texas put the place on the academic map" (p. 112). "I probably know more about [the mechanism of pericyclic reactions] than any other chemist who is still active" (p. 139). At other times his characteristic forthrightness results in statements that might be misconstrued as false modesty: "I have come up with a number of similar contributions that have given me an undeserved reputation for original thinking. I am not, in fact, original in the proper sense of the term. I am, however, good at solving problems..." (pp. 39–40). "I am hopeless at administration. I am good at seeing what has to be done but hopeless at getting it done. A good administrator operates by manipulating people. I have never been any good at this" (p. 67). "I have always been very bad at publicizing the things I have done" (p. 91). Unlike too many of us, he benefits from his experiences. In his concluding chapter, titled "Debts Owed, Lessons Learned," he decries the growing trend for conformity and the tendency for chemists to take their work too seriously, and he criticizes the policies of the National Science Foundation and the *Journal of the American Chemical Society*. Although he voices his opinions strongly, he is not opinionated: "I have always been ready, as the record shows, to abandon *any* chemical belief in the face of valid arguments or new evidence" (p. 184).

We warmly recommend this eminently readable and very human autobiography of Professor Dewar, graced by 46 photographs from his family albums, to organic chemists, undergraduate and graduate chemistry students, historians of chemistry, and anyone interested in the development of chemistry, the conduct of research, and the personal and professional lives of scientists.

The Inositol Phosphates. Chemical Synthesis and Biological Significance. By *D. C. Billington*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. XIV, 153 pp., hardcover DM 126.00—ISBN 3-527-28152-5/0-89573-977-1

It is now almost a decade since Michael Berridge and his collaborators reported in *Nature*: ".... micromolar concentrations of Ins(1,4,5)P_3 (1D-*myo*-inositol 1,4,5-trisphosphate) release Ca^{2+} from a non-mitochondrial intracellular store in pancreatic acinar cells. Our results strongly suggest that this is the same store that is released by acetylcholine." Thus, some 30 years after the beginnings of this field with the observation by Lowell Hokin of agonist-stimulated phospholipid turnover (the so-called "phospholipid effect") and 8 years after the correlation made by Michell in 1975 with agonist-stimulated intracellular Ca^{2+} release, the final missing molecular link was found in 1983 in the form of a second messenger, the polyphosphorylated cyclitol Ins(1,4,5)P_3.

Since 1983 progress in this new area of signal transduction has been nothing short of breathtaking. Indeed, Lowell Hokin recently remarked: "The phosphoinositide field is currently the number one field in biochemistry in the number of citations (excluding molecular biology)." Small wonder, then, that most workers in the field, be they chemists or biologists, find it almost impossible to keep fully abreast of events. Thus one tends to rely upon the all-too-frequent biological reviews to escape the need to digest the voluminous primary literature. Such reviews, however, rarely address chemical matters in any depth, if at all, and it is therefore a pleasure to see at last this new book, where the author has clearly made an effort to focus upon a very particular need, that of the biological and medicinal chemist.

With the opening of this new chapter in cellular signalling it was soon clear that there was a prime need for synthetic chemical involvement, and there has been a very significant revival of interest in the chemistry of inositols since the mid-1980s, beginning with the first synthesis of Ins(1,4,5)P_3 in 1986. While progress here has also been relatively rapid, and necessarily highly competitive, the chemistry of the new inositol phosphates is still a small enough field to be concisely reviewed. Until now, however, there have only been two comprehensive major chemical reviews in this area, and one, indeed, by the author of this present book. While "The Inositol Phosphates" clearly represents a useful addition to this literature, I admit to being more than a little apprehensive about how much further this book could go in relation to these existing reviews.

The chemical synthesis of inositol polyphosphates presented a number of problems, namely: the regiospecific protection of inositol in order to afford suitable intermediates for phosphorylation; the optical resolution of such intermediates; the polyphosphorylation of intermediates possessing vicinal diol functionalities, where it is essential to avoid the facile formation of 5-membered cyclic phosphates; deblocking of fully protected polyphosphates, without concomitant migration of phosphate groups; and finally, purification of the final water-soluble polyphosphate. Essentially, these problems have all been overcome and it is now, at least in principle, possible to synthesize any inositol polyphosphate. This message is well conveyed by the book. Much effort, however, is still being expended in the development of novel routes to optically active inositol phosphates and improvement upon the established methods developed to combat the above problems. All this information, and more, with clear summaries of a large number of synthetic strategies, is provided excellently in this book. Although clearly aimed at chemists, it would perhaps also be useful to biologists who want a concise survey of chemical progress and, as many do, a basic grounding in the more structural, and particularly stereochemical, aspects of this field. In view of this, the biological background here, while adequate for a chemical audience, forms only a minor part of the book and the author, wisely, does not attempt to become embroiled in any of the many controversies currently raging in this expansive field.

After equipping the reader in the earlier chapters with enough background biology to understand the rationale behind the synthetic work, the author launches into Chapter 3 which discusses in depth the basic problems of inositol polyphosphate synthesis, namely the protection, phosphorylation, deprotection, and resolution steps mentioned above. A systematic treatment of mono-, bis-, tris-, and tetrakisphosphates then follows, with detailed accounts of various approaches, covering most of the chemical literature up to 1991. A most welcome Chapter 8 describes some of the efforts expended in the synthesis of inositol phosphate analogues, now a major theme in organic chemistry, with the prospect of developing enzyme inhibitors, receptor antagonists, and perhaps even therapeutic agents of the future.

The final chapter provides an insight into some of the more recent synthetic activity, including some 1992 publications. Nevertheless, I regretted that the book as a whole could not be more up-to-date, presumably due to the production time-scale. As always in such a field, review articles and books run the risk of rapidly becoming out of date, and sadly this has been all too true for biological articles and books on the polyphosphoinositide pathway. However, since the volume of chemical work is clearly smaller than that in biology, and the synthetic chemistry reported here is well established and not the subject of anywhere near as much controversy, this may be less important in this case. I felt that the book ended rather abruptly, and I would have liked to see space given to a concise summary of chemical progress to date and, more especially, to speculation, philosophical and otherwise, on future chemical directions in this research area.

Despite these shortcomings, I can recommend "The Inositol Phosphates" to anyone who requires a comprehensive summary of some seven years of chemical research in this rapidly expanding field. It will provide an invaluable compendium for anyone contemplating synthetic work in this area. This book deserves a place upon the bookshelf of any active inositol phosphate or carbohydrate chemist, and it will hopefully give encouragement and heart to those chemists who have been too afraid of the fast-moving nature of this field to join in the game.

Fundamentals of Crystallography. (Series: IUC Texts on Crystallography, Vol. 2.) Edited by *C. Giacovazzo*. International Union of Crystallography, Oxford University Press, Oxford, 1992. XI, 654 pp., paperback £ 27.50.—ISBN 0-19-855578-4

Although chemical crystallography has undergone rapid developments and become more widely used during the last few decades, one could hardly claim that this has been accompanied by a corresponding surge in the publication of up-to-date monographs and textbooks on the subject. As in most cases, exceptions prove the rule; in particular the International Union of Crystallography has recently published a number of excellent books that go some way towards remedying this. The volume reviewed here also belongs to this category; under the editorship of C. Giacovazzo it deals with important aspects of modern crystallography, mainly chemical. All the authors are eminent representatives of the Italian school of crystallography, as also is the editor who has contributed three of the chapters.

What detailed aspects are covered? Appropriately one should first mention the three chapters by C. Giacovazzo: "Symmetry in Crystals", "Crystallographic Computing", and "The Diffraction of X-Rays by Crystals". These are followed by "Experimental Methods in X-Ray Crystallography" (H. L. Monaco), "Solution and Refinement of Crystal Structures" (D. Viterbo), "Ionic Crystals" (F. Scordari), "Molecules and Molecular Crystals" (G. Gilli), and "Protein Crystallography" (G. Zanotti). The book ends with a treatment of "Physical Properties of Crystals" by M. Catti. The last four chapters introduce aspects of crystal structure science that go far beyond merely describing the tools used for structure determination, and especially here one notes with approval that the authors have avoided following well-trodden paths in their presentation of the material. The book also excels by the exemplary way in which this has been done, and by the unusually clear layout, which is in the style of the textbooks by Atkins (lots of attractive illustrations and diagrams!). Furthermore, each chapter includes an account of the latest developments, while always taking care to put these into a practical context, which is a highly commendable approach. Thus the book makes very worthwhile reading, even for those with long experience in using the methods, especially as there are plentiful references to recent relevant

literature (about 850 citations!). A few minor criticisms follow. Chapter 2 on "Crystallographic Computing" seems a little out of place, and it would probably have been better to treat this subject in conjunction with "Solution and Refinement of Crystal Structures". The treatment of molecular crystals could definitely have been improved by omitting the discussion of bonding theory, which is in any case very elementary, and instead devoting more space to molecular mechanics. Lastly, the index could have been made rather more comprehensive.

To summarize, this book can certainly be recommended, and the remarkably low price is a further reason for approval. However, one might ask: is it only for the specialist? Happily it is not. It is exactly because it treats the more chemical and physical aspects of crystals and crystal structures that it should also be read by those who are interested only in the results of crystal structure determinations. If at the same time these readers take a glance at the sections on techniques, so much the better. However, all readers must be prepared to recognize that the authors make few concessions to those who would prefer a non-mathematical treatment.

Chemistry of the Solid-Water Interface. Processes at the Mineral-Water and Particle-Water Interface in Natural Systems. By *W. Stumm*. Wiley, Chichester, 1992. X, 428 pp., paperback £ 32.50.—ISBN 0-471-57672-7

The distribution and reactions of substances present in water are crucially affected by processes at the solid–water interfaces, and consequently the understanding of interfacial reactions has become one of the most important tasks for modern chemistry and neighboring disciplines. Where the interest is combined with ecological aspects, this task offers a particularly attractive field for those involved in water research. Werner Stumm, one of the leading pioneers of systematic water research, has made an important contribution towards the solution of this problem.

By approaching the subject from a physicochemical standpoint and making use of the latest knowledge, the author has written a textbook that is of value not only to water chemists but also to geochemists, chemical engineers, and others with an interest in aquatic systems. What are the main aspects covered? The introduction at once identifies adsorption, surface complexation, and colloids as topics for detailed consideration. This is followed by necessary digressions into the coordination chemistry of oxide surfaces with both inner sphere and outer sphere complexes and into surface charges, including an impressive image of a lead sulfide surface obtained by scanning tunneling microscopy (STM), which is also reproduced on the book's dust-cover.

The substances dealt with in the chapter on adsorption include synthetic surface-active agents from detergents, soil-derived substances, and various others that cannot be precisely identified but are of hydrological importance. Modern approaches to this topic emphasize the importance of kinetics and reversibility. The role of surface-controlled solvation processes in weathering is discussed in relation to precipitation studies, and the behavior of minute particles is considered from the standpoints of nucleation and solubility. On the important topic of the stability of colloidal systems the author discusses the particle–particle interactions in considerable detail. In contrast, the chapter on the reactivity and solubility of carbonates is relatively brief, giving the impression that readers are expected to be already familiar with this classical topic. Under redox processes the vanadates find a place as comparative outsiders alongside the iron and manganese compounds usually considered in this context.

The book ends with two chapters written by Stumm's coworkers: one on heterogeneous photochemistry (B. Sulberger) and another on trace levels of elements in surface waters (L. Sigg). Both articles begin with the theoretical fundamentals and lead up to examples illustrating the practical importance of the results. Not surprisingly, iron again emerges here as the main performer!

The literature references given for each of the eleven chapters are a good representative selection. The many schemes and diagrams are a useful aid to understanding the otherwise not readily digestible text. The didactic value of the book lies in its successful progression from simple considerations through more complex ideas to the applications. The textbook character is reinforced by the appendixes attached to the individual chapters, which include amplification of particular points, examples from practical situations, and exercise problems. It is unfortunate that this excellent approach has only been consistently followed in the early chapters. Also students would have greatly appreciated being given solutions, which they could use when appropriate, to the often quite difficult exercise problems. However, even without such help they will benefit greatly from working through this well written and sturdily produced book. It will quickly find a place on the desks of those who teach water science and others working in the field of heterogeneous aquatic systems.

Metals in Biological Systems. By *M. J. Kendrick, M. T. May, M. J. Plishka* and *K. D. Robinson*. Ellis Horwood, New York, 1992. 183 pp., hardcover $ 68.00.—ISBN 0-13-577727-5

There has been a need for an updated text at this level to cover short (5–10 lecture) undergraduate courses in the fast-moving field of metals in biological systems, so this publication will be of interest to students and teachers of the subject. The subject is now a required component of most chemistry courses, and is taught to students of biochemistry and medicinal chemistry. The book aims to provide both introductory and background material to the subject for over a dozen metal ions, together with details of physical techniques required for their study. The authors faced the considerable problem of what to leave out in such a book. Their selection of topics is pertinent and timely, but may not suit all potential readers. The book appears to aim at the market already covered by the more detailed book of M. N. Hughes (1972, 1981) or that by R. W. Hay (1983). Despite the advantage of its more recent publication date, the book under review is unlikely to replace these established texts, although it could be used to supplement either.

Certain aspects of this book make it unsuitable as an undergraduate text; indeed only sections of it could be recommended, and then only if accompanied by errata slips. The coverage of the topics is very uneven, betraying the four different hands involving in the writing, and a lack of cohesive overview of the camera-ready copy. The introduction illustrates the uneven approach, comprising a brief 1–2-page sum-

mary of the relevant elements via the Periodic Table, followed by three pages on the entatic state. Introductory coverage of proteins and amino acids perversely takes two pages in the middle of the 45-page chapter on physical techniques. Extensive biochemical background is assumed elsewhere.

Of the other 16 chapters, most are 4–6-page essays on a single element; the depth and coverage of these varies idiosyncratically, with the focus generally on metal ions as enzyme activators. The chapter on iron (25 pages) covers much of the expected ground and provides 8 references (the most recent 1982), but omits from the Fe–S protein section any mention of the Fe_3S_3 clusters, while the vanadium chapter (8 pages, 17 references mostly to recent primary sources) is generous for the present state of knowledge. The treatment of calcium, magnesium, and sodium in short separate chapters is very perfunctory—for calcium, only calmodulin-dependent processes are mentioned, with nothing on the mechanism of skeletal muscle control, one of the best-known allosteric processes in biology; nor is there any mention of the major role of calcium in bones and teeth. The sodium coverage has almost a page on non-biological ligands, and potassium does not merit a chapter on its own. Ion channels are not mentioned. Likewise, an effect of tungstate on steroid receptor complexes is quoted, but the short zinc chapter makes no mention of the much better understood zinc fingers. On the other hand, cobalt, manganese, molybdenum, and nickel are covered at about the right introductory level, as also are inorganic drugs.

Many whose native tongue is not English will read such texts; it is especially incumbent on authors to ensure clarity of text and accuracy in science and grammar, so that beginners will not be confused. The authors of this text did not succeed. Amongst the obvious slips, labels on legends did not match those on the figures or sometimes the text; a Nobelist's name is given two spellings on opposite pages, 66 and 67 (both wrong!); the crystal structure resolution for calmodulin is quoted on page 46 as 3.0 Å (long outdated) while on page 59 it is stated that no structure has been obtained! The number of grammatical and other trivial slips is high for such a short text, and the whole book clearly lacked an overall editorial survey. Any future edition will no doubt put right these faults. In the meantime, publishers should note that there is still a market for an updated text at this level.

Joyce C. Lockhart

University of Newcastle upon Tyne (UK)

Theoretical Aspects of Physical Organic Chemistry. The S_N2 Mechanism. By *S. S. Shaik, H. B. Schlegel,* and *S. Wolfe.* Wiley, New York, 1992. XV, 285 pp., hardcover $ 47.50.—ISBN 0-471-84041-6.

The Nobel award to R. A. Marcus for his efforts to relate thermodynamic and kinetic properties in order to describe the "simplest" chemical reaction, the transfer of a single electron, has certainly renewed interest in methods for the theoretical description of chemical reactions. In this book the authors set out to analyze S_N2 reactions by means of a semi-quantitative model on the basis of quantum-mechanical valence-bond considerations with configuration interaction. Their model also includes elements of the Marcus theory. According to the authors, "the model leads not only to linear free-energy relationships, the Marcus equation, and the Leffler–Hammond postulate, but also accounts for the role of frontier MO's, orbital symmetry, and so forth". Therefore, the book as a whole is also intended to serve as a general introduction to physical organic chemistry. The reader is first given a short introduction to the history of this discipline, starting with Menschutkin; nearly half the citations are to the authors' own publications. In the first chapter (36 pp.) the reader is made familiar with some fundamental concepts of physical organic chemistry. The Brønsted relationship, the significance of its exponent α, the Bell–Evans–Polanyi principle, and the Leffler–Hammond postulate are lucidly presented. A brief introduction to the Marcus theory is also given. However, other books or articles, such as those by L. Eberson, would do better service to beginners. The properties of energy hypersurfaces are described in Chapter 2 (47 pp.), mainly from a quantum-chemical point of view. The reader is confronted with numerical methods for the determination of stationary points on these hypersurfaces, even though these are not needed for the following discussions. In the next chapter (41 pp.), the basics of MO- and VB-models are presented in a mathematical fashion, taking the hydrogen atom and its radical anion and cation as examples. The authors' state correlation model is introduced in connection with the exchange reaction between H_2 and H. The thermodynamic parameters of an S_N2 reaction, such as the ionization potentials and electron affinities of the reactants, are defined in Chapter 4 (27 pp.), and methods for determining them are discussed. Parameters of importance for the model are deduced from them. In Chapter 5 (62 pp.) the thermodynamic and kinetic parameters are interrelated for the analysis of identity S_N2 reactions in the gas phase and in solution. Activation barriers and geometries of transition states are calculated by ab initio methods in combination with the authors' model, and are compared with experimental data. The final chapter (49 pp.) treats non-identity reactions. Author and subject indexes conclude the book.

The authors' aim is to make the virtues of their model known to a wider audience (their previous work is described in the preface as "seminal"). Justification for such an intention should be provided by the model's predictive power. For a publication designed as a textbook it is reasonable to expect authors to adopt a more critical approach to their own results than in original papers. Despite the authors' claim on page IX that "All of these predictions [of the model] were consistent with experimental data ...", a literature search yields at least one exception. On the basis of elements of the model presented in this book it was concluded that the direct reaction of nucleophiles with radical cations should be a "forbidden" process (A. Pross, *J. Am. Chem. Soc.* **1986**, *108*, 3537). This prediction proved to be incorrect, as shown experimentally (N. M. M. Nibbering, H. Schwarz et al., *ibid.* **1987**, *109*, 4810; see also H. I. Kettämaa et al., *Chem. Rev.* **1992**, *92*, 1649). At least a little hint ought to have been given to the reader, as the book covers the literature up to 1988 (in some instances up to 1990).

This book certainly cannot serve as an introduction to physical organic chemistry. Firstly, it covers only one part of this discipline, though an important one. Secondly, many aspects are treated so briefly that the novice is likely to misunderstand them, for example the Marcus theory and the ab initio MO methods. Topics that are not necessary to understand the model or its consequences are given much space, especially the lucid but essentially superfluous chapter on the numerical analysis of hypersurfaces. The authors' predilection for abbreviations tends to make the reader feel uncomfortable. Most often, they are explained only once (sometimes never, as in the cases of the RRKM theory or the "CEPA" approximation), but are used throughout the book.

A little help is provided by the brief subject index; otherwise the reader has to consult the original literature.

Nobody expects a book free of errors, and one can disregard misprints such as the resonance arrow for the Menschutkin reaction on page 1. More annoying is the use of different letters to describe the same property, for example, $\mathcal{A}$ on pages 136–7, but a three pages later. On account of the profusion of newly introduced symbols, this is very disturbing.

Whether the considerable time spent in understanding the mathematics and terminology of this model pays off for the "common" chemist, in order to describe experimental data semi-quantitatively with a better theoretical basis, may be left to his or her own discretion. The specialist familiar with the authors' original publications will probably not discover much new material. Most of the diagrams in this book have also been taken from the primary literature, sometimes in severely reduced form which makes them difficult to decipher.

To conclude: this book was meant to serve many, but turns out to be superficial in many aspects. Apart from the discussion about the quantitative validity of the model, the form of the book means that it will probably be useful to few other than specialists.

J. Jens Wolff
Organisch-Chemisches Institut
der Universität Heidelberg (FRG)

Synthetic Fluorine Chemistry. Edited by *G. A. Olah, R. D. Chambers* and *G. K. Surya Prakash.* Wiley, New York, 1992. XVII, 402 pp., hardcover £ 75.00.—ISBN 0-471-54370-5

The properties of fluorine, both as an element and in its compounds, differ so markedly from those of the other halogens that fluorine chemistry has developed as a distinct subject with its own special methods. Now, 106 years after elemental fluorine was first obtained, this branch of chemistry has become so extensive that to review it all is scarcely possible, even for an expert in the field. Accordingly, the aim of this book is not to present a systematic survey; instead it consists of 17 chapters in which leading scientists from universities and industry give comprehensive reviews of selected areas of inorganic and, more especially, organic fluorine chemistry. The book is based on papers presented at a symposium on Synthetic Fluorine Chemistry, which was organized by the Loker Hydrocarbon Research Institute of the University of Southern California in February 1990.

In Chapter 1 Schrobilgen describes the preparation and Lewis acid behavior of noble gas fluoride cations. Christe, Wilson, and Schack (Ch. 2) describe methods for replacing fluorine by oxygen in fluorides and oxyfluorides. Aubke, Cader, and Mistry (Ch. 3) present a comprehensive review of transition metal derivatives of strong protonic acids and superacids. Seppelt (Ch. 4) describes the preparation and properties of compounds containing carbon–sulfur multiple bonds stabilized by fluorine. Lagow, Bierschenk, Juhlke, and Kawa (Ch. 5) report on direct fluorination methods for the synthesis of perfluoropolyethers and on possible areas of application for these compounds. Adcock (Ch. 6) describes aerosol direct fluorination, claimed to be a universal method for perfluorinations. Rozen (Ch. 7) describes electrophilic fluorinations of organic compounds using fluorine or other fluorinating agents. Olah and Li (Ch. 8) demonstrate that onium-polyhydrogenfluorides have a wide range of applications as fluorinating agents. Burton (Ch. 9) describes the use of organometallic compounds containing perfluoroalkyl groups for the synthesis of organofluoro compounds. Prakash (Ch. 10) reports on nucleophilic perfluoroalkylations using perfluorotrialkylsilanes. Farnham (Ch. 11) describes the use of organosilicon reagents in synthetic organofluorine chemistry. Shteingarts (Ch. 12) discusses electrophilic *ipso* reactions of polyfluoroarenes from the standpoint of synthetic applications. Takenaka and Lemal (Ch. 13) discuss the perfluorobenzeneoxide–perfluorooxepin system. Krespan and Dixon (Ch. 14) describe the chemistry of perhalogenated dioxans and dioxens. Welch, Yamakazi, and Gimi (Ch. 15) report on the Claisen rearrangement of fluoroacetamide acetal as a method for asymmetric syntheses of compounds of biological interest. Chambers (Ch. 16) describes the preparation of some unusual fluorinated alkenes and dienes by reactions involving fluoride ions. Lastly Baum (Ch. 17) describes syntheses of fluorinated monomers for condensation polymerization.

The book covers quite a broad range of topics and gives a very good overview of the present state of experimental fluorine chemistry. It includes about a thousand references which afford a convenient way into the relevant literature. There is a nine-page subject index which greatly facilitates using the book as a reference source. The fact that it originates from a symposium is readily apparent from the widely differing styles of the chapters, some giving detailed treatments of only a few compounds while others treat many in a brief manner. However, this variety makes the book agreeable to read for someone who, like this reviewer, works through it from start to finish—for example, the reader who is just beginning work in fluorine chemistry.

Adsorption of Molecules at Metal Electrodes. (Series: Frontiers of Electrochemistry.) Edited by *J. Lipkowski* and *P. N. Ross.* VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1992. XI, 414 pp., hardcover DM 246.00, $ 145.00.—ISBN 0-89573-786-8, 0-89573-789-2 (set)/3-527-28008-1, 3-527-28007-3 (set)

An electrochemical double layer is formed at almost every type of phase boundary. The driving forces causing this are differences in the chemical potentials of the charge carriers that are common to both phases, even though they may be present in very different concentrations. The resulting electrical potential difference cannot be measured directly. Adsorbed molecules have a secondary effect on the electrochemical double layer. Where dipolar molecules are involved there is not only a chemical interaction with the surface but also a strong electrostatic field effect.

The volume reviewed here contains eight articles dealing with the adsorption of molecules at metal electrodes. However, the topics covered are much more specialized than the title leads one to expect. Of the metals considered, mercury and platinum are by far the predominant ones. Where the use of surface enhanced Raman spectroscopy (SERS) is described, silver and gold also feature, since these metals are specific for the technique. The two most important utility metals, iron and aluminum, are discussed only very briefly in the article by Plieth et al. The other phase is an electrolyte solution which contains not only the organic molecules but also ions such as HSO_4^- or CN^- that can be adsorbed. The methods used to study adsorption include the classical tech-

niques of ellipsometry and optical reflection spectroscopy, and also more modern methods such as infrared reflection absorption spectroscopy (IRRAS), SERS, and Raman second harmonic spectroscopy. It has thus become possible to obtain detailed information about the structure of the double layer, the nature of the adsorption, and the dynamics of phase transformations in monolayers. For example, benzonitrile molecules can be adsorbed in four different configurations relative to the electron lone pair of the nitrile group: planar, bent so that the triple bond of the nitrile group has a strong interaction with the surface through the formation of either two or four bonds, or "perpendicular". In the first two articles, by Guidelle and by Buess-Herman, the emphasis is on theoretical considerations and the use of molecular models, whereas the remaining chapters report detailed experimental results obtained by the various surface analytical techniques.

For the specialist this volume is undoubtedly a useful source of detailed information on the theory and methodology of such studies, and it covers the literature up to the end of the 1980s. Electrochemists can learn much from these impressive results. However, the practitioner who wishes to know, for example, how an acrylonitrile molecule lies on the surface of a cadmium cathode (as in the Monsanto process for the electrosynthesis of adiponitrile), or how typical corrosion inhibitors are adsorbed on iron, will find no information here. Also it is regrettable that none of the authors has taken the trouble to write a summary and evaluation of the methods, but that is usually the case. The book will find its way into libraries, but the high price is likely to deter individual scientists from buying it.

Tandem Organic Reactions. By *Tse-Lok Ho*. Wiley, Chichester, 1992. X, 502 pp., hardcover \$ 79.95.—ISBN 0-471-57022-2

Tandem reactions, also called cascade, domino, sequential, or one-pot reactions, are strictly speaking old hat. Perhaps one of the best-known tactical combinations is the Robinson tropinone synthesis, discovered more than 75 years ago, which makes four new σ bonds from three components in biomimetic fashion, and also the Robinson annulation, which has proved so valuable in steroid synthesis.

Tse-Lok Ho, previously with the NutraSweet company in Chicago and now at the National Taiwan University, a well-known author and prolific writer, whose earlier books include *Hard and Soft Acids in Organic Chemistry* (Academic Press, 1977), *Carbon–Carbon Bond Formation in Terpene Synthesis* (VCH, 1988) and *Polarity Control for Synthesis* (Wiley, 1991), has now produced a timely monograph on tandem reactions, selecting examples right up to 1992.

After a short preface and an introduction (Chapter 1), tandem reactions are classified, as far as this is possible and practical, by the *last step* of the sequence. The following 14 chapters deal with a wealth of practical examples, which have been put together by the author thanks to his wide knowledge of the literature and excellent memory, and also from his previous books. All methods for making carbon–carbon bonds are represented, including ionic, pericyclic, free radical, and transition metal mediated transformations. The headings of the 14 chapters are as follows: 2. Aldol Condensation; 3. Michael Reactions; 4. Tandem Vicinal Difunctionalization of Alkenes and Alkynes; 5. Dieckmann and Claisen Cyclizations; 6. Mannich Reactions; 7. Diels–Alder Reactions; 8. Other Cycloadditions; 9. Retro-Diels–Alder and Cheletropic Reactions; 10. Electrocyclic Reactions; 11. Ene, Retro-Ene, and Some Other Thermal Reactions; 12. Sigmatropic Reactions; 13. Rearrangements and Fragmentations; 14. Free Radical Reactions; 15. Miscellaneous Tandem Reactions.

However, the headings can only be a rough guide and cannot give the full flavor of the diverse chemistry that is described. For example, Chapter 4 contains examples of the Pauson–Khand and the Dötz reaction as well as biosynthetically patterned cationic polyene cyclizations. Chapter 8 includes the Vollhardt [2 + 2 + 2] and also higher cycloadditions. Structurally simpler examples and also complex natural products chemistry are well represented.

The structural formulas are well produced and capture the essence of a procedure, with a concise commentary. Thus the book complements and contrasts with other recent texts which focus mainly on the tools of the trade, i.e. *methods* for manipulating functional groups and the growing number of *reagents* for organic synthesis. As far as I could see the book contains no more than a few minor misprints and some inevitable misspellings of authors' names.

Whither tandem reactions? As a strategem or even as a principle of organic chemistry and synthesis, tandem reactions will undoubtedly continue to flourish. Elegance, aesthetic appeal, atom economy and functional group economy, convergence and also stereocontrol often blend to provide optimum access to complex molecular structures. In future it will be important to somehow measure the quality of a tandem reaction, since the number of steps is not necessarily an absolute criterion, for example if the flexibility and applicability are too narrow, or when it becomes too difficult to find the "reaction window" which may not be wide enough.[1] In this case, it may still be possible that two or three "inelegant" but well worked out steps are superior to the elegant but difficult tandem procedure.[2] Of course, the time factor, so important for industry for obtaining material for initial biological tests, may also be in favor of the linear and more conventional step-by-step approach.

In summary, Tse-Lok Ho's text is a welcome source book, also for graduate seminars, and it is a must for a young organic chemist setting out on his or her career. By exposing gaps in our current knowledge the book, together with other recent articles,[3–8] will stimulate discussion and new experimental work. Thus, it will help to evaluate the current state of the art and synthetic efficiency.[9]

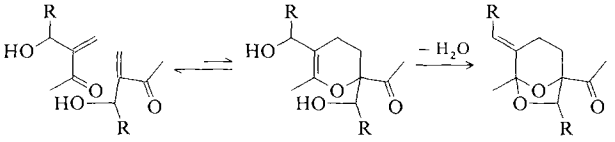
University of Hannover (FRG)

[1] For example, the important modification of using acetonedicarboxylic *acid* instead of acetonedicarboxylic *ester* in the tropinone synthesis was introduced by Schöpf almost 20 years after Robinson's first paper. See obituary of Clemens Schöpf by J. Thesing, *Chem. Ber.* **1979**, *112*, I–XIX.

[2] The converse also applies. For example, the tandem bicyclization of β-keto allyl alcohols to 6,8-dioxabicyclo[3.2.1]octanes involves an unfavorable hetero-Diels–Alder reaction in the first step, which is potentially reversible.



However, thanks to the hydroxy groups, the reaction is driven by the irreversible final cyclization (see Scheme). See also N. Daude, U. Eggert, H. M. R. Hoffmann, *J. Chem. Soc. Chem. Commun.* **1988**, 206; H. M. R.

Spectroscopy of Polymers. By *J. L. Koenig*. American Chemical Society, Washington DC, 1992. XVI, 328 pp., paperback $ 49.95.—ISBN 0-8412-1924-9

To characterize the structures of synthetic polymers one needs to determine various properties that are specific to polymers, such as the molar mass, tacticity, configuration and conformation, copolymerization statistics, etc. To these must be added the organization and dynamic behavior of the molecular chains in the solid state, or in the different forms of liquid crystalline polymers. Spectroscopic methods are becoming increasingly important as ways of investigating these properties. During the last decade there have been especially rapid developments in the areas of vibrational spectroscopy (Fourier transform infrared (FTIR) and Raman spectroscopy) and NMR spectroscopy, and these advances are described in the book by J. L. Koenig reviewed here. However, the title is somewhat misleading, since in addition to these two areas there are many other spectroscopic methods that are successfully applied to polymer studies. The book is based on the author's many years of experience in research and teaching in the two fields described, and it replaces his earlier book on the same subject. It is intended for graduate students and polymer scientists who are not experts in these areas of spectroscopy. Its purpose is to enable them to choose the most suitable methods to solve specific polymer problems, and to equip them with enough basic knowledge to make intelligent use of more advanced monographs and of the original literature.

This approach is an extremely useful one for practical laboratory work, and Koenig fulfills the task outstandingly well. In addition to clearly explaining the standard methods used, for example, to determine the microstructure of polymers in solution, he describes more recent developments such as attenuated total reflection (ATR) Raman spectroscopy and FT-Raman spectroscopy. Even some techniques that are complicated to explain, such as two-dimensional (2D) FTIR spectroscopy, are treated in a concise and understandable way. In the case of NMR spectroscopy a considerable amount of space is devoted to structural characterization, and especially to the dynamics of polymers in the solid state. The discussion makes it clear that the current state of the art in the NMR spectroscopy of solid polymers allows not only the determination of chemical structure using the CP–MAS (cross-polarization magic angle spinning) technique but also the measurement of various relaxation parameters. Last but not least, Koenig devotes a chapter to NMR imaging techniques and shows the potential of these methods for the characterization of elastomers and for studying diffusion processes, mainly using examples from his own work.

For each of the techniques covered Koenig begins with the basic physical principles, deliberately keeping the number of mathematical formulas to a minimum. This is followed by a discussion of the experimental details that are important in practice, then the applications of the method are illustrated by numerous examples from different areas of polymer research. The advantages and disadvantages of each method are clearly set out; here the author is not afraid to state his personal views which sometimes conflict with those expressed in the literature.

The book makes easy reading, thanks to the many useful illustrations and the excellently written text, and can be recommended for all graduate students and polymer scientists. It should find a place in the library of every laboratory concerned with the physics or chemistry of macromolecules, which expressly includes industrial laboratories.

Electron Transfer Reactions in Chemistry: Theory and Experiment (Nobel Lecture)**

By Rudolph A. Marcus*

Since the late 1940s, the field of electron transfer processes has grown enormously, both in chemistry and biology. The development of the field, experimentally and theoretically, as well as its relation to the study of other kinds of chemical reactions, presents to us an intriguing history, one in which many threads have been brought together. In this lecture, some history, recent trends, and my own involvement in this research are described.

1. Electron Transfer Experiments since the Late 1940s[***]

The early experiments in the electron transfer field were on "isotopic exchange reactions" (self-exchange reactions) and, later, "cross reactions." These experiments reflected two principal influences. One of these was the availability after the Second World War of many radioactive isotopes, which permitted the study of a large number of isotopic exchange electron transfer reactions in aqueous solution such as depicted in Equations (1) and (2), where the asterisk denotes a radioactive isotope.

$$Fe^{2+} + {}^*Fe^{3+} \rightleftharpoons Fe^{3+} + {}^*Fe^{2+} \quad (1)$$

$$Ce^{3+} + {}^*Ce^{4+} \rightleftharpoons Ce^{4+} + {}^*Ce^{3+} \quad (2)$$

There is a two-fold simplicity in typical self-exchange electron transfer reactions (so-called because other methods beside isotopic exchange were later used to study some of them): 1) the reaction products are identical with the reactants, thus eliminating one factor that usually influences the rate of a chemical reaction in a major way, namely the relative thermodynamic stability of the reactants and products; and 2) no chemical bonds are broken or formed in simple electron transfer reactions. Indeed, these self-exchange reactions represent, for these combined reasons, the simplest class of reaction in chemistry. Observations stemming directly from this simplicity were to have major consequences, not only for the electron transfer field, but also, to a lesser extent, for the study of other kinds of chemical reactions as well (see Shaik et al.[2]).

A second factor in the growth of the electron transfer field was the introduction of new instrumentation, which permitted the study of the rates of rapid chemical reactions. Electron transfers are frequently rather fast compared with many reactions that undergo, instead, breaking of chemical bonds and forming of new ones. Accordingly, the study of a large body of fast electron transfer reactions became accessible with the introduction of this instrumentation. One example was the stopped-flow apparatus, pioneered for inorganic electron transfer reactions by N. Sutin. It permitted the study of bimolecular reactions in solution in the millisecond time scale (a fast time scale at the time). Such studies led to the investigation of what has been termed electron transfer

[***] This article has not been consistently annotated. The relevant articles in the reference section have been arranged as follows: In [1] some of my important articles, largely from the 1956–1965 period, are listed. Some general references which review the overall literature are listed in [2], and several additional references for Table 1 and for the Figures in [3]. Classic texts on unimolecular reactions are given in [4].

cross reactions, that is, electron transfer reactions between two different redox systems, as in Equation (3), which sup-

$$Fe^{2+} + Ce^{4+} \rightleftharpoons Fe^{3+} + Ce^{3+} \quad (3)$$

plemented the earlier studies of the self-exchange electron transfer reactions. A comparative study of these two types of reaction, self-exchange and cross-reactions, stimulated by theory, was also later to have major consequences for the field and, indeed, for other areas.

Again, in the field of electrochemistry, the new post-war instrumentation in chemical laboratories led to methods that permitted the study of fast electron transfer reactions at metal electrodes. Prior to the late 1940s, only relatively slow electrochemical reactions, such as the discharge of an H_3O^+ ion at an electrode to form H_2, had been investigated extensively. They involved the breaking of chemical bonds and the forming of new ones.

Numerous electron transfer studies have now also been made in other areas. Some are depicted in Figure 1. Some of

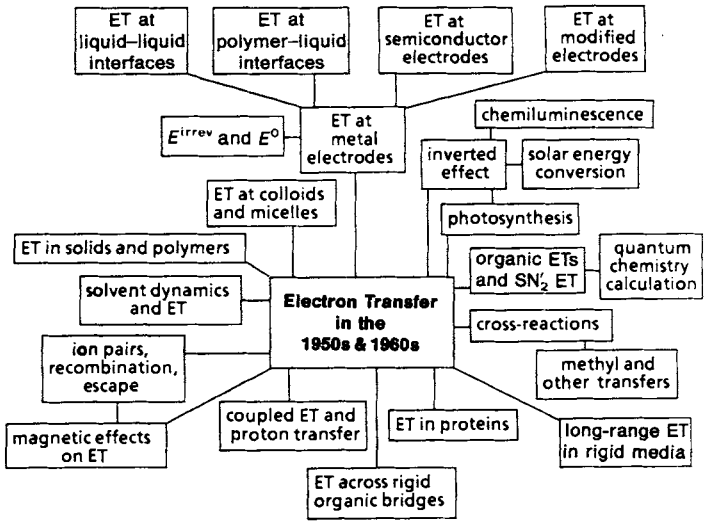

Fig. 1. Examples of topics in the electron transfer (ET) field (Marcus and Siddarth [2]).

these investigations were made possible by newer technology, in particular that of lasers, and now include studies in the picosecond and subpicosecond time regimes. Just recently, the non-laser technique of nanometer-sized electrodes has been introduced to study electrochemical processes that are still faster than those hitherto investigated. Still other recent investigations, important for testing aspects of the electron transfer theory at electrodes, involve the new use of an intervening, ordered, adsorbed monolayer of long-chain organic compounds on the electrode to facilitate the study of several effects such as varying the metal–solution potential difference on the electrochemical electron transfer rate.

In some studies of electron transfer reactions in solution, there has also been a skillful blending of these measurements of chemical reaction rates with organic or inorganic synthetic methods, as well as with site-directed mutagenesis, to obtain more hitherto unavailable information. The use of chemically modified proteins to study the distance dependence of electron transfer, notably by Gray and co-workers, has opened a whole new field of activity.

The interaction of theory and experiment in these many electron transfer fields has been particularly extensive and exciting, and each has stimulated the other. This lecture addresses the underlying theory and this interaction.

2. Early Experience

My own involvement in the electron transfer field began in a rather circuitous way. My background was in experimental measurements of reaction rates as a chemistry graduate student at McGill University (1943–1946) and as a post-doctoral associate at the National Research Council of Canada (NRC, 1946–1949). A subsequent post-doctoral study at the University of North Carolina (1949–1951) on the theory of reaction rates resulted in what is now known as RRKM theory (Rice, Ramsperger, Kassel, Marcus).

This field of unimolecular reactions reflects another long and extensive interaction between theory and experiment. RRKM theory enjoys widespread use and is now usually referred to in the literature only by its acronym (or by the texts written about it[4]), instead of by citation of the original articles.

After the theoretical post-doctoral period, I joined the faculty of the Polytechnic Institute of Brooklyn in 1951 and wondered what theoretical research to do next after writing the RRKM papers (1951–1952). I remember vividly how a friend of mine and a colleague at Brooklyn Poly, Frank Collins, came down to my office every day with a new idea on the liquid-state transport theory that he was developing, while I had none for my theoretical research. Perhaps this gap of not doing anything immediately in the theoretical field was, in retrospect, fortunate: In not continuing with the study of the theory of unimolecular reactions, for which there were too few legitimate experimental data at the time to make the subject one of continued interest, I was open for investigating quite different problems in other areas. I did, however, begin a program of experimental studies in gas phase reactions prompted by my earlier studies at NRC and by the RRKM work.

I also recall how a student in my statistical mechanics class in this period (Abe Kotliar) asked me about a particular problem in polyelectrolytes. It led to my writing two papers on the subject (1954–1955), one of which required a considerable expansion in my background in electrostatics to analyze different methods for calculating the free energy of these systems: in polyelectrolyte molecules, the ionic charges along the organic or inorganic molecular backbone interact with each other and with the solvent. In the process I read the relevant parts of the texts that were readily available on electrostatics (Caltech's Mason and Weaver's book was later to be particularly helpful!) When shortly thereafter I encountered some papers on electron transfer, a field entirely new to me, I was reasonably well prepared for treating the problems that lay ahead.

3. Developing an Electron Transfer Theory

3.1. Introduction

My first contact with electron transfer reactions came in 1955 as a result of chancing upon a 1952 symposium issue on the subject in the Journal of Physical Chemistry. An article by Bill Libby caught my eye—a use of the Franck–Condon principle to explain some experimental results, namely, why some isotopic exchange reactions that involve electron transfer between pairs of small cations in aqueous solution, such as reaction (1), are relatively slow, whereas electron transfers involving larger ions, such as $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ and MnO_4^-/MnO_4^{2-}, are relatively fast.

Libby explained this observation in terms of the Franck–Condon principle, as discussed in Section 4.1. The principle was used extensively in the field of spectroscopy for interpreting spectra for the excitation of the molecular electronic–vibrational quantum states. An application of that principle to chemical reaction rates was novel and caught my attention. In that paper Libby gave a "back-of-the-envelope" calculation of the resulting energy barrier for solvation that slowed the reaction. However, I felt instinctively that even though the idea—that somehow the Franck–Condon principle was involved—seemed strikingly right, the calculation itself was incorrect. The next month of study of the problem was, for me, an especially busy one. To place the topic in some perspective I first digress and describe the type of theory that was used for other types of chemical reaction rates at the time and continues to be useful today.

3.2. Reaction Rate Theory

Chemical reactions are often described in terms of the motion of the atoms of the reactants on a potential energy surface. This potential energy surface is really the electron energy of the entire system, plotted against the positions of all the atoms. A very common example is the transfer of an atom or a group B from molecule AB to form BC [Eq. (4)].

$$AB + C \longrightarrow A + BC \qquad (4)$$

An example of reaction (4) is the transfer of a hydrogen atom, such as in IH + Br → I + HBr, or the transfer of a CH_3 group from one aromatic sulfonate to another. To aid in visualizing the motion of the atoms in this reaction, the potential energy function for reaction (4) is frequently plotted as constant energy contours in a space whose axes are chosen to be two important relative coordinates such as a scaled AB bond length and a scaled distance from the center of mass of AB to C, as in Figure 2.

A point representing the reactants of this reacting system begins its trajectory in the lower right region of the figure in a valley in this plot of contours. When the system has enough energy, appropriately distributed between the various motions, it can cross the "mountain pass" (saddle-point region) separating the initial valley from the products' valley in the upper left of Figure 2, and so form the reaction products. The line xy in Figure 2, analogous to the continental divide in the Rocky Mountains in the United States separates systems that could spontaneously flow into the reactants' valley from those that could flow into the products' one. In chemists' terminology this line represents the transition state of the reaction.

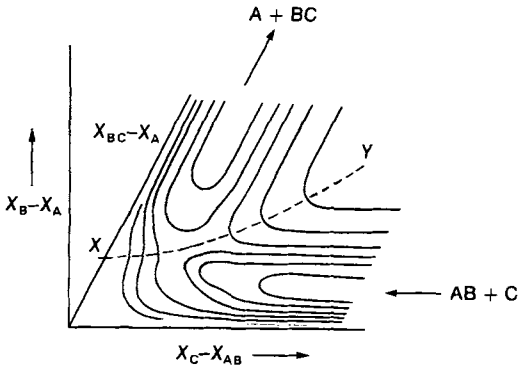

Fig. 2. Potential energy contours for reaction (4) in the collinear case. X_A = coordinates of A, etc.

In transition state theory, a quasi-equilibrium between the transition state and the reactant is frequently postulated, and the reaction rate is then calculated with equilibrium statistical mechanics. A fundamental dynamical basis, which replaces this apparently ad hoc but common assumption of transition state theory and which is perhaps not as well known in the chemical literature as it deserves to be, was given in 1938 by the physicist and one-time chemical engineer, Eugene Wigner. He used a classical mechanical description of the reacting system in the many-dimensional space (of coordinates and momenta). Wigner pointed out that the quasi-equilibrium would follow as a dynamical consequence, if each trajectory of a moving point representing the reacting system in this many-dimensional space did not recross the transition state (and if the distribution of the reactants in the reactants' region were a Boltzmann one). In recent times, the examination of this recrossing has been a common problem in classical mechanical trajectory studies of chemical reactions. Usually, recrossings are relatively minor, except in nonadiabatic reactions, where they are readily treated (see Section 4.1).

In practice, transition state theory is generalized to include as many coordinates as are needed to describe the reacting system. Further, when the system can tunnel quantum mechanically through the potential energy barrier (the pass) separating the two valleys, as for example frequently happens at low energies in H-transfer reactions, the method of treating the passage across the transition state region needs, and has received, refinement. (The principal problem encountered here has been the lack of "dynamical separability" of the various motions in the transition state region.)

4. Electron Transfer Theory: Formulation

4.1. Fundamental Considerations

In contrast to the above picture, we have already noted that in simple electron transfer reactions no chemical bonds are broken or formed, and so a somewhat different picture of the reaction is needed.

In his symposium paper in 1952, Libby noted that when an electron is transferred from one reacting ion or molecule to another, the two new molecules or ions formed are in the wrong environment of the solvent molecules, since the nuclei do not have time to move during the rapid electron jump: in reaction (1) an Fe^{2+} ion would be formed in some configuration of the many nearby dipolar solvent molecules that was appropriate to the original Fe^{3+} ion. Analogous remarks apply to the newly formed Fe^{3+} ion in the reaction. On the other hand, in reactions of complex ions, such as those in the $[Fe(CN)_6]^{-3}/[Fe(CN)_6]^{-4}$ and MnO_4^-/MnO_4^{2-} self-exchange reactions, the two reactants are larger, and so the change of electric field in the vicinity of each ion, upon electron transfer, would be smaller. The original solvent environment would therefore be less foreign to the newly formed charges, and so the energy barrier to reaction would be less. In this way Libby explained the faster self-exchange electron transfer rate for these complex ions. Further confirmation was noted in the ensuing discussion in the symposium: the self-exchange $[Co(NH_3)_6]^{3+}/[Co(NH_3)_6]^{2+}$ reaction is very slow, and it was pointed out that there was a large difference in the equilibrium Co–N bond lengths in the Co^{III} and Co^{II} ions. Again, each ion would be formed in a very foreign configuration of the vibrational coordinates, even though the ions are complex ions.

After studying Libby's paper and the symposium discussion, I realized that what troubled me in this picture for reactions occurring in the dark was that energy was not conserved: the ions would be formed in the wrong high-energy environment, but the only way such a non-energy-conserving event could happen would be by the absorption of light (a vertical transition), and not in the dark. Libby had perceptively introduced the Franck–Condon principle to chemical reactions, but something was missing.

In the present discussion, as well as in Libby's treatment, it was supposed that the electronic interaction of the reactants that causes the electron transfer is relatively weak. That view is still the one that seems appropriate today for most of these reactions. In this case of weak-electronic interaction, the question becomes: how does the reacting systm behave in the dark so that it satisfies both the Franck–Condon principle and energy conservation? I realized that fluctuations had to occur in the various nuclear coordinates, such as in the orientation coordinates of the individual solvent molecules and indeed in any other coordinates whose most probable distribution for the products differs from that of the reactants. With such fluctuations, values of the coordinates could be reached which satisfy both the Franck–Condon and energy conservation conditions and so permit the electron transfer to occur in the dark.

An example of an initial and final configuration of the solvent molecules for reaction (1) is depicted in Figure 3. Fluctuations from the original equilibrium ensemble of configurations were ultimately needed, prior to the electron transfer, and were followed by a relaxation to the equilibrium ensemble for the products after electron transfer.

The theory then proceeded as follows. The potential energy U_r of the entire system, reactants plus solvent, is a function of the many hundreds of relevant coordinates of the system, coordinates which include, among others, the position and orientation of the individual solvent molecules (and

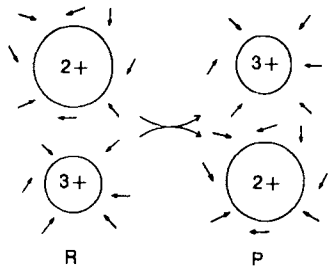

Fig. 3. Typical arrangement of solvent molecules surrounding reactants and products in reaction (1). The longer M–OH_2 bond length in the cation is indicated schematically by the larger ionic radius (Sutin, [2]).

hence of their dipole moments, for example), and the vibrational coordinates of the reactants, particularly those in any inner coordination shell of the reacting ions. (For example, the inner coordination shell of an ion such as Fe^{2+} or Fe^{3+} in water is known from EXAFS (*e*xtended *X*-ray *a*bsorption *f*ine *s*tructure) experiments to contain six water molecules.) No longer were there just the two or so important coordinates that were dominant in reaction (4).

Similarly, after the electron transfer, the reacting molecules have the ionic charges appropriate to the reaction products, and so the relevant potential energy function U_p is that for the products plus solvent. These two potential energy surfaces will intersect if the electronic coupling which leads to electron transfer is neglected. For a system with N coordinates this intersection occurs on an $(N-1)$ dimensional surface, which then constitutes in our approximation the transition state of the reaction. The neglected electronic coupling causes a well-known splitting of the two surfaces in the vicinity of their intersection. A schematic profile of the two potential energy surfaces in the N-dimensional space is given in Figure 4. (The splitting is not shown.)

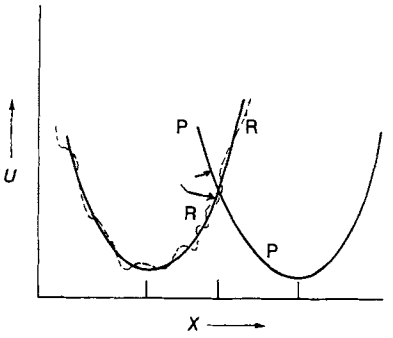

Fig. 4. Profile of potential energy surfaces for reactants plus environment (R) and for products plus environment (P). Solid curve: schematic. Dashed curve: schematic but slightly more realistic. The typical splitting at the intersection of the potential energy curves U_r and U_p is not shown (Marcus and Siddarth [2]). X = nuclear coordinates.

Due to the effect of the previously neglected electronic coupling and the coupling between the electronic motion and the nuclear motion near the intersection surface S, an electron transfer can occur at S. In classical terms, the transfer at S occurs at fixed positions and momenta of the atoms; the Franck–Condon principle is satisfied. Since U_r equals U_p at S, energy is also conserved. The details of the electron trans-

fer depend on the extent of electronic coupling and how rapidly the point representing the system in this N-dimensional space crosses S. (It has been treated, for example, by using as an approximation the well-known one-dimensional Landau–Zener expression for the transition probability at the near-intersection of two potential energy curves.)

When the splitting caused by the electronic coupling between electron donor and acceptor is large enough at the intersection, a system crossing S from the lower surface on the reactants' side continues onto the lower surface on the products' side; an electron transfer in the dark has then occurred. When the coupling is, instead, very weak, ("nonadiabatic reactions") the probability of successfully reaching the lower surface on the products' side is small and can be calculated by using quantum mechanical perturbation theory—for example, by using Fermi's "Golden Rule," an improvement over the 1-dimensional Landau–Zener treatment.

Thus, there is some difference and some similarity with a more conventional type of reaction such as reaction (4), whose potential energy contour plots were depicted in Figure 2. In both cases, fluctuations of coordinates are needed to reach the transition state, but since so many coordinates can now play a significant role in the electron transfer reaction because of the major and relatively abrupt change in charge distribution on passing through the transition state region, a rather different approach from the conventional one was needed to formulate the details of the theory.

4.2. Electron Transfer Theory: Treatment

In the initial paper (1956) I formulated the picture of the mechanism of electron transfer described in the previous section and, to make the calculation of the reaction rate tractable, treated the solvent as a dielectric continuum. Because of the orientation and vibrations of the solvent molecules, the position-dependent dielectric polarization $P_u(r)$ of the solvent in the transition state was not the one in equilibrium with the reactants' or the products' ionic charges. It represented instead, some macroscopic fluctuation from them. The electronic polarization of the solvent molecules, on the other hand, can rapidly respond to any such fluctuations and therefore is that dictated by the reactants' charges and by the instantaneous $P_u(r)$.

With these ideas as a basis, what was then needed was a method of calculating the electrostatic free energy G of this system and its still unknown polarization function $P_u(r)$. I obtained this free energy G by finding a reversible path for reaching this state of the system. Upon then minimizing G, subject to the constraint imposed by the Franck–Condon principle (reflected in the electron transfer occurring at the intersection of the two potential energy surfaces), I was able to find the unknown $P_u(r)$ and, hence, to find G for the transition state. That G was then introduced into transition state theory, and the reaction rate calculated.

During this research I also read and was influenced by a lovely paper by Platzmann and Franck (1952) on the optical absorption spectra of halide ions in water and later by work of physicists such as Pekar and Fröhlich (1954) on the closely related topic of polaron theory. As best as I can recall now, my first expressions for G during this months of intense activity seemed rather clumsy, but then with some rearrangement a simple expression emerged that had the right "feel" to it and that I could also derive by a somewhat independent argument. The expression also reduced reassuringly to the usual one, when the constraint of arbitrary $P_u(r)$ was removed. Obtaining the result for the mechanism and rate of electron transfer was indeed one of the most thrilling moments of my scientific life.

The expression for the rate constant k of the reaction is given by Equation (5), where ΔG^* is represented by Equation (6).

$$k = A\exp\left(\frac{-\Delta G^*}{k_B T}\right) \tag{5}$$

$$\Delta G^* = \frac{\lambda}{4}\left(1 + \frac{\Delta G^0}{\lambda}\right)^2 \tag{6}$$

The term A in Equation (5) depends on the nature of the electron transfer reaction (e.g., bimolecular or intramolecular), ΔG^0 is the standard free energy of reaction (and equals zero for a self-exchange reaction), and λ is a "reorganization term" composed of solvational (λ_o) and vibrational (λ_i) components [Eq. (7)].

$$\lambda = \lambda_o + \lambda_i \tag{7}$$

In a two-sphere model of the reactants, λ_o was expressed in terms of the two ionic radii a_1 and a_2 (which encompass the radii of any inner coordination shell), the center-to-center separation distance R of the reactants, the optical (D_{op}) and static (D_s) dielectric constants of the solvent, and the charge transferred (Δe) from one reactant to the other [Eq. (8)].

$$\lambda_o = (\Delta e)^2\left(\frac{1}{2a_1} + \frac{1}{2a_2} - \frac{1}{R}\right)\left(\frac{1}{D_{op}} - \frac{1}{D_s}\right) \tag{8}$$

For a bimolecular reaction, work terms, principally electrostatic, are involved in bringing the reactants together and in separating the reaction products, but are omitted from Equation (6) for notational brevity. The expression for the vibrational term λ_i is given by (9), where Q_j^r and Q_j^p are equi-

$$\lambda_i = \tfrac{1}{2}\sum_j k_j (Q_j^r - Q_j^p)^2 \tag{9}$$

librium values for the jth normal mode coordinate Q, and k_j is a reduced force constant $2k_j^r k_j^p/(k_j^r + k_j^p)$ associated with it. The superscripts r and p refer to reactants and products. (I introduced a "symmetrization" approximation for the vibrational part of the potential energy surface to obtain this simple form of (6)–(9), and tested it numerically.)

In 1957 I published the results of a calculation of the λ_i arising from a stretching vibration in the innermost coordination shell of each reactant, (the equation used for λ_i was given in the 1960 paper). An early paper on the purely vibrational contribution calculated by using chemical bond length coordinates and neglecting bond–bond correlation had already been published for self-exchange reactions by George and Griffiths in 1956.

I also extended the theory to treat electron transfers at electrodes, and distributed it as an Office of Naval Research

Report in 1957. The equations were published later in a journal paper in 1959. I had little prior knowledge of the subject, and my work on electrochemical electron transfers was facilitated considerably by reading a beautiful and logically written survey article of Roger Parsons on the equilibrium electrostatic properties of electrified metal–solution interfaces.

In the 1957 and 1965 work I showed that the electrochemical rate constant is given by (5)–(9), but A now is a value appropriate to the different "geometry" of the encounter of the participants in the reaction. The term $1/(2a_2)$ in Equation (8) is now absent because only one reaction ion is present, and R denotes twice the distance from the center of the reactant's charge to the electrode (it equals the ion–image distance). A term $e\eta$ replaces ΔG^0 in Equation (6), where e is the charge transferred between the ion and the electrode, and η is the activation overpotential, namely, potential difference between metal and solution relative to the value it would have if the rate constants for the forward and reverse reactions were equal. These rate constants are equal when the minima of the two free energy curves in Figure 5 have the same value for G.

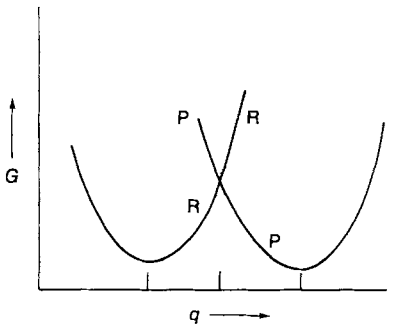

Fig. 5. Plot of the free energy of reactants plus environment vs. the reaction coordinate q (R) and of the free energy of products plus environment vs. reaction coordinate q (P). The three vertical lines on the abscissa denote, from left to right, the value for the reactants, the transition state, and the products (Marcus and Siddarth [2]).

When $|e\eta| < \lambda$, most electrons go into or out of quantum states in the metal that are near the Fermi level. However, because of the continuum of states in the metal, the inverted effect described below was now predicted to be absent for this process; that is, the electrochemical counterpart of Eq. (6) is applicable only in the region $|e\eta| < \lambda$: In the case of an intrinsically highly exothermic electron transfer reaction at an electrode, the electron can remove the immediate "exothermicity" by (if entering) going into a high, unoccupied quantum state of the metal, or (if leaving) departing from a low, occupied quantum state, each far removed from the Fermi level. (The inverted region effect should, however, occur for the electron transfer when the electrode is a narrow-band semiconductor.)

After these initial electron transfer studies, which were based on a dielectric continuum approximation for the solvent outside the first coordination shell of each reactant, I introduced a purely molecular treatment of the reacting system. The solvent was treated by statistical mechanics as a collection of dipoles in the 1960 paper, and later in 1965 a general charge distribution was used for the solvent molecules and the reactants. At the same time I found a way in this 1960 paper of introducing rigorously a global reaction coordinate in this many-dimensional (N) coordinate space of the reacting system. The globally defined coordinate so introduced was equivalent to using $U_p - U_r$, the potential energy difference between the products plus solvent (U_p) and the reactants plus solvent (U_r) (see A. Warshel, 1987). This coordinate is thus defined everywhere in this N-dimensional space.

The free energy G_r of a system containing the solvent and the reactants, and that of the corresponding system for the products, G_p, could now be defined along this globally defined reaction coordinate. (By contrast, in reactions such as that depicted by Figure 2, it is customary, instead, to define a reaction coordinate locally in the vicinity of a path leading from the valley of the reactants through the saddle point region and into the valley of the products.)

The potential energies U_r and U_p in the many-dimensional coordinate space are simple functions of the vibrational coordinates, but complicated functions of the hundreds of relevant solvent coordinates: there are many local minima corresponding to locally stable arrangements of the solvent molecules. However, I introduced a "linear response approximation," in which any hypothetical change in charge of the reactants produces a proportional change in the dielectric polarization of the solvent. (Recently I utilized a central limit theorem to understand this approximation better than is possible with simple perturbation theory and plan to submit the results for publication shortly.) With this linear approximation the free energies G_r and G_p became simple quadratic functions of the reaction coordinate.

Such an approach had major consequences. It depicted the reaction in terms of parabolic free energy plots in simple and readily visualized terms, as in Figure 5. With these plots the trends predicted from the equations were readily understood. It was also important to use the free energy curves, instead of oversimplified potential energy profiles, because of the large entropy changes which occur in many electron transfer cross-reactions, caused by changes in strong solvent interactions between ions and polar solvent. (The free energy plot is legitimately a one-coordinate plot, whereas the potential energy plot is at most a profile of the complicated U_r and U_p functions in N-dimensional space.)

With the new statistical mechanical treatment of 1960 and 1965 one could also see how certain relations between rate constants initially derivable from the dielectric continuum-based equations in the 1956 paper could also be valid more generally. The relations were based, in part, on Equations (5) and (6) and (initially via (8) and (9)) on the approximate relation (10), where λ_{12} is the reoganization term for

$$\lambda_{12} \cong \tfrac{1}{2}(\lambda_{11} + \lambda_{22}) \tag{10}$$

the cross-reaction, and λ_{11} and λ_{22} are those of the self-exchange reactions.

5. Predictions Based on the Theory

In the 1960 paper I had listed a number of theoretical predictions resulting from these equations, in part to stimu-

late discussion with experimentalists in the field at a Faraday Society meeting on oxidation–reduction reactions, where this paper was to be presented. At the time I certainly did not anticipate the subsequent involvement of the many experimentalists in testing them. Among the predictions was one that became one of the most widely tested aspects of the theory, namely, the cross-relation. This expression, which follows from Equations (5), (6), and (10), relates the rate constant k_{12} of a cross-reaction to the two self-exchange rate constants, k_{11} and k_{22}, and to the equilibrium constant K_{12} of the reaction [Eq. (11)], where f_{12} is a known function of k_{11}, k_{22} and K_{12} and is usually close to unity.

$$k_{12} \cong (k_{11} k_{22} K_{12} f_{12})^{1/2} \tag{11}$$

Another prediction in the 1960 paper concerned what I termed there the inverted region: In a series of related reactions, similar in λ but differing in ΔG^0, a plot of the activation free energy ΔG^* vs. ΔG^0 is seen from Equation (6) first to decrease as ΔG^0 is varied from zero to some negative value, to be zero at $\Delta G^0 = -\lambda$, and then to increase when ΔG^0 is made still more negative. The initial decrease of ΔG^* with increasingly negative ΔG^0 is the expected trend in chemical reactions and is similar to the usual trend in "Brønsted plots" of acid- or base-catalyzed reations and in "Tafel plots" of electrochemical reactions. I termed that region of ΔG^0 the "normal" region. However, the prediction for the region where $-\Delta G^0 > \lambda$, the inverted region, was the unexpected behavior, or at least unexpected until the present theory was introduced.

This inverted region is also easily visualized from Figures 6 and 7: Successively making ΔG^0 more negative by lowering the products' G curve vertically relative to the reactant curve, decreases the free energy barrier ΔG^* (given by the intersection of the reactants' and products' curves); that barrier is seen in Figure 6 to vanish at some ΔG^0 and then to increase again.

Other predictions dealt with the relation between the electrochemical and the corresponding self-exchange electron transfer rates, the numerical estimate of the reaction rate constant k, and, in the case of nonspecific solvent effects, the dependence of the reaction rate on solvent dielectric properties.

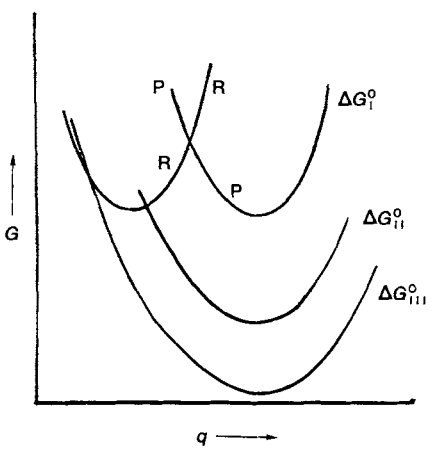

Fig. 6. Plot of the free energy G versus the reaction coordinate q for reactants (R) and products (P), for three different values of ΔG^0; the cases I to III refer to Figure 7 (Marcus and Siddarth [2]).

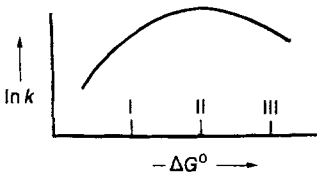

Fig. 7. Plot of $\ln k_r$ vs. $-\Delta G^0$. Points I and III are in the normal and inverted regions, respectively, while point II at which $\ln k_r$ is a maximum occurs at $-\Delta G^0 = \lambda$ (Marcus and Siddarth, [2]).

The testing of some of the predictions was delayed by an extended sabbatical in 1960–1961, which I spent auditing courses and attending seminars at the nearby Courant Mathematical Institute.

6. Comparison of Experiment and Theory

Around 1962 during one of my visits to Brookhaven National Laboratory, I showed Norman Sutin the 1960 predictions. Norman had either measured on his stopped-flow apparatus or otherwise knew rate constants and equilibrium constants that permitted the cross-relation [Eq. (11)] to be tested. He had about six such sets of data available. I remember vividly the growing sense of excitement we both felt as, one by one, the observed rate constants k_{12} more or less agreed with the predictions of the relation. I later collected the results of this and of various other tests of the 1960 predictions and published them in 1963. Perhaps by showing that the previously published expressions were not mere abstract formulae, but rather had concrete applications, this 1963 paper and many tests by Sutin and others appear to have stimulated numerous subsequent tests of the cross-rela-

Table 1. Comparison of calculated and experimental k_{12} values (Bennett [3]).

tion and of the other predictions. A few examples of the cross-relation test are given in Table 1.

The encouraging success of the experimental tests given in the 1963 paper suggested that the theory itself was more general than the approximations (for example, treating solvent as dipoles or employing unchanged force constants) used in 1960 and stimulated me to give a more general formulation (1965). The latter paper also contains a unified treatment of electron transfer reactions in solution and at metal electrodes, and served, thereby, to generalize my earlier (1957) treatment of the electrochemical electron transfer reactions.

The best experimental evidence for the inverted region was provided in 1984 by Miller, Calcaterra, and Closs, almost 25 years after it was predicted. This successful experimental test, which was later obtained for other electron transfer reactions in other laboratories, is reproduced in Figure 8. Possible reasons for not observing it in the earlier tests are severalfold and have been discussed elsewhere.

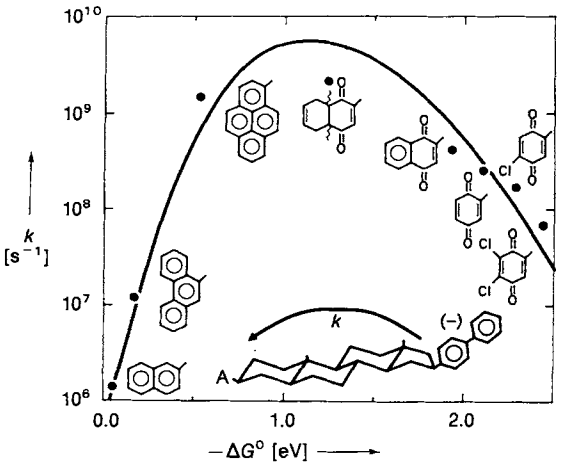

Fig. 8. Inverted region in the chemical electron transfer from a biphenyl group to an acceptor A. Dihydronaphthoquinone marks the changeover from normal (left) to inverse behavior (right). The solid curve was calculated for $\lambda_0 = 0.75$ and $\lambda_i = 0.45$ eV. The frequency of the high-frequency vibrations ω was 1500 cm^{-1} (Miller et al. [3]).

Previously, indirect evidence for the inverted region had been obtained by observing that electron transfer reactions with a very negative ΔG^0 may result in chemiluminescence: when the intersection of the G_r and G_p curves in such cases results in a high free energy of activation ΔG^* because of the effect of the inverted region, there may be an electron transfer to a more easily accessible G_p curve in which one of the products is electronically excited and which intersects the G_r curve in the normal region at a low ΔG^* (Fig. 9). Indeed, experimentally in some reactions 100% formation of an electronically excited state of a reaction product has been observed by Bard and co-workers, and results in chemiluminescence.

Another consequence of Equations (5) and (6) is the linear dependence of $k_B T \ln k$ on $-\Delta G^0$ with a slope of 1/2 when $|\Delta G^0/\lambda|$ is small. The behavior at electrodes is similar, but ΔG^0 is replaced by $e\eta$, that is, the product of the charge transferred and the activation overpotential. Extensive verification of both these results has been obtained. More recently, the curvature of plots of $\ln k$ vs. $e\eta$, expected from these equations, has been demonstrated in several experiments. The very recent use of ordered organic molecular monolayers on electrodes, either to slow down the electron transfer rate or to bind a redox-active agent to the electrode, but in either case to avoid or minimize diffusion control of the fast electron transfer processes, has considerably facilitated this study of the curvature in the $\ln k$ vs. $e\eta$ plot.

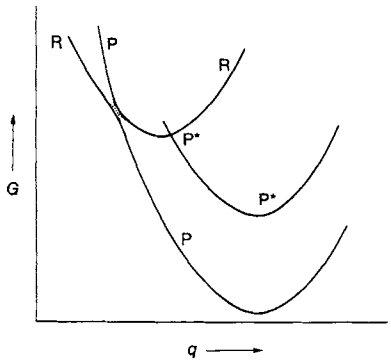

Fig. 9. The favored formation of an electronically excited state of the products (Marcus and Siddarth [2]), which prevents the observation of the inverse region.

Comparison of experiment and theory has also included the testing of absolute reaction rates of self-exchange reactions and the effect on the rate of varying the solvent (an effect sometimes complicated by ion pairing in the low dielectric constant media involved). The related problem of charge transfer spectra, as portrayed in (12) has also been examined. Here, the frequency of the spectral absorption maximum ν_{max} is given by Equation (13).

$$DA + h\nu \longrightarrow D^+A^- \tag{12}$$

$$h\nu_{max} = \lambda + \Delta G^0 \tag{13}$$

Comparisons with Equation (13) in which λ is expressed as in Equation (8) have included examples with effects of separation distance and solvent dielectric constant.

Comparisons have also been made of the self-exchange reaction rates in solution with the rates of the corresponding electron transfer reactions at electrodes. An example of the latter is the plot given in Figure 10, where the self-exchange

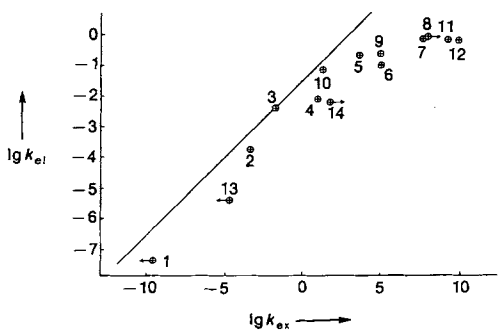

Fig. 10. Comparison of self-exchange electron transfer rates k_{ex} in solution, covering 20 orders of magnitude with rates of corresponding electron transfers at metal electrodes (k_{el}). The line with slope 1/2 shows the behavior predicted by theory (Cannon [2]).

rates are seen to vary by some twenty orders of magnitude. The discrepancy at high rate constants k is currently the subject of some reinvestigation of the fast electrode reaction rates, using the new nanotechnology. Most recently, a new type of interfacial electron transfer rate has also been measured: electron transfer at liquid–liquid interfaces. In treating the latter, I extended the cross relation to this two-phase system. It is clear that much is to be learned from this new area of investigation. (The study of the transfer of ions across such an interface, on the other hand, goes back to the time of Nernst and of Planck around the turn of the century.)

7. Other Applications and Extensions of the Theory

As noted in Figure 1, one aspect of the electron transfer field has been its continued and, indeed, ever-expanding growth in so many directions. One of these is in the biological field, where there are now detailed experimental and theoretical studies in photosynthetic and other protein systems. The three-dimensional structure of a photosynthetic reaction center, the first membrane protein to be so characterized, was obtained by Deisenhofer, Michel, and Huber, who received the Nobel Prize in Chemistry in 1988 for this work. A bacterial photosynthetic system is depicted in Figure 11; the protein framework holding fast the constituents in this reaction center is not shown.

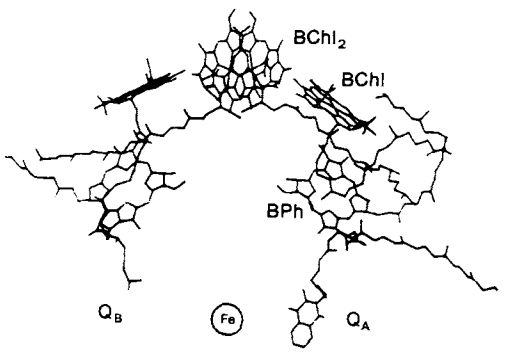

Fig. 11. The redox-active species involved in the initial charge separation in a bacterial photosynthetic center (Deisenhofer et al. and Yeates et al. [3]). The labels added conform to the present text; they include a missing Q_B.

In the photosynthetic system there is a transfer of electronic excitation from "antenna" chlorophylls (not shown in Figure 11) to a special pair $BChl_2$. The latter then transfers an electron to a pheophytin BPh within a very short time (≈ 3 ps), from it to a quinone Q_A in 200 ps, and thence to the other quinone Q_B. (Other chemical reactions then occur with these separated charges at each site of the membrane, bridged by this photosynthetic reaction center.)

To avoid wasting the excitation energy of the $BChl_2^*$ unduly, it is necessary that $-\Delta G^0$ of this first electron transfer to BPh be small. (It is only about 0.25 eV out of an overall excitation energy of $BChl_2^*$ of 1.38 eV.) In order that this electron transfer also be successful in competing with two wasteful processes, the fluorescence and the radiationless transition of $BChl_2^*$, it is also necessary that ΔG^* for that first electron transfer step be small and hence, by Equation (6), that λ be small. The reactants are large, and the immediate protein environment is largely nonpolar, so leading to a small λ [see Eq. (8)]. Nature appears, indeed, to have constucted a system with this desirable property.

Furthermore, to prevent another form of energy wastage, it is also important that an unwanted back electron transfer reaction from the BPh^- to the $BChl_2^+$ not compete successfully with a second forward electron transfer step from BPh^- to Q_A. That is, it is necessary that the back transfer, a "hole–electron recombination" step, be slow, even though it is a very highly exothermic process (about 1.1 eV). It has been suggested that the small λ (about 0.25 eV) and the resulting inverted region effect play a significant role in providing this essential condition for the effectiveness of the photosynthetic reaction center.

There is now a widespread interest in synthesizing systems that can mimic the behavior of nature's photosynthetic systems, and so offer other routes for harnessing solar energy. The current understanding of how nature works has served to provide some guidelines. In this context, as well as in that of electron transfer in other proteins, there are also relevant experiments in long-range electron transfer. Originally the studies were of electron tansfer in rigid glasses, performed by Miller and co-workers. More recently the studies have involved a donor and receptor held together by constructed rigid molecular bridges. The effect of varying the bridge length has been studies in the various systems. A theoretical estimate of the dependence of electron transfers on distance in a photosynthetic system was first made by Hopfield, who used a square barrier as model and an estimate of the barrier height based on molecular considerations.

Recently, in their studies of long-range electron transfer in chemically modified proteins, Gray and co-workers have studied systematically the distance or site dependence of the electronic factor by attaching an appropriate electron donor or acceptor to a desired site. For each such site the reactant was chosen so that $-\Delta G^0 \approx \lambda$, that is, the rate constant k is at the maximum of the $\ln k$ vs. $-\Delta G^0$ curve (see Eqs. (5)–(6)). The value of k then no longer depends on ΔG^*. Since ΔG^* is distance-dependent [see Eq. (8)], it is particularly desirable to make $\Delta G^* \approx 0$, so that the relative k values at the various sites now reflect only the electronic factor. Dutton and co-workers have treated data similarly for a number of reactions by using, where possible, the k at the maximum of each $\ln k$ vs. ΔG^0 curve. Of particular interest in such studies is whether there is a simple exponential decrease of the electronic factor on the separation distance between donor and acceptor, or whether there are deviations from this monotonic behavior, due to local structural factors.

In a different development, the mechanism of various organic reactions has been explored by several investigators, notably by Eberson,[2] in the light of current electron transfer theory, and also by Shaik and Pross in their analysis of a possible electron transfer mechanism vs. a conventional mechanism.

Theoretical calculations of the donor–acceptor electronic interactions, initially by McConnell and by Larsson, and later by others, my group among them, have been used to treat long-range electron transfer. The methods have recently been adapted to large protein systems. In our studies with

Siddarth we used an "artificial intelligence" searching technique to limit the number of amino acids used in the latter type of study.

Another area of much current activity in the field of electron transfer is that of solvent dynamics, which follows the pioneering treatment for general reactions by Kramers (1940). Important later developments for electron transfer were made by many contributors. Solvent dynamics affects the electron transfer reaction rate when the solvent is sufficiently sluggish. As we showed recently with Sumi and Nadler, the solvent dynamics effect can also be modified significantly when there are vibrational (λ_i) contributions to λ.

Computational studies, such as the insightful one of David Chandler and co-workers on the Fe^{2+}/Fe^{3+} self-exchange reaction, have also been employed recently. Using computer simulations they obtained a verification of the parabolic G curves, even for surprisingly strong fluctuations in G. They also extended their studies to dynamic and quantum mechanical effects of nuclear motion. Studies of the quantum mechanical effects of the nuclear motion on electron transfer reactions were initiated in 1959 by Levich and Dogonadze, who assumed a harmonic oscillator model for the polar solvent medium and employed perturbation theory. Their method was related to that used for other problems by Huang and Rhys (1951) and Kubo and Toyozawa (1954).

Important subsequent developments by various authors on these quantum effects include the first discussion of quantum effects for the vibrations of the reactants by Sutin in 1962 and the important work of Jortner and co-workers in 1974–1975, who combined a Levich and Dogonadze type approach to treat the high frequency vibrations of the reactants with the classical expression that I described earlier for the polar medium. These quantum effects have implications for the temperature dependence of k, among other effects. Proceeding in a different (classical) direction Savéant recently showed how to extend Equation (6) to reactions involving the rupture of a chemical bond by electron transfer, which he had previously studied experimentally: $M(e) + RX \rightarrow M + R + X^-$, where R is an alkyl group, X a halide, and M a metal electrode.

A particularly important early development was that by Taube in the 1950s, who received the Nobel Prize for his work in 1983. Taube introduced the idea of different mechanisms for electron transfer, the outer sphere and inner sphere electron transfers, which he had investigated experimentally. His experimental work on charge transfer spectra of strongly interacting systems ("Creutz–Taube" ion, 1959, 1973) and of weakly interacting ones has been similarly influential. Also notable has been Hush's theoretical work on charge transfer spectra, both of intensities and absorption maxima (1967), which supplemented his earlier theoretical study of electron transfer rates (1961).

There has been a spin-off of the original electron transfer theory to other types of chemical reactions as well. In particular, the ΔG^* vs ΔG^0 relation and the cross-relation have been extended to these other reactions, such as the transfer of atoms, protons, or methyl groups. (Even an analog of Equations (6) and (10) for binding energies instead of energy barriers has been introduced to relate the stability of isolated proton-bound dimers AHB^+ to those of AHA^+ and BHB^+!)

Since the transfer of these nuclei involves strong electronic interactions, it is not well represented by intersecting parabolic free energy curves, and a different theoretical approach was needed. For this purpose I adapted in 1968, a "bond-energy–bond-order" model of H. Johnston in order to treat the problem for a reaction of type (4). The resulting simple expression for ΔG^* is similar to Equation (6) when $|\Delta G^0/\lambda|$ is not large ($<\frac{1}{2}$), but differs from it in not having any inverted region. It has the same λ property as that given by Equation (10) and has resulted in a cross-relation analogous to Equation (11). The cross-relation has been tested experimentally for the transfer of methyl groups by E. Lewis, and the ΔG^* vs ΔG^0 relation has been used or tested for other transfers by the groups of Albery and Kreevoy, among others.

It is naturally gratifying to see one's theories used. A recent article, which showed the considerable growth in the use of papers such as the 1956 and 1964 articles,[5] points up the impressive and continued vitality of the field itself. The remarks above on many areas of electron transfer and on the spin-off of such work on the study of other types of reactions represent a necessarily brief picture of these broad-based investigations.

I would like to acknowledge my many fellow researchers in the electron transfer field, notably Norman Sutin, with whom I have discussed so many of these matters for the past thirty or more years. I also thank my students and post-doctorals, whose presence was a constant source of stimulation to me, both in the electron transfer field and in the other fields of research which we have explored. In its earliest stage and for much of this period, my research was supported by the Office of Naval Research and also later by the National Science Foundation. The support of both agencies continues to this day, and I am very pleased to acknowledge its value and timeliness here.

In my Nobel lecture, I concluded on a personal note with a slide of my great-uncle, Henrik Steen (né Markus), who came to Sweden in 1892. He received his doctorate in theology from the Univeristy of Uppsala in 1915, and was an educator and a prolific writer of pedagogic books. As I noted in the biographical sketch in Les Prix Nobel, he was one of my childhood idols. During my trip to Sweden to receive the Nobel prize, visiting with my Swedish relatives – some thirty or so of his descendants – has been an especially heartwarming experience for me and for my family. In a sense I feel that I owed him a debt, and that it is most fitting to acknowledge that debt here.

Protein Phosphorylation and Cellular Regulation I (Nobel Lecture)**

By Edwin G. Krebs*

Introduction

This presentation and the one to be given immediately thereafter [***] will be concerned with the reversible phosphorylation of proteins and the role of this process in biological regulation. In addition to discussing our own early contributions to this field, Ed Fischer and I will describe some of the developments that have occurred subsequently. These developments have led to the realization that protein phosphorylation constitutes a major mechanism by which cellular processes are controlled. My own remarks will review the historical background that provided the setting in which our joint work was carried out in the 1950s and early 1960s. Then I'll turn to a discussion of this work itself, to be followed by comments to the cyclic AMP dependent protein kinase. Finally I will talk about the intracellular transmission of hormone and growth factor signals through protein kinase cascades.

Background

By 1940, which is the year in which I entered medical school at Washington University in St. Louis, it was well established that the breakdown of glycogen in skeletal muscle and other types of cells occurs by the process of phosphorolysis, catalyzed by the enzyme phosphorylase (reviewed in ref.[1]). Carl Cori was Professor and Chairman of the Department of Pharmacology at Washington University when I started my training there, but he was soon to take over the Department of Biological Chemistry. I gradually came to know him, at first distantly, the way medical students usually know their professors, but later on somewhat better after I had become a teaching assistant in biochemistry. In this latter role I also became acquainted with Arda Green, who, together with Carl and Gerty Cori, was purifying rabbit muscle phosphorylase. It was not long until I began to hear about the unusual properties of this remarkable enzyme, which they had found existed in skeletal muscle in two different forms that they designated as phosphorylase *a* and phosphorylase *b*.[2, 3] The *a* form was purified and obtained as a crystalline enzyme. Kinetically, it was shown that phosphorylase *b* requires high concentrations of 5'-AMP for activity, whereas phosphorylase *a* is active in the absence of this nucleotide. Since the concentration of 5'-AMP required for the activity of phosphorylase *b* was considerably higher than that found in muscle, this form was considered to be physiologically inactive. Phosphorylase *a* was thought of as the physiologically active species. Evidence was obtained that the two forms are interconvertible within the cell, and it was postulated by the Coris that interconversion of the forms of phosphorylase constitutes a physiologically significant regulatory mechanism. Resting muscle was reported to contain phosphorylase predominantly in the *a* form, whereas electrically stimulated muscle contained the *b* form.[4] As will be discussed later (see below) the reverse is actually true. Regardless of this latter point, however, the finding that an enzyme might shuttle back and forth between two forms within the cell was a remarkable advance, which set the stage for important later developments.

The Coris were unaware of the chemical nature of the interconversion reactions of phosphorylase, but they did discover an enzyme that would convert phosphorylase *a* to phosphorylase *b* in vitro. This enzyme was called the "PR enzyme" based on the assumption that it acted by removing a prosthetic group from phosphorylase *a*, which was thought of as a holoenzyme form;[2] phosphorylase *b*, lacking the putative group, was considered to be the apoenzyme form. Based on the fact that phosphorylase *b* could be activated by 5'-AMP, this nucleotide bound to the enzyme was thought of as the likely candidate for the prosthetic group of phosphorylase *a*. However, all attempts to identify 5'-AMP as a product formed when phosphorylase *a* was converted to phosphorylase *b* by the PR enzyme were unsuccessful.[2, 3] Because trypsin treatment of phosphorylase *a* led to the formation of a phosphorylase *b*-like form, in other words an enzyme that could be activated by 5'-AMP,[3] it was believed that the PR enzyme might be a protease. No enzyme that could convert phosphorylase *b* to *a* in vitro in the presene of 5'-AMP, or under any other condition that these workers tried, could be demonstrated. This did not seem unreasonable, however, if it were supposed that such a conversion might require peptide bond biosynthesis, because at that time the likelihood that such a reaction could be shown to occur in vitro was considered unlikely. These early concepts with respect to the interconversion reactions of phosphorylase are illustrated in Figure 1.

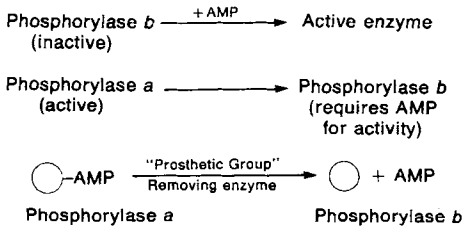

Fig. 1. Early concepts of the interconversion reactions of muscle phosphorylase. Inactive phosphorylase *b* becomes an active enzyme in the presence of 5'-AMP. Phosphorylase *a*, the physiologically active form of the enzyme, is inactivated by the prosthetic group removing (PR) enzyme. It was thought likely that 5'-AMP would be product of this reaction, but this could not be demonstrated.

[***] See the article immediately following: E. H. Fischer, *Angew. Chem.* **1993**, *105*, 1173–1180; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1130–1137.

Although as a medical student I heard about the research on phosphorylase, particularly as a result of my friendship with Arda Green, my first "hands-on" experience with this enzyme came after World War II had ended, when I started postdoctoral work in the Coris' laboratory. (My residency training in internal medicine had been interrupted by the war, and although at that time I expected to return to clinical medicine in due course, I had decided to work in a basic science department for a year or two before resuming hospital-based training.) The problem that was given to me by the Coris involved solubility measurements on phosphorylase, and I also studied the effect of protamine and polylysine on the two forms of the enzyme. It was of interest that in the presence of these polyanionic substances, inosinic acid and 5'-AMP were both very effective as activators of phosphorylase *b*. All of these studies on the effects of nucleotides on phosphorylase were carried out before the revelations of Jacob and Monod concerning allosterism and protein conformation and at that time were viewed simply as unexplained phenomenology. Indeed for several years Carl Cori advised against my publishing these findings unless I could explain them. Eventually, after Neil Madsen found that protamine could physically bind to phosphorylase, which was at least a step in the direction of how it might affect the activity of the enzyme, Cori let me send in my paper.

Although, as I have pointed out, knowledge with respect to the properties of phosphorylase as an enzyme increased significantly during the 1940s, it was often difficult to explain their physiological importance. This can be understood if one considered what was known about glycogen metabolism at that time. The epochal work of Leloir on the mechanism of glycogen synthesis was still to come, that is, the role of uridinediphosphate (UDG) in polysaccharide synthesis and the existence of the enzyme glycogen synthase were completely unknown. Hence, it was believed that phosphorylase is involved in glycogen synthesis as well as in glycogenolysis (Fig. 2). It was assumed that the direction of the phosphorylase reaction would be determined by the concentrations of the components of the reaction, particularly by the concentration of inorganic phosphate (P_i). This situation obviously made it difficult to interpret findings relating to the interconversion reactions of phosphorylase *a* and *b*. Nonetheless, in the late 1940s and the early 1950s a clear story was beginning to emerge with respect to the action of the glycogenolytic hormones, glucagon and epinephrine, and their effects on interconversion of the forms phosphorylase as studied in liver cells. Earl Sutherland, working initially in the Coris' laboratory and later independently at Western Reserve University, found that epinephrine and glucagon caused the rapid conversion of liver phosphorylase *a* to phosphorylase *b*,[5] and it was also shown that epinephrine caused the same change in the muscle diaphragm.[6] Inasmuch as epinephrine and glucagon were known to be glycogenolytic hormones, Sutherland's findings clearly supported the concept that the activation of phosphorylase is associated with glycogen degradation. Why then, should electrical stimulation and muscle contraction, which were also known to result in glycogenolysis, be associated with the conversion of phosphorylase *a* to the inactive form, phosphorylase *b*?[4]

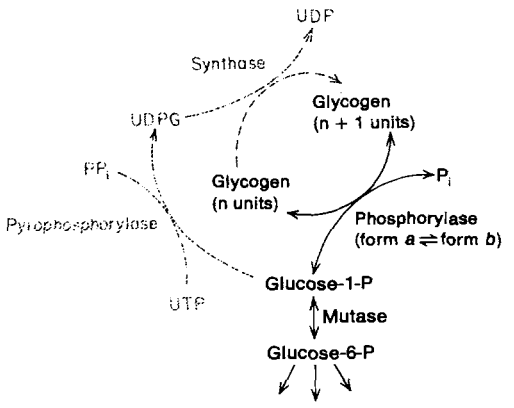

Fig. 2. Glycogen metabolism as depicted circa 1945. The stippled portion of the metabolic scheme was unknown. It was assumed that glycogen synthesis and degradation were catalyzed by phosphorylase and that the direction of the reaction was determined by the concentration of reaction components. Within the cell, phosphorylase was believed to shuttle back and forth between forms *a* and *b*, but the chemical nature of the interconversion reaction was unknown. Conversion of phosphorylase *a* to *b* had been demonstrated in vitro.

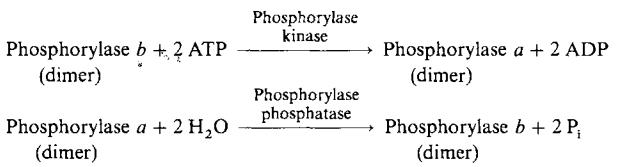
Conversion of Rabbit Skeletal Muscle Phosphorylase *b* to Phosphorylase *a* In Vitro

In Fall 1953, Ed Fischer joined the Department of Biochemistry at the University of Washington, where I was already a faculty member. As a graduate student in Geneva, Ed had worked on potato phosphorylase, and we thus shared a common interest in this particular enzyme. We discussed some of the puzzling features of phosphorylase and were particularly intrigued by the still-unsolved nature of the 5'-AMP effect, that is, how 5'-AMP activates phosphorylase *b* but is seemingly unnecessary for phosphorylase *a*. It seemed worthwhile purely as a secondary undertaking for each of us, since we both had problems that we considered as our major areas of concentration, to pool our efforts to see whether or not we could obtain information on this point. The initial experiment that we undertook together was simply to prepare pure crystalline phosphorylase *a* by the Coris' procedure.[7] However, our initial attempts to do this were woefully unsuccessful. The enzyme would not crystallize, a step that was essential in order to obtain pure protein. More puzzling was the fact that the partially pure enzyme, which we did obtain, was always in the *b* form rather than the *a* form. Insofar as we could determine we had followed the Coris' procedure exactly except that we had clarified the original muscle extract by centrifugation rather than by filtration through paper. Although this seemed like a trivial change, we nonetheless included the filtration step in our next preparation. To our surpise, this time we obtained phosphorylase *a*, which crystallized readily as it was supposed to do. Two conclusions could be drawn that would explain these results. First, "resting" rabbit muscle extracts must contain phosphorylase predominantly in the *b* form rather than the *a* form as had been postulated by the Coris,[4, 8] and second, filtration of muscle extracts through paper must trigger conversion of phosphorylase *b* to *a* in vitro.[9] Subsequently, we found that thorough washing of the filter paper before use eliminated conversion of *b* to *a*, implying that some component in the paper must have been extracted to account for the effect. It was also found that this conversion failed to occur if the muscle extract were aged prior to filtra-

tion. The critical component from the filter paper that was required in the *b*-to-*a* step was shown to be calcium ions, and the essential component in the extract that was lost on aging was found to be ATP.

Armed with the knowledge that there is an ATP requirement for conversion of phosphorylase *b* to phosphorylase *a*, we thought it likely that we were dealing with a phosphotransferase reaction in which the terminal phosphoryl group of ATP is being transferred either to the protein itself or possibly to a nonprotein component bound to the enzyme. It soon became apparent data a "converting enzyme", which could be separated that phosphorylase *b*, was required in the reaction.[10] After it had been determined that ADP as well as phosphorylase *a* were products of the reaction,[11] we spoke of this enzyme as phosphorylase *b* kinase, or simply phosphorylase kinase, rather than converting enzyme.[11] The nature of the Ca^{2+} requirement for the *b*-to-*a* reaction was not apparent immediately, but eventually it was determined by one of our graduate students, William L. Meyer, that the effect of this metal ion was twofold. On the one hand, Ca^{2+} was needed for the activation of a kinase activating factor (KAF), but in addition it was also required for the activity of phosphorylase kinase itself.[12] KAF was later shown to be a Ca^{2+}-dependent protease by another student, R. Bruce Huston.[13] (The current name for this protease is calpain.) We determined the stoichiometry of the conversion of phosphorylase *b* into phosphorylase *a*[11] and also obtained the amino acid sequence surrounding the phosphorylated serine in phosphorylase *a*.[14] It was demonstrated that inorganic phosphate is released in the muscle phosphorylase *a*-to-*b* reaction catalyzed by the PR enzyme, which could now be termed phosphorylase phosphatase. Thus, by the late 1950s, it was possible to write specific equations for the interconversion reactions of muscle phosphorylase (Scheme 1).



Scheme 1.

During the same period that our work on the muscle phosphorylase system was being carried out, very similar studies relating to liver phosphorylase were being conducted independently in the laboratory of Earl Sutherland at Western Reserve University. Sutherland's major co-workers in this effort were Walter D. Wosilait and Theodore W. Rall. In an early study[15] these investigators obtained evidence that inorganic phosphate was released when partially purified active liver phosphorylase was incubated with what they referred to as inactivating enzyme, and they also determined that phosphate was incorporated into phosphorylase when liver slices were incubated in the presence of ^{32}P-phosphate. Later they showed that both of the interconversion reactions of liver phosphorylase could be demonstrated in cell-free systems.[16, 17] A monumental "ancillary finding" that grew out of the work on liver phosphorylase by the Sutherland laboratory was, of course, the discovery of cyclic AMP, the first identified "second messenger" of hormone action.[18]

It is of interest to consider whether there had been any indications that the phosphorylation and dephosphorylation of proteins might be of regulatory significance prior to elucidation of the muscle and liver phosphorylase systems. The existence of phosphoproteins had, of course, been known for many years before 1950. Phosphoproteins were classified as "conjugated proteins" and for the most part consisted of proteins of nutritional significance associated with the feeding of the young, for example, casein in milk and several phosphoproteins found in egg yolk. Interestingly, it was also appreciated that pepsinogen contained one mole of firmly bound phosphate per mole of enzyme, but the significance of this was not (and still is not) known. It was also known that nonspecific phosphatases could catalyze the release of phosphate from phosphoproteins. In an important study that was carried out at about the same time as the work on phosphorylase was underway, Burnett and Kennedy described an enzyme that catalyzed the phosphorylation of casein.[19] These workers were aware of the high rate of turnover of phosphate in proteins and were the first to describe a protein kinase. In general, however, the realization that protein phosphorylation–dephosphorylation is a dynamic process affecting enzymes and that it is important in the control of metabolism and other cellular processes had not been foreseen.

Protein Phosphorylation and the Transmission of Extracellular Signals

As we have seen, an interest in the mechanisms of action of epinephrine and glucagon had an important part in work on the interconversion reactions of phosphorylase,[5, 6] which in turn led to the discovery of the dynamic phosphorylation and dephosphorylation of proteins. Going back even further, however, it can be noted that the original studies of the Coris, which led to the finding of phosphorylase itself, grew out of the longstanding interest of these investigators in the role of epinephrine in the regulation of glycogen metabolism.[20] That an interest in hormone action would contribute importantly to the development of the field of protein phosphorylation–dephosphorylation was no accident, since we now know that one of the major functions of protein phosphorylation as a regulatory process is in the transmission of signals that impinge on cells. This is true not only with respect to the transduction of hormone and growth factor signals but for other types of stimuli as well. For example, as mentioned earlier, electrical stimulation of muscle leads to changes in protein phosphorylation within the cell. It is probably more than coincidental that the extent of protein phosphorylation is much greater in eukaryotic cells than it is in prokaryotes, particularly in eukaryotic cells of higher animals that are subject to complex forms of external regulation.

It was apparent very early on that the relative amounts of phosphorylase *a* and *b* that are present within the cell at any particularly time depend on the relative rates of the phosphorylase kinase and phosphatase reactions, and it was anticipated that one or both of these enzymes must be subject

to regulation. Furthermore, two factors capable of influencing the balance between the two forms of phosphorylase had been found. As noted, these were calcium ions, identified as the metal ion that caused phosphorylase *a* formation in muscle extracts,[9] and cyclic AMP, which promoted phosphorylase *a* formation in liver cells and homogenates (reviewed in ref.[21]). We subsequently showed that cyclic AMP would also cause phosphorylase *a* formation in muscle extracts.[22] In the muscle system it was determined that the effects of Ca^{2+} and cyclic AMP in stimulating phosphorylase activation in vitro were a result of phosphorylase kinase activation rather than phosphorylase phosphatase inhibition.[11]

The Coupling of Muscle Contraction to Glycogenolysis

The finding that the major form of phosphorylase present in resting muscle is phosphorylase *b*[8] rather than phosphorylase *a*,[4, 7] together with the realization that phosphorylase *b* can be converted to phosphorylase *a* if Ca^{2+} is introduced into muscle extracts containing ATP,[9] made it possible to arrive at a rational position with respect to the effect of electrical stimulation on phosphorylase. In 1956[23] Cori was able to demonstrate that muscle contraction causes conversion of phosphorylase *b* to *a*, rather than the other way around; this was in keeping with the known effect of contraction on glycogen breakdown. The effect of Ca^{2+} on the activation of phosphorylase kinase now fit well into a scheme (Fig. 3), whereby this metal ion, acting as a messen-

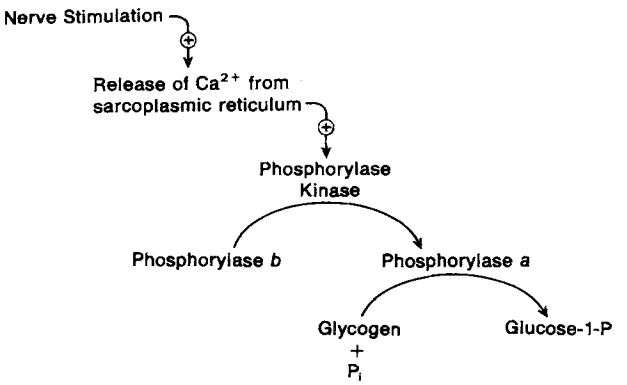


Fig. 3. The role of calcium ions in regulating glycogenolysis (ca. 1962).

ger substance associated with muscle contraction, could be responsible for the coupling of glycogenolysis (an energy-yielding process) to contraction (an energy-utilizing process). Of the two different mechanisms by which Ca^{2+} could regulate phosphorylase kinase, through limited proteolysis involving KAF or as a result of the requirement of phosphorylase kinase for Ca^{2+} per se,[12] only the latter was considered to be physiologically significant. The work of Ozawa et al.,[24] who quantified the effect of Ca^{2+} on the phosphorylase kinase reaction, was critical with respect to our understanding of this process. Many years later the actual mechanism by which Ca^{2+} stimulates phosphorylase kinase became apparent when it was found that calmodulin is a subunit of phosphorylase kinase.[25]

The Mechanism of Action of Cyclic AMP and the Cyclic AMP Dependent Protein Kinase

The mechanism by which cyclic AMP causes an increase in phosphorylase kinase activity turned out to be more complex than that of Ca^{2+}. Whereas Ca^{2+} is an essential activating component in the phosphorylase *b*-to-*a* reaction itself, cyclic AMP causes activation of phosphorylase kinase by promoting its phosphorylation. The first clue that phosphorylation might be involved in the activation of the kinase came with the finding that ATP is required in order to observe the activation reaction and the cyclic AMP effect in rabbit skeletal muscle extracts.[22] A key co-worker who carried out the initial experiment that revealed this requirement was a graduate student, Donald A. Graves. Activation of muscle phosphorylase kinase was characterized by marked enhancement of its activity as measured at pH 7 or below, and only moderate increases in activity were seen when the *b*-to-*a* reaction was carried out at higher pH values. The ratio of activity at pH 6.8 to activity at pH 8.2 was found to serve as a useful index of the state of phosphorylase kinase activation.[26] Significantly, once phosphorylase kinase had been activated by preincubation with ATP, the presence of cyclic AMP was no longer essential—as might be anticipated if the kinase were being modified covalently in an activation process stimulated by cyclic AMP.[22]

Phosphorylase kinase was purified extensively and obtained as a nearly homogeneous high molecular weight protein ($M_r = 1.2 \times 10^6$), which still retained the ability to be activated by preincubation with MgATP in a reaction that was strongly stimulated by cyclic AMP. Although there were indications that a second protein kinase might be involved in the activation process,[27] the kinetics of the reaction were complex and the work of DeLange et al.[28] suggested instead that an autocatalytic reaction was occurring. However, the existence of a separate "cyclic AMP dependent phosphorylase kinase kinase", which accompanied phosphorylase kinase kinase during its purification, was eventually established by Donal A. Walsh and John P. Perkins, postdoctoral fellows in my laboratory.[29] They succeeded in concentrating the new kinase about 200-fold from rabbit muscle extract and separated it completely from phosphorylase kinase. The kinase was referred to as the "cyclic AMP dependent protein kinase" rather than phosphorylase kinase kinase, because it was found[29] to have a broader specificity than would have been implied by use of the more restrictive name. In retrospect, the cyclic AMP dependent protein kinase probably represents the same activity reported by Huijing and Larner[30] to be involved in cyclic AMP stimulated glycogen synthase phosphorylation. The finding of a cyclic AMP dependent protein kinase separable from phosphorylase kinase made it possible to construct a complete cascade mechanism showing the effect of epinephrine on glycogenolysis (Fig. 4). This was the first example of a protein kinase cascade in which one protein kinase is phosphorylated and activated by another. Despite the potential usefulness of a cascade device (amplification of the signal, provision of branch points, etc.) very few other examples have been reported. Recently, however, a complicated multistep protein kinase cascade related to the action of numerous growth factors has been detected; this will be discussed at the end of this lecture.

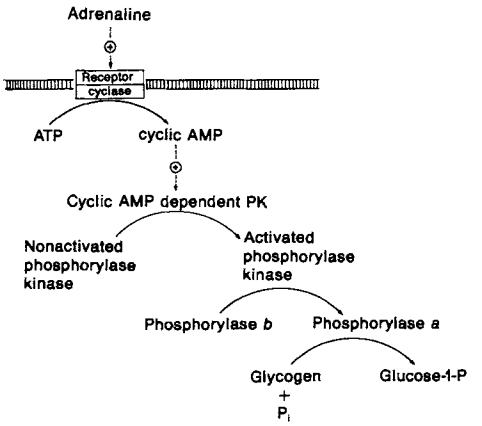

Fig. 4. The regulation of glycogenolysis by epinephrine (adrenaline).

The cyclic AMP dependent protein kinase has served as a prototype for studies on protein kinases in general. This kinase is made up of regulatory (R) and catalytic (C) subunits and has the general structure R_2C_2. In the next lecture Ed Fischer will speak about the mechanism by which cyclic AMP regulates the activity of the kinase. The catalytic subunit of this enzyme was the first protein kinase for which the complete amino acid sequence was determined,[31] and it was also the first protein kinase to have had its X-ray crystallographic structure elucidated.[32] The cyclic AMP dependent protein kinase also played a very significant part in our understanding of protein kinase specificity, which has become increasingly important as the number of known kinases has skyrocketed. Although it will not be possible to do more than touch on this latter topic here, it can be noted that the cyclic AMP dependent protein kinase was the first kinase for which a "consensus" phosphorylation site sequence was clearly recognized.[33-37] This sequence, Arg-Arg-X-Ser-X, is found in many, but not all, substrates for the cyclic AMP dependent protein kinase. In connection with the specificity studies that were carried out within my own laboratory, I would like to call particular attention to the work of David B. Bylund and Bruce E. Kemp.

A Protein Serine/Threonine Kinase Cascade Activated in Response to Insulin and Related Growth Factors

One of the enduring problems in endocrinology has been the question of the mechanism of action of insulin. Indeed, investigators have been interested in this area for decades, and over the years information on this subject has gradually accumulated through the application of whatever tools became available. At first, experiments were carried out with animals, later with perfused organs, eventually with isolated tissues such as the muscle diaphragm, and finally with cells in culture. Until comparatively recently it had not been possible, however, to demonstrate a meaningful insulin response in homogenates or other types of cell-free systems. Approximately ten years ago, however, it was found that the EGF receptor (EGF = epidermal growth factor) is a protein tyrosine kinase, and shortly after that it was determined that this is also true for the insulin receptor.[38,39] Now it is known that eight or nine different growth factor receptors are protein tyrosine kinases. These findings ushered in a new era of research with respect to insulin and related hormones and growth factors. However, although most workers in the field felt that it would now be a simple matter to identify meaningful substrates for these receptor/kinases and to elucidate the complete intracellular signal transduction pathway involved, this did not occur. Several tyrosine-phosphorylated proteins were found in cells treated with insulin or the other growth factors, but none of these proteins could at first be readily connected with the known cellular actions of the growth factors involved. Nonetheless, it was clearly demonstrated that the protein tyrosine kinase activity of these receptors is essentially for their action, and there was little if any doubt that initiation of their signals must involve ligand-stimulated tyrosine phosphorylation.

An investigator who is interested in determining the steps of a signal transduction pathway can either work "downstream" from a receptor in order to identify components of the pathway, or he can work "upstream" toward the receptor starting with a well-established cellular effect of the growth fact in question. A number of laboratories, including my own, which are interested in signaling from the insulin or related receptors, have used the latter strategy in their approach. The particular cellular effect that these groups have chosen as their starting point has been the activation of protein serine and threonine kinases, which results from the simulation of tyrosine kinases. It has long been known that the stimulation of protein tyrosine kinases in cells results in changes in serine/threonine phosphorylation as well as in changes in tyrosine phosphorylation, but the mechanism involved in the coupling of the two types of protein phosphorylation has been unknown.[40]

One of the cellular proteins that is readily phosphorylated on serine residues in response to the stimulation of receptors having protein tyrosine kinase activity is ribosomal protein S6, although the role of this phosphorylation insofar as the regulation of protein synthesis is not clear. This phenomenon had been discovered a number of years before, prior to the involvement of my own laboratory in the problem, and a good start had already been made in identifying components involved in regulating S6 phosphorylation. For example, it had been shown that in adipocytes or Swiss 3T3 cells stimulated by insulin an S6 kinase becomes activated,[41,42] and there was good evidence that the activation was due to covalent modification, in other words, phosphorylation. It was determined that the protein serine/threonine phosphatases would inactivate the activated proteins.[43,44] Maller and co-workers had shown that an S6 kinase (S6 kinase II), purified to homogeneity from *Xenopus laevis* eggs, could also be inactivated by protein phosphatases.[45] Importantly, this latter S6 kinase could be reactivated by a different protein serine/threonine kinase, microtubule-associated protein 2 kinase (MAP kinase), which was known to be stimulated by insulin treatment of 3T3 L1 cells.[46] These results strongly suggested the existence of a protein serine/threonine kinase cascade in which one growth-factor-activated protein kinase phosphorylated and activated a second protein kinase. Gregory et al.[47] confirmed these findings using a phosphatase-treated S6 kinase from rabbit liver and MAP kinase from insulin-stimulated rat 1 HIR_c B cells. Then in our laboratory we showed that an EGF or insulin-

stimulated MAP kinase from Swiss 3T3 cells could phosphorylate and activate an S6 kinase obtained from this same cell type.[48] MAP kinase, in its active form, appeared to have been activated as a result of serine/threonine phosphorylation, since it could be inactivated by protein phosphatase 2A. This suggested the existence of even a third protein serine/threonine kinase in this growth factor stimulated process.

A finding of major significance from Sturgill's laboratory was the fact that MAP kinase in its active form contains phosphotyrosine as well as phosphothreonine, and that in addition to being inactivated by protein phosphatase 2A, it can also be inactivated by CD45, a protein tyrosine phosphatase.[49] These investigators went on to show that phosphorylation of MAP kinase on tyrosine and threonine is essential for its activity, and it seemed likely that two different types of protein kinase, a protein serine/threonine kinase and a protein tyrosine kinase, would be involved as upstream components in its activation. There was no evidence, however, that a receptor-type protein tyrosine kinase could serve as either one of these kinases. It was thus of great interest to search for an enzyme or enzymes, MAP kinase kinases, that would catalyze MAP kinase phosphorylation and activation.

In our laboratory Natalie Ahn et al.[50] discovered two separable protein factors from Swiss 3T3 cells that catalyzed the activation of an inactive form of MAP kinase in vitro. Each of these factors required the presence of MgATP in order to bring about activation of MAP kinase, and it did not matter whether the latter had first been inactivated by a protein serine/threonine phosphatase or by a protein tyrosine phosphatase. This made it appear probable that the factors were "dual specificity" kinases capable of phosphorylating proteins or serine and threonine residues as well as tyrosine residues. The existence of such kinases had, in fact, been found in yeast. At first we hesitated to call the activating factors "MAP kinase kinases", because in work carried out by Rony Seger et al.[51] we had determined that MAP kinase can undergo a slow but distinct autophosphorylation reaction, in other words, that it can catalyze its own phosphorylation, and that in this reaction threonine and tyrosine residues are phosphorylated. Moreover, autophosphorylation resulted in activation of the kinase. This result made it appear possible that a MAP kinase kinase as such might be unnecessary and that the next "upstream" component could be a protein activator that simulated autophosphorylation. Eventually it was shown, however, that the MAP kinase activators were, in fact, protein kinases capable of phosphorylating a mutant form of MAP kinase that lacked enzymic activity.[52, 53] Moreover, amino acid sequence data obtained in our laboratory and elsewhere, showed that the activators contain protein kinase sequence motifs. Later, similar "activators", MAP kinase kinases, were found in PC12 cells stimulated by nerve growth factors or bradykinin.[54, 55] Gomez and Cohen showed that activated MAP kinase kinase could be inactivated by a protein serine/threonine phosphatase but was not affected by protein tyrosine phosphatases.[54] This latter result indicated that an additional "upstream" protein serine/threonine kinase, in other words a MAP kinase kinase kinase, was probably a component of the pathway. The present status of the MAP kinase cascade, without the putative MAP kinase kinase kinase, is shown in Figure 5.

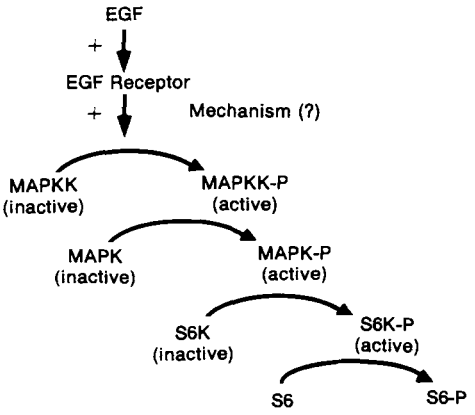

Fig. 5. The MAP kinase cascade. EGF = epidermal growth factor, MAP = microtubule-associated protein, K = kinase, SG = ribosomal protein S6.

Intense effort on the part of many different laboratories is currently centered on the question of the identity of MAP kinase kinase kinase and the mechanism by which such an enzyme might be regulated. It was reported by Kyriakis et al. that Raf-1 activates MAP kinase kinase and thus might itself be a candidate for the kinase kinase kinase.[56] This result was confirmed by Dent et al.[57] Other studies have implicated the possibility that cdc2 might be an "upstream" component of the MAP kinase cascade but not an immediate kinase kinase kinase itself.[58] Finally, there is considerable evidence that p21 ras is a component acting at some site between the receptor and the components of the cascade as currently identified.[59-62] A somewhat neglected area of study with respect to the MAP kinase cascade relates to the question of its precise function and the reasons for the existence of such a complicated scheme. It is probable that numerous substrates may exist for each of the protein kinases in the cascade, and in this connection it is noteworthy that a number of transcription factors appear to be targeted by MAP kinase and by the S6 kinase. The different kinases may also have specific metabolic enzyme targets that have not as yet been identified. Finally, some of the kinases may branch off and regulate still other kinases.[63]

Conclusion

In this talk I have reviewed the early work on the interconversion reactions of the two forms of glycogen phosphorylase and phosphorylase kinase. A third enzyme that played an important part in early work on protein phosphorylation–dephosphorylation was glycogen synthase. Much of the original research on that enzyme was carried out by Joseph Larner and his associates during the early 1960s. These investigators found that, in contrast to the effect of phosphorylation on phosphorylase and phosphorylase kinase, phosphorylation caused a decrease in the activity of the synthase. Because of the "field" of protein phosphorylation during the first ten years was dominated by those interested in glycogen metabolism, some even expressed the idea that perhaps regulation of enzymes by phosphorylation–dephos-

phorylation might be restricted to this area. However, the finding of a multifunctional cyclic AMP dependent protein kinase, which was almost immediately shown by Kuo and Greengard[64] to be very widespread in nature, served to change this concept. Another important finding that dispelled the idea that protein phosphorylation was very limited in scope was the report that pyruvate dehydrogenase is regulated by phosphorylation.[65] As can be noted in Figure 6, the number of enzymes reported to undergo regulation as a result of being phosphorylated started growing precipitously in 1970. If reports on protein phosphorylation involving nonenzymic proteins were included, the growth curve in Figure 6 would be even steeper. In the next talk Ed Fischer will

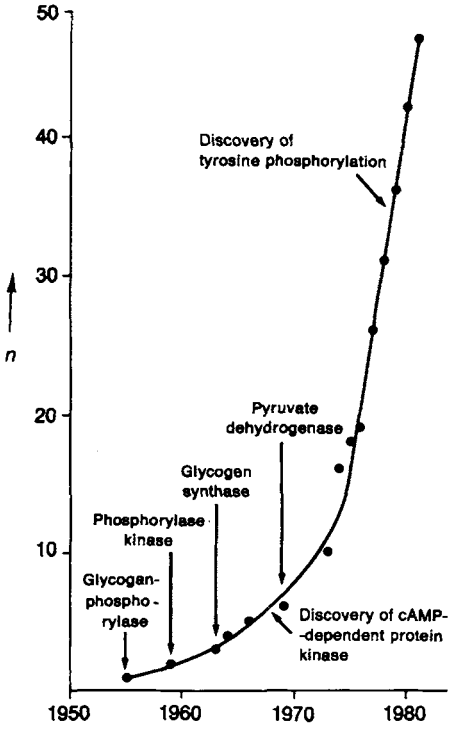

Fig. 6. Growth in an awareness of protein phosphorylation as a mechanism for regulating enzymes. The total number n of enzymes reported to undergo phosphorylation-dephosphorylation is plotted against years.

trace some of the developments that have contributed to this explosion. I anticipate that he may also "correct" some of the errors that I may have made in my historical account of our work together.

I would like to dedicate this lecture to my parents, who had the education of their children as a major goal in their lives, and to my wife, Deedy, who has always been extremely supportive of my work. In addition, I recognize the very important contributions made by numerous talented students and postdoctoral fellows, some of whom are not mentioned here, who for the most part carried out the actual experiments reported here, and in addition helped to provide direction for many of the studies that are reported.

Protein Phosphorylation and Cellular Regulation II (Nobel Lecture)**

By Edmond H. Fischer*

Introduction

In the preceeding contribution,[***] Ed Krebs retraced the early history of glycogen phosphorylase and its regulation by reversible phosphorylation. In retrospect, we were extraordinarily lucky in more ways than one to have selected this particular enzyme to work on. First, it is extremely abundant in skeletal muscle so that material was never limiting. In fact, when 20 years later, we undertook its total amino acid sequence with Ko Titani and Ken Walsh,[1] we used no less than 10 grams of the crystalline enzyme to complete the analysis. Second, the phosphorylation reaction was unambiguous, converting a totally inactive enzyme into a fully active species. Third, the phosphorylation ran to completion, introducing 1 mole of phosphate per mole of enzyme subunit. Fourth, only one site became phosphorylated; and fifth, this site occurred within a loose N-terminal arm of the molecule that could be easily cleaved by limited proteolysis, leaving behind the bulk of the enzyme intact. This made it easy to separate the phosphopeptide and determine its structure,[2] though it took a long time, since in the mid fifties sequences had to be carried out by paper chromatography. We could show that a single seryl residue had been phosphorylated (Fig. 1). Incidentally, it took another five years to

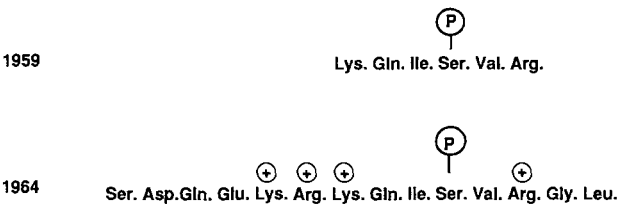

Fig. 1. Sequence of the site phosphorylated during the phosphorylase *b* to *a* reaction.

extend this sequence by nine residues.[3] The longer structure showed the presence of several positive charges, mainly upstream, and forming those recognition motifs whose significance became apparent only later.[4, 5]

The phosphorylation reaction was so straightforward and simple that there was no doubt in our minds that it would represent the prototype for such kinds of interconversions. As it turned out, it was really the exception. Six years went by before Joe Larner et al. identified the next enzyme to be regulated by phosphorylation–dephosphorylation, namely, glycogen synthase.[6] He found that this enzyme was inactivated rather than activated by phosphorylation,[7] which made sense: closing off the backward reaction when the forward one is turned on guarantees that there would be no recycling of the system that would inevitably result in a useless expenditure of energy. Joe Larner rapidly found, however, that far more than one phosphate was introduced during the interconversion;[8] about six per mole of synthase. At that time, the idea that a single phosphorylation event was all that was needed to alter the state of activity of an enzyme was so ingrained that I remember that we thought: "How can this be possible? It would imply that glycogen synthase is made up of six identical subunits, each of approximately 15000 molecular weight." And Joe Larner himself thought along these lines.[8, 9] Of course, we know today from his work as well as that of Phil Cohen,[10] Peter Roach,[11] and others, that the enzyme is phosphorylated on no less than seven sites by seven different protein kinases, all totally unknown at that time (Fig. 2). Furthermore, some of these

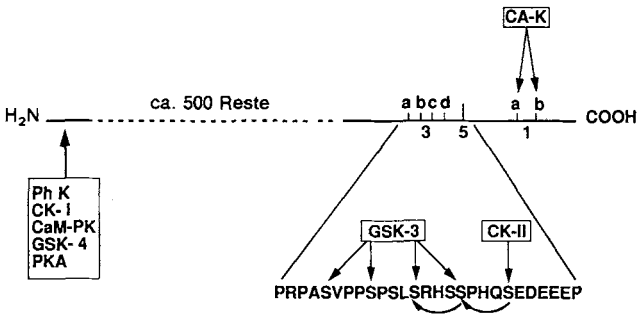

Fig. 2. Major phosphorylation sites in glycogen synthase. PhK, phosphorylase kinase; CK, casein kinase; CaM-PK, multifunctional calcium/calmodulin-dependent kinase; GSK, glycogen synthase kinase; PKA or CA-K, cAMP-dependent protein kinase (from ref. [11]).

phosphorylation events follow a most complicated program of successive reactions that have to proceed in a strictly prescribed order. The enzyme is inhibited by phosphorylation by glycogen synthase kinase 3 (GSK-3) but not until a first phosphate is introduced by casein kinase 2 (CK-2). This then allows phosphorylation of the next residue, then the next and the next after that until all sites are finally occupied.[12] Imagine the incredible difficulties we would have encountered had we decided to study this enzyme rather than phosphorylase.

We did not know at that time whether the phosphorylation reaction was a unique occurrence, a rare event restricted to the control of these two enzymes, or perhaps to carbohydrate metabolism. It was well known, for example, that during glycogenolysis, inorganic phosphate was picked up from the medium and used for the production of many sugar phosphate intermediates. Could nitrogen metabolism be reg-

ulated by another type of covalent modification, for instance, amidation/deamidation, or lipid metabolism by acetylation/deacetylation? Or had we discovered a more general type of reaction that would apply widely to many different systems. Once again, as luck would have it, reversible protein phosphorylation turned out to be one of the most widespread mechanisms by which cellular processes can be regulated.[13, 14]

Allosteric and Covalent Regulation

Here, a question should be raised. Ed Krebs already mentioned that phosphorylase could also be activated by AMP. Why are two mechanisms required to control the activity of an enzyme when, in both cases, they lead to an active conformation (Fig. 3)? According to the allosteric model proposed

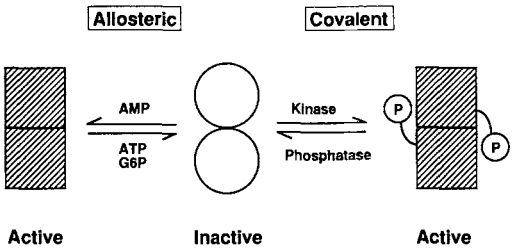

Fig. 3. Allosteric and covalent regulation of phosphorylase.

by Jacques Monod in the early 1960s, the enzyme responds to effectors that are generated during the normal maintenance of the cell and reflect its overall internal condition: is it proliferating or quiescent, actively metabolizing or not, what is its energy balance like, that is, its ratio of AMP to ATP, etc. According to the rule that enzymes are subjected to end-product or feed-back inhibition, phosphorylase would be expected to be inhibited by glucose-6-phosphate (G6P) that accumulates during its reaction, and by ATP, the ultimate end product of carbohydrate metabolism. By the same token, it would be activated by AMP as indeed it is. But then, many enzymes of carbohydrate metabolism would be similarly affected by the same effectors; in proceeding down the metabolic path, all these "doors" would become open at the same time. By contrast, the kinase reaction is highly specific: it allows the activation of phosphorylase only without affecting the activity of any other enzyme. Furthermore, and this is perhaps one of the major lessons we have learned over the last 30 years, covalent regulation responds mainly to extracellular signals (Fig. 4). These external signals come in the form of hormones, or neurotransmitters, growth factors, and other stimuli such as drugs, light, odorants, and perhaps touch in plants. Each signal will act on its own membrane receptor and either cause the release of second messengers (cAMP, cGMP, Ca^{2+}, diacylglycerol (DAG), inositol triphosphate (IP3), etc.) in reactions regulated by G-proteins, or induce the intrinsic tyrosine kinase activity of the receptors themselves. These second messengers or internal signals will act on kinases or phosphatases, then on target enzymes to finally elicit a physiological response. One finds here all the elements of a cascade system such as those described by Ed Krebs: enzymes acting on enzymes, resulting in the enormous amplification of an external signal. In addition, it allows the coordinated regulation of different physiological events through the pleiotropic action of some of the enzymes involved.

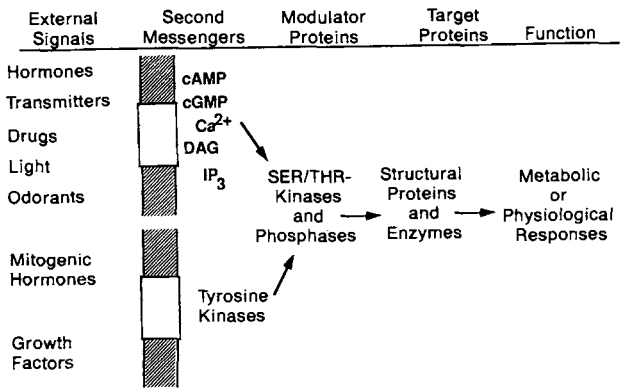

Fig. 4. Control of cellular processes by protein phosphorylation. Cascade systems triggered by extracellular stimuli.

The Protein Kinases

Today, one knows several hundred protein kinases that can be classified according to their mode of regulation or substrate specificity[15] (Table 1). Among the large family of

Table 1. Classification of protein kinases (PKs).

I.	Second messenger-dependent Ser/Thr PKs
A.	cyclic nucleotides: cAMP, cGMP PKs
B.	Ca^{2+}/calmodulin (CaM)-dependent kinase: phosphorylase kinase, MLCK, CaM kinase II
C.	diacylglycerol (DAG)/Ca^{2+}: PKC
II.	Second messenger-independent Ser/Thr PKs
A.	heme-, ds RNA-, (INF)-dependent eIF2 PKs
B.	CK-I, CK-II, GSK-3, S6 kinases
III.	Dual specificity (Ser/Thr and Tyr) PKs MAPK, MAPKK Wee1
IV.	Protein tyrosine kinases (PTKs)
A.	cellular or viral (oncogenic) PTKs
B.	receptor-linked PTKs

Ser/Thr kinases, some are dependent on the second messengers mentioned above, others on specific components of the system that they are called upon to regulate. Such is the case of the heme-regulated kinase that blocks the initiation of globin synthesis when heme or iron comes to be missing, or the double-stranded RNA-dependent kinase that is induced by interferon in cells under viral attack. There are also the so-called "independent kinases" such as the casein kinases for which no precise mode of control has been elucidated as yet.

Next come the mixed-function kinases that can phosphorylate their substrates on both tyrosine or serine/threonine, or that can be regulated by tyrosine and serine/threonine phosphorylation. This is the case for the enzymes that Ed Krebs has recently described:[16] microtubule-associated

protein (MAP) kinase, the MAP kinase kinase, perhaps Raf, or the cell cycle kinases such as $p34^{cdc2}$.[17] They stand guard at crucial crossroads of signal transduction. They form the link between a signaling system that originates at the membrane level and relies on tyrosine phosphorylation, and the more widespread serine/threonine phosphorylation reactions that occur downstream. Their dual control and specificity would ensure that no accidental initiation of important cellular events occurs at inappropriate times, just as one would need two keys to get access to a safety deposit box.

Finally, there is the large class of tyrosine kinases that will be discussed later. Not listed are the less common histidine kinases such as those involved in bacterial chemotaxis[18] and the double-headed kinase/phosphatase that regulates bacterial isocitrate dehydrogenase.[19]

Regulation of Protein Kinases

All these enzymes have homologous catalytic domains but vary greatly in the structure of their regulatory segments. They have consensus sequences, such as the motifs that are involved in the binding of ATP, by which they can be identified by searching the database.[20, 21] Most are regulated by segments that block their activity, often by virtue of the fact that they contain pseudo-substrate motifs that interact with, and shield, their catalytic sites. These autoinhibitory domains can exist on separate subunits as in the cAMP-dependent protein kinase (cAMP PK) first characterized by Ed Krebs, Don Walsh et al.,[22] or within the same peptide chain, as in the cGMP PK, where the two segments have become fused in the course of evolution. Initially, for the cAMP PK, the reaction seemed simple enough: the enzyme exists as an inactive complex between catalytic and regulatory subunits; cAMP induces a change in conformation in the regulatory subunits, resulting in the dissociation of the enzyme and the liberation of active catalytic subunits. It soon became apparent, however, that the inactive complex had a more substantial purpose, namely, to prevent the translocation of the free catalytic subunits to other compartments of the cell, particularly the nucleus.[23] But we know today that the regulation of this enzyme is even more sophisticated: the regulatory subunits themselves contain structural determinants that allow them to recognize and bind with high affinity to anchoring proteins distributed at specific locations within the cell.[24–27] More than two dozen of these have been identified; they are particularly abundant in the brain and the thyroid. Conceivably, some of these could colocalize with particular cAMP-generating receptors. This would confer a certain degree of selectivity to the hormonal response, by targeting the kinase toward a given set of substrates[27] (Fig. 5).

Enzyme translocation may also play an important role in the regulation of protein kinase C first described by Nishizuka et al.[28, 29] Depending on which subspecies of PKC is involved, the enzyme contains up to three regulatory domains responsible for the binding of Ca^{2+}, diacylglycerol, and phospholipids. Binding of these allosteric effectors can promote the translocation of the enzyme to the plasma membrane where it could bind to specific anchoring proteins.[30]

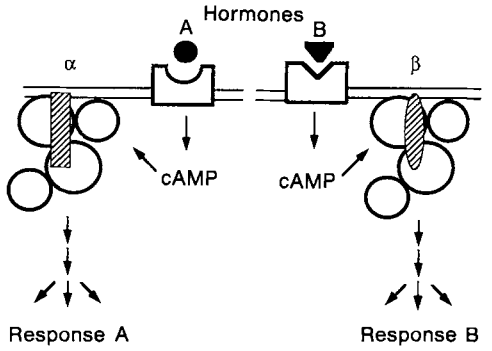

Fig. 5. Hypothetical selectivity in hormonal response by juxtaposition of cAMP-dependent protein kinase anchoring proteins with specific adenylate cyclase receptors.

Once again, this could determine which particular signal pathway would become affected.

Enzyme translocation might also be one of the functions of the cyclins, those regulatory subunits that are transiently expressed during various phases of the cell cycle. They associate strongly with the cell cycle-dependent kinases and operate particularly at the G1/S and G2/M transitions.[31–33] In *S. cerevisiae*, for instance, between four and five dozen cyclins have been identified.[34] While their multiciplicity would provide the cell with the redundancy it needs to protect itself from accidental failures, it would seem unlikely that their sole purpose would be to modulate the activity of the kinases. Some of these complexes must become operative at other set points along the cell cycle. More importantly, perhaps, they could be essential to target the enzymes toward those elements that become operative during the profound cytoskeletal reorganizations that accompany cell division.

Targeting of Serine/Threonine Phosphatases

Targeting subunits are particularly crucial for serine/threonine phosphatases because these enzymes are not geared to recognize specific sequences, or structural determinants within their substrates. Furthermore, unlike the kinases, they consist of just a few types of enzymes that have broad and overlapping specificities.[35–37] Thus they have to depend on regulatory subunits or binding proteins to direct them toward particular compartments of the cell where they will encounter particular substrates. That is the case, for instance, of the type 1 phosphatase whose catalytic subunit can bind to a glycogen-recognizing subunit, a myosin-recognizing subunit, or an inhibitory molecule called Inhibitor 2. In each of these forms, the enzyme recognizes a particular set of substrates. Formation or dissociation of these complexes is under hormonal control.[38–41] This is the theme that I propose to develop in the second part of this lecture, which is devoted to the role of regulatory/localization domains in the function of tyrosine phosphatases.

Protein Tyrosine Phosphorylation

Three remarkable discoveries, 15 years ago, generated considerable excitement in the field of cellular regulation by

protein phosphorylation. First, the finding by the groups of Ray Erickson[42,43] and Varmus and Bishop[44] that the product of the src gene responsible for the oncogenicity of Rous sarcoma virus was a protein kinase they designated as $pp60^{src}$. Second, the unexpected report by Tony Hunter and Bart Sefton that this kinase, unlike all previously known enzymes, phosphorylated its protein substrates exclusively on tyrosyl residues.[45] Third, the nontransforming homologue of v-src,[46-50] that is the cellular c-src, was identified. c-src encodes a product ($pp60^{c\text{-}src}$), which differs from its oncogenic viral counterpart by having, among other discrete mutations, a short extension at the C terminus. This extension carries a phosphotyrosyl residue that keeps the activity of the enzyme under control. Today we know of more than a dozen tyrosine kinases of cellular or viral origin, and their number continues to grow.[15,50]

Finally came the seminal discovery from the laboratory of Stanley Cohen[51,52] that the receptor for epidermal growth factor was itself a tyrosine kinase whose activity was induced by binding of the ligand. Since then, many families of receptors with tyrosine kinase activities have been identified.[53] They all have an external, ligand-binding domain, some with cystein-rich regions, a single transmembrane segment, and a cytoplasmic tyrosine kinase (PTK) domain (Fig. 6).

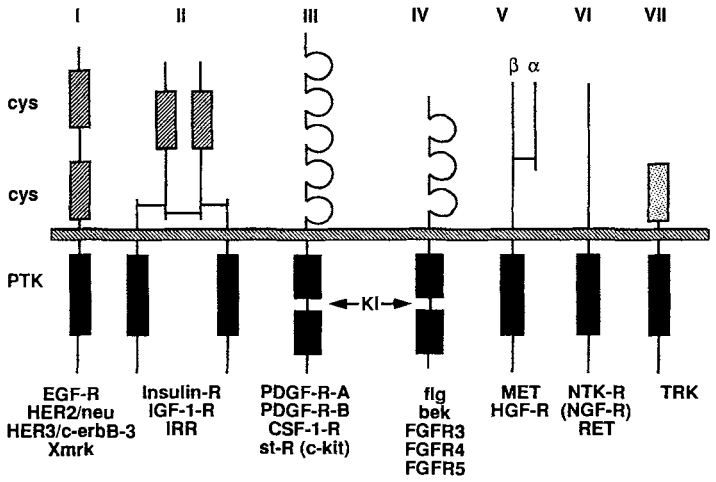

Fig. 6. Growth factor tyrosine kinase receptors.

Just as mutation of the intracellular tyrosine kinases can lead to cell transformation, mutation of the growth factor receptors can lead to oncogenic products. The first to be identified was the retroviral oncogene v-erb B[54,55] generated by a truncation of the external domain of the EGF receptor, its cellular progenitor. Many others have since been cloned and characterized; they usually result from truncation of the molecule at one end or the other or both, fusion with certain viral elements, and other kinds of mutations.

With accumulating evidence implicating tyrosine phosphorylation in cell proliferation and transformation, it is hardly surprising that many groups would become interested in the enzymes that would catalyze the reverse reaction, namely, the protein tyrosine phosphatases.

Protein Tyrosine Phosphatases

First evidence for phosphotyrosine dephosphorylation was obtained by Graham Carpenter and Stanley Cohen[51,56] by using A431 cell membranes overexpressing the EGF receptor, and allowing these to undergo autophosphorylation, and then monitoring their rate of dephosphorylation. Similar observations were made by Bart Sefton and Tony Hunter by using cells transformed with a temperature sensitive mutant of Rous sarcoma virus.[57] Then followed a flurry of studies by a number of groups, including our own six years ago.[58-60] The work was originated with Nick Tonks, a superb Post Doctoral Fellow and second generation Seattleite, since he had just obtained his PhD with Phil Cohen at Dundee, who himself had been in our laboratory some 20 odd years before. When we started, we also assumed that if transformation could be brought about by overexpression of the tyrosine kinases, or mutations that would render them constitutively active, then overexpression of the phosphatases might block or reverse these reactions. This assumption was too simplistic.

Within a couple of years, a tyrosine phosphatase was isolated in homogeneous form from human placenta.[61,62] The enzyme was totally specific for phosphotyrosyl residues and extremely active. It had a specific activity about one order of magnitude higher than most viral tyrosine kinases and up to three orders of magnitude higher than certain receptor tyrosine kinases. This high activity suggested that it had to be tightly regulated to allow for those mitogenic signals that are necessary for normal cell development.

The Leukocyte Common Antigen, CD45: A Tyrosine Phosphatase

The surprise came when the amino acid sequence of the enzyme was determined by Ken Walsh and Harry Charbonneau because it showed no homology with any of the other protein phosphatases.[63] However, a search of the data base indicated that the enzyme was structurally related to an abundant and already well-known surface antigen, the leukocyte common antigen also designated as CD45[64] (Fig. 7). The leukocyte common antigen represents a broad

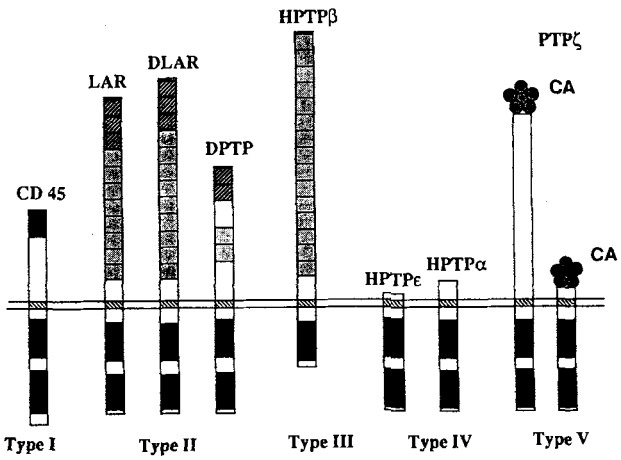

Fig. 7. Tyrosine phosphatase receptors.

family of membrane-spanning molecules found in all hematopoietic cells except mature erythrocytes.[65] Their intracellular moiety is highly conserved and contains two homologous domains of approximately 30 kDa each. It is those two domains that are structurally related to the placenta phosphatase. CD45 has been implicated in the regulation of lymphocyte function, including cytotoxicity, proliferation, and differentiation and in modulating interleukin-2 (IL2) receptor expression.

Here, I must open a parenthesis with biblical overtone. Had we obtained the sequence of the placenta phosphatase before that of CD45 was determined, nobody would have paid much attention—and we neither—because it would just have been the sequence of another enzyme. And it is those working on CD45—Ian Trowbridge, Allen Williams, Matt Thomas, etc.—who, once they got their sequence and searched for it through the data base, would have made the surprising observation that their receptor was, in fact, a tyrosine phosphatase. What this means is that in this business, it really pays to be last, precisely as recorded in the Gospel which states that "The last shall be first and the first last".

Since then, a great variety of receptor forms have been identified.[58-60] All but one display the same double catalytic domains in their cytoplasmic portion, but considerable diversity in their external segments (Fig. 7). Some have structural characteristics of cell adhesion molecules such as the leukocyte common antigen-related (LARs) first cloned by Saito and Schlossman. They are related to the Neural Cell Adhesion Molecules (N-CAMs) and fasciclin II, suggesting that they might be involved in homophilic cell–cell interactions and perhaps modulate morphogenesis and tissue development. Others contain fibronectin type III repeats and might be involved in cell–cell or cell–matrix signaling. Some have very short external domains. Perhaps the most intriguing receptors are the ones recently cloned independently by Schlessinger et al.[66] and Saito et al.[67] At the end of an external segment, one finds a large globular domain almost identical to carbonic anhydrase (CA) except that it contains only one of the three histidines involved in the binding of Zn^{2+}. Except for CD45, no ligand has been found for any of these structures.

The Intracellular Tyrosine Phosphatases in Cell Cycle Progression and Transformation

Likewise, the low molecular weight, intracellular protein tyrosine phosphatases (PTPs) display a great diversity of structures, either preceding or following a highly conserved catalytic core. These are undoubtedly involved in the regulation and localization of the enzymes (Fig. 8). Some PTPs have segments homologous to cytoskeletal proteins such as band 4.1, ezrin, and talin; others contain two src-homology 2 (SH2) domains which might allow them to interact with phosphotyrosyl residues at sites of autophosphorylation of growth factor receptors. Tyrosine phosphatases are also found as the gene products (YOPs) of virulence plasmids from bacteria of the genus *Yersinia* (such as *Y. pestis* responsible for the bubonic plague).

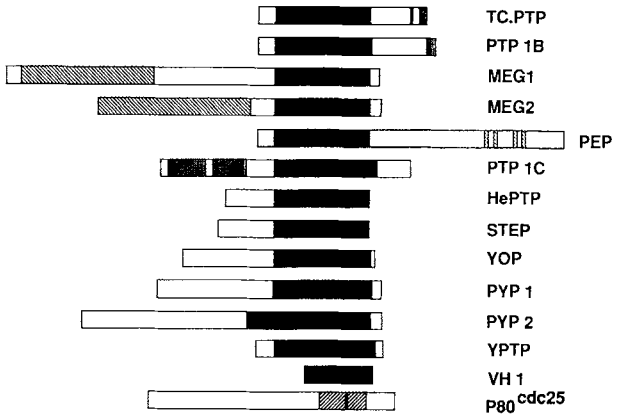

Fig. 8. Intracellular tyrosine phosphatases, aligned on the basis of their conserved, catalytic domains.

I would like to discuss now the role that these regulatory domains might play in enzyme localization and function, focussing on the human T-cell enzyme (Tc-PTP) cloned by Debbie Cool[68] (Fig. 9). The regulatory domain is entirely

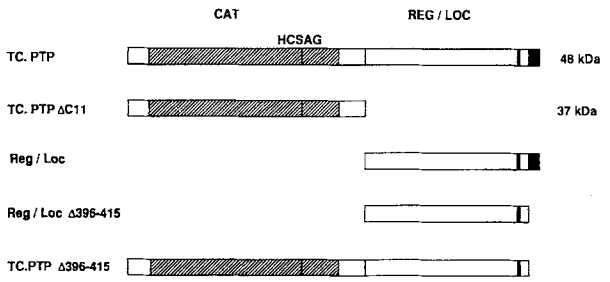

Fig. 9. Schematic representation of the human T-cell tyrosine phosphatase (TC-PTP) and some of its mutated forms. Illustrated are the full-length, wild-type 48 kDa enzyme, the 37 kDa truncated form containing only the catalytic domain; the 11 kDa regulatory/localization domain; and two mutant forms in which the hydrophobic 19-residue segment at the C terminus (dark band) has been deleted.

hydrophilic until one reaches the last 19 residues that are very hydrophobic, reminiscent of a transmembrane domain. There is also a short stretch of five basic residues that could serve as a nuclear localization signal.[68]

The 11 kDa segment of the enzyme, as well as other segments of putative physiological importance, was mutated. As a first step, a premature stop codon was introduced after the catalytic domain to delete the entire C-terminal tail. When this is done, the truncated enzyme becomes soluble, whereas the wild-type protein is particulate,[69, 70] localizing with the endoplasmic reticulum (ER). Expression of the C-terminal tail as a fusion protein with β-galactosidase shows that the soluble β-galactosidase now becomes attached to the ER. Finally, if one deletes just the C-terminal hydrophobic stretch, the enzyme localizes in the nucleus (J. A. Lorenzen, unpublished results).

Because of lack of time, I will only discuss the differences one observes in cell cycle progression and transformation when one expresses the wild-type enzyme versus its truncated form obtained by introducing a premature stop codon after the catalytic domain. In BHK cells, in which the wild-type enzyme is overexpressed, there is no obvious change in cell

morphology. By contrast, 60–70% of the cells expressing the truncated form become multinucleated[71] due to a failure in cytokinesis.

Multinucleation is not unusual; it can occur by cell fusion, with certain drugs or with antibodies against myosin ATPase since cytokinesis is an actomyosin-dependent process.[72, 73] But in all these instances, when nuclear division goes on, it goes on synchronously. What is unusual in these BHK cells is that nuclear division is more often than not asynchronous (Fig. 10): that is, one nucleus will divide while the other will not. Therefore, one will see cells with nuclei at all phases of cell cycle. At this time, we do not know which signals between the nuclei have been disrupted.

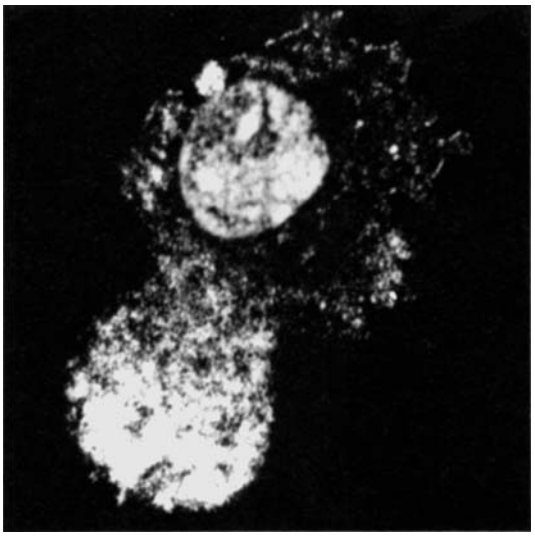

Fig. 10. BHK cells overexpressing the truncated 37 kDa form of the T-cell tyrosine phosphatase showing asynchronous nuclear division. The cell has rounded up around the lower nucleus ready to undergo mitosis. The nucleus on top is in an interphase configuration [7, 71].

Differences in cell behavior brought about by expression of the wild-type verses truncated T-cell enzyme can also be seen in cell transformation, by using the same highly tumorigenic BHK cell line. Transformation is the change a cell undergoes when it becomes malignant and no longer abides by the constraints under which a normal cell must operate. A normal cell does not grow on soft agar as it needs a solid support to which it can adhere, whereas a transformed cell will. As expected, the transformed BHK cell line grows readily on soft agar but it grows just as well, if not better, when transfected with the wild-type enzyme. By contrast, overexpression of the truncated form nearly abolishes growth under these conditions, as if transformation had been suppressed (D. Cool, unpublished results).

A similar enhancement in tumorigenicity by overexpression of the full-length phosphatase is observed when these cells are injected into athymic nude mice. The tumors produced are highly vascularized, as compared to tumors formed from control BHK cells. On the other hand, tumor formation is greatly reduced if not suppressed with BHK cells containing the truncated form. In several animals, no tumor was detected.

Since the nature of the transforming agent in these BHK cells was not defined, these studies were repeated in embryonic Rat-2 cells transformed with the well-characterized viral oncogene v-fms;[74] v-fms was first isolated from a feline sarcoma virus and belongs to the platelet-derived growth factor (PDGF) family of tyrosine kinase receptors.[75] Its nontransforming progenitor, the cellular protooncogene c-fms, encodes the receptor for CSF-1, the macrophage colony-stimulating factor. Binding of CSF-1 triggers signaling events that lead to the transcription of CSF-1 genes necessary for mononuclear phagocyte growth, differentiation and survival.[76]

Control Rat-2 cells display typical, nontransformed, cobblestone morphology—as opposed to the spindle-shape v-fms transformed cells.[74] Cells overexpressing the full-length enzyme have the same stringy transformed appearance, whereas clones containing the truncated form have the Rat-2, nontransformed cobblestone phenotype (Fig. 11). The

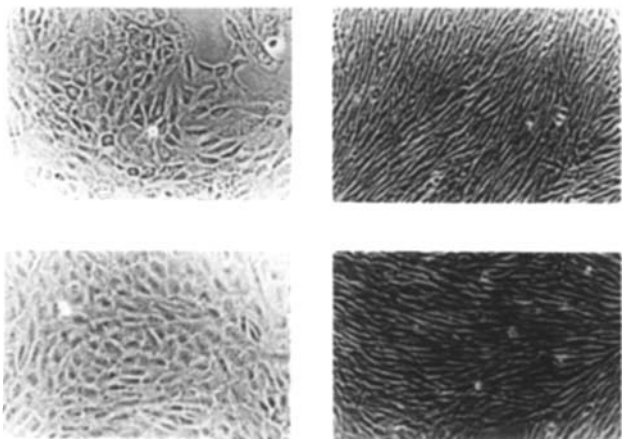

Fig. 11. Morphology of nontransformed Rat-2 cells (upper left) or cells transformed with v-fms (upper right). The v-fms-transformed cell lines were cotransfected with full-length T-cell tyrosine phosphatase (lower right) or its 37 kDa truncated form (lower left). The data indicate that while the full-length enzyme has not altered the transformed (spindle-shape) morphology, cells containing the truncated enzymes display a nontransformed phenotype.

transformed cells will grow on soft agar, the others will not. To achieve a high level of expression of the tyrosine phosphatase, the enzyme was packaged in retroviruses with which the cells were infected. None of the cells containing the truncated enzyme grew very well on soft agar. That these cells had reverted to a nontransformed state was further demonstrated by the appearance of their cytoskeleton (Fig. 12). Transformed cells exhibit a disruption of actin microfilaments and a loss of focal adhesions; that is, the structures through which normal cells adhere to their substratum. The actin fibers are restored in cells expressing the truncated enzyme and many more focal adhesions can be seen (D. Cool, unpublished results).

Finally, the same differences were observed in the ability of these two types of cells to form tumors when injected into nude mice. All cells containing the v-fms oncogenes produced large tumors, similar to those coexpressing the wild-type phosphatase. As observed in BHK cells, tumor formation was prevented in most cells transfected with the truncated enzyme.

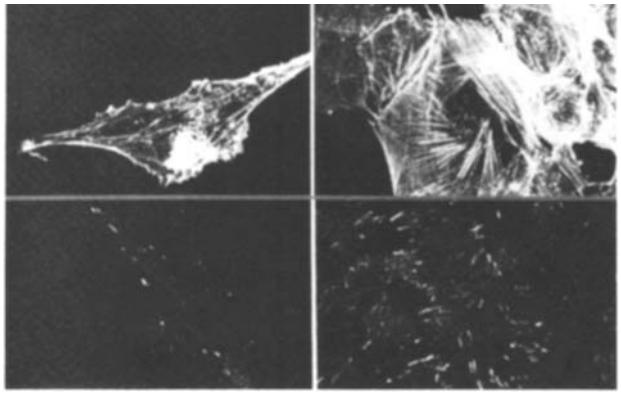

Fig. 12. Cytoskeleton morphology of v-fms transformed Rat-2 cells before (left) and after detransformation by coexpression of the truncated (37 kDa) form of the T-cell enzyme. Upper frames: actin stained with rhodamine-conjugated phalloidin; lower frames: stained with anti-vinculin antibodies to mark the focal adhesions (bright spots).

Concluding Remarks

The above results, plus others I did not have the time to develop, indicate that phosphatases cannot be viewed simply as providing an "off" switch in an "on/off" kinase/phosphatase system. In certain cases, and depending on the form of the enzyme involved, tyrosine phosphatases can clearly act synergistically with the kinases to bring about a particular physiological response. An obvious way by which they could do that would be by activating the src family kinases which are repressed by phosphorylation at the C terminus (Fig. 13). Furthermore, the factors that would determine

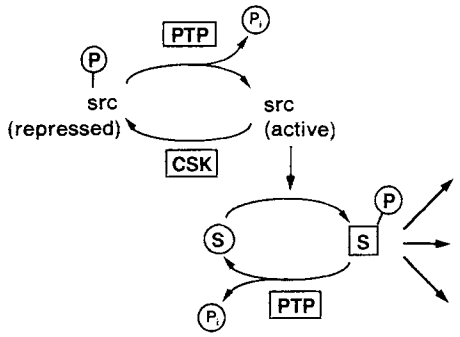

Fig. 13. Possible dual role of protein tyrosine phosphatases (PTP) in signal transduction. Upper reaction, activation of src family tyrosine kinases by dephosphorylation of the C-terminal phosphotyrosyl residue. Lower reaction, dephosphorylation of other tyrosine phosphorylated substrates to return the system to its original state. CSK is the cellular src kinase that represses enzymatic activity by tyrosine phosphorylation at the C terminus.

whether a phosphatase would enhance or oppose a kinase reaction would seem to depend less on its state of activity than on its subcellular localization. An analogous situation is found with $pp60^{v-src}$. Removal of the myristoyl group required for its binding to the plasma membrane does not affect its enzymatic properties but prevents its transforming abilities.[77] Association with the membrane is, therefore, essential for its oncogenicity. The above data indicate that if one wanted to control transformation through the phosphatases, one should try to manipulate the segments involved in their localization—or whatever anchoring proteins to which they may bind—rather than their catalytic domains. There are, of course, many questions that need to be answered. To mention a few:

a) What controls the activity of phosphatases under normal conditions? It may be easier to achieve high level expression of these enzymes in transformed lines in which the signal pathways are turned on, rather than in normal cells; as if a balance existed between kinases and phosphatases.

b) Do the differences between wild-type and truncated enzymes depend solely on their localization or is enzyme specificity also implicated?

c) Would the same effects be observed with any oncogene, including those that are not tyrosine kinases (such as ras, raf, mos, etc.)?

d) Which are the steps in the signaling pathway that are specifically affected by the enzymes? And finally:

e) If oncogenicity can result from an overexpression of tyrosine kinases, could oncogenicity also result from an underexpression of certain phosphatases?

All the processes Ed Krebs and I have described here have had something in common; they followed a similar pattern at the molecular level. Under the influence of an external stimulus, the state of phosphorylation of a protein or enzyme has been altered. This, in turn, has triggered a given cellular response. The finding that certain oncogenic agents may operate along the same principles may provide some clues as to the very mechanism of cell transformation. And who knows, perhaps with a little luck, a deeper understanding of these signaling pathways may suggest new avenues by which oncogenicity can be brought under control.

My scientific career has been profoundly marked by two long-standing collaborations, first with the late Eric A. Stein on α-amylases, then with Edwin G. Krebs, with whom I share this Award, on the protein phosphorylation problem. In addition to being the most valuable of colleagues, they have been two of my closest friends. I also owe a debt of gratitude to all those who joined the laboratory over the years, contributing their skills, original ideas, and maximum effort before moving on to pursue their own personal academic or research careers. The list would be too long were I to name them all; suffice to recall a few in chronological order: T. Yamamoto, M. Appleman, J. Hedrick, S. Shaltiel, S. Hurd, P. Cohen, L. Heilmeyer, B. Boeker, D. Gratecos, D. Malencik, C. Heizmann, H. Blum, M. Fosset, K. Lerch, J. Demaille, D. Brautigan, E. Villa-Moruzzi, L. Ballou, S. McNall, and N. Tonks. They have been superb collaborators; without them and all those I haven't been able to mention by name, including all my present collaborators, nothing that has happened could have happened.

I also owe a debt of gratitude to my wife Beverley for keeping her cool in the midst of recurring crises, whenever I had to prepare last-minute lectures or rush to the airport. Finally, a mountain of thanks goes to my secretary, Carmen Westwater for, time after time, wading through countless drafts of manuscripts, and retrieving lost letters, articles, or plane tickets. But those around me exaggerate when they call my office the "Bermuda Triangle".

My indebtedness goes to the National Institute of Diabetes and Digestive and Kidney Disease, NIH, for supporting my work from day one, and the Muscular Dystrophy Association for their unfailing help.

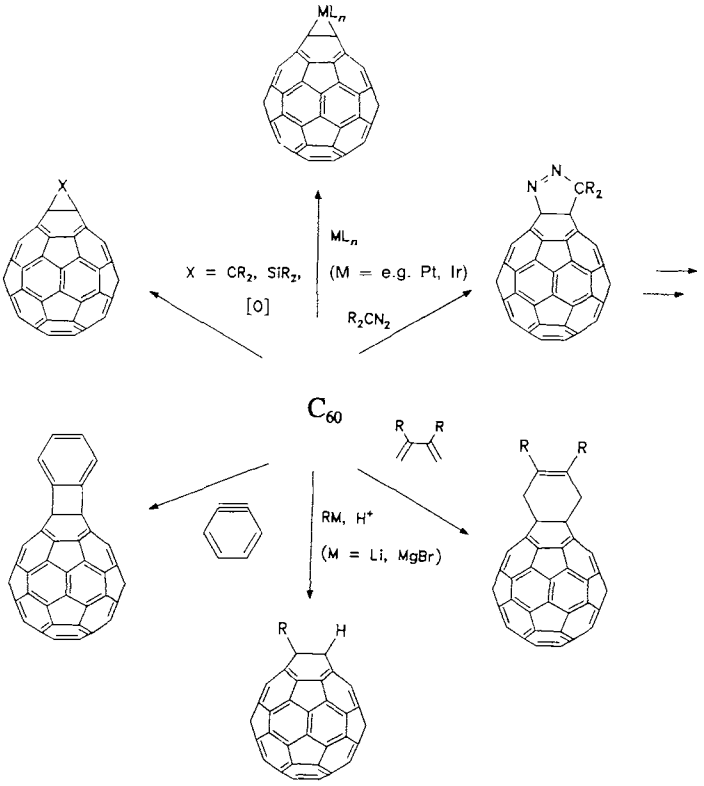
The Chemistry of the Fullerenes: An Overview

By *Andreas Hirsch**

Chemists' fascination with the fullerenes, the new soluble forms of carbon, is not founded merely on the geometric beauty of the molecules. Following the development of the synthesis of these spherical, cavity-containing molecules in preparative amounts,[1] these compounds and their chemically modified derivatives have been found to possess novel, remarkable properties. The soccerball-shaped buckminsterfullerene C_{60} has been at the forefront of these investigations. One notable feature of this molecule is its ready and reversible uptake of up to six electrons.[2] This high electron affinity was exploited in the first chemical modifications of C_{60}. For example, superconductors like K_3C_{60}[3] and ferromagnets like $[TDAE]C_{60}$ (TDAE = tetrakis(dimethylamino)ethylene)[4] were prepared by charge transfer with electropositive metals and organic donor molecules, respectively. Atoms may be deposited in the cavity within the cage. Helium was introduced to C_{60},[5a] and other noble gases[5b,c] and metal atoms[6] were included in fullerenes during their preparation.

Exohedral modifications of fullerenes in three dimensions by addition reactions and the development of preparative fullerene chemistry are particularly attractive to chemists. Materials with promising properties can be expected from these experiments. In principle the structure of the fullerenes provides access to a multitude of reaction products and positional isomers. Of course this can also make the purification and characterization of individual isomerically pure compounds more difficult. The following questions concerning the derivatization of fullerenes have been asked from the start: What kind of reactivity do the fullerenes have? Do they behave like a three-dimensional "superbenzene"? What are the structures of exohedral fullerene derivatives and how stable are they? In the meantime an entire series of successful reactions with C_{60} and also with C_{70} have been conducted, leading to well-defined fullerene derivatives (Scheme 1). Distinct regularities are already evident, which suggest a summary of the reactivity of the fullerenes. In order to avoid the problem of multiple derivatives that are difficult to separate, mainly monoadducts were prepared at first.

The first characterizable monoadduct $[C_{60}(OsO_4)(4\text{-}tert\text{-}butylpyridine)_2]$ was reported by Hawkins et al.[7] Its X-ray crystal structure confirmed the soccerball shape of C_{60}.[7b] The O-Os-O unit was shown to add regioselectively exclusively at a double bond common to two annelated six-membered rings (6-6 bond) in the fullerene framework. This structural analysis also provided the important finding that the 6-6 bonds (double bonds) are shorter than the bonds common to both a five- and a six-membered ring (5-6 bonds), which have single-bond character. According to this, C_{60} can be described topologically by annelated cyclohexatriene and [5]radialene units, as was also confirmed by the crystal structure analyses[8] and calculations[9] of underivatized C_{60}. The olefin character was also underlined in the reactions with coordinatively unsaturated transition metal complexes ML_n (M = Pt, Ir, etc.) conducted by Fagan et al. and Balch et al.[10] The formation of monoadducts always occurs at a 6-6 double bond (Scheme 1).



Scheme 1. Syntheses of exohedral fullerene derivatives. For clarity only the front sides of the fullerenes are shown.

The first investigations of the reactivity of C_{60} to organic reagents[11] proved that it is distinctly electrophilic and dieno/dipolarophilic. In a series of experiments[12] Wudl et al. and Diederich et al. showed that stoichiometrically controlled reactions with diazoalkanes and diazoacetates provide σ- or π-homoaromatic fullerenes with methano bridges. In several cases it was demonstrated that the primary step in these reactions is a [3 + 2] cycloaddition to form a dihydropyrazole.[12e] The thermally stable final products in these reactions are the opened, π-homoaromatic compounds **1** bridged at a 5-6 ring juncture, the corresponding opened compounds **2** bridged at a 6-6 ring juncture, or the closed, σ-homoaromatic fullerenes **3** bridged at the 6-6 ring juncture. In some cases several valence isomers are formed simultaneously, which are then converted into the most stable derivative by heating.[12e] The precise spectroscopic investigation of the fullerenes with methano bridges ("fulleroids")

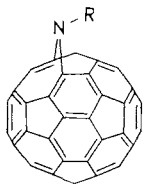
shows an impressive analogy to the annulenes with methano bridges. Reactions with suitable diazoalkanes allowed the synthesis of bridged fullerenes and polymers with fullerene units in the side chains.[12f] The opened azafulleroids **4** were obtained from C_{60} and organic azides by [3 + 2] cycloadditions and subsequent loss of nitrogen.[13]



4

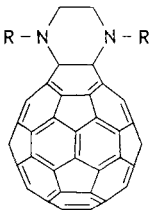
Defined, stable Diels–Alder adducts of C_{60} (Scheme 1) can be obtained from reactions with suitable dienes[14] and with isobenzofuran.[15] They are formed with high regioselectivity by addition to a 6-6 double bond exclusively, as was proved by ^{13}C NMR spectroscopy[14] and X-ray structure analysis.[14b]

The nucleophilic additions of Grignard and organolithium compounds and the subsequent protonation to form 1-organo-1,9-dihydrofullerenes-60[16, 17] reveal much about the reactivity of C_{60} (Scheme 1). Even in these two-step processes isomerically pure compounds are obtained. For good yields of the monoadduct, the reactions with reactive carbanionic nucleophiles must be carefully regulated. The nucleophile is added in portions and the reactions are monitored by high-performance liquid chromatography (titration).[16a, b] The fact that the stable final products isolated are exclusively the 1,9 derivatives clearly demonstrates that the negative charge in the anionic intermediates RC_{60}^- (C_s symmetry) is localized primarily on C9. Correspondingly, in these compounds the proton bound to the fullerene framework is very acidic. A pH value of 5.7 was determined for $C_{60}HtBu$.[16c] More recently the parent compound of the 1,9-dihydrofullerenes-60, $C_{60}H_2$, has been synthesized.[18] This simplest hydrocarbon derivative of C_{60} was obtained by addition of BH_3 and hydrolysis of the initial hydroboration product $C_{60}H(BH_2)$ with acetic acid. When deuterolysis was the last step, ^1H NMR spectroscopy proved that the 1,9 isomer was formed regioselectively.

The reaction of C_{60} with benzyne[19] does not provide a [4 + 2] cycloadduct but formally a [2 + 2] adduct (Scheme 1). The hypothetical [4 + 2] adduct would require formation of a 5-6 double bond, which is energetically unfavorable for the fullerene system.[20]

Carbenes,[21] silanediyls,[22], and oxygen[23] react with the double bonds of C_{60} (Scheme 1), and the monoadducts obtained were characterized completely. In all of these cases the products are closed fullerenes bridged at a 6-6 bond. An especially impressive example is the addition of glycosylidene carbenes to give fullerene sugar derivatives.[21]

Defined diaminofullerenes **5** have also been obtained by the reaction of C_{60} with secondary diamines such as *N,N'*-dimethylethylenediamine.[24] Noteworthy here is that dehydrogenated C_{60} derivatives are produced. The products are monoadducts that have lost the hydrogen atoms introduced with the diamine units.



5

A variety of substituents can be bound covalently to the fullerene framework with the addition reactions discussed briefly here. This preparative organic fullerene chemistry allows the synthesis of derivatives in which the properties of the fullerenes are combined with those of other classes of compounds. High regioselectivities and in most cases satisfactory to good yields are obtained.

Extensive investigations of the reaction of radicals with C_{60} and C_{70} were conducted in situ by ESR spectroscopy.[25] A series of alkyl radicals was generated either thermally or photochemically, and the ready formation of multiple addition products $C_{60}R_n$ was observed. The reaction was also directed to give monoalkyl radical adducts. The analysis of the spectra of $RC_{60}^{\cdot}$ (C_s symmetry) showed that the unpaired electron is predominently localized directly adjacent to the R-substituted C atom at position 9, as is also the case in the anions RC_{60}^-. The monoalkyl radical adducts are in equilibrium with their diamagnetic dimers $R-C_{60}-C_{60}-R$.

Multiple additions to fullerenes readily lead to reaction mixtures that are difficult to separate because of polyfunctionality. Several examples for defined multiple adducts are now known.[26] In the organometallic derivatives $[C_{60}\{M(PEt_3)_2\}_6]$ (M = Ni, Pd, Pt) the C_{60} framework is coordinated in an octahedral fashion by six η^2-$(Et_3P)_2M$ units,[26a, b] leading to the uncommon, approximately ideal T_h point group (ethyl groups neglected). The reaction of C_{60} with an excess of $[Ir(CO)Cl(PMe_2Ph)_2]$ provides two conformational isomers of $[C_{60}\{Ir(CO)Cl(PMe_2Ph)_2\}_2]$.[26c] In both isomers the iridium atoms are bound to 6-6 double bonds of the fullerene framework exactly across from each other; in other words, the second addition takes place on the opposite hemisphere. Bisosmylation of C_{60} affords five positional isomers of $[C_{60}\{OsO_4(py)\}_2]$,[26e] which were all separated. Here, too, the second attack takes place on the opposing hemisphere for electronic and steric reasons.

Whereas fluorination[27] and chlorination[28] of C_{60} led to uncharacterizable mixtures of products, the bromides $C_{60}Br_6$, $C_{60}Br_8$, and $C_{60}Br_{24}$ were crystallized and characterized.[29] The previously discussed examples mainly concerned 1,2-additions to 6-6 bonds. In contrast, bromination is preferentially a 1,4-addition for steric reasons. The regular

arrangement of the 24 bromine atoms in T_h-$C_{60}Br_{24}$ arises from two 1,4-additions at each pair of annelated six-membered rings such that the bromine substituents closest to each other are at 1,3-positions.[29b] Subsequent additions of Br_2 are unfavorable, since the bromine atoms would be bound to directly adjacent C atoms. The 1,4-addition mode is attributed to the large spatial requirement of bromine atoms. The fullerene framework must thus accept the energetically unfavorable formation of a 5-6 double bond.[20] The ratio of 1,2- to 1,4-additions (Fig. 1) depends in general on the interplay of the spatial requirement of the bound ligands and the destabilization associated with the 5-6 double bond. The bromides $C_{60}Br_6$ and $C_{60}Br_8$ are relatively unstable[29a] ($C_{60}Br_{24}$ is somewhat more stable) and lose Br_2 to regenerate C_{60}.

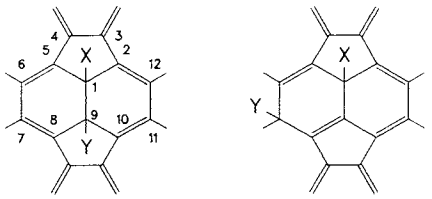


Fig. 1. 1,2-Addition product (A) and 1,4-addition product (B) of fullerene-60 with systematic numbering of the carbon atoms.

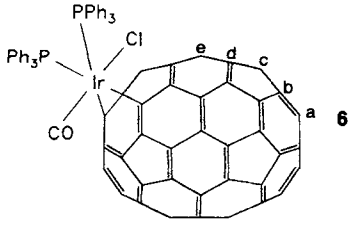
Other successful reactions of C_{60} include hydroaminations with primary and secondary amines,[11] addition of triethylphosphite,[11] addition of hydroxide,[30] reaction with lithium and subsequent methylation,[31] hydrogenation,[32] reaction with Lewis acids,[33] and reaction with NO_2^+.[34] The reaction products have not yet been separated or completely characterized in any of these cases. The addition reactions are frequently reversible.

The reaction of fullerene-60 with polymers having NH_2 groups in their side chains is an elegant method for the synthesis of polymer-bound C_{60}.[35] Some of these polymers are soluble, fulfilling an important prerequisite for further manipulations of these materials.

While all positions in C_{60} are identical, five sets of C atoms are found in C_{70}. It can be anticipated that the different bonds display different reactivities.[36] In both the reaction of C_{70} with $[Ir(CO)Cl(PPh_3)_2]$ to give $[(\eta^2\text{-}C_{70})Ir(CO)Cl(PPh_3)_2]$ (**6**)[37] and in hydroalkylations of C_{70},[16b] attack occurs at the a-b bonds at the poles. In the formation of the bisadduct from C_{70} and $[Ir(CO)Cl(PPh_3)_2]$, the second addition takes place at the a'-b' bond in the opposite hemisphere.[26b]



6

Based on the results obtained up until now, the chemistry of the fullerenes[38] can be summarized as follows:

- C_{60} reacts as an electron-poor olefin with fairly localized double bonds.
- Additions occur preferentially at a 6-6 double bond.
- Fullerenes with methano bridges may have either σ- or π-homoaromatic structures.
- 1,4-Additions take place with sterically demanding ligands; the introduction of the energetically unfavorable 5-6 double bond must be taken into account.
- In general the second addition occurs in the opposite hemisphere.
- Additions to C_{70} take place selectively at the most reactive double bonds at the poles.

Prediction of the Secondary Structure of Proteins from the Amino Acid Sequence with Artificial Neural Networks

By *Gisbert Schneider* and *Paul Wrede**

How does an amino acid sequence fold into its native three-dimensional structure (that is, the correct arrangement for the biological function of the protein)? A comprehensive answer to this question cannot be given yet. Too many factors influence the folding in vivo and in vitro. One potential approach to the solution is to consider the spatial structure of a protein molecule as a hierarchically constructed system (amino acid sequence → secondary structure → structure domains → tertiary structure and, where applicable, quaternary structure[1]), in order to understand the elementary steps of the folding process in this modular concept. An important first step is the prediction of secondary structures from the amino acid sequences.

A method frequently applied is the procedure of P. Chou and G. Fasman, which is based on a statistical analysis of known secondary structures.[2] The propensity of each amino acid to form part of a helix, a folded sheet, or a loop, calculated in this way, can then be used in the prediction of these structures for new sequences. The prediction is achieved through a concept that views the formation of a secondary structure as a local event that is limited to a short section of the amino acid sequence (a "window"). To predict the secondary structure at individual amino acids the window moves across the sequence. This has the particular advantage that the secondary structure at a certain sequence position is seen in the context of adjacent amino acids, and interactions between the amino acid residues within the sequence in question can be taken into account. Several concepts for the prediction of secondary structure have been developed that are based mainly on the moving window principle. A consistent approach stems from the interdisciplinary field of molecular biocomputing: sequence analysis with artificial neural networks.

Neural networks are ideally suited for parallel sequence processing and are increasingly applied for the study of biological macromolecules. The aim is the classification of nucleic acid and amino acid sequences on one hand and the prediction of the spatial structures and their functions on the other. For classification, mainly self-organizing Kohonen networks[3] and multilayer perceptrons[4] are used, which achieve a high precision and accuracy in classification, for example, of amino acid sequences according to their biological function.[5] However, we are still far away from an exact prediction of the tertiary and quaternary structure from amino acid sequences with these systems.[6–8] If such a prediction were possible, new routes for rational protein design through an intermediate synthesis of amino acid sequences entirely based on theoretical considerations and models would be opened. The reliable prediction of secondary structures is an important initial step. Other applications of other types of artificial neural nets in chemistry, for instance for

the processing of spectroscopic data of for the control of chemical processes, were described comprehensively by J. Gasteiger and J. Zupan.[9]

The development of artificial neural nets for the prediction of secondary structures from amino acid sequences was first attempted in 1988 by Qian and Sejnowski and in 1989 by Holley and Karplus.[4, 6, 10] The accuracy of their predictions was 63–64% (α, β, or random structures). This accuracy is also achieved by statistical methods. Now for the first time Burkhard Rost, Reinhard Schneider, and Chris Sander of the European Molecular Biology Laboratory (EMBL) in Heidelberg have reached an accuracy of over 70%[11, 12] in the prediction of secondary structures with neural networks. Also in the context of the Human Genome Project—the sequencing of the human genome—and the successfully completed sequencing of the chromosome III of the yeast *S. cerevisiae*,[13] the development of both existing and new methods for predictive and analytic methods is necessary for a systematic processing of the vast amounts of data. Apart from the potential application for the design of proteins, the EMBL group's distinctly improved prediction of secondary structures with artificial neural nets simply from the knowledge of the amino acid sequences reveals a promising approach for the biocomputing field for the study of the enormous amount of information in sequence data banks.

An artificial neural net for the analysis of the sequence of proteins is a computer program that recognizes patterns and correlations in sequence data. The success of the process depends among other factors upon the ability of the system to separate relevant from irrelevant information by parallel processing.[4, 9] Along the lines of the moving window concept, each new position within the sequence section is examined by the artificial neural net in relation to every other position of the sequence window. An example with a window span of five positions is shown in Figure 1.

The networks used by Rost et al. belong to the type most frequently used for sequence analysis in the class of feedforward nets (Fig. 1). The flow of information is in one direction: from the input to the output layer of the network. This

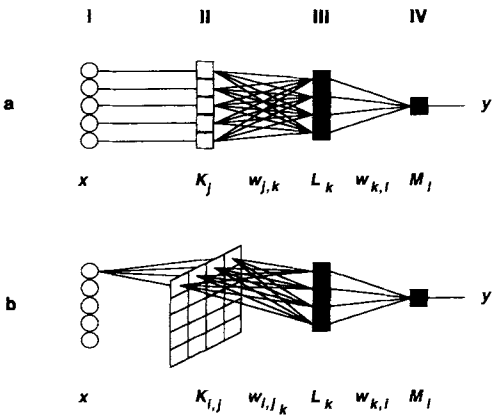

Fig. 1. Model of a general architecture for a three-layered artificial neural network for the analysis of amino acid sequences. The flow of information is in one direction only, from the sequence x (I) to the output unit (IV), which yields the value y, for example, a secondary structural type ("feedforward"). The net's units of the hidden layer (III) enable the calculation of any desired transformation function between an amino acid sequence (I) and the output unit (IV) of the network. An amino acid j is described a) by a binary or a physicochemical parameter K_j (II) or b) by a series of physicochemical properties $K_{i,j}$ (here $i = 1-4$)

is achieved by linking every unit of one layer only with units of the next layer. A significant advantage of this network architecture lies in the ability to approximate any input–output transformation.[14] This means that transformations between amino acid sequences (network input) and their structure or function (network output) can also be calculated. The transformation function $T(x)$ of a sequence pattern x that can be determined by a three-layered net (Fig. 1 a) is given by the number of the net's units (K_j,L_k,M_l) and the connections of the net with assigned weights $w_{j,k}$, $w_{k,l}$ [Eq. (a)]. $S(\mathrm{net_{in}})$ is the "transfer function" of a net unit, given in Equation (b).

$$T(x) = S(\sum_{l} w_{k,l} S(\sum_{j,k} w_{j,k} \xi_j)) \qquad \text{(a)}$$

$$S(\mathrm{net_{in}}) = \frac{1}{1 + e^{-(\tau\, \mathrm{net_{in}} + \sigma)}} \qquad \text{(b)}$$

As a rule a nonlinear sigmoidal function (Fermi function) is chosen; τ determines the steepness of the curve, σ its point of inflection.[9] In Equation (a), ε_j is the representation chosen for the amino acid j, for example, as a twenty-bit binary number (distributed coding, Fig. 1 b) or a set of physicochemical parameters (Fig. 1 b). An advantage of binary coding is that each amino acid can be precisely defined in a technical and complete manner, which is not self-evident for a description of the constitution by physicochemical properties. Nevertheless, relationships and similarities between amino acids can be expressed through their properties, which is particularly advantageous for the study of sequences that have little or no sequence homology in the formal description. The use of a nonlinear transfer function $S(x)$ allows the units also to represent nonlinear relationships between input and output that are often difficult to calculate[9] with statistical procedures, including those of Chou and Fasman.[2]

Therefore, when a description of relationships between sequence and structure or function has been achieved with an artificial neural network, similar structures or functions in new sequences can be predicted exactly. A penetrating, but easily understandable description of the way artificial networks function and their architecture is offered, for instance, by the book of J. Hertz, A. Krogh, and R. G. Palmer.[15]

How does an artificial neural network "learn" the right transformation between sequence and structure or function? To set up the desired transformation function, such as for the prediction of secondary structures, known exemplary sequences must be presented to the network. Such a training set contains sequences with known, experimentally confirmed secondary structures. The parameters of the transformation function of the network, in particular the connection weights, are then changed iteratively by learning and optimization algorithms until the secondary structures of the amino acid sequences predicted by the neural network correspond to the experimentally known data as well as possible. The back-propagation algorithm,[16] a gradient process for multilayer network models, and evolutionary algorithms[17, 18] have proved outstanding as optimization procedures. The evolutionary algorithm is based on a local stochastic search.

Whether a trained network is indeed suitable for general predictions of, for example, secondary structures is determined by giving it one or more test sets. A test set contains

sequences with known structures, like the training set, which were, however, not used in the training phase. A test set is thus a collection of data independent of the training set with which the artificial network's ability to generalize can be tested. This ability, apart from the fundamental question whether the prediction can be performed by the chosen method at all, is also determined by several, mostly empirical parameters, for example by the network architecture, the learning algorithm, the size and number of the net layers, and the suitability of the data representation. A new approach to computer-assisted optimization of these parameters has already been proposed ("structure evolution");[19] however, its applicability in the development of artificial neural networks for sequence analysis remains to be demonstrated.

A suitable representation of the sequence data that enables the general characteristic for the prediction to be found is crucial for the success of the method. On one hand, attention must be given to the representation of the amino acids; on the other hand the selection of the sequences and their grouping into one or more training sets is important.[10, 20, 21] In particular, the latter is apparently extremely important, as Rost and Sander pointed out. They established a series of training sets, each of which contained a number of homologous sequences—in other words, a "protein family". The artificial neural network thus had access in the learning phase to additional information on the evolutionary relationships between the sequences of a protein family and its secondary structures. This procedure was the decisive step that distinctly improved the accuracy of the prediction of secondary structure. The authors recommended it for the development of other predictive systems as well. So besides a suitable method for extraction of the salient characteristics (artificial neural networks), a suitable representation of the data is extremely important for success in the development of predictive systems!

Since the method for secondary structure prediction will be made available to a wide range of users through Electronic Mail at EMBL, the generalizability of the system ("PHD" method i.e., *P*rofile network from *Heid*elberg) can be subjected to a severe test. In addition, detailed instructions can be requested through the "Help" command to the address *PredictProtein@EMBL-Heidelberg.de*.[11, 12]

A criticism of secondary structure prediction itself is its limited implications, even when it is completely correct! The tertiary structure of a protein is the essential factor for the function of proteins, and their prediction lies far in the future. Nevertheless, the application of artificial neural networks point to a promising means to this end, not least because of their simplicity and universal applicability.

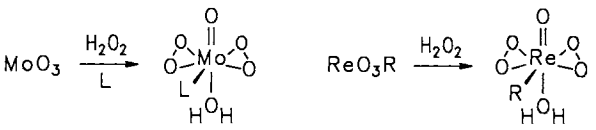
Metal-Mediated Oxyfunctionalization of Organic Substrates by Organometallic Intermediates—More Recent Developments and Perspectives

By *Jörg Sundermeyer**

The complex-catalyzed oxyfunctionalization of organic substrates is of fundamental importance, for example in chemical processes of Nature, in the synthesis of fine chemicals, and in the production of commodity chemicals.[1] Regardless of the results achieved in this interdisciplinary area of research, there is still a great lack of experimental evidence that could help to settle very controversial debate[2] about the mechanism of the metal-mediated C–O bond formation. The catalytically active complexes are usually differentiated on the basis of their mechanisms.[1e] Thus, there is a group of metal complexes that catalyzes the homolytic cleavage of the O–O bond of peroxides and triplet oxygen, a second group that induces its heterolytic cleavage, and a third that has at its disposal polarizable and transferable oxo functions such as $M-O^{\delta-}$, M=O, and $M\equiv O^{\delta+}$. The first group includes low- and high-spin complexes of Fe, Co, Ni, Mn, Cu, and other biologically relevant metals, which, for example, control the radical chain initiations as well as the propagation and inhibition of autoxidation reactions. In contrast, d^0 complexes of the second category (e.g. those of Ti, V, Mo, W, and Re) are diamagnetic and strong Lewis acids. These compounds activate H_2O_2 or alkyl hydroperoxides by formation of reactive d-block metal peracids [M–OOH], peroxides [$M(\eta^2\text{-}O_2)$], or peracid esters [M–OOR], that is, they polarize the O–O bond for nucleophilic attack of the substrate at the peroxidic oxygen atom. In contrast, electron-rich transition metals (Rh, Ir, Pd, Pt) cause an inverse polarization, which makes an electrophilic attack at the peroxy function more favorable. The group of reactive oxo complexes includes, for example, $[MnO_4]^-$, RuO_4, and OsO_4, well-established for hydroxylations.

Not so long ago the suggestion that organometallic intermediates might participate in polar oxygen-transfer reactions would have been refuted and considered as unrealistic. The knowledge accumulated over the last few years about oxo and peroxo complexes functionalized with organometallic groups demonstratrates that, in particular, the relatively nonpolar M–C bonds in complexes of molybdenum(VI), tungsten(VI), and rhenium(VII) can be stable under catalytic conditions (protic medium, hydroperoxides, O_2), and that they are sometimes essential for the activity and lifetime of a catalyst. In this respect the results of Herrmann et al. should be considered a breakthrough.[3] They have succeeded in bridging the gap between the Mimoun reagents of the type **1** (L = HMPA, DMF, etc.)[4] well established for epoxidations, and the classic Milas reagent $OsO_4/H_2O_2/t$BuOH[5] for the catalytic *syn* hydroxylation of olefins. The isolation and complete characterization of the catalytically active species **2**, R = CH_3,[3b] in the catalyst system $[ReO_3R]/H_2O_2/t$BuOH is worthy of note and stimulates comment.

Compounds **1** and **2** have the same pentagonal-bipyramidal molecular structure;[3b,4c] however, the equatorial [d^0-Mo-L] building block in **1** is replaced by the isoelectronic [d^0-Re-R] fragment in **2**. The symmetry and relative arrangement of all frontier orbitals[1b] are similar in the two compounds. This relationship between **1** and **2** is reflected in the similar reactivity of the two compounds, particularly in the *anti* hydroxylation of alkenes by means of the opening of epoxides formed as intermediates, and in the Baeyer–Villiger oxidation of ketones. However, it is already apparent that the Herrmann reagent excels as a result of higher reactivity (oxyfunctionalization of certain alkynes, similar as OsO_4[5d]) and high catalytic activity, whereas the readily prepared Mimoun reagent has proved successful primarily for stoichiometric reactions.[2a,4]



Why has it taken so long for the quality of oxo complexes of rhenium for catalytic oxygen-transfer reactions to be recognized and proven? As strange as it may sound, the key to success with **2** lies in its organometallic functionality. More polar Re–X groups (X = OR, NR_2, Cl, etc.) are generally more rapidly protolyzed to give catalytically inactive compounds than the relatively nonpolar Re–R unit in **2**, which is stable under catalytic conditions (weakly acidic, protic medium). From the Brønsted acidities of $[ReO(O_2)_2(CH_3)(H_2O)]$ (pK_s = 3.8) and $[ReO_3(CH_3)(H_2O)]$ (pK_s = 7.5) it can be concluded indirectly that the σ,π donor ability of an oxo ligand O^{2-} is significantly higher than that of a peroxo ligand O_2^{2-}, and that consequently the catalytically active species **2** is more Lewis acidic than its catalytically inactive monoperoxo precursor $[ReO_2(O_2)(CH_3)(H_2O)]$. Thus, not a low coordination number, but the π acidity of the d^0 metal center appears to be decisive for the catalytic activity of a peroxo complex. A molecular catalyst design based on adjustable ligand parameters from compounds of the type $[ReO(O_2)_2(R)(L)]$ has therefore moved within reach. We can eagerly await the catalytic efficiency of polymer-bound alkylrhenium peroxides.

Other organometallic compounds have also proven their value as precursors for catalysts in the activation of hydroperoxides. For example, Trost and Bergman have reported[6] that the molybdenum complex **3** catalyzes the epoxidation of olefins by alkyl hydroperoxides ROOH. In sharp contrast to **2**, **3** is not capable of activating H_2O_2, conversely **2** cannot activate alkyl hydroperoxides. The catalytically active species in the ROOH/**3**/olefin system has not been characterized unambiguously as yet; the authors report, however, that the surprisingly catalytic, inactive peroxo complex **4** forms from **3** and ROOH or H_2O_2 in a *deactivating* side reaction. Complexes with a $[(\eta^5\text{-}C_5Me_5)Mo(\eta^2\text{-}OOR)]$

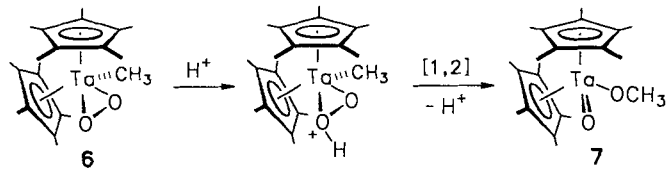
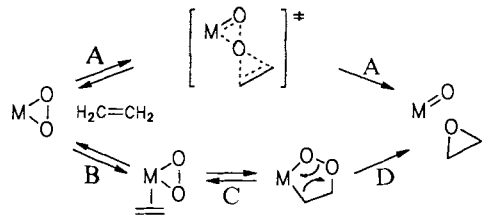
building block could be considered as a plausible organometallic intermediate for the oxygen-transfer step.

The stability of M–C bonds in the presence of hydroperoxides could also be confirmed for the structurally related alkyl complexes **5** (M = Mo, W; R = CH_3, CH_2SiMe_3).[7] An intramolecular [1,2] shift of the alkyl groups to one of the peroxidic oxygen atoms (similar to that which occurs in the tantalocene complexes, for example **6**, investigated in detail by Bercaw et al.[8a]) does not appear to be a preferred reaction pathway in analogous complexes of Mo, W, and Re. However, Bercaw et al. were able to show that the rearrangement of **6** into the alkoxy complex **7** does not take place either spontaneously or according to a first-order rate law, but is initiated by the attack of an electrophile (e.g. H^+) at the peroxo group.[8b]



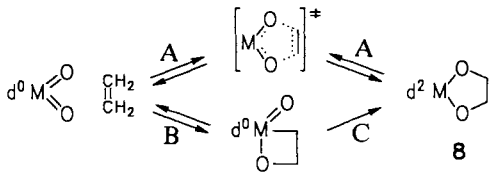
In spite of intensive efforts the knowledge accumulated to date about polar oxygen-transfer reactions on peroxo, hydroperoxo, and alkylperoxo complexes is not yet sufficient to decide whether to agree with the direct attack of the olefin at the positively polarized oxygen center[9] ("butterfly mechanism" without an organometallic intermediate, step A in Scheme 1) discussed by Chong and Sharpless, or with the



Scheme 1. Mechanistic alternatives for polar oxygen-transfer reactions of peroxo complexes.

mechanism postulated by Mimoun based on an olefin coordination, followed by a 1,3-dipolar cycloinsertion with the formation of a metalladioxacyclopentane and its cycloreversion (steps B–D in Scheme 1).[2a] The question of whether the metal center adopts only the activating role of a π-acidic substituent, analogous to that of a −I,−M substituent in percarboxylic acids or persulfonic acids, or whether in an equilibrium on account of unoccupied metal acceptor orbitals it forms weak π interactions[10] with the olefin to be oxidized, remains unanswered for the moment.

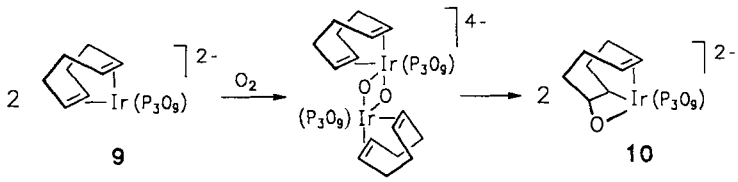
How easily well-established mechanistic ideas about the metal-mediated oxyfunctionalization of organic substrates can begin to falter is also illustrated by a very recent kinetic study by Göbel and Sharpless on the influence of the reaction temperature on the enantioselectivity of the asymmetric *syn* hydroxylation of olefins with chirally modified alkaloid–OsO_4 complexes.[11a] The Eyring plots for several olefin/alkaloid combinations provide clear indications of a multistep mechanism with at least two diastereoselective steps. Thus, a concerted mechanism (step A in Scheme 2) in the form of a 1,3-dipolar cycloaddition of the OsO_4 to the olefin can be ruled out, a fact which can be considered as evidence for but not proof of the two diastereomeric metallaoxetanes discussed as intermediates by Sharpless (step B in Scheme 2)[11b] and their diastereoselective [1,2] rearrangement into the glycolate complexes **8** (step C in Scheme 2). As for the



Scheme 2. Mechanistic alternatives for *syn* hydroxylations of olefins with OsO_4 complexes.

examples mentioned in Scheme 1, it is also shown here that the characterization of intermediate products on the reaction coordinate, even in matrix studies, is the safest way to remove doubts concerning the participation of organometallic intermediates.

The formation of the irida(III)oxetane **10** may serve as a model reaction for the metal-mediated transfer of oxygen to a coordinated olefin; the formation is explained by autoxidation of the iridium(I) cyclooctadiene complex **9** via the plausible dinuclear oxoiridium(III) intermediate.[12]



Closely related with steps B and C in Scheme 2 is also the [2 + 2] cycloaddition of ethylene to the neopentylidene function of [Re(C*t*Bu)(CH*t*Bu)(O*t*Bu)$_2$], followed by [1,2] rearrangement of the d^0-rhenacyclobutane intermediate into a d^2-rhenacyclopentene, recently described by Schrock et al.[13]

Many unanswered questions remain as a challenge to the researchers in this field, for example, the indisputable proof for a [2 + 2] cycloaddition of an olefin to an M=O group, proof of possible π interactions of olefins with the d^0 metal center of oxo and peroxo complexes and the existence of d^0-peroxymetallacycles (Scheme 1), and unequivocal evidence for a [1,2] shift of a metal-bound organic group R to a geminal oxo function (step C in Scheme 2) with reduction of the metal center.

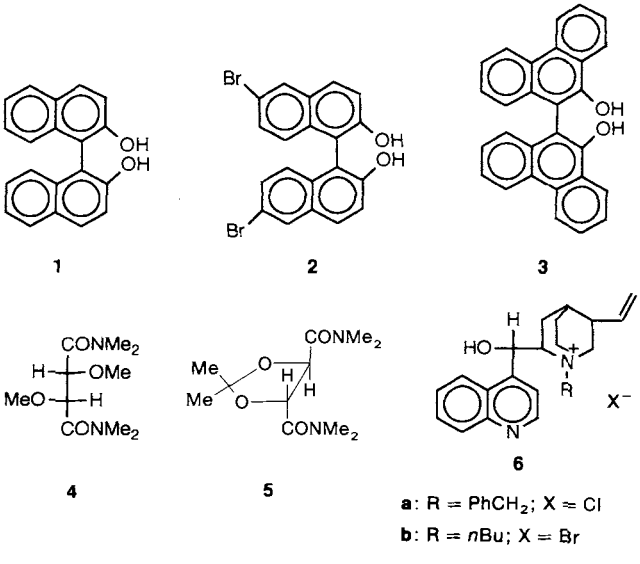
Separation of the Enantiomers of 2,2′-Dihydroxy-1,1′-binaphthyl and 10,10′-Dihydroxy-9,9′-biphenanthryl by Complexation with *N*-Alkylcinchonidinium Halides**

By *Koichi Tanaka, Toru Okada*, and *Fumio Toda**

The enantiomers of 2,2′-dihydroxy-1,1′-binaphthyl **1** are important C_2 symmetrical, chiral compounds, whose use is not only limited to asymmetric syntheses.[1] They are also used for the separation of racemates by the formation of inclusion complexes[2] and as chiral shift reagents.[3] The enantiomers of 10,10′-dihydroxy-9,9′-biphenanthryl **3** are also important chiral host compounds.[4]

Several methods for the separation of the enantiomers of **1**[5, 6] and **3**[6] have been reported. One of the most effective of these methods is the formation of inclusion complexes with optically active (*R,R*)-(+)-2,3-dimethoxy-*N,N,N′,N′*-tetramethylsuccinamide (**4**) and (*R,R*)-(+)-*N,N,N′,N′*-tetramethyl-2,2-dimethyl-1,3-dioxolane-*trans*-4,5-dicarboxamide (**5**), respectively.[6] One disadvantage of this method, however, is that the amide host compounds (**4** and **5**)[7] are not commerically available, and must be synthesized from tartaric acid prior to the resolution experiment.



1 **2** **3**

4 **5**

6

a: R = $PhCH_2$; X = Cl

b: R = *n*Bu; X = Br

Recently we have found that commercially available *N*-alkylcinchonidinium halides (**6**) are very effective for the resolution of **1**, the 6,6′-dibromo derivative **2**, and the biphenanthryldiol **3** by the formation of inclusion complexes. For example, when a solution of *N*-benzylcinchonidinium chloride (**6a**)[8] (0.74 g, 1.76 mmol) and *rac*-**1** (1 g, 3.5 mmol) in MeOH (20 mL) was kept at room temperature for 6 h, a 1:1 inclusion complex of **6a** and (+)-**1** was obtained, which precipitated as colorless prisms (0.89 g, 72% yield, m.p. 240–244 °C). The 1:1 complex was decomposed with dilute HCl. Subsequent extraction with AcOEt, followed by evaporation of the solvent gave (+)-**1** (95% *ee*; 0.35 g, 70% yield, $[\alpha]_D = +31.5$ ($c = 1.0$, THF)). Recrystallization of the crude product from MeOH gave (+)-**1** (100% *ee*; 0.3 g, 60% yield, $[\alpha]_D = +33.2$ ($c = 1.0$, THF)). The filtrate left after separation of the complex of **6a** and (+)-**1** was treated with dilute HCl to give (−)-**1** (42% *ee*; 0.62 g, 124% yield, $[\alpha]_D = -13.9$ ($c = 1.0$, THF)). This method is also effective for the separation of the enantiomers of **2**. In this case when a solution of **6a** (0.95 g, 2.26 mmol) and *rac*-**2**[9] (2 g, 4.5 mmol) in MeOH (2 mL)/AcOEt (10 mL) was kept at room temperature for 6 h, a 1:1 inclusion complex of **6a** and (−)-**2** was obtained, which precipitated in the form of colorless prisms (1.7 g, 89% yield, m.p. 229–232 °C). Decomposition of the complex with dilute HCl gave (−)-**2** (99% *ee*; 0.82 g, 82% yield, $[\alpha]_D = -51.0$ ($c = 0.9$, THF)). From the filtrate left after the separation of the inclusion complex, (+)-**2** (79% *ee*; 1.1 g, 110% yield, $[\alpha]_D = +40.7$ ($c = 1.0$, THF)) was isolated by treatment with dilute HCl. The enantiomeric purities of **1** and **2** were determined by HPLC by using a column containing an optically active solid phase, Chiralpak AS,[10] and hexane/EtOH (95:5) as an eluent.

Interestingly, however, **6a** was not suitable for the separation of the enantiomers of **3**, because **6a** does not form an inclusion complex with **3**. In contrast this separation was achieved by the use of *N*-butylcinchonidinium bromide (**6b**).[11] For example, when a solution of **6b** (0.14 g, 0.33 mmol) and *rac*-**3** (0.25 g, 0.65 mmol) in MeCN (10 mL) was kept at room temperature for 24 h, a 1:1 inclusion complex of **6b** and (+)-**3** was obtained, which precipitated as colorless prisms (0.22 g, 83% yield, m.p. 168–169 °C). Decomposition of the complex with dilute HCl gave (+)-**3** (100% *ee*; 0.1 g, 80% yield, $[\alpha]_D = +58$ ($c = 1.0$, $CHCl_3$)). From the filtrate left after the separation of the inclusion complex, (−)-**3** (58% *ee*; 0.15 g, 80% yield, $[\alpha]_D = -35$ ($c = 1.5$, $CHCl_3$)) was isolated by treatment with dilute HCl. The enantiomeric purity of **3** was determined by HPLC by using a column containing an optically active solid phase, Chiralcel OC,[10] and hexane/*i*PrOH (90:10) as an eluent. The cinchonidinium salt **6b**, however, does not form inclusion complexes with **1** or **2**. It is interesting that the inclusion behavior of the cinchonidinium derivatives **6** varies dramatically depending on the alkyl substituent at the bridgehead N atom of these compounds. This might be due to a kind of molecular recognition in the inclusion crystal.

Previously we have shown that **1** forms crystalline inclusion complexes with the alkali metal hydroxides LiOH, NaOH, KOH, and CsOH, and that these hydroxides can be isolated from aqueous solution by using the complex formation with **1**.[12] The presence of strong hydrogen bonds between the OH groups of **1** and the HO^- ions of the alkali

metal hydroxide in these complexes has been observed by the measurement of the IR spectra. Hydrogen bonds are also formed between the OH groups of **1**, **2**, and **3** and the halogen counterions of **6**. This was clarified by X-ray structure analyses of the corresponding inclusion complexes.[13] The X-ray crystal structures of these complexes will be reported in detail in the future.

Noteworthy is the very efficient chiral recognition in the formation of inclusion complexes of **6** with C_2 symmetrical chiral biaryldiol derivatives such as **1**, **2**, or **3**. They are particularly useful for the separation of the enantiomers of biaryldiols. It is also interesting that the behavior of the cinchonidine derivatives **6** is completely different from that of cinchonidine itself; the latter does not form inclusion complexes with **1**, **2**, or **3**.[14] These findings may be applicable to other combinations of salts of alkaloids or simple chiral alkylamines with biaryldiol derivatives.

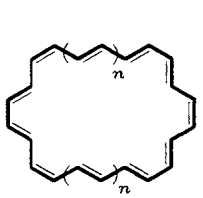
Porphyrins with Aromatic 26π-Electron Systems**

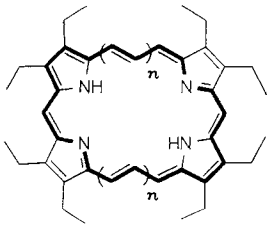
By *Thomas Wessel, Burchard Franck,* Manfred Möller,* Ute Rodewald,* and *Mechthild Läge*

In memory of Franz Sondheimer

With the synthesis of the aromatic [18]annulene **1a**, the hexavinylogous benzene, Sondheimer[1] achieved a major breakthrough: he provided valuable experimental evidence in support of the wide-reaching validity of the $(4n + 2)$ rule for aromatic π-electron systems.[2] Moreover, in agreement with HMO calculations,[3] it has been determined that also [22]annulene **1b** shows aromaticity at low temperatures, whereas resonance stabilization in [26]annulene **1c** is no longer[4] sufficient to stabilize the molecule in a planar conformation with aromatic properties.



1a: $n = 0$ (18π)
1b: $n = 1$ (22π)
1c: $n = 2$ (26π)



2a: $n = 0$ (18π)
2b: $n = 1$ (22π)
2c: $n = 2$ (26π)

We report here on the synthesis of [26]porphyrin **2c**, its crystal structure, its diatropicity, and initial investigations on electrophilic substitution. Thus it has been demonstrated that this cyclic, conjugated system with 26 π electrons is aromatic. Furthermore, the phenyl- and alkyl-substituted [26]porphyrins **8a** and **8b**, respectively, and a [26]azaporphyrin **9** were synthesized.

We recently described the synthesis of stable, aromatic [22]porphyrins, for example, **2b** with 22 π-electron perimeters;[5, 6] like the parent porphyrin **2a**, **2b** is a bisazaannulene. The pyrrole units situated at the corners stabilize the planar conformation without impairing the annulenoid conjugation, by the formation of individual π-electron sextets. Octaethyl[18]porphyrin **2a** prepared by Hans Fischer et al.[7] developed into the most frequently used porphyrin. In a similar way the bis- and tetravinylogues **2a** and **2c**, respectively, may find manifold applications.

Our synthesis of [26]porphyrin **3**[11] had helped to clarify whether the $(4n + 2)$ rule no longer applies to [26]annulene **1c** in general or only to annulene-type conjugated cyclic systems. Like compound **4**,[12] described almost at the same time by LeGoff et al., significant diamagnetic ring current effects in the ^{1}H NMR spectrum demonstrated that this system is aromatic. Furthermore, diatropic 26 π-electron systems have been described in which the annulene perimeter is planar, stabilized by six pyrrole units,[13, 14] or by allene and ethyne groups (dehydroannulenes).[15] In one case, a crystal structure analysis was carried out for a corrinoid hexapyrrole.[14]

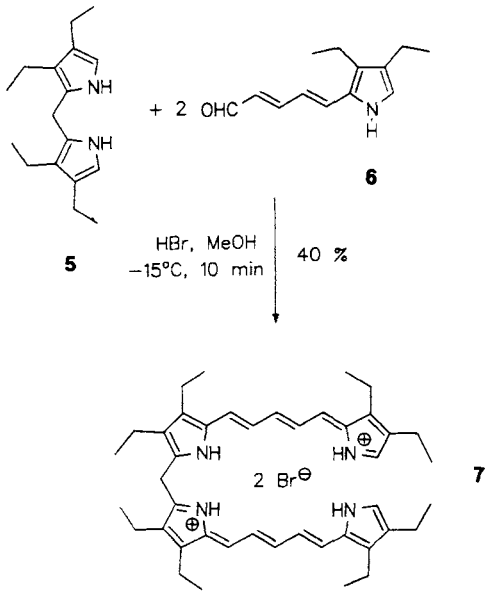
[**] Novel porphyrinoids, Part 12. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG (Ludwigshafen). Part 11: [5].

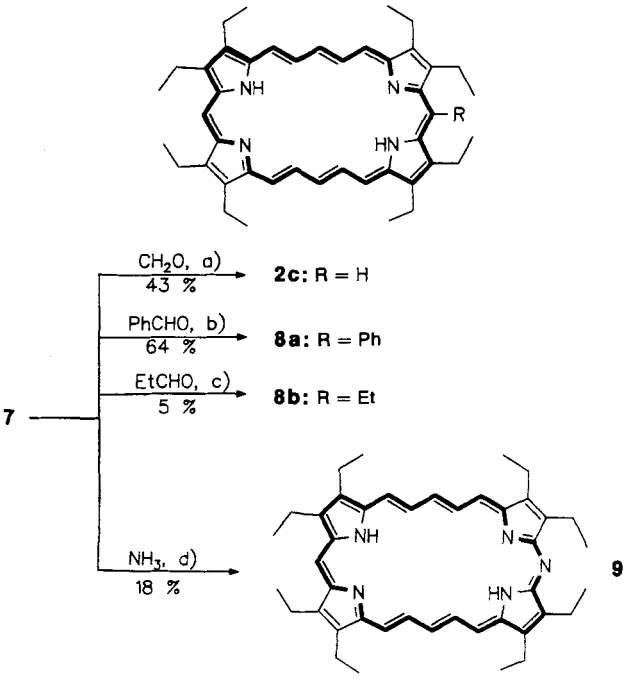
Analogous to the synthesis of the 22π compound **2b**,[6] for the octaethyl[26]porphyrin **2c**, a buildup by the "biladiene synthesis path" was considered, because it allows the simultaneous preparation of *meso*-substituted derivatives and a 14-aza[26]porphyrin (Scheme 1). However, it seemed doubtful whether the required, still unknown open-chain tetrapyrrole **7** with two heptavinylogous amidine systems was sufficiently stable. The condensation of **7** required that this compound although being a dication in acidic condensation medium can adopt the "hairpin" conformation.



Scheme 1. Synthesis of tetravinylogous biladiene **7**.

After intensive examination of alternative routes for the construction of **7**, its synthesis was achieved by condensation of dipyrrylmethane **5**[16] with the bisvinylogous pyrrole aldehyde **6**[17] in 40% yield. The bisvinylogous Vilsmeier formylation[17] of 3,4-diethylpyrrole with dimethylaminopentadienal proved to be suitable for the synthesis of **6**. Acid-catalyzed condensation of the open-chain tetrapyrrole **7** with formaldehyde/HBr and in situ dehydrogenation of the hydroporphyrinoid intermediate with DDQ (2,3-dichloro-5,6-dicyano-1,4-benzoquinone) gave the [26]porphyrin **2c** (red-violet in solution) in 43% yield (Scheme 2). Analogously, cyclization of **7** with benzaldehyde or propionaldehyde gave the 14-phenyl derivative **8a** and the 14-ethyl derivative **8b**, respectively. By reaction with ammonia and subsequent dehydrogenation, **7** could be converted into the 14-aza[26]porphyrin **9**. The spectroscopic data for these compounds are summarized in Table 1.

Experience has shown[6] that, because of its ethyl side chains, **2c** provides good preconditions for obtaining suitable single crystals for crystal structure analysis (Fig. 1). Crystallization from dichloromethane/trifluoroacetic acid (TFA) (20:1) gave the bistrifluoroacetate of **2c** as green, metallic, shiny cubic crystals. Measurements on this system, which had to be carried out at 170 K in order to fix the conformation of the [26]porphyrin dication, produced an unusual result. For example, the unit cell contains two different conformers of $\mathbf{2c}^{2+}$ in a ratio of 2:1. Two molecules occur—as regards the arrangement of their ethyl groups towards the ring plane—in an all-*trans* conformation with pseudo-C_2 symmetry. In this conformation, the ethyl side



Scheme 2. Synthesis of octaethyl[26]porphyrin **2c**, its 14-phenyl and 14-ethyl derivatives **8a** and **8b**, respectively, and its 14-aza derivative **9**. Reaction conditions: a) aqueous CH_2O, MeOH, HBr, 20 min reflux, then DDQ/CH_2Cl_2, 20 °C, 1.5 h; b) PhCHO, MeOH, HBr, 20 °C, 48 h (without DDQ); c) EtCHO, MeOH, HBr, 20 °C, 48 h (without DDQ); d) NH_3, MeOH, 10 min at 20 °C, then DDQ 1 h at 20 °C.

Table 1. Analytical data of **2c**, **8a**, **8b**, **9**, and **7** (without ^{1}H NMR signals of CH_2CH_3 groups; the new compounds have been completely characterized by elemental analyses and spectra).

2c: ^{1}H NMR (300 MHz, [D$_6$]DMSO/[D$_1$]TFA, TMS): $\delta = -9.79$ (t, $J = 13.8$ Hz, 4H, CHC*H*CHC*H*CH), −5.77 (br. s, NH), 12.26 (s, 2H, monomethine bridges CH), 13.51 (d, $J = 13.8$ Hz, 4H, C*H*CHCHCHC*H*), 14.35 (t, $J = 7.4$ Hz, 2H, CHCHC*H*CHCH); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2980, 2920, 2910 (CH), 1590 (conj. C = C); UV/VIS (CH_2Cl_2): λ_{max} [nm] (lgε) = 507 (5.44), 528 (5.23), 553 (4.93), 663 (4.39); UV/VIS (CH_2Cl_2 + 1% TFA): λ_{max} [nm] (lgε) = 512 (5.84), 694 (4.61); high-resolution MS: $C_{44}H_{54}N_4$: calcd. 638.4348, found 638.4362; correct C,H,N analysis.

8a: ^{1}H NMR (300 MHz, [D$_6$]*DMSO*/[D$_1$]*TFA, TMS*): $\delta = -7.95$ (m, 4H, CHC*H*CHC*H*CH), −4.27 (br. s, NH), −3.03 (br. s, NH), 8.17 (m, 3H, *m*- and *p*-Ph-H), 8.89 (d, $J = 7.1$ Hz, 2H, *o*-Ph-H), 11.39 (s, 1H, monomethine bridges CH), 12.68, 12.73 (2d, $J = 15.2$ Hz, each 2H, C*H*CHCHCHC*H*), 13.60 (t, $J = 12.9$ Hz, 2H, CHCHC*H*CHCH); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3020 (= CH), 2960, 2920, 2870 (CH), 1600 (conj. C = C), 760, 700 (monosubst. arene); UV/VIS (CH_2Cl_2): λ_{max} [nm] (lgε) = 512 (5.56), 544 (5.02), 673 (4.44); UV/VIS (CH_2Cl_2 + 1% TFA): λ_{max} [nm] (lgε) = 525 (5.69), 7.11 (4.52); high-resolution MS: $C_{50}H_{58}N_4$: calcd. 714.4661, found 714.4678; correct C,H,N analysis.

8b: ^{1}H NMR (300 MHz, [D$_6$]*DMSO*/[D$_1$]*TFA, TMS*): $\delta = -7.42$ (t, J = 13.4 Hz, 4H, CHC*H*CHC*H*CH), −3.92 (br. s, NH), −2.97 (br. s, NH), 11.08 (s, 1H, monomethine bridges CH), 12.39, 12.43 (2d, $J = 13.0$ Hz, each 2H, C*H*CHCHCHC*H*), 13.28 (t, $J = 12.8$ Hz, 2H, CHCHC*H*CHCH); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3015 (= CH), 2975, 2916, 2890 (CH); UV/VIS (CH_2Cl_2): λ_{max} [nm] (lgε) = 512 (5.59), 546 (5.20), 673 (4.53); UV/VIS (CH_2Cl_2 + 1% TFA): λ_{max} [nm] (lgε) = 520 (5.81), 545 (5.35), 710 (4.56); high-resolution MS $C_{46}H_{58}N_4$: calcd. 666.4661, found 666.4645.

9: ^{1}H NMR (300 MHz, [D$_1$]TFA, TMS): $\delta = -4.47$ (m, 4H, CHC*H*CHC*H*CH), 11.26 (s, 1H, monomethine bridges CH), 11.77, 12.03 (2d, $J = 12.5$ Hz, 4H C*H*CHCHCHC*H*), 12.53 (t, $J = 12.7$ Hz, 2H, CHCHC*H*CHCH); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3410 (NH), 2960, 2920, 2860 (CH); UV/VIS (CH_2Cl_2): λ_{max} [nm] (lgε) = 490 (5.23), 649 (4.45), 697 (4.18); UV/VIS (CH_2Cl_2 + 1% TFA): λ_{max} [nm] (lgε) = 503 (5.56), 681 (4.51), 735 (4.44); high-resolution MS $C_{43}H_{53}N_5$: calcd. 639.4300, found 639.4295; correct C,H,N analysis.

7: ^{1}H NMR (300 MHz, [D$_6$]DMSO, TMS): $\delta = 5.56$, 5.61 (2 br. s, 2H, bridges CH_2), 6.75–7.27 (m, 12H, C*H* = C*H*-C*H* = C*H*-C*H* and pyrrole-α-H), 11.06, 11.18 (2 br. s, each 2H, NH); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2980, 2910, 2860 (CH), 1570 (conj. C = C); UV/VIS (CH_2Cl_2): λ_{max} [nm] (lgε) = 785 (4.34), 621 (5.54), 410 (4.24), FD-MS (CH_2Cl_2, 8 kV, 8–15 mA): *m/z* 629 (M^+ − 2Br − H, 100%), 628 (M^+ − 2HBr, 78%); $C_{43}H_{58}Br_2N_4$; correct C,H,N,Br analysis.

chains of both dipyrrylmethane units are bent away from one another (Fig. 1a). The third molecule is in the *cis-trans* conformation and is centrosymmetric. The ring systems of the all-*trans* and the *cis-trans* conformations are almost planar with, comparably,[14] very small maximum deviations from the mean plane (19.8 and 18.0 pm, respectively). The bond lengths in the conjugated perimeter (Fig. 1b), that is in

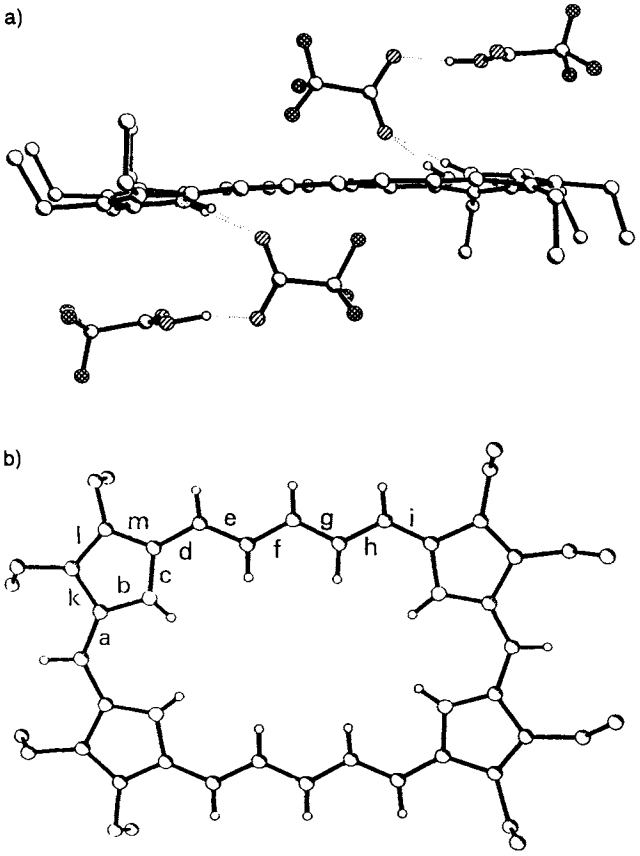


Fig. 1. Crystal structure of $\mathbf{2c}^{2+}$ bistrifluoroacetate. a) Side view of the all-*trans* conformation; b) View perpendicular to the arene plane of the all-*trans* conformation. Some characteristic distances [pm]: a = 139.1, b = 137.1, c = 137.3, d = 139.6, e = 138.1, f = 138.8, g = 139.2, h = 138.1, i = 139.1, k = 143.9, l = 137.5, m = 142.9.

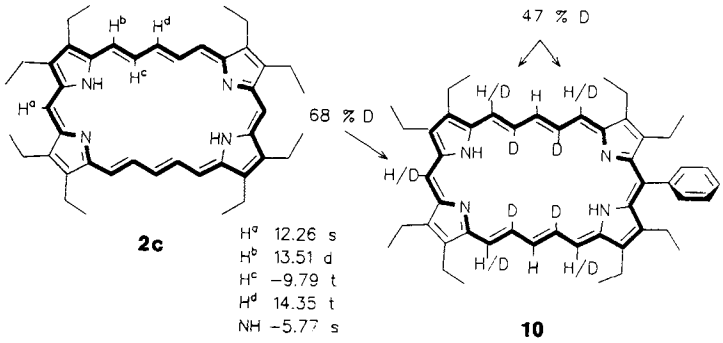
the C_1 and C_5 bridges and in the pyrrole units, are approximately equal (137.1–139.6 pm), and are in good agreement with those of $\mathbf{2a}^{2+}$.[19] Therefore, the [26]porphyrin **2c** fulfills the structural criteria of an aromatic system, that is it is planar and the bond lengths are approximately equal.

As expected, the ^{1}H NMR spectrum of **2c** as arene, shows significant diatropic ring current effects (Table 2, Scheme 3). The maximum difference between the δ values of the inner and outer protons $\Delta\delta = 24.1$ is approximately equal to the corresponding values for the [26]porphyrins **3** (25.31) and **4** (25.95). The diatropicity of the *meso*-substituted derivatives decreases from **8a** via **8b** to the aza derivative **9**, and lies in the range of that of [22]porphyrin **2b**.

The UV/VIS absorption spectra of the bisprotonated forms of the new [26]porphyrins, measured in CH_2Cl_2/TFA (Tables 1 and 2), are very similar. Compared with **2b**, they exhibit a bathochromic shift of 40–60 nm in the range of their most intensive Soret bands.

With the 14-phenyl[26]porphyrin **8a**, which is somewhat more stable than **2c**, electrophilic deuteration was carried out in D_2SO_4 (Scheme 3). NMR spectroscopic and mass



Scheme 3. ^{1}H NMR data of octaethyl[26]porphyrin **2c** and electrophilic deuteration of 14-phenyloctaethyl[26]porphyrin **9**.

Table 2. Maximum shift differences $\Delta\delta$ between the inner and outer protons in the ^{1}H NMR spectra of the new octaethyl[26]porphyrins(5.1.5.1) [20] (**2c**, **8a**, **8b**, **2b** in [D_6]DMSO/[D_1]TFA, **9** in [D_1]TFA); and their most intense (Soret bands) and longest wave UV/VIS bands in CH_2Cl_2/TFA.

Compound [20]	$\Delta\delta$	λ_{max} [nm] (lgε)
[26]porphyrin(5.1.5.1) **2c**	24.1	512 (5.84) 694 (4.61)
14-phenyl[26]porphyrin(5.1.5.1) **8a**	21.6	525 (5.69) 711 (4.52)
14-ethyl[26]porphyrin(5.1.5.1) **8b**	20.7	520 (5.81) 710 (4.56)
14-aza[26]porphyrin(5.1.5.1) **9**	18.9	503 (4.51) 735 (4.44)
[22]porphyrin(3.1.3.1) **2b**	22.3	460 (6.05) 691 (3.90)

spectrometric studies of the deuteration product **10** revealed that all of the inner bridge protons, and some of the outer bridge protons had been exchanged at a degree of deuteration of approximately 70% (determined by mass spectrometry). This result agrees with the aromaticity of **8a**. Noteworthy is especially the difference to the deuteration of [22]porphyrin **2b**, in which only the outer protons are replaced.[6] An explanation for this phenomenon, which will be reported later in connection with further deuterations of vinylogous porphyrins, is based on the size of the porphyrinoid rings, and the inductive effect of the phenyl substituents.[21]

[8] This applies particularly to the use of porphyrins as photosensitizers for photodynamic tumor therapy (PDT)[9] and the deactivation of viruses in transfusion blood (PDV)[10]. Owing to the longer wave VIS absorption of vinylogous porphyrins, light can be employed which is not absorbed by hemoglobin. Moreover, they do not form complexes with iron or other transition metals by which they would be deactivated in organisms as photosensitizers.

[20] For the nomenclature of vinylogous porphyrins, based on our suggestion [11], the number of C atoms in the *meso* bridges are in brackets after the name of the porphyrin. In the case of vinylogous porphyrins with different bridge lengths, the number of C atoms in the *meso* bridges, starting with the α-pyrrole unit (upper left) and moving clockwise, is given. Thus, the ring system **2c** has the name "[26]porphyrin(5.1.5.1)".

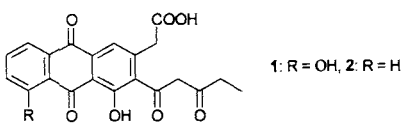
Synthesis of 4-Deoxyaklanonic acid and Its Microbial Conversion into Anthracyclinones**

By *Karsten Krohn,* Ernst Roemer, Michael Top,* and *Christina Wagner**

Dedicated to Professor Eckehard Volker Dehmlow on the occasion of his 60th birthday

Very little is known about the intermediates in the biosynthesis of polyketides on the way from the hypothetical enyzme-bound open-chain polyketo precursor to the cyclized final products.[1] A notable exception to this is aklanonic acid **1**, a partially cyclized anthracycline precursor which is produced by mutants of *Streptomyces galilaeus* and *Streptomyces peucetius*.[2] It was isolated as a block mutant product and is considered to be the most important intermediate in anthracycline biosynthesis.[3] The incorporation of isotopically labeled alkanonic acid **1** into a variety of anthracyclines has demonstrated that aklanonic acid is really an intermediate and not merely a shunt product.[4]

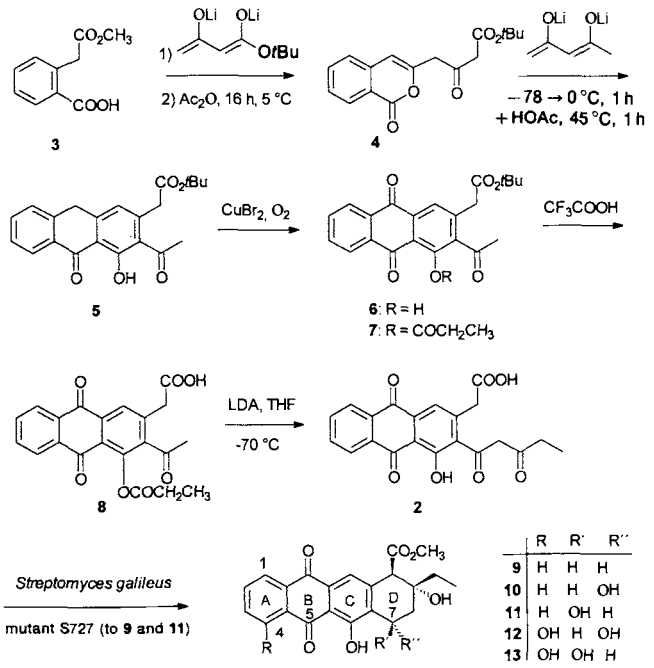
The discovery of aklanonic acid **1** led us to attempt the enantioselective cyclization of achiral ketoester precursors—



1: R = OH, **2**: R = H

as yet an unsolved problem in the synthesis of anthracylines—using a microbial conversion. We report here the synthesis and the biotransformation of the unnatural 4-deoxyaklanonic acid **2** to anthracyclinones of the aklavinone type.

The synthesis of **2** starts from the well-known homophthalate monoester **3**,[5] which is treated with an excess of the dilithium salt of *tert*-butylacetoacetate dianion (Scheme 1).



Scheme 1. LDA = lithium diisopropylamide.

The open-chain acid formed initially is cyclized without isolation with acetic anhydride to isocoumarin **4**[6] (57%). Treatment with a threefold excess of the dilithium salt of the acetylacetone dianion according to the procedure of Yamaguchi et al.[7] led to the formation of anthrone **5** (72%), which is oxidized by oxygen in the air in the presence of copper bromide to the anthraquinone **6** (87%). The transformation of the not very reactive phenol into the corresponding propionate **7** (82%) was achieved by using propionyl chloride in the presence of 5% 4-dimethylaminopyridine. To prevent a premature base-catalyzed cyclization during the final chain elongation step by a Venkataraman rearrangement,[8] the *tert*-butylester **7** was first saponified with trifluoroacetic acid to yield the acid **8** (98%). The intramolecular rearrangement of the acyl groups was achieved by reaction at −40 °C with LDA in THF. In addition to 70% of the chain elongation product 4-deoxyaklanonic acid **2** (C-acylation), about 30% of the saponification product **6** was isolated; **6** was probably formed by an O-acylation and can be reused in the reaction. The synthesis of aklanonic acid **1** was achieved in an analogous manner.[9]

The synthetic product **2** was then given to mutants of *Streptomyces* to see if they could use this unnatural precursor as substrate and convert it into enantiomerically pure 4-deoxyanthracyclinones not found so far in nature.

The mutant strain used (S727) was obtained by treating *Streptomyces galilaeus* (cinerubin producer) with the potent mutagen *N*-methyl-*N'*-nitro-*N'*-nitrosoguanidine (MNNG) (2 mg mL^{-1} at pH 9.0). The mutant strain S727 does not enrich anthracyclines or anthracyclinones and was first used to convert aklanonic acid **1** into cinerubin.[10] The wild type is known for it's abililty to produce aklavinone **12** and aklavinone-II **13**.[11]

Beutenbergstrasse-11, D-07745 Jena (FRG)

[**] This work was supported by the Bundesministerium für Forschung und Technologie.

A total of 34 mg of 4-deoxyaklanonic acid **2** was added to the cultures of the strain S727 in the feeding experiments (11 flasks each with 80 mL of culture medium). After an incubation period of 24 h, the pH of the cultures was adjusted to 8.5, and the metabolites were extracted with chloroform/methanol (9:1, v/v). Thin-layer chromatography revealed three red to violet minor products and two yellow major products. The polar compound (3 mg) exhibits the typical behavior of anthracyclinones hydroxylated twice in ring A (dehydration to yield fluorescent naphthacenediones). However, the results of NMR studies indicate that it is not identical with synthetic 4-deoxyaklavinone **10**,[12] and that in fact the compound in question is the C-7 epimeric 4-deoxyaklavinone-II **11**.[11, 12] The nonpolar major product, (17 mg, $[\alpha]_D^{20} = 31$ ($c = 0.2$ in methanol); m.p. 174.5 °C), was identified as 4,7-dideoxyaklavinone **9** by comparison with racemic synthetic compounds.[12] The enantiomeric purity was checked by using HPLC with a chiral column (Chiradex, Merck; gradient: T_0: 50%: 0.1% triethylamine buffered with HOAc to pH 4.4/50% methanol; t_{15}: 100% methanol). The racemic 4,7-dideoxyaklavinone[12] showed, as expected, two peaks; the product **9** from the microbial transformation corresponded to the enantiomer with a lower retention time. Although no values are available (e.g. optical rotation values) which could be used for a direct comparision for the determination of the absolute configuration, we assume that **9** has the natural (9*R*,10*R*) configuration, since the wild type of the mutant used also produces aklavinones with this absolute configuration.

Thus, we have demonstrated for the first time that relatively simple achiral unnatural precursors can be converted in a multistep biotransformation with high yield (56%) into optically active anthracyclinones. 4-Demethoxy analogues of daunorubicin compounds have already been clinically used and have proved to be more effective against tumors in vitro than the natural compounds.[13] With this new "hybrid" synthetic technique, in which chemical synthesis is combined with a multistep biotransformation, it will be possible to use other mutants to produce glycosidic anthracyclinones.[14] Furthermore, the synthesis of the biosynthetic intermediates **1** and **2** is designed to enable isotopic labeling and thus allow the biosynthesis to be investigated in more detail.

Competing $M{=}C_{carbonyl}$ and $M{=}C_{carbene}$ Bonds: Cycloaddition to the Metal–$C_{carbonyl}$ Bond in η^2-Thiocarbene Complexes**

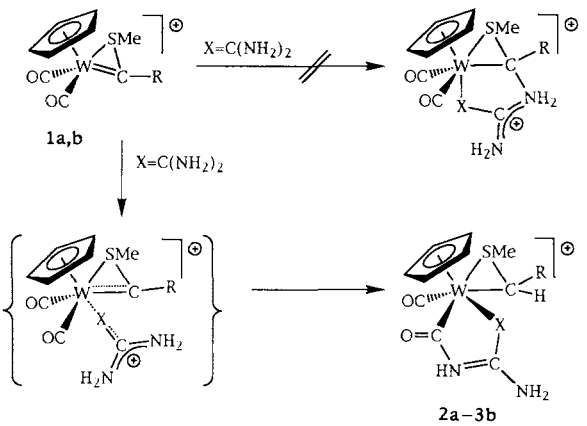
By *Fritz R. Kreissl,** *Wolfgang Schütt, Josef Ostermeier,* and *Eberhardt Herdtweck*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

Cycloadditions to metal–carbon multiple bonds are attaining increasing significance in metathesis[1–5] as well as in preparative organic and organometallic chemistry. In complexes in which the carbon atoms of the M=C units belong exclusively to carbonyl[6–10] or isonitrile ligands,[7, 11, 12] 1,3-dipoles preferably attack the M=C bond; thus, among other products, five-membered metallaheterocycles are formed. However, if additional carbene,[5, 13, 14] vinylidene,[15, 16] or carbyne ligands[17, 18] are present, the attack of the 1,3-dipole takes place at the M–C multiple bond of these groups.

Starting from $[Cp(CO)LM{\equiv}CR]$[19, 20] (M = Mo, W; R = Me, Ph, *p*-tolyl, NEt_2; L = CO, PR_3), 3*H*-1,2,3,4-triazametallol complexes[18, 21] can be prepared through a [2 + 3] cycloaddition with azido esters. In comparable cationic η^2-thiocarbene complexes $[Cp(CO)LM{=}C(R)SMe]^+$[22, 23] (M = Mo, W; R = Me, Ph, *p*-tolyl; L = CO), which include the complexes **1a** (M = W, R = Ph) and **1b** (M = W, R = *p*-tolyl) reported here, the attack of the dipole occurs at the $M{=}C_{carbene}$ bond and not at the $M{=}C_{carbonyl}$ bond; thus, thiatriazametallabicyclo[3.1.0]hexenes[24] are formed.

However, the attempt to bridge the metal–carbene bond with thio- or selenourea, which are significantly weaker dipoles failed! Furthermore, the $M{=}C_{carbonyl}$ bond, which is in competition with the $M{=}C_{carbene}$ bond, is more reactive; to our knowledge the first example of such reactivity. In the reaction of **1** with $X{=}C(NH_2)_2$ (X = S, Se) (Scheme 1), which occurs rapidly, the M=CO bond is bridged with the formation of a 1-thia/selena-3-aza-5-tungstacyclopenten-4-one. Together with the thiatungstacyclopropane system, the



Scheme 1. **1a–3a**: R = Ph; **1b–3b**: R = *p*-tolyl; **2**: X = S; **3**: X = Se.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

spirocycles **2** and **3** are obtained which precipitate in the form of yellow to red crystals.

The cycloaddition of thio- or selenourea leads to the appearance of two additional broad signals for the NH protons and one sharp singlet for the newly formed CH group in the ^{1}H NMR spectrum. In the $^{13}C\{^1H\}$ NMR spectrum, the protonation of the carbene carbon atom results in a drastic high-field shift ($\Delta\delta \approx 180$) of the corresponding signal. The molecular ion peaks of the spirocycles **2a,b**, and **3b** can be observed in the positive ion FAB mass spectra.

Compound **2a** crystallizes from acetonitrile/diethyl ether in the form of rhombohedral crystals. The single-crystal X-ray structure analysis[25] of **2a** shows a spirocyclic system with the central tungsten atom as the bridgehead between a heteroatom-substituted three-membered ring and a nearly planar metallaheterocycle (Fig. 1). The metal–sulfur bonds

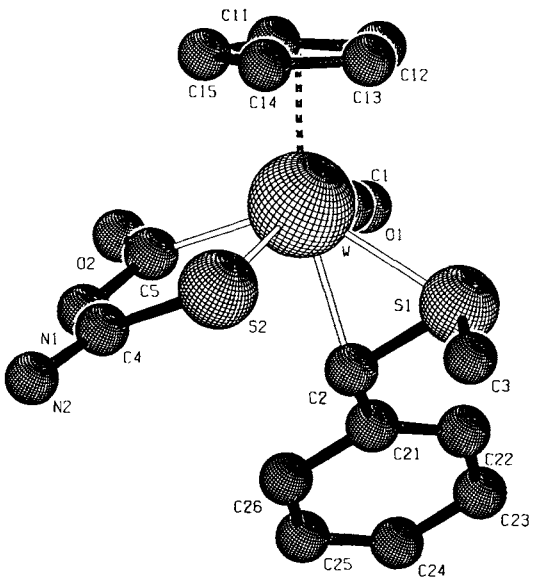

Fig. 1. Crystal structure of **2a**. Selected bond lengths [pm] and angles [°]: W-S1 244.2(1), W-S2 250.2(1), W-C1 201.1(5), W-C2 224.9(4), W-C5 218.8(4), C2-S1 178.6(4), S2-C4 171.5(4), C4-N1 134.4(5), C4-N2 131.2(4), N1-C5 139.8(4), C5-O2 121.8(5), C1-O1 114.8(5); S1-W-C1 85.8(04), S1-W-C2 44.5(1), S2-W-C5 79.3(1), C1-W-C2 76.3(2), W-S1-C2 62.0(1), W-C2-S1 73.5(2), W-C5-N1 117.0(3), C5-N1-C4 124.3(3), N1-C4-S2 119.7(3), N1-C4-N2 120.1(3), N2-C4-S2 120.2(3), C4-S2-W 99.6(1).

in both rings are between 244 and 250 pm long and, in comparison to those in $[Cp(CO)_2\overline{W=C(Ph)SMe}]^+$[22] (242.9 pm) and $[Cp(CO)_2(CF_3COO)\overline{W-CH(Me)SMe}]^+$[26] (247.5 pm), are considered to be single bonds. The protonation of the carbene carbon atom in the W-S-C three-membered ring leads to a lengthening of the W–C distance (224.9 pm). This distance now corresponds to those found for W–C single bonds (cf. $[Cp(CO)_3W(Ph)]$[27] ($d(W-C_{ipso}) = 232$ pm) and $[Cp(CO)_2(CF_3COO)W-CH(Me)SMe]^+$[26] ($d(W-C) = 224.8$ pm). The conversion of the terminal into a bridging carbonyl function is shown in the significant lengthening of the $W-C_{CO}$ bond; its length now lies between those found for double and single bonds.

For the formation of **2** and **3**, the nucleophilic attack of the chalcogen (S, Se) in $X=C(NH_2)_2$ at the tungsten center is considered to be the initial step. Thus, the resulting increase in the positive charge at the $C(NH_2)_2$ group should increase the acidity of the amine protons to such an extent that the protonation of the nucleophilic carbene carbon atom[13, 15] in **1** is made possible. The final linkage of the $C_{CO}-N$ bond between the carbonyl carbon atom and the imine nitrogen atom leads formally to the 1-thia-3-aza-5-metallacyclopenten-4-one. A protonation of the nucleophlic carbene carbon atom as initial step, as in the reaction of $[Cp(CO)_2\overline{W=C(R)SMe}]^+[BF_4]$ with CF_3COOH,[26] seems unlikely due to urea's lack of acidity. Furthermore, urea acts as a nitrogen base towards the comparable methyl-substituted cationic η^2-thiocarbene complex $[Cp(CO)_2\overline{W=C(Me)SMe}]^+$, and like triethylamine deprotonates the C methyl group with the formation of the thiovinyl complex $[Cp(CO)_2\overline{W-C(=CH_2)SMe}]$.[28]

Experimental Procedure

2a: **1a** (0.30 g, 0.57 mmol) in acetonitrile (10 mL) was treated with a solution of thiourea (0.04 g, 0.53 mmol) in acetonitrile (5 mL) at room temperature. During the reaction, the initially red solution slowly lightened in color. After 4 h the solvent was removed under high vacuum, the orange-yellow residue was washed several times with small amounts of dichloromethane, and subsequently recrystallized from acetonitrile/diethyl ether at −35 °C. Red crystals. Yield: 70%; m.p. 139.4 °C (decomp). IR (CH_3CN): $\tilde{\nu}$[cm^{-1}] = 2015 vs, 1634 m; MS (FAB): *m/z*: 517 $[M]^+$; ^{1}H-NMR (270.27 MHz, CD_3NO_2): δ = 9.71 (br, NH), 7.60 (br, NH_2), 7.24 (m, 5H, C_6H_5), 5.74 (s, 5H, C_5H_5), 4.87 (s, 1H, CH), 2.62 (s, 3H, SCH_3); $^{13}C\{^1H\}$ NMR (67.94 MHz, CD_3NO_2, 20 °C): δ = 209.3 (CO), 209.4 (W-CO-N), 184.6 (N-C-S), 142.4, 129.7, 128.3, 127.4 (C_6H_5), 92.9 (C_5H_5), 74.6 (W-C), 21.6 (SCH_3).

2b: Analogous to the preparation of **2a**, **1b** (0.27 g, 0.50 mmol) was treated with thiourea (0.035 g, 0.46 mmol) in acetonitrile (5 mL) and worked up. Pale yellow powder. Yield: 75%. IR (CH_3CN): $\tilde{\nu}$[cm^{-1}] = 2015, vs, 1635 m; MS (FAB): *m/z*: 531 $[M]^+$; ^{1}H NMR (270.27 MHz, CD_3NO_2): δ = 9.66 (br, NH), 7.56 (br, NH_2), 7.15 (m, 4H, C_6H_4), 5.73 (s, 5H, C_5H_5), 4.84 (s, 1H, CH), 2.61 (s, 3H, SCH_3), 2.38 (s, 3H, CH_3); $^{13}C\{^1H\}$ NMR (67.94 MHz, CD_3NO_2, 20 °C): δ = 209.4 (CO), 209.3 (W-CO-N), 184.7 (N-C-S), 139.4, 138.5, 130.2, 127.3 (C_6H_4), 92.8 (C_5H_5), 74.8 (W-C), 21.5 (SCH_3), 20.9 (CH_3).

3a: **1a** (0.37 g, 0.70 mmol) in dichloromethane (10 mL) was treated (in small portions) with selenourea (0.08 g, 0.65 mmol) in acetonitrile (10 mL) at −30 °C. After 6 h the mixture was worked up as for **2a**. Pale yellow powder. Yield: 60%. IR (CH_3CN): $\tilde{\nu}$[cm^{-1}] = 2014 vs, 1634 m; MS (FAB): *m/z*: 441 $[M]^+$; ^{1}H NMR (270.27 MHz, CD_3COCD_3): δ = 9.36 (br, NH), 8.57 (br, NH_2), 7.24 (m, 5H, C_6H_5), 5.85 (s, 5H, C_5H_5), 3.75 (s, 1H, CH), 2.71 (s, 3H, SCH_3); $^{13}C\{^1H\}$ NMR (67.94 MHz, CD_3COCD_3, −50 °C, $^1J(^{183}W,^{13}C)$ in parentheses): δ = 209.3 (CO, 140.5 Hz), 210.6 (W-CO-N, 125.1 Hz), 184.7 (N-C-Se, 106.0 Hz), 142.4, 129.7, 128.3, 127.3 (C_6H_4), 92.9 (C_5H_5), 74.6 (W-C), 21.5 (SCH_3)

3b: Analogous to the preparation of **3a**, **1b** (0.54 g, 1.00 mmol) in dichloromethane (10 mL) was treated (in small portions) with selenourea (0.11 g, 0.89 mmol) in acetonitrile (10 mL) at −30 °C. Analogous workup gave **3b** as a pale yellow powder. Yield: 69%. IR (CH_3CN): $\tilde{\nu}$[cm^{-1}] = 2013 vs, 1634 m; MS (FAB): *m/z*: 578 $[M]^+$; ^{1}H NMR (270.27 MHz, CD_3COCD_3): δ = 9.30 (br, NH), 8.60 (br, NH_2), 7.05 (m, 4H, C_6H_4), 5.84 (s, 5H, C_5H_5), 3.75 (s, 1H, CH), 2.69 (s, 3H, SCH_3), 2.33 (s, 3H, CH_3); $^{13}C\{^1H\}$ NMR (67.94 MHz, CD_3COCD_3, −50 °C): δ = 209.4 (CO), 210.3 (W-CO-N), 178.6 (N-C-Se), 139.3, 136.4, 129.3, 126.3 (C_6H_4), 91.4 (C_5H_5), 70.5 (W-C), 21.8 (SCH_3), 20.6 (CH_3).

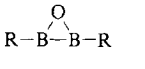
On the BO Bond Length in Oxadiboriranes**

By *Michael Bühl, Henry Frederick Schaefer III,** *Paul von Ragué Schleyer,** and *Roland Boese**

High-level ab initio calculations, an important source of accurate structural data,[1] can help decide among competing structural models obtained from experimental refinements.[2] Recently the first oxadiborirane (**1d**)[3] was synthesized and characterized by X-ray structure analysis. The accuracy was reduced due to disorder, but the refinement favored (model A) gave extremely long BO bond lengths (1.545(5) and 1.510(6) Å). These disagreed with the much shorter BO distances (1.409[4] and 1.403 Å[3]) which were calculated for the parent compound **1a**, both at the modest (HF/3-21G)[4] and at the higher (MP2/6-31G*)[3] level. We now report the results of a variety of quantum mechanical calculations which reveal that a second refinement (model B), although more disordered, provides a better description of the molecular geometry than the previously published crystal structure.

Conventional refinement of the X-ray diffraction data for **1d** (model A) resulted in an essentially linear CBBC arrangement; in accord with crystallographic centrosymmetry, the oxygen atoms were found with 50% probability on each side of the B–B bond.[3] The BBC angles of 178 and 182° exaggerated the trend towards linearity predicted computationally for the parent compound **1a**.[3,4] More importantly, the



1a, R = H **1c**, R = $C(SiH_3)_3$
1b, R = CH_3 **1d**, R = $C(SiMe_3)_3$

BO bond lengths of this model (A) did not agree with the ab initio calculated distances. An alternative, preliminary refinement with split positions, allowing for disorder of the boron atoms as well as the oxygen atom (model B), afforded BO separations of around 1.38 Å which are in much better agreement with the theoretical results. The R value of this model B, however, was not significantly better than that of model A. Since the theoretical geometries of the parent system **1a** might be different from those of the highly substituted compound **1d**, it was decided to publish the results for model A, the conventional refinement.[3]

We now have investigated the substituted derivatives **1b** and **1c** at the SCF/DZP level, as well as the parent oxadiborirane **1a** at higher levels of theory including large basis sets and more sophisticated treatments of electron correlation.[5,6] As apparent from the results in Table 1, there is no change in the theoretical conclusion. The computational evidence requires that **1a** does not possess a BO bond longer than about 1.39 Å. The CCSD(T)/TZ2Pf value (1.388 Å) should be reliable. The geometry changes upon methyl (**1b**)

Table 1. Geometries of oxadiboriranes **1a**–**1d**.

Cmpd.	R	Level	B-O [Å]	B-B [Å]	B-H [Å]	B-B-H [°]

and trisilylmethyl (**1c**) substitution are less than 0.01 Å for the BO separations (SCF/DZP level, lower part in Table 1). The structural differences between **1c** and **1d** should be even smaller.

Energy considerations also argue against model A: a partially optimized structure **1a′**, based on the published X-ray structure (i.e. **1a** with a fixed three-membered BBO ring but with freely optimized (B)–H positions), was 12.4 kcal mol^{-1} less stable (CISD/DZP level) than the fully optimized geometry (**1a**, C_{2v}).[7] Finally, the averaged IGLO ^{11}B NMR chemical shift[8] calculated by using this hypothetical structure (**1a′**), $\delta = 81.1$, does not agree with the value observed experimentally for **1d** ($\delta = 65.7$).[3] In contrast, the computed structures for **1a** give very good agreement: $\delta = 67.0$ (II′//MP2/6-31G*) and 66.3 (II′//CISD/DZP).[9]

Prompted by these apparent deficiencies of model A, the second, split model B was refined further.[10] The final molecular structure (Fig. 1) can be viewed as a superposition

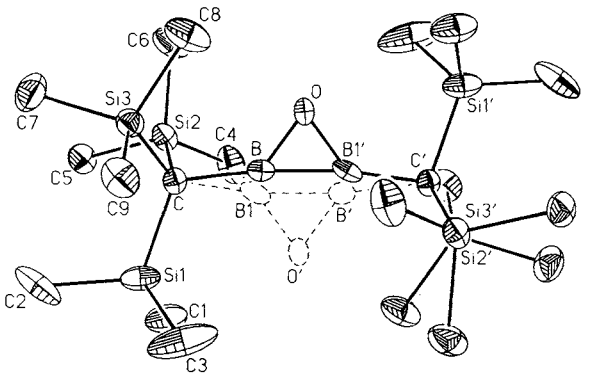

Fig. 1. Molecular structure of **1d** in the solid state (model B). The ellipsoids correspond to 50% probability of electron occupation, hatched and unhatched atoms are equivalent by crystallographic centrosymmetry, the disordered oxygen and boron atoms are drawn with dashed outlines, and the hydrogen atoms are omitted for clarity. Selected distances [Å] and angles [°] (standard deviation in parentheses): B-B1′ 1.599(9), B-O 1.347(7), B1′-O 1.365(7), B-C 1.607(7), B1′-C′ 1.510(7), O-B-B1′ 54.4(3), B-O-B1′ 72.3(4), C-B-B1′ 172.2(5), C′-B1′-B 171.9(5).

of two independent molecules disordered about the crystallographic inversion center. The "averaging" of the B and B1 as well as B1′ and B′ positions, leads to the apparently elongated BO separations of model A. The BO distances deduced from model B (1.347(7) and 1.365(7) Å) are now in much better agreement with the results of the ab initio calculations (1.378 Å for **1c**, Table 1). In contrast to model A, these BO bond lengths are also within the usual range observed for trigonal-coordinated boron (1.28–1.43 Å, mean value 1.365 Å),[11] and are close to the BO separations in Me_2B-O-BMe_2 (1.359(4) Å[12]), an acyclic reference compound.

Likewise, the BBC bond angles from model B (172.2(5) and 171.9(5)°) are in better accord with the ab initio values for **1c** (172.8°, Table 1) than those of model A (177.7(3)° and 182.3(3)°[3, 13]). Finally, the computed energy of **1a″**, employing the BBO ring dimensions derived from model B, is only 1.5 kcal mol^{-1} higher than that of the fully optimized structure of **1a** (CISD/DZP level).

In summary, the refinement employing model B results in much better agreement of theory and experiment and represents the molecular geometry of **1d** more reliably than that derived from model A.[3] However, correlations between the refined parameters (ADPs) increase the error margins of the experimental data beyond the commonly used 3 σ criterion. In addition, the large vibrational motion of the oxygen atom perpendicular to the BBO ring plane is expected to shorten the observed BO distance artificially. Also, the $SiMe_3$ positions should be affected by the disorder of the BBO ring. Some evidence for this can be detected by investigation of the ADPs of the respective atoms, but it was not possible to resolve them in split positions. Based on the ab initio data in Table 1, we recommend 1.39 Å as reference value for the equilibrium BO bond length in oxadiboriranes. While crystallographic criteria (i.e. *R* values) could not decide between the two alternative structural models A and B for **1d**, our theoretical results (geometries, energies, and NMR chemical shifts) unambiguously demonstrate that model B (Fig. 1) affords the more realistic experimental geometrical parameters.

This again demonstrates a general admonition: when their results do not agree with high level ab initio computations, experimentalists are encouraged to consider other possible interpretations of their data if this leads to better accord between theory and experiment.

Kaupp, Stuttgart, for this analysis.

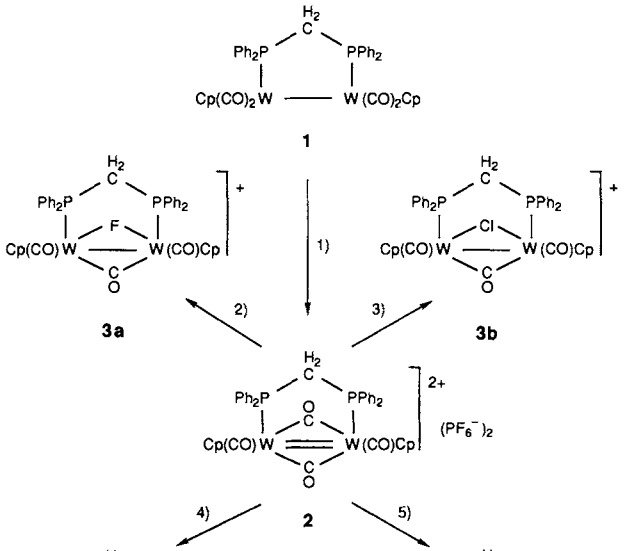
A Highly Electrophilic Unsaturated Ditungsten Dication**

By *M. Angeles Alvarez, M. Esther García, Victor Riera,* Miguel A. Ruiz, Claudette Bois*, and *Yves Jeannin*

Organometallic transition metal dimers with formal metal–metal bond order of two or higher are attractive species, since they usually react with a great variety of molecules under mild conditions. Members of this class of compounds include, for example, $[M_2(CO)_4L_2]$ $(M{\equiv}M)$ (M = Cr, Mo, W),[1a,b] or $[M_2(CO)_2L_2]$ $(M{=}M)$ (M = Co, Rh, Ir),[1b] (L = η^5-C_5H_5 (Cp), or related ligands); the electrophilicity of these complexes is perhaps their most chracteristic property. A positive charge in a molecule with a metal–metal multiple bond should therefore greatly enhance its electrophilicity. Such organometallic cations are, however, very scarce, and are generally synthesized through redox reactions,[2] and their chemistry has been little explored. Further interest in such transition-metal-based Lewis acids, arises from their potential use as homogeneous catalysts in a number of organic reactions.[3] We report here the preparation of the novel unsaturated cationic ditungsten complex $[W_2(\mu\text{-CO})_2(CO)_2(\mu\text{-dppm})Cp_2]^{2+}$ $(W{=}W)$ (dppm = $Ph_2PCH_2PPh_2$) as PF_6^- salt **2**, and about the remarkable electrophilicity of this complex; its reactions are summarized in Scheme 1.



Scheme 1. 1) 2[$FeCp_2$]PF_6, −10 °C, CH_2Cl_2, 5 min. 2) 25 °C, CH_2Cl_2, 10 min. 3) [$AsPh_4$]Cl, CH_2Cl_2, −30 °C, 10 min. 4) BH_3 · THF, CH_2Cl_2, −30 °C, 10 min. 5) MeOH, −30 °C, CH_2Cl_2, 5 min. The counterion for the cationic complexes **3a**, **3b**, **4** and **6** is PF_6^-.

The Reaction of **1** with two equivalents of $[FeCp_2]PF_6$ in dichloromethane at −10 °C gave almost quantitatively compound **2** as a violet microcrystalline precipitate.[4] The salt **2** is stable as a solid below −10 °C, but reacts rapidly in solu-

$[W_2(CO)_4(\mu\text{-dppm})Cp_2]$ **1**

$[W_2(\mu\text{-CO})_2(CO)_2(\mu\text{-dppm})Cp_2](PF_6)_2$ **2**

tion even below that temperature (for example, in acetone at −40 °C),[5] to give the green-brown fluorobridged tricarbonyl complex **3a** (as PF_6^- salt).[6] In this reaction a fluoride

$[W_2(\mu\text{-F})(\mu\text{-CO})(CO)_2(\mu\text{-dppm})Cp_2](PF_6)$ **3a**-PF_6

ion is transferred from the anion to the cation, and a CO ligand is liberated. Although fluoride abstraction from PF_6^- by mononuclear transition metal complexes has been observed in several instances,[7] there appears to be only one reported example involving a dinuclear system.[8] On the other hand, compound **3a**-PF_6 is, to our knowledge, the first organometallic complex in which a fluoro ligand bridges a metal–metal bond.[9] So far, we have not succeeded in growing suitable crystals of **3a**-PF_6, but have characterized its chloro analogue **3b**-PF_6 by X-ray crystallography (Fig. 1).[10]

$[W_2(\mu\text{-Cl})(\mu\text{-CO})(CO)_2(\mu\text{-dppm})Cp_2](PF_6)$ **3b**-PF_6

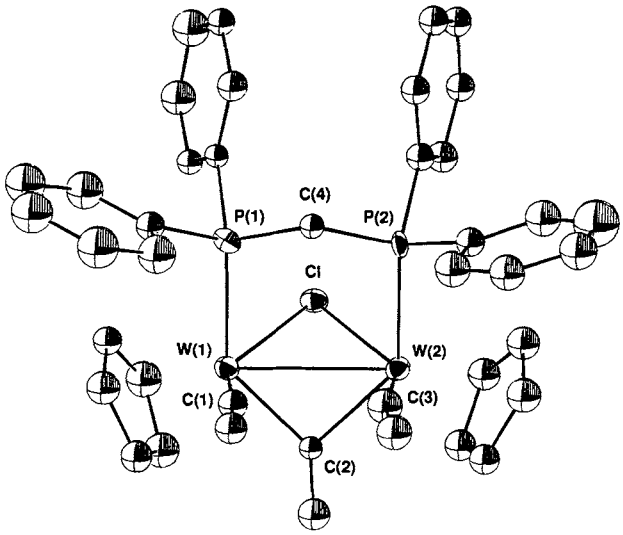

Fig. 1. Molecular structure of the cationic complex **3b** (ORTEP, thermal vibrational ellipsoids with 30% probability). Selected bond lengths [Å] and angles [°]: W(1)-W(2) 3.040(3), W(1)-Cl 2.494(8), W(2)-Cl 2.457(9), W(1)-C(1) 1.96(3), W(1)-C(2) 2.11(3), W(2)-C(2) 2.13(3), W(2)-C(3) 1.87(3); W(1)-Cl(1)-W(2) 75.8(2), W(1)-C(2)-W(2) 91.7(9), W(1)-C(2)-O(2) 136.8(30), P(1)-W(1)-C(1) 84.5(10), P(1)-W(1)-C(2) 134.0(9), Cl-W(1)-C(1) 134.8(11), Cl-W(1)-C(2) 76.5(8).

The latter is formed almost instantaneously through the reaction of **2** with [$AsPh_4$]Cl in dichloromethane at −30 °C. Spectroscopic data for these halogeno complexes indicate that they are isostructural,[6,11] and are in agreement with the geometry found in the crystal for **3b**-PF_6.[10] A metal–metal single bond is formulated for these compounds on the basis of the 18-electron rule, and this is consistent with the intermetallic separation in **3b** (3.040(3) Å). This lies in the range found for related cations with metal–metal single bonds (for example, 3.001(2) Å in $[Mo_2(\mu\text{-I})(\mu\text{-CH}_2PPh_2)$-

$(\mu\text{-PPh}_2)(CO)_2Cp_2]^{+}$[12] or 3.008(2) Å in $[Mo_2(\mu\text{-S}t\text{Bu})_2(CO)_4Cp]^{2+}$[13]).

Further evidence of the high electrophilicity of **2** is the unusual hydride abstraction forced upon $BH_3 \cdot THF$. This occurs quickly in dichloromethane at $-30\,^{\circ}C$ and gives the novel unsaturated hydrido complex **4**-PF_6 in very high yield

$[W_2(\mu\text{-H})(CO)_2(\mu\text{-dppm})Cp_2](PF_6)$ $(W{\equiv}W)$ **4**-PF_6

through spontaneous liberation of two CO ligands (Scheme 1). Compound **4**-PF_6 displays a resonance signal shifted to unusually low field for bridging hydrido ligands at $\delta = -2.6$,[14] which remains unchanged down to $-90\,^{\circ}C$. This deshielding may be an effect of the metal–metal multiple bonding.[15] As expected, this unsaturated hydrido complex reacts readily with CO to yield the saturated species **5**

$[W_2(\mu\text{-H})(CO)_4(\mu\text{-dppm})Cp_2](PF_6)$ **5**-PF_6

(counterion PF_6^-, two isomers),[16] similar to the dimolybdenum complex previously prepared by us,[3] and its hydrido ligands show resonances in the usual region in the ^1H NMR spectrum (δ = ca. -20).[17]

Other simple compounds interact with **2** at low temperatures. For example, **2** reacts instantaneously with MeOH at $-30\,^{\circ}C$ to give the methoxy-bridged species **6**,[18] which is

$[W_2(\mu\text{-OMe})(\mu\text{-CO})(CO)_2(\mu\text{-dppm})Cp_2](PF_6)$ **6**-PF_6

isostructural with compounds **3a** and **3b**. More complex reactions occur with compounds with P–H or C–H bonds, such as PPh_2H, MeC(O)H, or HC≡CPh, and these are currently under investigation.

Methyltrioxorhenium(VII) as Catalyst for Epoxidations: Structure of the Active Species and Mechanism of Catalysis**

By *Wolfgang A. Herrmann,* Richard W. Fischer, Wolfgang Scherer,* and *Monika U. Rauch*

Dedicated to Professor Hans Bock on the occasion of his 65th birthday

Oxides of transition metals in high oxidation states are common reagents and catalysts for olefin oxidation.[1] Despite many attempts no oxidation catalyst able to be "tuned" with substituents was found. This possibility is now in sight with the class of compounds $[RReO_3]$: the parent compound (R = CH_3) as well as derivatives (for example, R = $CH_2CH_2CH_2N(C_2H_5)_2$, cyclopropyl (c-C_3H_5)) efficiently catalyze the epoxidation of olefins with hydrogen peroxide under mild conditions, and direct the subsequent chemistry of the epoxides.[2]

We have now elucidated the active species of the catalytic system $[CH_3ReO_3]/H_2O_2$ and describe here the first isolated peroxo–metal complex with a metal–alkyl group that is stable to hydrolysis and to peroxide.

On treatment of methyltrioxorhenium (MTO, **1**) in water (or organic solvents) with an excess of hydrogen peroxide, a yellow solution (λ_{max} = 364 nm, $\varepsilon_\lambda(H_2O)$ = 610 L mol^{-1} cm^{-1}, ε_λ(THF) = 700 L mol^{-1} cm^{-1}) is obtained according to Scheme 1. This solution is stable for

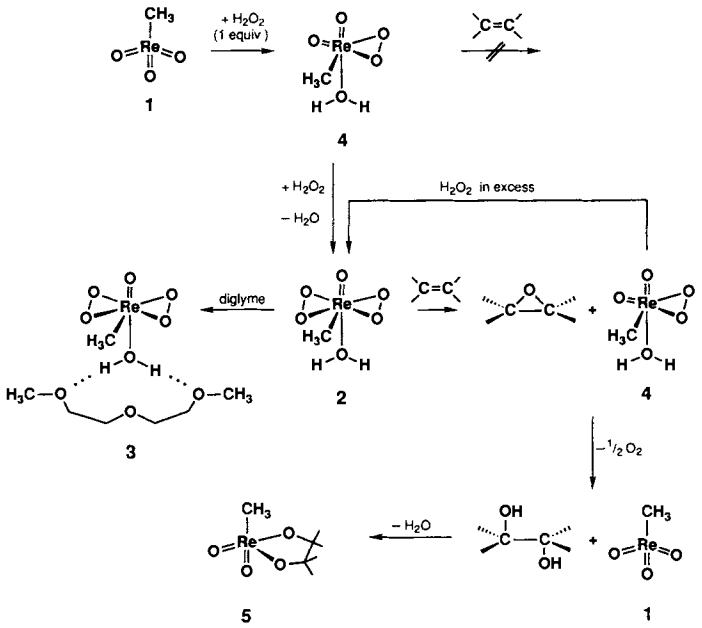
Scherer, M. Kleine, M. Elison, K. Rypdal, H. V. Volden, S. Gundersen, A. Haaland, *Bull. Soc. Chim. Fr.* **1992**, *129*, 655–662.



Scheme 1.

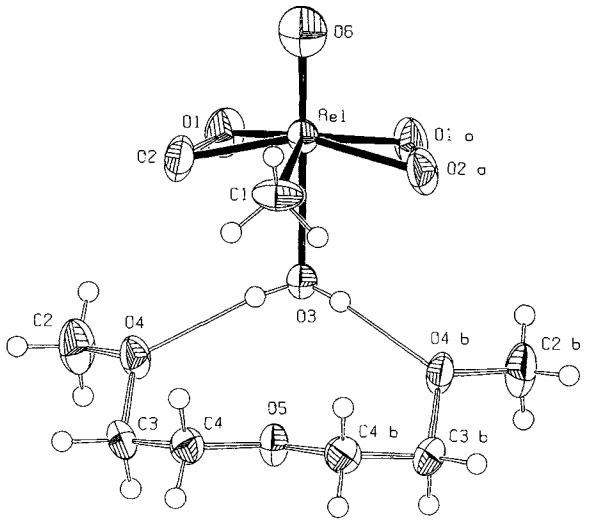


Fig. 1. Crystal structure (PLATON) of the diglyme adduct **3**. Selected distances [pm] and angles[°]: Re-C1 213.2(6), Re-O1 191.8(3), Re-O2 190.4(3), Re-O3 225.3(4), Re-O6 166.8(6), O1-O2 147.4(4), O3···O4 276.3(3), O3-H1 76(5), *H1*···O4 201(5); C1,Re,O3 80.4(2), C1,Re,O6 95.6(2), O3,Re,O6 175.9(2), O1,Re,O2 45.4(1), O3,H1,O4 168.7(7), M,Re,O3 77.8, M,Re,O6 103.4, M,Re,C1 105.4, M,Re,M 136.5 (M: center of the O1–O2 bond). The atoms labeled with a and b are generated by symmetry (reflection across the mirror plane $y = 1/4$ on which the atoms Re, C1, O3, O6, and O5 lie).

weeks at 0 °C and for days at room temperature. The compound **2** of composition $[CH_5O_6Re]$ can be extracted from it with diethyl ether, isolated as a solid (m.p. 55 °C, decomp. 65°C),[3] and sublimed under high vacuum at 25 °C; nevertheless heat stress should be carefully avoided (*danger of explosion*). In water **2** is a medium-strength Brønsted acid ($pK_s = 3.8$; cf. $[CH_3ReO_3]/H_2O$: $pK_s = 7.5$). The acidity of the coordinated water molecule is, however, not restricted to aqueous media: the (auto)protolysis has been detected by spectroscopy in dichloromethane and THF as well.[3]

Compound **2** is the first authentic organorhenium peroxo complex. It is particularly surprising that a metal-bound CH_3 group ($\delta(^1H) = 2.60$, $\delta(^{13}C) = 31$ in D_2O, 25 °C) can exist beside a peroxo ligand and coordinated water. Dissolved in THF, **2** exchanges its oxo group (Re=O) rapidly with $H_2{}^{17}O$, but *not* its peroxo oxygen atoms.[4] On addition of a little diglyme (diethyleneglycol dimethyl ether) to *n*-pentane/diethyl ether solutions, **2** affords thermally stable, orange-yellow single crystals of the 1:1 diglyme adduct **3** (yield > 95%). Like **2** this is very soluble in dichloromethane or ethereal solutions as well as in water. It melts at 40 °C without decomposition. Consistent with elemental analyses and IR and NMR spectra,[3, 5] and confirmed by single-crystal X-ray structure analysis (− 80 °C),[6] **3** displays two η^2-coordinated peroxo ligands besides the CH_3 ligand, as well as a coordinated water molecule, an oxo group, and one molecule of the triether diglyme per formula unit (Fig. 1). The aqua ligand holds the solvating ether molecule in the molecular arrangement by hydrogen bonds. The coordination of water is required by the type of constitution of the present complex: when **2** is crystallized from dichloromethane *without* diglyme, it also contains H_2O, apparently as a result of the very large Lewis acidity of peroxo-coordinated Re^{VII} (cf. pK_s!) In the crystal **2** is not solvated by diethyl ether. An entropic effect of the "half" crown ether diglyme appears to determine the constitution and exert a stabilizing influence. The strong water–rhenium bond in **2** and **3** explains why the H_2O ligand does not exchange with $H_2{}^{17}O$ (^{17}O NMR).

If each O_2 group is considered a coordinative unit, the molecular structure of the peroxo complex **3** can be described as a trigonal bipyramid; otherwise it is a pentagonal bipyramid. The *trans* ligands O6 and H_2O (O3) occupy the apical, and the methyl and both peroxo groups the equatorial positions. Diglyme is bound by linear hydrogen bonding between O3 and O4 to the peroxo complex. The interatomic distances in the peroxo groups correspond to published values (144.5(2)–144.9(2) pm).[7, 8] A similar geometry is displayed by adducts of bases of alkylrhenium oxides $[RReO_3 \cdot L]$ (L = quinuclidine; R = CH_3),[9] when both the η^2-O_2 ligands are (formally) replaced by two oxo ligands. The ligand L is, however, *trans* to the methyl group. As the existence of **3** shows, these complexes are certainly not sterically congested. Both the *cis* arrangement of the CH_3 and H_2O ligands and the stable H_2O coordination suggest that the prospect of generating configuratively stable, chiral peroxorhenium complexes with C,O- and C,N-chelating ligands is good.

The Re^{VII} peroxo complex **2**, which, surprisingly, could be isolated in the solid state, is the active species in the olefin epoxidation catalyzed by $[CH_3ReO_3]$ (**1**): λ_{max} and ε_λ of the UV/VIS spectra of **2** generated in situ (tenfold excess of H_2O_2 simulates catalytic conditions) and of isolated, analytically pure **2** (in each case in ether as solvent) are identical, as are the IR and NMR spectra (solvents CH_2Cl_2 and D_2O, respectively). In the ^{17}O spectrum of **2** in diethyl ether, two broad signals at $\delta = 422$ and 363 can be assigned to the peroxo groups ($\Delta_{1/2} = 1250$ Hz); the relatively small difference in chemical shift ($\Delta\delta = 59$) indicates that a rigid, η^2-coordination is also present in solution at −20 °C. From ^1H NMR studies it can be concluded that *two* equivalents of H_2O_2 are required for the formation of the active species;[2a] thus olefins like 2,3-dimethylbut-2-ene can be titrated or transformed very rapidly in solution even at temperatures as low as −25 °C with *isolated* **2** according to Scheme 1 in stoichiometric amounts (n(**2**):n(olefin) = 1:1) and form epoxides as primary products. In contrast, the monoperoxo complex **4** does not react with olefins to an extent worth mentioning. Only at 25 °C does the generated epoxide undergo slow ring opening to form the 1,2-diol as a result of water present in **2**. In the process the catalyst MTO (**1**) is released

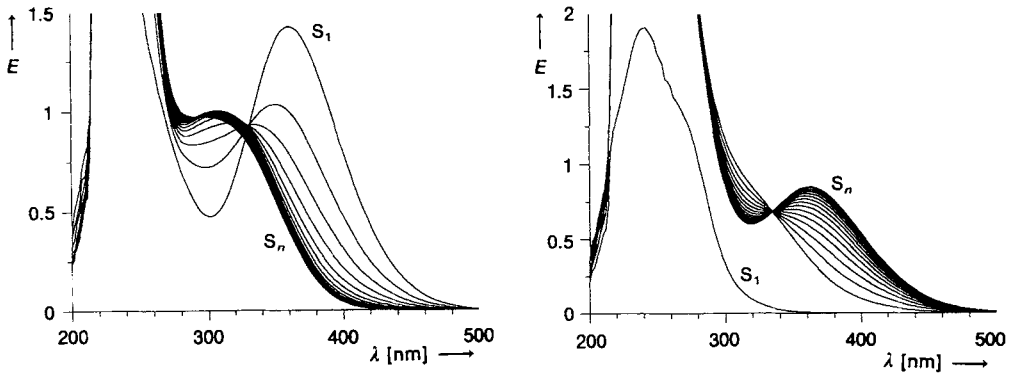

Fig. 2. Left: Change in the UV/VIS spectra during the course of the reaction of 2,3-dimethylbut-2-ene with isolated **2** in the absence of H_2O_2 in THF. $c(\mathbf{2}) = 2 \times 10^{-3}$ mol L^{-1}, c(olefin) $= 4 \times 10^{-3}$ mol L^{-1}, $T = 10\,^{\circ}C$, $t =$ 30 min. Right: Changes in the UV/VIS spectra during the course of the reaction of regenerated **1** with H_2O_2 to form **2**. $c(\mathbf{1}) = 1.1 \times 10^{-3}$ mol L^{-1}, $T = 20\,^{\circ}C$, $t =$ 60 min.

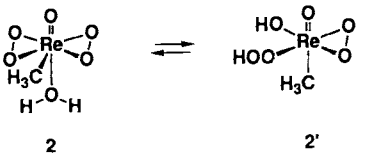
and forms the isolable condensation product **5** in a subsequent reaction (75% yield).[10] The reaction can be followed and quantified by gas chromatography.

Consistent with the results from gas chromatography, the regeneration of MTO (**1**) on the oxidation of 2,3-dimethylbut-2-ene from **2** is confirmed by UV/VIS spectroscopy. This regeneration is, however, not direct, but occurs via intermediate **4**, detectable in UV/VIS and NMR spectroscopy ($\lambda_{max} = 310$ nm, $\varepsilon_\lambda \approx 600$ L mol^{-1} cm^{-1}, $\delta(CH_3) = 3.2$, in [D$_8$]THF; isosbestic points are observed in the UV/VIS spectra of Fig. 2, left). Compound **4** is formed rapidly from **2** in the presence of olefins ($k_1 = 0.2\ s^{-1}$ at 10 °C) and finally transformed into **1** (Fig. 2, left). The decomposition **4** → **1** is accelerated only slightly by olefins (in contrast to the reaction **2** → **4**: in comparison to **2**, the monoperoxo complex **4** oxidizes olefins very slowly and inefficiently (^{1}H NMR) and can thus be considered inactive as regards epoxidation catalysis.[11] Alternatively, **4** can be generated directly from **1** (for example, in THF) and *one* equivalent of H_2O_2 according to an NMR/UV/VIS study. Consequently, **1** forms 1:1 and 1:2 adducts with aqueous H_2O_2. These adducts form concentration-dependent equilibria at low concentrations ($n(\mathbf{1})/n(H_2O_2) \leq 3$) according to NMR data.[2e] Regenerated **1** rapidly gives **2** with an excess of H_2O_2 (Fig. 2, right; here without detectable intermediate steps, $k_2 = 1.7 \times 10^{-3}\ s^{-1}$ at 20 °C).

In the absence of olefins, **2** decomposes much more slowly to **4**: $k_3(10\,^{\circ}C) = 3.5 \times 10^{-4}\ s^{-1}$, $k_3(40\,^{\circ}C) = 4.0 \times 10^{-3}\ s^{-1}$ (cf. Fig. 3, left). Under the catalytic conditions (excess of H_2O_2) **2** is, however, very stable. It can be assumed that in the catalytic cycle no free MTO (**1**) is generated, because **4** reacts much more rapidly with H_2O_2 to form **2** ($k_4(20\,^{\circ}C) = 5.0 \times 10^{-3}\ s^{-1}$) than it decomposes to form **1**. The reaction **1** → **4** with H_2O_2 is similarly slow (see Scheme 1 and Fig. 3, right).

The oxidizing power of **2** can also be seen in the immediate evolution of chlorine, bromine, and iodine on mixing **2** with solid or dissolved KCl, KBr, or KI. These reagents are also oxidized by **4**, which is additional proof of the presence of a peroxo group.

If the η^2-coordinated peroxo groups were not essential for the olefin epoxidation, organic hydroperoxides would also be active in oxidations with MTO (**1**). This does not occur.[2] Organic peroxides like *tert*-butylhydroperoxide, di-*tert*-butylperoxide, and organic peracids do not react with MTO. Since the existence—exemplified by compounds **2** and **3**—of bis(peroxo) Re^{VII} complexes like **2** is now proven, we give no significance to the hydroperoxo tautomer **2'** [Eq. (a)]. The ^{17}O NMR spectra (position and form of signals[12]) and the IR spectra in solution speak against the hydroperoxo form that is considered for many peroxo–metal species.



2 **2'** (a)

Our present results explain why MTO (**1**) is by far the most active rhenium epoxidation catalyst. In contrast to all other rhenium oxides, the molecularly defined, very reactive catalyst **2** is formed *quantitatively* with H_2O_2 and is not only stable to peroxide, light, acid, and water, but also to temperature in the presence of an excess of H_2O_2. The low metal coordination of MTO (**1**) and the H_2O_2-resistant Re–CH_3 group are the two crucial prerequisites for all these properties. All in all, the peroxide formation has a stabilizing function for alkyltrioxorhenium(VII) complexes: thermolabile

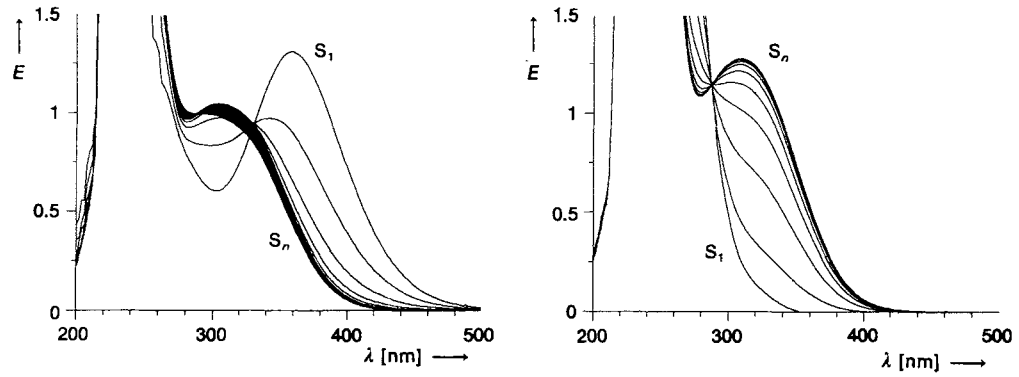


Fig. 3 Left: Changes in the UV/VIS spectra during the decomposition of **2** to form **1** via the intermediate **4**. $c(\mathbf{2}) = 2 \times 10^{-3}$ mol L^{-1}, $T = 40\,^{\circ}C$, $t = 48$ min. Right: Changes in the UV/VIS spectra during the course of the formation of **4** from **1** and H_2O_2. $c(\mathbf{1}) = c(H_2O_2) = 2 \times 10^{-3}$ mol L^{-1}, $T =$ 20 °C, $t = 8$ h.

cyclopropyltrioxorhenium yields a catalyst with H_2O_2 that is stable at elevated temperatures and even more active in epoxidation than the MTO derivative **2**.

Experimental Procedure

2: MTO (1.00 g, 4 mmol) was dissolved in distilled water (20 mL) at 25 °C. The solution was cooled to 0 °C, and perhydrol p.A. (5 mL of 30% H_2O_2) was added dropwise. After 10 min the yellow-orange solution was extracted with diethyl ether (50 mL). The ether extract was washed with water (3 × 20 mL) and dried twice with Na_2SO_4, and finally over 4 Å molecular sieves. (These operations should be performed as rapidly as possible to avoid decomposition.) The organic phase was quickly evaporated to dryness at 0 °C under high vacuum. The yellow residue was washed with *n*-pentane at 0 °C and finally dissolved in dichloromethane (if necessary with addition of a little diethyl ether). Analytically pure product was obtained on crystallization at −30 °C. Yield 960 mg (80%). Single crystals of **3** were obtained after addition of a small amount of diglyme to solutions of **2** in a mixture of diethyl ether and *n*-pentane (1:25) and slow cooling to −30 °C in screw-top vials that were not tightly closed.

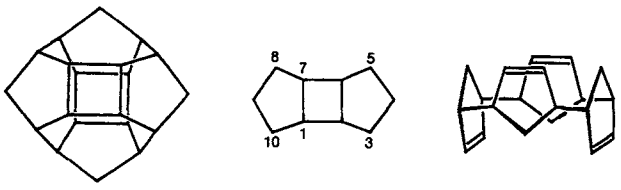
Golcondane: A Novel, Caged, Nonacyclic $C_{20}H_{24}$-Hydrocarbon of D_{2d} Symmetry**

By *Goverdhan Mehta** and *S. Hari Krishna Reddy*

The conception and creation of space-enclosing polycyclic hydrocarbons (polyhedranes) of novel shape and symmetry is an area of contemporary interest that elegantly blends aesthetics with synthetic challenge.[1] In recent years, the assembly of C_{20}-polyhedranes in particular received a great deal of attention from organic chemists and culminated in many notable achievements. These include the syntheses of $C_{20}H_{20}$-dodecahedrane by Paquette et al.[2a] and Prinzbach et al.,[2b] $C_{20}H_{20}$-pagodane by Prinzbach et al.,[2c] and $C_{20}H_{24}$-propella[3$_4$]prismane by Gleiter et al.[2d] to mention a few.



1 **2** **3**

Through this communication, we add a new member to this esoteric C_{20}-family and describe a short synthesis of a nonacyclic $C_{20}H_{24}$-hydrocarbon **1** ("golcondane")[3] of D_{2d} symmetry. Interestingly, the polycyclic ring system of **1** could be regarded either as a dimer of *cis,syn,cis*-tricyclo[5.3.0.0^{2,6}]decane (**2**) with an orthogonal union of the two units through C_3, C_5, C_8, and C_{10} or as a subsequent product of a head-to-tail, cyclic 1,4 tetramer of 1,3-cyclopen-

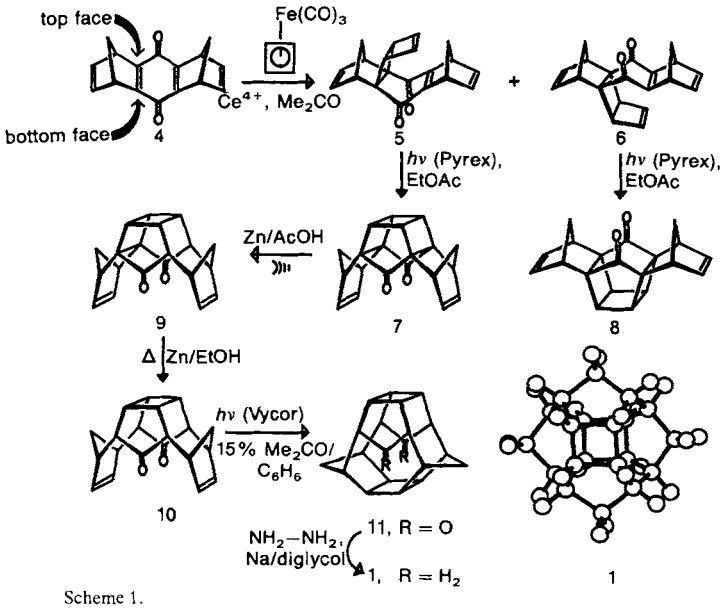
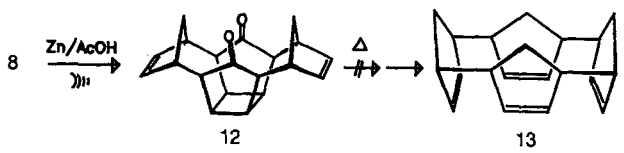
tadiene (**3**), in which the diametrically opposite pairs of double bonds have undergone [2 + 2] ring closure.

Reaction between *syn*-bisnorborneno-1,4-benzoquinone (**4**)[4] and cyclobutadiene (liberated from its iron tricarbonyl complex with ceric ammonium nitrate) furnished two [4 + 2] *endo* adducts **5**[5, 6] and **6**[5, 6] in a 55:45 ratio and 70% yield. On irradiation with a Hanovia 450 W Hg lamp through a pyrex filter, **5** and **6** underwent smooth intramolecular $[\pi_s^2 + \pi_s^2]$ ring closure to give nonacyclic, annulated bishomocubane diones **7**[5, 7] (61%) and **8**[5] (35%), respectively. The bishomocubanone moiety in **7** was opened through the reductive scission of cyclobutyl bonds conjugating the 1,4-dicarbonyl functionality.[8] Thus, reaction of **7** with Zn in acetic acid under ultrasonication furnished **9**[5] and **10**[5] (16:1, 85%). The octacyclic dione **9** in which one bond has been cleaved could be transformed to heptacycle **10**[5] on further exposure to Zn in ethanol in 30–40% yield. Alternatively, **10** could be accessed directly from **7** in a single-pot reaction with Zn in ethanol, albeit in somewhat lower yield (about 25%). The reductive opening of the cage in **7** rendered the two double bonds proximal, and irradiation of **10** from a 450 W Hanovia lamp led to the desired intramolecular [2 + 2] cycloaddition, and the nonacyclic dione **11**[5] (40%) was readily realized. Its structure was secured through X-ray crystal structure determination.[9] Deoxygenation of **11** presented considerable difficulties, but eventually a modified Wolff–Kishner reduction could be carried out to furnish the $C_{20}H_{24}$-hydrocarbon, golcondane (**1**, 10–20%),[5] which as expected exhibited a 3-line ^{13}C NMR spectrum (δ = 45.63, 41.04, 39.21), while **11** showed a 6-line ^{13}C NMR spectrum. The energy-minimized structure of **1** determined with MMX force-field calculations (Scheme 1, strain energy = 132.4 kcal mol^{-1}, ΔH_f° = 74.9 kcal mol^{-1}) exhibited structural parameters closely resembling those for its precursor dione **11** obtained by X-ray studies.



Scheme 1.

The nonacyclic, annulated bishomocubanedione **8** on zinc/acetic acid reduction also furnished the corresponding heptacyclic dione **12** (50%) through reductive scission of two C–C bonds. Several attempts at thermal [2 + 2] cycloreversion in **12** to furnish the novel head-to-head 1,4-cyclic tetramer **13** of 1,3-cyclopentadiene have not borne fruit so far (Scheme 2). Nonetheless, **10** and **12** are potential precursors for **3** and **13**, respectively, besides many other novel polycycles. These possibilities are currently being explored.



Scheme 2.

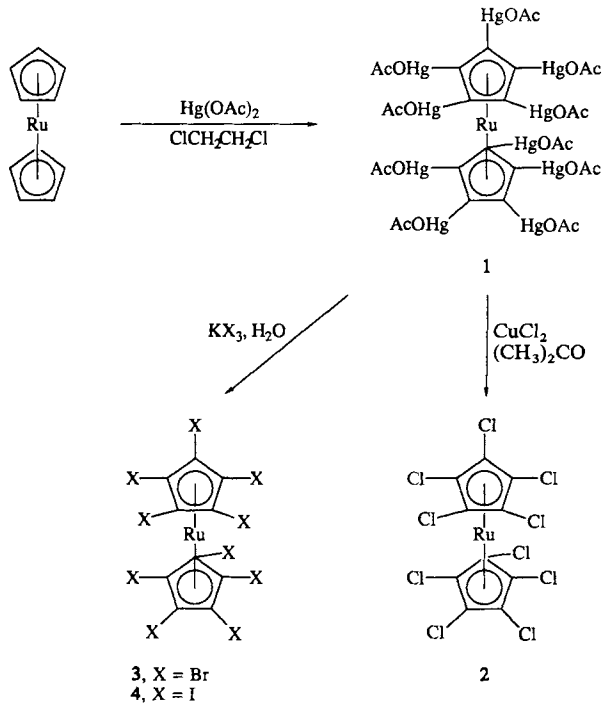
derivatives, due to the electron-rich character and high stability of the bis(cyclopentadienyl)iron(II) framework.[1] An early study by Fischer et al. on the mercuration of ruthenocene reported impure mono- and dimercurated complexes,[2a] while Nesmeyanov et al. demonstrated that ruthenocene could be monomercurated in low yield.[2b] Subsequent investigations have revealed that the reaction of ruthenocene with Hg^{II} salts often affords adducts with Ru–Hg bonds, rather than electrophilic substitution products.[3] We recently reported that pentamethylruthenocene is preferentially pentamercurated at the unsubstituted cyclopentadienyl ligand with mercuric acetate.[4] However, extension of mercuration reactions to other transition metal cyclopentadienyl complexes remains speculative due to the electron-poor nature of many complexes relative to ferrocene and pentamethylruthenocene. Herein we report that ruthenocene can be decamercurated in nearly quantitative yield and that the permercurated ruthenocene can be directly halogenated to efficiently afford decahaloruthenocenes. Permercuration of the electron-deficient ruthenocene suggests that a wide variety of permercurated cyclopentadienyl complexes may be accessible. Subsequent derivatization should then provide entry to a variety of new pentahalogenated cyclopentadienyl ligands.

Treatment of ruthenocene with mercuric acetate (10 equiv) in refluxing dichloroethane for 18 h afforded deca(acetoxymercurio)ruthenocene (**1**) in 88% yield as an off-white solid which precipitated from the reaction medium (Scheme 1). Complex **1** was rigorously insoluble in all common solvents, which prevented its analysis by NMR spectroscopy. The complex was, however, characterized by microanalysis and IR spectroscopy. In particular, the IR spectrum of **1** revealed strong absorption bands characteristic of the HgO_2CCH_3 functionality at 1570, 1403, 1382, 1337, and 643 cm^{-1}. By comparison, mercuric acetate showed strong absorption bands at 1555, 1400, 1330, and 653 cm^{-1}.



Scheme 1. Synthesis and reactions of **1**. The complexes **1** and **2** were prepared under reflux.

The fully mercurated nature of **1** was confirmed by its reaction with halogenating agents. Treatment of **1** with $CuCl_2$ (50 equiv) in refluxing acetone for 12 h afforded decachlororuthenocene (**2**) in 73% yield as a white crystalline solid after workup (Scheme 1). ^1H NMR spectra of the crude product **2** showed no signals that could be attributed to partially chlorinated ruthenocenes. Reaction of **1** with KBr_3 and KI_3 (prepared from KX and X_2 in water where X = Br or I) afforded decabromoruthenocene (**3**, 47%) and decaiodoruthenocene (**4**, 39%) as white and yellow-ochre solids, respectively.

In order to gain insight into the bonding involved in the decahalometallocenes, the X-ray crystal structure of **3** was determined.[5, 6] Figure 1 shows a perspective view of **3**, in

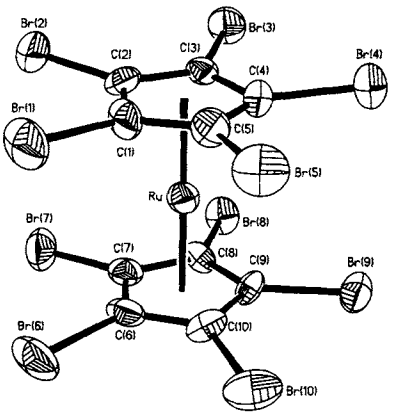


Fig. 1. An ORTEP view of **3** with 35% probability ellipsoids. Selected bond lengths [Å] and angles [°]: Ru-C(1) 2.153(23), Ru-C(2) 2.193(18), Ru-C(3) 2.167(16), Ru-C(4) 2.161(20), Ru-C(5) 2.176(24), Ru-C(6) 2.163(18), Ru-C(7) 2.168(20), Ru-C(8) 2.175(20), Ru-C(9) 2.169(19), Ru-C(10) 2.172(19), Ru-Cp(1) 1.80(2), Ru-Cp(2) 1.81(2); Cp(1)-Ru-Cp(2) 179.4(8).

which two eclipsed η^5-C_5Br_5 ligands are η^5-bonded to the ruthenium atom. The mean Ru–C bond lengths are 2.17 Å and the mean C–C and C–Br bond lengths 1.42 and 1.87 Å, respectively. The ruthenium–cyclopentadienyl centroid distances are 1.80(2) and 1.81(2) Å, with a (C_5Br_5)-Ru-$(C_5Br_5)'$ angle of 179.4(8)°. The ring-to-ring distance is 3.61 Å; thus the distance between the eclipsed interannular bromine substituents is shorter than the sum of their covalent radii (3.84 Å).[7] The bromine substituents are bent slightly out of the plane of the cyclopentadienyl ligands (range 1.7–6.4°, mean 4.2°), away from the ruthenium atom. Despite such close Br–Br contacts, the molecule retains an eclipsed conformation. The structure of **3** is very similar to that previously reported for **2**.[6b, 8] The halogen substituents are eclipsed in both **2** and **3**, and the interannular distances (**3**, 3.61 Å; **2**, 3.598 Å) and average Ru–C distances (**3**, 2.17 Å; **2**, 2.17 Å) are nearly identical. Moreover, the halogen atoms in **2** and **3** show small displacements out of the plane of the C_5 ring away from the ruthenium atom. Unlike **3**, the position of the halogen atoms in **2** could not be attributed to interannular interactions, since the Cl–Cl distances were larger than the sum of their van der Waals radii.

Decamercuration of the relatively electron-poor ruthenocene ($E^0 = 1.03$ V,[9] compared to ferrocene ($E_{1/2} = 0.31$ V[6c]) and pentamethylruthenocene ($E_{1/2} = 0.54$ V[6c])) suggests that a wide variety of other transition metal cyclopentadienyl complexes should undergo pentamercuration. In analogy with **1**, ferrocene can be decamercurated with mercuric acetate in refluxing dichloroethane to afford deca(acetoxymercurio)ferrocene, which can be halogenated

to afford decahaloferrocenes.[10] Chlorination, bromination, and iodination of **1** provides the complexes **2**–**4** in 39–73% yields. Complex **2** was previously prepared in 14% yield by repetitive lithiation/chlorination of ruthenocene.[11] The present synthesis of **2** from **1** is clearly superior.

In summary, pentamercurated cyclopentadienyl ligands should not be viewed as exotic species, but rather as potentially accessible and useful synthetic intermediates.

Experimental Procedure

1: A 250 mL round-bottomed flask was charged with Cp_2Ru (0.231 g, 1.00 mmol), $Hg(OAc)_2$ (3.187 g, 10.0 mmol), and dichloroethane (100 mL). The mixture was refluxed for 18 h, during which time an off-white solid precipitated. The precipitate was collected on a medium glass frit and was washed with hexane (40 mL). Vacuum drying afforded **1** as an off-white powder (2.492 g, 88%). M.p. 200–220 °C (decomposition range, with evolution of elemental mercury); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1570 (vs, C=O); correct C,H analysis.

2: A 250 mL round-bottomed flask was charged with **1** (1.00 g, 0.355 mmol), $CuCl_2$ (3.03 g, 17.8 mmol), and acetone (80 mL). The resultant mixture was refluxed for 12 h. The volatiles were removed under reduced pressure to give a dark oily solid. The solid was extracted with hexane (100 mL). The hexane extract was applied to a 3 cm column of silica gel on a coarse frit and was eluted with hexane (100 mL) to afford a colorless solution. Removal of the volatile components under reduced pressure, followed by vacuum drying afforded **2** as a white powder (0.149 g, 73%). M.p. > 300 °C (sublimes) [11]; $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 91.46 (s, C_5Cl_5); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1386 (m), 1351 (s), 1310 (m), 1095 (w), 928 (w), 811 (w), 703 (s), 564 (w), 409 (s); MS (20 eV): *m/z* 576 (M^+, 100%), the isotope distribution pattern of the parent mass envelope was identical with the calculated pattern.

3: A 100 mL round-bottom flask was charged with KBr (0.484 g, 4.07 mmol), bromine (0.208 mL, 4.07 mmol), and water (50 mL). The resultant mixture was stirred at ambient temperature for 0.5 h, and then **1** (1.146 g, 0.407 mmol) was added. The mixture was stirred at ambient temperature for 3 h, during which time a white precipitate formed. The crude product was collected on a medium-porosity glass frit and washed with methanol (20 mL). The precipitate was then extracted with dichloromethane (100 mL) to afford a colorless solution. This solution was applied to a 3 cm pad of silica gel on a coarse glass frit. Elution with dichloromethane (50 mL) afforded a colorless solution. Removal of the volatile components under reduced pressure afforded **3** as an analytically pure white powder (0.194 g, 47%). M.p. (sealed tube) > 300 °C; $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 84.51 (s, C_5Br_5); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1379 (m), 1302 (s), 1274 (w), 589 (s); MS (20 eV): *m/z* 1020 (M^+, 100%), the isotope distribution pattern of the parent mass envelope was identical with the calculated pattern; correct C,H analysis.

4: A 100 mL round-bottom flask was charged with KI (0.830 g, 5.00 mmol), iodine (1.269 g, 5.00 mmol), water (50 mL), and a stir bar. The resultant mixture was stirred at ambient temperature for 1 h and then **1** (1.409 g, 0.50 mmol) was added. The mixture was stirred at ambient temperature for 5 h, during which time an orange-colored precipitate formed. The crude product was collected on a medium-porosity glass frit and was washed with aqueous potassium iodide (0.1 M, 100 mL), water (20 mL), water (20 mL), and methanol (100 mL) to remove mercury impurities. The residue was placed in a paper thimble and was extracted with acetone in a Soxhlet extractor for 24 h to remove additional mercury impurities. Vacuum drying in a drying pistol for 24 h afforded **4** as a yellow-ochre powder (0.292 g, 39%). M.p. 240–260 °C (decomposition range); $^{13}C\{^1H\}$ NMR ([D$_6$]DMSO): δ = 69.94 (s, C_5I_5); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1246 (m), 506 (m); MS (20 eV): *m/z* 1110 ([M − 3I]$^+$, 3%), the isotope distribution pattern of the [M − 3I]$^+$ mass envelope was identical with the calculated pattern; correct C,H analysis.

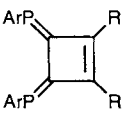
Synthesis and Structure of a Diphospha[4]radialene**

By *Kozo Toyota, Katsuya Tashiro*, and *Masaaki Yoshifuji**

Sterically protected phosphorus-containing multiple-bonded compounds are currently of interest. Our studies have centered on compounds that contain cumulative double bonds or conjugated π-electron systems with phosphorus atom(s) in low coordination states,[1,2] as well as diphosphenes[3] and phosphaethenes.[4] Recently Appel et al.,[5] Märkl et al.,[6] and ourselves[7–9] have reported the preparation and isolation of diphosphinidenecyclobutenes **1a**–**c**, which utilizes 2,4,6-tri-*tert*-butylphenyl (Ar) as a protecting group. We now report the synthesis and structure of a diphosphinidenecyclobutene with an extended π-electron system, namely a diphospha[4]radialene (1,2-dimethylene-3,4-diphosphinidenecyclobutane) **5**.



1a: R = $SiMe_3$
1b: R = Ph
1c: R = H

Ar = 2,4,6-tBu$_3$C$_6$H$_2$

The alkynyl-substituted phosphane **2** was prepared by the reaction of 3-phenyl-1-propynylmagnesium bromide with ArPHCl (spectroscopic data of **2** and the other new compounds are given in Table 1). By using the method employed for the preparation of **1a**, compound **2** was then converted into **3** (Scheme 1).[7] Subsequent bromination of **3** with 2 equivalents of *N*-bromosuccinimide (NBS) gave **4** as an intermediate, which was then allowed to react with butyllithium at −78 °C to give the first diphospha[4]radialene **5** as an orange solid.

Table 1. Selected spectroscopic data of **2**, **3**, and **5** [a].

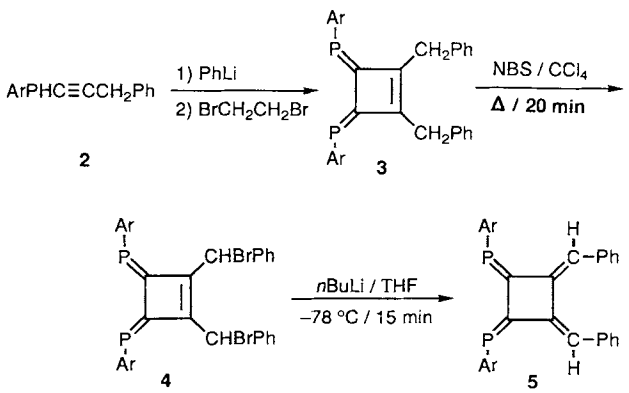
[a] NMR spectra: Bruker AC200P or Bruker AM600.



Scheme 1. Δ: heating under reflux.

The structure of (*E*,*E*,*E*,*E*)-1,2-dibenzylidene-3,4-bis-[(2,4,6-tri-*tert*-butylphenyl)phosphinidene]cyclobutane (**5**) was unambiguously confirmed by X-ray crystallography (Fig. 1).[10] The arrangement of the two phenyl groups in the benzylidene moieties is more crowded than that of the two bulky Ar groups, which point away from each other.

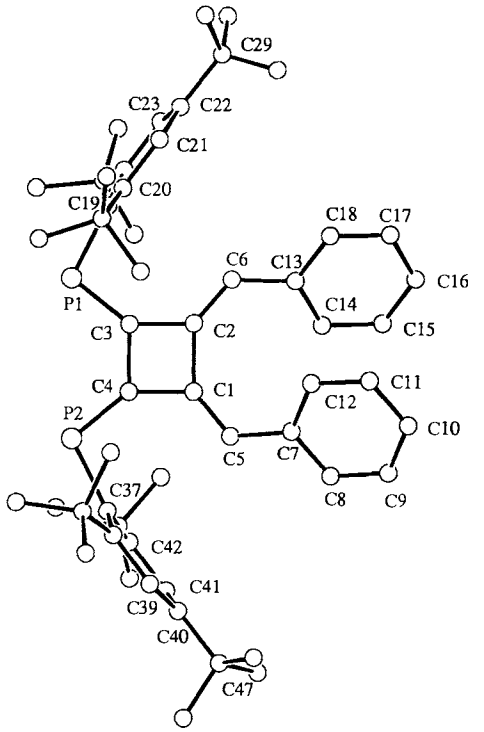


Fig. 1. Molecular structure of **5** (ORTEP). Important bond lengths [Å] and angles [°]: C1-C2 1.521(7), C2-C3 1.481(6), C3-C4 1.499(6), C4-C1 1.507(7), P1-C3 1.683(5), P2-C4 1.669(5), P1-C19 1.851(5), P2-C37 1.849(5), C1-C5 1.345(7), C2-C6 1.332(6), C5-C7 1.472(7), C6-C13 1.463(7); C3-P1-C19 101.2(2), C4-P2-C37 102.1(2), C1-C2-C3 89.6(4), C2-C3-C4 91.2(4), C3-C4-C1 89.4(4), C4-C1-C2 89.4(4), P1-C3-C2 141.1(4), P1-C3-C4 127.7(4), P2-C4-C3 129.4(4), P2-C4-C1 140.9(4), C1-C2-C6 139.1(5), C3-C2-C6 130.8(5), C2-C1-C5 139.5(5), C4-C1-C5 130.7(5), C1-C5-C7 127.9(5), C2-C6-C13 130.2(5), C5-C7-C8 119.4(6), C6-C13-C14 121.1(6), P1-C19-C20 119.6(4), P2-C37-C38 119.5(4).

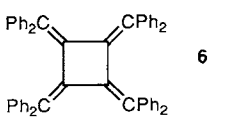
The atoms C1, C2, C3, and C4 are coplanar within 0.03 Å, and the atoms P1 and P2 only deviate from this plane by 0.15 and −0.01 Å, respectively. Furthermore, the atoms C5 and C6 lie almost in the plane (C1–C4) (deviations 0.22 and −0.23 Å, respectively); thus this radialene framework is almost planar. The two phenyl groups (C7–C12) and (C13–C18) form angles of 34.1 and 38.3°, respectively, with the (C1–C4) plane. The two Ar protecting groups are tilted by 78.2 and 91.9° from the plane (C1–C4), while their benzene rings are slightly deformed into boat forms; commonly observed for compounds with Ar–P units.[11] The "bow" atoms (C19 and C37) of these boat-shaped benzene rings are located 6.1° and 9.3° above the bottoms (C20, C21, C23, C24) and (C38, C39, C41, C42), respectively, while the "stern" atoms, (C22 and C40) are 4.2° and 4.2°, respectively, above the bottoms. In contrast to the octaphenyl[4]-radialene **6** reported by Iyoda et al.,[12] the overall shape of this diphospha[4]radialene **5** is highly symmetric.



6

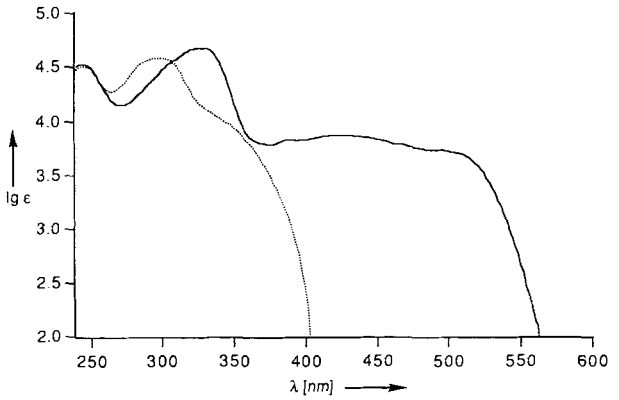


Fig. 2. UV/VIS spectra of **5** (solid line) and **3** (dotted line).

Figure 2 shows the UV/VIS spectra of the radialene **5** and the diphosphinidenecyclobutene **3**, indicating that the absorption spectrum of **5** shows a red shift compared to that of **3**. The absorption peaks due to $\pi-\pi^*$ transition for both **3** and **5** appeared at 243–244 nm with almost equal intensities, in contrast the absorption band at 298 nm due to the conjugated double bonds associated with phosphorus atom(s) for **3** is shifted by about 30 nm to a longer wavelength at 327 nm with a slightly increased intensity for **5**. Moreover, a featureless band above 400 nm appeared in the spectrum of **5**, indicating a very extended conjugated π-electron system. Similar bands also occur in the carbon analogues of **5**,[12, 13] suggesting that the diphospha[4]radialene **5** contains a new π-electron system,[14] which in terms of its electro-, photo-, and coordination chemistry is of interest.

Experimental Procedure

2: Under argon at room temperature, 3-phenyl-1-propyne (0.92 g, 7.9 mmol) in THF (5 mL) was added to one equivalent of ethylmagnesium bromide in THF (12 mL), and stirred for 3 h. To this solution was added 2,4,6-tri-*tert*-butylphenyl(chloro)phosphane (ArPHCl) (7.2 mmol)[15] in THF (10 mL) at 0 °C, and the mixture was stirred for 20 min. After workup (including chromatography on silica gel) and recrystallization from acetonitrile, **2** (1.3 g, 3.3 mmol) was obtained in 46% yield (based on the starting material $ArPH_2$ (2.0 g, 7.2 mmol) used for the preparation of ArPHCl).

3: Under argon and in the dark, **2** (1.3 g, 3.3 mmol) in THF (15 mL) was allowed to react with one equivalent of phenyllithium (1.05 M, cyclohexane/ether solution) at −78 °C, and then stirred for 30 min at room temperature. The solution was cooled to −78 °C and 1,2-dibromoethane (0.28 mL, 3.2 mmol) was added, the mixture was then gradually allowed to warm up to room temperature and stirred for 1 h. The chromatographic workup on silica gel gave **3** (0.31 g, 0.40 mmol) in 24% yield.

5: The cyclobutene **3** (52.8 mg, 0.0674 mmol) in CCl_4 (2.5 mL) was brominated with NBS (24.7 mg, 0.139 mmol) under reflux for 25 min. After the succinimide had been filtered off, the filtrate was concentrated to give a yellow solid. This solid contained about 60% [16] bromobenzylcyclobutene **4** (a 1:1 mixture of *dl* and *meso* form $\delta(^{31}P) = 175.8$ and 175.7). The dibromide **4** thus obtained was dissolved in THF (5 mL) and was allowed to react with butyllithium (0.135 mmol, 1.63 M, hexane) for 15 min at −78 °C and 30 min at room temperature in THF to give an orange solution. The solution was concentrated, and the resulting solid was washed with acetonitrile. Chromatographic workup (silica gel, hexane) gave 11.1 mg of **5** as an orange solid in 21% yield (based on **3**). Similar results were obtained when zinc powder (4 equiv) was used to eliminate the bromine (in diglyme at 50 °C for 13 h) (**5**, 21% yield).

Molecular Self-Organization of Amphotropic Cyanobiphenyl Mesogens**

By *Detlev Joachimi, Carsten Tschierske,* Henning Müller, Joachim Heinz Wendorff, Ludolf Schneider,* and *Ralf Kleppinger*

Hydrogen bonds are directed interactions whose energies lie between those of covalent bonds and nonspecific, intermolecular interactions. Intermolecular hydrogen bonds are, therefore, very important in the formation of macrostructures in biological systems. Molecular self-organization through hydrogen bonds also plays an important role in materials science. This is expressed, amongst other properties, in the formation of liquid crystalline phases which represent a state of matter characterized by order and mobility at the molecular level. The amphiphilic carbohydrate deriva-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Merck for the donation of chemicals. The names of the compounds in this publication do not conform to IUPAC nomenclature since cyanobiphenyl is an accepted term in the field of liquid crystals (Editorial note).

tives and polyhydroxyl amphiphiles which form lamellar or columnar macrostructures are an important class of compounds whose mesogenicity depends on the ability to form hydrogen bonds.[1] Amphiphilic *n*-alkane-1,2-diols, for example **1**, may be regarded as the simplest compounds of this type.[2] In certain temperature ranges these compounds show lamellar mesophases in which the molecules are arranged in layers, and the hydroxyl groups are linked through a dynamic network of cooperative hydrogen bonds. The liquid crystalline phases of these compounds can be modified and stabilized by the inclusion of rigid calamitic structural elements (Fig. 1).[3,4] Comparison of compounds **3** and **4** shows that

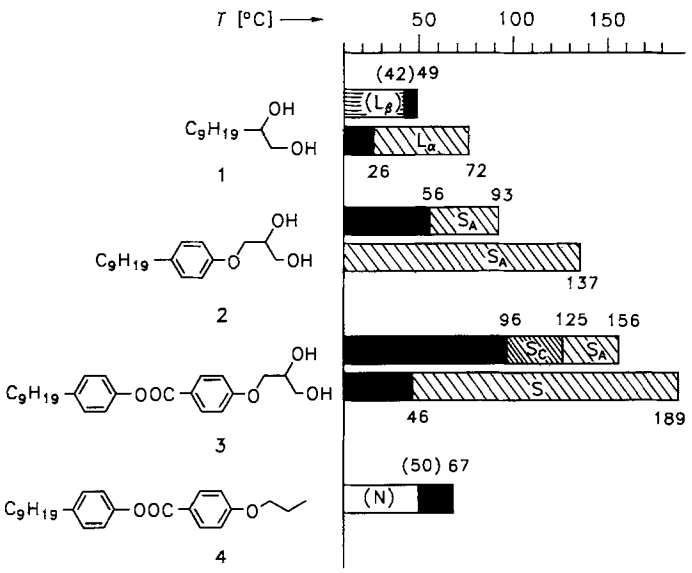

Fig. 1. The influence of calamitic structural elements of different lengths on the liquid crystalline properties of amphiphilic diols, and the comparison of the amphiphilic diol **3** [4] with a nonamphiphilic mesogen **4** [5]. The lower bars for compounds **1**, **2**, and **3** represent the lyotropic mesophase behavior of samples saturated with water. For an explanation of the abbreviations see Table 1 [a].

the introduction of a 1,2-diol unit to the end of an *n*-alkyl side chain of the nonamphiphilic phenyl benzoate **4** causes the change from a nematic mesophase to a smectic phase.

4'-Alkoxy-4-cyanobiphenyls are also known to be calamitic liquid crystals.[5] We have attempted to combine the two types of mesogenic molecular structures—the amphiphilic diols and the calamitic cyanobiphenyl mesogens—and have examined how this affects the ability for molecular self-organization.

The phase transition temperatures of the 4'-[ω,(ω − 1)-dihydroxyalkoxy]-4-cyanobiphenyls **5** which we have synthesized are collected in Table 1, and compared with the analogous 4'-alkoxy-4-cyanobiphenyls **6**. It can be seen that the stability of liquid crystalline phases is raised considerably by the introduction of the 1,2-diol unit. But in spite of the diol group no induction of a smectic phase is observed. On the contrary, while compound **6c** shows a smectic A phase stable up to 67 °C, the 1,2-diol derivative **5d** can be supercooled to 55 °C without any sign of a phase transition. The appearance of a smectic A phase is first observed with compound **5e**. Its stability increases with further chain extension (**5f**) and finally completely displaces the nematic phase. X-ray scattering measurements on the nematic phase of **5c** shows two diffuse halos. The halo observed in the wide angle range at $2\theta = 20°$ corresponds to a mean distance of

[b] Correct C,H analyses, ^{1}H NMR and ^{13}C NMR spectra available. [c] (*S*) enantiomer, see [6]. [d] Phase transition temperatures of the water-saturated samples. [e] Determined by observations of contact preparations in sealed glass capillaries with a polarization microscope. [f] From DSC measurements.

0.44 nm, and is assigned to the closely associated alkyl chains. In the narrow angle region there is a broad halo which is typical for a nematic phase. The average distance is about 1.5 nm, which indicates that no stable dimers, such as those known to occur with mesogenic carboxylic acids, are found in the nematic phase. Thus no influence of hydrogen bonding on the structural parameters can be demonstrated. Here the hydrogen bonds function exclusively as stabilizers of the mesophase. In Figure 2 sections of the IR spectra of compound **5c** and 1,2-propanediol are compared. The absorption maximum for both compounds shifts to higher wave numbers with rising temperature. This is a result of the breaking of intermolecular hydrogen bonds between the diol groups with rising temperature. In comparison with 1,2-

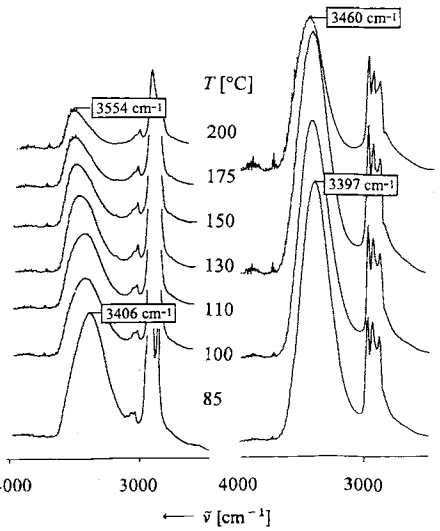

Fig. 2. Sections of the temperature-dependent IR spectra of compound **5c** (left) and 1,2-propanediol (right) in the range 2500–4000 cm^{-1}; measured with a BIORAD-FTS-40 spectrophotometer, in a heated thermal cell SPECAC P/N 21.500.

propanediol, the temperature dependence of the mesogenic diol **5c** is much more evident, and an especially large shift is observed in the region of the phase transition. This verifies that, already, in the nematic phase, some of the hydroxyl groups are not intermolecularly associated during the average time of the measurement. The formation of the nematic mesophase can, therefore, be explained by disorder in the layer structure. The cyano group could be responsible for this, since these can form hydrogen bonds with hydroxy groups.[7] This clearly gives rise to disorder in the smectic layer structure, and a nematic phase is thus favored. But when the length of the alkylene spacers between the diol head group and the cyanobiphenyl unit is further extended the effect of the separation of the hydrophobic and hydrophilic parts of the molecule becomes evident and leads to the formation of smectic layer structures. Similar results were also obtained by Griffin et al. in the investigation of 4′-(ω-hydroxyalkoxy)-4-cyanobiphenyls (for example **7** in Fig. 3).[8]

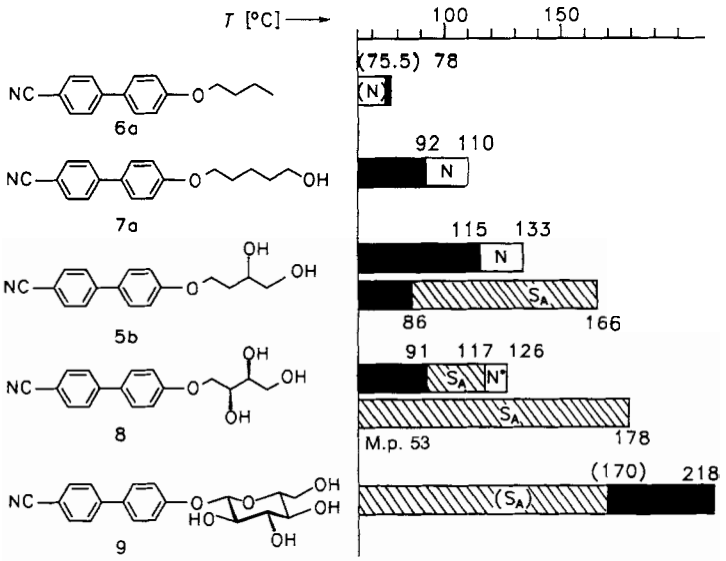

Fig. 3. The influence of the number of hydroxyl groups on the thermotropic mesophase behavior of 4-cyanobiphenyl mesogens **5**–**7** [8], **8** [10], and **9** [11]. The lower bars for compounds **5** and **8** represent the lyotropic mesophase behavior of the water saturated samples. For an explanation of the abbreviations see Table 1 [a].

With respect to mesophase stability, these compounds, since they only have one hydroxyl group available for intermolecular association, lie between the nonamphiphilic compounds **6** and the 1,2-diol derivatives **5**. Smectic mesophases could not be detected even for long-chain compounds of this class of substances.

Since the 4′-(ω,ω-1-dihydroxyalkoxy)-4-cyanobiphenyls **5** are amphiphilic compounds, their mesogenic properties should be influenced by the addition of water. The phase transition temperatures of samples of compounds **5b**–**e**, saturated with water, are compared with those of the anhydrous substances in Table 1. It is clear that the addition of water leads not only to a considerable stabilization of the mesophase, but also to the induction of a smectic layer structure.[9] We interpret this as meaning that the water molecules can be incorporated into the network of hydrogen bonds of the diol head group, strengthening the interactions between the groups and thus hindering the parallel movement of single molecules.

Increasing the number of hydrogen bonds should be possible not only by the inclusion of water molecules but, in general, by increasing the number of available hydroxyl groups in the vicinity of the head group. A comparison of **5b** with compounds **8**[10] and **9**[11] in Figure 3 clearly hows that covalent hydroxyl groups can also cause the induction of smectic mesophases. Thus, by influencing hydrogen bonds, it is possible to control specifically the molecular arrangement of amphiphilic molecules.

[9] The water uptake of these compounds is limited. To determine the water miscibility of the diols, mixtures of **5c** with increasing amounts of water were investigated by differential scanning calorimetry (DSC). With a molar ratio of diol to water of 1:3, the appearance of an ice peak, which is attributed to the crystallization of the "nonbound" water, could already be seen. At higher temperatures the water uptake should, however, be considerably higher.

[10] Compound **8** was obtained by the Mitsunobu etherification of 4′-hydroxy-4-cyanobiphenyl with 1,2-*O*-isopropylidene-3-(*O*-tetrahydropyran-2-yl)-L-threitol (L. De Gaudenzi, S. Apparao, R. R. Schmidt, *Tetrahedron* **1990**, *46*, 277–290), followed by removal of the protective group.

[11] The synthesis of compound **9** was achieved by treating acetobromoglucose with the sodium salt of 4′-hydroxy-4-cyanobiphenyl according to the method of J. Conchie, G. A. Levvy in *Methods in Carbohydrate Chemistry, Vol. 20* (Eds.: R. L. Whistler, M. L. Wolfrom), Academic Press, New York, **1963**, pp. 335–337.

The "Phosphonioyl(phosphoranediyl)carbene" $[(i\mathrm{Pr}_2\mathrm{N})_2\mathrm{P(H)CP}(\mathrm{N}i\mathrm{Pr}_2)_2]^+$ as a Source of New 1,3-Diphosphaallene Ylides: The First Carbodiphosphoranes with P–H Bonds**

By *Michèle Soleilhavoup, Antoine Baceiredo,* and *Guy Bertrand**

Several types of diphosphaallenes possessing either ylidic and/or genuine phosphorus–carbon double bonds (**A**,[1] **B**,[2] and **C**[3]) are known, and we recently the synthesis of the titel compound **1** which can be formally regarded as **D**.[4]

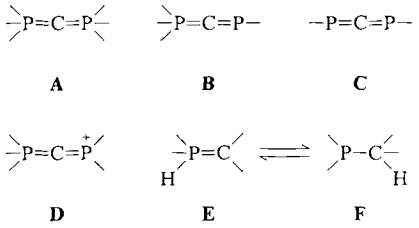
[**] This work was supported by the Centre National de la Recherche Scientifique. We thank Prof. R. Ahlrichs, Karlsruhe, for the preliminary communication of calculations and Dr. R. Reed for helpful discussions.

On the other hand, ylides with P–H bonds (**E**) are rare, and most of them are in equilibrium with the alkylphosphane form **F** (Scheme 1).[5] Here, we report the synthesis and rearrangement of the first carbodiphosphoranes (diphosphoranediylmethanes) with P–H bonds, as well as the deprotonation of the phosphonioyl(phosphoranediyl)carbene **1**, which leads formally to a transient new type of diphosphaallene $\overset{+}{P}=C=\overset{-}{P}$.

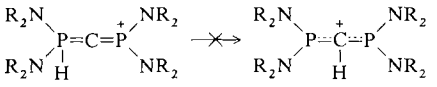


A **B** **C**

D **E** **F**

Scheme 1.

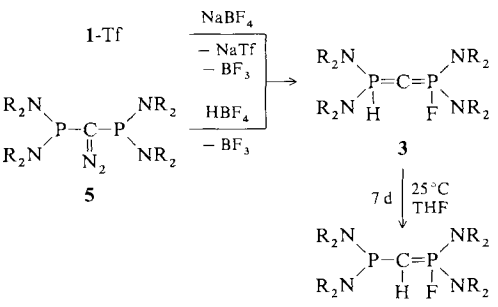
Surprisingly, compound **1** is stable with respect to the possible migration of the hydrogen atom to the central carbon atom, although calculations on the hydrogen analogue (H in place of *i*Pr) predict **2** to be more stable than **1** by 54 and 70 kJ mol^{-1} at the SCF and MP2 levels, respectively[6] (Scheme 2).



1 **2**

Scheme 2. Counterion $CF_3SO_3^-$ (Tf), R = *i*Pr.

This observation prompted us to treat compound **1** with a nucleophile in the hope of obtaining a carbodiphosphorane with a P–H bond. Indeed, the reaction of **1**-Tf with sodium tetrafluoroborate led to the desired carbodiphosphorane **3**. The ^{31}P NMR spectrum of **3** shows a doublet ($^1J_{PF}$ = 951.8 Hz) of doublets ($^2J_{PP}$ = 32.9 Hz) of doublets ($^3J_{PH}$ = 4.0 Hz) of quintets ($^3J_{PH}$ = 17.8 Hz) centered at δ = + 59.5, and a doublet ($^1J_{PH}$ = 524.2 Hz) of doublets ($^2J_{PP}$ = 32.9 Hz) of doublets ($^3J_{PF}$ = 15.3 Hz) of quintets ($^3J_{PH}$ = 16.1 Hz) centered at δ = 9.2, demonstrating that the carbodiphosphorane structure possesses a P–H and a P–F bond; this was further confirmed by a doublet of doublets of doublets at δ = 18.9 ($^1J_{PC}$ = 143.8 and 195.0 Hz, $^2J_{FC}$ = 24.8 Hz) in the ^{13}C NMR spectrum. Carbodiphosphorane **3** is thermally quite stable as a solid (m.p. 116 °C); in solution, **3** slowly rearranges into the isomeric phosphorus ylide **4** after one week at room temperature. It should be noted that **3**, the first carbodiphosphorane with a P–H bond, can be directly obtained by addition of tetrafluoroboric acid to diphosphinodiazomethane **5** (Scheme 3).



5 **3** **4**

Scheme 3. R = *i*Pr.

It was thus tempting to try to synthesize a carbodiphosphorane featuring two P–H bonds. Reaction of **1** with *tert*-butyllithium[7] gave the desired compound **6** which was characterized in solution. The $^{31}P\{^1H\}$ spectrum showed a singlet at δ = – 8.0, but the definitive proof of the structure was given by the ^{31}P NMR ^1H coupled spectrum which was an AA'XX'$M_4M'_4$ system with $^1J_{PH}$ = 465, $^3J_{PH}$ = 1, $^2J_{PP}$ = 158, $^4J_{HH}$ = 0, and $^3J_{PH(CH)}$ = 15 Hz; the calculated and experimental spectra are shown in Figure 1. The carbodiphosphorane **6** rearranged in solution at room temperature in the course of about 16 h to give the phosphorus ylide with a P–H bond (**7**). This compound was also not stable and was completely transformed overnight into the diphosphinomethane **8** (Scheme 4).

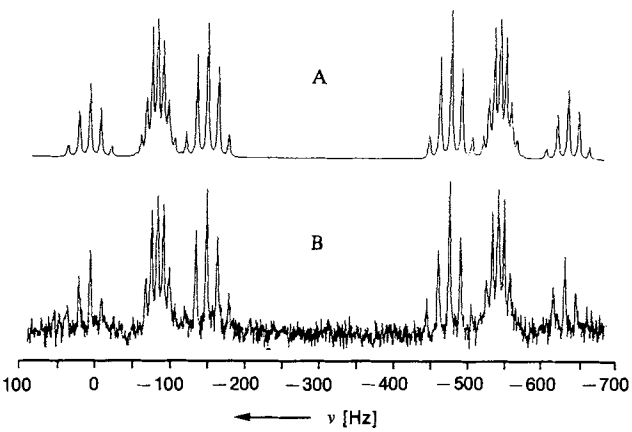


Fig. 1. Calculated (A) and experimental (B) ^{31}P NMR spectra (32.438 MHz) of **6**. Standard: 85% H_3PO_4.

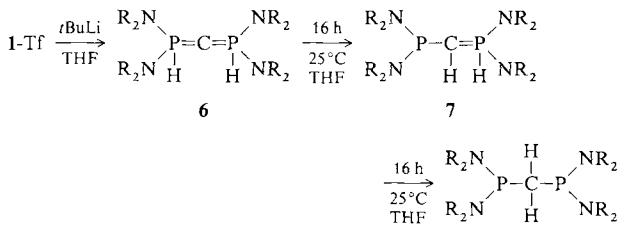
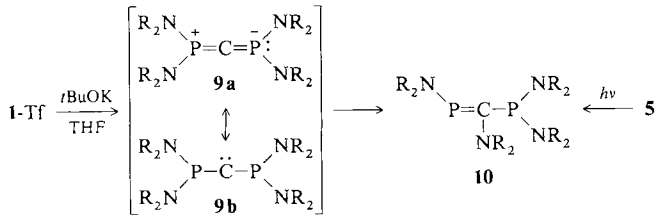


6 **7** **8**

Scheme 4. R = *i*Pr.

The addition of fluoride in the reaction of **1** with boron tetrafluoroborate demonstrated the strong Lewis acid character of the three-coordinate phosphorus center of **1**, while the reaction with *tert*-butyllithium showed that **1** can be easily reduced. It is also possible to abstract the proton from **1**. A clean reaction occurred when **1** was treated with potassium *tert*-butoxide leading to the phosphaalkene **10**, resulting from 1,2-shift of a diisopropylamino group from phosphorus to carbon. Note that the intermediate in this reaction can be formally regarded as a diphosphaallene **9a** or a diphosphinocarbene **9b**; indeed, we have already shown that the phosphaalkene **10** can be obtained by photolysis of the corresponding diazo compound **5**[8] (Scheme 5).

It is of interest to compare these experimental results with theoretical predictions for model compounds carrying amino



Scheme 5. R = *i*Pr.

in place of diisopropylamino substituents.[6] Compound **3** is a local minimum on the potential energy surface, but appeared to be 110 and 116 kJ mol^{-1} above **4**, at the SCF and MP2 level, respectively. In the same way, **6** is 120 kJ mol^{-1} above **7**, which is 140 kJ mol^{-1} higher than **8**. The surprising stabilities of **3**, **6**, and **7** are probably due to the presence of bulky substituents, since the tetracoordinate P–H ylide form better accommodates the steric hindrance than does the tricoordinate CH form. Lastly, the isomerization of **9** → **10** is not surprising since phosphaalkene **10** was found to be 220 kJ mol^{-1} lower in energy than **9**.

This work demonstrates the great potential of **1** as a building block for the synthesis of new metastable species, predicted by theory to be thermodynamically high in energy.

Experimental Procedure

3: To a solution of **1** (1 mmol) in dichloromethane (5 mL) was added the equimolar amount of $NaBF_4$ at room temperature. After the solution had been stirred for 2 h, the solvent was removed under vacuum, and the residue was washed several times with Et_2O. This afforded **3** as white powder (70%; m.p. 116 °C.) ^{31}P NMR: δ = 59.5 (dddq, J(P,P) = 32.9 Hz, J(P,F) = 951.8 Hz, J(P,H) = 4.0 and 17.3 Hz), 9.2 (dddq, J(P,P) = 32.9 Hz, J(P,F) = 15.3 Hz, J(P,H) = 524.2 and 16.1 Hz); ^{13}C NMR: δ = 17.9 (ddd, J(P,C) = 143.8 and 195.0 Hz, J(F,C) = 24.8 Hz, =C=), 22.7 (s, CH_3), 22.9 (d, J(P,C) = 2.6 Hz, CH_3), 46.4 (d, J(P,C) = 4.4 Hz, CHNP), 48.1 (dd, J(P,C) = 5.7 Hz, J(F,C) = 2.5 Hz, CHNPF); ^{1}H NMR: δ = 1.25 (d, J(H,H) = 6.8 Hz, 48 H, CH_3), 3.70 (m, J(H,H) = 6.8 Hz, 8 H, CHNP), 7.20 (dt-like, J(P,H) = 524.2 Hz, J(P,H) = J(F,H) = 4.0 Hz, 1 H, HP=C=P).

4: A solution of **3** (1 mmol) in THF (5 mL) was stirred at room temperature for one week. After evaporation of the solvent, **4** was obtained as a viscous oil (90%); ^{31}P NMR: δ = 71.2 (dddq, J(P,P) = 81.1 Hz, J(P,F) = 1015.4 Hz, J(P,H) = 17.3 and 16.8 Hz), 39.3 (broad d, J(P,P) = 81.1 Hz); ^{13}C NMR: δ = 22.7 and 23.2 (s, CH_3), 23.8 and 23.9 (d, J(P,C) = 7.1 and 6.8 Hz, CH_3), 28.1 (ddd, J(P,C) = 99.6 and 44.5 Hz, J(F,C) = 15.3 Hz, = CH), 47.6 (d, J(P,C) = 12.1 Hz, CHNP), 49.0 (t-like, J(P,C) and J(F,C) < 2 Hz, CHNPF); ^{1}H NMR: δ = 1.11 and 1.21 (d, J(H,H) = 6.6 Hz, 24 H, CH_3), 1.35 and 1.42 (d, J(H,H) = 6.9 Hz, 24 H, CH_3), 2.75 (ddd, J(P,H) = 16.8 and 5.4 Hz, J(F,H) = 10.9 Hz, 1 H, = CH), 3.4 (dsept, J(P,H) = 12.8 Hz, J(H,H) = 6.6 Hz, 4 H, CHNP), 3.9 (dsept, J(P,H) = 17.3 Hz, J(H,H) = 6.9 Hz, 4 H, CHNP).

6: To a solution of **1** (1 mmol) in [D_8]THF (5 mL) was added the equimolar amount of *t*BuLi at −78 °C. Compound **6** was characterized in solution by ^{31}P NMR without any further purification (Fig. 1).

7: After 16 hours at room temperature **6** in [D_8]THF solution rearranged to give **7** in near quantitative yield, according to NMR spectroscopy. ^{31}P NMR: δ = 49.5 (br d, J(P,P) = 174.7 Hz), 13.1 (br dd, J(P,P) = 174.7 Hz, J(P,H) = 486.3 Hz).

8: After 16 hours at room temperature **7** in [D_8]THF solution rearranged to give **8**. The solvent was removed under vacuum, and compound **8** was crystallized at −20 °C from a toluene/pentane solution as colorless crystals (85%); m.p. 167–168 °C; MS: m/z 477 (M + H$^+$); ^{31}P NMR: δ = 44.0; ^{13}C NMR: δ = 24.2 and 24.6 (s, CH_3), 24.1 and 24.5 (d, J(P,C) = 3.3 and 10.7 Hz, CH_3), 30.3 (t, J(P,C) = 21.9 Hz, CH_2), 46.3 (t-like, J(P,C) = 5.0 Hz, NCH); ^{1}H NMR: δ = 1.15 and 1.17 (d, J(H,H) = 6.6 Hz, 48 H, CH_3), 2.1 (t, J(P,H) = 5.0 Hz, 2 H, CH_2), 3.40 (dsept, J(P,H) = 7 Hz, J(H,H) = 6.6 Hz, 8 H, CHN).

10: To a solution of **1** (1 mmol) in THF (5 mL) was added at −78 °C the equimolar amount of *t*BuOK. After the solution had been warmed up to room temperature, the solvent was removed under vacuum, and the residue was extracted with pentane (10 mL). Evaporation of the solvent afforded **10** as a viscous oil (45%) [8].

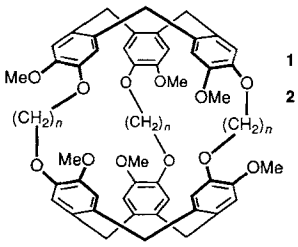
Complexation of Methane and Chlorofluorocarbons by Cryptophane-A in Organic Solution**

By *Laurent Garel, Jean-Pierre Dutasta*, and *André Collet**

The design of hosts capable of binding neutral substrates is of great interest in supramolecular chemistry, and, in this context, the capture of the smallest aliphatic hydrocarbons and fluorocarbons still remains a challenging problem.[1] We report here the complexation of methane and of some small chlorofluorocarbons (CFCs) by a synthetic receptor of the cryptophane family.[2] The methane complex is amazingly stable, and the study of its properties sheds light on some important factors that may govern the formation of supramolecular assemblies made of neutral partners.

We have shown that cryptophane-E (**1**) is an excellent receptor for neutral tetrahedral substrates such as isobutane, even in an organic solvent in which hydrophobic forces are absent.[3] This host proved unsuitable for the complexation of methane, presumably because this substrate is too small (V_{vdW} = 28.4 Å^3).[4] This result led us to use cryptophane-A (**2**),[5] the cavity of which is about 8% smaller in volume than that of **1**.[6] Prior to this work, little had been reported about the complexing properties of **2**.[2]



1 n = 3 (cryptophane-E)
2 n = 2 (cryptophane-A)

When methane was bubbled for 30 s at room temperature through a solution of **2** in $(CDCl_2)_2$,[7] the ^{1}H NMR spectrum showed a broad singlet at δ_{obs} = − 3.05, indicating that

[**] We are grateful to the Centre National de la Recherche Scientifique (CNRS) for a grant (to L. G.).

CH_4 was reversibly bound, and that a fast exchange occurred between the free (signal at δ_f) and complexed (δ_c) molecules (Fig. 1a). On increasing the amount of CH_4 stepwise up to 1.35 times that of **2**, (Fig. 1b to g), δ_{obs} moved downfield (from $\delta = -3.05$ up to $\delta \approx -2$), as a result of the decrease of the host/guest ratio; a plot of $\delta_f - \delta_{obs}$ as a function of this ratio showed that only *one* methane molecule is present in the host cavity. When a solution containing (0.9 equivalents of methane was cooled to 199 K, the guest signal split into two singlets at $\delta_f = +0.14$ and $\delta_c = -4.36$, corresponding to the free and complexed molecules (Fig. 1h).

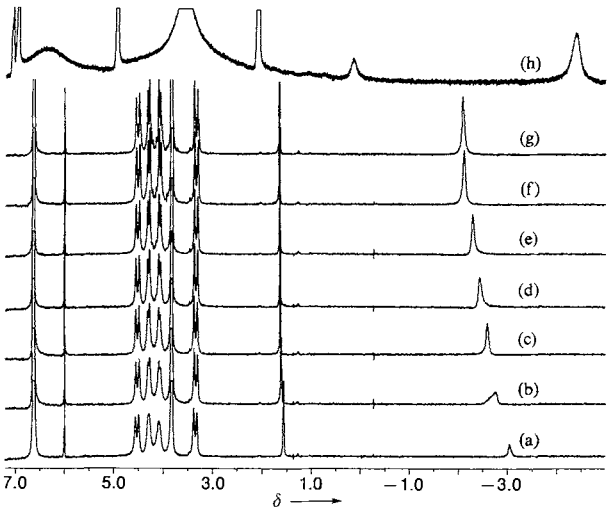

Fig. 1. 200 MHz ^{1}H NMR spectra of host **2** (2.5×10^{-2} M) in $(CDCl_2)_2$ at 298 K, in the presence of increasing concentrations of methane (from 0.33 equivalents in (a) to 1.35 equivalents in (g); (h) spectrum recorded at 199 K in the presence of 0.9 equivalents of methane (ca. 40% of [D_8]toluene was added to prevent freezing).

Treatment of the NMR data[8] provided the binding constant for the complexation of CH_4 to **2** in $(CDCl_2)_2$ at 298[9] and 199 K ($K_a = 130 \pm 20$ M^{-1} and 520 ± 160 M^{-1}, respectively). The enthalpy of binding ΔH_a^0 is therefore negative (around -1.6 kcal mol^{-1}), and the entropy ΔS_a^0 weakly positive ($+4$ cal mol^{-1} K^{-1}). The methane complex of **2** is thus about as stable as the isobutane complex of **1**.[3] Lineshape analysis[10] of the guest NMR signals between 199 and 298 K furnished the half life of the complex $t_{1/2}$ of 6×10^{-6} s at 298 K and 9×10^{-3} s at 199 K; the corresponding dissociation barriers are $\Delta G_d^{\#} = 10.5$ and 9.8 kcal mol^{-1}, respectively.

To our knowledge, the only reported studies on the complexation of small fluorinated hydrocarbons have dealt with the enantioselective recognition of the anesthetic halothane by α-cyclodextrin,[11] and of CHFClBr by cryptophane-C.[12] We investigated the interaction of CHF_2Cl and CF_2Cl_2 with **2** in $(CDCl_2)_2$, and found that both were complexed, albeit less strongly than CH_4. For CHF_2Cl, K_a was (roughly) 0.3 M^{-1} at 298 K and 12 ± 3 M^{-1} at 253 K;[13] owing to the lack of precision, the measurements at 298 K do not provide reliable ΔH_a^0 and ΔS_a^0 values. For CF_2Cl_2, K_a was 13 ± 4 M^{-1} at 298 K.

Relevant data on the properties of these complexes are given in Table 1. In Figure 2, the free energy of binding ($-\Delta G_a^0$) for all the complexes of **2** known to date is plotted as a function of the guest size, together with a similar plot for

Table 1. ^{1}H and ^{19}F NMR chemical shifts ($\Delta\delta = \delta_f - \delta_c$), binding constants ($K_a$), free energies of association (ΔG_a^0), and energy barrier for dissociation ($\Delta G_d^{\#}$) for some complexes of **2** with various guests in 1,1,2,2-[D_2]tetrachloroethane.

Guest	V_{vdW} [Å^3]	$\Delta\delta$	K_a [M^{-1}] (298 K)	ΔG_a^0 [kcal mol^{-1}] (298 K)	ΔH^0 [kcal mol^{-1}]	ΔS^0 [cal mol^{-1} K^{-1}]	$\Delta G_d^{\#}$ (T [K]) [kcal mol^{-1}]
CH_4	28.4	4.50	130	−2.9	−1.6	+4	10.5 (298)
CHF_2Cl	50.6	4.59 (^{1}H) 1.80 (^{19}F)	0.3	+0.7			
CF_2Cl_2	65.2	4.85 (^{19}F)	13	−1.5			14.1 (283)
CH_2Cl_2	55.6	4.33	475	−3.7	−3.3	+1	13.1 (265)
CH_2Br_2	64.8	4.28	320	−3.4	−1.3	−7	12.8 (258)
$CHCl_3$	72.2	4.33	230	−3.2	−8.2	−16	14.7 (298)

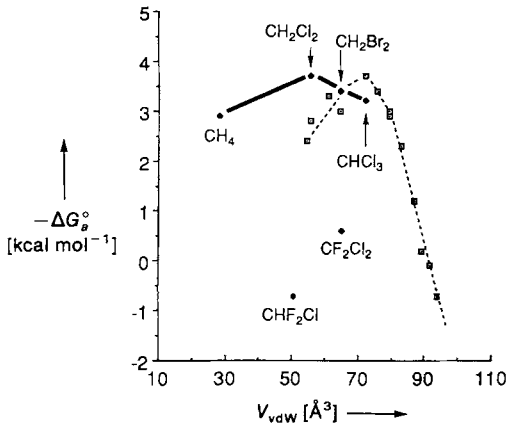

Fig. 2. The solid line represents the free energy of formation $-\Delta G_a^0$ at 298 K for a series of complexes of **2** as a function of the size (V_{vdW}) of the guest molecules; the dotted line shows a similar set of data for host **1** (taken from ref. [3]).

cryptophane-E **1**.[3] For the non-fluorinated substrates, host **2** appears to be less selective than **1**, and its size preference is around 55 Å^3 (dichloromethane), instead of 72 Å^3 (chloroform) for **1**. The amazing stability of the methane complex is both enthalpic and entropic in origin (see Table 1), and this feature may result from favorable host–guest interactions and disfavorable solvent–guest interactions. The observation that cryptophane-E **1** does not bind methane in $(CDCl_2)_2$ suggests that the host–guest interactions are dominant in the stabilization of the methane complex of **2**; this view is supported by the results of MMX force field calculations. A stereoview of the energy-minimized structure of the supermolecule (or host–guest complex) is shown in Figure 3. The methane molecule lies close to the

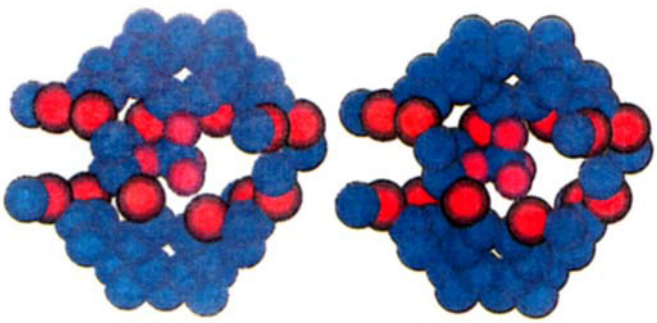

Fig. 3. Stereoview of the energy-minimized structure of the [CH_4/**2**] supermolecule (MMX force field calculation). For clarity, the van der Waals radii of the atoms shown have been reduced by 0.65 Å.

center of the cavity, and the mean distance between the guest and the arene carbon atoms of the host is 4.5 Å; about 20% larger than the sum of the van der Waals radii. This separation is almost exactly that required to reach the *maximum of attractive forces* in a van der Waals interaction potential.[14]

It is obvious from Figure 2 that the relatively large stability difference between the CH_4 complex and the CFC complexes of **2** is not related to size parameters. We cannot yet give a good interpretation for this observation. The CFCs are much more soluble in $(CDCl_2)_2$ than methane, which may indicate the existence of favorable solvent–guest interactions, and may disfavor their inclusion in the cavity of **2**.

At the microscopic level, the fact that methane and related small molecules can be so easily captured by a cryptophane to form stable supermolecules raises some questions about the *state of matter* in the interior of the host cavity. For one molecule of chloroform in host **2**, which has a spherical cavity of 81.5 Å^3, the occupancy factor[15] ϱ is 0.886, which would correspond to a *very closely packed crystal*. In this case, the magnitudes of ΔH_a^0 (-8.2 kcal mol^{-1}) and of ΔS_a^0 (-16 cal mol^{-1} K^{-1}) are actually quite comparable with the heat and entropy of crystallization of organic compounds, and the description of this complex as an ordered *pseudocrystal*, in which host and guest are at contact distance, may seem relevant. For one molecule of methane in the same cavity, the occupancy factor is 0.348; by comparison, the magnitude of ϱ is 0.77×10^{-3} in the gas state (1 atm and 298 K), 0.173 at the critical point (45.6 atm and 190.6 K), and 0.67 in the solid at 0 K. It follows that the best description of the interior of the complex would be a *supercritical fluid*, in which the methane molecule behaves like a small sphere colliding with the walls of the cavity of **2** for a few μs (at 298 K) before escaping. It is amazing to consider that, translated to the macroscopic level, one molecule of methane in the cavity of **2** is equivalent to one mole of methane reduced to a volume of 49 mL and exerting a pressure of 610 atm at 298 K![16]

Even though our knowledge of the guest behavior in the interior of such supermolecules is still very imprecise, we suggest that a description of these species in terms of equivalent macroscopic states of matter is soundly based, and may provide an interesting clue to understanding their properties. Such information may also be of great interest for the design and synthesis of new host systems.

[4] Molecular sizes are expressed here as van der Waals volumes (V_{vdw}), calculated according to A. Bondi, *J. Phys. Chem.* **1964**, *68*, 441-451.
[5] J. Gabard, A. Collet, *J. Chem. Soc. Chem. Commun.* **1981**, 1137–1139; J. Canceill, A. Collet, *ibid.* **1988**, 582–584.
[6] The cavity volume in **1** and **2** was estimated with the molecular modeling software PCMODEL. For both cryptophanes, the cavity is almost spherical in shape, with a mean diameter D of 9.07 Å for **1** and 8.92 Å for **2**. The corresponding van der Waals diameters D_{vdw} (obtained by substracting from D twice the van der Waals radius of an arene carbon atom (1.77 Å)) were 5.53 Å for **1** and 5.38 Å for **2**, and the van der Waals volumes of the cavities were 88.5 and 81.5 Å^3, respectively. These volumes are in agreement with those of the largest neutral molecules that could be complexed in the cavity of these hosts: *tert*-butyl chloride (91 Å^3) for **1**, chloroform (72 Å^3) for **2**. These volumes do not apply to charged guests such as $(Me_3NR)^+$ ions; see A. Collet, J.-P. Dutasta, B. Lozach, *Bull. Soc. Chim. Belg.* **1990**, *99*, 617–633.
[7] This solvent (110 Å^3) is too big for the cavity of **2**.
[8] See for example R. Macomber, *J. Chem. Educ.* **1992**, *69*, 375–378.
[9] There is no significant difference between the values of K_a in pure $(CDCl_2)_2$ and in the mixture of $(CDCl_2)_2$ and [D$_8$]toluene (1.6:1, v:v) used for the low-temperature experiments.

[13] The ^{1}H and ^{19}F NMR spectra gave the same values of K_a.
[14] The attraction between two neutral atoms is maximum at a separation 1.24 times larger than the sum of the van der Waals radii; see J. Israelachvili, *Intermolecular and Surface Forces*, 2nd ed., Academic Press, London, **1992**. This feature sheds light on earlier remarks that, in such host–guest complexes, the size of the best guest is about 20% smaller than that suggested by CPK models: see [3], and F. Diederich, *Angew. Chem.* **1988**, *100*, 372; *Angew. Chem. Int. Ed. Engl.* **1988**, *27*, 362–386.
[15] The occupancy factor (sometimes called packing coefficient) is defined as $\varrho = V_{vdw}(\text{guest})/V_{vdw}(\text{cavity})$.
[16] This pressure was calculated by using the principle of corresponding states, for an occupancy factor of 0.348. For details, see, for example, P. W. Atkins, *Physical Chemistry*, 4th ed., Oxford University Press, Oxford **1990**, pp. 4–26.

[*tert*-Butylcyanide · Lithium Bis(trimethylsilyl)-amide]$_2$, a Model of the Intermediate RCN · MR′ Complex Formed in Reactions of Cyanides RCN with Organometallic Compounds R′M**

By *Gernot Boche*,* *Ira Langlotz*, *Michael Marsch*, *Klaus Harms*, and *Gernot Frenking*

Dedicated to Professor H. M. Walborsky on the occasion of his 70th birthday

Cyanides RCN (R = alkyl, aryl, heteroaryl, etc.) can react with organometallic compounds R′M (R′ = alkyl, aryl, NR_2, etc.; M = Li, Na, K, etc.) by deprotonation or addition.[1] As in the case of the reactions of carbonyl compounds with organometallic compounds,[2] the initial formation of a complex RCN · MR′ is possible. Wakefield et al.[3] consider the RCN · MR′ complex **3** to be a necessary intermediate in reactions of benzyl cyanide (**1**) with *two* molar equivalents of the base R′M (lithium bis(trimethylsilyl)amide, lithium diisopropylamide, or *n*-butyllithium) followed either by dialkylation (on treatment with ≥ 2 molar equivalents of R″-Hal) or dideuteration (with ≥ 2 molar equivalents of D_2O) to give **5** (Scheme 1).[4]

Evidence for the quasi-dianion complex (QUADAC) **2** from the NMR spectrum indicated that a *sequential* deprotonation/alkylation (deuteration) process should be involved rather than the proposed reaction via the "dianion" **6**: QUADAC **2** is selectively alkylated (deuterated) to give the RCN · MR′ complex **3**, which in turn is converted by an *intra*molecular proton shift (R″Hal or D_2O (!) compete with the complexed cyanide RCN for the base R′M!) to the dimeric mono "anion" **4**; a further alkylation of the latter then gives **5**. We have been able to demonstrate the existence of QUADAC **2**[5] and the dimeric "anion" **4**[6] by means of X-ray crystal structure determinations. We now present

Results of MP2/6-31 + G*//HF/6-31G* calculations of H_3CCN (C_{3v}), $LiNH_2$ (C_{2v}), the complex $H_3CCN \cdot LiNH_2$ (C_s), and the transition state for the deprotonation of H_3CCN in the $H_3CCN \cdot LiNH_2$ complex (C_s); E_{rel} [kcal mol^{-1}] and bond lengths [pm] are given. Bond and torsional angles [°] in the transition state: C-C-N 165.9, C-N-Li 92,6, N-Li-N 114.2, Li-N-H 92.5, N-H-C 161.2, H-C-C 93.8; H-N-Li-N ±113.4, H-C-C-N ±117.0.

proof of the existence of the "missing link", an RCN·MR′ complex of the type **3**: Figure 1 shows the structure of [*tert*-butylcyanide·lithium bis(trimethylsilyl)amide]$_2$ (**7**).[7–10]

[*t*BuCN·LiN(SiMe$_3$)$_2$]$_2$ **7**

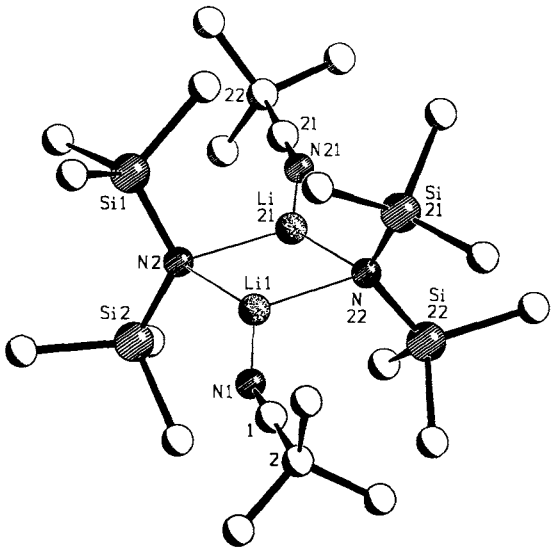

Fig. 1. Crystal structure of **7**. Selected distances [pm] and angles [°]: C1-N1 113.6(5), C21-N21 114.2(6), C1-C2 147.1(6), C21-C22 145.1(7), Li1-N2 203.0(7), Li1-N22 203.7(7), Li21-N2 203.4(7), Li21-N22 201.7(7), Li1-N1 204.6(7), Li21-N21 205.1(8); N1-C1-C2 179.5(4), N21-C21-C22 179.7(5), C1-N1-Li1 159.8(4), C21-N21-Li21 163.1(4). The carbon atoms are denoted only by a number.

As is often the case for lithium amides,[14] **7** exists in the form of a Li-bridged dimer; the third coordination sites of Li1 and Li2 are occupied by *t*BuCN. The structure of **7** is thus similar to those of the complexes of lithium bis(trimethylsilyl)amide with the esters *tert*-butylisobutyrate and *tert*-butylpivalate recently characterized by Williard, Liu, and Lochmann;[2e] the analogous dietherates containing Et_2O and THF have been known for some time.[15]

Ab initio calculations[16] at the MP2/6-31 + G*//HF/6-31G* level confirm both the stability of RCH·MR′ complexes such as **3** and **7** and the energetically favorable *intra*molecular proton shift which must occur in the case of **3** (Scheme 2).[18]

Thus the complex $H_3CCN \cdot LiNH_2$ is 18.7 kcal mol^{-1} more stable than its components H_3CCN and $LiNH_2$. Only 7.8 kcal mol^{-1} is required to reach the transition state for the proton shift in the complex $H_3CCN \cdot LiNH_2$. The initial complexation of RCN and MR′ to give RCN·MR′ thus also favors the subsequent reaction of the latter. It is therefore apparent that complexes of the type RCN·MR′ are probably of general importance in the reactions of cyanides RCN with organometallic compounds R′M.

Experimental Procedure

Preparation of single crystals of **7**: *n*-Butyllithium (0.63 mL, 1.6 M in hexane, 1.00 mmol) was added to a solution of hexamethyldisilazane (161 mg, 1.00 mmol) in diethyl ether (0.5 mL) at 0 °C. After 30 min the solvent mixture was removed under vacuum (oil pump) and the remaining lithium bis(trimethylsilyl)amide dissolved in 0.6 mL diethyl ether. The solution was cooled to −78 °C and treated with *tert*-butylcyanide (83 mg, 1.00 mmol). Single crystals of **7** were obtained after 3 d at −26 °C. Yield: 53 mg (21%).

[4] The degree of aggregation of a complex of the type RCN·MR′ was initially less important for us than its actual existence. The same is true for compounds **2**, **3**, and **4** as formulated by Wakefield (Scheme 2). It is also clear that $H_3CCN \cdot LiNH_2$, for which calculations of the complex stability and the *intra*molecular proton abstraction were carried out, is only a model.

[16] The calculations were carried out with complete geometry optimization and subsequent calculation of the vibrational frequencies at the HF/6-31G* level. The transition state is characterized by an imaginary frequency, while the minima show only real frequencies. The reaction energies were obtained by taking the correlation energy into account with the help of second-order Møller–Plesset perturbation calculations [17] at the MP2/6-31 + G* level. The zero-point vibration energy was scaled with a factor of 0.9 and is contained in the calculated energies. The program package Gaussian 90 was used: M. J. Frisch, M. Head-Gordon, G. W. Trucks, J. B. Foreman, H. B. Schlegel, K. Raghavachari, M. A. Robb, J. S. Binkley, C. Gonzalez, D. J. DeFrees, D. J. Fox, R. A. Whiteside, R. Seeger, C. F. Melius, J. Baker, R. Martin, L. R. Kahn, J. J. P. Domino Reactions of 4-Ene-1,2,3-triol Derivatives

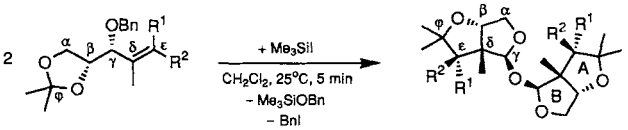
By *Johann Mulzer*,* *Stefan Greifenberg*, *Jürgen Buschmann*, and *Peter Luger*

Domino reactions via carbocationic intermediates are of considerable importance in synthesis and biosynthesis.[1] We report a sequence consisting of at least eight individual steps which is terminated by dimerization to give bis(furanoside) derivatives.

The enetriol derivatives **1a–c**,[2] readily available from (*R*)-2,3-isopropylideneglyceraldehyde in two steps, were treated with trimethylsilyl iodide to give the diastereomerically pure bicyclic products **2a–c** in acceptable yields (Scheme 1). With other Lewis acids such as aluminum



Scheme 1. **a**, $R^1 = H$, $R^2 = Me$; **b**, $R^1 = R^2 = H$; **c**, $R^1 = Et$, $R^2 = H$. Yields based on **1**; 50% is considered to be the maximum possible yield: **2a**, 24%; **2b**, 37%; **2c**, 18%.

trichloride, tin tetrachloride, trimethylsilyl trifluoromethanesulfonate, trimethylsilyl cyanide, and trimethylsilyl chloride, unidentifiable mixtures were obtained or the starting material was recovered. As expected, the ^1H and ^{13}C NMR spectra of **2a–c** show only half of the signals because of the C_2 symmetry of the molecules (Table 1). The dimeric structures can be deduced from the high-resolution mass spectra. The relative configuration was confirmed by X-ray structure analysis (Fig. 1)[3] for **2a** and by NOE difference spectra for **2b** and **2c**. The absolute configuration follows from the fact that the stereogenic center at C_β is unchanged throughout the reaction.

Table 1. Selected spectroscopic data for compounds **2a–c**.

2a: Colorless crystals; $[\alpha]_D^{20} = -124.2$ ($c = 0.95$ in $CHCl_3$); ^1H NMR ($CDCl_3$, 270 MHz): $\delta = 0.86$ (d, $J = 7.5$ Hz, 3H), 1.05 (s, 3H), 1.08 (s, 3H), 1.24 (s, 3H), 1.69 (q, $J = 7.5$ Hz, 1H), 3.72 (d, $J = 10$ Hz, 1H), 3.80 (dd, $J_1 = 10$ Hz, $J_2 = 3.2$ Hz, 1H), 4.04 (d, $J = 3.2$ Hz, 1H), 4.41 (s, 1H); ^{13}C NMR ($CDCl_3$, 68 MHz): $\delta = 10.14$, 15.07, 21.61, 28.29, 51.32, 57.63, 72.21, 84.84, 87.52, 104.82; IR (KBr pellet): $\tilde{\nu} = 2972$ s, 2935 m, 2898 m, 2974 w, 1465 m, 1389 m, 1379 w, 1369 m, 1258 w, 1227 m, 1177 m, 1141 m, 1104 m, 1069 s, 980 vs, 932 m, 902 m, 860 m, 763 w, 612 w, 519 w cm^{-1}; MS (EI, 80 eV, 60 °C): *m/z* (%): 339 (0.8), 199 (3.6), 185 (7.6), 169 (100), 43 (49.8).

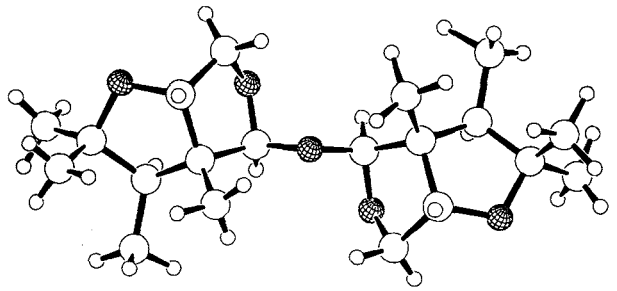

Fig. 1. Crystal structure of **2a** [3,4].

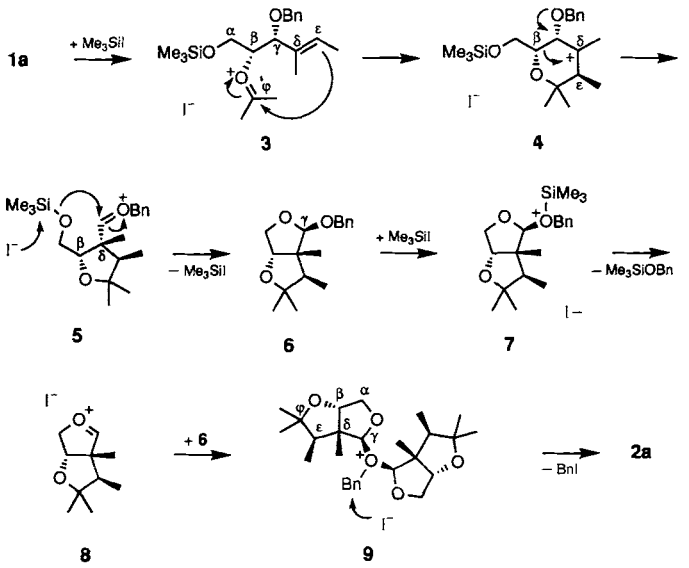
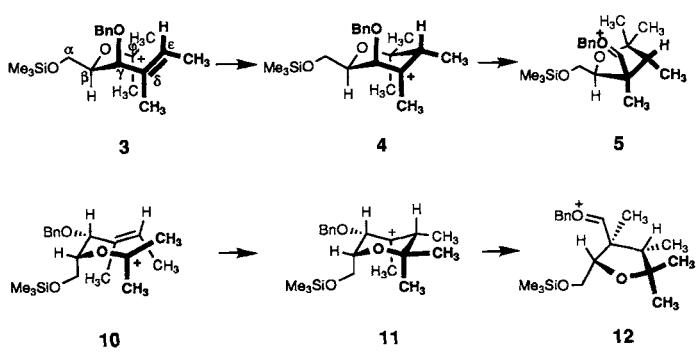
Prins cyclization. Subsequent pinacol rearrangement provides **5**.[5] Desilylation and cyclization affords the tetrahydrofuran **6**, whose labile glycosidic bond is cleaved by trimethylsilyl iodide to give the cyclic oxonium ion **8**. Unreacted glycoside **6** adds to **8** to form dimer **9**, which eliminates benzyl iodide giving **2a**. The overall yield is roughly 50%, which indicates an average yield of 91% for each step.



Scheme 2. Mechanism for the formation of **2a**.

In this sequence the stereogenic center at C_β controls the configurations at C_α, C_δ, and C_ε. Conformations **3** and **10** are the possible transition states for the Prins cyclization (Scheme 3). Conformation **3** is clearly preferred, since the side chain at C_β is equatorial. This explains the formation of **4**. The pinacol rearrangement proceeds suprafacially, and thus only **5** is formed from **4**. Starting from **10**, an analogous sequence would generate **12**, which cannot form a second ring due to the *trans* arrangement of the necessary appendages.[6] Finally, the stereogenic center at C_γ is formed by attack of **6** at the less hindered, convex face[7] of the bicyclo[3.3.0]octane structure **8**. According to our proposed mechanism, the geometry of the double bond in **1** reappears in the A ring in **2**. The rearrangements of **1a–2a** (*E* olefin) and **1c–2c** (*Z* olefin) do confirm this.



Scheme 3. Intermediates in the formation of the glycoside.

Within the limits of HPLC detection (±5%) the rearrangements are stereoselective. Their preparative value lies in the synthesis of complex bis(furanosides) from simple precursors. At present we are investigating the formation of cross-coupled bis(furanosides) from mixtures of unlike enetriols **1**.

Experimental Procedure

1a (1.00 g, 3.6 mmol) in CH_2Cl_2 (2 mL) was stirred at 0 °C with Me_3SiI (0.57 mL, 4.0 mmol, 1.1 mol equiv). After 5 min the reaction was quenched with MeOH, and stirred for approximately 15 h over solid $Na_2S_2O_3$. The mixture was concentrated under vacuum and diluted with ether. The organic phase was washed several times with water and dried over Na_2SO_4, and the solvent was removed under vaccum. Preparative column chromatography (silica gel, hexane/ethyl acetate 5:1) gave **2a** (310 mg, 24%) as colorless crystals, m.p. 134 °C.

Scheme 1. Synthesis of the fullerene bases **5**, **6**, and **7**.

If a diamine such as *N,N'*-dimethylethylenediamine (**2**), piperazine (**3**), or homopiperazine (**4**) is allowed to react with C_{60} (**1**) in toluene between 0 and 100 °C and both reactants are present in low concentrations,[2] the predominant products formed are the mono- and bisadducts.[3] Contrary to expectations, an exact 1:1 ratio of reactants is not necessary in order to obtain high proportions of the monoadduct. Even in the presence of up to a 14-fold molar excess of the diamines **2**, **3**, or **4**, relatively high proportions of the corresponding monoaddition products are obtained when the reaction is stopped at 50–80% conversion of C_{60} (**1**). The bias towards formation of the monoadduct is also influenced by the structure of the diamine and is most pronounced in the case of piperazine (**3**) and least pronounced in the case of *N,N'*-dimethylethylenediamine (**2**).

The mono- and bisaddition products[3] formed in the reaction of **2**, **3**, or **4** with C_{60} (**1**) as well as unreacted **1** can be separated by conventional column chromatography on silica gel. In the case of the piperazine–C_{60} adducts, six regioisomeric bisaddition products can be separated on SiO_2 in addition to recovered **1** and the principal product, the monoadduct. Separation of the regioisomeric bisaddition products in the case of the reactions with the diamines **2** and **4** requires more effort; further chromatography is necessary after removal of unreacted **1** and the monoadduct.[4] The mono- and bisadducts isolated by the above procedure were found to be pure according to thin-layer chromatography (TLC). The homogeneous composition of the samples was further confirmed by high-performance liquid chromatography (HPLC) on two different stationary phases (RP 18 and SiO_2).

Adducts containing more than two diamine units per **1** are also formed in yields of around 15–50% with respect to reacted **1** when up to a 14-fold molar excess of the diamine is employed. These adducts are not isolated by the procedure described above.

The mono- and bisadducts crystallize as deep brown-black solids, in part as well-formed needles. They are soluble in CS_2, but are otherwise only sparingly soluble in solvents over a range of polarities. The presence of the mono- and bisadducts was established from the elemental analyses and mass spectra. Mass spectrometric and NMR spectroscopic analyses show that these derivatives are not adducts arising from nucleophilic addition, that is to say with two hydrogen atoms attached to C_{60} for every diamine unit. They are actually the corresponding "dehydrated" C_{60} derivatives. The expected signals characteristic of hydrogen atoms bonded to

Table 1. Selected physical data for the monoadducts **5**, **6**, and **7** (all compounds gave correct C,H,N analyses) [a].

5: $C_{64}H_{10}N_2$; M = 806.80; MS (FAB): m/z 807 (MH^+), 806 (M^-); IR [b] (strong bands): ν = 2940, 2880, 2840, 2795, 1465, 1445, 1430, 1050, 730 cm^{-1}; ^1H NMR (360 MHz, $CS_2/CDCl_3$): δ = 3.49 (s, 6H; CH_3), 3.96 (s, 4H; CH_2)

6: $C_{64}H_8N_2$, M = 804.78; MS (FAB): m/z 805 (MH^+), 804 (M^-); IR [b] (strong bands): ν = 2970, 2940, 2870, 1455, 1430, 1300, 1245, 1040, 1015, 850 cm^{-1}

7: $C_{65}H_{10}N_2$; M = 818.81; MS (FAB): m/z 819 (MH^+); IR [b] (strong bands): ν = 2950, 2910, 2860, 1460, 1450, 1430, 1180, 1110, 1035, 1010 cm^{-1}; ^1H NMR (360 MHz, $CS_2/CDCl_3$): δ = 4.63 (m, 2H; CH_2), 4.49 (q, 2H; CH_2), 3.94 (m, 2H, CH_2) 3.82 (q, 2H; CH_2), 2.63 (m, 1H; CH_2) 2.47 (m, 1H, CH_2)

[a] As a result of fragmentation, a signal at m/z 720 (molecular peak of **1**) also appears in every mass spectrum (matrix: 3-nitrobenzyl alcohol). M^+ or M^-: Mass spectra in which cations or anions, respectively, are observed after ionization. [b] IR spectra were recorded on crushed crystal aggregates on KBr with a Bruker IR microscope coupled to a Bruker IFS 88 spectrometer.

C_{60} are absent both in the ^1H and ^{13}C NMR spectra. Both hydrogen atoms introduced with each diamine unit have thus been eliminated. The mass spectra of the monoadducts **5**, **6**, and **7** (Table 1) provide further support for the dehydrogenated structure. Only 15 signals appear in the C_{60} region of the ^{13}C NMR spectrum of **6** (Fig. 1). This is an

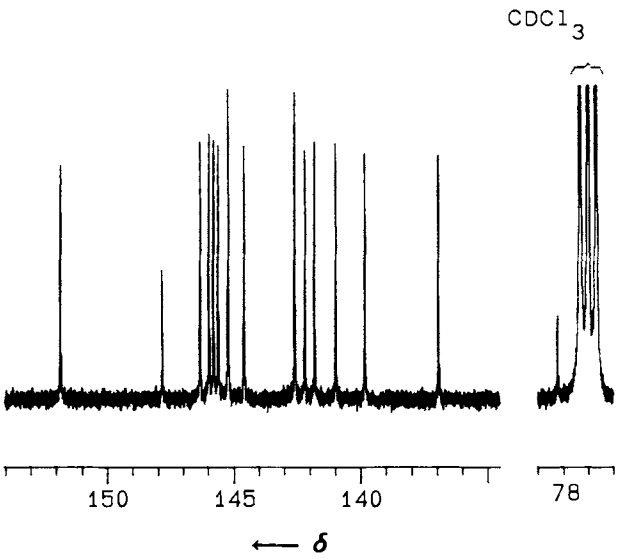

Fig. 1. ^{13}C NMR spectrum (90.5 MHz, $CS_2/CDCl_3$) of **6** in the C_{60} region.

indication of a highly symmetrical structure. The ^1H NMR spectra of **5**, **6** (Fig. 2), and **7** also point to a highly symmetrical structure. The simple pattern of signals in the ^1H and ^{13}C NMR spectra clearly show that **5**, **6**, and **7** have a symmetrical dehydrogenated structure (see Scheme 1) in which both nitrogen atoms of the diamine are bonded to neighboring C_{60} atoms of a 6-6 bond. This is yet another example of the strong preference shown by C_{60} (**1**) towards reaction at what is probably the energetically most favored position,[5] the 6-6 bond. The bonding of a diamine across a 5-6 bond, which would result from the formal addition of the diamine to two neighboring 6-6 bonds that form part of the [5]radialene structure of a pyracylene unit, can be rejected.

The purified regioisomeric bisadducts formed in the reactions of **2**, **3**, and **4** with **1** have analogous structures to those of the monoadducts. The mass spectra once again provide unambiguous support for the dehydrogenated structure. Six regioisomeric bisadducts from the reaction of **1** with **3** were separated cleanly by chromatography. They show striking differences in polarity as seen from the large variations in the

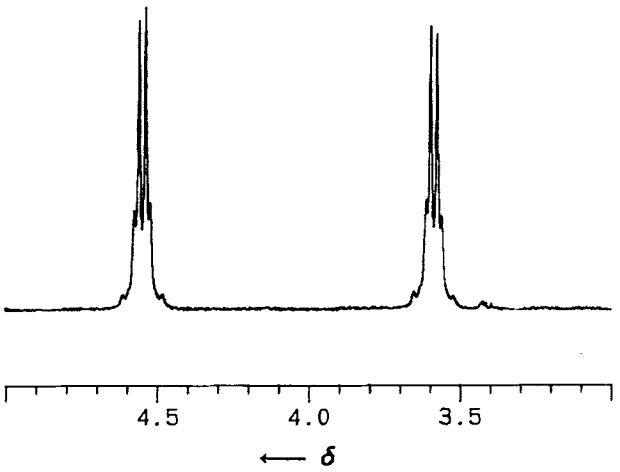

Fig. 2. ^{1}H NMR spectrum (360 MHz, $CS_2/CSCl_3$) of **6**.

TLC R_f values. The R_f values for the six bisadducts measured on Kieselgel 60 (coating thickness 0.25 mm; eluent CH_2Cl_2/C_2H_5OH 10/1) vary between 0.46 and 0.10, whereas the R_f value for the monoadduct **6** is 0.56 ($\pm$0.02). The IR spectra of the six bisadducts differ in the fine structure of the bands. No N–H bands were observed (typically around 3300 cm^{-1}).

Mono- and bisadducts were obtained in overall yields of 50–85% calculated on the basis of reacted **1** (45–70% based on total quantity of **1** used); compound **6**, for example, was isolated in yields of up to 53% with respect to the total quantity of **1** used in the reaction.

This reaction provides selective access to diamino and tetraamino derivatives of C_{60} **1** for the first time.

Experimental Procedure

6: A solution of 1110 mg of **1** (C_{60}/C_{70} 98/2) (1.5 mmol **1**) in 600 mL of toluene was treated with a solution of 1035 mg of **3** (12 mmol) in 183 mL of toluene under a nitrogen atmosphere. The resulting mixture was stirred for five days at 50 °C. After filtration, the solution was loaded onto a silica gel/CH_2Cl_2 column (40 × 3.6 cm), and 192 mg of **1** was eluted with 1200 mL of CH_2Cl_2. A CH_2Cl_2/CH_3OH (100/0.8) mixture was then used as eluent. After 2.5 L of compound-free eluate was collected, 560 mg of a brown-black compound was eluted from the column with a further 1.5 L. After treatment with ether, suction filtration, and drying, 507 mg of pure, crystalline **6** was isolated (42% with respect to total amount of **1** used; 49.5% with respect to reacted **1**). The column was further eluted with CH_2Cl_2/CH_3OH (100/2 and 100/4). After 1 L of compound-free eluate, 4 L (100/4) containing 110 mg of a mixture of five bisadducts were collected. These bisadducts were in turn be separated on a silica gel column (80 × 3.0 cm) using an analogous procedure to that described above. Further elution with 1.5 L (100/6) gave, after addition of ether to the crystalline residue, suction filtration, and drying, 90 mg of the most polar bisadduct according to TLC (SiO_2) (HPLC >92% pure); $C_{68}H_{16}N_4$ (M = 888.91); elemental analysis; calculated: C 91.88, H 1.81, N 6.30%, found: C 90.2, H 1.7, N 6.0%.

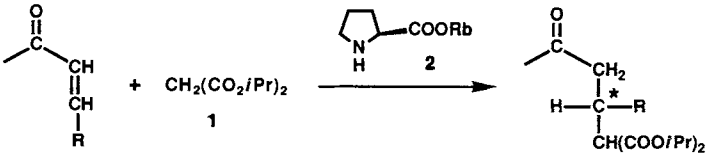
A Catalytic Enantioselective Michael Addition of a Simple Malonate to Prochiral α,β-Unsaturated Ketones and Aldehydes**

By *Masahiko Yamaguchi,** *Tai Shiraishi*, and *Masahiro Hirama*

Distinct progress has been made in the catalytic asymmetric Michael addition of prochiral enolates to acceptors for example, enantioselective addition of indane-1-one-2-carboxylate to methyl vinyl ketone.[1] These reactions rely on the differentiation of donor enantiofaces by chiral catalysts. In contrast, very little success has been achieved in the enantioselective Michael addition of an enolate to prochiral acceptors, despite the high potential of this reaction to produce various chiral carbon centers.[2] The conventional methods appear to be highly substrate specific, and enantiomeric excesses attained have generally not been high. We disclose herein the first catalytic asymmetric Michael addition of a simple malonate ion to prochiral enones and enals, which employs the readily available rubidium salt of L-proline (**2**).[3] The optical yields are substantial for this type of reaction, and the method can be applied to a range of acceptors to give adducts of predictable absolute configurations.

The Michael addition of dimethyl malonate in methanol catalyzed by the lithium salt of L-proline gave racemates.[4] However, appreciable asymmetric inductions were observed when the reactions were carried out in chloroform. Furthermore, the rubidium salt **2**[5] was found to possess remarkably high catalytic activity compared with the lithium salt, and higher optical yields were attained with diisopropyl ester **1**[6] (Scheme 1). Enantioselectivities up to 77% *ee* were



Scheme 1. The asymmetric Michael addition of diisopropyl malonate **1** to prochiral acceptors catalyzed by the rubidium salt of L-proline (**2**).

attained with 5 mol% of catalyst **2** (or 20 mol% with the less reactive substrates) (Table 1). Applicability to various Michael acceptors such as aliphatic and aromatic cyclic enones, cyclic enones, and enals should also be noted.

The catalyst **2** used contains water molecules as shown by elemental analysis.[7] The reaction rate was considerably lower in the presence of molecular sieves (4 Å), and a small amount of water was found to promote the reaction. Yields of adducts were very low with 5 or 10 mol% of the rubidium salts of *N*-methyl-L-proline and *N*-benzyl-L-proline, L-prolinol, L-proline, pyrrolidine, or triethylamine. Thus, both the secondary amine moiety and the metal carboxylate moiety of **2** are essential for the high catalytic activities. Since the activities and basicities of these amines are not correlated, **2** not only functions as a base but also involves some substrate activation.

5	2-cycloheptenone	59	91	59	+22.4°	*R* [d]
6	2-cyclohexenone	46	87	49	+2.3°	*R* [d, g]
7	(*E*)-$(n\text{-}C_3H_7)CH{=}CHCHO$	17	58	41	+4.6°	
8	(*E*)-$CH_3CH{=}CHCHO$	3	63	35	+5.6°	*S* [f]

[a] Isolated yields are shown. All the adducts gave satisfactory ^1H NMR, ^{13}C NMR, and IR spectra, as well as elemental analyses. [b] Enantiomeric excesses were determined by ^1H NMR spectroscopy (400 or 600 MHz) on ketals synthesized from the adducts and (2*R*,3*R*)-2,3-butanediol. [c] Obtained in $CHCl_3$ at 22–26 °C, $c = 1.01 - 1.04$. [d] The adducts were converted into known methyl esters by decarboxylation and esterification for the determination of the absolute configurations. Entry 1: D. Enders, K. Papadopoulos, *Tetrahedron Lett.* **1983**, *24*, 4967; Entry 4: K. Tomioka, K. Yasuda, K. Koga, *ibid.* **1986**, *27*, 4611. Entry 5: Compared with the compound described in footnote [g]. Entry 6: G. H. Posner, M. Weitzberg, T. G. Hamill, E. Asirvatham, H. Cun-Heng, J. Clardy, *Tetrahedron* **1986**, *42*, 2919. [e] 20 mol% of **2** was employed. [f] The product of the entry 8 was treated with MeLi or PrMgBr (THF, −78 °C) and oxidized (pyridinium dichromate or Swern oxidation) to give the products of the entries 1 and 2, respectively. The three compounds possessed the same absolute configuration. [g] Methyl(*R*)-(+)-3-oxocyclohexaneacetate, synthesized from the adduct by decarboxylation and esterification, was treated with diazomethane for ring enlargement: T. J. Boer, H. J. Backer, *Org. Synth. Collect. Vol.* **1963**, *4*, 225. Separation of the regioisomers gave methyl (*R*)-(+)-3-oxocycloheptaneacetate, $[\alpha]_D^{24} = +21.4$ ($c = 1.27$, $CHCl_3$).

The malonate **1** attacked cyclic (*Z*)-enones preferentially from the *Re* face (entry 5 and 6 of Table 1), and acyclic (*E*)-enones from the *Si* face (entries 1, 2, 4, and 8).[8] In other words, the nucleophile attacks from the same side of the enone plane irrespective of its stereochemistry (Fig. 1). The preference was also observed in reactions of a nitroalkane.[9]

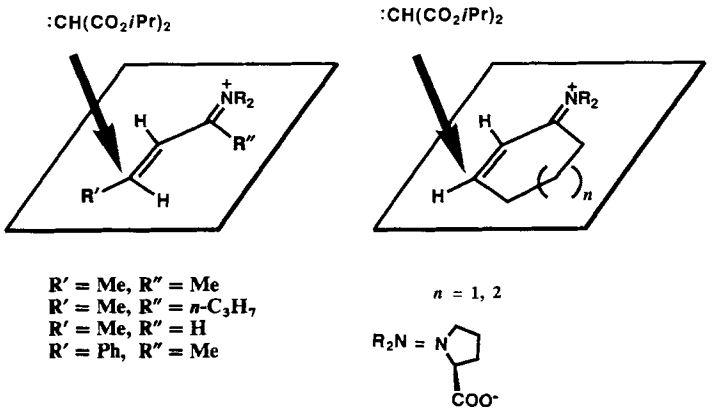

Fig. 1. The attack of the malonate ion on a postulated intermediate in the asymmetric addition.

These asymmetric inductions take place through enantioface differentiation of acceptors rather than recognition of differences in two β substituents. They therefore are relatively inert to structure variations of acceptors and donors, which may be the origin of the wide applicability of the present asymmetric process. Although related phenomena have been known in the diastereoselective Michael addition reactions to chiral unsaturated amides,[10] we are not aware of the concept in catalytic reactions. We presume that the unfavorable substrate specificity of the conventional reactions[2] may at least be partially due to the use of methods to recognize β substituents, which can be quite sensitive to the structure of acceptors and donors.

Reversible iminium salt formation in nonprotic solvents is one explanation for the above asymmetric inductions. Independent experiments demonstrated a high reactivity of an unsaturated iminium salt towards malonate addition. When an iminium salt, prepared from (*E*)-4-phenyl-3-buten-2-one and pyrrolidine,[11] was treated with dimethyl malonate in the presence of a catalytic amount of triethylamine at 25 °C, the starting material was consumed in several hours giving the 1,4 adduct after an aqueous workup. No 1,2 adduct was detected. Essentially no reaction took place with the enone itself under these conditions.

Experimental Procedure

Under an argon atmosphere, a mixture of **1** (1.30 mL, 6.72 mmol), 2-cycloheptenone (0.50 mL, 4.48 mmol), and catalyst **2** (46 mg, 0.22 mmol) in chloroform (5 mL) was stirred for 59 h at 25 °C. The reaction was quenched by adding 2 N HCl. Diisopropyl (+)-(3-oxocycloheptyl)malonate (1.21 g, 91%) was obtained by the usual workup.

[5] To obtain reasonable yields of the optically active Michael adducts in chloroform, 100 mol% of the lithium salt was required. Use of 10 mol% of the sodium or potassium salt of L-proline gave adducts in high yields but in low enantiomeric excesses.

[6] Reaction of dimethyl malonate in the presence of 10 mol% of **2** for 15 h gave the (*R*)-adduct in 88% yield and 40% *ee* Di-*tert*-butyl ester gave the (*R*)-adduct in 39% yield and 65% *ee* after 63 h.
[7] The catalyst **2** was conventiently prepared from the reaction of one equivalent of L-proline and rubidium hydroxide monohydrate (Kanto Chemical Co.) in methanol at 25 °C for 1–3 h. After evaporating the solvent, **2** was dried at 25 °C in vacuo. M.p. 269–271 °C (decomp); $[\alpha]_D^{23} = -61.2$ ($c = 0.99$, MeOH). Correct elemental analysis (C,H,N) for $C_5H_8NO_2Rb \cdot 1/2\,H_2O$.
[8] Although **1** attacked from the *Re* face of (*E*)-4-phenyl-3-buten-2-one (entry 4), this is simply a matter of the nomenclature. The sense of the asymmetric induction is the same as with other acyclic Michael acceptors (Fig. 1).
[9] Reaction of 2-nitropropane with 2-cyclohexenone and (*E*)-3-penten-2-one in the presence of **2** (5 mol%) for 24 h gave the adducts of the same asymmetric induction mode in 58% *ee* (61% yield) and 69% *ee* (48% yield), respectively. Details will be reported elsewhere.

A Novel Mixed-Valence Tetranuclear V^{II}/V^{III} Complex Isolated from 3,5-Di-*tert*-Butylcatechol/Vanadium(II)/Sodium Methoxide System for Dinitrogen Reduction

By *Nataly P. Luneva,* Svetlana A. Mironova, Alexander E. Shilov, Mikhail Yu. Antipin,* and *Yuri T. Struchkov*

Development of the coordination chemistry of bivalent vanadium, particularly for nonorganometallic complexes, lagged well behind that of most other first-row transition elements.[1] There has, however, been a steady growth of interest in the synthesis, structural characterization, and reactivity of bivalent vanadium complexes because of their ability to reduce a variety of substrates.[2] The complexes of vanadium(II) with catechol are of particular interest because they can reduce molecular dinitrogen under ambient conditions.[2b]

We report here the crystal structure of a novel mixed-valence tetranuclear V^{II}/V^{III} complex isolated from a solution of VCl_2, 3,5-di-*tert*-butylcatechol (dbcat), and $NaOCH_3$. The complexes of V^{II} with dbcat formed in methanol in the presence of sodium methoxide are powerful reducing agents: they evolve H_2 from the solvent [Eq. (a)] and reduce dinitrogen [Eq. (b)]. Figure 1a shows that H_2 evolution occurs at a

$$2\,V^{II} + 2CH_3OH \longrightarrow 2\,V^{III} + H_2 + 2CH_3O^- \quad (a)$$

$$6\,V^{II} + N_2 + 6CH_3OH \longrightarrow 6\,V^{III} + 2NH_3 + 6CH_3O^- \quad (b)$$

considerable rate for 3–4 h, and the total H_2 yield[3] is about 50%. The complete oxidation of V^{II} to V^{III} [Eq. (a)] requires 8–10 days. The reduction by V^{II} of N_2 [Eq. (b)] competes with that of methanol [Eq. (a)], and the NH_3 yield[3] gives a measure of the activity of the V^{II} complexes to reduce N_2. The increase in $NaOCH_3$ concentration results in the enhancement of the NH_3 yield up to the apparently limiting value of 40–45% at $[NaOCH_3] \geq 0.8$ M. Figure 1b shows that the reduction of N_2 to NH_3 proceeds for 2–3 hours, and

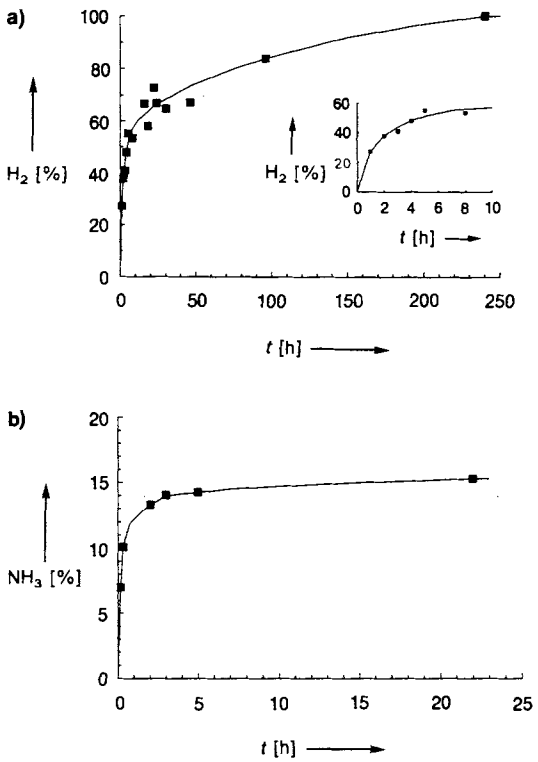

Fig. 1. The variation with time of the dihydrogen evolution (a) and ammonia formation (b). Initial conditions: VCl_2 3.5×10^{-4} mol, dbcat 1.88×10^{-3} mol, $NaOCH_3$ 1.5×10^{-3} mol, $V = 7.5$ mL, N_2 pressure 75 atm.

further reduction is practically brought to a stop. Chemical analysis shows that during the first 2–3 hours approximately 50% of the initial V^{II} oxidizes to V^{III}, and 15–18% of NH_3 [Eq. (b)] and 35–38% of H_2 [Eq. (a)] is formed. The retardation of the V^{II} oxidation rate may be explained by the formation of the relatively stable mixed-valence V^{II}/V^{III} complex, which is not able to reduce N_2 and demonstrates poor activity in the dihydrogen evolution from methanol.

The mixed-valence V^{II}/V^{III} complex with the composition of **1** is crystallized in the form of yellow-brown rhombuses.

$$[Na_2V_4(OMe)_2\{O_2C_6H_2(tBu)_2\}_4\{OC_6H_2(OH)(tBu)_2\}_2(MeOH)_8] \quad \mathbf{1}$$

The structure of **1** was elucidated by X-ray analysis (Fig. 2)[4] In **1** two V^{II} ions and two V^{III} ions are present on the base of chemical analysis, but from the X-ray data the V atoms are undistinguishable. Each vanadium center exhibits a distorted octahedral coordination involving the oxygen atoms. V1 is coordinated to two O atoms (O(8) and O(9)) of the methanol molecules, two μ_3-bridging atoms (O(7) and O(7a)) of the methoxy ligands, and another two bridging O atoms (O(1) and O(6)) from different dbcat molecules. V2 is coordinated to the μ_3-bridging O(7a) atom of the methoxy ligand, the μ_2-bridging O(1a) atom of a dbcat molecule, and four O atoms (O(3), O(4), O(5), and O(6) of two chelating dbcat molecules. The V–O distances range from 1.954(5) to 2.158(5) Å and correspond to the expected values. Sodium atoms are located in the centers of distorted tetrahedrons formed by oxygen atoms. Each sodium atom is coordinated by two O atoms (O(10) and O(11)) of the methanol molecules and by two O atoms (O(3) and O(5)) of different dbcat molecules. Na and V atoms are linked by the μ_2-bridging O(3) and O(5) atoms.

The architecture of the central part of **1** is similar to that found earlier for the Mg–Mo–alkoxide complexes.[5] It is

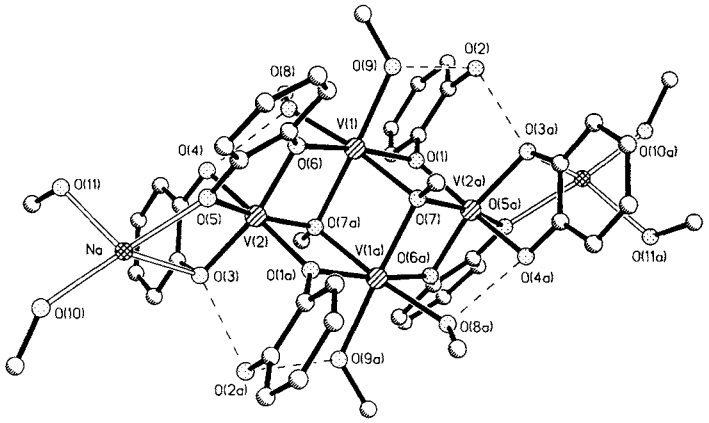

Fig. 2. Crystal structure of the complex **1** (*tert*-butyl groups and H atoms omitted). Important distances [Å]: V(1)–O(1) 2.110(5), V(1)–O(6) 2.118(5), V(1)–O(7) 2.122(4), V(1)–O(7a) 2.149(5), V(1)–O(8) 2.158(5), V(1)–O(9) 2.142(5), V(2)–O(1a) 1.970(5), V(2)–O(3) 2.010(5), V(2)–O(4) 2.036(4), V(2)–O(5) 1.980(5), V(2)–O(6) 1.954(5), V(2)–O(7a) 2.060(5), V(1)···V(2) 3.059(2), V(1)···V(1a) 3.193(2), V(1)···V(2a) 3.241(2), Na–O(10) 2.285(7), Na–O(11) 2.292(6), Na–O(3) 2.246(6), Na–O(5) 2.296(6), Na···V (2) 3.250(4), O(2)···H···O(3a) 2.796(5), O(9)···H···O(2) 2.815(5), O(8)···H···O(4) 2.644(5). The index a indicates the centrosymmetrical coordinate transformation.

probably stabilized by the intramolecular hydrogen bonds, whose geometrical parameters correspond to hydrogen bonds of the medium strength. The OH groups of the coordinated methanol molecules and "free" OH groups of dbcat ligands are the proton donors in these hydrogen bonds.

The formation of relatively stable **1** is a characteristic feature of the V^{II} system with dbcat. In the V^{II} systems with another catechols,[6] a mixed valence V^{II}/V^{III} complex is not formed, and all initial V^{II} is oxidized to the mononuclear V^{III} complex containing three ligands. An X-ray analysis of this type of complex, e.g. $K_3[V^{III}(cat)_3]$, showed that six O atoms of three catechol (cat) molecules are arranged octahedrally around the metal center.[7] In the case of dbcat, the coordination of the third ligand is hindered sterically, and it is possible that structure of the isolated V^{II} complex is not substantially different from that of the initial V^{II} complex that reduces molecular nitrogen.

Experimental Procedure

N_2 reduction and H_2 evolution kinetics have been performed as previously described [2d]. VCl_2 was synthesized by dissolving vanadium metal in hydrogen chloride under argon. The mixed valence V^{II}/V^{III} complex **1** was crystallized from the solution containing VCl_2 (3×10^{-4} mol), dbcat (1.5×10^{-3} mol), and $NaOCH_3$ (4×10^{-3} mol) in 10 mL of methanol. Thirty to forty hours are required for the formation of proper crystals from the initial reaction mixture (yield about 10–15% of total vanadium). The crystals dissolve easily in methanol. The concentration of V^{II} in the solution has been determined by titration with $(NH_4)_2Fe(SO_4)_2$ in sulfuric acid in the presence of safranine T. The total V concentration has been determined by atomic absorption analysis.

The First Neutral Adamantanoid Iron(III)–chelate Complex: Spontaneous Formation, Structure, and Electrochemistry**

By *Rolf W. Saalfrank,* Bernd Hörner, Dietmar Stalke,* and *Josef Salbeck*

One of the most interesting new aspects of synthetic chemistry is endohedral chemistry, that is, the chemistry inside cages.[2] Consequently it is necessary to be able easily to build up intramolecular cavities with variable diameters.

On treatment of dimethyl malonate with methylmagnesium iodide or methyllithium/metal(II) chloride and oxalyl chloride at −78 °C in tetrahydrofuran and subsequent workup with aqueous ammonium chloride, we obtained, by spontaneous self-assembly,[1, 3, 4] the tetranuclear chelate complexes **1a** (M^{2+} = Mg, Mn, Co, Ni, Zn).[1, 5]

The doubly bidentate bridging ligand L^1 is formally obtained by the template coupling of two dimethyl malonate monoanions with oxalyl chloride to form tetramethyl 2,3-dihydroxy-1,3-butadiene-1,1,4,4-tetracarboxylate followed by subsequent spontaneous double deprotonation.

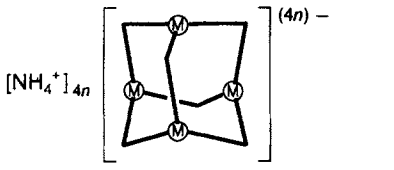
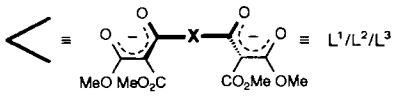
[**] "Adamantanoid" Chelate Complexes, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. B. H. thanks the Freistaat Bayern for a post-graduate fellowship; J. S. thanks Prof. Dr. J. Daub, University of Regensburg, for supporting his research. We are grateful to Priv.-Doz. Dr. H. U. Hummel, University of Erlangen-Nürnberg, for advice and Prof. Dr. R. Glaser, Ben-Gurion University of the Negev, Beersheva, Israel for stimulating discussions. We thank Prof. Dr. F. Vögtle and Dr. S. Schuth, University of Bonn, for recording the FAB-MS spectrum, Prof. Dr. A. X. Trautwein, Dr. E. Bill and C. Butzlaff (Dipl.-Phys.), Medizinische Universität zu Lübeck, for the recording of a Mössbauer spectrum, as well as magnetic measurements.—Part 2: [1].

We were convinced that the size of the cavity of the tetrametallate(4−) ions **1a** could be tailored with suitable spacers. In place of the anions **1a**, it should also be possible to obtain *neutral* tetranuclear metal–chelate complexes by using M^{3+}, instead of M^{2+}, ions.





1a: Ⓜ ≡ M^{2+}, $n = 1$, L^1:X = —

1b: Ⓜ ≡ Fe^{3+}, $n = 0$, L^1:X = —

1c: Ⓜ ≡ Fe^{3+}, $n = 0$, L^2:X =

1d: Ⓜ ≡ Fe^{3+}, $n = 0$, L^3:X =

Consequently we doubly deprotonated tetramethyl 2,2'-terephthaloyldimalonate[6] with sodium hydride at 20 °C. We then treated the resulting dianion L^2 with an iron(III) chloride solution and obtained ruby-red crystals upon workup. According to elemental analysis and FAB-MS data (FAB = Fast Atom Bombardment) the compound, of composition $Fe_4L_6^2$, is the tetranuclear iron(III) chelate complex **1c** (for details see [8]).

The ^1H and ^{13}C NMR spectra of $Fe_4L_6^2$ (**1c**) do not unambiguously establish the structure of this compound. Thus an X-ray crystallographic structure analysis of this complex was carried out.[9] According to this analysis, **1c** crystallizes as a neutral, adamantanoid, tetranuclear iron(III) chelate complex (Fig. 1)—the first of its kind.[12] The nucleus of the complex forms an almost ideal tetrahedron, with an Fe(III) ion in each of the corners. The six edges of the tetrahedron are each formed by the doubly bidentate, doubly negatively charged, bridging ligands L^2 (distances between facing phenyl centers approximately 10 Å). Six oxygen atoms surround each of the four Fe^{III} ions in an octahedral arrangement (Fig. 2).[13]

Two enantiomeric pairs [(*Δ*)-, (*Λ*)-*fac*, and (*Δ*)-, (*Λ*)-*mer*] are principally possible for octahedral complexes of the type MA_3B_3 [with bidentate ligands $M(AB)_3$].[14] The $Fe_4L_6^2$ complex has an exact S_4 symmetry in the crystal and is thus achiral (*meso* form). This means that the ligands L^2 around the four iron centers in **1c** are arranged facially and that two of the four iron centers have the same configuration [(*Δ*, *Δ*)-/(*Λ*, *Λ*)-*fac*]. This is in contrast to the chiral, racemic, *T*-symmetrical complexes **1a**, in which all four metal centers (M^{2+} = Mg, Mn, Co, Ni, Zn) are identically coordinated [(*Δ*, *Δ*, *Δ*, *Δ*)-*fac* or (*Λ*, *Λ*, *Λ*, *Λ*)-*fac*].[1, 5]

The cyclic voltammogram under aprotic conditions[15] shows the reduction of the $Fe_4L_6^2$ complex **1c** as a quasi-reversible signal pair centered at −550 mV (Fig. 3, left). The peak potential difference ΔE_p at a scan rate of 250 mVs^{-1} is 170 mV; the reduction peak is slightly broadened ($E_p - E_{p/2}$ = 135 mV), but shows no further splitting.[16] In thin-layer voltammetry, at a layer thickness of 15 μm and a scan rate of 10 mVs^{-1}, the reduction is also seen as a quasi-reversible signal pair with a peak potential difference of 60 mV. The half-peak widths are also broader ($\Delta E_{p/2}$ = 220 mV for the reduction, 170 mV for the reoxidation), but the signals show no further structure. Thin-layer coulometry shows that four electrons are transferred under every signal, whereas a multi-

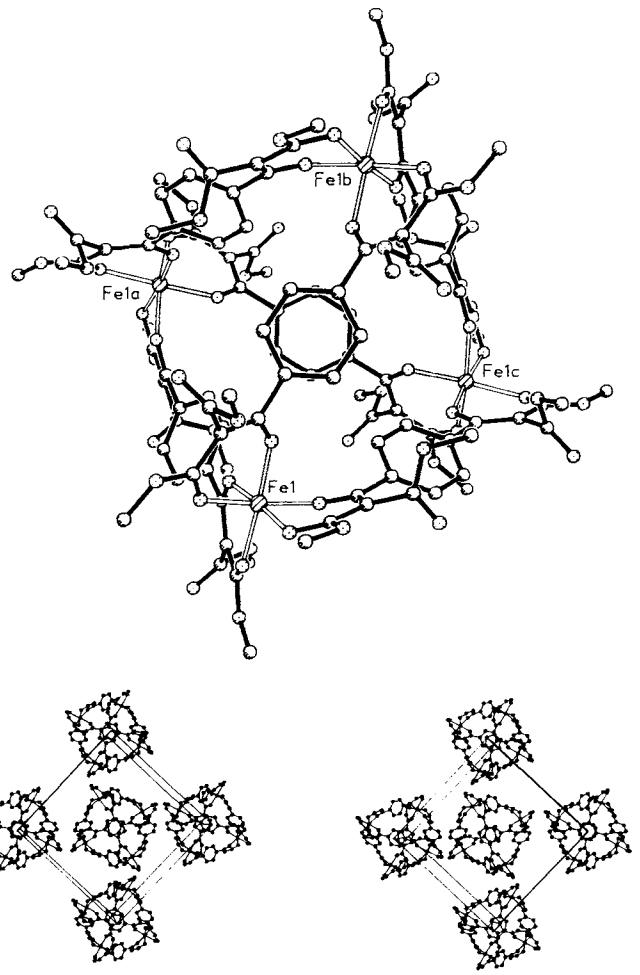


Fig. 1. Top: Crystal structure of **1c** (view along the crystallographic S_4 axis; H atoms omitted; C atoms white; O atoms dotted). Bottom: Stereoview of the crystal packing of **1c** (view along the crystallographic S_4 axis; for reasons of clarity the methoxy and methoxycarbonyl groups as well as the solvents of crystallization $C_4H_{10}O$, C_3H_6O, and H_2O have been omitted).

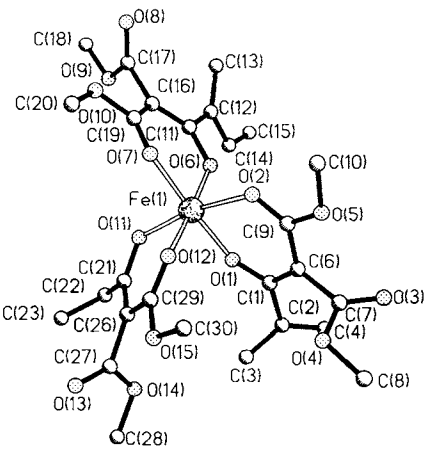

Fig. 2. Coordination sphere of a Fe^{3+} ion in **1c**. Selected distances [Å] and angles [°]: Fe(1)-O(1) 1.946(4), Fe(1)-O(2) 2.039(4), Fe(1)-O(6) 1.926(4), Fe(1)-O(7) 2.016(4), Fe(1)-O(11) 1.950(4), Fe(1)-O(12) 2.043(4), Fe(1)···Fe(1a) 10.028, Fe(1)···Fe(1b) 10.375; O(1)-Fe(1)-O(2) 85.66(15), O(6)-Fe(1)-O(7) 85.7(2), O(11)-Fe(1)-O(12) 85.0(2).

sweep experiment shows the complete chemical reversibility of the redox process. This reversibility is confirmed by spectroelectrochemical as well as voltabsorptometric measurements. Following the reduction spectroelectrochemically gives continually changing absorption signals, but no recognizable intermediates for a partially reduced complex are observed. It is conspicuous that the longest wave absorption signal of **1c** at 450 nm does not completely disappear, but only reduces in intensity to a quarter of its extinction. Also, no further absorptions at long wavelengths for mixed-valent species occur (Fig. 3, right). In the UV region the spectral changes are analogous. Thus no, or only very weak, electronic interactions ("metalloautism") exist between the iron centers in **1c**. The redox process is therefore formally a one-potential four-electron transfer.[17, 20]

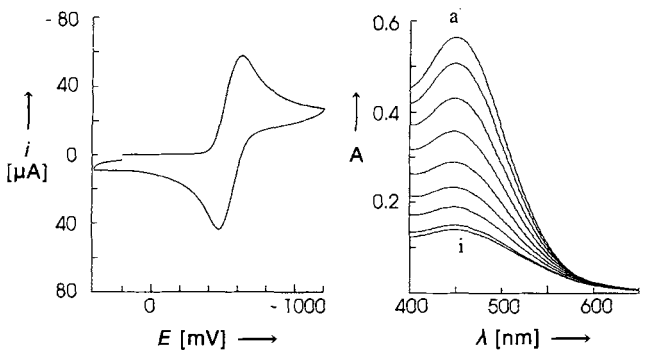

Fig. 3. Left: Cyclic voltammogram of **1c** in a 0.1 M solution of tetraethylammonium tetrafluoroborate in acetonitrile, $c = 10^{-3}$ M, scan speed 250 mVs^{-1}. Potentials vs. ferrocene/ferrocenium (Fc/Fc^+). Right: Spectroelectrogram of **1c** in solution of 0.1 M tetrabutylammonium hexafluorophosphate in acetonitrile. Potentials (a–i): −300, −400, −500, −550, −600, −700, −750, −800 (vs. Fc/Fc^+).

Furthermore Mössbauer and magnetic measurements are in agreement with the results of the electrochemical studies on **1c**. The Mössbauer spectrum shows a signal broadened by relaxation with an isomeric shift δ at 293 K of 0.6 mm s^{-1}. Magnetic measurements (SQUID-susceptometer, temperature range 10–300 K) give a temperature-independent value of 11.55 μ_B for the effective magnetic moment μ_{eff}.[24] This result agrees well with the calculated value of the magnetic moment ($\mu_{calc} = 11.83\ \mu_B$) for four magnetically isolated high-spin iron(III) centers that show no interactive phenomena in the investigated temperature range.[25]

We shall report elsewhere on the simple iron(III) chelate complex **1b** and the iron(III) chelate complex **1d** with biphenyl as spacer.

[16] The peak potential difference ΔE_p of 170 mV, and also the peak width $E_p - E_{p/2}$ of 135 mV, stay essentially constant with variation of the scan speed in the region 50–250 mV^{-1}. In the region 50–250 mV the ratio of peak current i_p and the square root of the scan rate are constant. The use of tetrabutylammonium hexafluorophosphate as conducting salt leads to considerably larger values: $\Delta E_p = 300$ mV, $E_p - E_{p/2} = 299$ mV at 250 mVs^{-1}.

[17] A random number of noninteracting identical redox centers in a molecule should show a current potential behavior with the same characteristics as a reversible one-electron transfer (e.g. $\Delta E_p = 58$ mV). This is only valid, however, when the redox centers show *Nernstian behavior* [18]. In the case of a partial diffusion control, signal broadening occurs. Signal forms comparable to ours result from the simulation of cyclic voltammograms for a

formal two-electron transfer under similar conditions for the rate constants of the charge transfers [19].

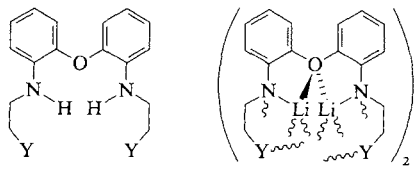
Dilithiation of Two Diphenyl Ethers Each Containing Two $NHCH_2CH_2Y$ (Y = OMe, NMe_2) Side Arms in *ortho* Positions: Assembly of "Adamantanoid" $Li_4O_2N_4$ Cores**

By *Ian Cragg-Hine, Matthew G. Davidson,* Oldrich Kocian, Francis S. Mair, Ehmke Pohl, Paul R. Raithby, Ronald Snaith, Neil Spencer*, and *J. Fraser Stoddart**

Lithium amides are important synthetic organic reagents, and consequently much work has been done in order to elucidate their structures both in solution and in the solid state.[1, 2] Until recently however, the structures of only simple monolithiated complexes of secondary amines were known. To our knowledge only two dilithiated amide complexes exist. Recently we published the results of dilithiating naphthylamine, providing the first example of a dilithiated primary amine; it is a Li_{20} species held together by $(NaphN)^{2-}$ anions (Naph = naphtyl) and ether ligands.[3] We have also obtained the structure of a dilithiated diamine $(PhLiNCH_2CH_2NLiPh) \cdot 3\,HMPA$[4] (HMPA = hexamethylphosphoric triamide), containing the commonly observed[2] Li_2N_2 core. Such a core also featured in the first lithiated diazacrown.[5] We now report on the dilithiation of two diamines, 2,2′-bis(2-methoxyethylamino)diphenyl ether (**1**) and 2,2′-bis(*N*,*N*-dimethylethylenediamino)diphenyl ether (**2**), which give the lithium amides **3** and **4**, respectively.



1, Y = OMe
2, Y = NMe_2

3, Y = OMe
4, Y = NMe_2

The possibility of intramolecular coordination, coupled with the increased flexibility of **1** and **2** over the cyclic crown ethers suggested that the use of an additional Lewis base donor such as $(C_2H_5)_2O$ or HMPA would be unnecessary. Indeed, dilithiation of the diamines **1** and **2** and the subsequent crystallization of products **3** and **4** from toluene solution was achieved in the absence of a Lewis base donor.

The X-ray crystal structure analyses[6] of diamines **3** and **4** exhibit an adamantanoid metal-containing core, a structural motif that is unprecedented in the chemistry of Group I metal complexes (Fig. 1 and 2).[7, 8]

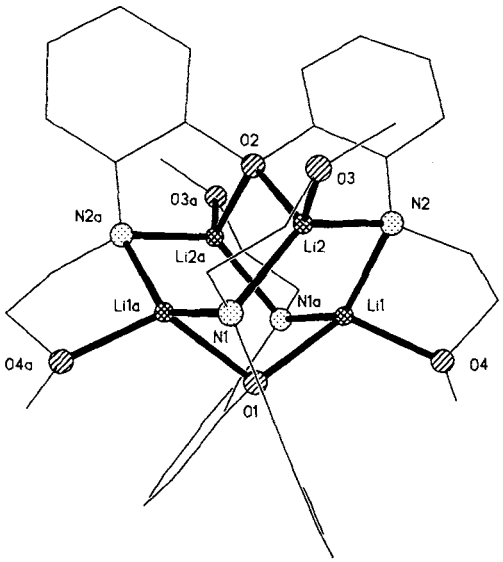


Fig. 1. Molecular structure of **3** (for clarity, the carbon framework is not shown in detail and hydrogen atoms have been omitted).

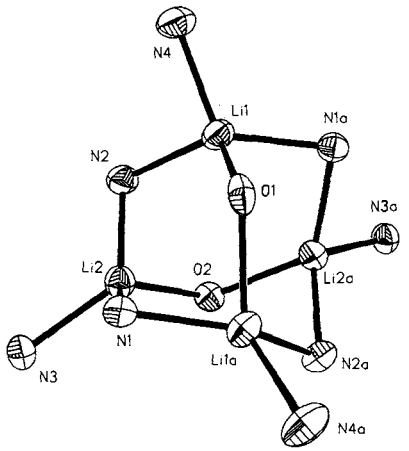

Fig. 2. Adamantanoid $Li_4O_2N_8$ central core of **4** (thermal ellipsoids at the 50% probability level).

Sheldrick and Dr. D. Stalke (University of Göttingen) for the use of X-ray facilities for the determination of the structure of **3**.

Formation of an Li_2N_2 ring within a monomeric dilithiated diamine (perhaps with additional coordination between the Li ions and the O and Y centers) was not observed. Molecular models show that such an arrangement would be highly strained. Considering structure 3 (Fig. 1) and firstly just one monomeric unit within it reveals that N1a–H has been deprotonated by Li1 and N1–H by Li1a. These two lithium centers are then both coordinated by the diaryl ether linkage (Li1–O1 and Li1a–O1). This is the first observation of this bonding mode for Ar–O–Ar (Ar = aryl) with lithium.[2, 9] The OMe groups of the side arms cannot satisfactorily act as intramolecular Lewis base donors so it is at this stage that the complex dimerizes spontaneously. The monomeric units containing (as yet) two two-coordinate lithium ions and two noncoordinating side arms slot together almost orthogonally, and each deprotonated amide N atom forms an intermolecular μ_2-bridge (Li1–N2, Li1a–N2a, Li2–N1, and Li2a–N1a), thus forming the adamantanoid core. Such an arrangement now allows the side arms of each monomer to coordinate to the lithium ions and complete their coordination spheres. In **4**, precisely the same intra- and intermonomer coordinations operate, save that the side arms are now Me_2 groups (Fig. 2). In retrospect, for both **3** and **4**, such an arrangement, although unpredicted, appears (as shown by space-filling molecular models) to be ideal. The two monomer units have been clamped together by the tendency of the lithium atoms to attain their favored fourfold coordination without inducing steric strain on the organic framework.

The conceptual view of this dimerization as self-recognition of two monomers is lent credence by considering the bond lengths within the cores of the solid-state structures (Fig. 3). The bonds within one monomeric unit are highlighted in boldface. In **3** the averaged[10] amide N–Li bonds within a monomeric unit are shorter (196 pm) than the amide N–Li bonds between monomers (203 pm). The Li–O linkages between Li atoms of one monomer and the OMe groups of the other are considerably shorter (192 pm) than the intramonomer one involving the O atom of the Ar–O–Ar unit (207 pm). This is significant as it is these intermolecular Li–OMe interactions that clamp the two monomers together. Furthermore, of all the interactions with Li of electronegative centers only these Li–Y ones are terminal; all others involve *bridging* of two Li atoms. In **4** where $Y = NMe_2$, however, these side-arm interactions are no longer the shortest bonds (Fig. 3).

	A	B	C	D
3 [Y=OMe]	196	203	207	192
4 [Y=NMe_2]	199	206	212	211

Fig. 3. The core of complexes **3** and **4** showing average intramolecular (A and C) and intermolecular (B and D) bond lengths in pm [10]. Bonds and atoms of one monomeric unit are in boldface.

This subtle difference in the binding between monomeric units in **3** and **4** is reflected in the solution studies. The room-temperature ^1H NMR of **3** in C_6D_6 shows an ABCD coupling pattern for the pair of methylene groups on the side arm of the ligand that is consistent with the persistence of the solid-state structure in solution. Cryoscopy in benzene also indicates that the dimer remains intact in solution [$n = 1.97 \pm 0.06$ for a 0.025 M solution (concentration expressed in terms of monomer)]. In **4**, the room-temperature solution behavior indicates a less rigid structure, consistent with the looser solid-state binding.

Further differences in behavior are to be expected with variation of metal size, metal valency, and identity of bridging and terminal functionalities. Such variations are being investigated.

Experimental Procedure

For **1**, bis(2-aminophenyl) ether, readily available from reduction of bis(2-nitrophenyl) ether [11] with hydrazine hydrate in the presence of 10% Pd on carbon, was converted into a bis(methoxyacetamide) by reaction with methoxyacetyl chloride. This amide was then reduced with $LiAlH_4$ in boiling THF to give the diamine **1** as a yellow oil, which crystallized on standing. Yield 90%, m.p. 42–43 °C. Satisfactory C,H, and N analyses. ^1H NMR (300 MHz, $CDCl_3$, 293 K, TMS): $\delta = 3.34$ (s, 6H, OCH_3), 3.34 (t, 4H, $J = 5.5$ Hz, CH_2), 3.59 (t, 4H, $J = 5.5$ Hz, CH_2), 4.58 (bs, 2H, NH), 6.56–6.64 (m, 2H, ArH), 6.71–6.78 (m, 4H, ArH), 6.96–7.07 (m, 2H, ArH). ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 144.06, 139.90, 124.21, 117.68, 116.92, 111.38, 71.11, 58.79, 43.38$. MS(CI): m/z 317 ($M + H^+$, 100%), 259(43), 201(14), 186(12), 166(13), 152(32), 132(18), 120(26), 110(35) 94(50), 76(47), 59(18), 44(28).

For **2**, bis(2-aminophenyl) ether was converted into a bis(chloroacetamide) by reaction with chloroacetyl chloride. This was then treated with 40% aqueous $(CH_3)_2NH$ to form the corresponding bis(N,N-dimethylacetamide). Reduction of this, again with $LiAlH_4$, gave the diamine **2** as a yellow oil. Yield 89%. Satisfactory C,H, and N analyses. ^1H NMR (300 MHz, $CDCl_3$, 293 K, TMS): $\delta = 2.20$ (s, 12 H, CH_3), 2.53 (t, 4H, $J = 6$ Hz, CH_2), 3.21 (q, 4H, $J = 5.5$ Hz, CH_2), 4.70 (t, 2H, $J = 5$ Hz, NH), 6.59 (dt, 2H, $J = 8$ Hz, $J = 1.5$ Hz, ArH), 6.73 (dt, 4 H, $J = 8$ Hz, $J = 1.5$ Hz, ArH), 6.99 (dt, 2H $J = 8$ Hz, $J = 1.5$ Hz, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) $\delta = 143.94, 140.12, 124.14, 117.53, 116.52, 111.28, 58.18, 45.31, 41.37$. MS(CI): m/z 343 ($M + H^+$, 100%) 298(5), 272(20), 181(10), 165(10), 110(16), 94(18), 72(50), 58(84), 46(25).

3: *n*-Buthyllithium (4.0 mmol, 2.5 mL of a 1.6 M hexane solution) was added to a chilled solution (0 °C) of **1** (0.632 g, 2.0 mmol) in dry toluene (8 mL) under nitrogen. The product, a white precipitate, was warmed into solution (60 °C). A crop of colorless crystals was deposited after standing at room temperature overnight (0.322 g, 49%); m.p. > 300 °C, satisfactory C, H, and N analyses. ^1H NMR (250 MHz, C_6D_6, 293 K, TMS): $\delta = 2.77$ (s, 3H, OMe) 2.80, 2.92, 3.28, 3.45 (D,C,B and A, respectively, of an ABCD system; see above for labels; 4×1 H, $^2J_{AB} = 7$ Hz, $^3J_{AC} = 17$ Hz, $^3J_{AD} = 16$ Hz, $^3J_{BC} = 28$ Hz, $^3J_{BD} = 7$ Hz, $^2J_{CD} = 7$ Hz), 6.45 (t of d, 1 H, aryl H *meta* to amide), 6.67 (dd, 1 H, aryl H *ortho* to amide), 7.10–7.2 (m, 2H, other arene-H). Assignments were by a combination of coalesence behavior, selective decoupling, and COSY experiments and were confirmed by a NMR simulation program.

4: As for **3**, **2** (0.684 g, 2.0 mmol) was lithiated (4.0 mmol, 2.5 mL of 1.6 M *n*-butyllithium in hexane) to produce crystals of **4** (0.361 g, 51%); m.p. 230–233 °C, satisfactory C,H, and N analyses. ^1H NMR (250 MHz, C_6D_6, 293 K, TMS): $\delta = 1.70$ (s, 6H, Me_2N), 2.24, 2.89 (br.s, 2×2H, CH_2CH_2), 6.23 (t of d, 1H, aryl *meta* to amide), 6.48 (dd, 1H, aryl *ortho* to amide), 6.95 (t of d, 1H, aryl *meta* to ether), 7.14 (dd, 1H, aryl *ortho* to ether).

Polymeric Hemiporphyrazines, a New Class of Rodlike Macromolecules Suitable for the Langmuir–Blodgett Technique

By *Andreas Ferencz, Roland Ries*, and *Gerhard Wegner**

Macromolecules composed of stacks of macrocyclic repeat units have received considerable attention as building blocks of supramolecular architectures.[1–7] Such rodlike macromolecules are frequently insoluble as a consequence of inherent chain-stiffness. Attachment of flexible, short side chains to the perimeter of the macrocyclic subunits makes these macromolecules soluble in ordinary organic solvents, thus allowing their processing. Macromolecules of this type are called "hairy rods". They can be spread at the air–water interface of a Langmuir trough, if the overall geometry of the macromolecules and the structure of the side chains are suitably chosen. The side-chain segments may be considered as bound solvent that helps in the formation of the monomolecular layers on the Langmuir trough, which are subsequently transferred layer by layer to planar substrates by the Langmuir–Blodgett (LB) technique. The rheological features linked to the transfer process lead to a preferential alignment of the macromolecules with their long axes in the direction of transfer. The main-chain orientation thus produced is fixed during the course of the transfer. Therefore, a highly ordered and anisotropic layered structure is achieved in which all macromolecules are aligned parallel with their director axes in the plane of the substrate pointing in the dipping direction.

This correlation of geometry and chemical structure of the macromolecules with ordering phenomena, and thus the possibility to create novel supramolecular architectures, was first exemplified with alkoxy-substituted phthalocyaninato-poly(siloxane)s **1a**.[8] It has since been extended to a variety of chemically quite different, but topologically related systems.[9, 10] Among these are helical poly(peptide)s, for example, poly(alkyl L-glutamate)s, cellulose ethers, poly(silane)s with sterically demanding substituents, and poly(2,5-dialkoxy-2,4-phenylene)s. The prominent feature common to all of these types of molecules is the cladding of the stiff backbone with flexible side chains that results in ideal or nearly ideal cylindrical symmetry. The consequence of this topological structure is the densest hexagonal packing of the molecules in the layered structure yet observed experimentally by X-ray techniques in many cases. However, polarization of the side-chain segments ("hairs") at the air–water interface of the Langmuir trough gives rise initially to double layers in the course of the transfer, which relax into the dense hexagonal packing after a short annealing of the samples.

These results triggered the question whether other fundamental geometries of molecularly defined objects exist that could produce supramolecular architectures with different packing symmetries. Stimulated by the very interesting optical and electrical properties of the systems obtained from stacked macromolecules (the phthalocyaninatopoly(siloxane) **1a** (PcPS) being a good example), hemiporphyrazinatopoly(germanoxane) (hpPG, **1b**) was selected as a target (Fig. 1). Macromolecules of this type should be shaped like a square box and therefore exhibit a completely different packing in the solid state, which is enhanced by the substitution pattern of the alkoxy side chains.

The synthesis of **1b** starts from 2,6-diaminopyridine, which is treated with dialkoxy-substituted isoindoline to give the hemiporphyrazine hpH_2.[11] The latter reacts with germanium tetrachloride in quinoline to give the hemiporphyrazinato-dichlorogermane, the monomer of the subsequent polycondensation.[12–14] This is achieved in di-2-methoxyethyl ether with the addition of stoichiometric amounts of tetra(acetonitrilo)copper(I) trifluoromethanesulfonate in analogy to the preparation of PcPS. In the case of dimethoxydioctyloxy-hemiporphyrazinatopoly(germanoxane) ($hpPGC_1C_8$), the polymer precipitates as a brownish solid when the reaction medium is cooled from 140 °C to room temperature. The polymer is completely soluble in chloroform or THF. The degree of polymerization P_n, determined by HPLC, shows a broad distribution; the fraction of highest molecular mass has a degree of polymerization of 12. Solutions of the polymer in chloroform show broad absorption bands in the UV/VIS spectra, the exact spectral location and extinction depending on P_n. The unfractionated polymer **1b** ($hpPGC_1C_8$, R_1 = methyl, R_2 = *n*-octyl) exhibits these bands at $\lambda \approx 280$, 340, and 390 nm. The polymer is actually a copolymer composed of two monomer units that are positional isomers. The monomers were not separated into the isomers, because previous investigations on the spreading and ordering behavior of "hairy-rod" systems had shown that the creation of supramolecular architectures by the LB

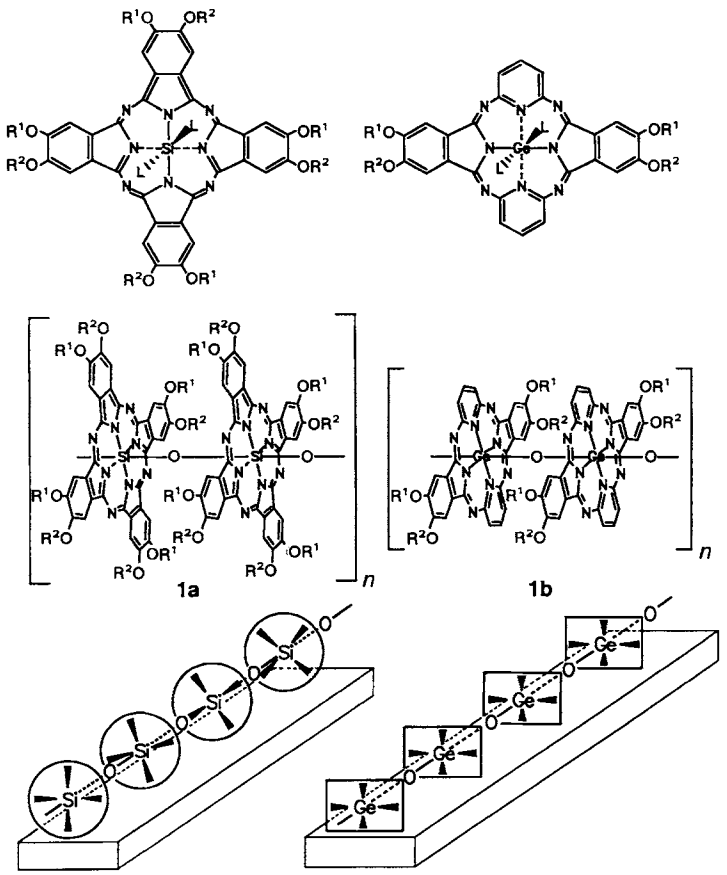

Fig. 1. Structure of surface-active derivatives of phthalocyaninatopoly(siloxane)s (**1a**) and hemiporphyrazinatopoly(germanoxane)s (**1b**) for comparison. Top: monomers, L = Cl; middle: section of the polymer chain; bottom: position of the macromolecules relative to the substrate plane in the Langmuir–Blodgett layers. $R^1 = OCH_3$; $R^2 = OC_8H_{17}$ (in reality, mixtures of the positional isomers are used).

technique is substantially enhanced if ordering phenomena in the side-chain region of the macromolecules are suppressed by introducing positionally isomeric repeat units.

The unfractionated polymer hpPGC$_1$C$_8$ (that is a mixture of homologues with approximately normal distribution of chain lengths) can be spread at the surface of a Langmuir trough from a dilute solution in chloroform. A monomolecular film is thus obtained, the force–area diagram of which is very similar to those reported for PcPS (20 °C, pure water subphase). The films collapse at a surface pressure $\pi > 30\ mN\,m^{-1}$; the area per monomer unit is calculated to be 1.00 nm^2. Transfer to hydrophobic substrates is straightforward and is carried out at $\pi = 20\ mN\,m^{-1}$ (20 °C) and a transfer speed of about $1\ cm\,min^{-1}$. The transfer ratio is unity and remains constant even after more then 100 layers have been transferred to the same substrate. A dependence of the spreading and transfer properties on the degree of polymerization has not been found in our investigations.

The measurements that serve to characterize the structure of the layered assemblies have been performed on samples of 20–30 monolayers each. The UV/VIS spectra demonstrate dichroic behavior of the samples if recorded with polarized light. The absorption is always larger for light polarized normal to the dipping direction. The films are birefringent—as expected—with $n_{\parallel}$ (parallel to the dipping direction) $< n_{\perp}$ (normal to dipping direction). The dichroism is particularly strong in the IR region of the spectrum. The dichroic ratio of certain vibrational bands in the region of 860–710 cm^{-1} reaches a value $D = A_{\parallel}/A_{\perp} = 7$ even for fresh samples.[15] The reverse behavior is seen for the bands associated with ring vibrations around 1600 cm^{-1}. However, in the region of the valence bands of the side-chain segments at 2800–3000 cm^{-1}, no dichroism is observed. Consequently, the bond directions and groups associated with the side chains must be isotropically distributed as in a liquid. Grazing-incidence-reflection (GIR) spectroscopy allows further characterization of the IR-active groups with regard to their orientation normal to the substrate plane.[16]

In this mode all bands that have an associated dipole transition moment containing a component in the direction of the polymer backbone are very small, and the bands of the alkoxy side chains have the identical intensity distribution as in the transmission spectra, but substantial changes become obvious in the intensity pattern of the ring vibrations. This points toward a double orientation of the macromolecules within the substrate plane with regard to their main axes and leads to the speculation that consecutive macrocycles are threaded onto the Ge-O-Ge-O main chain in an eclipsed fashion. Further evidence comes from the X-ray powder diagram of the freeze-dried samples. It shows three peaks, the corresponding Bragg distances of which are $d = 2.80$, 1.32, and 0.35 nm. These values correspond to the width and height of the constitutional units and the periodicity of the repeat (0.35 nm) predicted by molecular models. The product of molecular width (2.80 nm) and periodicity (0.35 nm) gives the value of the base area (0.98 nm^2), in excellent agreement with the value of 1.00 nm^2 determined from the force–area isotherms.

An important question is the following: how are the molecules arranged within the LB layers relative to the substrate plane—flat, edge-on, like tiles on a roof, or disordered? X-ray investigations at grazing incidence of the beam serve to answer the question. The corresponding diagram obtained from a multilayer sample (30 monolayers) on a silicon substrate is shown in Figure 2. A series of Kiessig

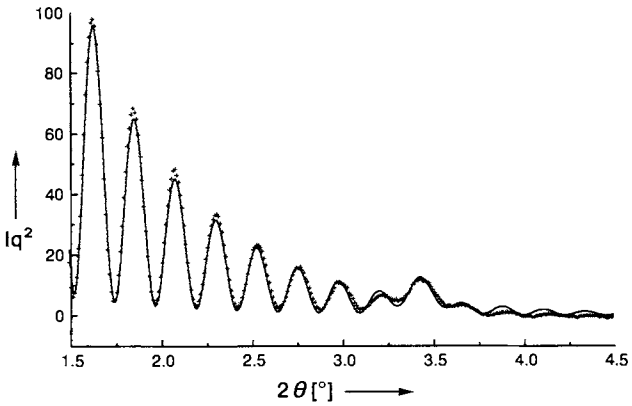

Fig. 2. X-ray diffractogram (at grazing incidence) of 30 monolayers of hpPGC$_1$C$_8$ (**1b**) deposited onto a silicon wafer. The coordinates are diffracted intensity $I\cdot$ (momentum transfer $q = 2\sin\theta/\lambda)^2$ and glancing angle θ; (+) measured data, (−) data calculated according to [19].

fringes is seen, which indicates an excellent quality of the film (homogeneity, lack of surface defects). The surface roughness is ±50 pm. The total thickness of the film is readily calculated from the angular distance between consecutive minima; a value of $D = 38.85$ nm is obtained. The periodicity of the layers is calculated as $d = 2.59$ nm from the position of the weak Bragg peak. These data demonstrate

the presence of double layers (since $(30/2) \times 2.59\ \text{nm} = 38.85\ \text{nm}$) and that the molecules lie flat within the layers ($2.59\ \text{nm}/2 \approx 1.30\ \text{nm}$).

Further proof of these findings comes from the results of electron diffraction on 20-monolayer films that were transferred directly to a carbon film-coated microscopic grid. The diffraction pattern found at normal incidence of the electron beam shows a crescent-shaped reflection on the meridian ($d = 0.35$ nm) and a strong reflection on the equator at $d = 2.87$ nm. A reflection corresponding to a d value of 1.30 nm is not observed. This corroborates the model in which the molecules are pictured as extended, rectangular boxes lying flat within the layers. The lateral interaction between the molecules contained in the individual layers occurs through the alkoxy side chains, which serve as a "glue". This type of packing of the macromolecules is sketched schematically in Figure 3.

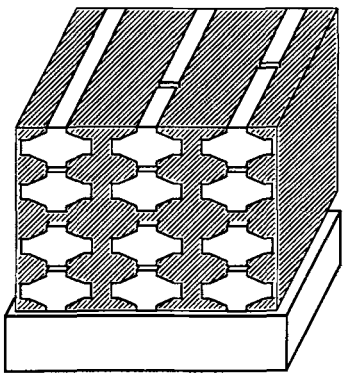

Fig. 3. Sketch of the supramolecular architecture of LB multilayers obtained from hpPGC$_1$C$_8$ (**1b**); the volume filled by the side-chain moieties (C$_1$ and C$_8$) is hatched.

The discrepancy in the Bragg values of the lateral reflections in X-ray and electron diffraction is—most probably—caused by small variations in the packing density, which depend to some extent on preparation and annealing conditions. The effect has been known quite well from previous investigations on PcPS.[9]

The quality of the mutual correlation of the layers can be deduced from the changes in intensity of the 2.87 nm reflection when the sample is rotated around the direction of the long axes of the macromolecules. The correlation length amounts to approximately 4 layers; that is, consecutive layers are in register.

A few experiments in combination with PcPS serve to indicate the usefulness of hpPG: it is not only possible to prepare alternating double layers of high quality, but one can also co-spread PcPS and hpPG (c(PcPS): c(hpPG) = 1:2); the force area diagram of this mixture shows only one step (collapse pressure at 30 mNm^{-1}), the area required of PcPS and hpPG is additive, and the transfer ratio ($\pi \approx 20$ mNm^{-1}, 20 °C, 1 cm min^{-1}) amounts to unity. The LB film obtained shows Kiessig fringes at grazing incidence diffraction, although the reduced intensity indicates a certain roughness of the film, which may be induced by the differences in thickness of the constituent macromolecules. The polymer hpPG seems to lie predominantly flat in these films, since the intensity pattern in the GIR spectra remains identical to the pure substance.

Experimental Procedure

Solvents were obtained from Fluka or Aldrich and were used as received except where stated otherwise. Dialkoxydiiminoisoindoline and tetra- (acetonitrilo)copper(I) trifluoromethanesulfonate were synthesized as described in references [8, 17, 18].

Dimethoxydioctyloxy-hemiporphyrazine, hpH$_2$ C$_1$, C$_8$: Freeze-dried 5-methoxy-6-octyloxy-1,3-diiminoiso-indoline (9.56 g, 31.5 mmol) and 2,6-diaminopyridine (3.44 g, 31.5 mmol) were dissolved in 80 g chloronaphthalene. The mixture was repeatedly degassed and stirred under nitrogen for 40 hours at 170 °C. To stop the reaction the mixture was cooled to about 50 °C and poured into 200 mL of *n*-hexane. The fine red or green-brown precipitate was washed with *n*-hexane and acetone. Repeated recrystallization from toluene gave the red product with a yield of approximately 15% (freeze-dried from benzene). IR(KBr): $\tilde{\nu}$[cm^{-1}] = 3445 m, 3070 vw, 2990 vw, 2920 m sh, 2870 m sh, 2850 m, 1660 s sh, 1655 s, 1605 w, 1585 m, 1545 m, 1495 s, 1465 m, 1455 m sh, 1435 w, 1350 s br, 1270 m, 1225 s, 1215 s sh, 1150 w, 1140 w, 1035 m, 860 w, 815 m, 760 w, 730 w, 710 w, 550 w br, 500 w br; ^{1}H NMR (CDCl$_3$, 300 MHz): δ = 10.21 (s, 2H, N-H), 7.68 (t, 2H, pyr-H), 7.38 (d, 4H, ind-H), 6.96 (d, 4H, pyr-H), 4.14 (t, 4H, CH$_2$), 3.99 (d, 6H, OCH$_3$), 1.90 (q, 4H, CH$_2$), 1.52–1.10 (m, 20H, CH$_2$), 0.87 (t, 6H, CH$_3$); UV/VIS: λ_{max} [nm] = 266, 306, 344 sh, 358, 376 sh.

Dimethoxydioctyloxy-hemiporphyrazinatogermanium dichloride, GehpCl$_2$ C$_1$,C$_8$: Freeze-dried hpH$_2$ (C$_1$,C$_8$) (1.8 g, 2.38 mmol) and freshly distilled quinoline (7 mL) were mixed under nitrogen and degassed. After addition of GeCl$_4$ (0.51 mL, 4.47 mmol) by syringe through a septum, the mixture was heated as fast as possible with an oil bath preheated to 170 °C. After about 8 minutes when the color changed to green-blue, the reaction was stopped by pouring the reaction mixture into 150 mL of methanol. The greenish-blue precipitate was rinsed with methanol and acetone, dissolved in chloroform (red-violet solution), and after evaporation of the solvent, freeze-dried from benzene (yield approximately 75%). For further purification column-filtration through neutral Al$_2$O$_3$ with chloroform/methanol (99:1) as eluent is possible. IR(KBr): $\tilde{\nu}$[cm^{-1}] = 3430 m br, 2950 m sh, 2920 m, 2870 m sh, 2850 m, 1670 m, 1620 s, 1580 s, 1550 m, 1495 m, 1470 m, 1455 w sh, 1445 w, 1360 s, 1290 w, 1245 s, 1215 w, 1155 w br, 1055 m, 820 w, 770 vw, 725 w; ^{1}H NMR (CDCl$_3$:CD$_3$OD = 20:1, 300 MHz): δ = 7.44 (t, 2H, pyr-H), 7.15 (d, 4H, ind-H), 6.80 (d, 4H, pyr-H), 4.05 (t, 4H, CH$_2$), 3.89 (s, 6H, OCH$_3$), 1.84 (q, 4H, CH$_2$), 1.50–1.10 (m, 20H, CH$_2$), 0.87 (t, 6H, CH$_3$); UV/VIS: λ_{max} [nm] = 271, 353, 385, 407, 532 sh, 562, 622 sh.

Dimethoxydioctyloxy-hemiporphyrazinatopoly(germanoxane), hpPGC$_1$C$_8$: Freeze-dried GehpCl$_2$(C$_1$,C$_8$) (100 mg, 0.11 mmol) and tetra(acetonitrilo)-copper(I)trifluoromethanesulfonate (102 mg, 0.27 mmol) were combined in freshly distilled, dry di-2-methoxyethyl ether and degassed. The mixture was heated under nitrogen for 1–2 h to 140 °C. After cooling to room temperature it was poured into 50 mL of methanol. The deep brown precipitate was washed with methanol, dissolved in chloroform, and filtered through a Teflon membrane filter (pore-size 5 μm). Evaporating the solvent and freeze-drying from benzene gave the product in a yield of nearly 100%. HPLC (RP18 column, 12.8 cm length, 5 μm diameter, in methanol–THF gradient (0 to 100%)) results in sharply resolved peaks for trimers (first peak) to dodecamers (last peak). IR(KBr): $\tilde{\nu}$[cm^{-1}] = 2950 m sh, 2920 m, 2870 m sh, 2850 m, 1660 w, 1625 s, 1580 s, 1545 m, 1495 s, 1470 w sh, 1450 w, 1360 s, 1300 w, 1245 s, 1215 m, 1150 w br, 1070 s, 1030 w, 860 m br, 810 m, 770 vw, 715 m, 635 w; ^{1}H NMR (CDCl$_3$, 300 MHz): δ = 7.0–5.7 (m, br, ≈ 10H), 3.65 (s br, ≈ 10H), 1.78 (s br, ≈ 8H), 1.32 (m, ≈ 20H), 0.88 (s br, ≈ 6H); UV/VIS: λ_{max} [nm] = 276, 343, 387, 414 sh.

For the electron diffraction experiment, carbon films with a thickness of about 6 to 10 nm were applied to Ni electron-microscopy grids. These grids could be fastened to a Teflon-coated magnetic rod and used directly in the LB technique. The preparation of the other LB substrates and the characterization of the LB films used methods described elsewhere [9, 10].

lar extinction coefficient ($\varepsilon = 138000$) and appears bathochromically shifted by 74 nm relative to the longest wavelength band in the spectrum of **1b**.

Unambiguous structural proof for the cross-conjugated butatriene structure of **3a** was obtained by low-temperature X-ray analysis of crystals grown from acetone (Fig. 2).[10]

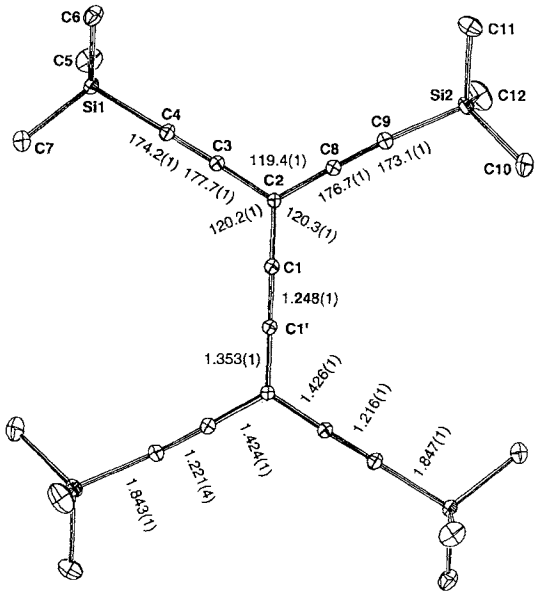

Fig. 2. X-ray crystal structure of **3a**. Vibrational ellipsoids are shown at the 50% probability level.

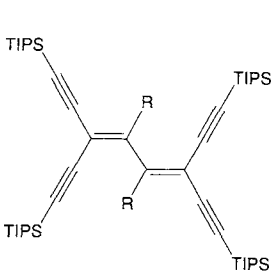
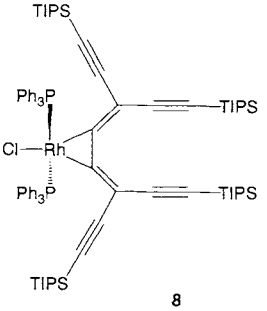
The chromophore in **3a** is nearly planar: the maximum deviation from the least-squares plane through the tetraethynyl[3]cumulene framework is 0.09 Å. Bond lengths and angles are within the range expected from previous X-ray data for tetraethynylethene[1,2] and butatriene derivatives.[11] All attempts to deprotect **3a** or **3b** without decomposition or polymerization have so far been unsuccessful.

In an attempt to prepare the [4]radialene **5**, we followed a procedure of West et al., who had dimerized "diquinoethylene, a cross-conjugated butatriene, to form a [4]radialene in the presence of triphenylphosphane, which presumably initiates the reaction by nuleophilic attack on the central cumulenic double bond.[7] When the tetraalkynylcumulene **3b** was treated for 12 h at 20 °C with an excess of PPh_3 in hexane, benzene, or CH_2Cl_2 solutions, no evidence for formation of the [4]radialene **5** was obtained but, instead, the 1,3-butadiene **7a** was isolated as a yellow oil in 78% yield.[9] In the ^1H NMR spectrum of **7a**, the olefinic protons appear at $\delta = 7.24$. The UV/VIS spectrum of **7a** (Fig. 1) is less structured than the spectrum of **1b** or **3b**, which is indicative of a less rigid chromophore, and the longest wavelength band of **7a** at $\lambda_{max} = 392$ nm appears at a position between the corresponding bands in **1b** and **3b**. In contrast to **1b** and **3b**, the cross-conjugated 1,3-butadiene **7a** is highly fluorescent, and the emission maxima are observed at $\lambda_{em} = 400$, 423, and 447 nm (Fig. 1, insert).

The specific and very mild reduction[12] of cumulene **3b**, initiated by attack of triphenylphosphane at the central double bond, yields a zwitterion, which is protonated at the vinylic carbanion center by traces of moisture.[13a] The resulting hydroxide ion subsequently reacts with the vinylic phosphonium ion by elimination of triphenylphosphane oxide and a second protonation to form **7a**. This mechanism is



7a R = H
7b R = D



8

supported by the observation that reduction of **3b** in the presence of D_2O affords exclusively the dideuterated butadiene **7b**. Previously, the reduction of double bonds with phosphanes had only been described for activated olefins HRC=CRH (R = CO_2Me, COPh),[13a] and for 7,7,8,8-tetracyanoquinomethane (TCNQ) and tetracyanoethylene (TCNE).[13b] We propose that facile reduction of **3b** occurs, since a) the two diethynylmethylene fragments with their sp carbon atoms exert an activating, electron-withdrawing effect on the central double bond, therefore facilitating the attack of PPh_3, and b) these fragments help to stabilize the resulting zwitterion through delocalization of the anionic charge.[14] Accordingly, 1,4-bis(pentamethylene)-1,2,3-butatriene[6] is not sufficiently activated to be reduced with PPh_3.

Rhodium(I) is known to form stable η^2 complexes with both butatrienes[15] and alkynes,[16] and we were interested to determine whether regioselective complexation occurs with **3b**, which features both types of π systems. When **3b** was treated at 20 °C with one equivalent of $[Rh(PPh_3)_3Cl]$ in CH_2Cl_2, complex **8** (m.p. 202–203 °C) was obtained in 57% yield as an orange-yellow solid.[9] In this conversion, butadiene **7a** was consistently isolated as a by-product in 40% yield, presumably due to the reaction of **3b** with the one equivalent of PPh_3 that is liberated during the formation of **8**. The ^1H NMR spectrum of **8** in $CDCl_3$ shows a complex pattern for protons of the TIPS group, presumably due to hindered rotation of these groups as a result of steric hindrance in the complex. The ^{13}C NMR spectrum shows two sets of acetylenic carbons at $\delta = 108.4$ and 104.3 (Si–*C*≡C) and at 93.6 and 92.7 (Si–C≡*C*), which is indicative of the symmetrical structure resulting from complexation at the central cumulenic bond. The two metallacyclic carbon atoms exhibit a multiplet at $\delta = 146.7$ due to coupling to both rhodium as well as phosphorous.

Unambiguous proof for the selective complexation at the central double bond of the butatriene unit in **8** was provided by the low-temperature X-ray analysis on crystals grown from acetone solution.[10] The compound crystallizes in the space group $P\bar{1}$, and the asymmetric unit contains two independent molecules of which molecule 1 is shown in Figure 3. The Rh–C bond lengths of 2.00 ± 0.01 Å are within the range of those previously found in cumulene–rhodium complexes.[15] The C–C bond in the metallacycle (1.35 Å) is considerably longer than the C=C bond in **3b** (1.25 Å), which reflects the lower bond order due to the coordination with the rhodium. The two PPh_3 ligands are axially coordinated; the analysis of the C(phenyl)–P coupling constants in the ^{13}C NMR spectrum also provides support for *trans* coordination of the phosphanes in the solution complex.

The geometry of the central framework of the complex, consisting of the tetraethynylcumulene carbon atoms, the rhodium, and the chlorine atoms, is roughly planar (within 0.34 Å) in both molecules 1 (Fig. 3B) and 2. However, the

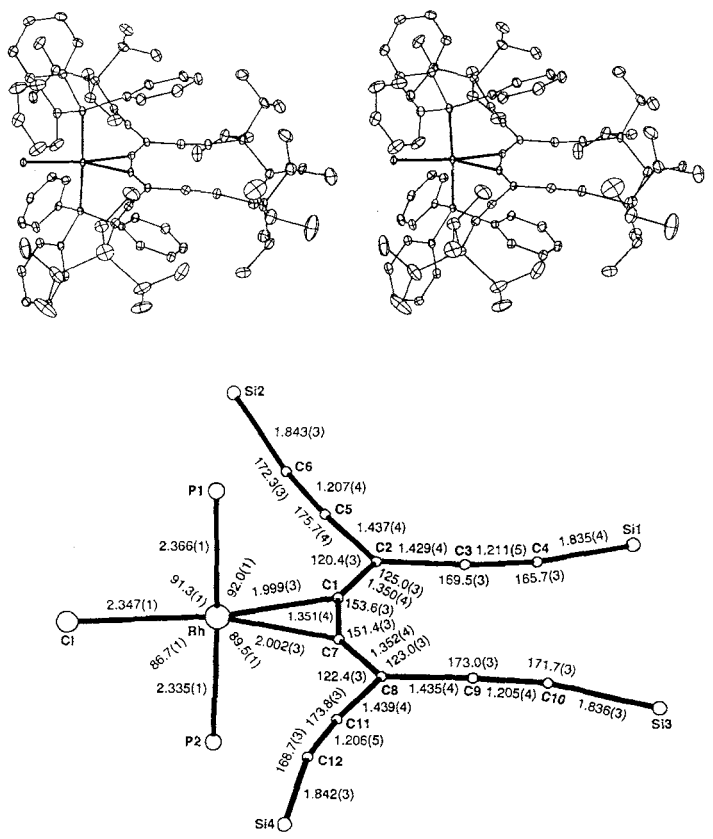


Fig. 3. X-ray crystal structure of **8**. Vibrational ellipsoids are shown at the 30% probability level.

complexation to rhodium and the presence of the two bulky phosphane ligands lead to marked angle distortions in the cross-conjugated π system of **8**. In molecule 1 (Fig. 3B), the exocyclic CCC angles at the metallacycle are 153.6(3)° and 151.4(3)°. These angles would force the two TIPS groups Si1 and Si3 into very close contact if the corresponding two C–C≡C–Si fragments were perfectly linear. To avoid severe violation of van der Waals space, bond angles at sp carbon atoms in these fragments adopt values between 165.7° and 173.0°, and, as a result, the distance between the two TIPS groups increases. The two other ethynyl fragments are also distorted by the steric hindrance between the TIPS groups Si2 and Si4 and the bulky triphenylphosphane ligands. To minimize steric repulsion, bond angles at sp carbon atoms in these two fragments vary between 168.7° and 175.7°. Similar distortions are also observed for molecule 2 in the unit cell of **8**.

Following the preparation of the first tetraethynylcumulene derivatives, we are now directing our efforts towards the synthesis of perethynylradialenes.

Experimental Procedure

3b: To a solution of the dibromoolefin **6b** (1.0 g, 1.83 mmol) in dry Et_2O (15 mL) at −110 °C was added dropwise 1.14 mL of a solution of *n*BuLi (1.83 mmol, 1.6 M) in hexane. The mixture was stirred for 1 h at −100 °C, after which a solution of CuI · PBu_3 (1.83 mmol) in Et_2O (15 mL) was added. The resulting red solution was stirred for 1 h at −85 °C, then allowed to warm to 20 °C within 5 h. The reaction mixture was filtered over SiO_2 and, after evaporation of the solvent, purified by chromatography (SiO_2, hexane) to afford 300 mg of **3b** (42% yield) as a yellow solid; m.p. (MeOH) >150 °C (decomp.); IR (KBr) $\tilde{\nu}$ = 2943, 2865 (C–H), 2144 (C≡C), 1628 (C=C), 1224 (C–Si) cm^{-1}; ^1H NMR ($CDCl_3$) δ = 1.09 (s, 84H); ^{13}C NMR ($CDCl_3$) δ = 150.6 (s, =C=), 104.2 (s, C≡C–Si), 100.1 (s, C≡C–Si), 87.7 (s, C–C≡C), 18.5 (q, CH_3), 11.3 (d, CH); UV/VIS (hexane): λ_{max} = 424 (ε = 138000), 404 (44600), 390 (51200), 373 (23800), 360 (18500), 322 (15400), 303 (12600), 230 (22300), 220 nm (19400); EI-MS *m/z* 773 (M^+, 100% relative intensity). Correct elemental analysis for C, H.

[9] All new compounds have been fully characterized by ^1H NMR, ^{13}C NMR, IR, and UV spectroscopy, mass spectrometry, and elemental analysis.

[10] Single crystals of **3a** ($C_{24}H_{36}Si_4$, M_r = 436.89) were grown at 235 K from acetone and mounted, without warming, on a CAD4 diffractometer equipped with a graphite monochromator ($Mo_{K\alpha}$ radiation) and a cooling device. X-ray crystal data at 85 K: monoclinic space group $P2_1/c$ (no. 14), ϱ_{calcd} = 1.024 g cm^{-3}, Z = 2; a = 10.870 (2), b = 10.121(2), c = 15.241(2) Å, β = 122.30(2)°, V = 1417.3 Å^3. The molecule has a crystallographic center of symmetry. The structure was solved by direct methods (SHELXS86) and refined by full-matrix least-squares (SHELXL92) with an exponentially modified weight factor with r = 4 Å^2 (J. D. Dunitz, P. Seiler, *Acta Crystallogr. Sect. B* **1973**, *29*, 589–595). $R(F)$ = 0.027, $wR(F^2)$ = 0.105 for 146 variables and 4552 reflection intensities with $I_o > 3\sigma(I_o)$ and $H = 2\sin\theta/\lambda < 1.62$ Å^{-1} (C and Si atoms anisotropic, H atoms isotropic with a riding model). Single crystals of **8** ($C_{84}H_{114}P_2Si_4RhCl$, M_r = 1436.5) were first obtained at 293 K from acetone and mounted on the diffractometer described above. Cooling of the crystals from 293 to 85 K produced twinned intergrowths with a large mosaic spread. To circumvent this problem, crystals were grown at ≈ 235 K, then mounted on the diffractometer without warming and cooled slowly to 85 K during 24 h. X-ray crystal data at 85 K: triclinic space group $P\bar{1}$ (no. 2), ϱ_{calcd} = 1.13 g cm^{-3}, Z = 4; a = 13.738(3), b = 23.426(4), c = 27.769(6) Å, α = 108.48(2), β = 92.78(2), γ = 95.32(2)°, V = 8411(3) Å^3. The asymmetric unit contains two independent molecules and probably one or two highly disordered acetone molecules. The structure was solved by the Patterson method (SHELXTL PLUS) and refined by full-matrix least-squares, with an exponentially modified weight factor r = 5 Å^2. $R(F)$ = 0.034 for 1657 variables and 19909 reflection intensities with $I_o > 3\sigma(I_o)$ and $H = 2\sin\theta/\lambda < 1.2$ Å^{-1} (all non-H atoms anisotropic, H atoms isotropic and fixed). All TIPS groups show relatively large thermal motion, even at 85 K, and some exhibit orientational disorder as well (especially in molecule 2). Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

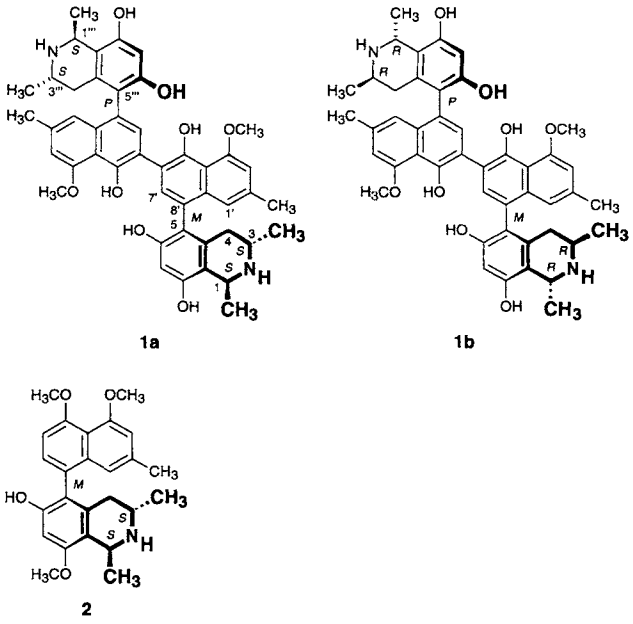
The Absolute Configuration of Michellamine B, a "Dimeric", Anti-HIV-Active Naphthylisoquinoline Alkaloid**

By *Gerhard Bringmann,* Rainer Zagst, Manuela Schäffer, Yali F. Hallock, John H. Cardellina II,* and *Michael R. Boyd*

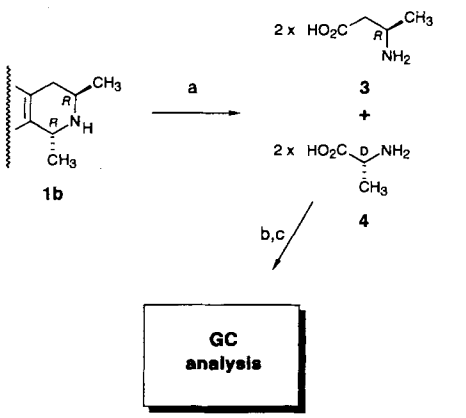
Dedicated to Professor Wolfgang Steglich on the occasion of his 60th birthday

The michellamines constitute an intriguing novel class of naturally occurring "dimeric" naphthylisoquinoline alkaloids, isolated from a West African *Ancistrocladus* species.[1] Of these, especially michellamine B is distinguished by a high anticytopathic activity aginst HIV-1 and HIV-2.[1] Also, from a chemical point of view these naturally occurring quateraryls are remarkable in many regards: Besides the unprecedented "dimeric" naphthylisoquinoline structure, even the molecular "halves" are unique with respect to their high polarity resulting from the presence of three phenolic OH groups. Furthermore, they are based on an unusual 5,8′-coupling type,[2] which is otherwise realized only in the "monomeric" naphthylisoquinoline alkaloid ancistrobrevine B (**2**).[3,4] The constitution of michellamine B was established by extensive ^1H and ^{13}C NMR experiments.[1] The relative configuration at the two stereocenters C1 and C3 was proved to be *trans* for both isoquinoline parts. While constitutionally identical, the molecular halves were shown to be diastereomorphous to each other, for example by the nonequivalence in ^{13}C NMR, which exhibits 46 signals for michellamine B. As simultaneously established for ancistrobrevine B (**2**),[3,4] the configurations at the biaryl axes relative to the stereocenters in michellamine B were elucidated by specific NOE interactions of the protons at C1′ and C7′ with the corresponding diastereotopic protons at C4.[1] According to these studies, the two molecular halves have different relative configurations at their centers relative to their axes. By contrast, no information has so far been obtained concerning the *absolute* configuration of michellamine B, which was arbitrarily assigned as **1a**, that is, (1*S*, 3*S*)-configurated,[1] consistent with most other *Ancistrocladus* alkaloids,[5] such as **2**. In this paper, we describe the elucidation of the absolute configuration of michellamine B as **1b**, by application of an oxidative degradation procedure recently developed for "ordinary", that is, "monomeric", naphthylisoquinoline alkaloids.[6]

Based on the above-mentioned NMR findings, michellamine B could indeed be represented either by **1a**, with (*S*)-configuration at *all* the stereocenters and different absolute configurations at the axes, or by its enantiomer **1b**. Yet, the diastereomorphous relationship of the two molecular moieties might also arise from a heterochiral character of the stereocenters (i.e., 1*R*, 3*R*, 1‴*S*, 3‴*S*), with the axes having identical configurations (i.e., 5*M*, 5‴*M* or 5*P*, 5‴*P*, respectively). These two additional stereoisomers would also fit in with the above-mentioned experimental results and did not seem too improbable, since West African *Ancistrocladus* plants do produce pairs of related alkaloids that are stereochemically identical at the axes, but different, for example, at C3.[7–9]



For this reason, the absolute configuration at C1 and C3 of both halves of michellamine B would be best analyzed by a ruthenium-mediated transformation into the amino acids alanine and 3-aminobutyric acid, simple chiral compounds that are easy to analyze stereochemically. The oxidative degradation of michellamine B (9.3 mg) was performed as developed for "monomeric" naphthylisoquinolines,[6] by treatment of the alkaloid with $NaIO_4$ (99 mg) and catalytic amounts of $RuCl_3$ (0.1 mg) in $MeCN/CCl_4$/aqueous phosphate buffer at room temperature (Scheme 1). The resulting amino acids were converted into their methyl esters with MeOH/HCl and derivatized with (*S*)-α-methoxy-α-trifluoromethylphenylacetic acid via its acid chloride ("*R*-MTPA-Cl"), to give the Mosher-type derivatives. Analysis by gas chromatography (fused silica capillary column, 30 m × 0.33 mm inner diameter, coated with DB1) revealed two peaks, which could unambiguously be assigned as (*R*)-3-aminobutyric acid (**3**, t_R=21.2 min) and D-alanine (**4**, t_R=15.6 min) by coinjection with racemic as well as enantiomerically pure standard samples.



Scheme 1. Oxidative degradation of michellamine B (**1**). Reaction conditions: a) $RuCl_3$, $NaIO_4$, 1 h; b) MeOH, HCl, 5 h; c) MTPA-Cl, NEt_3, 1 h.

For a further confirmation, the configurationally known[10,11] naphthylisoquinoline alkaloids ancistro-

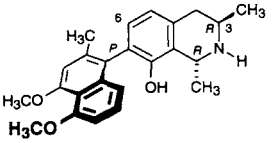
5



6

cladine (**5**, 1*S*, 3*S*) and dioncophylline A (**6**, 1*R*, 3*R*) were also subjected to the same degradation conditions, thus serving as additional standards. The exclusive formation of the amino acids (*R*)-**3** and D-**4** in a practically enantiomerically pure form (> 95:5) clearly shows that both tetrahydroisoquinoline parts are stereochemically identical. This excludes the above-mentioned stereoisomers with identical configurations at the axes, but enantiomorphous tetrahydroisoquinoline parts. Furthermore, the identification of both amino acids in their (*R*)-configurated forms clearly rules out stereoisomer **1a**, thus unambiguously demonstrating michellamine B to be represented by the stereostructure **1b**, that is, a (1*R*, 3*R*, 5*M*, 1‴*R*, 3‴*R*, 5‴*P*) configuration. Of course, this result again and independently confirms the relative *trans* configurations in both heterocyclic systems.

The work described in this paper represents the first complete elucidation of the full stereostructure of a "dimeric" naphthylisoquinoline alkaloid. Michellamine b (**1b**) is a constitutionally symmetrical, but heterochiral coupling product of two atropodiastereomeric biaryl alkaloids. These two naphthylisoquinoline "halves" formally do not constitute typical Ancistrocladaceae-type alkaloids (that is, with (*S*)-configuration at C3 and an oxygen function at C6, as realized, for example, in **2** and **5**), nor typical Dioncophyllaceae-type alkaloids, that is, with (3*R*)-configuration and no oxygen at C6, like in **6**), but rather one of the "mixed" Ancistrocladaceae/Dioncophyllaceae-type hybrids,[7, 12] since they combine the two properties by having (3*R*)-configuration *and* an oxygen function at C6.

Novel Synthesis of Tetrasubstituted β-Lactones: The Use of Indium in the Electrochemically Supported Reformatsky Reaction**

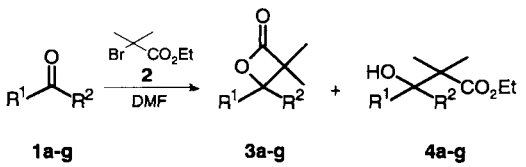
By *Hans Schick,** *Ralf Ludwig, Karl-Heinz Schwarz, Katharina Kleiner,* and *Annamarie Kunath*

Dedicated to Professor Hans Gross on the occasion of his 65th birthday

The discovery of biologically active natural products with a β-lactone structure, for example, lipstatin,[2] esterastin,[3] lupeolactone,[4] valilactone,[5] obafluorin,[6] and oxazolomycin,[7] has attracted more interest in efficient syntheses for β-lactones. An up-to-date summary of the synthetic methods available today for this class of substances may be found in the literature.[8, 9] We chanced across a surprisingly simple synthesis of tetrasubstitued β-lactones during studies on the electrochemical generation of the Reformatsky reagent from ethyl 2-bromo-2-methylpropanoate (**2**) by using indium as the sacrificial anode.[10]

In previous investigations heat evolution in a Reformatsky reaction, which is often difficult to control, could be regulated conveniently if the Reformatsky reagent is not generated by the reaction of the α-bromoalkanoate with zinc powder, but by using a zinc anode in an electrolysis cell. With this method succinic anhydride was converted by reaction with alkyl 2-bromoalkanoates in good yields into 2-substituted 1-alkyl 5-hydrogen 3-oxohexanedioates.[11] The use of other metals as sacrificial anode showed that indium gave even better yields than zinc.[1] This prompted us to study the electrochemical transformation of 2-bromoalkanoates with ketones at an indium anode as well.

On electrolysis of **2** and cyclohexanone (**1a**) at an indium anode with a cell voltage of 30 V, the crystalline β-lactone **3a** was obtained in 80% yield instead of the expected liquid β-hydroxy ester **4a** (Scheme 1). The structure of **3a** could be



1a-g **3a-g** **4a-g**

Scheme 1. Addition of the bromo ester **2** to the carbonyl compounds **1a–g** in the electrochemically supported Reformatsky reaction at an indium anode. For **a–g**, see Table 1.

deduced unambiguously from the characteristic IR band at 1810 cm^{-1}, the elemental analysis, and the agreement of the ^1H and ^{13}C NMR signals, as well as of the melting point with published data.[8] Under the same conditions the ketones **1b–f** afforded the β-lactones **3b–f** in yields of about 60%. A high-pressure liquid chromatographic (HPLC) study of the crude products obtained by flash chromatography allowed the detection of the expected β-hydroxy esters **4** in small amounts as minor product. The yields and the ratios of β-lactones **3** to β-hydroxyalkanoates **4** are collated in Table 1.

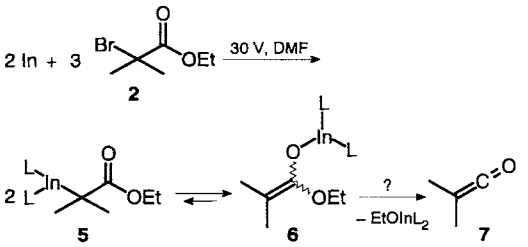
f	Ph	Ph	61	1820	>99:1
g	Ph	H	93	-	<1:100

[a] The yields refer to the fractions containing **3** and **4** obtained by flash chromatography. [b] The ratio of **3**:**4** was determined by HPLC of the crude product obtained from flash chromatography. [c] According to HPLC the two isomers of **3b** are formed in a ratio of 4:1. [d] The yield is based on **1e** that reacts. The conversion was not complete.

Although the Reformatsky reaction has often been employed—also with other metals like magnesium,[12] cadmium,[13] nickel,[14] cerium,[15] manganese,[16] and also indium[17–19]—as a standard method for the synthesis of β-hydroxyalkanoates, the formation of β-lactones has apparently not been observed before. At any rate, no reference to such a possibility appears in surveys either on the Reformatsky reaction[20] or on β-lactones.[8, 9]

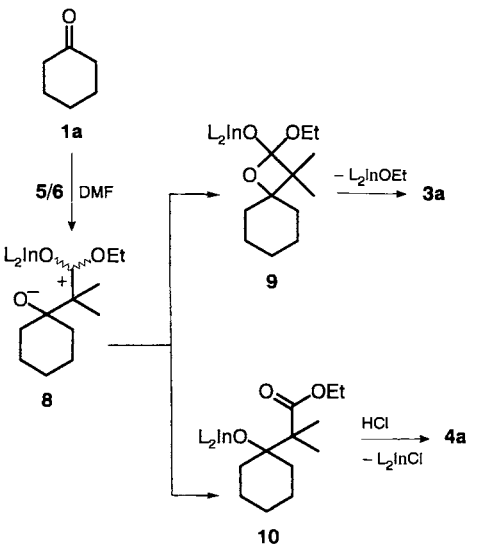
To explain the course of the reaction, it can be assumed that organoindium compounds of type **5**[21] or indium enolates of type **6**[22] are formed in the electrochemical reaction of indium and the bromo ester **2** (Scheme 2). These react as



Scheme 2. Formation of possible intermediates in the electrolysis of bromo ester **2** at an indium anode (L = Br, Me_2CCO_2Et, or $Me_2C{=}C(O)OEt$).

nucleophiles, for instance with the carbonyl group of **1a** to form the adduct **8** (Scheme 3). This seems to afford preferentially the β-lactone **3a** by elimination of an indium alcoholate from the ortho ester derivative **9**. The hydroxy ester **4a** formed as minor product arises in the hydrolytic workup if **8** first rearranges to the indium alcoholate **10**. This is in any event the generally accepted course of the Reformatsky reaction with zinc.[20] That the β-lactone **3a** in the described reaction is formed before the hydrolytic workup can be seen from the typical signals of **3a**—in particular at $\delta = 85.1$ and 176.1—in the ^{13}C NMR spectra of the unhydrolyzed reaction solution.

Although the Lewis acid catalyzed addition of ketenes to aldehydes and ketones is a general possibility for the synthesis of β-lactones,[8, 9] this reaction can apparently be disregarded for the formation of the β-lactones **3** observed here. If the ketene **7** could be formed from the ester enolate **6** by elimination of an indium alcoholate (see Scheme 2), it should then add more readily to aldehydes than to ketones.[23] This was, however, not observed: benzaldehyde, in contrast to benzophenone, afforded exclusively the β-hydroxy ester **4g** (Table 1).



Scheme 3. Interpretation of the formation of the β-lactone **3a** and the hydroxy ester **4a** from the ketone **1a**.

According to the results available at present, tetrasubstituted β-lactones can be prepared in good yields from ketones and ethyl 2-bromo-2-methylpropanoate (**2**) in an electrochemically supported Reformatsky reaction with indium as sacrificial anode. The preparative possibilities and limitations of this special application of the Reformatsky reaction for the synthesis of β-lactones containing four different substituents and the suitability of other metals are under investigation.

Experimental Procedure

3a: In a thermostatable, one-compartment electrolysis cell provided with an indium rod as anode and a nickel gauze as cathode, **1a** (0.491 g, 5 mmol) and **2** (2.926 g, 15 mmol) were electrolyzed under argon in *N*,*N*-dimethylformamide (DMF)/tetrahydrofuran (1/1, 10 mL) in the presence of tetrabutylammonium bromide (0.322 g, 0.1 mmol) at 50 °C at a cell voltage of 30 V. When no more **1a** could be detected by thin-layer chromatography, the mixture was stirred without current for a further 2 h. Ice (25 g) and HCl (5%, 25 mL) were added, and the mixture was extracted with EtOAc (5 × 20 mL). The combined extracts were washed with water (3 × 10 mL), dried with Na_2SO_4, and evaporated to dryness under reduced pressure. The residue was purified by flash chromatography on silica gel 60 (230–400 mesh, E. Merck) with hexane/EtOAc (10/1) and recrystallized from hexane; yield 0.672 g (80%), m.p. 108–110 °C (published value [8]: 109–111 °C).

Transformation of the First Zirconocene Alkyne Complex without an Additional Phosphane Ligand into a Dinuclear σ-Alkenyl Complex by Hydrogen Transfer from η^5-C_5H_5 to the Alkyne Ligand**

By *Uwe Rosenthal,* Andreas Ohff, Manfred Michalik, Helmar Görls, Vladimir V. Burlakov,* and *Vladimir B. Shur*

Dedicated to Dr. habil. Erhard Kurras on the occasion of his 65th birthday

Metallocene alkyne complexes with Group 4 metals without additional ligands $[Cp_2M(RC{\equiv}CR')]$ are highly reactive and can be prepared and characterized only in rare cases. We synthesized the first complexes of this type with M = Ti, **1a**,[1] **1b**,[2, 3] and **1c**,[4] according to Equation (a). Complex **1b** is the only one of this type that was characterized by X-ray crystal structure analysis. In addition, a thermally unstable complex with R = R′ = Me was described.[5]

$$[Cp_2TiCl_2] + Mg + RC{\equiv}CR' \xrightarrow[-MgCl_2]{20\,^\circ C,\ THF} Cp_2Ti(C(R)=C(R'))\quad (a)$$

1a: R = R′ = Ph
b: R = Ph, R′ = $SiMe_3$
c: R = R′ = $SiMe_3$

Analogous zirconium complexes $[Cp_2Zr(RC{\equiv}CR')]$ are unknown, however, since in the reactions analogous to (a) they react further with the alkyne to form substituted zirconacyclopentadienes $[Cp_2Zr{-}C(R')=C(R){-}C(R)=C(R')]$, for example for R = R′ = Ph[6] and R = Ph, R′ = $SiMe_3$.[7] Nevertheless, a series of zirconocene alkyne complexes $[Cp_2Zr(PR_3)(RC{\equiv}CR')]$ has been synthesized with stabilizing phosphane ligands.[8–12] When bis(trimethylsilyl)acetylene was used, the first zirconocene alkyne complex without an additional phosphane ligand, **2**, was obtained; we report here on its synthesis, structure, and properties.

Complex **2** was prepared from the reaction of zirconocene dichloride with equimolar amounts of magnesium and

$[Cp_2Zr(thf)(Me_3SiC{\equiv}CSiMe_3)]$ **2**

bis(trimethylsilyl)acetylene in THF at room temperature [Eq.(b)]; the complex contains a weakly bound THF molecule.

$$[Cp_2ZrCl_2] + Mg + Me_3SiC{\equiv}CSiMe_3 \xrightarrow[-MgCl_2]{20\,^\circ C,\ THF} Cp_2Zr(thf)(C(SiMe_3)=C(SiMe_3))\quad (b)$$

2

Complex **2** crystallizes in orange, monoclinic prisms, which become colorless above about 100 °C and melt at 139–141 °C with decomposition. The compound is very air and moisture sensitive.

Although the acetylene carbon atoms in **2** should not be equivalent, in ^{13}C NMR spectra between + 30 and −30 °C they give rise to only one singlet at $\delta = 212.9$[13] ($[Cp_2Zr(PMe_3)(Me_3SiC{\equiv}CSiMe_3)]$ has signals at $\delta = 177.3$ and 205.1[12]). Accordingly, the carbon and hydrogen atoms of the Me_3Si groups in **2** also give rise to one singlet each in the ^{13}C and ^1H NMR spectra, respectively. This apparent equivalence of the two halves of the alkyne in solution can be explained by a fast exchange of free and coordinated THF molecules. Measurements in noncoordinating solvents such as [D_6]benzene are not possible because cleavage of THF is immediately followed by a spontaneous reaction (see [Eq.(c)]).

The IR spectrum of **2** ($\nu(C{\equiv}C) = 1581\ cm^{-1}$) indicates a complex with zirconacyclopropene structure. In the X-ray structure analysis[14] of **2** (Fig. 1) the zirconium center has a

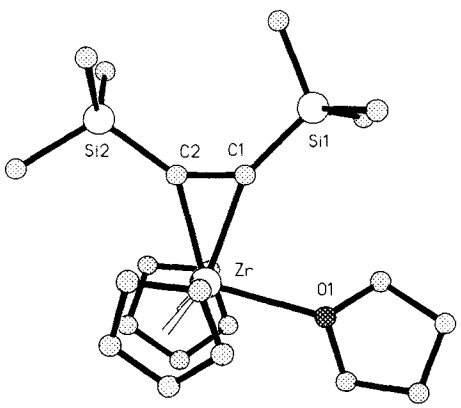

Fig. 1. Crystal structure of **2**. Selected distances [Å] and angles [°]: C1-C2 1.302(9), Zr-C1 2.260(7), Zr-C2 2.204(7), Zr-O1 2.390(5); C1-C2-Si2 143.5(6), C2-C1-Si1 134.4(6), C1-Zr-C2 33.9(2), O1-Zr-C1 86.8(2), O1-Zr-C2 120.7(2), Cp1-Zr-Cp1A 130.5(3).

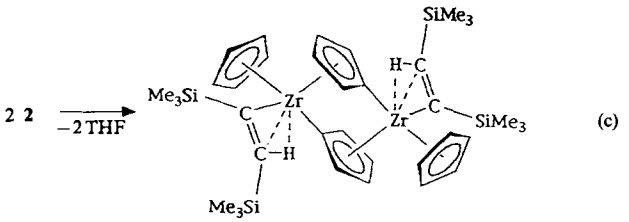
tetrahedral coordination sphere composed of Cp ligands, alkyne, and tetrahydrofuran. The molecule has *m* symmetry; the mirror planes pass through the central atom, the alkyne carbon atoms, the Si atoms, and the O atoms as well as both β-C atoms of the THF ligand. Thus, in the solid the halves of the alkyne are not equivalent.

The distance between the two alkyne carbon atoms in the complex (1.302(9) Å) is close to that of a C–C double bond (in $[Cp_2^*Ti(Me_3SiC{\equiv}CSiMe_3)]$ 1.309(4) Å ($Cp^* = \eta^5$-C_5Me_5),[3] $[Cp_2Zr(PMe_3)(HC{\equiv}CnBu)]$ 1.286(5) Å[8]). The relatively long Zr–O separation of 2.390(5) Å in **2** (in $Cp'_2Zr\{(Z)$-$C(CH_3){=}C(CH_3)(nPr)\}(thf)](BPh_4)$ 2.289(6) Å ($Cp' = C_5H_4Me$),[15] in $[Cp_2Zr(CH_3)(thf)]$-(BPh_4) 2.122(14) Å,[16] in $[Cp_2Zr(thf)(Me_3SiN{=}CHPh)]$ 2.376(9) Å[17]) is further proof of the loose Zr–THF interaction deduced from spectroscopic data which is the cause for the reaction shown in Equation (c).



(c)

3

When complex **2** is dissolved in pentane or benzene, or heated under vacuum (oil pump), the THF ligand is lost completely; the shift of a hydrogen atom from the η^5-C_5H_5 ligand to the alkyne then results in formation of the dinuclear σ-alkenyl complex **3** [Eq.(c)].

Complex **3** crystallizes in colorless prisms which melt at 142–143 °C with decomposition and are very air and moisture sensitive. The structure of the compound was determined by NMR spectroscopy[18] and X-ray structure analysis [19] (Fig. 2). In this dinuclear complex the zirconium

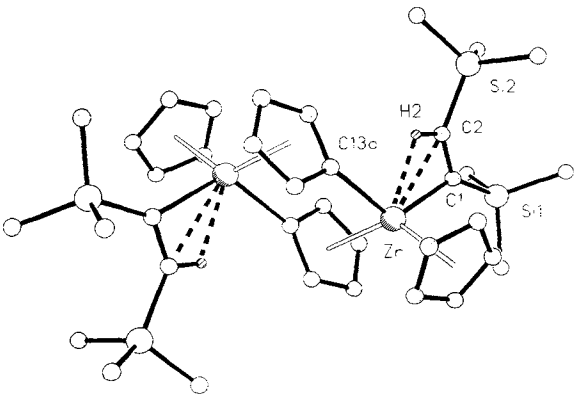


Fig. 2. Crystal structure of **3**. Selected distances [Å] and angles [°]: C1-C2 1.318(5), Zr-C1 2.244(3), Zr-C2 2.566(3), Zr-H2 2.14(1), C2-H2 1.10(3), Zr-C13 2.349(3), C13a-H2 2.41(1); C1-C2-Si2 135.3(3), C2-C1-Si1 133.3(3), C1-Zr-C2 30.9(1), Zr-H2-C2 99.5(8), Cp1-Zr-Cp2 132.3(1).

atoms are linked by two bridging $\eta^1{:}\eta^5$-cyclopentadienyl ligands. The agostic interaction between the alkenyl C–H bonds and the zirconium centers is an interesting structural feature in this complex.

Bridging C_5H_4 ligands are not unusual (see for example $[\{Cp[\mu$-$(\eta^1{:}\eta^5$-$C_5H_4)]Ti(PMe_3)\}_2]$[20]). The distances and angles in the Zr–C=C–H portion of **3** correspond for the most part to those of zirconocene alkenyl halides (see for example $[Cp_2Zr(Cl)\{C(SiMe_3){=}CHPh\}]$[21]).

The agostic interaction CH → Zr in **3** is also evident from the small coupling constants $^1J(C_\beta$-H) of 96 and 97 Hz, the large difference in the ^{13}C NMR chemical shifts between the signals of the C_α and C_β carbon atoms ($\Delta\delta = 130$), and the downfield shifts of the C_β–H signals in the ^1H NMR spectra, $\delta = 7.28$ and 7.52.[21] The distance between the hydrogen atom involved in the agostic bond and the zirconium atom is 2.14(1) Å.

Two sets of signals appear in the ^1H and ^{13}C NMR spectra of **3** in THF or benzene; even the spectra of the isomerically pure sample characterized by X-ray crystallography show these sets of signals in the ratio 1:2.5, which indicates the formation of two isomers not previously characterized. In addition, **3** converts slowly into **2** in THF. Complexes **2** and **3** display the typical reactivity of zirconocene alkyne complexes, for example, in reactions with acetone, water, and CO_2.[22] The results of these studies will be reported in due course.

The differences in the synthesis and reactivity of the titanocene and zirconocene alkyne complexes can be traced back to the difference in the atomic radii of the central atoms. Thus in the case of the larger atom, zirconium, coordination of THF to give **2** and the subsequent elimination of THF providing **3** are possible.

Experimental Procedure

All experiments were conducted under anaerobic and anhydrous conditions.

2: A mixture of $[Cp_2ZrCl_2]$ (2.10 g, 7.2 mmol), finely cut magnesium (0.18 g, 7.4 mmol), and bis(trimethylsilyl)acetylene (1.62 mL, 1.23 g, 7.2 mmol) in THF (25 mL) was stirred at 20 °C for 3 h and then concentrated under vacuum until crystals started to form. Pentane (15 mL) was added and the reaction mixture filtered through a G3 frit. The solid was washed with THF/pentane (1/3, 15 mL) and then extracted with this solvent mixture (50–60 mL). The extract was concentrated to dryness under vacuum, leaving the orange complex **2** (2.5 g, 75%) (correct elemental analysis).

3: a) Complex **2** (0.988 g) was dissolved in benzene (20 mL), the solution filtered, and concentrated under vacuum to a volume of approximately 5 mL. Colorless crystals formed after one day. The remaining solution was decanted off and the crystals washed with benzene/pentane (1/1) and then dried under vacuum (oil pump) to give **3** (0.573 g, 69%) (correct elemental analysis).

b) Complex **2** (0.1 g) was heated at 100 °C for 10 min under vacuum (oil pump); a colorless powder formed which is identical to product **3** obtained from method a).

The H atoms were first localized by using difference Fourier synthesis. In the refinement all H atoms except H2 were placed in idealized positions (*d*(C–H) = 0.95 Å) and treated with a common isotropic temperature factor B_{iso} = 8.0 $Å^2$. The position of H2, which was obtained by difference Fourier synthesis, is essential to the interpretation of the structure. Both this position and the temperature factor were refined, then the temperature factor alone was refined. Comparison of the distances and angles for the atoms interacting with H2 (Zr, C2, and C13A) shows the structures obtained by the two refinement procedures do not differ significantly. Thus the position of H2 seems realistic. The final *R* value converged at 0.039 (R_w = 0.043)[14].

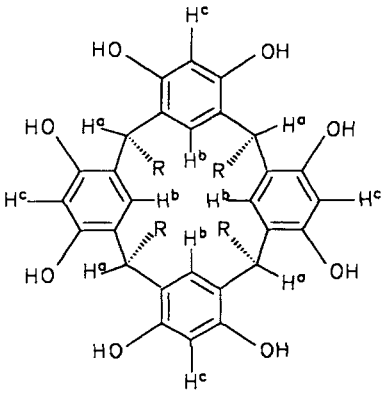
Host–Guest Complexes between Calix[4]arenes Derived from Resorcinol and Alkylammonium Ions**

By *Tino Lippmann, Horst Wilde, Maren Pink, Andrea Schäfer, Manfred Hesse,* and *Gerhard Mann**

Interest in water-soluble calix[4]arenes as models for synthetic enzymes and receptors has increased during the last few years.[1–6] The tetraanion of all-*cis*-tetramethylcalix[4]-arene **1** derived from resorcinol, which exists in aqueous alkaline solution, serves as the anionic host molecule in complexes with alkylammonium ions; the energy of formation of such complexes ΔG°_{298} is between 1.3 and 6.4 kcal mol^{-1} ($K = 10–10^4$).[7–9] We have now obtained crystals of a complex of **1** for the first time. The structure of these complexes



1: R = CH_3
2: R = *n*-C_9H_{19}

is of particular interest because tetraphenols with a crown conformation (C_{4v} symmetry) have hitherto been known only for calix[4]arenes[10] derived from phenol, not resorcinol. Disregarding bridged resorcinol tetramers,[11,12] crystal structure analyses of phenolic calixarenes show the complexation of solvents, for example, acetonitrile[13] and methyl ethyl ketone;[14] in these complexes the hosts exist in the C_{2v}-symmetric boat conformation.

Octol **1** was dissolved with alkylammonium sulfates **3**–**11** in neutral or slightly acidic solution (ethanol/water 2:1) by warming. The complexes that crystallized were examined by using elemental analysis and ^1H NMR spectroscopy.

$(Et_3HN)_2SO_4$ **3**	$(nPr_2H_2N)_2SO_4$ **4**
$(nBu_2H_2N)_2SO_4$ **5**	$(MeH_3N)_2SO_4$ **6**
$(Me_2H_2N)_2SO_4$ **7**	$(Me_3HN)_2SO_4$ **8**
$(Et_2H_2N)_2SO_4$ **9**	$[(tBuCH_2)H_3N]_2SO_4$ **10**
$[(c\text{-}C_6H_{11})H_3N]_2SO_4$ **11**	

Distinct 1:1 complexes with sharp melting points were obtained with the ammonium sulfates **3**–**5**; crystalline complexes with undefined stoichiometric composition formed with **6**–**9**.

The ^1H NMR spectra (400 MHz) of the complexes **1**·**3** (m.p. 248–250 °C), **1**·**4** (m.p. 242–243 °C), and **1**·**5** (m.p. 227–231 °C) (all recrystallized from ethanol) with the same absolute concentrations show a slight shift of the signals caused by complex formation compared with those of the pure host compound: $\Delta\delta = 0.02–0.07$. The signals of the aromatic protons H^c bonded to the upper rim and those of the H^b protons are shifted to low field, the H^a protons are shifted to high field.[15] Integration of the ^1H NMR signals and the elemental analyses support a 1:1 ratio between the host compound **1** and the bis(alkylammonium sulfates).

The marked complexation of the alkylammonium ions by the calixarene crowns is made clearer by the mass spectra obtained with electrospray ionization (ESI).[16,17] The most intense peak in the ESI spectrum of complex **1**·**3** is assigned to the species complexed to one triethylammonium ion (*m/z*

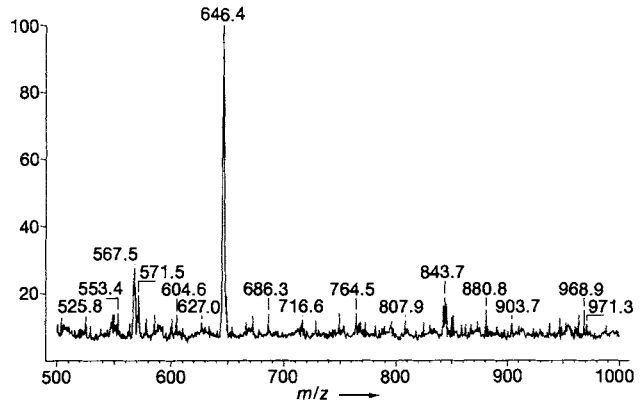

Fig. 1. ESI mass spectrum of the 1:1 complex **1**·**3**.

646 = 544 + 102) (Fig. 1). Although intense peaks can be detected for an excess of ammonium ions, only a weak signal is observed for the uncomplexed host molecule **1** (M = 544). Stable complexes in the gas phase, in other words free from solvophobic interactions, have hitherto been described only for a few host–guest compounds.[18–20]

The proposed host–guest composition is supported by variation of the substituents. Complex **1**·**5** with the nBu$_2$H$_2$N$^+$ ion as guest shows the expected base peak at m/z 674 = 544 + 130, complex **2**·**3** correspondingly at m/z 1095 = 993 + 102. As expected, ammonium ions with branched alkyl groups, for example **10** and **11**, do not form complexes with the hosts **1** and **2**.

Complex **1**·**3**, which we examined after recrystallization from ethanol at low temperature,[21] is the first crystalline host–guest compound in which the all-*cis*-tetramethylcalix[4]arene derived from resorcinol exists in approximately conical form with C_{4v} symmetry (Fig. 2).

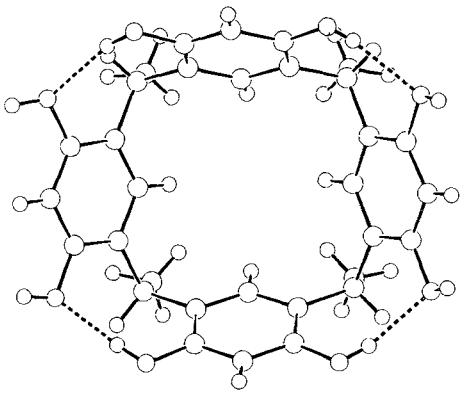

Fig. 2. Molecular geometry of the host compound **1** in the crystal (crown conformation).

The eight torsional angles of **1** reflect the conformation of the macrocycle.[22] Comparison of the torsional angles of the boat form of the host–guest compound **1**·MeC(O)Et with those of **1**·**3**·4EtOH (appropriate elemental analysis and ^{1}H NMR spectrum) makes the difference in conformation quite clear.[23] As shown in Figure 3, the crystalline compound **1**·**3** has a layer structure, composed of alternating hydrophilic and hydrophobic layers.

The hydrophobic layers are formed from pairs of calixarene molecules, which are facing each other in the region of the methyl groups (lower rim). The hydrophilic layer is formed from triethylammonium ions, sulfate ions, the hydroxyl groups of the calixarene, and also from the solvent (ethanol).

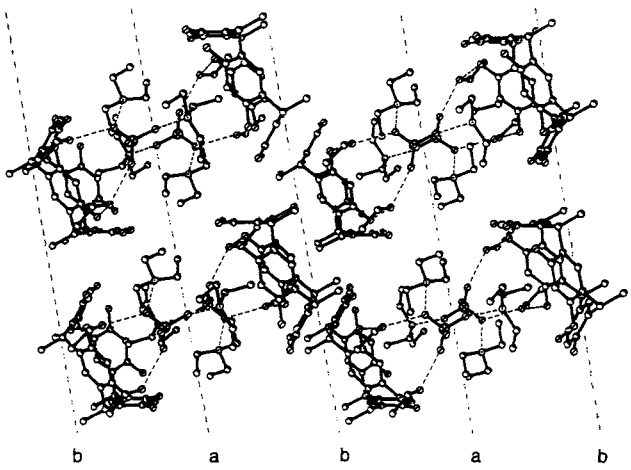

Fig. 3. Structure of **1**·**3**·4EtOH (SHELXTL-PLUS, viewing direction (010)) showing the paired arrangement of the calixarene crowns with intercalated hydrophilic compounds (triethylammonium ions, sulfate ions, ethanol molecules); hydrophilic/hydrophobic layers are formed in the crystal. Hydrophilic layer = a, hydrophobic layer = b.

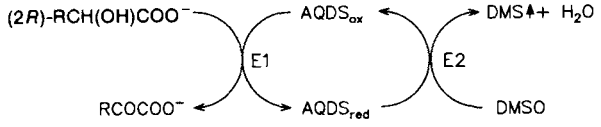
Selective Dehydrogenation of Aldonic and Aldaric Acid with an *R*-Configurated α-Carbon Atom to 2-Oxocarboxylic Acids, and Reduction of the Oxo Group of *N*-Acetylneuraminic Acid with *Proteus mirabilis***

By *Carsten Schinschel* and *Helmut Simon**

Dedicated to Professor Lothar Jaenicke on the occasion of his 70th birthday

Regio- and stereoselective reactions of carbohydrates and their derivatives that proceed without the use of protecting groups are of considerable interest. The key reaction in the synthesis of L-ascorbic acid is, for example, the microbial dehydrogenation of D-sorbitol to L-sorbose by *Acetobacter suboxidans*. We have found that suitably cultivated cells of *Proteus mirabilis* can selectively and quantitatively dehydrogenate an *R*-configurated C- atom in α-position to the carboxylate group of aldonic or aldaric acids to an oxo group.

The sequence of reactions shown in Scheme 1 yielded pent-2-ulosones and hex-2-ulosones from aldonic acids of the pentose and hexose series, respectively. We carried out the reactions on a preparative scale (10 mmol) with resting cells of *P. mirabilis* in 100–200 mM solution without buffer. Even in 500 mM solution D-gulonate was dehydrogenated almost quantitatively. The stable and inexpensive artificial electron acceptor AQDS ($E_0' = -184$ mV) proved useful here.



Scheme 1. Enzymatic dehydration of (2*R*)-aldonic and -aldaric acids. E1 = HVOR [(2*R*)-hydroxycarboxylate-viologen oxidoreductase]; AQDS = anthraquinone 2,6-disulfonate, E2 = dimethyl sulfoxide reductase; DMSO = dimethyl sulfoxide; DMS = dimethyl sulfide. (2*S*)-RCH(OH)COO⁻ is not converted and has no inhibitory effect. The R groups can be inferred from Table 1.

The enzyme HVOR(E1) that we found in *P. mirabilis* and *P. vulgaris*[1] dehydrogenates (2*R*)-hydroxycarboxylates and transfers the electrons to AQDS (1 mM). This reagent then donates them to DMSO reductase (E2), which is also present in the cells, and finally reduces DMSO to DMS. Because of its volatility and its low solubility in water, DMS is lost from the system, which is maintained at 38 °C, but can be condensed and reoxidized. By using AQDS concentrations of approximately 200 mM, it is also possible to carry out the reaction with HVOR alone, although the isolation of the oxo acid is more complex by this method. The acids were obtained as their sodium or potassium salts.

A summary of the results is given in Table 1. In all but one case, the microbial reactions proceeded almost quantitatively. Reactions with phosphorylated or glycosylated aldonates also proceeded smoothly, as was demonstrated by the dehydrogenations of 6-phospho-D-gluconate and 4-*O*-(β-D)-galactopyranosido)-D-gluconate (lactobionate). Although the two aldaric acids (Table 1) reacted more slowly than the aldonic acids, the products were obtained in good yield.

Table 1. Isolated pent- and hex-2-ulosonates and 2-oxoaldarates characterized by ^{13}C NMR spectroscopy.

[a] According to HPLC [TEAP = Si 100, 5 μm, 4.6 × 250 mm (Serva Heidelberg), 10% acetonitrile, 20 mM KH_2PO_4/H_3PO_4, pH 3.0–3.2, 1 mL min^{-1}]. [b] 360 MHz, D_2O, pH 7, 25 °C, 3-trimethylsilylpropanesulfonate. The values refer to the ^{13}C NMR signals of C-2 in the α and β form. [c] PN = mmol product per kg biocatalyst and hour [4]. [d] D-*threo*-Pent-2-ulosonate appears to exist in solution at pH 7 not only as a hemiacetal but also to a considerable extent as a lactone. The chemical shift of the α-CO group of the lactone at δ = 85.90 indicates that it may be hydrated. [e] According to the NMR spectrum only one hemiacetal form is found. The product was converted into D-ascorbic acid.

The productivity numbers (PN) vary by up to a factor of four. However, yields are generally very high, even for the more slowly reacting aldonic acids. The PN ratios for 50% conversion and complete conversion also vary. Since the K_m values we determined for various aldonic acids are less than 1 mM, the variation in the PN ratios may be due to differences in the k_{cat} values or to product inhibition. No overoxidation was observed. The products were also isolated in analytically pure form in passable to very good yields (Table 1).

None of the starting materials revealed a peak in the ^{13}C NMR spectrum near $\delta = 100$ (in D_2O), but this signal was present in all the products, and is characteristic of the carbonyl group arising from the dehydrogenation, which is

[**] This research was supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 145), BASF AG, and the Fonds der Chemischen Industrie. We thank Dr. H. White for assistance with all cultivation, N. Schmuderer for technical assistance, and Prof. Dr. C. Wandrey, Jülich, for several grams of *N*-acetylneuraminic acid.

present as a hemiacetal.[2] L-Gluconic acid does not fulfill the steric requirements for the reaction with HVOR, and was indeed not transformed.

D-*xylo*-Hex-2-ulosonate, the dehydrogenation product of D-gulonate, was converted to D-ascorbic acid. Its ^{13}C NMR spectrum is identical to that of authentic L-ascorbic acid.

The dehydrogenations described were also carried out with purified HVOR.

The reaction sequence shown in Scheme 1 is also suitable for selective dehydrogenation of the (*R*) enantiomer of racemates.[3] Reductions of 2-oxocarboxylic acids in the carbohydrate series are also effectively possible. Thus, the α-carbonyl group of *N*-acetylneuraminic acid was reduced quantitatively to the hydroxyl group by *P. mirabilis* when formate was used as the reducing agent. The ^{13}C NMR signal at $\delta = 97.99$ disappeared, and a new signal emerged at $\delta = 71.52$. We assume that the resulting product has an (*R*)-configurated α-position, as we have proved in several dozen other cases.[4, 5]

We have recently reported the reduction of numerous other multifunctional 2-oxocarboxylic acids to (2*R*)-hydroxycarboxylic acids and their chemical transformation to a variety of compounds with three chiral centers.[5] From structurally very diverse 2-oxocarboxylic acids it is therefore possible to obtain enantiomerically pure (2*R*)-hydroxycarboxylic acids, from (2*R*)-hydroxycarboxylic acids one may produce 2-oxocarboxylic acids, and from *rac*-2-hydroxycarboxylic acids both the pure (*S*) enantiomers and the 2-oxocarboxylic acids are accessible.

The dehydrogenations shown in Scheme 1 were in principle carried out using the methods previously developed for the preparative synthesis of pyruvate from (*R*)-lactate in up to 650 mM solutions.

Several years ago, the preparation of 2-oxoaldonic acids by catalytic oxidation of aldonic acids was described.[7] The yields in this case reveal a pronounced time optimum, and in most cases, the product contained five or six by-products.

In the transformations described here, specially cultivated *P. mirabilis* cells were used which have $>20\ U\,mg^{-1}$ of HVOR in the crude extract with respect to pyruvate reduction, and approximately $8\ U\,mg^{-1}$ for (*R*) lactate dehydrogenation (1 U produces 1 μmol product per minute).[8] These are exceptionally high values for redox enzymes in crude extracts. The activities are significantly less for the carbohydrate derivatives we studied, but for the transformations described they are nonetheless very useful indeed. In assessing these results, one must take into account that baker's yeast typically reduces keto compounds with productivity numbers of 5–50. Dehydrogenations (i.e. oxidations) with yeast are virtually unknown.

The enzyme present in *P. mirabilis* and *P. vulgaris*, HVOR, reveals by far the broadest substrate range of any 2-hydroxycarboxylate oxidoreductase yet studied. This is true not only for the enzyme substrates, but also for the artificial electron carriers. We have found up to twenty suitable electron carriers, which vary in their standard redox potential by more than 650 mV and therefore allow both quantitative reductions and dehydrogenations (i.e. oxidations).[8] The enzyme is nonetheless completely stereospecific. Till now, this substrate range has not even been nearly matched by any pyridine nucleotide-dependent 2-oxoacid reductase,[9] even after extensive protein engineering.[9, 10] For pyridine nucleotide-dependent redox enzymes, cofactor regeneration is generally more complicated, and quantitative dehydrogenations on a preparative scale are difficult to carry out for thermodynamic reasons. In addition, severe product inhibition often occurs.

Experimental Procedure

Commercially unavailable aldonic acids were synthesized by oxidation of the corresponding aldoses [11].

Preparation of the reaction solution and the dehydrogenation itself were carried out under a nitrogen atmosphere, and the pH of the buffer-free solution was held constant during the reaction with the help of a pH-stat and 2 N sodium hydroxide. The reaction solution consisted of 200 mM substrate as its sodium or potassium salt, 300 mM DMSO, 1 mM AQDS, 5 mM ethylenediaminetetraacetic acetate, and 0.001 mM tetracycline in 50 mL water, and contained 0.8 g (dry weight) of *P. mirabilis* cells. A slow stream of nitrogen was passed through the gently stirred mixture at 38 °C, and the course of the reaction was monitored by high-performance liquid chromatography (HPLC). At the end of the reaction, the pH of the mixture was brought to 3.5 with perchloric acid, the protein precipitate was removed by centrifugation, and the supernatant was treated with active charcoal and filtered. The free acid was isolated by chromatography on a 10 × 210 mm AG-50-W-XB (200–400 mesh) column in the H^+ form (Bio-rad, Munich). The pale yellow solution was then brought to pH 8.0 with sodium or potassium hydroxide and lyophilized. The residue was taken up in 200 mL methanol containing almost 2% water and stirred for one hour. The sparingly soluble sodium or potassium salts were filtered off and washed with methanol and acetone.

D-ascorbic acid was synthesized from D-*xylo*-hex-2-ulosonate as previously described [12].

The reduction of *N*-acetylneuraminic acid to 5-acetylamido-3,5-dideoxy-D-*erythro*-L-manno-nonanoic acid was carried out at 38 °C with *P. mirabilis* instead of *P. vulgaris* as previously reported [5]. The reaction solution consisted of 100 mM substrate as its sodium salt, 100 mM formate, and 1 mM benzylviologen in 40 mL water, and contained 0.2 g (dry weight) of *P. mirabilis* cells. The pH was held constant at 7.0 with 1 N formic acid. Yield 98%.

A Self-Replicating System from *Three* Starting Materials**

By *Thomas Achilles* and *Günter von Kiedrowski**

Nucleic acid systems capable of self-replicating in the absence of enzymes probably played a key role in the origin of life on earth.[1] The first example for nonenzymatic self-replication was found in the condensation of the complementary trideoxynucleotides $^{Me}CCGp$[2] and $^{HO}CGGp$,[2] which

[*] Prof. Dr. G. von Kiedrowski, Dipl.-Chem. T. Achilles
Institut für Organische Chemie und Biochemie der Universität
Albertstrasse 21, D-79104 Freiburg (FRG)
Telefax: Int. code + (761)203-2815

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

yields the self-complementary hexadeoxynucleotide template ^{Me}CCGCGGṗ in the presence of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDC).[3] The product was formed by two reaction pathways, one of which was autocatalytic and described by a rate equation with a reaction order of 1/2 with respect to the template concentration (square root law).[3,4] Substituting the 5′-OH group of ^{HO}CGGṗ with an amino group resulted in a drastic increase of the reaction rates particularly for the autocatalytic reaction path for which the expected parabolic increase of template concentration could be observed.[5]

Meanwhile, a series of self-replicating systems have been reported in which the templates are always formed from two constituents.[6] Other approaches to self-replication of artificial systems have also been developed.[7] However, it was pointed out that in the previous systems selection processes cannot occur and that to study information transfer phenomena, complex systems with three or more starting materials are required.[1a]

Here, we report on self-replication experiments with three starting materials: 5′-methylthiomethyl(MTM)-trideoxynucleotide-3′-phosphate (**A**), 5′-aminodimer-3′-phosphate (**B**), and 5′-amino-2′,5′-dideoxyguanosine-3′-(*o*-chlorophenyl)-phosphate (**C**). These compounds and other model compounds were synthesized by the phosphotriester method in solution.[8] In the presence of EDC and 1-methylimidazole (MeIm), the 3′-phosphate groups of reactants **A** and **B** react with the 5′-amino groups of reactants **B** and **C** to form 3′-5′-phosphoamidate bonds (Fig. 1).[2] The reactions were carried out at 20 °C on a nanomole scale in 1 μL capillaries[9] and were monitored by HPLC on a RPC-18 column.[10] The phosphoamidate products **AB**, **AC**, and **BC** were identified from conversions of pairs of the appropriate reactants. In the reaction of all three of the reactants, the product **ABC** was also detected. **ABC** is formed both from **AB** + **C** and from **A** + **BC**, which causes the concentrations of the intermediates **AB** and **BC** pass through maxima (Fig. 2, left). As neither **AB** nor **BC** is present initially, the rate of formation of **ABC** at the start is zero. The tetramer **AC** is always formed

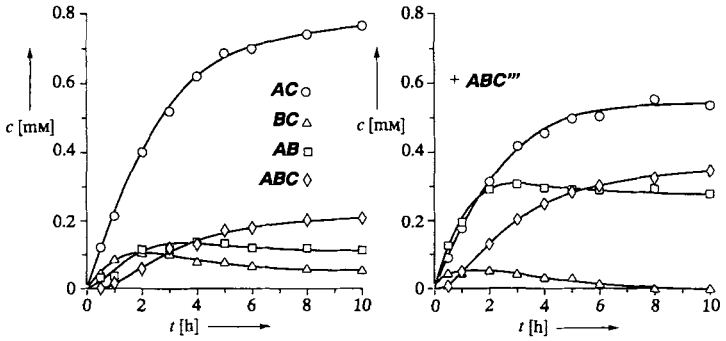

Fig. 2. Left: concentrations as a function of time of the trimer **BC**, the tetramer **AC**, the pentamer **AB**, and the hexamer **ABC** formed from the condensation of **A**, **B**, and **C** in the presence of EDC and 1-methylimidazole [9], as determined by HPLC [10]. Right: the same condensation in the presence of 1 mM of the hexamer template **ABC'''**.

as the major product in this reaction (Fig. 2, left). Most likely, the tetramer **BB** is a further major product which, however, could not be separated from its precursor **B** on RPC-18 columns under a variety of conditions.[11,12]

In order to estimate the amount of **BB** synthesized, the reaction between 5′-azidodimer-3′-phosphate ^{N3}CGp (**B″**) and 5′-aminodimer-3′-(2-phenylthioethyl)phosphate ^{H2N}CGp^{PTE} (**B′**) in the presence of EDC and 1-methylimidazole was examined (model reaction 3, see below). The tetramer **BB′** could be separated from its precursors by HPLC.[12] The conversion reached 30% after four hours;[9] under the same reaction conditions for **B**, the conversion rate of a 2 mM solution should be doubled, as there are two equivalent synthetic pathways leading to **BB**. Analogous model reactions, each with a 5′-protected 3′-phosphate reactant and a 3′-protected 5′-amino reactant were also carried out for the other individual reaction steps [reactions (1) to (7)].[2,9]

$$^{MTM}CCGp\ (\mathbf{A}) + {}^{H2N}CGp^{PTE}\ (\mathbf{B'}) \longrightarrow {}^{MTM}CCGpnCGp^{PTE}\ (\mathbf{AB'}) \quad (1)$$

$$^{MTM}CCGp\ (\mathbf{A}) + {}^{H2N}G\dot{p}\ (\mathbf{C}) \longrightarrow {}^{MTM}CCGpnG\dot{p}\ (\mathbf{AC}) \quad (2)$$

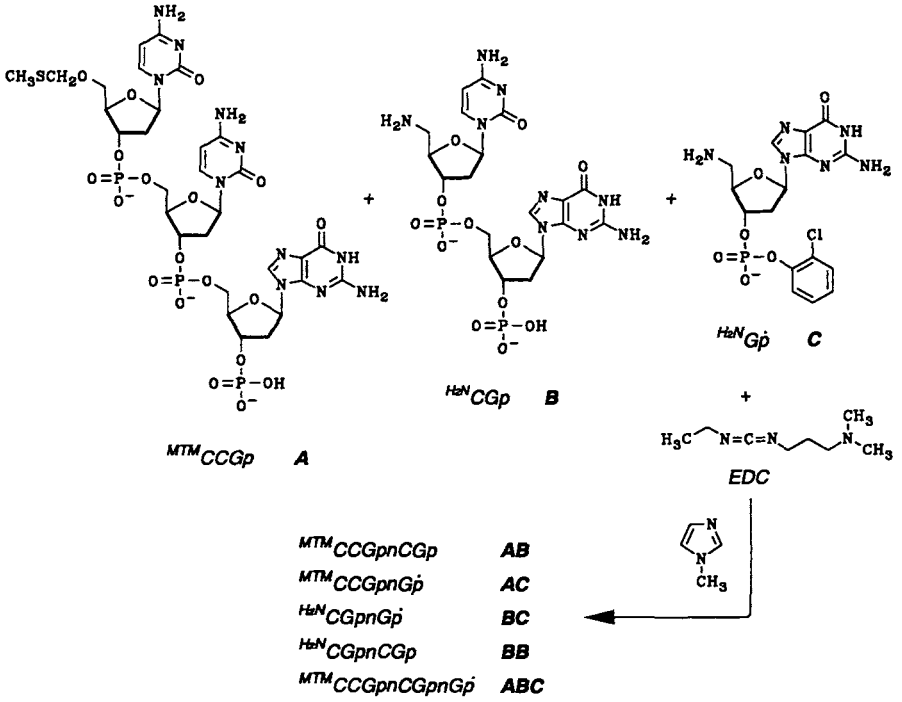

Fig. 1. Overall reaction of the self-replicating system from **A**, **B**, and **C**.

^{N3}CGp (**B''**) + ^{H2N}CGp^{PTE} (**B'**) ⟶ ^{N3}CGpnCGp^{PTE} (**BB'**) (3)

^{N3}CGp (**B''**) + ^{H2N}Gṗ (**C**) ⟶ ^{N3}CGpnGṗ (**BC'**) (4)

^{N3}CGp (**B''**) + ^{H2N}Cṗ (**X**) ⟶ ^{N3}CGpnCṗ (**BX**) (5)

^{HO}CCGCGp (**AB''**) + ^{H2N}Gṗ (**C**) ⟶ ^{HO}CCGCGpnGṗ (**ABC'**) (6)

^{MTM}CCGp (**A**) + ^{H2N}CGGṗ (**BC''**) ⟶ ^{MTM}CCGpnCGGṗ (**ABC''**) (7)

In order to detect possible catalytic, cross-catalytic, or autocatalytic effects (couplings) caused by the products, the condensation reaction between **A**, **B**, and **C**, as well as the above model reactions were followed in the presence of the oligodeoxynucleotides ^{HO}CCGG (**AC'**),[13] ^{HO}CCGCG (**AB'''**),[13] and ^{Me}CCGCGGṗ (**ABC'''**).[2, 3] These oligonucleotides have the same base sequences as the products **AC**, **AB**, and **ABC**, but differ in respect of their backbone and the terminal groups. Investigations into the template-dependent synthesis of ^{MTM}CCGpnCGGṗ from ^{MTM}CCGp and ^{H2N}CGGṗ showed that ^{Me}CCGCGGṗ (**ABC'''**), which has a central 3′-5′-phosphodiester bond, displays the same template properties within the limits of measurement as ^{HO}CCGpnCGGṗ, which has a central 3′-5′-phosphoamidate bond.[5] From this, we assume that **AC'**, **AB''**, and **ABC'''** also have at least similar template properties to **AC**, **AB**, and **ABC**, respectively. In the case of template effects of the products, the observed rates always obey the square root law,[3, 4] that is, the reaction order is 1/2 with respect to the template. To determine the apparent rate constants of the template-dependent and -independent reaction pathways (k_a and k_b, respectively) the initial stage of each experimental concentration–time profile was analyzed by means of the computer program SimFit[6g] on the basis of the reaction model portrayed in reactions (8) and (9). **P** and **N** represent the

P + **N** → **PN** (k_b) (8)

P + **N** + 1/2 **T** → **PN** + 1/2 **T** (k_a) (9)

3′-phosphate and 5′-amino components respectively, **PN** the reaction product, and **T** the template. Provided that **PN** and **T** have the same sequence, the initial concentration of **PN** was taken to be the template concentration, and the sum of the concentrations (**PN** + **T**) was then evaluated. The results of these model studies are summarized in Figure 3 in a semiquantitative fashion.

The template-independent synthesis of the products **PN** can proceed from single-stranded reactants as well as double-stranded complexes between the reactants. Complexes of the type **P** · **N**, **P** · **P**, and **N** · **N** are conceivable. Investigations into the synthesis of hexameric 3′-5′-phosphoamidates from trimeric reactants have shown that a complementary trimer pair—as, for example, in model reaction 7—always react faster than a noncomplementary trimer pair, both in the template-dependent (autocatalytic) and in the template-independent reaction pathways.[14] The enhancement of the template-independent synthetic pathway was explained by the stabilization of the transition state through stacking interactions when two **P** · **N** complexes come together.[14] Thermodynamic data for the formation of complexes of oligonucleotides show that complexes with less than three consecutive CG base pairs are unstable under the reaction conditions and can only exist in very small concentrations.[15] The reactions (4) and (5) should thus represent G-G and G-C couplings in single-stranded reactions: $k_{GG} = 1.8 \times 10^{-2}\ M^{-1}s^{-1}$, $k_{GC} = 0.9 \times 10^{-2}\ M^{-1}s^{-1}$. The model reactions (6) and (7) proceed much faster than (4) and (5), respectively. For these model reactions it must be assumed that double-stranded complexes of the type **P** · **P** and **P** · **N**, containing four and three CG base pairs, respectively, participate in the reaction: $k_b(6) \approx 5 \times k_{GG}$, $k_b(7) \approx 4 \times k_{GC}$. In the case of reaction (6), the assumption of a high population of **P** · **P** complexes is supported by the fact that this reaction is first order with respect to **AB''**, and in addition, that no measurable acceleration by **ABC'''** and **AB'''** can be detected. The synthesis of **ABC'** should proceed within a termolecular complex, in which the pentamer **AB''** functions on the one hand as a reaction partner of **C** and on the other as a template (Fig. 3, dashed line). It should be noted, however, that this template-catalysis by a reactant is not an autocatalytic or a cross-catalytic feedback.

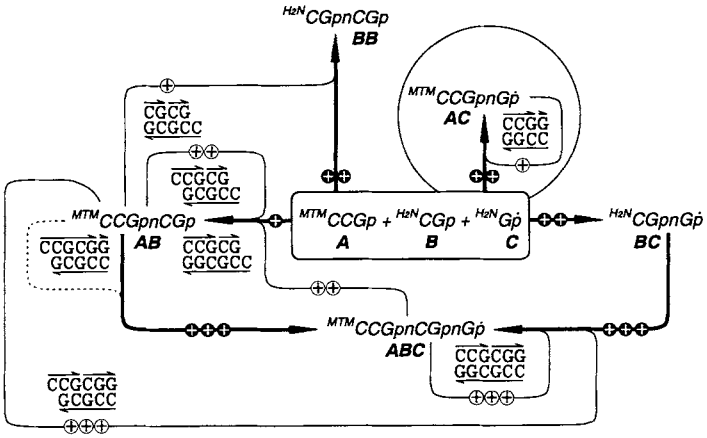

Fig. 3. Reaction scheme of the condensations between **A**, **B**, and **C**. The synthetic pathways to the products are depicted with boldface arrows. The apparent rate constants of the template-independent syntheses are classified as follows (symbols on dark background): ⊕ $k_b < 10^{-2}\ M^{-1}s^{-1}$, ⊕⊕ $10^{-2}\ M^{-1}s^{-1} \le k_b \le 3 \times 10^{-2}\ M^{-1}s^{-1}$, ⊕⊕⊕ $k_b > 3 \times 10^{-2}\ M^{-1}s^{-1}$. The thin lines represent template effects that originate from the templates and lead to the synthetic pathways. The coupling strength (efficiency) of these template effects—as ascertained by using the model templates **AC'**, **AB'''**, and **ABC'''**—are depicted by the quotient $\varepsilon = k_a/k_b$ and are classified as follows (symbols on light background): ⊕ $\varepsilon \le 20\ M^{-1/2}$, ⊕⊕ $20\ M^{-1/2} < \varepsilon < 150\ M^{-1/2}$, ⊕⊕⊕ $\varepsilon \ge 150\ M^{-1/2}$. In the immediate vicinity of the symbols are the relevant termolecular complexes. The arrows above and below the symbols for bases represent the 5′ → 3′ direction. No couplings exist at all between the main product (circled) and the rest of the products. EDC acts as activator.

The whole reaction process of the condensation of **A**, **B**, and **C** can be understood as a catalytic network with a total of six (feedback) couplings (Fig. 3). However, only those couplings with sufficient efficiency (categories ⊕⊕ and ⊕⊕⊕) exert a notable influence. The latter couplings only affect the synthesis of the hexameric template **ABC** and that of its pentameric precursor **AB**, but not the synthesis of the tetrameric main product **AC**. Furthermore, a situation exists where **AB** and **ABC** compete with **AC** to incorporate the common reactants **A** and **C**. If two (noncoupled) self-replicating molecules compete for one or more reactants, the addition of one autocatalyst ought to augment its own synthesis, while the synthesis of the competitor is suppressed. In fact, a comparison of the left and right parts of Figure 2 shows that the formation of the tetramer **AC** decreases in the presence of the hexameric model template **ABC'''**, whereas the autocatalysts **AB** and **ABC** are clearly formed more quickly. Broadly speaking, this finding can be regarded as a first, though very concealed, example of information transfer and selection. A true ("Darwinian") selection process will only be realized in a system in which the autocatalytic growth of the template concentration is exponential rather than parabolic.[1e, 4a, 16]

[9] The following standard conditions were chosen for all described reactions: T = 20 °C; 0.2 M EDC; 0.1 M MeIm/pH 7.2; reactant concentrations: 2 mM.

[10] Nucleosil C18, 4 × 250 mm; A: 0.1 M sodium hydrogen carbonate, B: acetonitrile/water 30:70 (v/v); flow rate 1 mL min^{-1}; gradient (B): 18%–28% in 5 min, 28%–42% in 2 min, 42%–50% in 4 min, 50%–75% in 2.5 min, and 0.5 min 75%; detection at λ = 254 nm.

[11] As trace products in the conversion of (**A** + **B** + **C**), all possible oligomerization products of the type $\mathbf{B}_n$, $\mathbf{AB}_n$, $\mathbf{B}_n\mathbf{C}$, and $\mathbf{AB}_n\mathbf{C}$ are assumed ($n > 1$), because each amino reactant ($\mathbf{B}_n$, $\mathbf{B}_n\mathbf{C}$) can in principle be condensed with each 3′-terminal phosphate reactant ($\mathbf{AB}_n$, $\mathbf{B}_n$) to give the corresponding 3′,5′-phosphoamidate. However, with the exception of **ABC**, higher condensation products could not be reliably identified in the HPLC profile.

[12] The elution behavior of the nucleotide reactants on C18 is determined mainly by the terminal groups. Compounds with polar termini, for example **B** and **BB**, elute immediately and hence cannot be separated.

[13] **AC′**, **AB″** and **AB‴** were prepared by solid-phase synthesis (phosphoamidite method). The formation of phosphodiesters between 3′-phosphates and the terminal hydroxy groups of these templates is negligible under the reaction conditions; the templates can be regarded as inert.

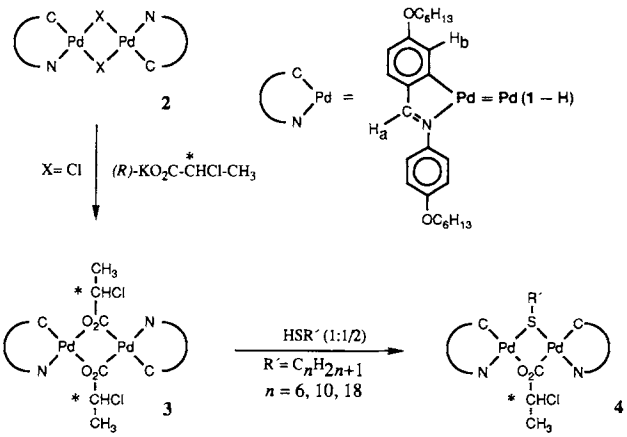
Metallomesogens with a Cholesteric Mesophase**

By *Maria J. Baena, Julio Buey, Pablo Espinet,* Heinz-S. Kitzerow*, and *Gerd Heppke*

Metallomesogens, liquid crystals containing coordinated metal atoms, have seen a rapid development in the last few years.[1] In a very short period metallomesogens displaying almost every mesophase previously found in organic mesogens—calamitic (nematic and smectic phases), discotic, polymeric, and amphiphilic phases—have been reported. Rather surprisingly, chiral metallomesogens are scarce; only one material displaying a chiral smectic C mesophase (and hence ferroelectric) had been reported[2] until very recently, when two paramagnetic chiral smectic C metallomesogens were described.[3] There is no representative of the chiral nematic (cholesteric, Ch) mesophase. We report here the first metallomesogens displaying cholesteric behavior, which have been obtained within the now-large family of metallomesogens derived from *ortho*-palladated imines and azines.[2, 4]

p-$C_6H_{13}O$–C_6H_4–CH=N–C_6H_4–OC_6H_{13}-p **1**

Imine **1** reacts with $Pd(OAc)_2$ in acetic acid (50 °C, overnight) to give complex **2a** (X = OAc) which shows no mesogenic behavior (crystalline/217 °C/isotropic) (Scheme 1).[5] Treatment of **2a** in CH_2Cl_2 with HCl (Pd/HCl = 1/1) affords **2b** (X = Cl) (crystalline/176 °C/S_A/247 °C/isotropic) which, on treatment with (*R*)-$KO_2CCHClMe$ in CH_2Cl_2/acetone (1/1), yields complex **3** (crystalline/152 °C/S_A/186 °C/isotropic/203 °C/S_A'/224 °C/isotropic). All the complexes gave satisfactory C,H,N-analyses. The mesogenic behavior of the planar complex **2b** and the nonmesogenic behavior of the folded compound **2a** are to be expected from our previous results,[2, 4] but the meso-



Scheme 1. **2a**: X = OAc; **2b**: X = Cl.

[**] This work was supported by the Comisión Interministerial de Ciencia y Tecnología (Project MAT90-0325), the Consejería de Cultura de la Junta de Castilla y León, Iberdrola, (stipend for M. J. B.), and the Deutsche Forschungsgemeinschaft (SFB 335).

genic behavior of the folded complex **3** is unexpected and remarkable. We had expected that the 2-chloropropionato ligand, which is bulkier than the acetato ligand, would disturb the molecular packing and hinder mesogenic behavior more; however, the dipole moment introduced with the C–Cl bond apparently increases the strength of the intermolecular interactions enough to compensate for the unfavorable steric effect, and **3** is indeed mesomorphic. The compound is also remarkable for its double-melting behavior.[6]

Treatment of **3** with mercaptans HSC_nH_{2n+1} (Pd/HSR = 2/1) produces the mixed-bridge compounds **4** (**4a**: $n = 6$; **4b**: $n = 10$; **4c**: $n = 18$). The complexes gave satisfactory C,H,N-analyses; molecular weight determinations in $CHCl_3$ and ^1H NMR spectra are also consistent with a bridged dinuclear compound. We discuss only the data obtained for **4a**; the results for **4b** and **4c** are similar. The easily observable signals for H_a ($\delta = 7.83$, s) and H_b ($\delta = 7.49$ d, $J = 2.34$ Hz) indicate a unique *cis* arrangement of the two imine moieties in the complex.[7] In contrast, the chloro- and carboxylato-bridged complexes **2** and **3**, respectively, have *trans* structures. To the best of our knowledge bridged dimers with *ortho*-palladated ligands either have *trans* structures (and hence have no net dipole moment) or are mixtures of *trans* and *cis* isomers, in which the latter is typically the very minor component. The carboxylato/thiolato bridges of the compounds described here seem to force a *cis* arrangement. This is particularly interesting in view of possible applications of these compounds as frequency doublers in nonlinear optics, where a net dipole moment is required.[8]

All three compounds **4a–4c** show a cholesteric mesophase in a certain range of temperatures (**4a**: crystalline/140 °C/cholesteric/157 °C/isotropic; **4b**: crystalline/109.5 °C/S_A/115.2 °C/cholesteric/137.6 °C/isotropic; **4c**: crystalline/92 °C/S_A/128.3 °C/cholesteric/131.7 °C/isotropic). In order to characterize their chirality in mesophase conditions,[9] we measured the pitch of the cholesteric phase induced by **4a** and **4c** in mixtures of the respective chiral metallomesogen and RO-TN 404 (a commercial, wide-range nematic solvent from Hoffmann-La Roche, containing cyano-substituted biphenyls and pyrimidine derivatives), by applying the Grandjean–Cano method.[10]

The cholesteric mixtures show a temperature dependence of the pitch p which is characterized by a divergence of p and an inversion of the helical screw sense with changing temperature (Fig. 1). At low temperatures we found a right-handed cholesteric helix ($p > 0$), at high temperatures a left-handed one ($p < 0$). Similar inversions of the helical pitch have been previously reported in organic systems.[11–14] The induced chirality can be described by the helical twisting power $k = p^{-1}c^{-1}$, which is independent on the concentration c of the chiral compound for most substances. From the temperature dependence of this quantity (Fig. 2) the inversion temperatures $T_i = 89.8$ °C for compound **4a** and $T_i = 100.4$ °C (extrapolated) for compound **4c** are obtained.

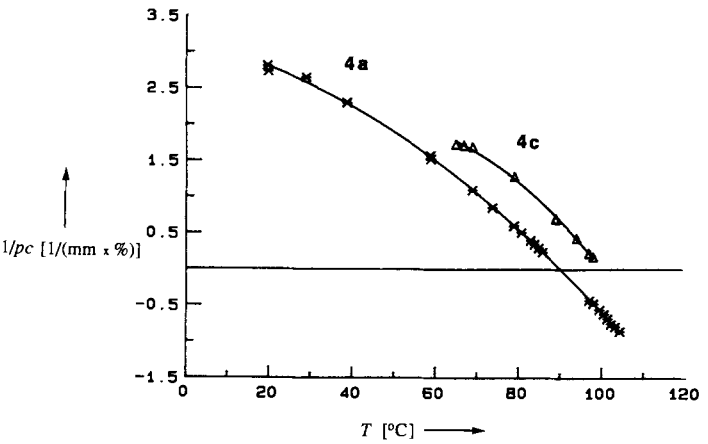

Fig. 2. Temperature dependence of the helical twisting power for **4a** and **4c** (p = cholesteric helical pitch, c = concentration of the chiral compound in wt%).

The relationship between the unusual temperature dependence of the pitch of the cholesteric helix and the chemical structure of the new mesogens calls to mind earlier investigations on mesogenic esters of (*S*)-1,2-propanediol and (*R,R*)-2,3-butanediol which also show a helix inversion.[12] Like compounds **4a–4c**, the structure of these esters is characterized by two large mesogenic groups that are connected to each other. It was proposed that the inversion effect is due to the presence of two conformers, which induce cholesteric structures with opposing helical screw senses, and which are in temperature-dependent thermodynamic equilibrium. The observations presented here seem to confirm that molecules containing two mesogenic wings tend to favor helix inversion. However, it should be noted that twist inversion has also been observed in compounds exhibiting a different type of structure.[13, 14]

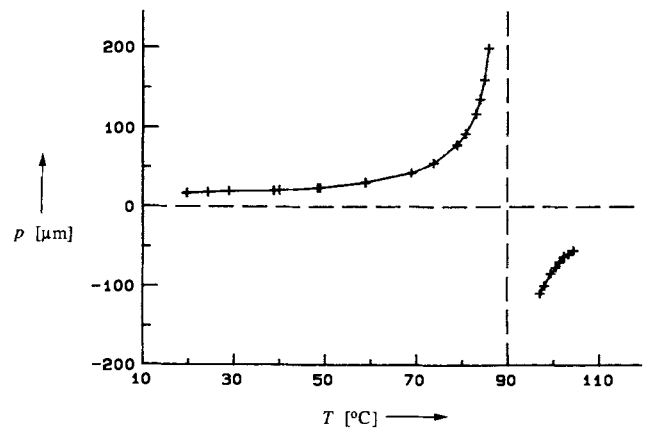

Fig. 1. Temperature dependence of the cholesteric pitch p for a mixture of 21.2 wt% of **4a** and 78.8 wt% of the commmercial nematic solvent RO-TN 404.

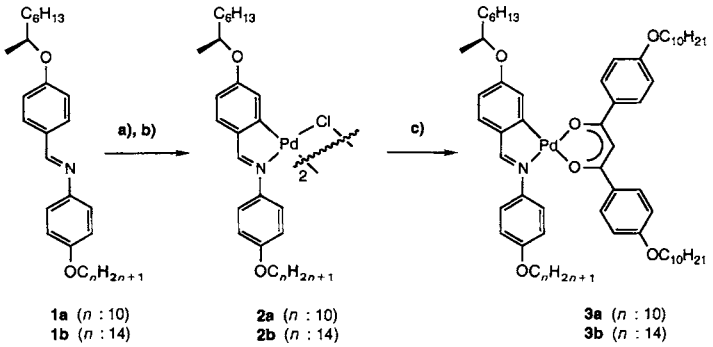
Improved Properties of Ferroelectric Liquid Crystals from Palladium β-Diketone Complexes**

By *María Jesús Baena, Pablo Espinet,* María Blanca Ros, José Luis Serrano,** and *Amaya Ezcurra*

Ferroelectric liquid crystals (FLCs)[1] are one of the main interests in research on liquid crystals. Although many organic mesogens are known for FLCs, there are few examples of analogous metal complexes[2, 3] and most of them have high transition temperatures that affect their thermal stability. The first FLC metallomesogen reported,[2] a dimeric *ortho*-palladated azine complex (a mixture of isomers), displayed some undesirable drawbacks: high transition temperatures (K 102 °C SmC* 119 °C SmA 149 °C I) leading to thermal instability in the mesophases and a very long switching time (nearly one second). We then discovered that altering the highly symmetrical molecular shape of these dimers results in lower melting points.[4] Whereas dimeric compounds $[\{(C\text{-}N)PdCl\}_2]$ (C-N = *ortho*-palladated imine with long alkyl chains) form SmA and SmC phases at high temperatures,[5] monomeric complexes [(C-N)Pd(acac)] form N and SmA phases at noticeably lower temperatures. Thus the monomeric complexes may be taken repeatedly to the isotropic state without signs of decomposition.[4]

Taking these two observations into account, we aimed to synthesize ferroelectric metallomesogens with low transition temperatures, which would allow potential applications as both liquid crystals and in nonlinear optics.[6] Our first approach was the introduction of chirality in the alkyl chains of the above-mentioned acac complexes,[4] but this did not lead to the desired SmC* phases. However, analogues **3a** ($n = 10$) and **3b** ($n = 14$) with modified β-diketonate ligands formed a ferroelectric SmC* liquid crystalline phase at lower temperatures, showed thermal stability under working conditions, and displayed switching times a *thousand times shorter* than that of the first ferroelectric metallomesogen described.[2]

The synthesis of compounds **3** from **1** (Scheme 1) proceeded via the dinuclear complexes **2**. The reaction of **2a, b**[5] with thallium(I) β-diketonate[7] in CH_2Cl_2 provided the mononuclear complexes **3a** and **3b**, respectively. Both complexes gave correct elemental analyses, and ^1H NMR and IR spectra in full agreement with the structure proposed.



Scheme 1. a) $Pd_3(AcO)_6$/AcOH; b) HCl/MeOH; c) Tl [*p*-$H_{21}C_{10}OC_6H_4CO)_2$-CH]/CH_2Cl_2.

The thermotropic behavior of the β-diketonate derivatives was studied by optical microscopy and differential scanning calorimetry (DSC) at 10 K min^{-1} (Table 1). Smectic A and chiral smectic C phases were assigned on the basis of their optical textures and confirmed by X-ray diffraction studies. The chiral smectic C phase showed a characteristic focal-conic texture, and no dechiralization lines were observed. The ferroelectric properties of these two β-diketonate complexes—spontaneous polarizations (P_s), switching times (τ_E), viscosities (γ_c), and tilt angles (θ)—are summarized in Table 1.[8] Figure 1 shows the dependence of P_s and θ of the ferroelectric palladium complexes on temperature.

These metallomesogens have moderate P_s values with maxima at 29 and 22 nC cm^{-2} for **3a** and **3b** respectively, and maximum optical tilt angles very close to the optimum tilt angle in FLCs of 22.5°. It is noteworthy that the tilt angles could not be calculated from the X-ray diffraction measurements, as no significant differences between the layer thickness at the SmA and SmC* phases were detected.[10]

The switching times of the new ferroelectric palladium complexes **3a, b** are on the order of milliseconds. Although this is noticeably slower than the switching times of typical organic FLCs (microseconds), these new complexes switch three orders of magnitude faster than the first palladium

(*S*)-**1a**	57.0	−5.5 [c]	−33	25.4	77
(*S*)-**1b**	58.7	−3.5 [c]	−24	21.8	64

[a] 15% binary mixture of **1** [14]. [b] $T = T_c - 10$ °C (T_c = SmA–SmC* transition temperature determined by optical microscopy). [c] Maximum value.

complex described,[2] and are even faster than polymeric FLCs[11] and in the range of FLCs from dimeric organic compounds.[12]

The dielectric behavior of **3a, b** was also studied at different frequencies (Fig. 2) by using a method described elsewhere.[9a, 13] The SmC* phase is characterized, as usual, by an additional contribution to ε', which is mainly due to the helical structure. This additional contribution decreases and finally disappears when the frequency increases, as the responsible mechanism relaxes.

It is worth noting that none of the Schiff bases used as ligands are liquid crystals (**1a**, C-I 60.3 °C and **1b**, C-I 44.3 °C). The ferroelectric behavior of these chiral organic compounds was evaluated in 15% binary mixtures[14] in which the SmC* phase was induced. As can be seen in Table 2, the $P_s/\sin\theta$ values extrapolated to 100% **1a** and **1b** are 77 and 64 nC cm^{-2}, respectively, at temperatures 10 K below the SmA–SmC* transition of the corresponding binary mixture.

If we compare the $P_s/\sin\theta$ values of compounds **1** and **3** (data independent of T), it seems that the P_s values of the chiral organic ligands slightly decrease on complexation. However, since complexation leads to dramatic structural changes, which undoubtedly modify the arrangement of the molecular dipoles at the SmC* mesophase, this may be a misleading effect and further studies will be needed before any conclusions about the effect of the metal atom can be reached.

Experimental Procedure

3a, b: To a stirred solution of the corresponding dimeric complex **2** (0.05 mmol) in 20 mL of CH_2Cl_2 was added a stoichiometric amount of thallium β-diketonate. A white precipitate of TlCl immediately formed. After stirring at room temperature for 1 h, the precipitate was filtered off and the solution was filtered through a 20-cm silicagel column using CH_2Cl_2 as an eluent. The resulting solution was concentrated to dryness, and the residue was triturated in a mixture of acetone/ethanol (1/3) to obtain a yellow solid, which was filtered and washed with ethanol. Complexes **3a** and **3b** gave correct elemental analyses. Representative spectroscopic data of the palladium complexes: **3a** IR (Nujol), $\tilde{\nu}$[cm^{-1}] = 1608(C=N), 1591 (C=O), 1544 (C=C), 1254 (C-O), 1023 (C-O); ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.83–0.95 (m, 12H, CH_3), 1.24–1.60 (m, 50H, CH_2), 1.39 (d, 3H, J(H,H) = 6.0 Hz, CH_3), 1.72–1.90 (m, 8H, CH_2), 3.9–4.0 (m, 6H, CH_2), 4.59 (m, 1H, CH), 6.60 (dd, 1H, J(H,H) = 8.24 Hz, J(H,H) = 2.40 Hz, CH), 6.61 (s, 1H, CH), 6.79 (d, 2H, J(H,H) = 8.97 Hz, CH), 6.90 (d, 2H, J(H,H) = 8.97 Hz, CH), 6.93 (d, 2H, J(H,H) = 8.97 Hz, CH), 7.29 (d, 1H, CH), 7.31 (d, 2H, J(H,H) = 8.79 Hz, CH), 7.42 (d, 2H, J(H,H) = 8.79 Hz, CH), 7.71 (d, 2H, J(H,H) = 8.79 Hz, CH), 7.97 (d, 2H, J(H,H) = 8.97 Hz, CH), 7.99 (s, 1H, CH).

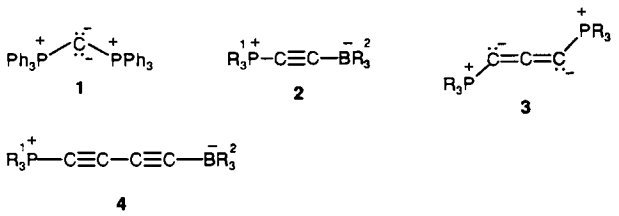
1,3-Bis(triphenylphosphoranylidene)allene and Tribenzyl(4-methyldiphenylphosphoniobutadiynyl)borate, Stabilized C_3 and C_4: Confirmation of a Hypothesis

By *Hans Jürgen Bestmann,* Dariusch Hadawi, Harald Behl, Matthias Bremer,* and *Frank Hampel*

Different hypotheses have been put forth for the formation of fullerenes. According to one proposal, for example, small carbon units arise from C_1 and grow into long chains, which in turn then form rings.[1, 2] The fragmentation of fullerenes apparently proceeds by the continuous cleavage of C_2 units.[3] C_3 is found in interstellar space.[4] The chemical reactivity of short-lived C_1, C_2, C_3, and C_4 is being investigated in particular by Skell et al.[5] The question of whether these small, highly reactive species can be stabilized can be answered as follows:[6] In hexaphenylcarbodiphosphorane **1**, a compound known for many years, a C_1 unit is stabilized by two triphenylphosphane donor molecules.[7] In complex **2**, which has a betaine structure, stabilized C_2 was prepared by attaching a donor molecule (tertiary phosphane) to one C atom and an acceptor molecule (borane) to the other C atom.[6] We postulated[6] that C_3 should also be stabilized by two donor molecules in **3** and C_4 with a donor molecule and an acceptor molecule at either end of the C_4 chain as in **4**. We report here on our verification of this postulate.



1 **2** **3**

4

A compound of type **4** could be prepared quite easily, since its synthesis follows that of **2**. Treatment of diacetylene **5**[8] with ethylmagnesium bromide (**6**) provided the Grignard compound **7**, which was allowed to react with chlorodiphenylphosphane (**8**) to give the light-sensitive butadiynyldiphenylphosphane (**9**).[9, 10] The reaction of **9** with butyllithium (**10**) in THF provided the corresponding Li compound **11**,[11] which was converted into the borate complex **13** by treatment with tribenzylborane (**12**).[12] The reaction of **13** with methyl iodide led to the desired product, tribenzyl(4-methyldiphenylphosphoniobutadiynyl)borate (**15**).[13] The crystals that formed from the reaction mixture were recrystallized from dimethylformamide. They are colorless, light sensitive, and can be stored in a refrigerator only for a limited time. The spectroscopic data of **15** are listed in the references.[13] Two C≡C stretching bands are found in the IR spectrum. In the ^{13}C spectra the values of the coupling constants $J(P,C)$ decrease as expected from C_α to C_β (C_α: $^1J(P,C) = 193.8$ Hz, C_β: $^2J(P,C) = 38.1$ Hz); C_γ does not couple with the P atom. The signal for C_δ cannot be recognized due to the effects of the quadrupole moment of the neighboring B atom, similar to the case for compounds of type **2**.[6] The positions of the ^{31}P NMR and ^{11}B NMR signals indicate that both atoms are tetracoordinate, as in **2**.

Recrystallization of **15** from dimethylformamide provided crystals suitable for an X-ray structure determination; the resulting structure is shown in Figure 1.[14a] The solvent dimethylformamide is included in the crystal lattice. The diacetylene character of the betaine compound is apparent. The distances between C1 and C2, and C3 and C4 (120.5(6) and 121.1(7) pm, respectively) correspond to those of triple bonds. The C2–C3 separation, 136.1(6) pm, is in accord with that of a single bond between two sp-hybridized C atoms.[15] The P1–C4 distance is 171.7(5) pm and that between B1 and C1 159.5(7) pm. These bond lengths are almost identical to the analogous data for compound **2** with $R^1 = C_6H_5$, CH_3, $R^2 = C_6H_5$. The structure of **15**, like that of **2**, is also not linear but slightly bent.

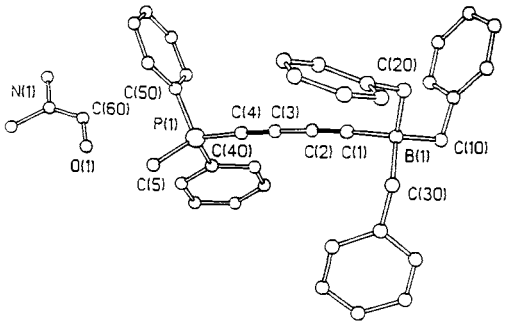

Fig. 1. Crystal structure of **15**. Selected bond angles [°]: B1-C1-C2 176.7(5), C1-C2-C3 177.0(5), C2-C3-C4 179.2(5), P1-C4-C3 175.7(5).

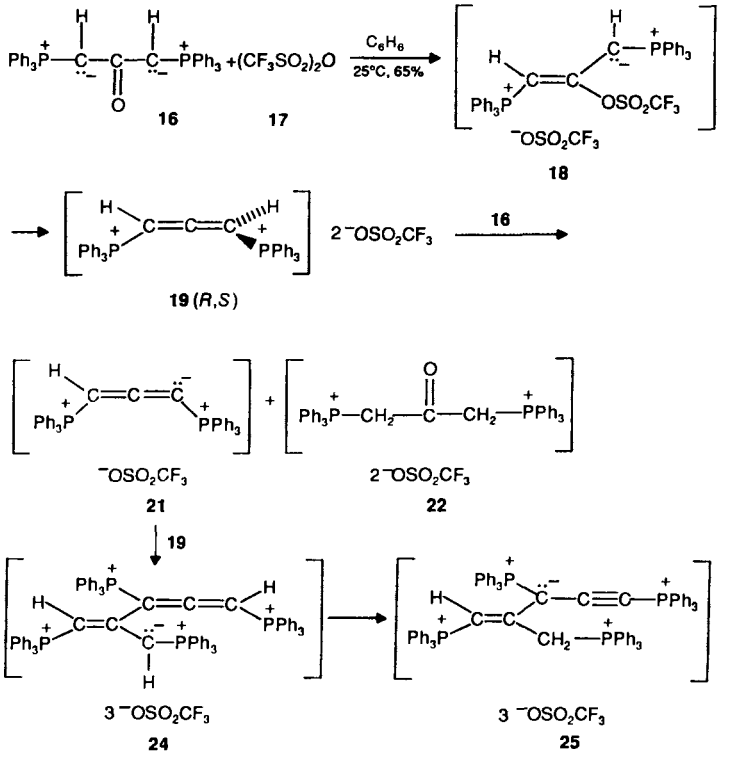
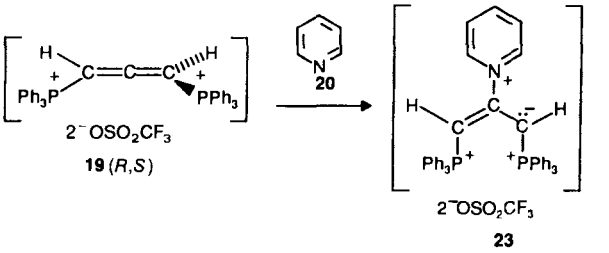
The synthesis of a compound of type **3** was more difficult. The final successful synthesis is outlined here. 1,3-Dibromoacetone was converted into bisphosphonium ylide **16**[16] and then treated with trifluoromethanesulfonic anhydride (**17**) in benzene. Besides allene-1,3-diylbisphosphonium trifluoromethanesulfonate (**19**), compound **25**[17] and bisphosphonium salt **22** formed. The compounds were separated by fractional crystallization from dichloromethane/ether. We assume that **16** and **17**,in analogy to reactions of other acyl ylides, react to give primarily *O*-trifluromethylsulfonated phosphonium triflate **18**[18] which is not isolable but is converted into **19** by an E1-cb-type reaction. We explain the simultaneous formation of **22** and **25** as follows: allenediylbisphosphonium salt **19** reacts with unreacted bisylide **16** by ylide transfer[19] to yield **22** and the "half ylide" **21**, which attacks the middle, strongly electrophilic C atom of the cumulene unit of **19**. The resulting intermediate **24** is converted into **25** by a proton shift. Consistent with this proposed mechanism, **25** is formed when **19** is treated with one mole equivalent of a base such as sodium (bistrimethylsilyl)amide (**26**).[20] Under optimized conditions the formation of **22** and **25** can be suppressed in the reaction of **16** with **17**.



The strong electrophilicity of the middle C atom in **19** is also evident from the quantitative reaction of **19** upon dissolution in pyridine. Compound **23** is obtained both in solution and after evaporation of the solvent as an oily compound; this bis(phosphonio)propenide cation[21] shows typical NMR signals.[22]



Both **19**[23] and **25** were characterized by X-ray crystallography. The structure of **19** does not have any special features. The result of the structure analysis of **25** is shown in Figure 2.[14b] In this molecule overburdened with phenyl groups, the geometry about the triple bond is not linear (C1-C2-C3-P2; for angles and distances see Fig. 2), as is also the case in **15**.

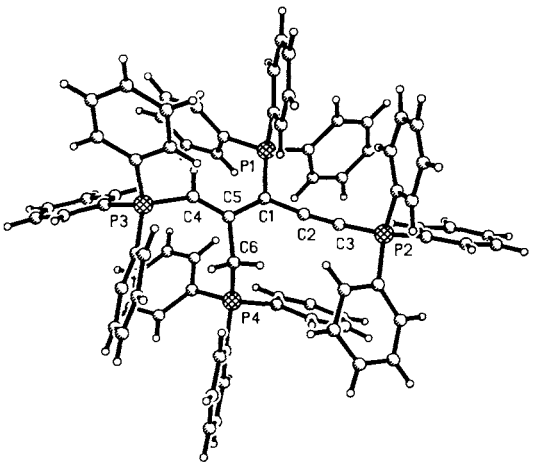


Fig. 2. Crystal structure of **25**. Selected bond lengths [pm] and angles [°]: C2-C3 120.7(23), C4-C5 134.3(21), C5-C6 155.7(19); C1-C2-C3 173.3(15), C2-C3-P2 156.5(14).

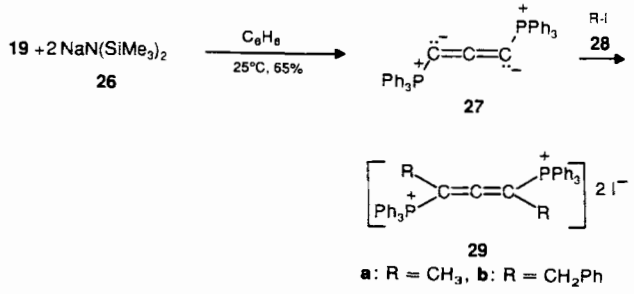
Treatment of allenediylbisphosphonium salt **19** with two mole equivalents of sodium (bistrimethylsilyl)amide (**26**)[20] led to **27**, the first compound of type **3**.[24] In the IR spectrum of this orange-red amorphous powder the absorption at 2060 cm^{-1} provides evidence of a cumulene system. In the ^{31}P NMR spectrum a signal is observed at $\delta = -10.4$, which is shifted to much higher field relative to that of **19** ($\delta = +19.9$); we observed a similar upfield shift previously in the conversion of vinylphosphonium salts into phosphacumulene ylides.[25] Only the signals of the aromatic H atoms are seen in the ^1H NMR spectrum of **27**. In the ^{13}C NMR spectrum the triplet at $\delta = 159.2$ ($^2J(P,C) = 30$ Hz) is assigned to the middle atom of the allene unit. The equivalent quasi-anionic C atoms give rise to a doublet of doublets at $\delta = 36.8$ ($^1J(P,C) = 122.1$ Hz, $^3J(P,C) = 15.3$ Hz).

The reaction of **27** with alkyl iodides provides further support for the proposed structure. The reaction with methyl

iodide yields (1,3-dimethylallene-1,3-diyl)bisphosphonium diiodide **29a**; with benzyl iodide the corresponding bis(benzyl) derivative **29b** is obtained.[26] Characteristic allene bands are found in the IR spectrum. In the ^{13}C NMR spectra of **29a** and **29b** no coupling is evident between the two P atoms and the middle C atom of the allene unit; in **27**, on the other hand, the corresponding C atom gives rise to a triplet. One explanation is that the $^2J(P,C)$ coupling constant in allenediyl(bisphosphonium) salts happens to be zero.[27]



The synthesis of **15** and **27** provides experimental confirmation for the simple theoretical approach for stabilizing "naked" C_1 to C_4 previously proposed. We assume that in general C_n units, when n is odd, can be stabilized by two donor molecules (e.g. phosphanes) at either end of the C_n unit; when n is even, C_n can be stabilized analogously by one donor molecule and one acceptor molecule.

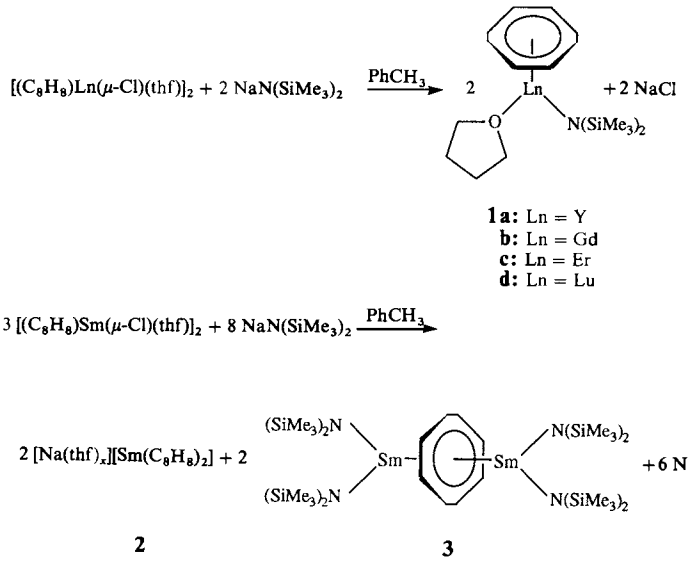
$[\{(Me_3Si)_2N\}_2Sm\{\mu\text{-}(\eta^8\text{:}\eta^8\text{-}C_8H_8)\}\text{-}Sm\{N(SiMe_3)_2\}_2]$: An Inverse Organolanthanoid Sandwich Complex**

By *Herbert Schumann,* Jörn Winterfeld, Lothar Esser,* and *Gabriele Kociok-Köhn*

Dedicated to Professor Hans Bock on the occasion of his 65th birthday

The planar π-electron system of aromatic hydrocarbons is not only capable of forming bonds to metals on one of its faces leading to half-sandwich or sandwich complexes such as $[(\eta^6\text{-}C_6H_6)Cr(CO)_3]$ or ferrocene, respectively, but can also bind metals on both of its faces (inverse sandwich); this was first observed in triple-decker sandwich complexes discovered by Werner and Salzer in 1972.[1] Later Schmidbaur et al.[2] found that "Menshutkin complexes"[4] which are formed between benzene and either arsenic, antimony, and bismuth, and which have been known since 1882[3] also belong to the type of inverse-sandwich complexes. Also the 10 π-electron system of the cyclooctatetraene dianion can bind a metal atom to each of the two faces of the arene, giving rise to symmetric complexes such as [K(diglyme)-$\{\mu\text{-}(\eta^8\text{:}\eta^8\text{-}C_8H_4Me_4)\}$K(diglyme)][5] and [K(diglyme)-$\{\mu\text{-}(\eta^8\text{:}\eta^8\text{-}C_8H_8)\}Ce(\eta^8\text{-}C_8H_8)$] (diglyme = diethyleneglycol dimethyl ether)[6] as well as to unsymmetric complexes such as $[(\eta^8\text{-}C_8H_8)Nd(thf)_2\{\mu\text{-}(\eta^2\text{:}\eta^8\text{-}C_8H_8)\}Nd(\eta^8\text{-}C_8H_8)]$[7] and $[Li(thf)_2\{(\mu\text{-}(\eta^2\text{:}\eta^8\text{-}C_8H_8)\}Sm\{CH(SiMe_3)_2\}_2]$.[8]

We have now found in the form of (cyclooctatetraene)bis{di[bis(trimethylsilyl)amido]samarium(III)} **3**, a simple inverse sandwich complex of a 4f element: (cyclooctatetraene)lanthanoid chloride (lanthanoid = Y, Gd, Er, and Lu) react as expected with sodium bis(trimethylsilyl)amide to form the half-sandwich complexes **1a–d**. In contrast to that, (cyclooctatetraene)samarium chloride reacts under the same conditions to give the inverse-sandwich complex **3** and sodium bis(cyclooctatetraene)samarate(III) **2** (Scheme 1).



Scheme 1.

The extremely air- and moisture-sensitive compounds **1a–d** can be obtained in a crystalline form in yields of 42–58%. The presence of THF in **1a–d** can clearly be shown by elemental analyses, as well as by NMR spectroscopy (^{1}H, ^{13}C) of the diamagnetic compounds **1a** and **1d**. We obtained well-shaped single crystals of the lutetium complex **1d** by slow cooling of a saturated cyclopentane solution. The X-ray crystal structure analysis[9] revealed three symmetrically independent molecules per asymmetric unit. The solid-state structure of **1** is shown in Figure 1. Assuming that the centroid of the η^8-bound cyclooctatetraene unit is the center of this ligand, we can consider the lutetium atom to be pseudo-trigonal planar coordinated. The mean Lu–C distances

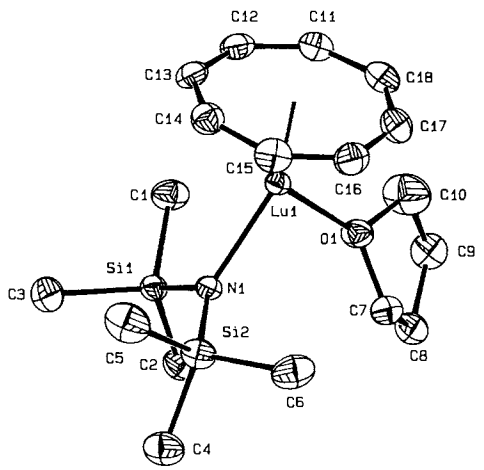


Fig. 1. Structure of **1d** (one molecule of the asymmetric unit [9], without hydrogen atoms). Selected bond lengths [pm] and angles [°] with standard deviations: Lu1-N1 219.7(3), Lu1-O1 231.1(2), Lu1-$(C_8H_8)_z$-(molecule 1) 172.9, Lu...C1 317.0(4); N1-Lu1-O1 86.4(1), $(C_8H_8)_z$(molecule 1)-Lu1-N1 147.0, $(C_8H_8)_2$ (molecule 1)-Lu1-O1 126.0, Lu1-N1-Si1 113.1(2), Lu1-N1-Si2 123.5(2), N1-Si1-C1 108.5(2), N1-Si1-C2 114.2(2), N1-Si1-C3 113.9(2), N1-Si2-C4 113.3(2), N1-Si2-C5 111.7(2), N1-Si2-C6 110.4(2).

[**] Organometallic Compounds of the Lanthanoids, Part 79. This work was supported by the Fonds der Chemischen Industrie (doctoral grant for J. W.), the Deutsche Forschungsgemeinschaft, and the Bundesministerium für Bildung und Wissenschaft in the framework of the research area "Synthese und Strukturaufklärung niedermolekularer Verbindungen". Part 78: H. Schumann, M. Glanz, H. Hemling, F. H. Görlitz, *J. Organomet. Chem.* in press.

(251.2(5) pm for molecule 1, 250.0(5) pm for molecule 2, and 251.2(5) pm for molecule 3) are in good agreement with the corresponding bond length in $[(\eta^8\text{-}C_8H_8)Lu(o\text{-}C_6H_4CH_2NMe_2)(thf)]$ (255(1) pm),[10] when the different coordination numbers are taken into consideration. The mean value of the Lu–N bond (219.3(3) pm) is similar to the Y–N bond length in $[(\eta^5\text{-}C_5Me_5)_2Y\{N(SiMe_3)_2\}]$ (227.4(5) and 225.3(5) pm),[11] provided that the smaller ionic radius of lutetium has been taken into consideration. Noteworthy is the asymmetric conformation of the amido ligand. Thus, in molecule 1 the Lu-N1-Si1 angle (113.1(2)°) is 10.4(4)° smaller than the Lu1-N1-Si2 angle. The same is true for the N1-Si1-C1 angle (108.5(2)°), which is smaller than the N1-Si1-C2 (114.2(2)°) and N1-Si1-C3 (113.9(2)°) bond angles. Analogous distortions also occur in molecules 2 and 3. It is, however, unclear whether these distortions are due to γ-agostic bonds between the methyl groups of the amido ligand and the Lewis acidic lanthanoid center, or only a result of packing effects, since the shortest Lu–C(methyl) distance in molecule 1 is 317.0(4) pm (322.0(4) pm in molecule 2 and 318.0(4) pm in molecule 3), and this is very large in comparison with Lu–C-σ bonds such as in $[\{Me_2Si(\eta^5\text{-}C_5Me_4)\}(\eta^5\text{-}C_5H_4)Lu\{CH(SiMe_3)_2\}]$ (d(Lu–C$_\alpha$) = 236.5(7) pm)[12] or in $[(\eta^5\text{-}C_5H_5)_2Lu(CH_2SiMe_3)(thf)]$ (d(Lu–C$_\alpha$) = 237.6(17) pm).[13]

The compounds **2** and **3** are also very highly air and moisture sensitive. Compound **3** is thermally extremely stable (decomp 196 °C). In the ^{1}H NMR spectra of **2** and **3**, the influence of the paramagnetism of the Sm^{3+} ion on the protons of its ligands is evident. Thus, the C_8H_8 ring of **3** (in [D$_8$]toluene) has a chemical shift of $\delta = 9.29$, and the $SiMe_3$ groups a chemical shift of $\delta = -2.32$, whereas in the ^{1}H NMR spectrum of **2** (in [D$_8$]THF) the signal of the C_8H_8 ring occurs at $\delta = 13.3$ ($\nu_{1/2}$ = 50 Hz). Compounds **2** and **3** can be separated easily from each other as a result of their differing solubilities in various solvents. Whereas the sandwich complex **2** is only highly soluble in polar solvents such as THF, the trimethylsilyl groups in **3** provide for good solubility in nonpolar solvents such as *n*-hexane or cyclopentane. Suitable single crystals of **3** for an X-ray crystal structure analysis[14] were obtained by cooling a saturated *n*-hexane solution. In the crystal, **3** is a centrosymmetric molecule with an inverse sandwich structure (Fig. 2). Like the Lu^{3+} ion in **1d**, the Sm^{3+} ions in **3** have a pseudo-trigonal planar coordination sphere consisting of one η^8 interaction with the bridging cyclooctatetraene unit and two σ bonds to the amido ligands. The Sm–cyclooctatetraene vectors are almost perpendicular (88.9°) to the plane of the cyclooctatetraene ligand. The amido ligands are eclipsed; the N1-Sm-Sm'-N2' torsion angle is 4.45(8)° (Fig. 3). Owing to the competition of

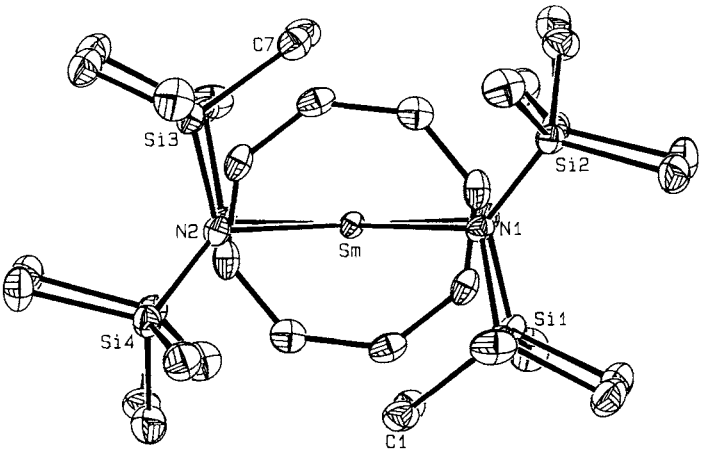

Fig. 3. View of **3** along the Sm–Sm axis.

two Sm^{3+} ions for ten π electrons of the bridging eight-membered ring, the mean Sm–C distance is 14.3 pm greater than the corresponding distance in $[Li(thf)_2\{\mu\text{-}(\eta^2\text{:}\eta^8\text{-}C_8H_8)\}Sm\{CH(SiMe_3)_2\}_2]$ (d(Sm–C) = 268.8(5) pm).[8] The mean Sm–N bond length (228.0(2) pm), however, correlates with the corresponding distances in the homoleptic amido lanthanoid complexes $[Eu\{N(SiMe_3)_2\}_3]$ (d(Eu–N) = 225.9(9) pm)[15] and $[Nd\{N(SiMe_3)_2\}_3]$ (d(Nd–N) = 229(9) pm).[16] Remarkably, in the solid-state structure of **3**, one methyl carbon atom (C1 and C7) of each amido ligand is found very close to the lanthanoid center. The Sm···C1 distance is 310.5(2) pm and the Sm···C7 distance 297.0(2) pm. These distances are thus significantly shorter than the sum of the van der Waals radii of a methyl group and of a samarium(III) ion, but somewhat longer than the Sm–C(methyl) bonds in $[(\eta^5\text{-}C_5Me_5)_2Sm\{\mu\text{-}Me)AlMe_2\}_2(\mu\text{-}Me)\}_2Sm(\eta^5\text{-}C_5Me_5)_2]$ (d(Sm–C(Me)) = 274.3(16) and 275.0(16) pm)[17] or in $[(\eta^5\text{-}C_5Me_5)_2SmMe(thf)]$ (d(Sm–C(Me)) = 248.4(14) pm).[17] Due to the close contact of the two methyl groups to the Lewis acidic lanthanoid center, the Sm-N1-Si1 (110.5(1)°) and the Sm-N2-Si3 angles (106.8(1)°) are smaller than the Sm-N1-Si2 (130.2(1)°) and the Sm-N2-Si4 angles (133.0(1)°). The same is true for the N1-Si1-C1 and N2-Si3-C7 bond angles (107.8(1) and 107.1(1)°, respectively), which are about 5–8° smaller than the usual N1-Si1-C and N2-Si3-C angles. Finally, Scheme 2 summarizes complexes that also display the type of γ-agostic interaction, which has been described for **3**.

Experimental Procedure

All operations were carried out under an argon atmosphere in dry, oxygen-free solvents.

General procedure: To a suspension of $[(\eta^8\text{-}C_8H_8)Ln(\mu\text{-}Cl)(thf)]_2$ [22, 23] (Ln = Y, Gd, Er, Lu, Sm) in toluene (50 mL) at −60 °C was added $NaN(SiMe_3)_2$, the mixture was continually stirred and allowed to warm up to room temperature over 12 h. After the solvent had been removed under vacuum, the residue was treated with *n*-hexane (70 mL), stirred, allowed to settle, and the solution was decanted off. When the extract was cooled to −25 °C, **1a**–**d** and **3** were obtained in a crystalline form.

1a: $[(\eta^8\text{-}C_8H_8)Y(\mu\text{-}Cl)(thf)]_2$ (0.88 g, 1.46 mmol), $NaN(SiMe_3)_2$ (0.54 g, 2.94 mmol); yield 0.58 g (47 %) colorless crystals; m.p. 119 °C (decomp); correct C, H, N analysis; ^{1}H NMR (270 MHz, C_6D_6, 25 °C, TMS): δ = 6.59 (s, 4H, C_8H_8), 3.12 (m, 2H, THF), 0.94 (m, 2H, THF), 0.06 (s, 9H, $SiMe_3$); ^{13}C NMR (67.9 MHz, C_6D_6, 25 °C, TMS): δ = 94.9 (d, $^1J(^{13}C,^{89}Y)$ = 2.5 Hz, C_8H_8), 71.2 (THF), 25.0 (THF), 3.9 ($SiMe_3$); MS (70 eV): *m/z* (%): 353 (19) $[M^+-THF]$, 338 (41) $[M^+-THF-Me]$, 193 (26) $[(C_8H_8)Y^+]$, 146 (100) $[Si_2Me_6^+]$.

1b: $[(\eta^8\text{-}C_8H_8)Gd(\mu\text{-}Cl)(thf)]_2$ (0.66 g, 0.89 mmol), $NaN(SiMe_3)_2$ (0.33 g, 1.80 mmol); yield 0.45 g (51 %) colorless crystals; m.p. 112 °C (decomp); correct C, H, N analysis; MS (70 eV, ^{158}Gd): *m/z* (%): 422 (3) $[M^+-THF]$, 407 (9) $[M^+-THF-Me]$, 262 (9) $[(C_8H_8)Gd^+]$, 146 (100) $[Si_2Me_6^+]$.

1c: $[(\eta^8\text{-}C_8H_8)Er(\mu\text{-}Cl)(thf)]_2$ (0.54 g, 0.71 mmol), $NaN(SiMe_3)_2$ (0.26 g, 1.42 mmol); yield 0.30 g (42 %) pink crystals; m.p. 116 °C (decomp); correct C, H, N analysis; MS (70 eV, ^{166}Er): *m/z* (%): 430 (1) $[M^+-THF]$, 415 (5) $[M^+-THF-Me]$, 270 (2) $[(C_8H_8)Er^+]$, 146 (100) $[Si_2Me_6^+]$.

1d: $[(\eta^8\text{-}C_8H_8)Lu(\mu\text{-}Cl)(thf)]_2$ (0.64 g, 0.83 mmol), $NaN(SiMe_3)_2$ (0.30 g, 1.64 mmol); yield 0.49 g (58 %) colorless crystals; m.p. 143 °C (decomp); correct C, H, N analysis; ^{1}H NMR (270 MHz, C_6D_6, 25 °C, TMS): δ = 6.55 (s, 4H, C_8H_8), 3.08 (m, 2H, THF), 0.91 (m, 2H, THF), 0.07 (s, 9H, $SiMe_3$); ^{13}C NMR (67.9 MHz, C_6D_6, 25 °C, TMS): δ = 94.0 (C_8H_8), 71.8 (THF), 25.0 (THF), 4.2 ($SiMe_3$); MS (70 eV): *m/z* (%): 439 (13) $[M^+-THF]$, 424 (36) $[M^+-THF-Me]$, 279 (14) $[(C_8H_8)Lu^+]$, 146 (100) $[Si_2Me_6^+]$.

3: $[(\eta^8\text{-}C_8H_8)Sm(\mu\text{-}Cl)(thf)]_2$ (0.71 g, 0.98 mmol), $NaN(SiMe_3)_2$ (0.48 g, 2.62 mmol); yield 0.22 g (32 %) orange crystals; m.p. 196 °C (decomp); correct C, H, N analysis; ^{1}H NMR (270 MHz, [D$_8$]toluene, 25 °C, TMS): δ = 9.29 (s, 2H, C_8H_8), −2.32 (s, 9H, $SiMe_3$); ^{13}C NMR (67.9 MHz, [D$_8$]toluene, 25 °C, TMS): δ = 82.6 (C_8H_8), 1.9 ($SiMe_3$).

[9] Crystal data for **1d**: $C_{18}H_{34}LuNOSi_2$, M_r = 511.61, colorless, parallelepiped-shaped crystals ($0.24 \times 0.15 \times 0.42$ mm^3), monoclinic space group $P2_1/c$ (no. 14), a = 2392.8(6), b = 2115.0(2), c = 1320.4(4) pm, β = 104.68(3)°, $V = 6464(3) \times 10^{-30}$ m^3 determined from 96 reflections with 24° < 2θ < 27.4°, Z = 12, ρ_{calcd} = 1.58 g cm^{-3}, λ = 71.069 pm, $\mu(Mo_{K\alpha})$ = 47.0 cm^{-1}. Absorption correction by ψ scan. 10448 independent reflections in the range 1° ≤ 2θ ≤ 50° with ω-2θ scan were measured at a crystal temperature of −155 °C on an Enraf-Nonius diffractometer. The structure was solved with Patterson (SHELXS-86) and difference Fourier methods (SHELX-76). The full-matrix least-squares refinement of 622 parameters derived from 9346 reflections with $F_o > 4\sigma(F_o)$ converged at R = 0.022 and R_w = 0.029 ($w = 1/\sigma^2(F_o) + 0.0003F_o^2$). The three symmetrically independent molecules in an asymmetric unit have no close contacts. By superimposing any pair of molecules such that the Lu, O, and N atoms coincide, we find that the C_8H_8 ring atoms also coincide. This result contrasts with that observed for the THF molecules and the amido ligands, which exhibit considerable angular dispersion about the Lu–O and Lu–N bonds, respectively. Thus, three clearly different conformers are present in the asymmetric unit [14].

Investigation of the Surface Structure of the Zeolites FAU and EMT by High-Resolution Transmission Electron Microscopy**

By *Viveka Alfredsson,* Tetsu Ohsuna, Osamu Terasaki,* and *Jan-Olov Bovin*

Synthetic zeolites, produced in tons per year, are important products in the chemical industry. Although synthetic zeolites are primarily used in detergents, synthetic faujasites (FAU) are most widely employed as catalysts and as adsorbents of water or organic compounds. Naturally occurring zeolites are used in wastewater treatment. The cubic zeolite FAU has, aside from its recently discovered hexagonal polymorph EMT, the most open zeolite framework known (although there exist aluminium phosphates with less dense structures). The structure of FAU consists of sodalite cages (truncated octahedra) joined with double six-rings.[1] The sodalite cages are related by inversion in all four directions.

Andersson, Manchester, and S. W. Carr, Unilever Research, for providing the EMT specimen and A. Carlsson, Lund, for help with the computer graphics. T. O. thanks Prof. D. Watanabe, Iwaki, for encouragement; O. T. thanks Prof. S. Andersson, Lund, for encouragement. We also thank the National Center for Electron Microscopy, Lawrence Berkeley Laboratory, and the U.S. Department of Energy for providing the NCEMSS and IFTOOL software programs. A. Fogden, Lund, is acknowledged for linguistic comments on the text.

So-called supercages with a diameter of 13 Å are thus created within the framework. Along the [110] directions, channels are formed by interconnection of the super cages. The space group of FAU is $Fd\bar{3}m$, and its lattice parameter is 24.7 Å.[2] In the closely related structure of EMT (space group $P6_3/mmc$, $a = 17.3$ Å, $c = 28.8$ Å),[2] the double six-rings possess mirror symmetry along the c axis. Two different types of large cages are thus formed—one larger than the cubic supercage and one smaller with an elliptical shape. Until recently the hexagonal polytype was merely a hypothetical structure known as Breck's structure six (BSS),[1, 3] but it can now be synthesized with crown ethers serving as crystallization templates.[4] Intergrowths of the two polymorphs have been confirmed: the recurrent twinning of FAU results in a local formation of EMT,[5] and in the synthesis of both structures crown ethers direct the crystallization towards EMT or FAU.[6] Slabs of the faujasite structure (Fig. 1) are then connected either by inversion (FAU) or by mirror reflections (EMT).

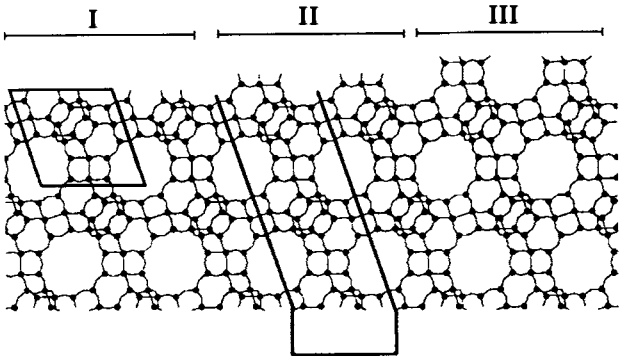

Fig. 1. Projection of the FAU structure along [110]. The Si atoms are drawn as black spots and the Si-O-Si bonds as bent lines. A FAU slab is defined as the part of the structure between the two heavy diagonal lines. In the hexagonal EMT structure the slabs are related by mirror symmetry. The upper edge of the structure displays the atom arrangements of the three structure models used in the computer image simulations. The rhombus marks the possible surface growth unit at the steps of the surface.

High-resolution transmission electron microscopy (HRTEM) gives a direct image of crystal structures, their defects, and local variations. It is an indispensable method for the elucidation of intergrowths. HRTEM investigations of zeolites have previoulsy been limited to the Si-richer forms. Usually the zeolite structures disintegrate rapidly in the electron beam, and it has been suggested that the amount of water retained by the framework, in turn depending on the number of aluminum atoms, is a critical factor.[7] Hence, the hydrophobic ultrastable zeolite Y (USY) and silicalite are normally better suited to HRTEM investigations. The NaY zeolites (FAU) (Si/Al = 2.8) investigated here, which are in the original form, were sufficiently stable for the atomic structure images of clean surfaces to be recorded for the first time. We attribute this stability to the high crystallinity of the samples. The crystals investigated contained practically no defects, apart from the twin planes in FAU, which are equivalent to intergrowths of narrow slabs of the hexagonal structure (EMT). The surfaces were also clear and sharp without contamination. The possibility of observing untreated zeolites is, of course, a great advantage, as the samples do not have to be altered in any way prior to the HRTEM studies and can thus be imaged exactly in their original form.

The crystals of the zeolite samples were dispersed in water or acetone and then collected on perforated carbon films. Since the crystals were not crushed, the HRTEM images show the form of the surfaces as they appear after synthesis or after the hydrothermal treatment (USY). The Si/Al ratios were 2.8 for the FAU samples and 3.1 for the EMT samples. The electron micrographs were recorded with a JEM-4000EX microscope operated at 400 keV. This microscope has a spherical aberration constant of 1.0 mm and a resolution limit of 1.6 Å. A television camera (Gatan 622) with an image intensifier was employed to permit focusing at very low beam intensities. The crystal structure of FAU determined from X-ray diffraction was taken as a basis for creation of the different models of the {111} surfaces with the IFTOOL programs (R. Kilaas, Berkeley, personal communication). The image simulations were performed with the NCEMSS programs.[8] The optical parameters of the microscope were used in the calculations.

The form of the FAU crystals investigated in this work is determined almost exclusively by {111} faces. Other kinds of faces sometimes appear at the intersection of the {111} faces, but these are poorly defined. The crystals are often wedge-shaped, becoming thinner at the position where four {111} faces intersect. This intersection, corresponding to the corner of an octahedron, is rounded off in all cases. The particles are crystalline to the very edge. It has been observed that the shape of the zeolite crystals can be altered when they become amorphous during irradiation,[9] but this was not the case here.

There are clear resemblances between the experimental images and the model of the crystal and surface structure shown in Figure 1. When a FAU crystal is viewed along the [110] direction, one set of channels is parallel to the electron beam. Between the large channels, recognizable as large white spots in the micrographs (Fig. 2), three smaller white

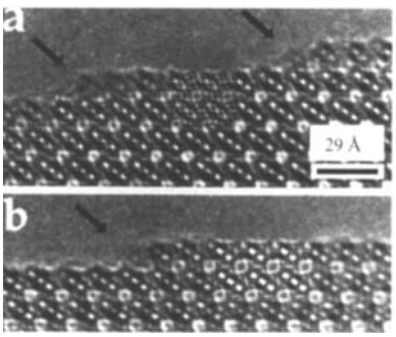

Fig. 2. HRTEM surface profile images of a {111} surface on a FAU (NaY) crystal recorded with the electron beam parallel to [110]. a) Image of the surface showing two surface steps, each 14.3 Å high, close to the octahedral top of the crystal. A simulated image for the surface model I (see Fig. 1) calculated for a focus of −900 Å and a crystal thickness of 50 Å is inserted. b) A surface step situated on the same {111} surface. A computer-simulated image of model I calculated for a focus of −700 Å and a crystal thickness of 50 Å is inserted.

spots are visible, which correspond to smaller channels in the framework (see Fig. 1). The middle spot is a projection of three Si-O four-rings, while the other two correspond to six-rings of Si-O. The dark spots at the centers of the large channels are artefacts due to insufficient transfer by the objective lens for reflections with small scattering vectors.[10, 11]

The {111} surfaces of the FAU crystals observed in this investigation are always terminated identically. Since the

surface terminates in the middle of the large channels, the edge seen in the image resembles the edge of a postage stamp. The most likely surface structure was determined by comparison of HRTEM images with computer simulations for three types of surface models (see Fig. 1). All of the models have the same number of "dangling" bonds, each ending with an oxygen atom. The hydrogen atom in the terminal OH group[1] was ignored in the image calculations since it is a very weak scatterer of electrons. The three surface models were chosen to terminate in the following ways:

1) with an incomplete sodalite cage (model I),
2) with a complete sodalite cage (model II),
3) with a complete double six-ring (model III).

The computer-simulated HRTEM images were calculated for crystal thicknesses of 50 Å and 200 Å with an objective lens focus series ranging from 0 to −900 Å (underfocus conditions) in steps of 100 Å. The simulated images displaying the closest match to the experimental ones are inserted in Figures 2 and 3.

The electron micrographs in Figures 2a and b show two different areas of the same {111} surface of a FAU crystal. Since the crystal is wedge-shaped and its support angle is unknown, the focus conditions are not identical. The variation in the crystal thickness has very little influence when the thickness does not exceed 200 Å. For this crystal surface model I gives the best fit, although distinguishing between model II with the completed sodalite cage and model I is somewhat difficult. The third model is easily rejected, since the surface in this model typically possesses two types of depressions: one is formed by the half-sphere of the supercage, has only the "closed" SiO_4 bonds on its surface, and has a diameter of 13 Å—the perfect size to accommodate a small 55-atom metal cluster; the second depression created by half of a sodalite cage, is significantly smaller (6.2 Å), and has an entrance surrounded by six dangling Si-O-H groups.

The crystal imaged in Figure 3a reveals an intergrowth of the hexagonal zeolite EMT and FAU, its cubic counterpart.

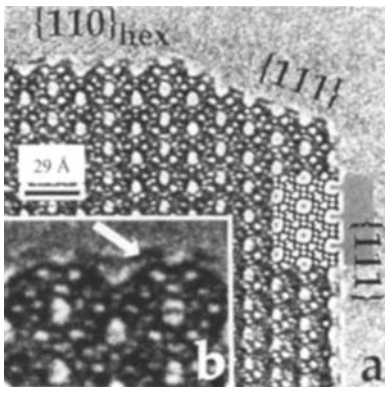

Fig. 3. a) Surface profile image of an EMT crystal along [110] showing the intergrowth with FAU (right). A simulated image for model III calculated for a crystal thickness of 200 Å and a focus of −700 Å is inserted. b) The enlargement of the $\{110\}_{hex}$ surface shows clearly (arrow) the contrast from the double Si-O six-rings, similar to that on the {111} surface.

The right side of the crystal is FAU. As was the case for FAU in Figure 2, the surfaces of the crystal are clear and without contamination. Crystals of EMT are plate shaped; as the specimen here is imaged end-on, the projection distance is great (several hundred Å). The inserted image was calculated for a crystal thickness of 200 Å. The {111} surface of the FAU part of the crystal (Fig. 3a, on the right) displays a structure image closely related to that of model III (see Fig. 1). This is apparent on comparison of the simulated image of focus −700 Å with the experimental one. Models III and I posess the common feature of completed double six-rings. The image of the $\{110\}_{hex}$ surface (the horizontal crystal surface in Fig. 3b) exhibits a similar termination of the surface structure. Since the EMT structure arises from chemical twinning[12] of unit-cell-width slabs of the FAU structure (marked in the model in Fig. 1) with mirror reflection as the twin operation, the EMT $\{110\}_{hex}$ surface would be expected to consist of unit-cell-width $\{111\}_{cubic}$ surface planes of the FAU structure. This is the appearance of the $\{110\}_{hex}$ surface in the image displayed in Figure 3b with a surface termination made up of double six-membered Si-O rings.

The {111} surface structures are different, as shown in Figures 2 and 3a. Although the latter possesses the large depression made out of the supercage, the sodalite cage is now closed. In this case the supercage is more complete, and the overall surface is more "rugged". The different surface structures can be traced back to the manner of preparation of the two samples. The EMT sample was synthesized with crown ethers as templates,[4] whereas the FAU crystal was prepared by the conventional hydrothermal method. The rugged {111} surface structures of the EMT crystal can be explained by the fact that the crown ether is probably adsorbed on the surface during the crystal growth and gives rise to more complete cages when incorporated in the crystal.

In several cases we found steps on the {111} surface of FAU crystals (see Figs. 2a and b). These steps are positioned at the ends of the crystal growth planes, suggesting that the crystal growth took place along the {111} surface one layer at the time. This implies that the growth rate is high along the {111} surface and relatively low perpendicular to it. The {111} planes will thus dominate the shape of the crystal, conferring upon it an octahedral habit, which is confirmed by the HRTEM images. The height of the surface steps is identical to the distance of unit cell repeat in this direction (14.3 Å). In the three steps shown in Figure 2, the detailed image contrasts differ in structure, permitting some conclusions to be drawn. The step at the left in Figure 2a is situated near the top of the octahedral crystal and has an appearance distinct from that of the other two steps. It comprises two unfinished rows of the unit marked as a rhombus in Figure 1, which contains the three small channels (the three white spots in the HRTEM image). This image is obtained from the projection of the top triangular {111} surface of the crystal. The step at the right in Figure 2a displays only one unfinished unit with the small channels but is of almost the same contrast as the adjacent one. This indicates that the row is nearly as long as the whole surface. The contrast of the third step (Fig. 2b) is weaker than the former one, implying that this row of units is shorter in projection. Similar surface steps caused by incomplete {001} planes have been observed by HRTEM for EMT.[13]

USY, the ultrastable form of FAU, is obtained after several post-synthesis treatments. The standard means of accomplishing a siliceous form of zeolite Y is hydrothermal treatment. First, Na^+ is exchanged for NH_4^+, whereupon the zeolite is heated in steam. This process is repeated several times in order to remove the aluminum as completely as possible, after which the zeolite is leached in acid to extract the intrachannel aluminum species. This treatment creates "mesopores", believed to be large cavities in the framework.

The HRTEM images of USY crystals differ from those of NaY (see Fig. 2), although the average crystal structure images appear similar and the crystal habit is also preserved. For USY zeolites we never observed clean crystal edges such as those in NaY. The crystals of USY are always completely enclosed by a thin amorphous layer (see Fig. 4). We are certain that these layers are not caused by irradiation, since they are present even when the bulk of the crystal is undamaged. We have also found USY crystals to be more stable under the electron beam than the zeolite forms containing aluminum. Under the amorphous layer, surface steps (see arrow in Fig. 4) similar to those observed in FAU (see Fig. 2) can be discerned. This may be taken as an indication that the structure as a whole is not changed in any significant way during the dealumination process and that the amorphous constituents originally come from inside the particle (possibly from the mesopore areas) and not from the surface. Alternatively, it may be postulated that the crystal disintegrates during dealumination, starting with the outer surface layers, progressing one layer at the time. In this case the step will actually be the antithesis of a growth mechanism.

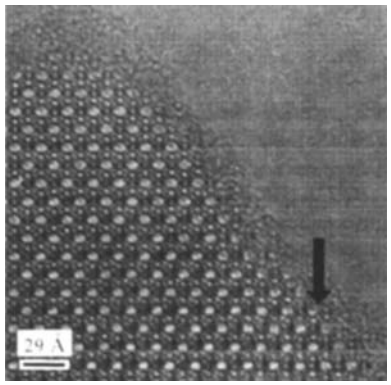

Fig. 4. HRTEM image of the top part of an octahedrally shaped USY crystal (dealuminated FAU zeolite), recorded with the electron beam parallel to [110]. The {111} surface, and most likely the whole crystal, is covered with a thin amorphous layer approximately 25 Å thick. The arrow points to what might have been a step on the {111} surface before the dealumination process.

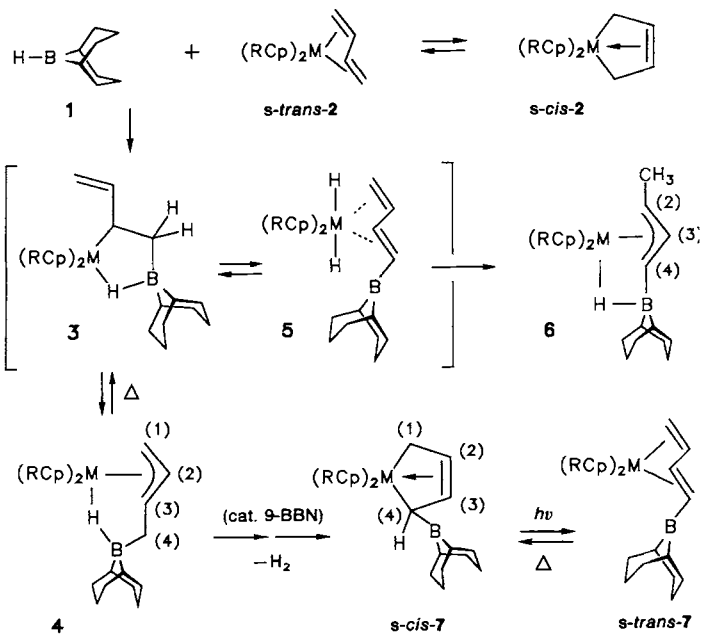
C–H-Activation by Reaction of (Butadiene)zirconocenes and -hafnocenes with 9-BBN**

By *Gerhard Erker*,* *Ralf Noe*, *Doris Wingbermühle*, and *Jeffrey L. Petersen*

Activation and designed functionalization of organic substrates in organometallic compounds through the simultaneous influence of two metallic centers on a ligand is a matter of current discussion. Experimental realization of this basically attractive concept, however, could only be accomplished in a few cases.[1] Generally, a combination of transition elements, for the most part even of two like d-block elements, were employed. Had there been more attempts to combine the effects of a transition metal and an electropositive main group element, there would probably have been more examples of dimetallic activation of organic compounds to date. With just that combination we achieved stoichiometric C-H activation of 1,3-butadiene under fairly mild reaction conditions.

We treated (η^4-butadiene)bis(η^5-methylcyclopentadienyl)-zirconium (**2a**)[2] with a molar equivalent of 9-borabicyclo[3.3.1]nonane (9-BBN, **1**; in the following the abbreviation 9-BBN is used for the borane as well as the boryl substituent). The addition is complete in toluene at room temperature within 5 h, and compound **4a** can be isolated in 86% yield (Scheme 1). The product **4a** has a metallacyclic framework with an endocyclic (π-allyl)zirconocene unit. The assignment of the structure follows from the characteristic



Scheme 1. M = Zr, R = CH_3 (**a**), R = H (**b**); M = Hf, R = H (**c**).

IR (KBr): $\tilde{\nu}$ = 3111, 1440, 1014, 804 cm^{-1} (Cp)

s-*trans*-**7c**: ^{1}H NMR ([D$_8$]toluene, 200 MHz, 300 K): δ = 4.87 and 4.79 (s, each 5 H, Cp), 3.45–3.33 (m, 2 H, 2-H, 3-H), 3.02 (m, 1 H, 1-H *syn*) 2.2–1.8 (br m, 14 H, 9-BBN), 1.52 and 1.25 (m, each 1 H, 1-H *anti*, 4-H); ^{13}C NMR ([D$_8$]toluene, 50 MHz, 235 K): δ = 99.8 and 99.6 (C-2, C-3), 99.4 and 99.0 (Cp), 76.5 (^1J(C,H) = 127 Hz, C-4), 57.8 (^1J(C,H) = 154 and 147 Hz, C-1), 38.1, 38.0, 32.5, 29.5, 26.6, 22.0 (*C*H$_2$, 9-BBN), 30.9, 26.3 (*C*H, 9-BBN).

Thermolysis of **4a** (approximately 2 wt% in toluene, 100 °C, 40 min) yields nearly quantitatively **6a**, isomeric to **4a**, as a rearrangement product. It still contains a μ-H bridge spanning Zr and B. Typical spectroscopic data indicate that a crotyl ligand carrying a 9-BBN substituent at C4 (for numbering see Scheme 1) is now η^3-coordinated to the zirconium atom. X-ray structure analysis (Fig. 1[4]) shows **6a** to possess

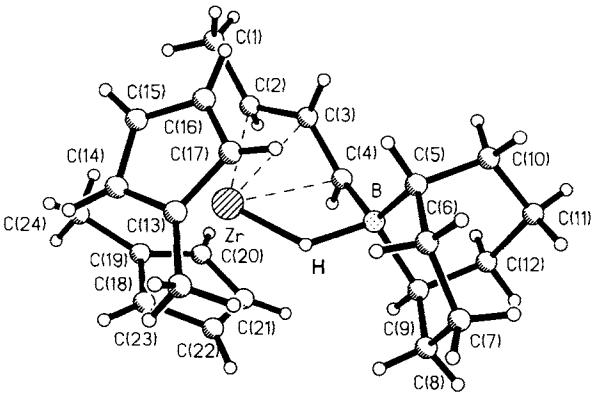

Fig. 1. Molecular structure of **6a** in the crystal. Selected bond lengths [Å] and angles [°]: Zr-C(2) 2.564(8), Zr-C(3) 2.449(8), Zr-C(4) 2.425(6), Zr-H 1.85(6), B-H 1.40(5), B-C(5) 1.604(11), B-C(9) 1.611(12), B-C(4) 1.556(12), C(3)-C(4) 1.393(12), C(2)-C(3) 1.402(13), C(1)-C(2) 1.492(13); center of Cp(1)-Zr-center of Cp(2) 128.0, Zr-H-B 119.1(40), H-B-C(4) 94.2(28), C(5)-B-C(9) 107.5(7), C(1)-C(2)-C(3) 124.9(8), C(2)-C(3)-C(4) 122.9(8), C(3)-C(4)-B 127.7(6).

a metallacyclic skeleton with a 1,3-disubstituted (π-allyl)zironocene unit. The two substituents (CH$_3$ at C2 and R$_2$B of 9-BBN at C4) have a *syn* arrangement with respect to the π-allyl unit.

This thermally induced isomerization, after addition of the boryl substituent, involves transfer of a hydrogen atom from one end of the initial butadiene ligand to the other. We think that this C-H activation first requires the formation of a (σ-allyl)metallocene **3** from **4**.[5] β-Hydride elimination in the five-membered metallacycle[6] then leads to an equilibrated mixture of isomers of [η^2-1-(9-BBN)butadiene]dihydridozirconocene (**5**) from which the observed product **6** can be formed by intramolecular hydrozirconation.

A [1-(9-BBN)butadiene]zirconocene unit is preformed in the hypothetical intermediate **5** of this reaction sequence. By successive addition and elimination of hydrido ligands, it should be possible to generate an isomer of **5** with hydrido ligands in a *cis* arrangement. The *cis* isomer can then form a stable [η^4-1-(9-BBN)butadiene]metallocene by eliminating molecular hydrogen. This was actually accomplished: addition of 9-BBN to [η^4-butadiene]zirconocene (**2b**) at room temperature yields the metallacyclic compound **4b**. Subsequent thermolysis (100 °C, 1 h) leads to a 9:1 mixture of the zirconium complex **6b** containing a boryl-substituted crotyl ligand and the [s-*cis*-η^4-1-(9-BBN)butadiene]zirconocene (s-*cis*-**7b**). At 100 °C, product **7** formed by H$_2$-elimination competes with the rearrangement product **6**. A high yield of [η^4-1-(9-BBN)butadiene]zirconocene can be obtained by direct transformation of **4b** at an elevated temperature (approximately 100 °C) with more 9-BBN (approximately 10 mole percent) as a catalyst. Mechanistic details of the dialkylborane-induced formation of **7** are presently underway.

Starting from the easily available (s-*cis*-η^4-butadiene)-hafnocene[2], we have developed a simple direct route to [η^4-1-(9-BBN)butadiene]hafnocene. An equimolar mixture of (butadiene)hafnocene and 9-BBN in toluene was stirred for 1 h at 50 °C and heated for another 3 h at 100 °C. The solvent was distilled off, and the residue extracted with boiling *n*-heptane. From the extract, [s-*cis*-η^4-1-(9-BBN)-

butadiene]hafnocene (s-*cis*-**7c**) precipitated as orange crystals in approximately 50% yield.[7] Photolysis of s-*cis*-**7c** (10% solution in toluene) quantitatively yields the s-*trans*-**7c** isomer, which in turn isomerizes to the more stable s-*cis*-**7c** above 0°C [s-*trans*-**7c** → s-*cis*-**7c**: $\Delta G^{\neq}$ (300 K) = 22.6 ± 0.5 kcal mol^{-1}].[8]

Our experiments show that C–H bonds in simple organic substrates can be easily activated by using a combination of a main group element and a transition metal. Since many complexes with combinations of moieties containing d-block metals and main group elements are now easily accessible,[9] we shall devote attention to these "heterodimetallic" compounds as stoichiometric reagents or catalysts for the activation of organic substrates.

BOOKS

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Book Reviews

The Chemistry of Organophosphorus Compounds. Vol. 2: Phosphine Oxides, Sulphides, Selenides and Tellurides. (Series: The Chemistry of Functional Groups. Series editor: *S. Patai.*) Edited by *F. R. Hartley*. Wiley, Chichester, 1992. XVI, 647 pp., hardcover £ 160.00.—ISBN 0-471-93056-3

The comments of this reviewer (*Angew. Chem.* **1992**, *104*, 109; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1046) on the first volume of the four-volume series "The Chemistry of Organophosphorus Compounds", which appeared in 1990, are also applicable to this second volume. No major handbook on

organophosphorus chemistry has been published for a long time, and this new series is therefore very welcome. Many developments have occurred in this field during the last twenty years, and it is important that they should be covered in a work of this kind.

The area covered by Volume 2, namely phosphine oxides, sulfides, selenides, and tellurides, is certainly one of the most important parts of organophosphorus chemistry. However, some related compound classes are not covered in this volume, for example the important class of phosphine imides of the type XYZP(=NR), where X, Y, and Z are hydrocarbon groups, which can be regarded as formally related to phosphine oxides. In reviewing this volume it would have been helpful to be given a detailed plan for the complete series. Such an overall plan should at least be provided with Volumes 3 and 4 that are still to be published.

Returning to the present volume, there is no doubt that it offers an up-to-date and (almost) complete description of a very important area of organophosphorus chemistry, which is treated in detail in more than 600 pages. The editor has aimed at emphasizing important recent developments rather than attempting an encyclopedic coverage. The subjects covered by the eight chapters are: structure and bonding in tertiary phosphine chalcogenides (D. G. Gilheaney); structure and stereochemistry of secondary and tertiary phosphine chalcogenides (M. J. Gallagher); electrochemistry of organophosphorus(v) compounds (K. V. S. Santhanam—here the subject matter is by no means limited to phosphine chalcogenides); photochemistry of phosphine chalcogenides (M. Dankowski); spectroscopy of phosphine chalcogenides (G. Davidson); methods for preparing phosphine chalcogenides (A. K. Bhattacharya and N. K. Roy); chemical properties and reactions of phosphine chalcogenides (R. S. Edmundson); coordination chemistry of phosphine chalcogenides, and analytical and catalytic applications (T. S. Lobana).

The volume gives a comprehensive and up-to-date survey of the field of phosphine chalcogenides. Numerous references to the original literature are included, extending to very recent work. Each chapter begins with an introduction giving the background to the topic, and continues up to the most recent developments. As well as giving an overall picture, the chapters indicate where more detailed information can be found.

The chapter on the spectroscopy of phosphine chalcogenides is especially welcome, and covers UV/visible, vibrational, and NMR spectroscopy. It would have been desirable to have a chapter like this in Volume 1, especially with regard to NMR studies, and one hopes that Volumes 3 and 4 will also include these aspects.

The sequence of the chapters does not seem entirely appropriate; in particular, Chapters 6 and 7 (on preparative methods, chemical properties, and reactions) should, in my view, have been placed at the beginning of the book. The term "phosphine chalcogenides" is not interpreted in the same way by all the authors: in some chapters it is taken to mean only tertiary phosphine chalcogenides, whereas in others it includes both secondary and tertiary phosphine chalcogenides. There is also a lack of uniformity in the formula diagrams, with the phosphorus–chalcogen double bonds shown too long in some cases, giving an unattractive appearance. Inconsistencies are also evident in the literature coverage. For example, there is some confusion with regard to citing the Russian literature, which is especially important in organophosphorus chemistry: sometimes only the English translation is cited, whereas in other (rarer) cases only the Russian original is cited; it would have been better always to give both. Where citations in unusual or obscure journals are given, they are not always accompanied by the *Chemical Abstracts* reference. Unfortunately some authors' names have become garbled; sometimes the same name appears several times with different spellings, and so on. Moreover, it seems that the authors essentially interpret phosphine chalcogenides as compounds with only one phosphorus atom; I found no obvious mention of related compounds with two or more phosphine chalcogenide centers (for example, linked together through heteroatoms). Some other related compound types also appear to be absent. Thus, in cases where one needs to make an exhaustive search it is necessary to consult other sources. The volume includes a detailed author index and a (less comprehensive) subject index, both of which are useful.

Now that two of the four volumes have appeared, it can be said that the overall impression is still favorable, and the remaining two volumes are awaited with interest.

Enantioselective Synthesis. Natural Products from Chiral Terpenes. By *Tse-Lok Ho*. Wiley, Chichester, 1992. XII, 324 pp., hardcover £ 56.00.—ISBN 0-471-54819-7.

The development of methods for the synthesis of enantiomers (rather than racemates) is a very important area of research. A new book on this subject will therefore interest many, but expectations will be high. This book deals with an important sub-domain, namely natural product synthesis starting from simple, chiral natural building blocks having high enantiopurity—the chiral pool, in the present case terpenes. The essential point is, of course, that the chirality and the enantiopurity of the building block are transferred, wherever feasible, into the synthetic target compound.

In the preface it is stated that "... there is an apparent lack of a comprehensive summary of terpene-based syntheses" and one sentence later that "... consequently it seems worthwhile to collate and discuss the important contributions in this area". Now it is clearly impossible to treat this huge area in this single, relatively thin volume. A selection must have been made, but it is up to the reader to find out what the selection is. This is the only really serious criticism I have. Nowhere does the author define the actual scope of the book.

The author has restricted himself mainly to multi-step syntheses, which are described and discussed, but with very little background information, and to starting materials that are almost exclusively monoterpenes (citronellene, citronellol, linalool, oxidized derivatives; limonene; menthone, piperitone, perilla aldehyde and related compounds; pulegone; carvone; carenes and thujone; pinenes; camphor and congeners; other terpenes).

The chapter on the camphors, for example, contains about 50 references, whereas the review article on the same subject by Money—which is cited—contains 240 primary references, many of which contain multiple citations. The difference is due to the fact that the latter review covers not only the types of syntheses dealt with in the book, but also all the classical chemistry that has made the multiple functionalizations of the camphors possible. This chemistry is only mentioned in passing in the book, and without real help as to how to get access to it ("... a thorough knowledge of its (camphor's) chemistry is most critical [Money, 1985]").

It is more difficult to judge how comprehensive the coverage of the syntheses is. We again selected the camphors and

made a computer on-line search in *Chemical Abstracts*; almost everything we found there was dealt with in the book. But I also compared with one of our lists of publications that are important for the perfumery industry, and only a fraction of that material was covered. The coverage is thus not comprehensive, but in my opinion a good representative selection has been made.

The book contains a total of about 450 references, almost exclusively from the primary literature. There are also a few theses, abstracts of ACS meetings, private communications, and two books, namely Simonsen's *The Terpenes* and the author's *Polarity Control*. The reader is referred to Simonsen's multivolume text as a source of basic terpene chemistry. It is still an important text, but it appeared in the fifties. If one cites this, then one should at least also give a selection from the many more recent handbooks, such as Erman's *Chemistry of the Monoterpenes; an Encyclopedic Handbook* (1985). Books that have similar or related objectives, such as the indispensable five-volume standard text *Asymmetric Synthesis* by Morrison and Scott (1983–1985), Hanessian's *Total Synthesis of Natural Products: The 'Chiron' Approach* (1983), and Corey and Cheng's *The Logic of Chemical Synthesis* (1989), are not mentioned. Corey's "logic-centered methodology" is instead covered by the 1969 article by Corey and Wipke in *Science*. To the best of my knowledge, the word carbogen ("During the last fifty years complex carbogen synthesis has extended its frontier to near the conceivable limit.") comes from the book by Corey and Cheng. A related word is chirogen (neologism?, "camphor is an excellent chirogen...") but the sense that it has here does not fit an earlier definition by Eschenmoser (chirogenic, *Helv. Chim. Acta* **1990**, *73*, 1373). Both terms are used without explanation or reference. A few review articles such as the one by Money are there but are not recognizable as such in the text. The limits of the literature coverage are not indicated. Most of the references are from the eighties. There is one from 1958 and five from 1991, none before or after.

I return to the contents, which are of course mirrored by the references that I discussed. I estimate that about 350 syntheses (!) are summarized in the accepted format, by means of schemes composed of formulas, arrows, letters, and footnotes. The formulas are well-drawn but usually not identified (no numbers or letters). When they are, and this is mainly done for the final products, they are identified by a name. The schemes are likewise not identified but appear in the text where they are discussed. The text consists of concise—sometimes perhaps too concise—analyses of the synthetic strategies ("Space is devoted therefore mostly to strategic considerations and unusual observations"), in a rather personal style, but that is a minor matter of taste. The whole, schemes and text, is well-integrated, and one does get a good overview. Here the author has done a very good job.

But also with regard to indexes and to some really essential data, limited and sometimes arbitrary and inconsistent choices have been made. Also the citations in the text (e.g., Money, T. (1985)) and the format of the references in the bibliography at the end of the book (Money, T. (1985) *Nat. Prod. Rep.* **2**: 253.) are inconvenient and different from standard practice in the chemical literature. There is a four-page index of the synthetic targets covered [from achillin via cornorsterone, (+)-7,8-epoxy-2-basmen-6-one, estrone, *ar*-himachalene, nootkatone, sex pheromone (banded cucumber beetle, California red scale, corn rootworm, stink bug, yellow scale) to zonarene], but neither an index of starting materials nor an author index. However, the starting materials can be found via the list of contents at the beginning of the book. The 15-page bibliography at the end of the book is of little use when one is searching for a senior author, as the references are listed alphabetically by the first-named author and, moreover, one cannot refer back to the text (no page number is given). With a few exceptions, authors and research groups are only identified by these first-author citations.

The "optical purities" of the starting materials are not always defined, and when they are then only qualitatively ("not of high optical purity"). It would be better to refer to the enantiopurities since these are relevant and the term enantiomerically pure is used in parallel to optical purity. $[\alpha]_D$-values are also not given routinely, and when they are given this is done without specifying the solvent and temperature (e.g., "(*R*)-pulegone, $[\alpha]_D$ +23°, has found frequent service in synthesis due to its optical purity..."). The chiralities of the starting materials and the products are not defined uniformly [(−)-camphor, (*R*)-(+)-pulegone, β-elemenone, *ent*-occidentalol]. There are almost no references dealing with enantiopurities, $[\alpha]_D$-values, and chiralities. Prices are sometimes indicated qualitatively ("The cost of (−)-carvone is much less than that of the (+)-isomer." "(*R*)-(+)-Limonene, $[\alpha]_D$ +126.8°, is probably the most abundant and cheapest enantiomerically pure cyclic olefin available from natural sources.")

Last but not least, the title is misleading. A step in a synthetic sequence that leads more or less preferentially to one enantiomer is enantioselective, for example the enantioselective hydrogenation of a prochiral substrate (according to Eschenmoser, a chirogenic step), and one can extend that meaning to the entire sequence. The book deals with something else and this is indicated in the subtitle, but racemates are also chiral.

McGraw-Hill Encyclopedia of Science and Technology. 7th Edition. Edited by *S. P. Parker*. McGraw-Hill, New York, 1992. 20 volumes; 13450 pp., hardcover $ 1900.00.—ISBN 0-07-909206-3

Since 1960, when the first edition of the *McGraw-Hill Encyclopedia of Science and Technology* first appeared, it has served the science information needs of students, scholars, and the general public by offering up-to-date, authoritative, and comprehensive coverage of all disciplines in science and engineering. The new 7th edition, which continues to fulfill this purpose, represents the culmination of five years of substantial revision and updating to reflect the numerous scientific and technological developments that have occurred since the 6th edition (1987). The material on entire disciplines, including chemistry, medicine, physics, electronics, computers, telecommunications, and the earth sciences, has been extensively revamped. Three thousand distinguished scientists and engineers from around the world (including 21 Nobel laureates), more than 200 of whom are new to this edition, participated in this work of accurate, lucid, objective, thorough, and rigorous scholarship.

Prepared with the assistance of a 15-member international advisory board and 75 distinguished consulting editors, the encyclopedia contains 7500 signed, alphabetically arranged, and cross-referenced articles (230 entirely new, 700 rewritten by new authors, and 800 extensively revised), covering 81 major subject areas from acoustics to virology. Among the new articles are those on adhesive bonding, anxiety states, atom clusters, bioelectronics, chaos, climate modeling, compact disk, laser cooling, foot disorders, fiber-optic

imaging, fuzzy sets and systems, superstring theory, oxygen toxicity, magnetic levitation, psychosomatic disorders, Kepler's laws, sonochemistry, flexible manufacturing systems, and quasicrystals. Each article begins with a clear definition of the subject, establishing the conceptual foundation for the following discussion that moves progressively from elementary to advanced concepts. The articles consistently discuss both theoretical and practical aspects, thus providing valuable insights into real-world connections between the two.

Lavishly illustrated, the set contains more than 13000 drawings, maps, charts, diagrams, and photographs (1960 of which are new to this edition); 15 of the 81 pages of striking full-color photographs are new. The volumes are exceptionally well-designed with an outstanding visual layout (wide margins, easy-to-read type, and bold headings). Numbered figures, equations, and reactions are referenced throughout the text, 50000 cross-references allow quick access to related articles, and up-to-date bibliographies (some with references as late as 1990) facilitate further research. Numerical data are given throughout in both U.S. customary and international (SI) units.

Volume 20 contains a list of contributors (79 two-column pages), a 13-page discussion of scientific notation with conversion tables, and six new comprehensive study guides based on standard curriculum outlines in physics, chemistry, biology, geosciences, health, and engineering. It also includes a subject index (28 four-column pages) listing alphabetically all 7500 article titles under the 81 major subject headings, making subject-related browsing easy, and an analytical index (more than 160000 entries in 478 four-column pages, referred to by library educators as the "perfect index") permitting quick access to specific terms. The encyclopedia can be updated annually by the *McGraw-Hill Yearbook of Science and Technology*, which is cross-referenced to the parent set and features the same extensive illustrations and bibliographies.

I was disappointed by the lack of entries for two of the most active recent research areas in my own field of chemistry, namely buckminsterfullerenes and cold fusion, but considering the broad interdisciplinary scope of the encyclopedia it was inevitable that some topics would be omitted. Thus the series remains the preeminent, essential reference source for accurate information in any area of science or technology. Its cost will probably limit its purchase to libraries and laboratories, and therefore students, teachers, scholars, and laypersons may wish to buy the one-volume *McGraw-Hill Concise Encyclopedia of Science and Technology*, 2nd edition, abridged from the Encyclopedia's 6th edition (lxxvi + 2222 pp., $ 110, 1989; for review see George B. Kauffman, *Today's Chemist* Dec. **1989**, *2(6)*, 16).

Electron and Proton Transfer in Chemistry and Biology. (Series: Studies in Physical and Theoretical Chemistry, Vol. 78.) Edited by *A. Müller, H. Ratajczak, W. Junge*, and *E. Diemann*. Elsevier, Amsterdam, 1992. XVI, 394 pp., hardcover HFl 355.00/$ 203.00.—ISBN 0-444-88862-4

In 1992 the Nobel Prize for Chemistry was awarded to Rudolph A. Marcus in recognition of his work on the theory of electron transfer, and thus the publication of this book on electron transfer processes is timely (although it was, of course, planned before the announcement of the Nobel Committee's decision). This volume of nearly 400 pages reports on the proceedings of an international conference held on 19–21 September 1990 at the Center for Interdisciplinary Research of the University of Bielefeld.

The wide range of topics includes contributions from physical, inorganic, organic, and organometallic chemistry, as well as from biochemistry, microbiology, biophysics, and theoretical physics. There is a correspondingly broad spread in the disciplines, origins, and objectives of the authors, and likewise in those of the potential readers. Accordingly, the editors have faced a demanding task in choosing the contributions and in arranging and linking them together.

The description of systems in which *electron transfer* occurs begins with simple metal ions and complexes (R. D. Cannon, B. Jezowska-Trzebiatowska et al., A. Vogler et al., W. Kaim, H. So et al.), then goes on to systems of increasing complexity, such as membrane systems (M. Grätzel), proteins (C. C. Moser et al., W. Haase et al., D. J. Lowe), and eventually whole microorganisms (A. Kröger et al.). Next comes a group of articles on biological systems in which there is a coupled transfer of *electrons and protons* (G. von Jagow et al., T. A. Link, E. Takahashi et al., E. K. Pistorius, W. Junge et al.). Continuing then to studies of *proton transfer*, the topics move from biological processes (M. Gutman et al., C. Sandorfy) back again to "purely chemical" reactions (H. Ratajczak, G. Zundel, H.-H. Limbach, D. Borgis, E. Kryachko).

The basic reaction mechanisms are discussed, including a very brief introduction to the "Marcus–Hush paradigm", and articles which focus on thermal or photochemically induced inter- or intramolecular electron transfer, and the problem of mixed valency in metal-oxygen clusters. The elementary processes involved can be studied in detail for model systems by spectroscopic methods, magnetic measurements, or neutron diffraction. Models for both natural and artificial photosynthetic systems have been investigated. Remarkably high efficiencies for the conversion of solar to electrical energy have been obtained with an "artificial leaf". The Marcus equations for the rate of electron transfer are used to analyze the redox reactions in bacterial photosynthesis centers, leading to conclusions about the spatial arrangement of the redox centers in the protein. Another aspect of biochemical electron transfer that is examined is the magnetic interaction between the metal centers. In the context of nitrogen fixation and analogous reactions, the occurrence of successive or concerted multielectron transfer is discussed (in the latter case the formation of highly reactive free radical intermediates is avoided). This is followed by a discussion of the enzyme-controlled flux of electrons in the bacterial system *Wolinella succinogenes*.

Redox reactions are closely related to the uptake or release of protons. This aspect is discussed for biological reaction pathways, taking as examples quinol oxidation, quinone reduction, water oxidation, and the formation of adenosine triphosphate (ATP) in respiration and photosynthesis. The diffusion of protons within apomyoglobin and their reaction with the Schiff base chromophore in rhodopsin is then discussed. The volume ends with a discussion of hydrogen bonding and its effects on proton transport in liquid phases (amine/hydrogen halide and amine/phenol complexes in aprotic solvents), solid phases, and organic glasses, first for small-molecule model systems then from a theoretical standpoint.

The book ranges over all aspects of the subject, from theoretical studies (e.g., Kryachko's description of the soliton model of proton transfer) to practical applications (Grätzel's article on solar energy conversion), and thus it undoubtedly

lives up to the title and the claims made in the preface. It would certainly have been possible to produce a book with a different balance of emphasis. For example, there are scarcely any references to electrochemical reactions, despite the fact that in many cases these are good model systems for coupled and biologically relevant electron and proton transfer processes. However, any choice of topics for such a book is inevitably subjective, and reflects the interests of the conference participants and organizers. A more serious criticism in my view is that insufficient attention has been given to linking together the individual contributions. The preface emphasizes the interdisciplinary approach ("...biology has become the ground where the various disciplines of science ... are meeting again"; "students of the life sciences will always rely on ... investigations of simpler and cleaner systems that are the object of pure physics and chemistry"), and that is exactly why it would have been desirable to have sections in the text to link and interrelate the disciplines, so as to overcome the barriers that exist, often even in the terminology. Also only a few of the articles are in the nature of reviews, and some report results on the authors' special research topics. Consequently the book is not very suitable as an introduction to the field, but is rather in the nature of a snapshot of current research activity.

On careful reading of some individual articles one is struck by the large number of errors, leading one to ask whether the manuscripts were checked before typesetting. For example, pages 95–109 contain 22 cases of incomplete sentences, incorrect symbols, errors of sign in equations (!), and spelling errors. To cite only the most glaring example found, what is one supposed to make of "dimethyltetraaza (ref. 14) annulene" (p. 338)? Presumably what is meant is dimethyltetraaza[14]annulene (although strictly speaking it refers to the dibenzo derivative of this compound). One might reasonably expect that, for a book costing over $ 200, errors of this kind would not occur so frequently as is found here. The same applies to the lack of consistency in book and journal citations. In some of the articles the style is too much like a transcript of a lecture. Occasionally the English would have benefited from a little polishing by the editors, as there are whole sentences whose meaning can only be deciphered with difficulty.

For readers who are engaged in research in the fields described and want to look beyond the confines of their own specialism, this book should be worth buying, provided that they are prepared to overlook the minor shortcomings of presentation mentioned above. They will discover from it some surprising parallels between chemistry and biology in the area of electron and proton transfer.

Organic Photochemistry. A Comprehensive Treatment. (Physical Chemistry Series.) By *W. Horspool* and *D. Armesto*. Ellis Horwood/Prentice Hall, New York, 1992. XVI, 521 pp., hardcover $ 90.00.—ISBN 0-13-639477-9

As editor of the book *Synthetic Organic Photochemistry* (1984) and as the author of the annual reviews of the photochemistry of carbonyl compounds in the Royal Chemical Society's *Specialist Periodical Reports on Photochemistry*, W. Horspool is certainly widely recognized as a leading expert on light-induced reactions of organic molecules. It was therefore almost a foregone conclusion that a new book on organic photochemistry should have him as one of its authors.

The book consists of seven chapters as follows: a brief general introduction to molecules in electronically excited states; the photochemical behavior of hydrocarbons; photochemical reactions of molecules containing oxygen, sulfur, nitrogen, and halogens; and lastly a survey of the main experimental requirements for carrying out photochemical reactions. The authors have undoubtedly succeeded in putting together a very comprehensive summary of the armory of light-induced reactions of organic molecules that can be used for synthetic purposes. The book can therefore be recommended for all readers seeking a good general overview of this subject. As seems to be generally unavoidable, there are a few printing errors, such as the repetition of a whole sentence (p. 234) or of a literature citation (p. 345), and also quite a number of errors in authors' names in the references. German-speaking readers will notice that the literature survey in the introduction fails to mention the photochemistry volume (IV 5a, b) of "Houben-Weyl".

Although the publishers describe the book as a "timely review" it is, unfortunately, not really so in the sense of being up-to-date. Except for the chapter on organonitrogen compounds, which has been partly updated by including the authors' most recent work on aza-di-π-methane rearrangements (with five literature references for 1990 onwards), the most recent publications are not adequately covered. It is certainly possible to cover the latest work in books of this kind, as J. Kopecky has clearly demonstrated in his book *Organic Photochemistry* (VCH, 1992). Leaving aside the fact that these two books treat the subject differently, and the significant difference in price between the two, this matter of up-to-dateness is by itself a sufficient reason for me to recommend that students wishing to learn about this field should preferably buy Kopecky's book.

Organic Synthesis in Japan. Past, Present, and Future. In Commemoration of the 50th Anniversary of the Society of Synthetic Organic Chemistry, Japan. Edited by *R. Noyori*. Tokyo Kagaku Dozin, Tokyo, 1992. XI, 565 pp., hardcover ¥ 14000.—ISBN 4-8079-0369-1

The Society of Synthetic Organic Chemistry in Japan was founded in 1942. At that time chemists in Europe could already look back on more than fifty years of achievement in this field, both in the laboratory and on an industrial scale, and also on some impressive successes in natural products chemistry, especially in structure determination. The aim of the newly formed society was to foster close collaboration between universities and industry, and to stimulate and encourage research in organic synthesis. As R. Noyori points out in the preface, chemists in Japan have a different scientific and cultural background from their counterparts in other countries, which influences motivation, the approach to solving problems, and the way that research projects are carried out in practice. These special circumstances and Japan's geographical position have contributed to the fact that initially the development of chemistry there was not so rapid as that occurring in Europe and the USA during the same period. Even today, although the successes of Japanese chemical research compare well with those in other leading industrial countries, certain characteristics that we generally associate with the "Japanese mentality" are discernible. To mark the fiftieth anniversary of its formation the Japanese

Society of Synthetic Organic Chemistry has now undertaken a sort of stocktaking review, with contributions by 60 authors drawn from academia and industry. These mainly very personal contributions highlight some important developments that have taken place in Japan in synthetic organic chemistry, and describe the most outstanding research results achieved in recent times.

The first part of the book is devoted to the history of the development of synthetic chemistry in Japan, with descriptions of some milestones in the areas of the synthesis of natural products and biologically active substances (Y. Ban, M. Matsui, M. Yamaguchi), organic synthesis in the pharmaceutical industry (K. Morita), industrial synthesis (Y. Ito), and syntheses of molecular energy storage media, organic conductors, and ferromagnetic materials (Z. Yoshida). In a more general article H. Nozaki discusses the changes that have occurred over the years in the areas on which synthetic organic chemistry has concentrated.

In the second part 53 authors (of whom 36 are from universities and 17 from industry) describe their best research results. The majority of the literature citations belong to the last ten years. The contributions extend over a wide range of synthetic organic chemistry, but an emphasis on certain topics is clearly evident. These include the synthesis and modification of complex natural products (e.g., 1-oxacephems, taxanditerpenoids, 1,3-polyols, macrolides, glycoconjugates, pyrethroid insecticides), metal-assisted selective transformations (especially those using palladium or the ruthenium(II)-BINAP reagent, and new Lewis acid catalyzed reactions), syntheses based on organoboranes and organosilanes, and stereochemically controlled reactions. On the other hand, some classes of interesting compounds other than natural products that have been synthesized in Japan are perhaps somewhat under-represented here. Rather predictably, modern developments in the chemistry of organoheteroelement compounds are treated only in the context of aids to organic synthesis (see above), not from the standpoint of the synthesis of the compounds themselves. Looking at the list of authors one can, of course, point to a few notable omissions, but it is certainly not possible to achieve completeness in a collection of this kind.

With regard to the future of Japanese organic chemistry as mentioned in the title, most of the comments are to be found in the first part of the book, but some of the authors in the second part also make projections. In academic research some important future trends are: a) studies aimed at a better understanding of organometallic reactions, especially with regard to (stereo)selective reactions, and closer links between inorganic chemistry and synthetic organic chemistry; b) chemical synthesis in combination with methods based on fermentation and enzyme-catalyzed reactions; c) the synthesis of molecules with useful photochemical, electrical, or magnetic properties. For industry, Y. Ito predicts that future objectives will include: a) technologies for protecting the global environment and conserving natural resources—such projects will require cooperation between industry and universities; b) a strengthening of speculative basic research, with a willingness on the part of management to take risks; c) international collaboration in the development of new chemical technologies; d) a close integration of chemistry, biotechnology, electronics, and physics at the molecular level. Many of these future perspectives could apply equally in Germany, as also could the urgent appeal to policy-makers to increase investment in education and basic research.

The book has a consistent layout and very attractive presentation, which is greatly helped by the clear and excellently reproduced formula diagrams. The title page of each contribution carries a photograph of the author with a biographical note on his scientific work. Although the book does not cover the whole field exhaustively, it is certainly an important and valuable source of information on the present state of synthetic organic chemistry in Japan.

Orbital Symmetry and Reaction Mechanism. The OCAMS View. By *E. A. Halevi.* Springer, Berlin/New York, 1992. XXII, 310 pp., hardcover DM 68.00.—ISBN 3-540-50164-9/0-387-50164-9

When, in 1992, someone writes a book about the relationship between orbital symmetry and reaction mechanism, it can be assumed that it is not so much an account of the latest results as a review and appraisal of a line of development that extends back at least to 1965. It was then that Woodward and Hoffmann, with their principle of the conservation of orbital symmetry, initiated a revolution in chemistry that is almost without equal. This book leaves no doubt that the stimulus generated by that simple idea could not have come about without the existence at that time of a receptive intellectual climate, characterized by a lack of the fundamental knowledge needed to understand reaction mechanisms. The author does not assume that the reader will be satisfied with a superficial argument; instead he adopts a rigorous approach that is a continuous theme throughout the book. He starts by noting that it would be very convenient if one could make predictions about a reaction mechanism on the basis of symmetry. The second stage is to determine whether or not the system goes beyond the range of validity of the molecular orbital (MO) theory; in other words, one has to distinguish between MO, configurational, and state correlation. The third stage is concerned with the rigorous description of the transition structure in energetic terms, from which one can decide whether a symmetry argument is to be accepted or rejected.

The author takes considerable care to prepare the ground by explaining aspects of symmetry that are needed later. The uninitiated reader is gently "led by the hand" through the necessary stages, and the reader with previous knowledge will probably not start with any special advantage. The unconventional approach in which symmetry and symmetry reduction are treated simultaneously is certainly very convincing, but the combining of this with the illustration of the behavior of atomic p-orbitals in a magnetic field relates only to an imaginary experiment and not to the actual situation. Because of the electron spin the 2p state undergoes not a threefold but a fourfold splitting. The treatment of the Zeeman effect without including the electron spin is a dubious approach, and should at least have been preceded by an explanatory note. Considering that fundamental aspects of d-orbitals are discussed in some detail, it would have been appropriate to explain that there is an infinite number of legitimate ways of choosing a set of five d-orbitals. In fact the discussion is always confined to the one set that can easily be generated from the complex functions for spherical symmetry, and which is easy to handle in the case of octahedral symmetry, where the axes can be chosen in accordance with the ligands. Thus even the equivalence of the functional forms is abandoned. On the whole this first third of the book covers all the most important preparative material for what is to follow. This includes molecular orbitals and normal

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1993 0570-0833/93/0808-1220 $ 10.00+.25/0

vibrations, as well as orbital correlation diagrams for diatomic molecules. The two fundamental rules, namely the non-crossing rule and the Walsh rules, are only briefly mentioned, and the reader is apparently expected to understand these already.

The next 100 pages are devoted to classical thermal reactions. These are analyzed from the OCAMS (orbital correspondence analysis in maximum symmetry) standpoint that the author has himself developed. Compared with the Woodward–Hoffmann rules this has the advantage of providing a rigorous formalism that leads directly to the thermally favored reaction mechanism, avoiding the need to consider all conceivable mechanisms in turn (and perhaps to overlook the one that is of most interest). The information that OCAMS gives about a mechanism is of a relative nature, and is conceptually related, in a broad sense, to the Walsh rules. It therefore undoubtedly comes nearer to the truth than topological considerations. About 40 topical examples are described in detail and clearly illustrated.

It is only in the final third of the book that the electron spin is introduced. Spin-forbidden processes are incorporated into the OCAMS approach, and examples that involve intersystem crossing are described. About a dozen carefully chosen examples of reactions involving electronically excited states are described. At the time when the Woodward–Hoffmann rules were being applied to photochemical reactions without sufficient care, inappropriate mechanisms were assumed in many cases. Only four examples from inorganic chemistry are described, and from these one can conclude that the orbital symmetry approach is best reserved for carbon compounds, since there is always doubt as to whether the condition of kinetic stability is satisfied for inorganic compounds, so that no reliance can be placed on results from symmetry considerations. The appendix contains character tables and group correlation tables that are a valuable aid in studying the examples.

The text is excellent in both its intellectual content and style, and the book provides ample evidence of the author's rich fund of experience.

Science as Writing. By *D. Locke*. Yale University Press, New Haven, 1992. X, 237 pp., hardcover \$ 30.00/£ 18.50.—ISBN 0-300-05452-1

The author of this book, David Locke, started as a chemist. His mentor was S. William Pelletier, with whom he synthesised atisine, an alkaloid. The work was published in the *Journal of the American Chemical Society* in 1959. At present, David Locke teaches English at the University of Florida. He is thus able to describe science as an insider. When he refers to style in science, the example he brings forward (who else?) is that of Robert B. Woodward. This issue of scientific style is one that elicits considerable current interest. A whole periodical, *Science in Context*, is devoted to the question of style in science, not only on the part of an individual, but within a field of science or a national tradition. This book is well-researched and jargon-free. It puts to rest our cherished notion of science as methodically built from the objective gathering of facts. It has other uses also. It will help to devise an efficient rhetoric for one's scientific discourse. It should help to restore to science a measure of personal style, as opposed to the fastidiously repetitive hyperspecialization that masquerades in its stead.

Locke brings to bear on his precious little book an in-depth understanding of the scientific process. The third chapter contrasts expressionless, humorless writing, as seemingly required in publications, both with shop talk in the laboratory, and with the emotional involvement in their work by eminent scientists such as Charles Darwin. This empathy for one's brainchild is beautifully exemplified by Barbara McClintock's animation of the genome; it is for her a living entity. Locke deals next with the rhetoric of science, of which *The Origin of Species* is a prime example. He shows convincingly that the lack of impact of Mendel's discovery, even though the contemporaries knew of it, stems from a revolutionary finding having been presented in the language of normal, run-of-the-mill science. He uses Einstein's introduction of relativity theory to demonstrate the importance of story-telling to conveying a novel world-view. In a chapter with the felicitous title "The Art of Artless Prose", the author focuses on the irony that permeates great texts, such as Galileo's *Dialogues* or *The Double Helix*. He draws attention also to the virtue of understatement, as a device to prepare for the hard-hitting punch line (such as that, one may add, in Woodward and Hoffmann's *The Conservation of Orbital Symmetry*: "Exceptions? There are none.") The book throbs with vital insights. In Chapter 5, on "The Putative Purity of Science", Locke comments perceptively on the existence of a scientific oligarchy, in between decision-makers and the scientific community: "ultimately, it determines what is scientifically thinkable, until the unorthodox idea thrusts its way into the arena, with the force of scientific genius, skillful rhetoric, and iron determination behind it."

The main virtues of Locke's book are his intimate familiarity with living science; the smooth readability buoyed by a constantly pleasing style and by recourse to major texts, known by everyone, for its examples; the constant criticism of the myth of science as an objective and neutral process. These qualities are sometimes drawbacks. One might argue that to focus on scientific revolutions and masterpieces is too selective. Normal science is also to be considered advantageously as writing. One might also argue, on a different tack, that scientific advances can be uncoupled from ideological hangups: Jacques Loeb (p. 154ff.) is remembered for the study of tropisms, more than for his obsession with getting rid of free will.

Deconstruction has been a slogan during the post-modern, post-structuralist period from which we are emerging. This debunking movement has helped to jettison the myth of science as the progressive buildup of the laws of nature from objective facts. Its own mythological view of science nevertheless borders on the ridiculous and, to this writer, is unacceptable. It rests on microsociological studies of laboratory life. They find that science is akin to a power play: its conclusions would be, according to this critical analysis, merely a negotiated settlement between the human participants. Locke's essay is far above such ultrasimplifications. He uses various complementary approaches so as to provide a realistic, multidimensional view of science. His metaphor of science as writing is much more productive, and he pushes it to all its implications without ever forcing the evidence to conform to his model.

How Nature Synthesizes Vitamin B_{12}—A Survey of the Last Four Billion Years

By A. Ian Scott*

This review contains an account of recent experimental results in the continuing saga of vitamin B_{12} biosynthesis (largely from the author's laboratory) as well as a personal view of future directions of research in natural product biosynthesis. The emphasis is on the powerful combination of molecular biology in the search for, and the expression of, the genes encoding the biosynthetic enzymes and state-of-the-art spectroscopic techniques, in order to "view" the biochemical events as they take place in the NMR tube. As a logical development of these approaches, the feasibility of one-flask, multienzyme synthesis of natural products is addressed.[**] Implicit throughout is the profound change in the "tools of the trade" of the bioorganic chemist, thanks to the harnessing and exploitation of cloning techniques and the resultant availability of enzymes which can make carbon–carbon bonds. It is also our desire to alert organic chemists, who may wish to take advantage of these technical developments, to the fact that they will be rewarded by a new world of natural catalysts capable of high yielding, synthetic chemistry often with a surprising, but welcome, lack of substrate specificity. Finally we hope to convey our enthusiasm for the methods now at the disposal of present and future generations of chemists for studying Nature's synthetic routes to complex natural products.

1. Introduction: The Early Experiments

"It is a tangled skein and I am looking for a loose end."
"The Creeping Man"[***]

The complex mechanisms underlying the biosynthesis of the tetrapyrrolic cofactors (Fig. 1) which mediate such diverse processes as respiration (heme), photosynthesis (chlorophyll), methanogenesis (coenzyme F430), six-electron sulfite and nitrite reduction (siroheme), and vitamin function (B_{12} and its coenzyme—the corrinoids) have intrigued biochemists since the 1940s when Shemin et al.[1] and Neuberger et al.[2] began their classic studies of heme biosynthesis. Indeed, by ingesting [^{15}N]glycine, Shemin showed that his own heme nitrogen atoms were labeled by this amino acid.[1] From these and other pioneering studies using [^{14}C] labeling and chemical degradation,[3] it was revealed by painstaking experiments that in mammals, glycine and succinyl CoA combined to form 5-aminolevulinic acid (ALA), the universal building block for both porphyrins and vitamin B_{12}. Our own work in this field began 25 years ago when, by whole cell feeding of ^{13}C-enriched precursors to *Propionibacterium shermanii*, it was established by NMR spectroscopy that the pathway to B_{12}, beginning with ALA, continues via porphobilinogen (PBG) to the unsymmetrical

A. Ian Scott was born in Glasgow, Scotland in 1928 and received B.Sc., Ph.D., and D.Sc. degrees from Glasgow University. Following postdoctoral studies with M. S. Newman (Ohio State University) and Sir Derek Barton (Birkbeck College and Glasgow), and a lectureship at Glasgow University (1957–62), he occupied chairs of organic chemistry at U.B.C., Vancouver, Sussex, and Yale, before moving to Texas A & M University in 1977 where he is now Davidson Professor of Science and Director of the Center for Biological NMR. His research insterests are concentrated at the interfaces of organic chemistry, NMR spectroscopy and genetic engineering of natural product biosynthesis. The combination of these techniques have led his investigations into the use of stable isotopes, enzymology, and gene expression to study the mechanisms and synthetic power of the enzymes which mediate the biosynthesis of alkaloids, antibiotics, vitamins, and steroids. His work has been recognized by numerous awards, the most recent being the A. C. Cope Scholar Award of the American Chemical Society. He is a Fellow of the Royal Societies of London and Edinburgh and the European Academy of Arts and Science, a Member of the Scientific Academy of Siena, and a Founding Member of the Yale Sherlock Holmes Society.

uroporphyrinogen (uro'gen), (a route shared with all the cofactors in Fig. 1) before entering the chiral world of corrins, whose stereochemical complexity is largely a result of C methylation of the pyrrolic rings by *S*-adenosylmethionine (SAM).[4] The next 10 years witnessed the isolation (with L. Siegel and G. Müller) of two partially methylated intermediates (factors II and III) on the way to corrins, by using cell-free systems of *P. shermanii* and *Clostridium tetanomorphum*.[4] It is now clear that these oxidized pigments or "factors", are carried through the biosynthetic machinery at the level of hexahydroporphyrin, and although the stable isobacteriochlorin structures of factors II and III were conveniently elucidated by ^{13}C NMR spectroscopy on submilligram amounts,[4] the true substrates for the biosynthetic methyltransferases are now known to be their reduced (and much more labile) forms, the precorrins 1–3 (Fig. 2).[5a]

1.1. Dating of the B_{12} Pathway and Some Medical Implications

There is no apparent, formal change in oxidation level throughout the pathway from ALA to the corrinoid structure of B_{12}. This fact, taken together with the phylogeny of the B_{12}-producing organisms[6] and Eschenmoser's remarkable prebiotic simulation of uro'gen III synthesis from glutamine dinitrile[7] suggests that the prerequisite not only of the type III porphyrinogen, but of a prebiotic corrin template, bearing protons at the positions associated with biological C methylation, was quite feasible. The primitive anaerobes (methanogenic bacteria) which make B_{12} (but not heme) can be dated to about 3.79×10^9 years,[8] whereas the modulation of oxygen by the respiratory (heme) pigments and oxygenic photosynthesis (chlorophyll) was not required

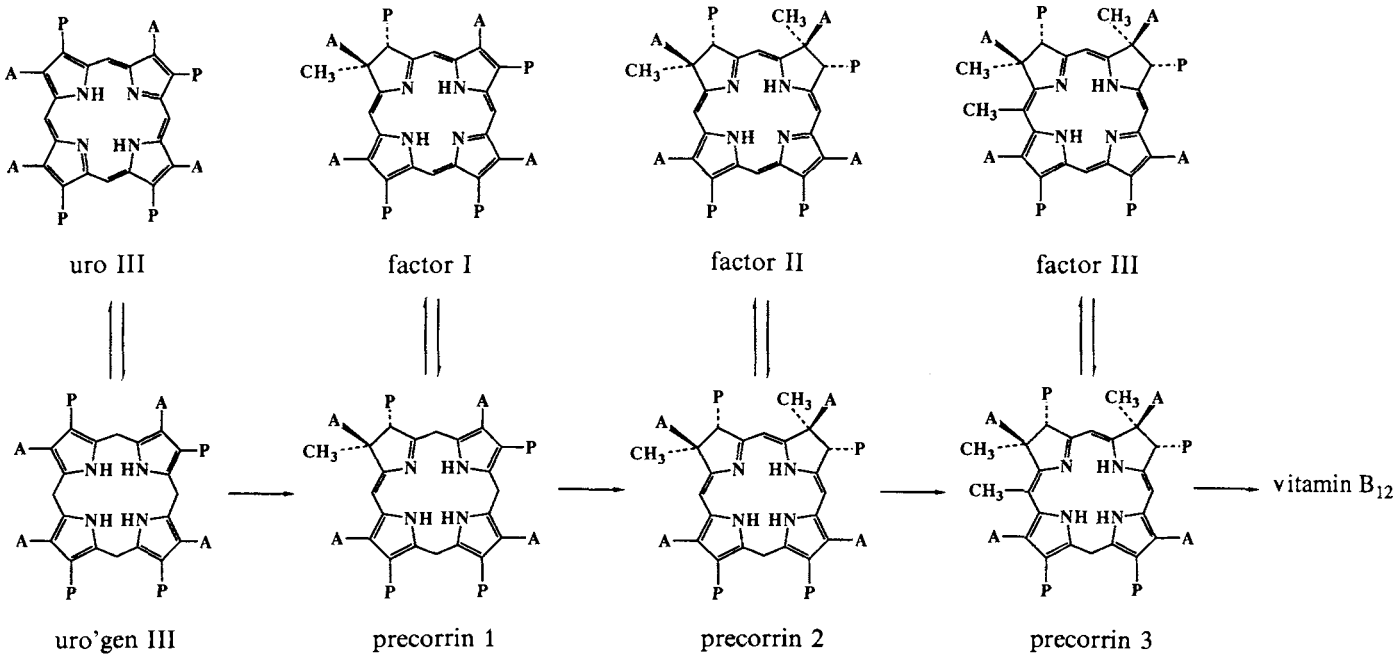

Fig. 2. The precorrins 1–3 and the corresponding oxidized "factors" I–III.

Our discussion will concentrate on what is now known about the biosynthetic enzymes which produce corrin from ALA; a process which involves as many as 20 steps along a pathway rich in mechanistic complexity. We have omitted any discussion of the events which transform the simplest corrin, cobyrinic acid, to cyanocobalamin (vitamin B_{12}), by amidation and addition of the "nucleotide loop" whose aminoisopropyl alcohol, phosphate, ribose, and dimethyl benzimidazole moieties are furnished from threonine, guanosine triphosphate, ribose, and riboflavin, respectively. The physiologically active coenzyme B_{12} bears a 5-deoxyadenosyl group in place of the cyanide function in cyanocobalamin. Due to the facile exchange of the sixth (axial) ligand it appears that the cyanide group was first introduced as an artifact of the original isolation of B_{12} due to the presence of CN^-/ions in the animal charcoal used in the purification process.[5b]

until sufficient O_2 entered the earth's atmosphere about 1.7 billion years ago.[6, 8] Thus, the ancient organisms had learned to synthesize corrins from type III uro'gen or to produce methane from coenzyme F430 long before the oxidized pigments (hemes, cytochromes) were required.[6] Although endowed with a much more complex stereochemical motif than planar heme, the cobalt–corrin complex was surely the earliest organometallic cofactor, along with nickel-containing coenzyme F430, whose biosynthetic pathway shares precorrin 2 as a common precursor. Whereas primitive methanogenesis mediated by F430 can be understood, the function of the early corrins is not so easy to deduce. One possibility would be methyl transfer from methyl cobalamin leading to cobalamin-dependent methionine synthesis[9] or the carboxylation of methyl cobalamin to form acetate.[10] Whatever may have been the biological function of corrins in archaebacteria, their subsequent evolution and recruitment

to a functional coenzyme has now provided modern organisms (and man) with a spectacular series of 1,2-shifts mediated by coenzyme B_{12}—to say nothing of ribonucleotide reductase. All of these reactions depend on homolytic fission of the unique cobalt–carbon bond embedded in a water-soluble structure—the hallmark of the B_{12} coenzyme rearrangements.[11] As discussed later, this evolutionary hierarchy is of considerable interest with regard to the ubiquitous presence of type III uroporphyrinogen-derived pigments right down to present-day man who requires the four genes, *hem*A-D, necessary for synthesis of uro'gen III, to produce heme for his hemoglobin. As an historical aside, the disease of acute intermittent porphyria caused by the deficiency of the *hem*C gene (which encodes porphobilinogen (PGB) deaminase, the polymerizing enzyme of tetrapyrrole biosynthesis) lay at the heart of the "Royal Madness" in the House of Hanover,[12] whose most celebrated victim was George III. It has recently been suggested[13] that this congenital deficiency (and hence deranged behavior) was also linked with the tragic life of Vincent van Gogh.

2. The Enzymes of Tetrapyrrole Assembly Encoded by *hem*A-D

"When a fact appears to be opposed to a long chain of deductions
it invariably proves to be capable of bearing some other interpretation."
"A Study in Scarlet"

2.1. ALA Synthesis: Two Routes to a Simple Molecule

The structure of the C_5 building block, ALA, in fact conceals a duality of genetic origin. Thus, the action of ALA synthase, discovered by Shemin, involves the decarboxylative condensation of glycine and succinyl CoA mediated by pyridoxal phosphate (Fig. 3a). A more primitive route features the reduction of glutamyl-tRNA to glutamate semialdehyde (GSA) (Fig. 3b) by a dehydrogenase encoded by the *hem*A gene of *Escherichia coli*. This is followed by a remarkable intramolecular transposition of the amine and carbonyl functionalities of GSA to ALA under the control of *hem*L. This "C_5 pathway" was first discovered in plants[14] (which do not make B_{12}), but has now been found to operate[14] in many B_{12}-producing organisms such as *Salmonella* and *Clostridium thermoaceticum*.[15] The classical Shemin sequence,[1,3] however, is probably restricted to photosynthetic bacteria, yeast and mammals.

Regardless of the origin of the ALA, the next step involves the dehydrative self condensation of ALA to PBG. This reaction is catalyzed by the enzyme ALA dehydratase, which is encoded by *hem*B. Overexpression of dehydratase[16,17] (to 40 mg/L^{-1} in engineered *E. coli* cells), and immobilization on sepharose has provided us with a convenient synthesis of PBG in ^{13}C-labeled forms, suitable for the many studies involving ^{13}C enrichment of the later, more complex intermediates and has furnished the first enzyme in the repertoire of catalysts for multienzyme synthesis, using the readily available ALA as substrate.

2.2. Porphobilinogen Deaminase: An Enzyme with Many Surprises in Store!

The next enzyme, PBG deaminase, encoded by *hem*C, catalyzes the tetramerization of PBG **1** to preuro'gen (hydroxymethylbilane, HMB) **2**,[18,19] which is cyclized with rearrangement to the unsymmetrical uro'gen III **3** by uro'gen III synthase[19–21] (Fig. 4). In the absence of the uro'gen III synthase, HMB **2** dehydrates spontaneously to uro'gen I **4**, which, although strictly not a natural product, turns out to be a substrate for some of the methyltransferases of the vitamin B_{12} pathway.

We have constructed a plasmid pBG101, containing the *E. coli hem*C gene[22,23] encoding deaminase. *Escherichia coli* (TB1) transformed with this plasmid produces deaminase at levels greater than 200 times those of the wild strain[23] (30–40 mg L^{-1}). This allows access to substantial quantities of pure enzyme for detailed study of the catalytic mechanism and for the preparation of the later intermediates.

Deaminase is an unusually helpful enzyme since a covalent bond is formed between each incoming substrate molecule and enzyme,[24–30] thus allowing isolation of covalent complexes containing up to 3 PBG units (E-S_1–E-S_3). With adequate deaminase in hand it was found that a novel cofactor is covalently attached to one of the four cysteine residues of the enzyme (Cys 242) in the form of a substrate-derived dipyrromethane. The free α-position of which becomes the site of attachment of the four PBG-molecules during the catalytic cycle (Figs. 5 and 6).

Thus, a mutant strain of *E. coli* (*hem*A-requiring ALA for growth) in the presence of [5-^{13}C]ALA **6** afforded highly

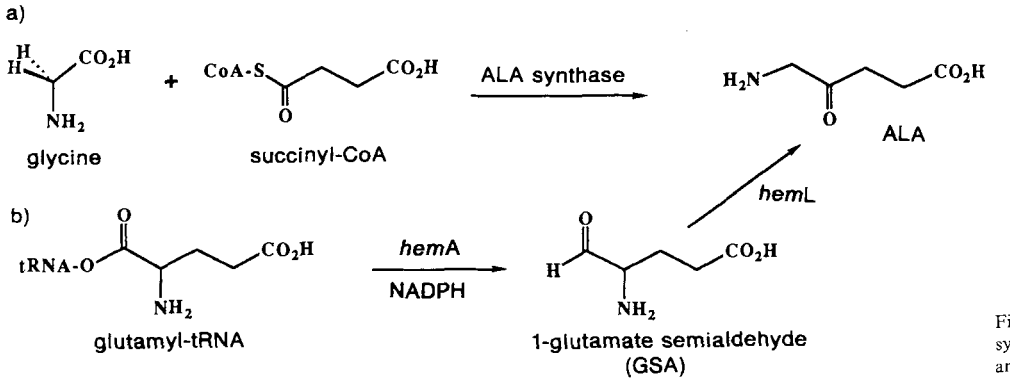

Fig. 3. The two mechanisms of ALA synthesis: a) the "Shemin" pathway and b) the "C_5" pathway.

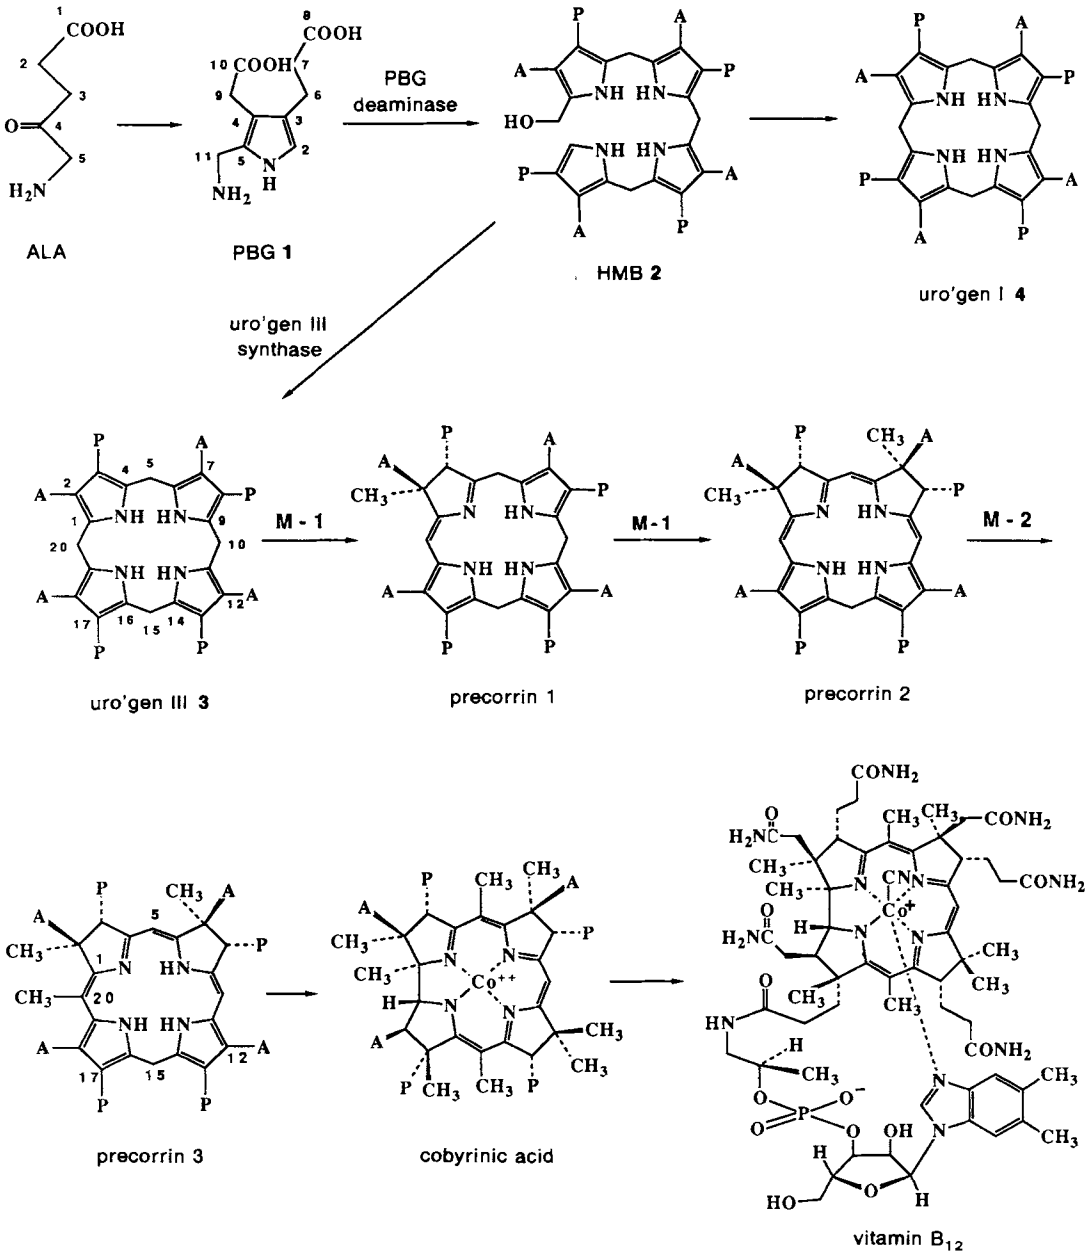

Fig. 4. The "early" precursors of vitamin B_{12}. From ALA to precorrin 3. A = CH_2COOH, P = CH_2CH_2COOH.

^{13}C-enriched enzyme for NMR studies. At pH 8, the signals for the enriched carbon atoms of the dipyrromethane cofactor were clearly recognized at $\delta = 24.0$ (py-CH_2-py), 26.7 (py-CH_2-X), 118.3 (α-free pyrrole), and 129.7 (α-substituted pyrrole) (Fig. 5A). The signals are sharpened at pH 12 (Fig. 5B), and the CH_2X resonance is shifted to $\delta = 29.7$ in the unfolded enzyme. Comparison with synthetic models reveals that a shift of $\delta = 26.7$ is in the range expected for an α-thiomethyl pyrrole (py-CH_2-SR). Confirmation of the dipyrromethane (rather than oligopyrromethane) came from the ^{13}C INADEQUATE spectrum taken at pH 12 which reveals the expected coupling only between the py-CH_2-py group ($\delta = 24.7$) and the adjacent substituted pyrrole carbon atom ($\delta = 128.5$) (Fig. 5C). When the enriched deaminase was studied by ^1H-detected heteronuclear filtered spectroscopy (Fig. 5D), only five protons (from a total of nearly two thousand!) attached to ^{13}C-enriched nuclei were observed in accord with structure **5** (Fig. 5 top). A specimen of deaminase was then covalently inhibited with the suicide inhibitor [2,11-$^{13}C_2$]2-bromo PBG **8** (Fig. 6) to give a spectrum consistent only with structure **9**, recently confirmed by electrospray mass spectrometry ($M_r = 34\,559$).[30b] The site of covalent attachment of substrate (and inhibitor) is therefore the free α-pyrrole carbon atom of the dipyrromethane cofactor in the native enzyme, leading to the structural and mechanistic proposal for deaminase portrayed in Figure 6.

It was then found that two moles of PBG are incorporated autocatalytically into the apoenzyme (isolated by overexpression in a *hem*B-strain of *E. coli* which does not make PBG)[28] and that the first (kinetic) encounter of PBG deaminase with substrate involves attachment of PBG (with loss of NH_3) to the α-free pyrrole position of the dipyrromethane to form the E-S_1 complex **7** (Fig. 6).[29, 30a] The process is repeated to produce the unstable "tetra PBG" (E-S_4) adduct

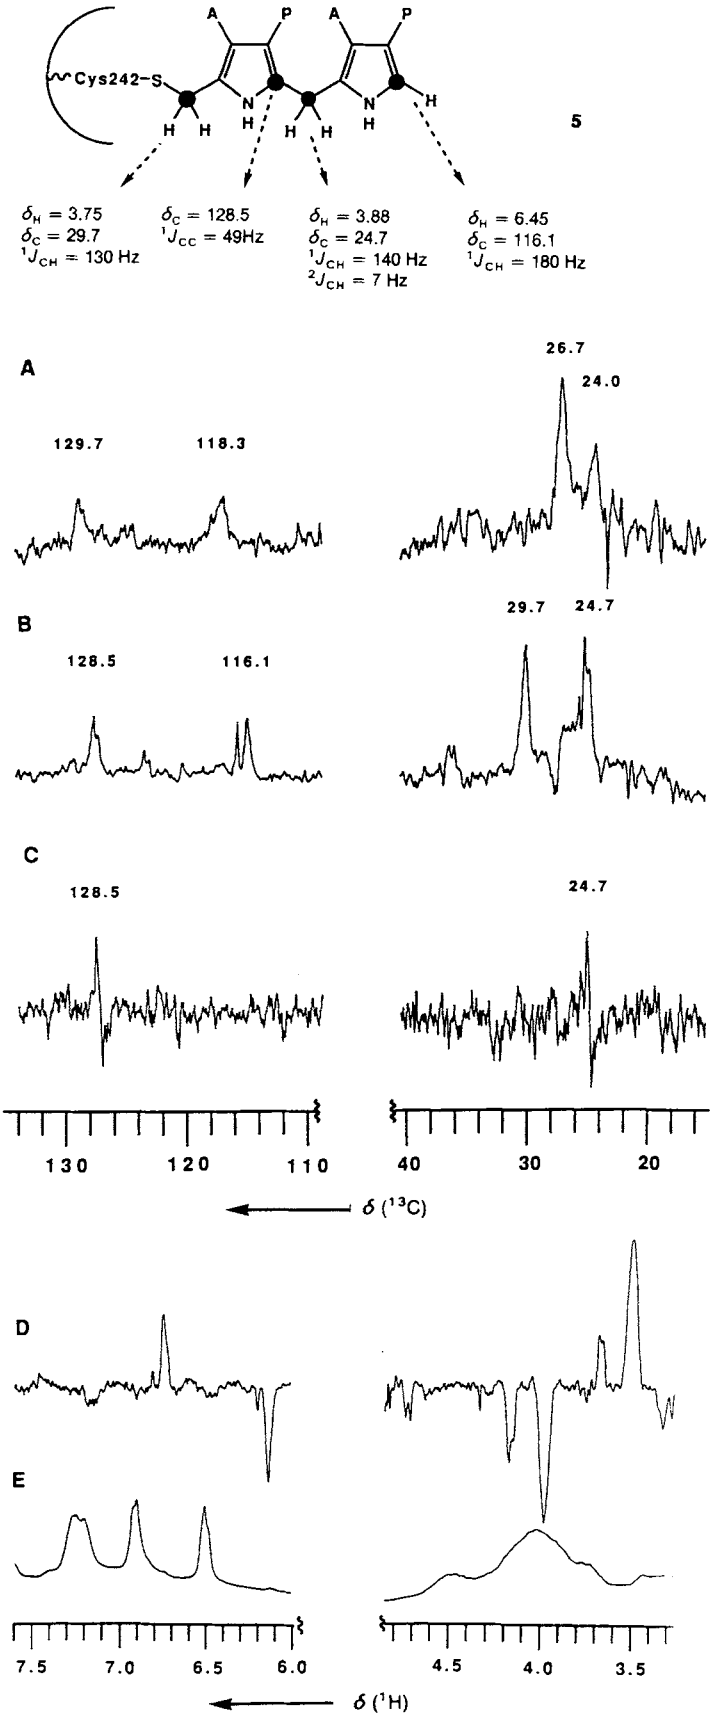

Fig. 5. High-field NMR spectra of PBG deaminase from *E. coli* (ca. 1 mM) specifically ^{13}C-enriched in the dipyrromethane cofactor by [5-^{13}C]ALA (**6**). A) 125 MHz ^{13}C NMR difference spectrum between separate deaminase samples (pH 8) grown in the presence or absence of [5-^{13}C]ALA **6**, which shows the four signals of the ALA-derived ^{13}C-enriched carbon atoms. B) Difference spectrum of the same samples as in (A), recorded at pH 12. Upon alkaline denaturation, the resonance signal assigned to the thiomethyl carbon atom shifts downfield to δ = 29.7; in closer agreement to a model cysteine thiomethylpyrrole conjugate. C) ^{13}C INADEQUATE NMR spectrum (pH 12) of [5-^{13}C]ALA-derived deaminase which demonstrates the coupling of adjacent carbon atoms, confirming the head-to-tail dipyrromethane structure. D) Isotope-edited 300 MHz ^{1}H NMR spectrum (pH 12) of biosynthetically enriched deaminase (2 mM), showing the three pairs of signals originating from only those protons directly bound to the ^{13}C carbon atoms derived from [5-^{13}C]ALA **6**. The observed antiphase splittings are due to the one-bond ^{1}H-^{13}C coupling. E) Normal ^{1}H NMR spectrum of the same sample, illustrating the degree of selection afforded by the pulse sequence for spectrum D. Above the spectra is shown the structure of the dipyrromethane cofactor **5**; the ^{1}H and ^{13}C NMR chemical shifts and coupling constants obtained at pH 12 are given.

10, which was recently detected (M_r = 35107) by electrospray MS.[30b] Site-specific cleavage of the hexapyrrole chain (at ⟶ ; see Fig. 6) releases the azafulvene (**11**) which becomes the substrate of uro'gen III synthase after stereospecific hydration[19] to HMB **2**. The bilane **2** is stable at pH 12, but is cyclized chemically to uro'gen **4** at pH $\leq$8 (Fig. 4). Independent, complementary work in 1987/1988 from two other laboratories[31, 32] reached identical conclusions regarding the catalytic site. The ^{13}C labeling defines the number of PBG units (two) attached in a head-to-tail motif to the native enzyme at pH 8, and reveals the identity of the nucleophilic group (Cys-SH) which anchors the dipyrromethane (and hence the growing oligopyrrolic chain) to the enzyme. Site-specific mutagenesis[23] and chemical cleavage[31, 32] were employed to determine that Cys 242 is the point of attachment of the cofactor.

The use of the α-carbon atom of a dipyrromethane as the nucleophilic group responsible for oligomerization of four moles of PBG (with loss of NH_3 at each successive encounter with an α-free pyrrole) is not only remarkable for the exquisite specificity and control involved, but is, as far as we know, a process unique in the annals of enzymology in that the substrate is actually used not only once, but twice in the genesis of the active site cofactor! Even more remarkable is the fact that the apoenzyme is automatically transformed to the active holoenzyme by addition of two PBG units without the intervention of another enzyme.

2.3. Uro'gen III Synthase: The Molecular Acrobatics of the "Ring D Inversion"

We now turn briefly to the enzyme for the rearrangement, uro'gen III synthase. The early ideas of Bogorad et al.[33] involving the aminomethylbilane (AMB) **12** as a putative substrate, were helpful in finally tracking down the elusive species which, after synthesis by PBG deaminase, becomes the substrate for uro'gen III synthase. This was shown to be HMB **2**, and at this stage (1978) the lack of activity of AMB (**12**) as substrate relegated the latter bilane to an interesting artefact produced quantitatively by addition of ammonia to deaminase incubations (Fig. 6). However, with the acquisition of substantial quantities of pure uro'gen III synthase obtained by cloning the genes *hem*C and *hem*D together[34] and overexpression in *E. coli*, now at a level several hundred times greater than that described elsewhere,[35a] the substrate specificity of the synthase (formerly called cosynthetase) has been reinvestigated. Ever since its conception by Mathewson and Corwin in 1961,[33b] the spiro compound **13** (Fig. 6) has been a favorite construct with organic chemists, since both

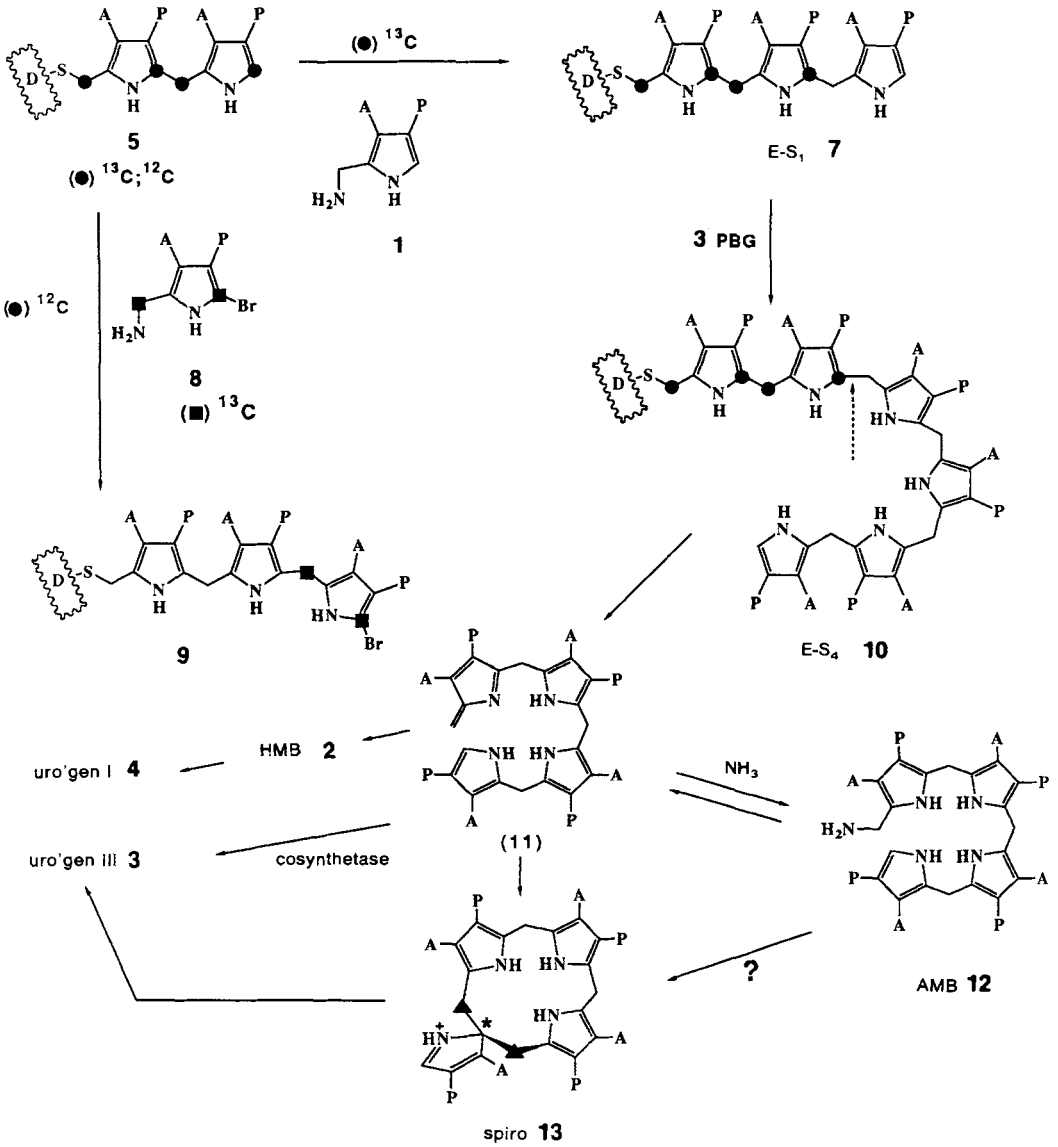

Fig. 6. The remarkable dipyrromethane cofactor of PBG deaminase, covalently attached to Cys242 of the enzyme and its role in tetrapyrrole assembly, showing the "spiro" mechanism (**13**) for the action of uro'gen III synthase (cosynthetase).

its genesis through α-pyrrolic reactivity and its fragmentation—recombination rationalize the remarkable intramolecular formation of uro'gen III from the linear bilane preuro'gen (HMB) **2** through inversion of ring D. A careful search for the spiro compound (**13**) was conducted at subzero temperatures in a cryosolvent (−24 °C; ethylene glycol/buffer) by using various ^{13}C isotopomers of HMB as substrate.[34] Although the synthase reaction could be slowed down (20 h rather than 20 s), no signals corresponding to the quaternary carbon atom (labeled with an asterisk in **13**; $\delta \approx 80$) or to the α-pyrrolic methylene groups (labeled with a black triangle; $\delta = 35-40$) could be observed. It was also found that totally synthetic AMB **12** (thus free of deaminase which can catalyze interconversion of AMB into HMB) also served as a slow but productive substrate for uro'gen III synthase at high concentrations (1 mmol in both enzyme and substrate). Regardless of which version of the bilane system (HMB, AMB) is involved, the fact that no intervening species free of enzyme was observed strongly suggests that the intermediate is enzyme-bound and therefore difficult to detect. Indirect evidence for the "spiro" mechanism was adduced when it was found that one of the enantiomers of the corresponding synthetic ring D-lactam served as an inhibitor of uro'gen III synthase.[36a] We recently proposed an alternative to the "spiro intermediate" **13** hypothesis, which is still consistent with the known facts.[34] and is based on a concept of self assembly with the formation of a lactone (see Fig. 7). It was suggsted that generation of the azafulvene (**11**) is followed not by carbon–carbon bond formation (to give **13**, but by closure of the macrocycle to the macrolide. The regiospecificity of this step is reflected by the failure[21] of synthetic bilanes lacking the acetic acid side chain at position 17 in ring D to undergo enzyme-catalyzed rearrangement to the type III system, together with the observation that a "switched" bilane carrying a propionate at position 17 (and an acetate at position 18) does indeed give a certain amount of (rearranged) uro'gen I (but also uro'gen III) enzymatically.[21, 36b] This indicates that lactone formation could also be achieved (but less efficiently) by a propionate group at position 17. The subsequent chemistry is

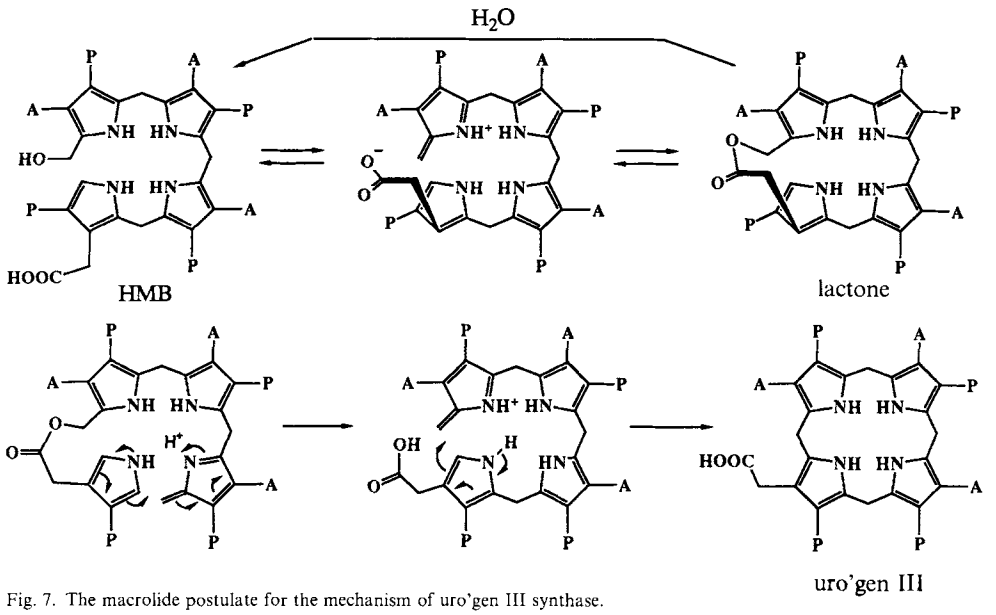

Fig. 7. The macrolide postulate for the mechanism of uro'gen III synthase.

quite similar to the fragmentation–recombination postulated for the spiro system except that a "twisted macrolide" becomes the pivotal intermediate species and the sequence proceeds as shown in Figure 7. Although this novel hypothesis is rather difficult to test experimentally, specific chemical traps for a lactonic intermediate, combined with the use of ^{18}O labeling are being employed to confirm or refute the possible role of a macrolide mechanism for uro'gen III synthase, whose cryptic mechanism has posed a biochemical puzzle for over three decades.

3. The Search for the Missing Intermediates: Genetic Engineering to the Rescue

"It is an old maxim of mine that when you have excluded the impossible, whatever remains, however improbable, must be the truth."
"The Beryl Coronet"

3.1. The First Methyltransferases: Their Specifities, and the Synthesis of Precorrins 1 and 2

The first of the methylases catalyzes the sequential formation of factors I and II (Fig. 2) and has been named *S*-adenosylmethionine uro'gen III methyltransferase (SUMT). SUMT was first partially purified from *P. shermanii* by G. Müller[37] and has been overexpressed in *Pseudomonas denitrificans*.[38] In *E. coli* it was found that the *Cys*G gene encodes uro'gen III methylase (M-1) as part of the synthetic pathway to siroheme, the cofactor for sulfite reductase, and overproduction (30 mg L^{-1}) was achieved by the appropriate genetic engineering.[39a] Although, SUMT and M-1 appear to perform the same task, it has been found that their substrate specificities differ.[39b,c] Thus, it has been possible to study in detail the reaction catalyzed by M-1 directly by NMR spectroscopy and to provide rigorous proof that the structure of precorrin 2 is that of the dipyrrocorphin tautomer of dihydro-factor II (dihydrosirohydrochlorin). Uro'gen III (enriched from [5-^{13}C]ALA **6** at the positions labeled with a black square in Fig. 8) was prepared by mixing dehydratase, deaminase, and uro'gen III synthase and then incubating them with M-1 and [$^{13}CH_3$]SAM. The resultant ^{13}C NMR spectrum of precorrin 2 revealed only one sp^3-enriched carbon atom assigned to C-15, thereby locating the reduced center. By using a different set of ^{13}C labels (● from [3-^{13}C]ALA) and [$^{13}CH_3$]SAM, the sp^2 carbon atoms at C-12 and C-18 were located as well as the sp^3 centers coupled to the pendant ^{13}C-enriched methyl groups at (*) C-2 and C-7. This result confirms an earlier NMR analysis[40a] of precorrin 2 isolated by careful anaerobic purification of the methyl ester, and shows that no further tautomerism takes place during the latter procedure. The two sets of experiments mutually reinforce the postulate that precorrins 1, 2, and 3 all exist as hexahydroporphinoids, and recent labeling experiments[40b] have provided good evidence that precorrin 1 is discharged from the methylating enzyme (SUMT) as the species with the structure shown in Figure 4.

However, prolonged incubation (2 h) of uro'gen III with M-1 provided a surprising result: the UV and NMR spectra changed dramatically from those of precorrin 2 (a dipyrrocorphin) to the chromophore of a pyrrocorphin, hitherto known only as a synthetic tautomer of hexahydroporphyrin.[41a] At first sight, this event seemed to signal a further tautomerism of a dipyrrocorphin to a pyrrocorphin catalyzed by the enzyme, but when [$^{13}CH_3$]SAM was added to the incubation, it was found that a third methyl group signal appeared in the region $\delta = 19-21$ of the NMR spectrum. When uro'gen III was provided with appropriate ^{13}C labels (● in Fig. 8), three pairs of doublets appeared in the sp^3 region ($\delta = 50-55$) of the pyrrocorphin product. The necessary ^{13}C pulse-labeling experiments[41c] together with appropriate FAB-MS data finally led to the structural proposal (Fig. 8)[41b,42] for the novel trimethylpyrrocorphin produced by "overmethylation" of the normal substrate, uro'gen III, in presence of high concentration of enzyme. Thus, M-1 has been recruited to insert a methyl group in the

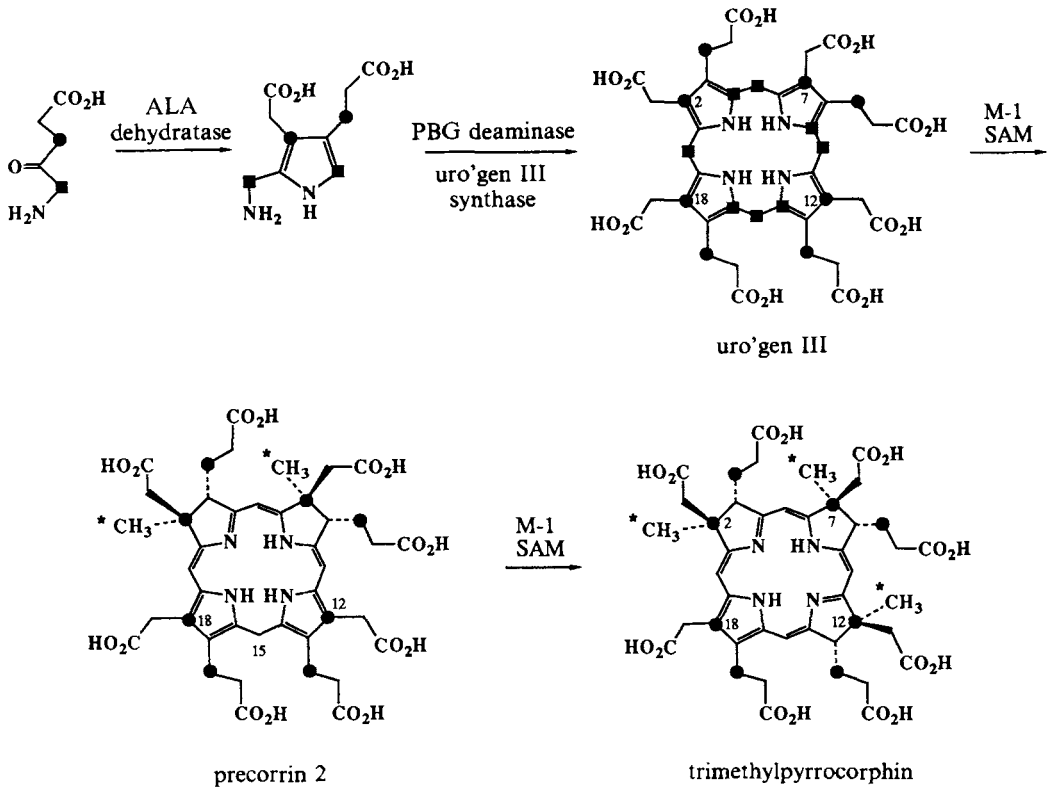

Fig. 8. Synthesis of procorrin 2, C methylation of uro'gen III by the enzyme uro'gen III methylase (M-1) and "overmethylation" of the product in a clockwise direction. The ^{13}C-enriched centers used to assign the carbon centers and C–C coupling were inserted from [3-^{13}C](●)-[5-^{13}C](■) ALA and [$^{13}CH_3$]SAM (*).

C ring and to synthesize the long sought "natural" chromophore. This chromophore corresponds to that of the postulated precorrin **4**, although in this case the regiospecificity is altered from ring D to ring C. The lack of specificity of M-1 was further exploited to synthesize a range of "unnatural" isobacteriochlorins and pyrrocorphins based on isomers of uro'gen III. Thus, uro'gen I produces the methylated products corresponding to precorrin 2 and the type I pyrrocorphin (Fig. 9). These compounds are reminiscent of a series of tetramethyl type I corphinoids, factors S1–S4, isolated from *P. shermanii*[43,44] which occur as their zinc complexes as discussed in Section 3.2. The totally synthetic isomers, uro'gens II and IV, in which the acetate (A) and propionate (P) side chains are positioned in the orders AP, PA, AP, PA and AP, AP, PA, PA, respectively, can also serve as substrates for M-1, remarkably producing the corresponding 2,7-dimethylisobacteriochlorins in both cases.[42b] When uro'gen I was incubated with SUMT,[45] isolation of factor II of the type I (sirohydrochlorin I) family revealed a lack of specificity for this methyltransferase also, although in the latter studies no pyrrocorphins were observed. This may reflect a control mechanism in the *P. denitrificans* enzyme (SUMT) which does not "overmethylate" precorrin 2, as is found for the M-1 from *E. coli*, whose physiological function is to manufacture sirohydrochlorin (factor II)[39b] for sulfite reductase, which itself is necessary for cysteine synthesis.[4] The fact that *E. coli* does not synthesize B_{12} could reflect an evolutionary process in which the C-methylation machinery has been retained, but is only required to insert the C-2 and C-7 methyl groups.

The sites of C methylation in both the type I and III series are also reminiscent of the biomimetic C methylation of the

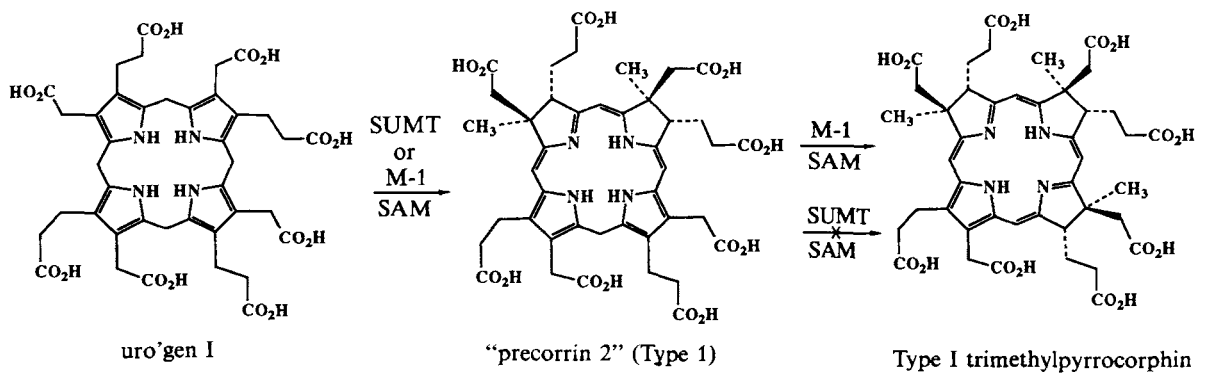

Fig. 9. Overmethylation of uro'gen I by M-1 (but not by SUMT!).

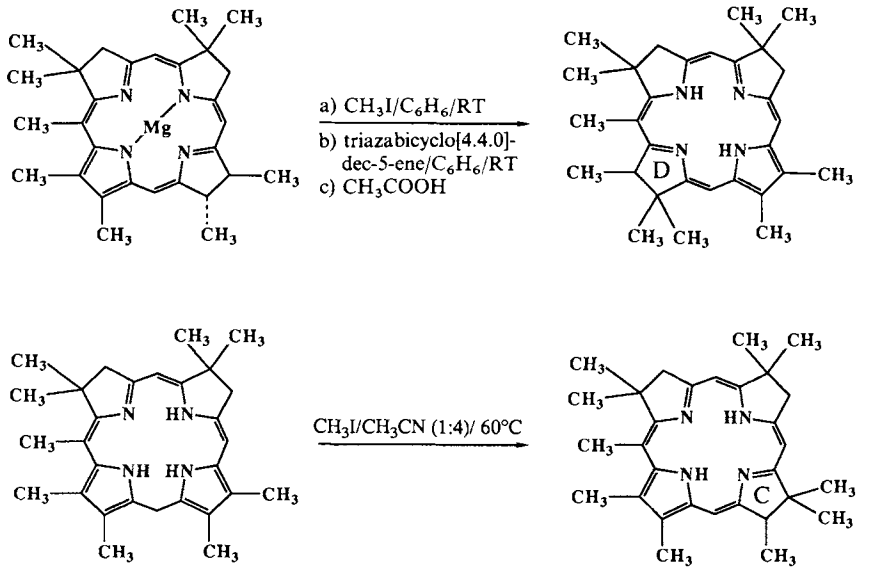

Fig. 10. "Metallic" control of regiospecificity in Eschenmoser's biomimetic C methylation of pyrrocorphins. Note that in the presence of Mg^{2+}, methylation occurs in ring D rather than ring C. RT = room temperature.

hexahydroporphyrins discovered by Eschenmoser et al.,[46] and the regiospecificity is in accord with the principles adumbrated[47] for the stabilizing effect of a vinylogous ketimine system (Fig. 10). Thus, the chemical dipyrrocorphin to pyrrocorphin conversion not only leads to the favored ketimine system of the pyrrocorphin but in the presence of a methyl group at C-20 becomes controllable through the presence of coordinating metal. The fascinating result of these in vitro models is that ring D (C-17) methylation can be achieved in the presence of magnesium, which corresponds to the methylation sequence found in Nature. The above experiments made us more optimistic that the methylases of the B_{12} pathway, which synthesize both natural and unnatural pyrrocorphins and corphins, could now be harnessed to prepare several of the missing intermediates of the biosynthetic pathway. Also of note is that the instability of these substances towards oxygen rationalizes our previous inability to isolate any new intermediates under aerobic conditions (> 5 ppm O_2), other than factors I–III formed by oxidation of the corresponding precorrins 1–3 (Fig. 2).

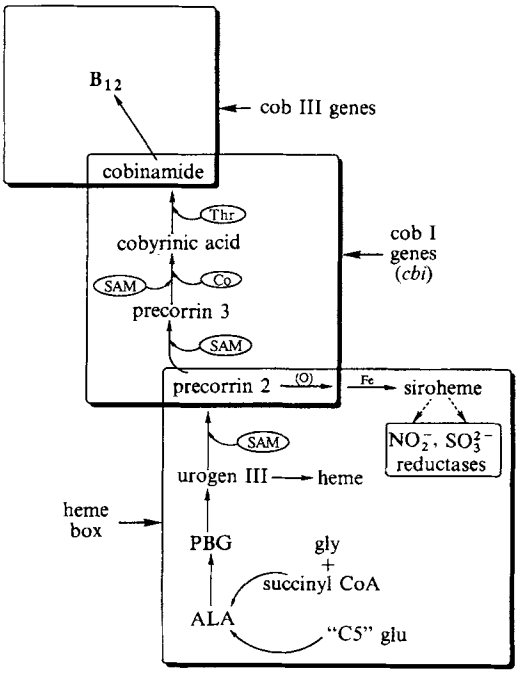

Fig. 11. The heme (*E. coli*) and Cob (*Salmonella*) gene boxes of B_{12} biosynthesis.

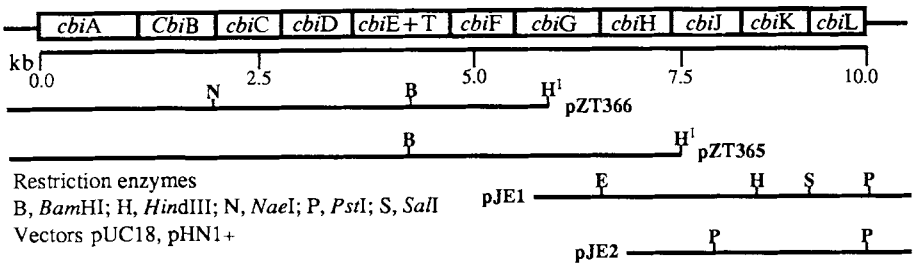
3.2. On the Road to Corrins: A Change of Horses from *E. coli* to *Salmonella*

Our search for the biosynthetic enzymes leading to precorrin 2 has so far relied on the "heme gene box" (Fig. 11) in *E. coli*. This is responsible for the synthesis of precorrin 2, a precursor of sirohydrochlorin[39b] (factor II), which, by insertion of iron, forms siroheme, a cofactor for the six-electron *E. coli* sulfite reductase.[4] Fortunately, the heme and corrin pathways intersect in *E. coli* and *Salmonella typhimurium*. Although *E. coli* does not make B_{12}, the discovery by J. Roth et al.[48a] that anaerobic fermentation of *S. typhimurium* produces vitamin B_{12}, has opened the way to enhance our knowledge of vitamin B_{12} synthesis by using the vast array of genetic and cloning techniques available with this organism. Three loci at minutes 13, 34, and 41 have been identified by mutation and complementation studies.[48] The main gene cluster at 41 minutes contains the machinery (Cob I) necessary for the synthesis of cobinamide from precorrin 2 (Fig. 11), a process involving six C methylations (at C-1, C-5, C-12, C-15, C-17, and C-20), decarboxylation (of the acetate residue at C-12), ring contraction, loss of acetic acid (from C-20 and its attached methyl), amidation, and cobalt insertion under control of the *cbi* genes. Thus, the CobI region responsible for cobinamide synthesis contains all of the *cbi* genes encoding these biosynthetic functions. Through the generosity of Professor Roth we were able to use his 10 kb sequence data to clone and overexpress the gene products, corresponding to the 12 open reading frames (ORFs) necessary to synthesize cobyrinic acid from precorrin 2 (Fig. 12).

Ten of the *cbi* genes found in the *cob* operon of *S. typhimurium* were subcloned for expression from the four different plasmids (Fig. 12). All of these genes except *cbi*D were



Genes	Plasmid	Construction

Fig. 12. Subcloning of the *cbi* genes from *S. typhimurium* for expression. The *cbi* genes in plasmid pBR 329 (pZT365, pZT366, pJE1, and pJE2) were a generous gift from Dr. J. Roth, University of Utah. The superscripts (1–4) relate to the footnotes at the bottom of the figure.

expressed in *E. coli* as determined by SDS-PAGE polyacrylamide gel electrophoresis), and seven of the gene products were purified from the soluble fraction of cell lysates of the appropriate strain. Two further gene products, those of *cbi*G and *cbi*J were found in the insoluble fraction. The amino terminal sequence of each of the purified proteins was determined and used to confirm the location of the open reading frames predicted from the nucleotide sequence.[48c] The gene products of *cbi*E, *cbi*F, *cbi*H, and *cbi*L were shown to be SAM-binding proteins, and based on their homology with other methyltransferases,[49a, b] are considered to be the most likely candidates for methyltransferase activity. The *P. denitrificans cob*L gene product has recently been reported[49c] to have two functions, methylation (of C-5 and C-15) and decarboxylation of the ring C acetate. SDS-PAGE and NH_2-terminal sequence analysis revealed that two separate gene products in *S. typhimurium* (*cbi*E and *cbi*T) correspond to the *cob*L gene product with *cbi*E homologous to the methyltransferase region and *cbi*T homologous with the decarboxylase region, that is in *Salmonella* the 5,15-methylase and decarboxylation activities are separated.

From its homology with the gene product of *cob*I in *P. denitrificans* (31% identity, 71% conservation), the *cbi*L gene product was predicted to be the *S. typhimurium* precorrin 2 methyltransferase (M-2), and using this expressed protein, or more efficiently the *cob*I enzyme, the multienzyme one-flask synthesis of precorrin 3 from the building block ALA was accomplished (Fig. 13).This was achieved both in the NMR tube and preparatively (on the multimilligram scale), by adding the five overexpressed enzymes to the substrate ALA in the presence of SAM.[50] The structure of precorrin 3, a dipyrrocorphin with the constitution shown (Fig. 13), revealed subtle differences compared with the precorrin 2 in the ^{13}C NMR spectrum, which reflected the influence of the new methyl group at C-20 on the conjugated system. This resulted in a preponderance of the tautomer whose electronic array is prepared for the next C-methylation step, and is directly observed by ^{13}C enrichment by NMR spectroscopy.

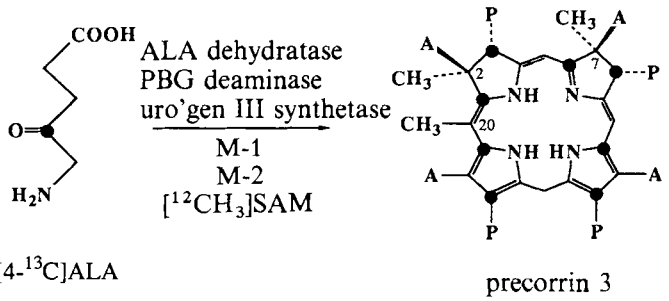

Fig. 13. Multienzyme synthesis of precorrin 3. M-2 is precorrin 2 methyltransferase.

As a guide to the anticipated order of insertion of the remaining methyl groups on the periphery of this last intermediate, precorrin 3, we recall the earlier pulse-labeling experiments. In these experiments the substrates uro'gen III and precorrins 2 and 3 (as factors II and III respectively) were incubated with SAM for several hours with a cell-free extract capable of synthesizing cobyrinic acid followed by a pulse of [$^{13}CH_3$]-labeled SAM. By examining the different intensities of the [$^{13}CH_3$]methyl resonances in the resultant cobester, the sequence of methyl group insertion was found (in three independent studies)[51a–c] to correspond to C methylation at C-17, followed by that at C-12 (now known to occur first at C-11, see below) then at C-1, C-5, and C-15. This differentiation between C-5 and C-15 was found in *P. shermanii*,[51a] while the reverse order for the C-5 and C-15 insertions was deduced by using *Clostridium tetanomorphum* extracts.[51b] In the third study (*P. denitrificans*)[51c] no distinction could be made between the C-5 and the C-15 methylation. However, the welcome agreement that C-17 is the first site of alkylation on the precorrin 3 template and is followed by C methylation at C-11 then C-1 imposes certain restrictions on the type of structure expected for the missing intermediates precorrins 4, 5, and 6, corresponding to methyl insertion at C-17, C-11, and C-1, respectively. Inspection of the stereochemistry of the methyl group ab C-17 in vitamin B_{12} reveals that, of the five methyl groups on quarternary

carbon centers in the vitamin, only that at C-17 is β oriented. This configuration was rationalized as long ago as 1976[4] when we suggested that methylation actually occurred at C-19 followed by ring opening and reclosure (by an allowed 16π-electron process) to give the β-oriented C_{19}-methyl group. Subsequently two [1,5]sigmatropic shifts led to the β-oriented methyl group at C-17. In other words, just like the situation now revealed at C-11 in which the attached methyl group migrates later to C-12, the final resting place of the fourth methylation (at C-17) might be preceded by a similar event, in which case precorrin 4 might correspond to either C-19 or C-18 β-methylated structures shown in Figure 14.

In order to begin the task of unveiling the remaining precorrin intermediates, precorrin 3 was incubated in turn with each of the putative, overexpressed methyltransferases from *cbi*E, H, F, and L in the presence of SAM. A surprising result was obtained. The only C methylation observed was that catalyzed by the gene product of ORF-7 (*cbi*F) and turned out to be methylation at C-11! The new compound, identified as the kinetic product by direct NMR observation (Fig. 15), is a modified corphin bearing a fourth methyl group at C-11. Since biochemical conversion of this corphin to cobyrinic acid has not yet been demonstrated, we have named the new compound 4x,[52] and its structural variant recalls one of the four possible structures proposed for factor S3.[43, 44] The spectroscopic data for the latter metabolite

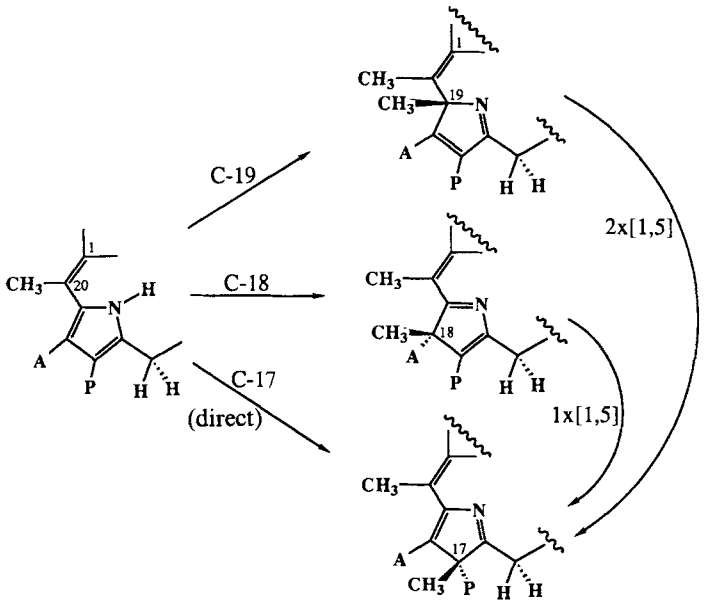

Fig. 14. Possible sites of C methylation in ring D of precorrin 3 and subsequent [1,5] sigmatropic shifts which rationalize the methyl group insertion finally observed at C-17 in corrins.

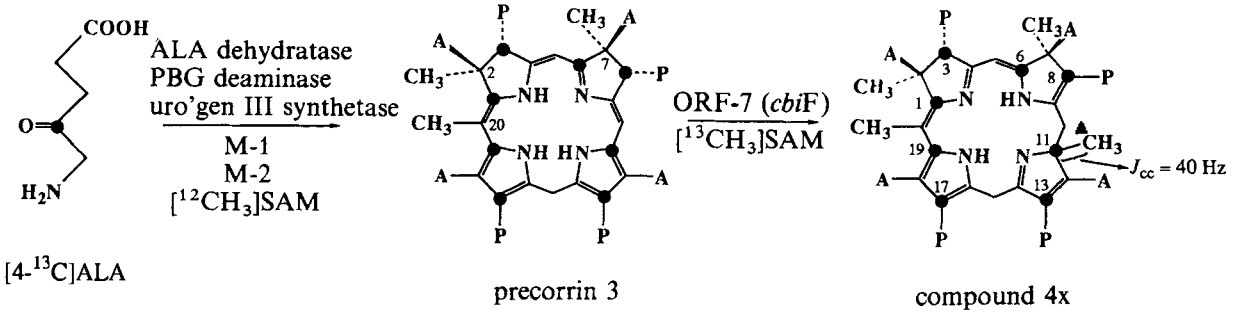
isolated from *P. shermanii*[43, 44] could not distinguish between methylation at C-1 or C-11, but it is now clear that the correct isomer is the one in which (α)-methylation at C-11



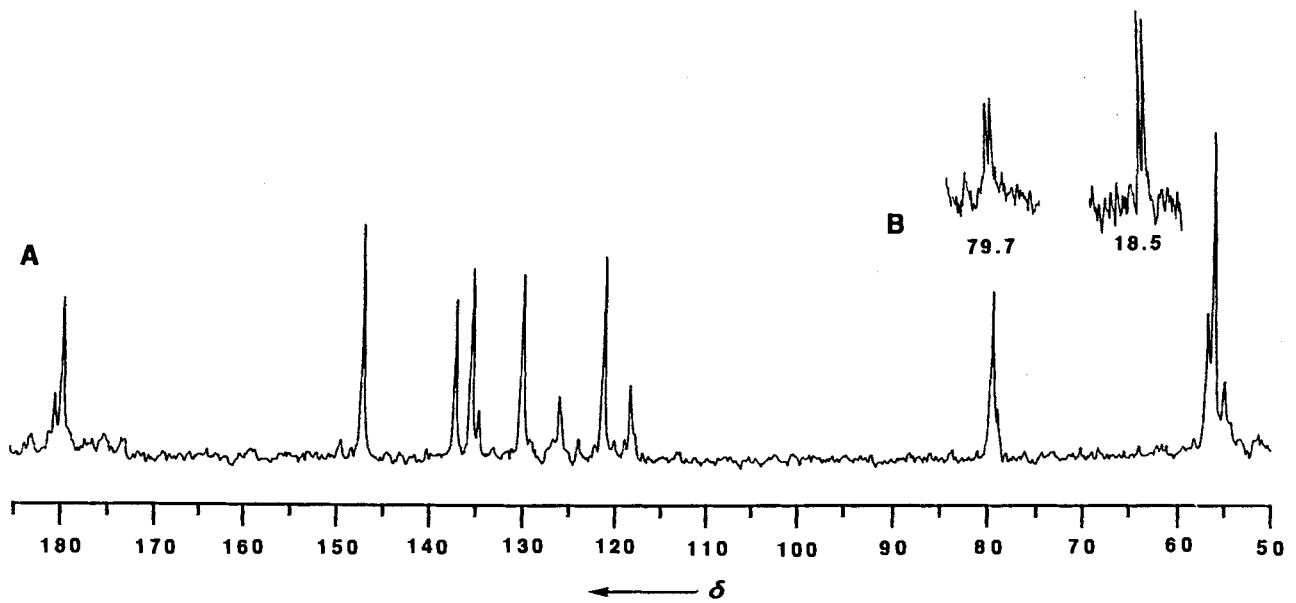


Fig. 15. Multienzyme synthesis of compound 4x with the gene product from *cbi*F and SAM. The ^{13}C NMR spectrum of 4x (A) reveals three sp^2 resonances at $\delta = 134.8$, 136.5, and 120.7 (C-8, C-13, and C-17, respectively), but only one signal at $\delta = 55.5$ for one sp^2 propionate terminus (C-3), and one at $\delta = 79.7$, typical of an sp^3 carbon atom (C-11) adjacent to a nitrogen atom. The inset B shows the coupling (J(C,C) = 40 Hz) of the new signal for $^{13}CH_3$ ($\delta = 18.5$) to the signal for C-11 at $\delta = 79.7$.

(≡C-16) has taken place on the uro'gen I template. The new structural proposal for factor S3 was nicely confirmed by a second multienzyme synthesis, this time using [4-^{13}C]ALA as substrate in a one-flask reaction mixture, containing dehydratase, deaminase (→ uro'gen I) *cys*G,[*] *cbi*F, and SAM (Fig. 16a). In the absence of the last of these enzymes (*cbi*F) the product 2,7,12-trimethylpyrrocorphin (Fig. 9) accumulates, but when the fourth enzyme (*cbi*F) was added, a new signal appeared at $\delta = 79$ heralding the insertion of a fourth (α-) methyl group on the C-16 position (Fig. 16a). The resultant zinc complex (in the form of its octamethyl ester) was identical in every respect with factor S3 isolated earlier from *P. shermanii*.[52b] It only remains to define the absolute configuration of the new chiral center at C-16 and to test for the putative [1,5]sigmatropic shift to transform factor S3 into factor S1 (Fig. 16b). These new findings[52] suggest a lack of substrate specificity in C methylation by the methyltransferases and provide a welcome confirmation of the function of *cbi*F as a methyltransferase which attacks the α position of pyrrole rings of pyrrocorphins, whether type III or type I. Furthermore, these results open the door to synthetic chemistry based on C methylation at electron-rich centers.

The discovery that factor S3 could be synthesized from uro'gen I, M-1, and *cbi*F,[52b] has profound implications for the methylation sequence and stereochemistry of corrin biosynthesis, since stereospecific methyl transfer has been effected on an "unnatural" substrate. In the light of these recent findings we now return to a discussion of the modulation of the regio- and stereochemistry of the post-precorrin 3 methylases by coordination with divalent metals.

[*] This abbreviation is used for both the gene and the gene product.

3.3. The Role of Metals in Corrin Biosynthesis

Since coordinating metal ions, for example Zn^{2+}, Co^{3+}, are present in the substrate for both type I and type III te-

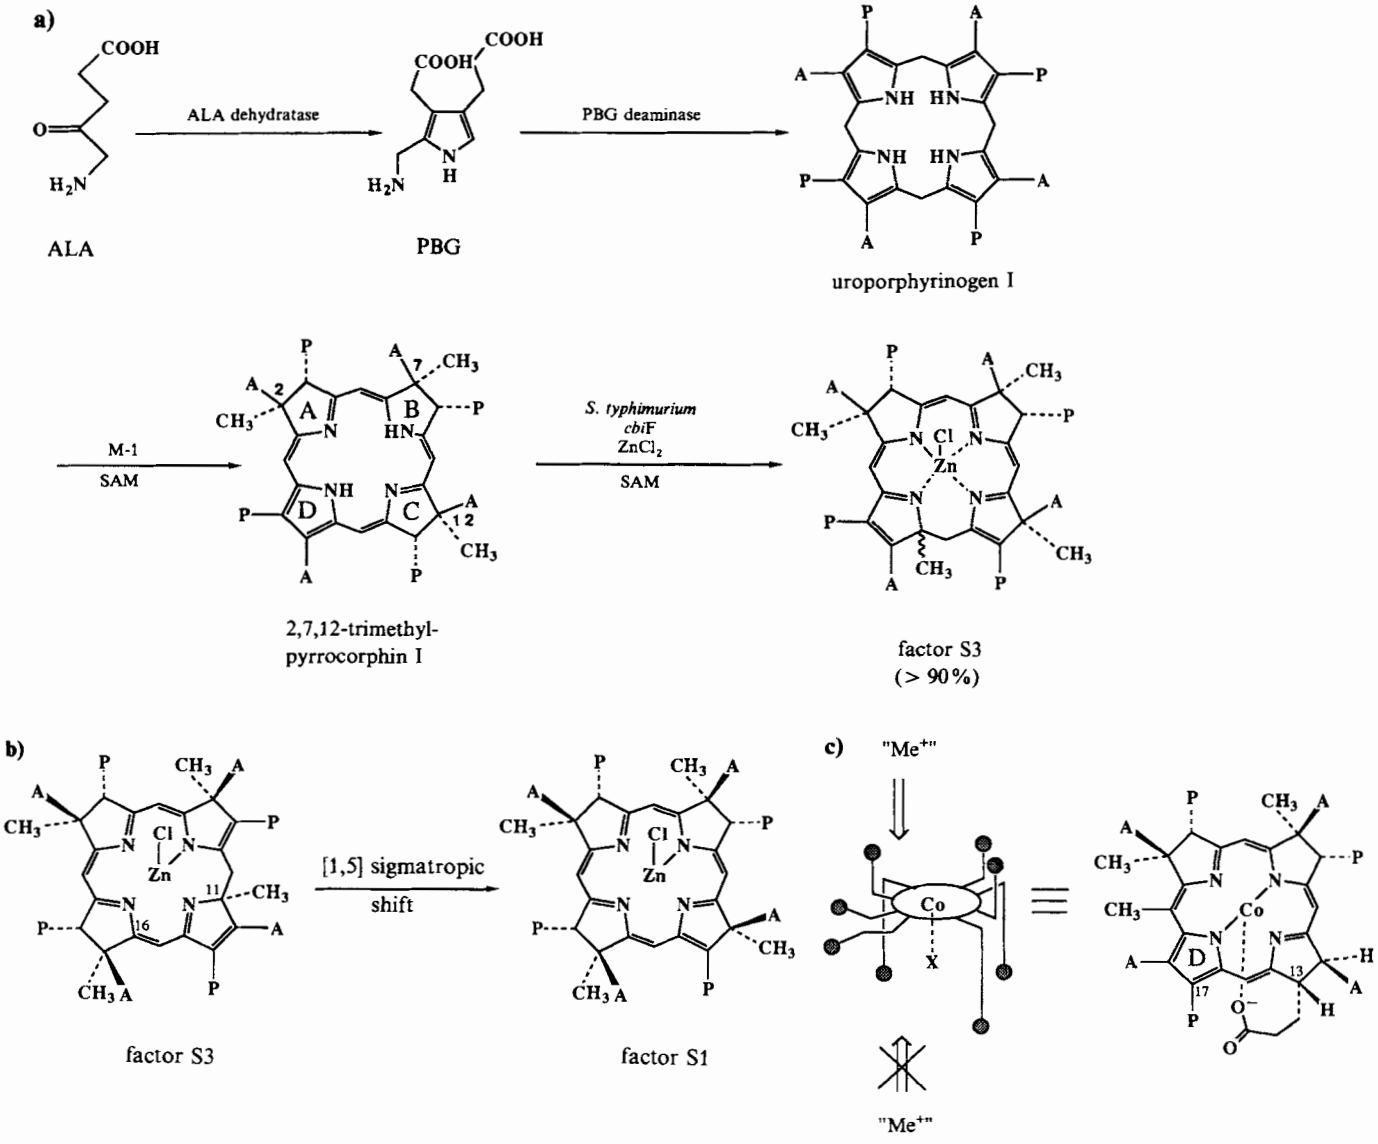

Fig. 16. a) Multienzyme synthesis of factor S3. b) A rationalization of a (chemical?) connection between factors S3 and S1. Note that the symmetry of the type I template allows clockwise rotation of the structure shown for factor S3 through 90° to change the apparent order of the C-methylation steps. c) Possible role of the three propionate side chains in the ring D pyrrocorphin tautomer of cobalt precorrin 3 to direct the incoming methyl group from SAM to the (upper) β face at the fourth (southwest) propionate terminus.

tramethylation, we can now speculate that the regio- and stereospecific C methylation of metalated precorrin 3 is controlled both by the inductive effect of the methyl group at C-20 and by the coordinating metal. Thus, cobalt precorrin 3 can be prepared for C-17 methylation by tautomerization to the ring D pyrrrocorphinate (Fig. 16c) which has the thermodynamically favorable all-*trans* configuration of the side chains (beginning with ring A). This process requires an α-orientated ring C propionate at C-13 whose interaction with the coordinating sphere of the metal together with the propionate side chains at C-3 and C-8 provide steric shielding on the α face of the macrocycle, allowing the fourth methylation (at C-17) to occur exclusively on the β face. This argument also holds for possible β methylation at C-18 (or even C-19) as discussed above.

On the other hand, in the recently described *P. denitrificans* mutant,[49, 53, 54] which harbors the eight genes necessary for the synthesis of the metal-free precorrin 6x[53, 54] (and hence hydrogenobyrinic acid), the absence of cobalt suggests that zinc or magnesium can be substituted for cobalt in order to achieve the same regio- and stereospecificity of C methylation and ring contraction as found in the cobalt series. Since the presence of a coordinating metal obviously exercises strict regiocontrol on this type of process, our metal-free substrates must now be reinvestigated in the form of their complexes with cobalt and zinc in order to determine the effect of the metal on the specificity of C methylation in corrin biosynthesis. The special role of cobalt is discussed in Section 4.

3.4. Comparison of *Salmonella* and *P. denitrificans* Genes for Corrin Synthesis

We are now in a position to compare the homologies and functions of the cloned genes of *Salmonella* and *Pseudomonas* (Fig. 17). Amino acid sequence comparisons of the gene products predicted from the nucleotide sequence of the *P. denitrificans* and *S. typhimurium* genes revealed homology between: *cob*H and *cbi*C; *cob*I and *cbi*L; *cob*J and *cbi*H; *cob*K and *cbi*J; *cob*L and *cbi*E + T; and the *cob*M and *cbi*F gene products. No homologues were found for the *cob*F, *cob*G, *cbi*D, and *cbi*G gene products (Fig. 17).

The *P. denitrificans* enzymes responsible for reduction of precorrin 6x to 6y (*cob*K), the bismethylation and decarboxylation of 6y to 8x (*cob*L), and the rearrangement of the latter to hydrogenobyrinic acid (*cob*H) have recently been described (Fig. 18).[49, 55, 56a] The remaining genes (*cob*F, G, J, M) most likely encode enzymes responsible for the synthesis of precorrin 6x from precorrin 3, a process which must involve several labile intermediates derived from SAM-dependent C methylations at C-1, C11, C-17, and ring contraction/deacylation (from C-20 and its attached methyl). None of these intermediates has been isolated from lysates of the recombinant *P. denitrificans* strain; they are presumably destroyed by the procedures used for the isolation of precorrin 6x (oxidation/esterification).

We have still to find C-17 and C-1 methylases, the ring contractase/deacylase and cobalt insertase enzymes. The structure recently suggested for precorrin 8x formed by C-5, C-15 methylation and decarboxylation in ring C, and the

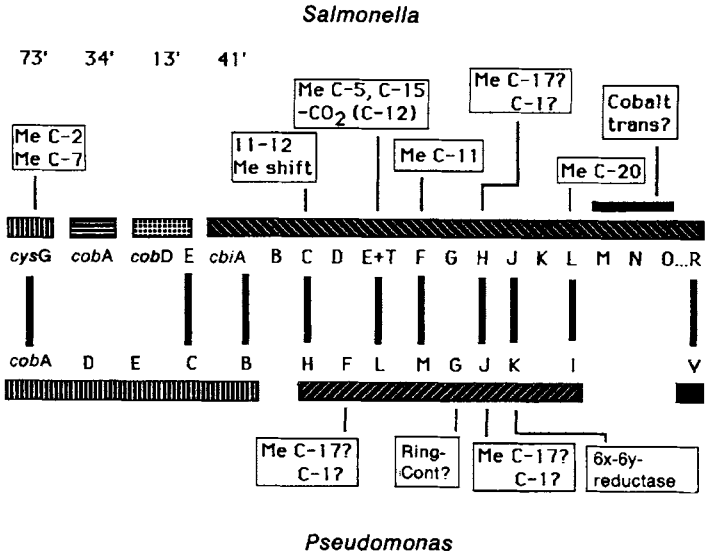

Fig. 17. The location and functions of some of the known genes for B_{12} biosynthesis in *Salmonella typhimurium* [49, 50] and *Pseudomonas denitrificans* [50, 53–56]. In *S. typhimurium* the genes map at 13', (*cob*D, *cob*E: addition of aminopropanol), 34' (*cob*A; adenosylation), 41' (*cbi*A-R; cobinamide biosynthesis), and 73' (*cys*G; uro'gen III methyltransferase). Homologies between the *S. typhimurium* and *P. dentrificans* gene products are shown. See the text for a discussion of their functions.

gene (*cob*H) encoding the mutase for the subsequent C-11 → C-12 transposition (Fig. 18) are important clues[55, 56, 56c] for the mechanism of corrin biosynthesis. It must be borne in mind, however, that none of these species bear cobalt, and that the final product in the eight gene system overexpressed in *P. denitrificans* is hydrogenobyrinic acid (cobalt-free cobyrinic acid). The absence of cobalt in the *P. denitrificans* metabolites precorrin 6x to 8x suggests that the gene for cobalt insertion resides elsewhere than the eight gene cluster used for overexpression,[56b] and that in this organism, amidation of cobyrinic acid takes place before cobalt insertion, remembering that complete cobalt-free corrinoids (including the nucleotide loop) have been found in photosynthetic bacteria. Thus, *Rhodopseudomonas spheroides* and *Chromatium vinosium* produce cobalt-free corrinoids,[57] as does the *P. denitrificans* strain that has been genetically altered by introduction of a plasmid bearing eight genes for corrin synthesis.[53] On the other hand, hydrogenobyrinic acid is not a precursor of cobyrinic acid in *P. shermanii*,[58] and even in the genetically altered *P. denitrificans* strain, cobalt can be inserted into the product, hydrogenobyrinic acid, only by chemical means. Since metallic cofactors seem important in the anaerobic B_{12} producers, it can be suggested that, in aerobes, divalent metal ions such as Mg^{2+} and Zn^{2+} can act as surrogates for cobalt and, on extraction (≡decomplexing), the metal-free corrinoid or precorrinoid is isolated. The reverse situation is found in *P. shermanii* (and presumably in *S. typhimurium*), since once cobalt is inserted into precorrins 2 and 3 (see Section 4), it cannot escape at a later stage from the strong coordinating ligands of the ring-contracted intermediates corresponding to precorrin 6x etc. for it is well known that cobalt cannot easily[59] be removed chemically from cobyrinic acid, cobalamins, and B_{12} without destroying, or at least cutting open, the macrocyclic ligand. Whether the presence (or absence) of cobalt in the precorri-

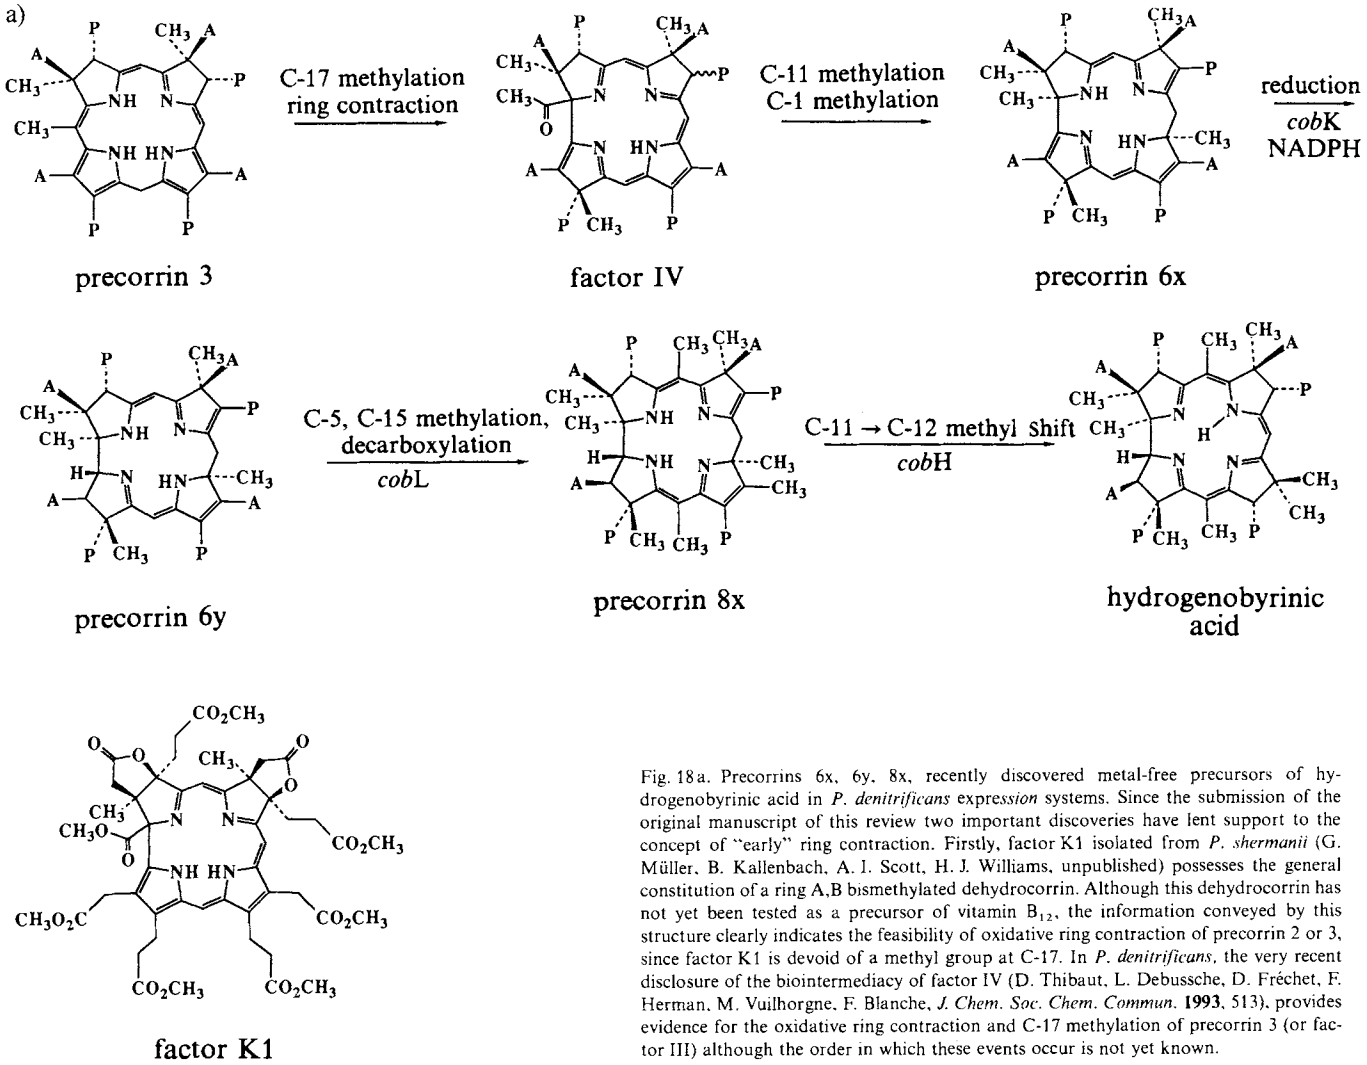

Fig. 18a. Precorrins 6x, 6y, 8x, recently discovered metal-free precursors of hydrogenobyrinic acid in *P. denitrificans* expression systems. Since the submission of the original manuscript of this review two important discoveries have lent support to the concept of "early" ring contraction. Firstly, factor K1 isolated from *P. shermanii* (G. Müller, B. Kallenbach, A. I. Scott, H. J. Williams, unpublished) possesses the general constitution of a ring A,B bismethylated dehydrocorrin. Although this dehydrocorrin has not yet been tested as a precursor of vitamin B_{12}, the information conveyed by this structure clearly indicates the feasibility of oxidative ring contraction of precorrin 2 or 3, since factor K1 is devoid of a methyl group at C-17. In *P. denitrificans*, the very recent disclosure of the biointermediacy of factor IV (D. Thibaut, L. Debussche, D. Fréchet, F. Herman, M. Vuilhorgne, F. Blanche, *J. Chem. Soc. Chem. Commun.* **1993**, 513), provides evidence for the oxidative ring contraction and C-17 methylation of precorrin 3 (or factor III) although the order in which these events occur is not yet known.

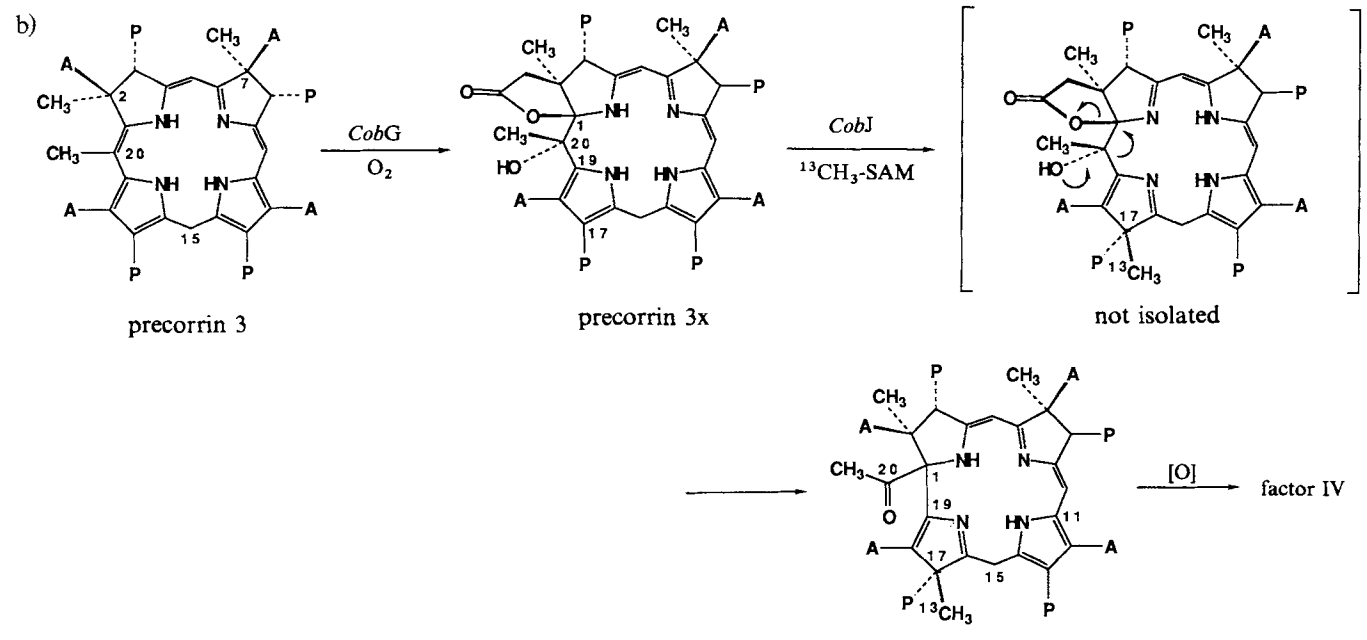

Fig. 18b. Note added in proof (July 15, 1993): Experimental evidence for the sequence between precorrin 3 and factor IV involving a new intermediate, precorrin 3x, with the *P. denitrificans* genes *cob*G and J has been obtained recently. An oxidative step (*cob*G) is followed by pinacol-type ring contraction and methylation at C-17 (*cob*J) to give precorrin 4, which on oxidation gives a product identical with factor IV (A. I. Scott, C. A. Roessner, N. J. Stolowich, J. B. Spencer, C. Min, *FEBS Lett.*, **1993**, in press).

noid intermediates radically alters the sequence of biosynthetic events such as C methylation, ring contraction, oxidation level, and amidation remains to be determined by exchange of the two classes of substrate, metalated and metal-free, between the biosynthetic enzymes of the aerobic and anaerobic B_{12}-producing bacteria.

Although it would seem inconceivable to organic chemists (and evolutionary theorists) that two distinct pathways should run parallel to such a complex target as B_{12} (or even cobyrinic acid), the circumstantial evidence now suggests that the enzymes of the aerobic and anaerobic pathways make and handle subtly different substrates—one set cobalt-free, the other coordinated with cobalt.

4. Cobalt Insertion: Experiments with *P. shermanii*

"When you follow two separate chains of thought, Watson, you will find some point of intersection which should approximate the truth."
"The Disappearance of Lady Frances Carfax"

In collaboration with G. Müller[60] we have shown that in *P. shermanii* extracts, cobalt is inserted into precorrins 2 and 3, and that the resultant metal complexes serve as substrates for cobyrinic acid synthesis in this organism (Fig. 19).

When we compared the synthetic capabilities of cell-free extracts from *P. shermanii* grown (A) in the absence and (B) in the presence of Co^{2+}, the oxidized cobalt complex of precorrin 2 (cobalt factor II) could be isolated only after incubation of extract (A) with ALA, SAM, and Co^{2+}, while the cobalt complex of factor III was isolated directly from extract (B). Extracts (A) and (B) were then partially purified (gel filtration) to remove endogenous small molecules. While the purified system **A** synthesizes cobyrinic acid only with the added substrates SAM/Co^{2+}/ALA or SAM/Co^{2+}/factor III, purified system **B** is capable of corrin synthesis in the presence of SAM but in the absence of Co^{2+} or any other substrate.

Direct confirmation of the role of cobalt precorrin 3 as a true substrate came from the incorporation of doubly labeled ($C^3H_3/^{14}C$) cobalt factor III with retention of two-thirds of the original $^3H/^{14}C$ ratio, as required for the loss of the C^3H_3 group and C-20 as acetic acid. Competition experiments clearly demonstrate intact bioconversion without interchange of coordinated metal, of cobalt factors II and III to cobyrinic acid, although in the absence of ethylenediaminetetraacetic acid (EDTA) some exchange of cobalt between the complexes can be detected. By careful experimentation it was possible to demonstrate the cell-free conversion of ^{14}C-labeled cobalt factor II in the presence of [C^3H_3]SAM to cobalt factor III, which exhibits a $^3H/^{14}C$ ratio of 1.15, and to cobyrinic acid with the $^3H/^{14}C$ ratio (5.65) expected for the five introduced methyl groups. Finally it could be shown that cobalt insertion in *P. shermanii* is an enzymatic process, when cobalt factor III was isolated after incubation of factor III with a *P. shermanii* homogenate.[60b] Thus, there is no longer any doubt that in *P. shermanii* (and presumably in *Salmonella*) cobalt is inserted much earlier in the pathway than in *P. denitrificans*.

5. Ring Contraction: Temporal Resolution of a Unique Isotope Exchange at a Carbonyl Group on the Way to B_{12}

"It is quite a three-pipe problem."
"The Red Headed League"

The structure of precorrin 6x dictates that, in *P. denitrificans*, ring contraction takes place between precorrins 3 and

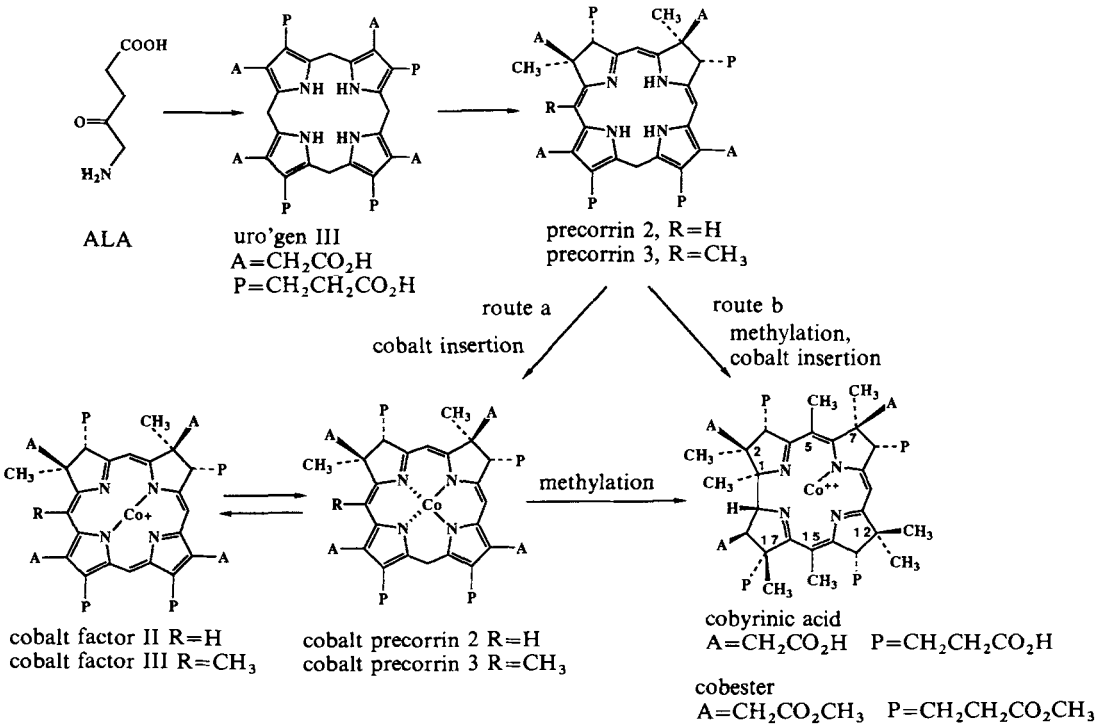

Fig. 19. Temporal resolution of cobalt insertion (into precorrins 2 and 3; route a) in *P. shermanii*.

6x, that is before the last two methylations (C-5 and C-15) and decarboxylation (C-12 acetate). No evidence is yet available for the intermediacy of species corresponding to precorrins 4a, 5a, and 6a; the structures of which are shown in Figure 20. However, in *P. shermanii* it has been possible to

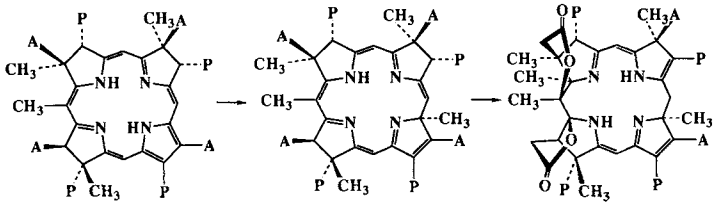

Fig. 20. Proposed structures of the missing intermediates, precorrins 4a, 5a, and 6a. Since several tautomeric and even isomeric(!) structures are possible for the undiscovered tetra- and pentamethyl intermediates, we have used the term 4a and 5a to denote this uncertainty. The same is true for the hexamethyl series where only 6x has been characterized. Thus, C-1 methylation in ring A may have been preceeded by C-20 alkylation and 1,2-migration as part of the ring contraction process. Although C-11 methyltransferase activity has been shown (Fig. 15), none of the research groups involved in B_{12} biosynthesis has yet identified the gene product responsible for C-17 methylation, corresponding to the putative structure for precorrin 4a but see Figure 18. The logical possibility, therefore, remains that ring contraction precedes methylation at C-17 (and hence C-11). In other words, the ring-contractase may use precorrin 3 (or even factor III!) as a substrate. This would constitute some violation of our cherished preconceptions about the timing of the extrusion of acetic acid from C-20, and its attached methyl group, and yet another major surprise in the convoluted saga of Nature's synthetic strategy for corrin synthesis. Experimental proof must now be sought for such a hypothesis by using the gene libraries from *S. typhimurium* and *P. denitrificans*. See also legend for Figure 18.

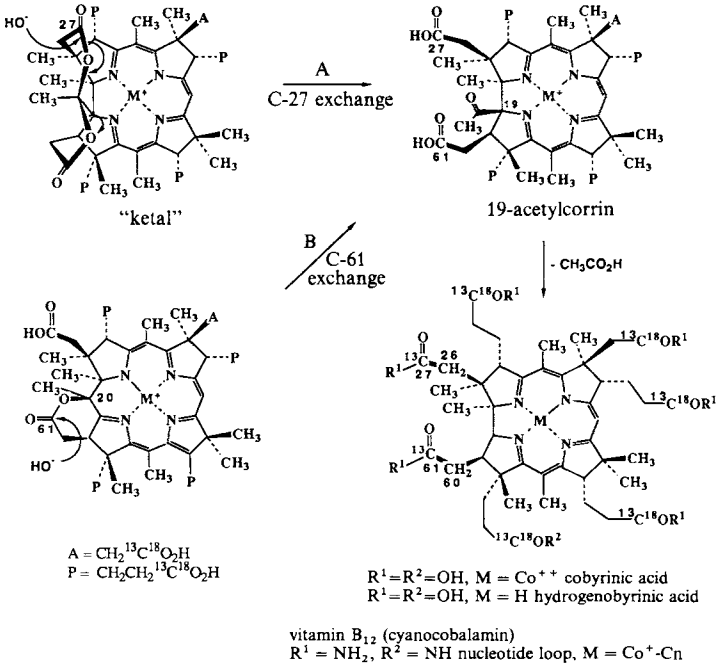

Fig. 21. Proposed mechanisms for $^{18}O/^{16}O$ exchange during ring contraction. The proposals are given in their original form although it is now known that ring contraction can take place on a cobalt-free structure with six or less methyl groups and that in aerobic organisms the acetyl group is at C-1 rather than C-19 (see Fig. 18).

show by NMR experiments that a unique carbonyl group at C-27 (the ring A carboxyamide group of B_{12}) is involved in the mechanism of ring contraction following C methylation at C-17, C-11, and C-1.

It was found[61] by ^{18}O labeling that during B_{12} biosynthesis almost complete $^{18}O/^{16}O$ exchange of the carbonyl oxygen atom of one of the three acetamido groups takes place. This result has profound bearing on the proposed mechanism of corrin biosynthesis. Thus, in one hypothesis,[62] δ-lactone formation between the acetate group (C-27) of ring A and C-20 has been proposed to rationalize the ring contraction of the porphyrinoid to the corrinoid template (mechanism A; Fig. 21), leading to incorporation of solvent label by hydrolysis. A second hypothesis[63] involves the sole intervention of the ring D acetate carbonyl group (C-61) in δ-lactone formation to C-20, followed by a subsequent hydrolysis step in which exchange of ^{18}O label ($\geq 50\%$) exclusively at C-61 would be observed (mechanism B; Fig. 21). The unambiguous assignment of the ^{13}C NMR signals for these two acetate carbonyl C atoms now become crucial, since the analysis for $^{18}O/^{16}O$ exchange is based on the isotopic shifts of ^{18}O on the $^{13}C{=}O$ resonances. Unfortunately, in the NMR spectra of cobalamins[64-66] the two carbonyls in question (C-27 and C-61) usually differ by less than $\Delta\delta = 0.3$ in chemical shift, and in several instances are superimposable.[65,66] The problem was solved by enhancing the resolution of the 2D experiment by specific ^{13}C enrichment. Cyanocobalamin was biosynthetically enriched at all seven carbonyl carbon atoms from [1-^{13}C]ALA, using cells of *P. shermanii*. The resulting high-resolution (<4 Hz/pt in F_1) HMBC spectrum clearly resolves all seven carbonyl carbon atoms. More importantly, C-27 and C-61, separated by only $\Delta\delta = 0.2$ in the one-dimensional spectrum, can be assigned unambiguously by correlation to their adjacent protons, H-26 ($\delta = 2.35$) and H-60 ($\delta = 2.70$) (Figs. 22A, B). The chemical shifts of these protons have been previously assigned.[65] This establishes that the correct assignment for C-27 ($\delta = 178.40$) had indeed been chosen in the earlier work, that is the acetate group of ring A, rather than that of ring D, uniquely participates at least once (and possibly more than once) in reactions whose mechanisms require almost complete exchange of ^{16}O from the medium with the ^{18}O-labeled carbonyl group at C-27.[67]

The next question concerns the timing of the loss of ^{18}O, that is before or after the formation of uro'gen III, the first tetrapyrrolic macrocycle of the B_{12} pathway. This question can, in principle, be answered by observation of the ^{18}O induced chemical shift changes in the ^{13}C NMR spectrum of a sample of urogen III derived from [1-^{13}C,1-$^{18}O_2$]5-aminolevulinic acid (ALA). Although distinction can be made between the two sets of ^{13}C signals comprised of four acetate and four propionate carbonyl groups of urogen III, specific assignments for the individual acetate and propionate carbonyl groups cannot be made for reasons of symmetry. Accordingly, a method for removing this impasse was devised in order to provide unequivocal assignment for the acetate carbonyl groups of rings A and D, and information about possible ^{18}O exchange beyond urogen III, that is, after the insertion of the first two methyl groups in the biosynthetic intermediate precorrin 2 at C-2 and C-7. As discussed in

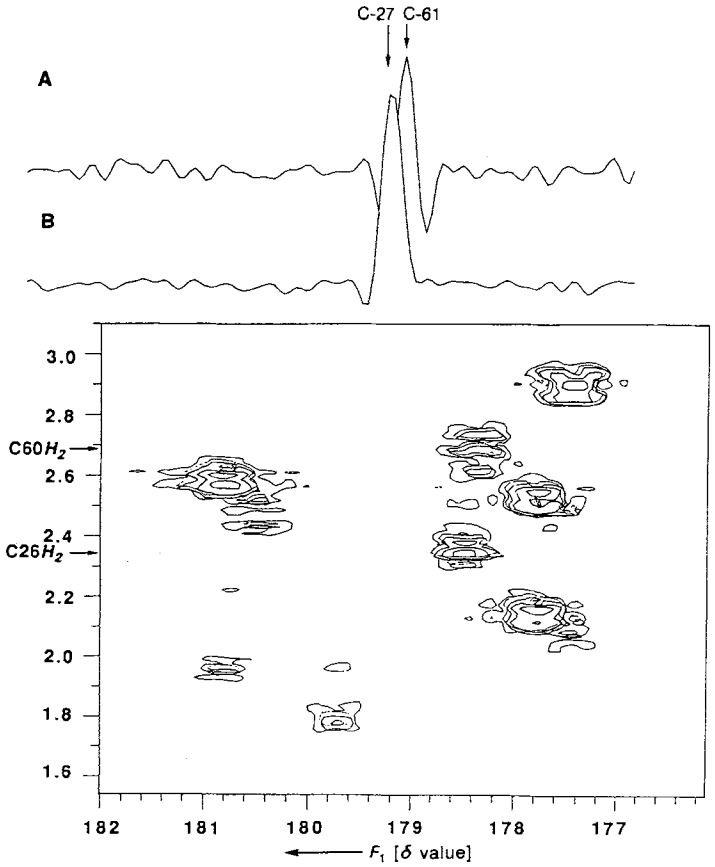

Fig. 22. 2D HMBC NMR spectrum (300 MHz, ^1H; 75 MHz, ^{13}C) of cyanocobalamin isolated from *P. shermanii* grown on [1-^{13}C]ALA. Spectra **A** and **B** represent slices through $\delta = 2.70$ and $\delta = 2.35$, respectively, confirming the two bond correlation between C-61 ($\delta = 178.28$) and H-60 in **A**, and C-27 ($\delta = 178.40$) and H-26 in **B**. See Figure 21 for numbering system.

Section 3.1, uro'gen III can be efficiently C methylated in the presence of SAM by M-1 to give the trimethylpyrrocorphin in which all four acetate carbonyl groups are cleanly resolved in the ^{13}C NMR spectrum. When the trimethylpyrrocorphin (Fig. 8) was prepared from [1-^{13}C,1-$^{18}O_2$]ALA with the required set of enzymes in $H_2{}^{16}O$, analysis of the ^{18}O perturbed ^{13}C chemical shifts for the acetate and propionate carbonyl groups of the product revealed that no exchange of ^{18}O by solvent ^{16}O had taken place. Thus, the major exchange of the oxygen atom of the ring A acetate carbonyl group of cyanocobalamin with water from the medium must occur in an intermediate after precorrin 2. The result[67] is important not only in defining the timing of the exchange, but in providing a protocol for analyzing the fate of ^{18}O in the carbonyl groups of urogen III. One of these carbonyl groups might be induced to undergo trapping of ^{16}O under conditions of high pH. This would be a test for possible lactonic intermediates during uro'gen III formation as discussed above.

Returning to the mechanism of corrin biosynthesis, it is now clear that the ring A acetate (C-27) serves at least once in a scaffolding role before and/or during the ring contraction step, and is released by hydrolysis at C-27. The ring D acetate, which may still be involved in ketal formation of the 19-acetyl system (Fig. 21), however, neither suffers direct hydrolysis nor participates in the hydrolytic step envisaged in a previous hypothesis.[63]

6. Evolution of the Porphyrin–Corrin Pathway: Why Type III?

"In solving a problem of this sort, the grand thing is to be able to reason backwards."
"A Study in Scarlet"

There seems no doubt that dual or parallel pathways exist for corrin synthesis in the primitive anaerobes when compared with the (anaerobic) photosynthetic and aerobic microorganisms (Fig. 23). The "preregistration"[47] of a prebiotic corrin template may well have diverted the subsequent biochemical machinery to a type III rather than a type I world, since the genes for uro'gen III synthesis were required for the subsequent ring-contraction step which requires juxtaposition of the two adjacent acetate side chains[47] in ring A and D of uro'gen III. Thus, when heme, chlorophyll, and the cytochrome pigments became necessary cofactors for oxygen transport, photosynthesis, and O_2 activation, respectively, the natural choice was uro'gen III, since this template was already in place as a necessary component of corrin synthesis under genetic control. These intriguing questions will be difficult to answer directly, but even within the context of "modern" B_{12} biosynthesis the duality of pathways (with or without O_2) suggest a vestige of evolutionary preference which now appears to be lateral rather than vertical.

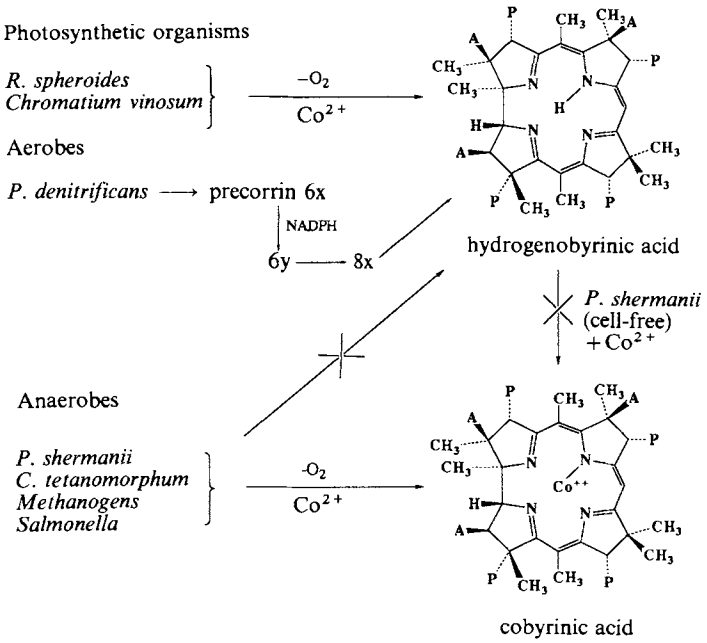

Fig. 23. Parallel, oxidative and metal-free routes to corrins in bacteria.

7. Epilogue

"It is a capital mistake to theorize before you have all the evidence."
"A Study in Scarlet"

This account of vitamin B_{12} biosynthesis has shown how, over the last 25 years, both our earlier ideas and the tech-

niques available for the experimental resolution of the problems of the B_{12} biosynthetic mechanisms, including the isolation of post-uro'gen III intermediates, have been tempered by the fire of experience. By use of modern gene technology and NMR spectroscopy it has at last been possible to break through the previously impenetrable shroud of mystery surrounding Nature's chosen route to vitamin B_{12}. Even with these superb tools, given to us from physics and biology, several steps of the pathway remain cryptic, and it may take yet another technical advance to solve the remaining fascinating problems of enzymatic methylations at carbon atoms C-1 and C-17, the "black box" of ring contraction/deacetylation, and finally cobalt insertion. However, it does appear that at last the beginning of the end is in sight. The many surprises encountered along the way have deepened our respect for the elegant and finely tuned processes used to forge the enigmatic porphyrinoid–corrinoid connection. The adage "to travel hopefully is better than to arrive" can truly be applied to our journey along the road to corrins, and in many ways we will be exhilarated, yet saddened, when the last mysteries of vitamin B_{12} enzymology are solved.

Our expedition along the road to B_{12}, frequently uphill, was shared and made possible by my previous graduate students, postdoctorals, and technical assistants, all of whom contributed great skill and energy to this convoluted, yet rewarding search. In chronological order beginning in 1967 they were: Dr. D. White (Upjohn), Dr. C. A. Townsend (John Hopkins), Dr. K. Okada (Nagoya), Dr. M. Kajiwara (Tokyo), Dr. R. J. Cushley (Victoria, B.C.), Dr. E. Lee (Seoul), Dr. B. Yagen (Jerusalem), Dr. N. Georgopapadakou (Roche), Dr. K. S. Ho (Massachusetts), Dr. S. Klioze (Hoechst), Dr. G. H. Temme (Dow), Dr. I. M. Armitage (Yale), Dr. S.-L. Lee (Corning), Dr. T. Takahashi (Japan), P. Demou (Yale), Dr. D. Petrocine (New York), Dr. K. Kang (Korea), Dr. H. Klein (Cologne), Dr. A. Gossauer (Fribourg), Dr. A. J. Irwin (Ontario), Dr. S. K. Chung (Korea), (The late) Dr. K. Obata (Japan), Dr. P. J. Whitman (New Jersey), Dr. G. Burton (Buenos Aires), Dr. H. Nordlov (Stockholm), Dr. P. Fagerness (Upjohn), Dr. S. Hosozawa (Otsuka Co.), Dr. H. Matsumoto (Daiichi Co.), Dr. J. B. Hansen (Kopenhagen), Dr. K. Shishido (Japan), Dr. J. N. S. Evans (Pullman, Washingon), Dr. N. E. Mackenzie (Tucson), Dr. R. L. Baxter (Edinburgh), Dr. A. Boyd (Edingburgh), Dr. R. C. Davies (Edinburgh), Dr. I. Ichinose (Japan), Dr. T. Oh-hama (Japan), Dr. S. K. Grant (Merck), Dr. P. Karuso (Australia), Dr. T. Hoshino (Japan), Dr. K. Clemens (Scripps Institut), Dr. A. R. Jacobson (Cambridge, Mass.), Dr. P. Yon-Hin (Houston), and Dr. D. Becker (Israel).

A special word of thanks is due to my senior collaborators: Professors G. Müller (Stuttgart), P. M. Jordan (London) and J. Roth (Utah). I am indebted to the present group of highly motivated, young colleagues whose recent discoveries form the main theme of this account: Drs. P. J. Santander, R. Danso-Danquah, M. D. Gonzalez, M. J. Warren, K. Iida, C. Pichon, T. Xue, P. Nayar, J. B. Spencer, Ms. B. P. Atshaves, Ms. K. Campbell, Ms. S. Estrada, and Messrs. N. Anousis, C. Min, S. Ozaki, and J. Park. Their research efforts in the areas of molecular biology, enzymology, and NMR spectroscopy were guided at all times by Drs. Charles Roessner, Neal Stolowich, and Howard Williams whilst Mr. Y. Gao provided untiring help with NMR instrumentation.

We thank the National Institues of Health (NIH), the National Science Foundation (NSF), the Robert A. Welch Foundation, the Science and Engineering Research Council (SERC) (UK), and NATO for generous financial support.

[4] Review: A. I. Scott, *Acc. Chem. Res.* **1978**, *11*, 29. Factor II turned out to be identical with sirohydrochlorin, the metal-free cofactor of *E. coli* sulfite reductase which requires siroheme, the iron complex of factor II, as part of its biochemical machinery to synthesize cysteine in a six-electron reductive process. It is remarkable that sulfite reductase employs a B_{12} intermediate in this way. (A. I. Scott, A. J. Irwin, L. M. Siegel, J. N. Shoolery, *J. Am. Chem. Soc.* **1978**, *100*, 316).

Schopf), Princeton University Press, Princeton, NJ, USA, **1983**. The time-honored British billion (10^{12}) has recently been usurped by the "New World" billion (10^9) as used in this article. British readers therefore should make the mental adjustment and note that the journal *Nature*, a bastion of correct English usage, will henceforth adopt this convention (1 billion = 10^9) as discussed therein (*Nature*, **1992**, *358*, 2).

[10] L. J. Ljungdahl, H. G. Wood in *B_{12}, Vol. 2*, (Ed.: D. Dolphin), Wiley, New York, **1982**, Chapter 7.
[11] Almost the entire second volume of *B_{12}* [(Ed.: D. Dolphin) Wiley, New York, **1982**] is devoted to the fascinating rearrangements catalyzed by coenzyme B_{12}. It is quite remarkable that although organisms such as *Salmonella typhimurium* do not appear to require B_{12} for their well-being, the genes for B_{12} synthesis have been retained, albeit silently. Thus, *S. typhimurium*, normally cultivated aerobically, only makes the vitamin when grown anaerobically (R. M. Jeter, B. M. Olivera, J. R. Roth, *J. Bacteriol.* **1984**, *170*, 2078). The question then arises as to what "anaerobic" function can be ascribed to B_{12} in these and related organisms such as the methanogenic bacteria.

[41] a) R. Schwesinger, R. Waditschatka, J. Rigby, R. Nordmann, W. B. Schweizer, E. Zass, A. Eschenmoser, *Helv. Chim. Acta* **1982**, *65*, 600; R. Waditschatka, Dissertation, no. 7707, *Die Porphyrinogen ⇄ Pyrrocorphin-Tautomerisierung*, ETH Zürich, **1985**; b) M. J. Warren, N. J. Stolowich, P. J. Santander, C. A. Roessner, B. A. Sowa, A. I. Scott, *FEBS Lett.* **1990**, *261*, 76. c) That the structure of the trimethylpyrrocorphin (Fig. 8) conforms to a "clockwise" direction of C methylation could be shown by a pulsed isotopic dilution experiment in which heavy ^{13}C enrichment at C-2 and C-7, medium enrichment at C-12, and very slight enrichment at C-18 in the substrate, uro'gen III was achieved by conversion of differentially ^{13}C-enriched E-S complexes of deaminase to HMB (Fig. 4), thence to uro'gen III with cosynthase. The ^{13}C NMR spectrum of the C-methylated product of this specimen of uro'gen III, the trimethylpyrrocorphin (Fig. 8), showed strong (sp^3) signals for C-2, C-7, a medium (sp^3) signal for C-12, and almost no signal in the sp^2 region corresponding to C-18, showing that the third methylation had occurred at C-12. On the other hand, due to the inherent symmetry of the type I template, the corresponding trimethylpyrrocorphin (Fig. 9) does not betray its methylation sequence, since the third methyl group could have been introduced formally at C-12 or C-17, as can be seen by rotating the structure through 90°. We will assume for the subsequent argument that the methylations are in conformity with the type III system (Fig. 8), that is they are always performed in a *clockwise* direction.

[52] a) C. A. Roessner, M. J. Warren, P. J. Santander, B. P. Atshaves, S.-I. Ozaki, N. J. Stolowich, K. Iida, A. I. Scott, *FEBS Lett.* **1992**, *301*, 73; b) S.-I. Ozaki, C. A. Roessner, N. J. Stolowich, G. Müller, unpublished results. We have recently found (J. B. Spencer, A. I. Scott, unpublished results) that the *cysG* gene product (M-1) turns out to have at least three functions in addition to C methylation of uro'gen III to precorrin 2. Thus, in the presence of M-1 and NAD, precorrin 2 is dehydrogenated to factor II (sirohydrochlorin; Fig. 2) which, on addition of Fe^{2+} (again in the presence of M-1) is catalytically metalated to siroheme (Fig. 1). It has also been found with uro'gen I as substrate, that *cysG* not only inserts three C-methyl groups (at C-2, C-7, and C-12) (Fig. 9), but also catalyzes the insertion of Zn^{2+} in the resultant trimethylpyrrocorphin, and surprisingly, uses this metal substrate for inserting a fourth methyl group at C-17, leading to the multienzyme synthesis of factor S1. Contrary to our previous ideas, this has a separate biosynthesis and is not derived by a 1,2-shift of the C-11 methyl group of factor S3 (Fig. 14). Also in recent work (with J. B. Spencer, C. A. Roessner, and N. J. Stolowich) it has been demonstrated that *cysG* not only serves as an iron and zinc chelatase, but will also introduce Co^{2+} into factor II. Thus, *cysG* is the first methyltransferase and may also be the cobaltochelatase of the anaerobic B_{12} pathway, a proposal which has received welcome confirmation by the demonstration (B. S. Goldman and J. R. Roth, *J. Bacteriol.*, **1993**, *175*, 1457–1466) that 66 *cysG* mutants of *Salmonella typhimurium* are unable to synthesize either siroheme or vitamin B_{12}. To summarize, *cysG* ($M_r \approx 50000$) appears to be the ancestral methyltransferase/dehydrogenase of anaerobic B_{12}-producing bacteria, and the subsequent specialized methyltransferases (such as SUMT, $M_r \approx 26000$) have lost this multifunctionality which also includes metal insertion (Fe^{2+}, Co^{2+}, Zn^{2+}, Ni^{2+}) and the capacity to "overmethylate" the (di)pyrrocorphinate template at positions C-12 and C-17. The metal and NAD binding sites are associated with the N-terminus residues 1–200, as evidenced by mutagenesis and truncation studies (M. J. Warren, personal communication). The *cysG* gene product should therefore be renamed siroheme synthase.

[62] The mechanism suggested for the ring-contraction step is a stereoelectronically dictated dyotropic 1,2-migration of antiperiplanar groups within the dilactonic ensemble (ref. [47]). Precorrins 4a, 5a, and 6a are hypothetical structures predicted by the sequence of C methylation deduced indirectly from pulse-labeled ^{13}C NMR experiments, and are based on chemical models (ref. [47]). The connection between the postulated 6a and precorrin 6x, the known metal-free intermediate from *P. denitrificans*, involves ring contraction and loss of acetic acid in a process which raises the oxidation level (in precorrin 6x) by one double bond equivalent (Fig. 18). It has yet to be proved if the same mechanism is operational in *P. shermanii* since a) cobalt is already in place before ring contraction and b) there appears to be no requirement for NADPH (6x → 6y). This again suggests dual pathways for aerobic and anaerobic B_{12}-producing organisms, the latter requiring no change in the oxidation level from ALA to cobyrinic acid.

[63] H. C. Uzar, A. R. Battersby, *J. Chem. Soc. Chem. Commun.* **1985**, 585; F. J. Leeper, *Nat. Prod. Rep.* **1985**, *2*, 561. In the two mechanisms proposed in references [47, 63] it has been assumed that all five C methylations and decarboxylation in ring C have taken place before ring contraction. The actual sequence may be modulated by the presence or absence of cobalt in the substrates. Thus, in aerobic, genetically engineered *P. denitrificans* the isolable intermediate precorrin 6x has already undergone ring contraction and deacylation, but still has to receive C-5 and C-15 methyl groups, to undergo a C-11 to C-12 methyl shift with decarboxylation, and NADPH-mediated reduction to form hydrogenobyrinic acid which is not metalated enzymatically in this system (Fig. 18). However, in *P. shermanii* the substrates for subsequent C methylations (and ring contraction) are the cobalt complexes of the precorrins (Fig. 19). For clarity the mechanistic proposals for ring contraction are given in their original form.

Peptidomimetics for Receptor Ligands—Discovery, Development, and Medical Perspectives

By Athanassios Giannis* and Thomas Kolter

Peptides, as neurotransmitters, neuromodulators, and hormones, influence a multitude of physiological processes by signal transduction mediated through receptors. In addition, during the last 20 years their role in the appearance or maintenance of various diseases could be unequivocally proven. Agents that can imitate or block the biological functions of bioactive peptides (agonists or antagonists, respectively) can be considered as aids for the investigation of peptidergic systems and also as therapeutic agents. The suitability of bioactive peptides as therapeutic agents was examined after preliminary pharmacological experiments. It was thereby shown that based on their pharmacological properties, for example degradation by peptidases or poor bioavailability, they could be employed as drugs in only a few cases. To solve this problem peptidomimetics, compounds that act as substitutes for peptides in their interaction with receptors, have been synthesized. In comparison with native peptides they show higher metabolic stability, better bioavailability, and longer duration of action. Peptidomimetics with antagonistic properties were also developed within the range of these investigations. As a result, new types of treatment and therapy for a series of diseases are possible. Although peptidomimetics have been developed largely by empirical methods (e.g. modification of native peptides, optimization of lead structures), methods for rational design based on investigations into the structure of peptide–peptide receptor complexes and studies of conformation energies, among others, are gradually being established.

1. Introduction

A multitude of biologically active peptides have been discovered and characterized during the last 30 years.[1–3] Many of these have been found in both neuronal and in nonneuronal tissues. Representative examples include somatostatin, substance P, cholecystokinin, endorphin, enkephalin, angiotensin II, and endothelin. After binding to their membrane-bound receptors, these neurotransmitters, neuromodulators, and hormones influence cell–cell communication and control a series of vital functions such as metabolism, immune defense, digestion, respiration, sensitivity to pain, reproduction, behavior, and electrolyte levels. Thus, they are of enormous medical interest. The number of native and modified peptides used as drugs is constantly increasing, and this trend should continue during the next few years.[4]

As a result of major advances in organic chemistry and in molecular biology[5] most bioactive peptides have been prepared in larger quantities and made available for pharmacological and clinical experiments. Thus, in the last few years new methods have been established for the treatment and therapy of a series of diseases, and hopes have also been raised for the therapy of other illnesses in which peptides have been implicated. However, the use of peptides as drugs is limited by the following factors: a) their low metabolic stability towards proteolysis in the gastrointestinal tract and in serum; b) their poor absorption after oral ingestion, in particular due to their relatively high molecular mass or the lack of specific transport systems or both; c) their rapid excretion through liver and kidneys; and d) their undesired effects caused by interaction of the conformationally flexible peptides with various receptors (Fig. 1). In addition, a bioactive peptide can cause effects in several types of cells and

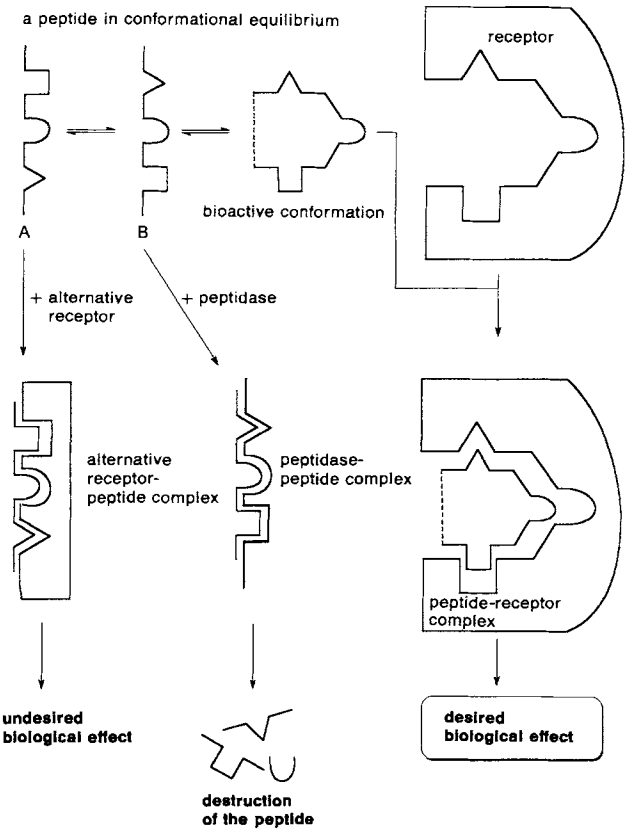

Fig. 1. In solution peptides exist in a variety of conformations that are in dynamic equilibrium with each other. If a conformational restriction (broken line) is introduced to the bioactive conformation of the peptide, forms A and B cannot arise. Thus, the interaction with alternative receptors and peptidases is suppressed or does not occur. In this fashion a desired biological effect can be obtained (modified after ref.[6]).

organ systems, since peptide receptors and/or isoreceptors can be widely distributed in an organism.

From the pharmacological and medical viewpoint it is frequently desirable to not only imitate the effect of the peptide at the receptor level (agonism) but also to block the receptor when required (antagonism). The same pharmacological considerations mentioned above hold for peptidal antagonists, but, in addition, their development in the absence of lead structures is more difficult. Even today it is not unequivocally clear which factors are decisive for the agonistic effect and which for the antagonistic.[12]

In recent years intensive efforts have been made to develop peptidomimetics[6-14] that display more favorable pharmacological properties than their prototypes. A *peptidomimetic* is a compound that, as the ligand of a receptor, can imitate or block the biological effect of a peptide at the receptor level.[8, 15] As the ligand of an enzyme it can serve as substrate or as inhibitor. Ligands as enzyme inhibitors will be considered here only in special cases. We will restrict our discussion to peptidomimetics for receptor ligands including not only ligands of peptidal nature but also nonpeptide ligands.

2. Discovery and Development of Peptidomimetics

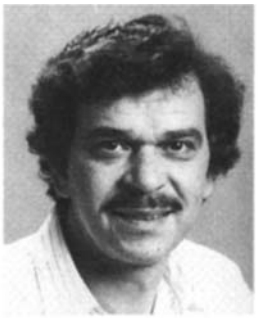
The following requirements exist for the pharmacological properties of a peptidomimetic: a) metabolic stability, b) good bioavailability, c) high receptor affinity and receptor selectivity, and d) minimal side effects. A major problem in the development of such agents is the discovery of a lead structure that can then be optimized, for example by the use of molecular modeling programs. Information concerning the three-dimensional structure of the peptide–receptor complex, the subsequent signal transduction, and the coordination and interaction with other signal transduction systems and integration in the organism, as well as knowledge of the biosynthesis, transport, release, and inactivation of the peptide are also extremely helpful.

Regardless of their mode of action (as neurotransmitters, neuromodulators, hormones), biologically active peptides show some common characteristics:[16] they are synthesized in the ribosomes as higher molecular forms (prepro forms). The pro forms are formed by cleavage of an N-terminal signal peptide by peptidases. During the subsequent vesicular transport to the Golgi apparatus they are processed further to their active forms and finally transported to the intracellular storage pools. They are released from the latter after stimulation (exocytosis). Inactivation of these peptides results mainly from the action of proteolytic enzymes (endo- and exopeptidases).

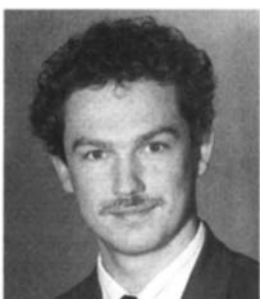
Although considerable progress has been made in the characterization of the receptors and in research into the mechanism of signal transduction, difficulties are encountered in structural investigation of the peptide–receptor complex. The application of newer NMR methods here is quite promising.[17b]

The native peptide itself, the pharmacological properties of which should be optimized, generally serves as lead structure for the development of peptidomimetics. With few exceptions peptides of small to medium size ($< 30-50$ amino acid units) exist unordered in dilute aqueous solution in a multitude of conformations in dynamic equilibrium (see Fig. 1). If a receptor ligand has the biologically active conformation per se, in other words the receptor-bound conformation, then an increased affinity toward the receptor is expected, since the decrease in entropy on binding is less than that on the binding of a flexible ligand. In solution and in the absence of the receptor, the biologically active conformation can be poorly populated and is frequently quite different from the conformation obtained by, for example, X-ray structure analysis in the solid state.[17]

A generally applicable and successful method so far for the development of peptidomimetics involves formation of conformationally restricted analogues that imitate the receptor-bound conformation of the endogenous ligands as closely as possible.[6, 14, 18, 19] Investigations of these analogues show them to have increased resistance toward proteases,



Athanassios Giannis was born in 1954 in Drama, Greece. He studied chemistry from 1972 to 1980 and medicine from 1978 to 1988 at the University of Bonn. After completing his diploma thesis with Prof. Reetz, he worked on his doctoral thesis with Prof. Sandhoff on the synthesis of glycosides. He received his "habilitation" in chemistry and biochemistry in 1992 for his research on the synthesis of chiral building blocks from D-glucosamine hydrochloride and of inhibitors of the glycosphingolipid metabolism. His research interests include amino sugars, amino aldehydes, and amino alcohols, as well as biochemical aspects of glycoconjugates, peptide aldehydes, and peptidomimetics.



Thomas Kolter was born in 1963 in Bonn and studied chemistry there from 1984 to 1989. The subject of his diploma thesis with Prof. Sandhoff was the synthesis of inhibitors of the sphingolipid metabolism. He received his Ph.D. at the beginning of 1993 for his research on chiral amino aldehydes and the synthesis of peptidomimetics with A. Giannis. Currently, he is working on the total synthesis of modified gangliosides under the auspices of the "Sonderforschungsbereich" for research on glycoconjugates and contact structures of the cell surface.

that is, an increase in the metabolic stability, as well as increased selectivity and thereby fewer side effects.[6] The fact that frequently only a small number of four to eight amino acid side chains of the peptide are responsible for the recognition of the ligand by the receptor turns out to be favorable for this approach.[9, 17a] In such cases the rest of the molecular framework serves to fix the pharmacophores in a specific spatial arrangement. In addition, in the part of the peptide not directly involved in the interaction between the ligand and the receptor, additional binding affinity to various receptor types (an "address") or to an interface (the plasma membrane) can be localized. The half-life of the ligand can also be controlled by the existence of cleavage sites for proteases in this region of the molecule. Simplification of the structure of the ligand by removal or modification of this part of the molecule leads to a simultaneous increase in the protease resistance by the removal of cleavage sites. The resistance toward amino- and carboxypeptidases can be increased independently by acylation of the N-terminal group and by amidation of the C-terminus.

An important step in the development of conformationally restricted peptide ligands is the identification of the amino acid side chains necessary for receptor recognition. For this reason shorter analogues are also synthesized to identify the minimal sequence required for biological activity. The significance of parameters such as stereochemistry, charge, and hydrophilicity can be examined by systematic changes in the individual amino acids. Compounds with rigid conformations are then produced, and the most active structures selected by studying the conformation–activity relationships. This more-or-less empirical procedure is time-consuming and costly. New techniques that permit the controlled synthesis of a great variety of peptides (peptide libraries) and allow the careful examination of receptor binding are promising.[5, 20, 21] The hope of discovering new lead structures in this way and optimizing these with respect to their pharmacological properties appears to be justified.

The poor bioavailability of peptide-based drugs can hinder or even prevent their therapeutic use. A generally applicable concept for overcoming these difficulties is not yet available. Despite the advances in this area[22] "it is ironic that, with the exception of angiotensin converting enzyme (ACE) inhibitors and cholecystokinin antagonists (CCK), medicinal chemists have been unable to harness the profound pharmacologic effects of peptides by the discovery of bioavailable analogues."[8] If one also takes into account that the application of peptide-based drugs can cause immunological reactions,[23] the development of low molecular mass nonpeptide ligands appears to be urgently necessary.

The design of *nonpeptide ligands* is still in its infancy: the discovery of lead structures in large-scale screening is essential. Collections of substances (compound libraries) and single compounds, mostly natural products, are examined for their biological activity. These compounds are frequently conformationally restricted analogues of peptides that show the required characteristics for recognition by receptors. The structure is then optimized with regard to receptor affinity, selectivity, and other pharmacological properties. The fungal metabolite asperlicin can be mentioned here as an example of a lead structure discovered by large-scale screening and optimized in research aimed at the development of cholecystokinin antagonists (see Section 4.5).

The opioid alkaloids are classic examples of nonpeptide ligands that were later discovered to be mimetics of endogenous peptides. Morphine (**1**) imitates the effect of, for example, β-endorphin (**2**) (an endogenous opioid composed of 31 amino acids), at one of the recognition sites on the receptor common to both compounds. This example demonstrates unequivocally that it is possible, in principle, to use a small compound as a substitute for a relatively large peptide. In addition to morphine there is a whole series of other known drugs whose peptidomimetic character has already been demonstrated (see Sections 4 and 5).

In the following sections established methods available for the design of peptidomimetics will be discussed. Selected examples of peptidomimetics (both peptide- and nonpeptide-based), including their possible use in therapy, are the topic of Section 4. Biological and biochemical aspects of the endogenous peptides will also be treated there.

3. Strategies for the Synthesis of Peptidomimetics

3.1. Modification of Amino Acids

Several possibilities exist for the synthesis of conformationally restricted and/or metabolically stable peptidomimetics at the amino acid level. The systematic exchange of individual amino acids by α-C-alkylated-, α-N-alkylated-, and D-amino acids is well established. In addition, α,β-unsaturated, cyclic, and β-amino acids, as well as amino acids with sterically demanding side chains may also be employed.

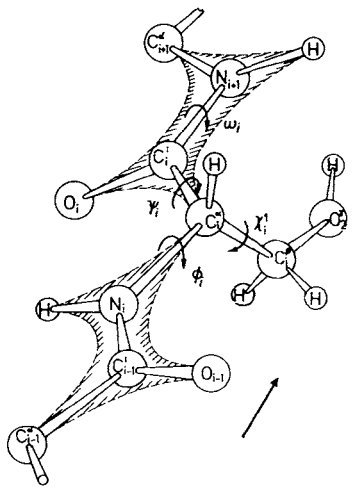

Fig. 2. Definition of the dihedral angles Φ,Ψ,χ, and ω of a peptide[24b].

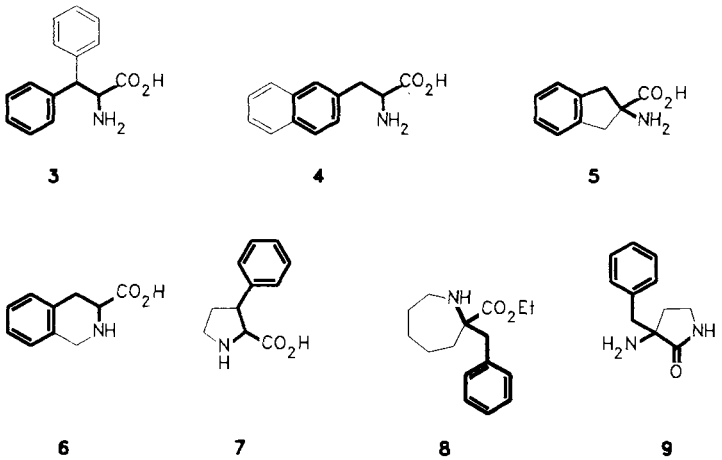
Since the effect of such substitution on the conformational parameters Φ, Ψ, χ, and ω (for definitions see ref.[24] and Fig. 2) and also on the biological activity of the resulting peptides has been summarized in other reviews,[7a, 10] we will only refer here to examples of structures and syntheses of individual compounds.

The structures of some analogues of the amino acid phenylalanine (Phe) are shown in Scheme 1. The number of possible conformations can be limited by the introduction of sterically demanding groups (**3** and **4**) or rigid bridging units. Compounds **3** and **5** are components of potent ligands of the angiotensin II receptor with agonistic or anatagonistic activity.[25] A simple preparative approach to indanaminocarboxylic acid **5** and other related compounds was achieved by alkylation of the benzylidene derivative of glycine ethyl ester with suitable electrophiles.[26] Gonadotropin-releasing hormone (GnRH) antagonists, which contain 2-naphthylalanine **4** in addition to other nonnatural amino acids, show high affinity for the receptor by negligible release of histamine (compound **125**). A new enantioselective synthesis of (*S*)-**4** and other α-amino acids of general utility was recently described by Corey et al.[27] Compound **4** and other Phe analogues can also be obtained in optically pure form by alkylation of chiral imidazolidinones.[28]

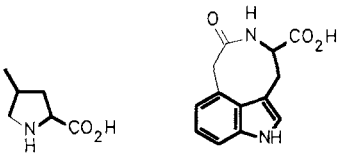


Scheme 1. Sterically demanding and conformationally fixed analogues of phenylalanine; the structure of the amino acid is highlighted.

The tetrahydroisoquinolinecarboxylic acid **6** (Tic) is a phenylalanine analogue in which the dihedral angle χ can only encompass a very small range. The preferred conformation and thus the topology of the side chain depends on whether Tic is N-terminal ($\chi = +60°$ for D-Tic) or N-acylated ($\chi = -60°$ for D-Tic) in the peptide.[29] D-Tic is a component of various opioid antagonists with high selectivity for the μ receptor.[30] Tic, together with other Phe analogues, has been incorporated into a cyclic opioid peptide analogue and the corresponding effects on conformation and receptor selectivity examined.[31]

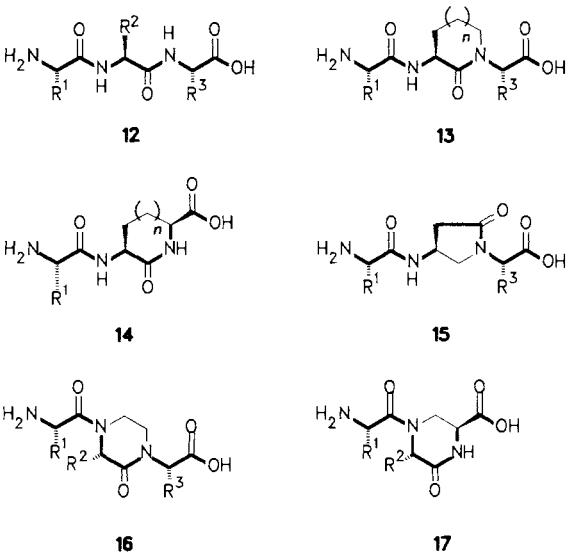
An asymmetric synthesis based on the imidazolidinone method of Seebach et al.[32] provides access to the four stereoisomeric α,β-dimethyl derivatives of Phe and Tic.[33] Proline derivative **7**, substituted in the 3-position, was synthesized in racemic form and the *trans* derivative obtained enantiomerically pure after cleavage of the racemate.[34] The corresponding 3-propyl derivative was incorporated as a norleucine analogue in a C-terminal tetrapeptide of cholecystokinin (CCK), which shows higher affinity for the central CCK receptor than Boc-CCK itself.[35] Lactam **8** is also a Phe analogue,[36] lactam **9** a C-terminal phenylalanine amide analogue.[37]

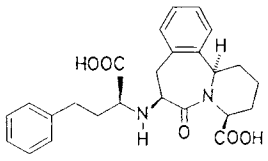
The 4-methyl-substituted proline derivative **10** and compound **11** are conformationally restricted leucine[38] and tryptophan analogues,[39] respectively. (The structure of the amino acids is highlighted; the stereochemistry of **10** and **11** is not shown.) A new entry to C-alkylated peptides has been described by Seebach et al.:[40] the alkylation of polydeprotonated *N*-Boc-protected oligopeptides was achieved regio- and stereoselectively on glycine and sarcosine residues without racemization.



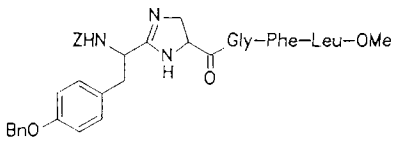
3.2. Dipeptide Analogues

Bridging between two neighboring amino acids in a peptide leads to a dipeptide mimetic, the conformative flexibility of which is limited in comparison with that of regular dipeptides. Some possibilities for forming such bridges are shown by the structural modifications of peptide **12**: incorporation of lactams (→ **13**–**15**) and piperazinones (→ **16**, **17**). γ-Lactams and δ-lactams[41] of type **13** have been designed to some extent as "turn mimetics"; in several cases the incorporation of such structures into peptides leads to biologically active compounds. Syntheses that permit the incorporation of side chains have also been described. The structural variation in compounds of type **13** can be extended further by





18

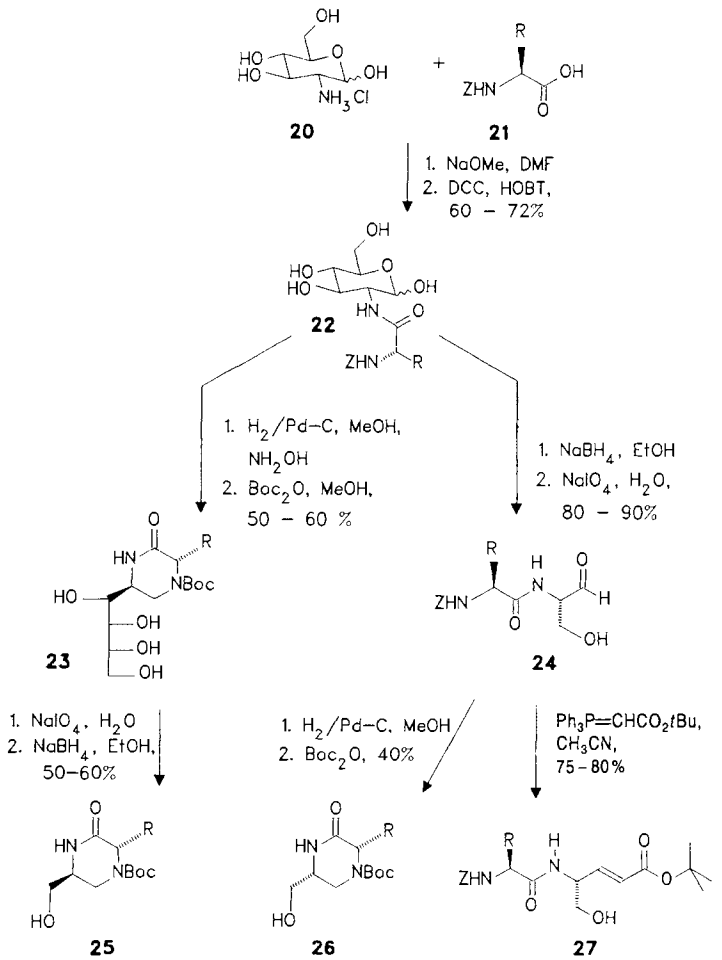


19

reduction or increase in the size of the lactam ring, by incorporation of heteroatoms,[42] or by annelation to aromatic rings. Compounds such as **18**,[43] currently the most potent inhibitor of the angiotensin-converting enzyme (ACE) known, belong to this category. Lactams of type **14** ($n = 1$)[44] and compounds **29** and **30** are also dipeptide mimetics. In **29** and **30** two neighboring methylene groups in the eight- and seven-membered rings, respectively, have been formally replaced by sulfur or with benzoannelated methine groups. The lactam derivative **15** was designed following the observation[45] that a corresponding aspartimide, which appeared as an artefact in peptide synthesis, led to an octapeptide derivative of the human growth hormone (hGH) with biological activity.[46] The incorporation of a lactam of type **15**, synthesized as the racemate, led to a biologically active hGH analogue.

Various substituted 2-oxopiperazines, for example **16** and **17**, are components of leu-enkephalin analogues.[47] A piperazinone of type **16** is a component in the structure of compound **91**, a selective antagonist of the neurokinin (NK)2 receptor. A synthesis of suitably substituted 2-oxopiperazines as precursors to compounds of type **17** is shown in Scheme 2.[48] The configuration of the chiral center is adjusted by choice of starting material or by the reaction conditions. Further syntheses of chiral piperazinones are summarized in the references.[49]

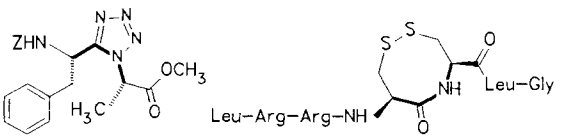
Another possible approach to bridging two neighboring amino acids by bridging the peptide strand in the direction of the original amide oxygen atom is illustrated by imidazoline **19**.[50]



Scheme 2. Synthesis of chiral 2-oxopiperazines of type **17**. The stereochemistry of products **25** and **26** is adjusted by choice of starting material and reaction conditions. Compound **27** is a dipeptide analogue with C-terminal vinylogous amino acids; R = benzyl, isopropyl, methyl. DMF = dimethyl formamide, DCC = dicyclohexylcarbodiimide, HOBT = hydroxybenzotriazole, BOC = *tert*-butoxycarbonyl, Z = benzyloxycarbonyl.

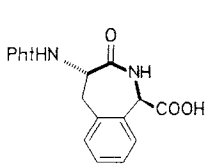
3.2.1. Analogues of Dipeptides with cis Configuration at the Amide Bond

The partial double bond character of the amide C–N bond leads to *E*/*Z* isomers. In peptides generally only the more stable (by about 8 kJ mol^{-1}) *trans* configuration is found. An exception is given by peptidyl-proline and peptidyl-*N*-alkyl amino acid groups, in which the *cis* configuration can also be appreciably populated.[51] Amide bonds with *cis* configurations not involving imino acids have been found, for example, in cyclic peptides[52] and in a linear peptide in the conformation induced by binding to a model membrane.[53] β Turns can also contain *cis*-configurated amide bonds.[54] In order to simulate the "*cis*-amide bonds" that could occur in the biologically active conformation of a peptide, the corresponding dipeptide analogues were synthesized. Compounds **28**,[55] **29**,[56] **30**,[57] and **31**[58] are examples; incorporation of **31** into a cyclic hexapeptide analogue of somatostatin led to a compound with biological activity. Whether the concept of *cis*-amide mimetics will prove itself in practice remains to be seen.

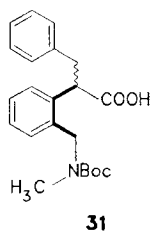


28

29



30



31

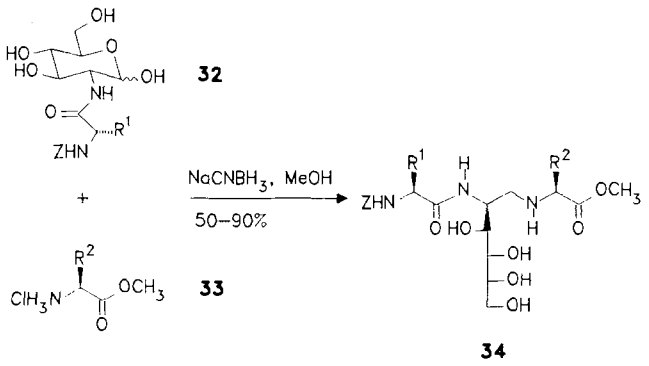
3.3. Modification of the Peptide Backbone

Modification of the peptide backbone leads primarily to an increase in the biological half-life in comparison with that

of parent compounds, and only secondarily, if at all, to restrictions in conformation.

3.3.1. Isosteric Replacement of the Amide Bond

Replacement of an amide bond by a suitable mimetic[59] was particularly important for the development of enzyme inhibitors. In the area of receptor ligands this concept has hitherto been less successful. Examples of ligands that are still biologically active after exchange of an amide group for an isosteric group include the [Tyr^1-(*E*)-CH=CH-Gly^2]-leu-enkephalin analogue[60] and the [Phe^8-(*E*)-CF=CH-Gly^9]-substance P analogue.[61] A route to the discovery of antagonists could lie in the exchange of the amide group for (CH_2NH), which led to the development of a gastrin[62] and bombesin antagonist.[63] Compounds containing the isosteric CH_2NH group are quite different, especially in their electronic properties, from those containing the amide group; the isosteric compounds may be obtained by reduction of the latter with $LiBH_4/(CH_3)_3SiCl$.[64, 67] Another preparative possibility is the reductive amination of suitably protected α-aminoaldehydes with amino acid derivatives,[65] during which racemization of the aldehyde can occur. An example of the racemization-free synthesis of such a derivative is shown in Scheme 3.[66] In a recent publication[67]

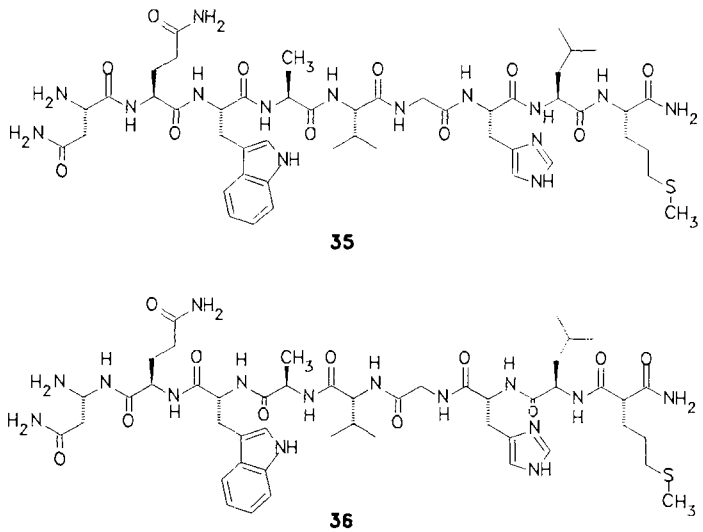


Scheme 3. Racemization-free synthesis of an isosteric aminomethylene peptide derivative; R^1 = benzyl, *para*-hydroxybenzyl, R = methyl.

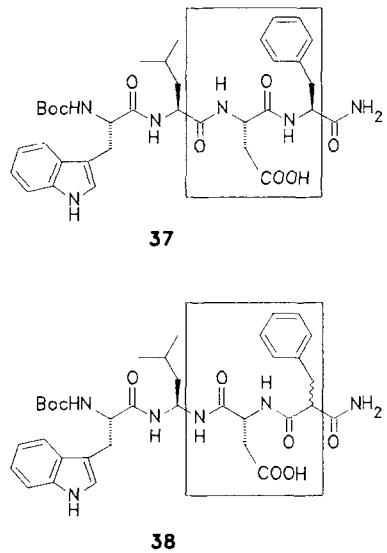
amide surrogates were incorporated into a CCK-B receptor ligand and the influence of the various structures systematically analyzed and quantified. An accurate imitation of the amide bond with regards to lipophilicity, geometry, and hydrogen bond donor or acceptor properties could not be correlated with the measured receptor affinity. Apparently, parameters other than those investigated, possibly also conformational effects, are responsible, and a convincing imitation of the amide bond in the ground state has not yet been achieved.

3.3.2. Retro-Inverso Isomers

A further approach for changing the peptide backbone is the use of retro-inverso modifications.[68] In this method the L-amino acids of a peptide are exchanged for D-amino acids, and simultaneously the direction of the peptide is reversed. The topology of the side chains, with the exception of proline groups, is largely maintained, and such structures are no longer substrates for proteases. The retro-inverso modification itself does not contain any conformational restrictions when compared with the native peptide. One problem is that for noncyclic peptides the end groups and, thereby, their charges are not complementary to those of the native peptide and must either be substituted by the introduction of "false" ends or the retro-inverso structure must be incorporated into a larger peptide. Examples are shown in Schemes 4[71] and 5.[69] A more recent example of the synthesis of such a compound is given in the literature.[70] The small number of retro-inverso derivatives[71] that actually show activity comparable to that of the original compounds indicates that the peptide backbone is also important for recognition by the



Scheme 4. The C-terminal nonapeptide **35**, which has the full agonist activity of bombesin (see **102**), and the retro-inverso isomer **36** with modified end groups, which does not bind to the receptor.

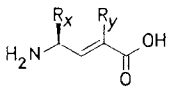


Scheme 5. The C-terminal *N*-Boc nonapeptide of gastrin **37** and the partially retro-inverso isomer **38**, which is an antagonist of the gastrin receptor.

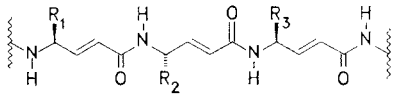
receptor or that there are indeed differences in the topology[72] of both compound classes.

3.3.3. *Further Modifications of the Peptide Backbone*

In a recently published study[73] it was shown that peptides containing vinylogous amino acids **39** in place of "normal" amino acids are rich in secondary structure elements. Peptides such as **40**, for example, are conceptually related to



39

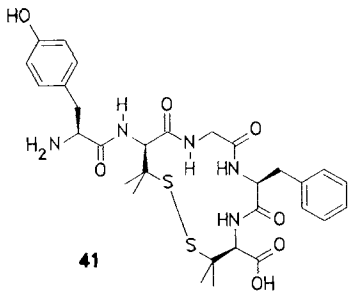


40

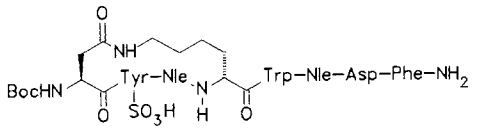
hexose-DNA and could lead to the development of substances similar to peptides with modified backbones. A new entry to vinylogous peptides of type **27** via the chemically and configurationally stable dipeptide aldehyde **24** is shown in Scheme 2.[48b]

3.4. Global Restrictions of Conformation

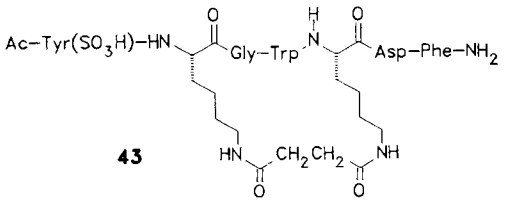
Global[10] restrictions in the conformation of a peptide are possible by limiting the flexibility of the peptide strand through cyclization. For this purpose, amino acid side chains that are not involved in receptor recognition are connected together or to the peptide backbone. Three representative examples are compounds **41**–**43**: partial structures of each peptide are made into rings by linking two penicillamine residues with a disulfide bridge, by formation of an amide bond between a lysine and an aspartate group, or by connecting two lysine groups with a succinate unit.



41



42



43

Compound **41** is a cyclic enkephalin analogue with selectivity for the δ opiate receptor;[74] BC 197 (**42**)[75] and JMV 30 (**43**)[76] (IC_{50}[*] = 1.3 nM, 10000 times more selective to the cholecystokinin A receptor) are agonists to the cholecystokinin B receptor, found largely in the brain.

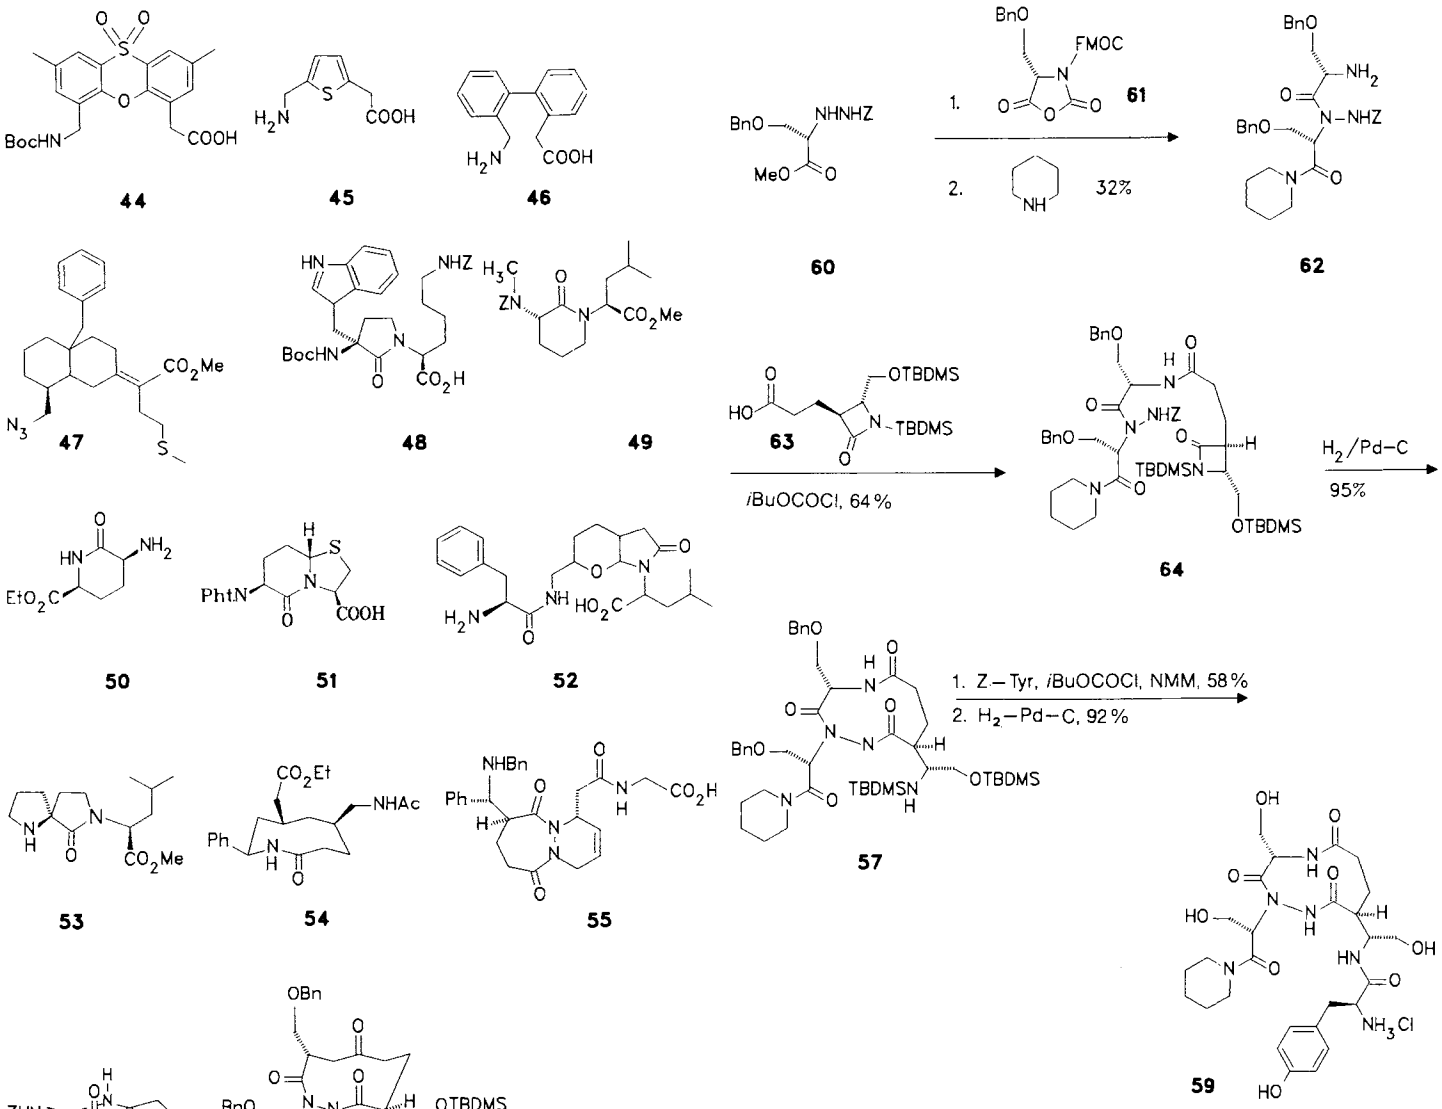
3.5. Imitation of Secondary Structures: β Turns

A crucial disadvantage of the methods referred to so far is that the resulting conformation cannot be predicted. As a result biophysical investigations are necessary to obtain conformation–activity relationships for each and every derivative prepared. For this reason it is desirable to have methods available that induce a specific target conformation. Numerous experiments in the design and synthesis of secondary structure mimetics have been conducted. A secondary structure mimetic is a building block that forces a defined secondary structure after its incorporation into a peptide. The requirements of such a conformation mimetic are the following: the desired conformation should be mimicked as exactly as possible, and the synthesis should permit the introduction of the desired side chains. In addition, practical aspects such as stability under the conditions used for synthesis of the peptide and removal of protecting groups must be considered.

A β turn is a segment composed of four amino acids (*i* to *i* + 3) that occurs when a peptide strand changes its direction. If, on the other hand, the segment is composed of three amino acids, one speaks of a γ turn. β Turns are classified according to their conformation. The criteria employed include the torsion angles at the amino acids *i* + 1 and *i* + 2. These angles are compared to those observed in proteins and peptides with secondary structure[7b] (for a definition of the torsion angles see Fig. 2). In linear peptides (and proteins) turns arise mainly due to the tendency to form intramolecular hydrogen bonds.[17a] The β turn is a structural motif common to many biologically active, cyclic peptides and has been postulated in many cases for the biologically active form of linear peptides.[7b] For this reason it is the most frequently imitated secondary structure. It can be assumed that the side chains are important for the recognition by the receptor. γ Turns are also found in peptides, albeit to a lesser extent, and are imitated by appropriate mimetics.[77]

A selection of compounds designed and synthesized as β turn mimetics is shown in Scheme 6.[11] The majority of these compounds have been shown to be inactive after incorporation in model peptides. Compound **59** (Scheme 7)[91] imitates a β turn in the sequence Tyr-Ser-Gly-Ser-Thr (**58**), a component of the hypervariable region of a monoclonal antibody against the reovirus type 3 receptor.[92] Compound **59** is the first example of a low molecular mass immunoglobulin mimetic developed on the basis of an X-ray structure analysis of the antigen–antibody complex. Cyclopeptide **59** is resistant toward proteases and imitates the binding and functional properties of the native antibody. The synthesis of **59**

[*] IC_{50} is the concentration of an antagonist that reduces the maximum action of an agonist by 50%.



Scheme 6. Representative β turn mimetics. **44**[78], **45**[79], **46**[80], **47**[81], **48**[82], **49**[83], **50**[84], **51**[85], **52**[86], **53**[87], **54**[88], **55**[89], **56**[90], and **57** (see Scheme 7). is shown in Scheme 8. Three other biologically active derivatives of β turn mimetics are **65**–**67**. Compound **65** is a GnRH derivative and agonist, in which the amino acids glycine and

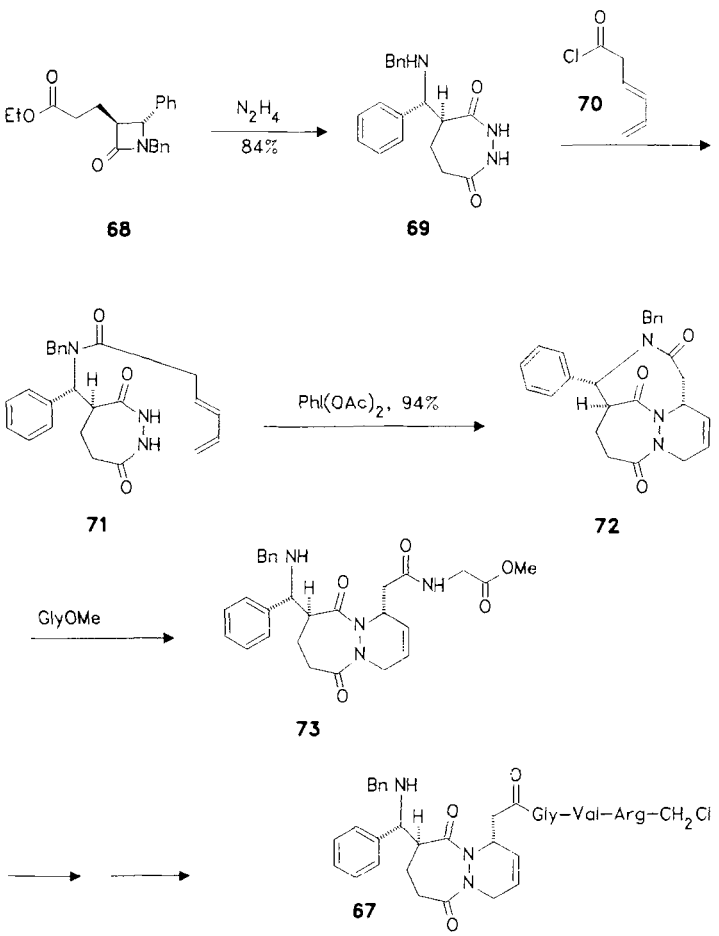
leucine in the positions $i+1$ and $i+2$ of a postulated β turn have been replaced by a γ-lactam. In vivo **65** is 2.4 times more effective than GnRH and in vitro 8.9 times more effective.[93] Compound **66** contains spirolactam **53** in place of Gly^9 and Leu^{10} in [Trp^{11}]-substance P. It is one of the most potent peptide-based antagonists of the neurokinin 1 receptor.[94] Compound **67** imitates the thrombin-bound structure of the fibrin peptide A and is an inhibitor of this protease. An overview of the synthesis of **67** is given in Scheme 9.



Scheme 9. Synthesis of **67**.

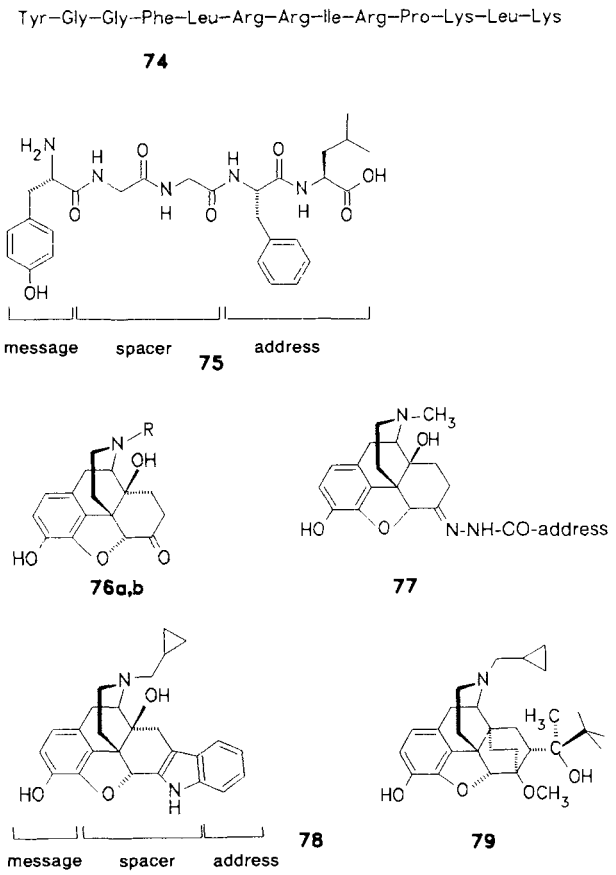
4. Examples of Peptidomimetics

4.1. Opioids (Endorphins, Enkephalins, Dynorphins)

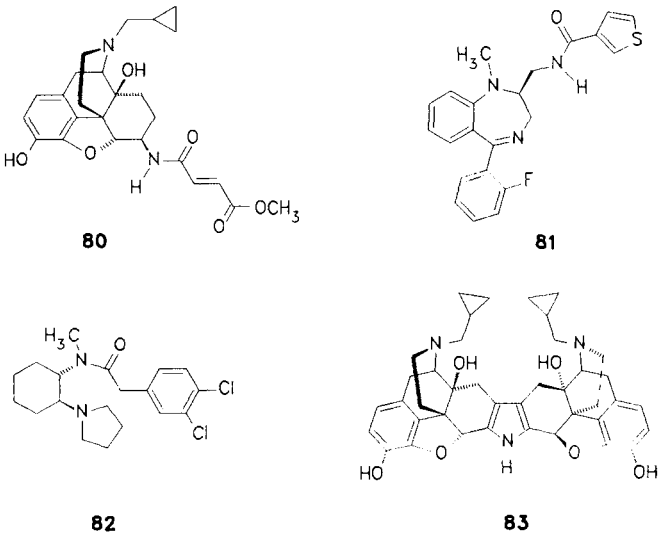
Morphine—the main constituent of opium—has been used and misused for its pain-killing and euphoria-generating effect for over two and a half thousand years. Countless morphine derivatives have been synthesized and examined in the search for morphine's mechanism of action and with the aim of developing a nonaddictive analgesic. With the help of these compounds it was possible to discover various opioid receptors in animal organisms. The demonstration of such receptors[95] suggested the existence of the corresponding endogenous ligands: the characterization of enkephalin in the mid-1970s[96] was followed by the discovery of endorphin[97] and dynorphin.[98] These endogenous opioids are biosynthesized by posttranscriptional processing[99] of the corresponding higher molecular mass precursors pro-opiomelanocortin, proenkephalin A, and proenkephalin B, both in neurons and also in nonneuronal cells, for example in cells of the adrenal medulla and in leucocytes.[100] Surprisingly, the presence of morphine and codeine in the brain of various animals was recently demonstrated.[101] To answer the question whether they are of exogenous origin or—as speculated at the beginning of this century[102]—of endogenous origin, cell culture experiments were conducted which showed that liver cells from mice possess the enzymes necessary for the decisive step of conversion of exogenously administered reticulin to salutaridine (with morphinan framework)![103] Adrenal and brain cells, on the other hand, are not able to convert reticulin into salutaridine. Thus, the question of the existence of a complete biosynthetic route for morphine in animal organisms remains unanswered.

From the pharmacological viewpoint endogenous opioids are very similar to morphine:[104] they also have analgesic properties, lead to physical addiction and depression of respiration, depress the cough reflex, stimulate the release of vasopressin, and inhibit gastric fluid secretion and the motor activity of the intestine. In addition, they appear to act as tumor suppressants and as inhibitors of cell division.[105] The effects of opioids are transmitted by receptor-induced modulation of the intracellular levels of c-AMP and Ca^{2+}, apparently involving various G proteins.[106]

Opium alkaloids were later shown to be mimetics of the endogenous opioids. Independent experiments on the interaction of opiate receptors with the corresponding agonists and antagonists demonstrated that there are at least three distinct types of opiate receptors with differing specificity, anatomic location (in both central and peripheral nervous systems; both pre- and postsynaptic in neurons), and physiological importance. These three types are designated μ, κ, and δ. The δ opioid receptor was recently cloned for the first time, expressed in COS cells, and characterized pharmacologically.[106c] It is assumed that dynorphin (**74**) and enkephalin (**75**) are the endogenous ligands for the κ and δ receptors, respectively, whilst a protein with selectivity for the μ receptor has not yet been found (Scheme 10).[107] Comparison of the amino acid sequence of the endogenous peptide ligands shows that their N-terminals have the common grouping Tyr-Gly-Gly-Phe, regardless of the receptor specificity. This sequence is apparently essential for molecular recognition by the opiate receptor, is the same for all receptor types, and, after a concept[108] developed for adrenocorticotropic hormone (ACTH), is designated as "message". A different, neighboring sequence for the given receptor types, designated as "address", is responsible for the selectivity. According to a modified[109] interpretation of this model, which also can be extended to nonpeptide ligands of opiate receptors, the message is located in the Tyr^1 residue and separated by two glycine groups that function as spacers from the address sequence, which begins with Phe. On the basis of this model it was possible to develop ligands of type **77** from the μ-selective opioid antagonist oxymorphone (**76a**) by attaching the appropriate "address" sequence. Ligands **77** bind selectively to the δ and κ receptors. Naltrindole (**78**) was synthesized analogously as the first nonpeptide anatagonist with selectivity for the δ opioid receptor.[109]



Scheme 10. Dynorphin (**74**), Leu-enkephalin (**75**), oxymorphone (**76a**, R = methyl), naloxone (**76b**, R = allyl), a universal opioid antagonist **77**, and synthetic opioid derivatives **78**, **79**. Hybrid structures **77** containing a morphine framework (message) and peptide (address) are selective ligands of the δ receptor (address = Phe-Leu-OH) and the κ receptor (address = Phe-Leu-Arg-Arg-Ile-OMe). Naltrindole (**78**) is the first nonpeptide ligand for the δ receptor. Buprenorphin (**79**) is an opioid with low potential dependency. Other ligands with selectivity for the opioid receptor types include compounds **80**–**83**, morphine (**1**, μ agonist), amd DPDP 50 (**41**, δ agonist).



The pyrrole ring of the indole residue serves as a rigid spacer, fixing the phenylene group in the conformation required for it to serve as a component of the δ address. Finally, a comparison of the structure of oxymorphone (**76a**) with that of naloxone (**76b**) appears to be interesting: replacement of the *N*-methyl group of **76a** with an *N*-allyl group leads to the universal opioid antagonist naloxone (**76b**)! Other ligands for the various opioid receptors are the selective and irreversible μ antagonist β-funaltrexamine (**80**),[110a] as well as the κ-selective agonists tifluadom (**81**) and U-50488 (**82**).[110b] The C_2-symmetric compound norbinaltorphimine (NorBNI, **83**)[111] is a highly potent opioid antagonist with good selectivity for the κ receptor.

A wealth of other peptide- and nonpeptide-based ligands of opioid receptors have been synthesized and investigated pharmacologically.[109, 112, 113] "While our knowledge of the opioid receptor system has increased tremendously, this new information has not yet led to the development of a major new therapeutic agent."[113] In particular it has not yet been possible, despite initial hopes, to develop an opiate with strong analgesic potency that is not addictive and does not suppress respiration (a frequent cause of death following morphine overdose). Nevertheless, some practical successes and interesting new developments in the area have been achieved:

a) Buprenorphine (**79**) is a partial agonist of the μ receptor. After sublingual application approximately 50% is absorbed (for comparison, only 5% of the morphine applied orally passes into the blood stream). After successful absorption buprenorphine binds slowly to the receptor and dissociates from it equally slowly. It is precisely this property that leads to the unusually low potential for addiction of this agent. After treatment has stopped only mild withdrawal symptoms are observed. This pharmacological profile, together with the absence of respiratory suppressant and psychotomimetic effects, has contributed to the clinical success of buprenorphine.[114]

b) Based on the knowledge that 1) nerve endings of peripheral sensory neurons possess opioid receptors and that 2) the leucocytes that migrate to inflamed tissues may help alleviate pain by virtue of their opioids,[115] a new approach for producing analgesia was recently reported. In arthroscopic knee operations morphine is applied intra-articularly (in the knee joint). It has been shown that the postoperative analgesia is both stronger and longer lasting than that obtained by intravenous application of morphine. The well-known side effects of morphine do not appear with this type of application.[116] These results suggest that central opioid receptors are not the exclusive target of systemically administered morphine (Fig. 3) and confirm the necessity for the development of potent, orally active opioid analgesics that cannot pass the blood–brain barrier, thus precluding the serious side effects triggered by their action in the central nervous system.[117]

c) An exciting and interesting possibility for the pharmacotherapy of pain is offered by the benzodiazepine derivative tifluadom (**81**), a κ receptor agonist. Although clinical studies are still not available, animal experiments show that **81** is an effective opioid analgesic without undesired effects such as respiratory depression or addictive potential.[118]

Considering the importance of substance P (Fig. 3) and cholecystokinin for the perception of pain and the fact that potent substance P and cholecystokinin antagonists (see Sections 4.2 and 4.5) are now available, the future of pain therapy can be viewed with optimism.

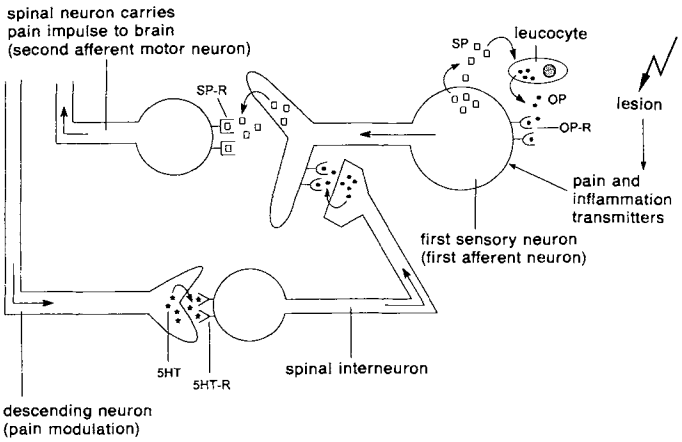


Fig. 3. Components of the pain transmission system (OP = opioid, OP-R = opioid receptor, 5HT = serotonin (5-hydroxytryptamine), 5HT-R = serotonin receptor, SP = substance P, SP-R = substance P receptor). Specific interneurons of the spinal cord use opioids as neurotransmitters. The interneurons act directly on the centrally directed ends of the primary sensory neurons (first afferent neuron) and suppress the conduction of pain impulses from the periphery to the spinal cord by release of opioids. Substance P is an important neurotransmitter in the pain-transmitting synapses. The pain impulse is carried to the brain by the second afferent neuron. The neuron descending from the brain modulates the activity of the spinal interneuron and in this process uses serotonin, among others, as a neurotransmitter. The activation of the peripheral nerve endings of sensory neurons, for example, during inflammation, also leads to the release of substance P in the area of the lesion. The result is that leucocytes migrate to this area. Endogenous opioids released from the leucocytes bind to the peripheral opioid receptors of the first afferent neurons, leading to a reduction in intensity of the pain impulses (modified after ref.[258] and taking refs. [115,259] into account).

4.2. Tachykinins (Substance P, Neurokinins A and B)

Tachykinins are peptides with a length of ten or eleven amino acids that act as neurotransmitters or neuromodulators in various parts of the central and peripheral nervous systems.[119] These peptides possess a common C-terminal sequence Phe-X-Gly-Leu-Met-NH_2. The best known and most investigated tachykinin, substance P (**84**), was discovered by von Euler and Gaddum in 1931.[120] In 1971 the amino acid sequence of substance P was determined,[121] and it was synthesized using solid-phase synthesis.[122] Peptides with structural similarities to tachykinins have also been isolated from lower organisms.

The biosynthesis of tachykinins takes place by way of two preproproteins; substance P (**84**) and neurokinin A (**85**) are released from one of these by posttranscriptional processing and neurokinin B (**86**) from the other. The receptors for substance P and for neurokinins A and B are designated NK 1–3. The supposed endogenous ligands are, corresponding to the different relative receptor affinities, substance P for NK 1, neurokinin A for NK 2, and neurokinin B for NK 3. NK 2 is found predominantly in the peripheral nervous system and NK 3 in the central nervous system, whereas NK 1 exists in both the central and peripheral nervous systems. The receptors from various mammals were sequenced and expressed.[123] They belong to the G protein-coupled receptor superfamily with seven α-helical transmembrane segments as the common structural feature. The transmembrane segments V–VII are responsible for the recognition of the common tachykinin sequence (message sequence), whereas the segments I–IV and the N-terminal (extracellular) part of the receptors bind to the variable part of the tachykinin (address sequence).[124] The individual receptors are quite homologous; after they bind their endogenous ligands they act by intracellular release of 1,4,5-inositoltrisphosphate, diacylglycerol, and cyclo-AMP (c-AMP) as second messengers.

The physiological significance of tachykinins is still poorly understood, not least because of the absence of selective antagonists. The effects of substance P have been examined the most. It triggers contraction of the smooth muscles of the respiratory, the gastrointestinal, and the urogenital tract, has diuretic and natriuretic properties, and in addition is a potent stimulator for the secretion of saliva, pancreatic juice,

95

and bile. Substance P acts in the periphery, causing the symptoms characteristic of inflammation, including dilation of blood vessels (vasodilation) and the extravasation of plasma from the blood vessels. It induces the release of interleukin-1, interleukin-6, and tumor necrosis factor-a from human monocytes.[125] On the other hand, some cytokines appear to increase the rate of biosynthesis of substance P.[126] This mutual influence of substance P and cytokines could be significant in rheumatoid arthritis.[127] There is also evidence for the participation of substance P in pathophysiological events of inflammatory intestinal diseases (Crohn's disease, colitis ulcerosa):[128] in general the specific sensory neurons of the dorsal root ganglions seem to use substance P as a transmitter substance at pain-conveying synapses. The same neurons, on the other hand, can regulate or maintain an inflammatory process (for example, rheumatoid arthritis) by release of substance P into the area of an inflammation innervated by them (see Fig. 3). Neurokinin A has effects similar to those of substance P, whereas neurokinin B operates as a pain reliever by the release of ligands of the opiate receptor. Substance P and neurokinin A facilitate the dopaminergic excitation pathway. Thus, an agonist could be useful in the therapy of Parkinson's disease, which is characterized by a loss of dopaminergic neurons in the substantia nigra. Finally, substance P acts neurotrophically and is able to arrest the neurotoxic effects of the β-amyloid protein regarded as causing the pathogenesis of Alzheimer's disease.[129]

In the development of antagonists it became apparent that residues 7–11 of substance P contain the minimal sequence required for biological activity. Exchange of Phe^7 or Gly^9 by D-Trp or other aromatic D-amino acids leads to an antagonistic effect of the resulting peptides.[119a] The compounds developed on this basis initially showed an affinity for the receptors several orders of magnitude lower than that of the endogenous ligands and allowed only an incomplete characterization of the receptors, because of overlapping specificity.

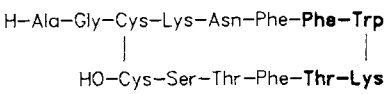
The first potent, competitive nonpeptide antagonist for the NK 1 receptor is CP-96345 (**87**),[130] which emerged from a screening process. Only the (2*S*,3*S*) enantiomer of **87** is effective; it shows no agonistic activity and has an affinity for the NK 1 receptor comparable to that of its endogenous ligand, substance P. Other potent nonpeptide antagonists for the NK 1 receptor are RP 67580 (**88**)[131] and the steroid derivative **89**.[132] Compound **90**[133] is also a nonpeptide NK 1 antagonist, although it is not suitable for further tests because of its lower affinity and high toxicity.

More recent examples of NK 2 selective antagonists based on peptides include **91**,[134] the cyclic hexapeptide **92**,[135] and the hexa- and heptapeptides **93** and **94**.[136] Recently, SR 48968 (**95**) was described as a potent, selective NK 2 antagonist.[137] Presently the most potent NK 3 antagonists are a (4–10) fragment of neurokinin A, in which Val^7 and Gly^8 have been replaced by Trp and β-alanine, respectively, and a (4–10) fragment of neurokinin B that contains MePhe instead of Val^7 and β-alanine in place of Gly^8.[138]

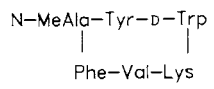
Tachykinin antagonists promise useful properties, in particular inhibition of inflammation and relief of pain. In addition, it is also conceivable that they could be used in asthma therapy and in the treatment of some autocrine tumors.

4.3. Somatostatin (Somatotropin-Release Inhibiting Factor, SRIF)

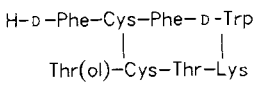
Somatostatin (**96**),[139–141] a cyclic tetradecapeptide, is formed in the hypothalmus and inhibits the release of growth hormone (GH) by the pituitary gland. In other parts of the brain somatostatin acts as a neurotransmitter and as a neuromodulator; participation of somatostatin in the peripheral nervous system in the perception of pain has been proposed. Outside the nervous system it has been found in the secretory cells of the intestine and pancreas, and in the salivary glands. It serves in these organs as an autocrine and paracrine regulator. Somatostatin formed in the δ cells of the pancreas inhibits the release of insulin and glucagon by the β and α cells of the pancreas, respectively. In the digestive tract motility is inhibited by somatostatin and the blood supply restricted. The secretion of gastric acid and gastrin is also reduced. Another effect is the reduction in secretion of pancreatic enzymes and the absorption of carbohydrates, triglycerides, and water.



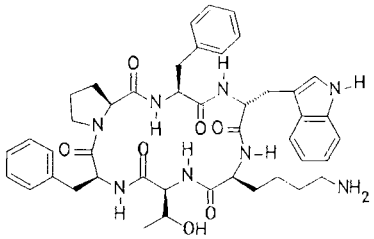
96



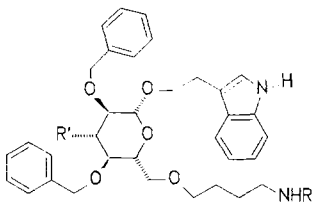
97



98



99



100a : R=R'=H
100b : R=CH_3CO, R'=OCH_2Ph

Somatostatin is synthesized as a preproprotein with a molecular mass of approximately 8 kDa. Through alternative posttranscriptional processing it is transformed into the mature hormone and to SRIF-28, which is also active. Receptors for somatostatin have been isolated from various tissues and biochemically characterized.[139] The somatostatin receptor from the brains of rats has recently been cloned and expressed in COS-1 cells.[142] This receptor belongs to the family of receptors coupled to G proteins with seven transmembrane regions. The binding of somatostatin to its receptor causes a G protein-mediated inhibition of adenylate cyclase activity and reduces the permeability of the plasma membrane to calcium ions.[139]

The main therapeutic use of somatostatin is in the treatment of acute gastrointestinal diseases such as gastric ulcers and particularly in the treatment of life-threatening bleeding in the gastrointestinal tract. It is also used in the treatment of pancreatitis and after surgery on the pancreas. Somatostatin has not been successful, however, in the treatment of diabetes mellitus. In patients with type I diabetes (juvenile form, absolute shortage of insulin), a temporary reduction in the blood glucose level has been observed after infusion of somatostatin. The condition of patients with type II diabetes (adult diabetes, relative shortage of insulin) deteriorates after application of somatostatin because of inhibition of the remaining insulin secretion.

Numerous peptide-based somatostatin agonists have been synthesized and pharmacologically tested, especially by Veber and co-workers. A critical discussion of this topic has been published recently.[143] Seglitide (MK 678, **97**)[144] is more active than somatostatin by one to two orders of magnitude, but clinical trials with the compound were terminated because of side effects (steatorrhea = malfunction of the absorption of fats). Another somatostatin agonist, octreotide (SMS 201-995, **98**)[145] is used in the therapy of acromegalia (enlargement of the ends of body parts and inner organs because of increased release of growth hormone by the pituitary gland).[146] The treatment of carcinoid tumors[147] and intestinal scleroderma, which is otherwise difficult to treat,[148] with octreotide appears promising. Octreotide labeled with ^{123}I has also been used successfully as a diagnostic agent for the detection of various tumors that have somatostatin receptors.[149]

Compounds **97**, **98**, and **99**[150] simulate a β turn between the Phe^7 and Thr^{10} residues of somatostatin, a structural characteristic that was postulated after extensive studies of structure–activity relationships. In agreement with the theory that a D-amino acid in the $i+1$ position stabilizes a β turn,[151] Trp^8 is replaced by D-Trp in these compounds.

Compound **100a** was described as the first nonpeptide somatostatin mimetic.[152] 3-Deoxy-β-D-glucose serves as a scaffold for the attachment of the first three side chains of the postulated β turn: Phe^7, Trp^8, and Lys^9. The compound binds to a somatostatin receptor of the pituitary gland with an IC_{50} value of 1.3 μM. A compound that contains a 1,2,3,5-tetrasubstituted D-xylofuranose unit in place of the central deoxyglucose shows comparable activity.[153]

In more recent investigations with **100a** and the structurally related derivative **100b** the following interesting aspects were reported: at low concentration **100a** behaves as a somatostatin agonist, whereas at higher concentration it shows antagonistic properties; thus it is the first somatostatin antagonist ever reported. Furthermore, **100a** behaves as an antagonist of the β_2-andrenergic receptor (IC_{50} = 3 μM), which is also coupled to G protein. Surprisingly, **100a** displays a much higher affinity toward the substance P receptor (agonistic effect, IC_{50} = 0.18 μM), whereas derivative **100b** is a potent antagonist (IC_{50} = 60 nM) for the substance P receptor!

4.4. Gastrin-Releasing Peptide (GRP, Bombesin-27)

Gastrin-releasing peptide (GRP, **101**), a peptide composed of 27 amino acids, is closely related to bombesin (**102**), a

Ala–Pro–Val–Ser–Val–Gly–Gly–Gly–Thr–Val–Leu–Ala–Lys–Met–Tyr–Pro–Arg–Gly–Asn–His–Trp–Ala–Val–Gly–His–Leu–Met–NH_2

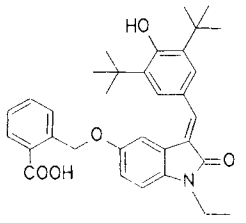
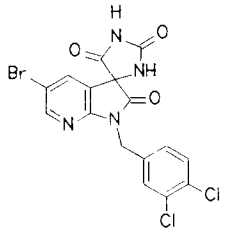
102



103



104

tetradecapeptide isolated from amphibians. It has been found in the central and peripheral nervous systems, as well as in the gastrointestinal tract and in neuroendocrine cells of the lungs. It effects the contraction of the smooth muscles of the gastrointestinal tract and the uterus, and stimulates the release of gastrin, glucagon, pancreatic amylase, cholecystokinin, and somatostatin.[154]

The GRP receptor from Swiss 3T3 cells was recently cloned, sequenced, and expressed in xenopus oozytes.[155] It is a G protein-coupled receptor that surprisingly also stimulates a tyrosine kinase.[156] The substrate of this kinase is the focal adhesion kinase p125 ($p125^{FAK}$), which is activated by phosphorylation and as a result has an effect on cell growth and cell adhesion.[156b, 156c]

The interest in GRP antagonists results from the fact that GRP acts as a potent autocrine/endocrine growth factor in small-cell lung cancer (SCLC).[157] Various GRP antagonists are capable of inhibiting the GRP-induced growth of these bronchial carcinomas in vitro.[158] [Leu^{14}-ψ-CH_2NH-Leu^{13}]bombesin[159] and the nonapeptide pyroGlu-Gln-Trp-Ala-Val-Gly-His-Phe-ψ-[CH_2S]Leu-NH_2 with a dissociation constant K_d of 3 nM[160] are among the most potent GRP antagonists presently known. Interestingly, the nonapeptide pyroGlu-Gln-Trp-Ala-Val-Gly-His-Phe-Leu-NH_2 is a potent GRP agonist (K_d = 0.2 nM)! This example also proves the value of the CH_2S group (another isosteric group for the amide bond) in the development of peptide antagonists.

The synthesis and properties of two nonpeptide antagonists of GRP have been described recently.[161] Compounds **103** and **104** are antagonists of the binding of GRP to the corresponding receptors in the rat brain (IC_{50} = 1.5 μM). However, the same compounds are, up to a concentration of 30 μM, inactive toward the human SLCL cell line N592. Unlike the endogenous ligands these mimetics are apparently capable of discriminating between species-specific receptor types.

4.5. Cholecystokinin and Gastrin

The peptide hormone cholecystokinin[162, 163] (CCK) exists in numerous biologically active forms (CCK-58, CCK-

39, CCK-33, CCK-8 **105**, CCK-4 = tetragastrin) with a common C-terminus. It exists in the nervous system both centrally (CCK-8 is the most common neuropeptide in the brain) and peripherally. It was originally demonstrated to be one of the hormones responsible for regulating the function of the digestive tract. Structurally it is related to the intestinal hormone gastrin (**106**); the two compounds have a common C-terminal pentapeptide. Similarities also exist with the decapeptide caerulein isolated from frogs.

Asp–Tyr(SO_3H)–Met–Gly–Trp–Met–Asp–Phe–NH_2 **105**

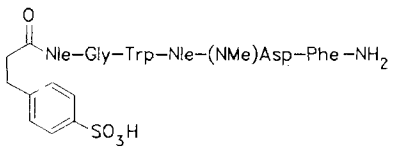
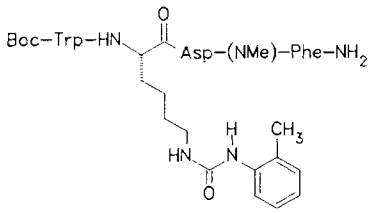
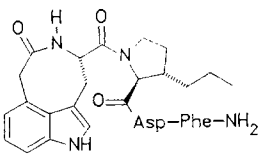
107



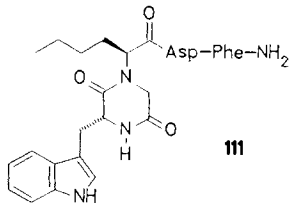
108



109



110



111

In the digestive tract cholecystokinin stimulates the contraction of the gall bladder and simultaneous relaxation of the sphincter of oddi, increases the release of insulin, increases the secretion of enzymes from the pancreas, and inhibits the secretion of gastrin and the emptying of the stomach.

In the central nervous system cholecystokinin acts as a neuromodulator/neurotransmitter, has an anxiety-generating (anxiogenic) and appetite-suppressing effect, whilst at the spinal level it antagonizes the effect of opiates and thereby acts as an antianalgesic.[164]

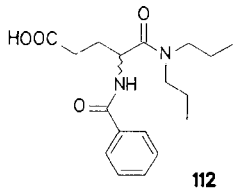
Two receptor subtypes could be characterized: the predominantly peripheral CCK-A receptor and the largely central CCK-B receptor. At the molecular level the binding of an agonist with the CCK-A receptor in acinus cells of the pancreas causes the G protein-mediated release of inositol 1,4,5-trisphosphate and calcium ions, activation of the protein kinase C, and the opening of calcium-dependent chloride channels. The CCK-A receptor from the rat pancreas has been cloned, sequenced, and expressed in foreign cells (xenopus oocytes).[165] The sequence shows similarities to other representatives of the G protein-coupled receptor family. The CCK-B receptor, a protein with a molecular mass of 74 kDa,[166] is closely related or possibly identical to the peripheral gastrin receptor and effects a G protein-mediated phosphatidylinositol-4,5-bisphosphate hydrolysis after stimulation through an agonist.[167] The canine CCK-B (gastrin) receptor has been cloned, sequenced, and expressed in COS-7 cells.[168] It also shows similarities to representatives of the family of G protein-coupled receptors.

Numerous CCK-A receptor agonists based on peptides have been developed. In contrast to the endogenous peptides these show much higher metabolic stability. An example of such a compound is the CCK-7 analogue **107**: replacement of the sulfuric acid ester function (acid labile and essential for biological function) by a methyl sulfonyl group and of methionine by norleucine increases the stability. This analogue shows higher receptor affinity ($K_i = 1$ nM) and complete agonistic affinity (amylase secretion by the pancreas and contraction of the ileum).[169] Exchange of the sulfuric acid group by an acetate or tetrazolyl group is tolerated by the receptor.[170] Other peptidal CCK-A selective agonists are A-71378 (**108**, $IC_{50} = 0.42$ nM, 700 times more selective for the CCK-A receptor)[171] and A-71623 (**109**, $IC_{50} = 4$ nM, >1000 times more selective).[172]

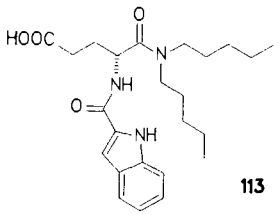
Several peptide-based CCK-B receptor agonists have also been developed. Examples include the two cyclic compounds **42** and **43** mentioned in Section 3.4, and the conformationally rigid derivatives A-63387 (**110**) and **111**. Compound **110** ($IC_{50} = 0.7$ nM, 9000-fold selectivity for the CCK-B receptor)[173] contains the tryptophan analogue **11**, referred to in Section 3.1, whereas compound **111**[174] contains a dioxopiperazine as a dipeptide analogue.

While the area of indications for the CCK agonists appears to be limited, the therapeutic potential of CCK antagonists lies in the treatment of diseases of the digestive tract (gastritis, pancreatitis, endocrinic tumors such as insulinomes and gastrinomes), neuropsychiatric disorders (anxiety, panic, cognitive dysfunction, schizophrenia), and pain.

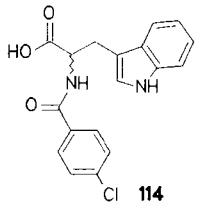
Potent nonpeptide antagonists of the CCK receptors have been developed by optimization of lead structures. Proglumide (**112**), which has been used for a long time in therapy of pancreatitis, served as the lead structure in the development of, for example, the CCK-A antagonist **113**.[175] Benzotript (**114**) and **112** served as the models in the development of the CCK-A antagonist **115**[176] ($IC_{50} = 21$ nM). The discovery of the fungal metabolite asperlicin (**116**)[177] as a CCK-A antagonist ($IC_{50} = 1$ μM) represents a milestone in this area and permitted the development of the selective, orally active CCK-A antagonist MK-329 (**117**)[178] (previously L-364718, $IC_{50} = 0.08$ nM), as well as the CCK-B antagonist L-365260 (**118**)[179] ($IC_{50} = 2$ nM). The



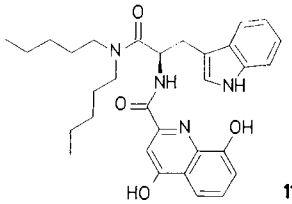
112



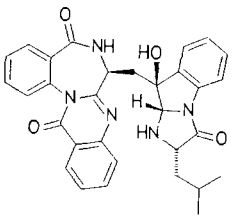
113



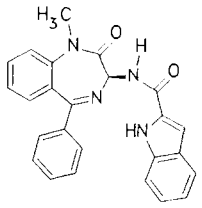
114



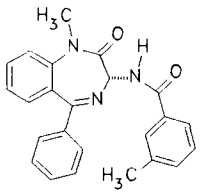
115



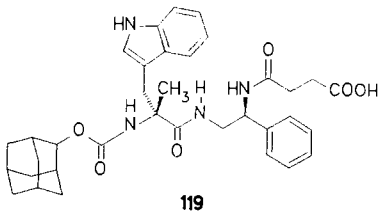
116



117



118



119

similarity of asperlicin with the clinically well-established benzodiazepines was the main driving force for the synthesis of the compounds MK-329 and L-365260. In this context it is worth mentioning that some benzodiazepines such as diazepam act as weak CCK-A antagonists. The benzodiazepine derivative tifluadom (**81**) developed initially as a κ-opioid receptor *agonist* later also turned out to be a CCK-A *antagonist*![180]

The observation that the minimal sequence of the C-terminal tetrapeptide of CCK (Trp-Met-Asp-Phe-NH_2) is necessary for the biological activity at central CCK receptors led to the synthesis of the dipeptide derivative Boc-Trp-Phe-NH_2 as a weaker CCK-B agonist.[181] The modification of this structure, supported by investigations of conformational energy[182] of the tetrapeptide Trp-Met-Asp-Phe-NH_2, culminated in the synthesis of the orally active dipeptoid CI-988 (previously PD-134308) **119**, which showed itself to be a selective CCK-A antagonist ($IC_{50} = 1.7$ nM with 1000 times greater selectivity for the CCK-B receptor).[183] The compound CI-988 is the first example of a rationally developed nonpeptide ligand for a neuropeptide receptor.

Compounds CI-988 (**119**) and L-365260 (**118**) have shown very interesting pharmacological effects in animal experiments. They have strong anxiolytic properties, but at the same time show no sedatory effects. The generation of dependence has not been observed.[184] Regarding these properties they are far superior to the benzodiazepines. Nevertheless, an appetite-increasing effect seen in animal experiments should be taken into consideration before clinical application of these new CCK-B antagonists.[185] Neither CI-988 nor L-365260 alone have analgesic properties; however, they can increase the analgesic effect of morphine and the duration of this effect.[186] These results suggest that CCK is the physiological opioid antagonist.[187]

4.6. Gonadotropin-Releasing Hormone (GnRH, LH-RH)

The gonadotropin-releasing hormone GnRH[188] (**120**) is synthesized in the hypothalmus and then secreted. In the anterior lobes of the pituitary gland it acts to release gonadotropins, in other words, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). After GnRH binds to its membrane-bound receptor, LH and FSH are released. Then a G protein-mediated activation of phospholipase C together with an increase in the intracellular concentration of free Ca^{2+}[189] occurs, and activation of calmodulin follows as a direct consequence. Recent investigations[189] also confirm the participation of leukotrienes as second messengers in the GnRH-induced release of gonadotropins by cells of the pituitary gland.

The gonadotropins are heterodimeric glycoproteins with common α and different β subunits. They function as nonspecific superordinate sex hormones: FSH stimulates maturation of follicles and estrogen biosynthesis in females, and the generation of spermatozoa in males; in females LH causes ovulation and formation of corpus luteum and estrogen;

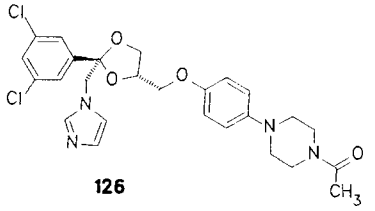
125



126

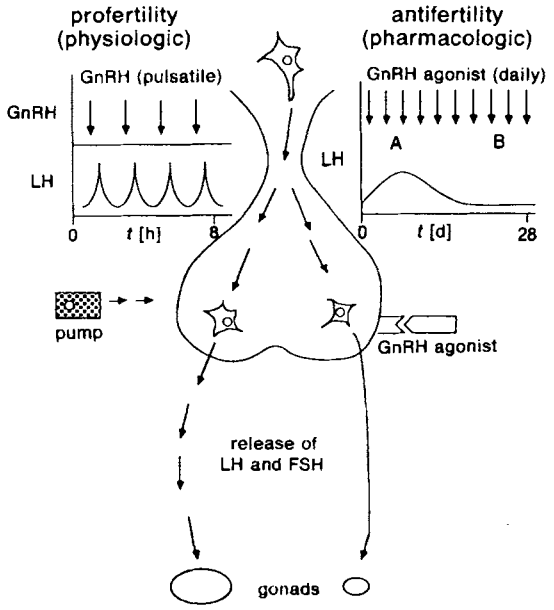


Fig. 4. Mechanism of action of gonadotropin-releasing hormone (GnRH) and GnRH agonists with long-lasting effects. The treatment of fertility problems requires the pulsatile application of natural GnRH (physiological type of application, left). This type of application imitates the physiological secretion of GnRH by the hypothalmus. For suppression of the pituitary gland gonadal axis, long-lasting GnRH agonists are administered in depot form or taken once daily (pharmacological application, right). After an agonistic initial phase A, which can last several days to weeks, a long-lasting inhibition of the gonadotropin secretion results that is practically complete and selective (antagonistic phase B). By terminating administration of the GnRH agonist the inhibition can be reversed[188].

in males the release of testosterone and biosynthesis of androgens is triggered.

Under physiological conditions GnRH is released in a pulsatile fashion (Fig. 4).[188] Continuous application of GnRH (or a GnRH agonist) causes an initial increase in gonadotropin release by the pituitary gland, followed by reduction and finally cessation of gonadotropin release. The exact molecular mechanism responsible for this phenomenon has not yet been unequivocally clarified, but there is some evidence suggesting that it involves a loss of GnRH receptors in the pituitary gland (down-regulation of the receptors) or their decoupling from the intracellular effector system in the pituitary gland or both. Thus, the action of GnRH can be both imitated and antagonized by the choice of the method of application!

Suppression of the release of the gonadotropins is possible directly by application of GnRH antagonists. It is advantageous hereby that the initial phase of increased secretion of LH, FSH, and sexual hormones is not observed. GnRH and its analogues are used primarily in the following areas:[191]

a) In the treatment of fertility disorders, for example in patients with a deficiency of GnRH. The use of an external pump, through which native GnRH is administered in pulses, is necessary for the reasons previously given.

b) For the selective and reversible suppression of the pituitary gland gonadal axis. The continuous application of GnRH is necessary here. Alternatively, long-lasting GnRH agonists or antagonists can be used. Examples of diseases that can be treated in this fashion include endometriosis, polycystic ovarian disease, and prostate carcinomas. GnRH agonists have been used hitherto for this purpose because, overall, they show fewer side effects in comparison with the first-generation antagonists. For the antagonists tested to date, the side effects are generally caused by the release of histamine.

A multitude of peptide-based GnRH analogues has been synthesized so far. The exchange of Gly^6 by D-amino acids and substitution in the 10-position leads to agonists that are much more potent in comparison with GnRH itself and that to some extent have found clinical application. Among these are leuprolide (**121**), buserelin (**122**), and histrelin (**123**), which are 15, 20, and 210 times more active than native GnRH, respectively. Another potent GnRH agonist is the azapeptide [D-Ser(tBu)^6,azaGly^{10}]-GnRH (goserelin).[192] The improved effect of these compounds can be traced back both to the blocking of catabolism at positions 6 and 10 and to the better receptor binding and increased hydrophobicity, which leads to depot formation in the body and increased half-life.

There are indications that the receptor-bound conformation of GnRH shows a Tyr^5-Gly^6-Leu^7-Arg^8-β-II′ turn.[193] Incorporation of a β turn mimetic in this position leads to peptide **65**. Although this compound shows an in vivo effect only 2.4 times greater than that of GnRH,[194] it provides an indication for the existence of a β turn in the biologically active GnRH conformation. This observation also initiated the application of lactams as turn mimetics.

GnRH agonists such as buserelin[195] and leuprolide[196] find application in the treatment of metastasic prostate cancer, the growth of which is dependent on sex hormones. Thus the simultaneous application of antiandrogens is necessary in order to forestall an androgen-induced initial intensification of the symptoms.

The GnRH agonist nafarelin (**124**) has recently been used successfully in the therapy of the gynecological disease endometriosis (an increased estrogen level seems to be responsible for the pathogenesis of this disease), treatment of which is otherwise difficult.[197] In comparison with the steroid derivative danazol used hitherto for this purpose, nafarelin possesses fewer side effects and is apparently tolerated very well by patients.[198] In this context is it also important to comment that many endocrinologists believe that GnRH analogues are the most important advance since the discovery and application of synthetic estrogens and progestagens in the treatment of gynecological diseases.[198]

Typically GnRH antagonists are modified at positions 1 and 10 for protection from exopeptidases, and a D-amino acid is incorporated at position 2. An example for an antagonist with negligible histamine release is antide (**125**).[199]

The accidental observation[200] that high oral doses of the antimycotic drug ketoconazole (**126**) cause a reduction of the serum testosterone level and subsequent remission in prostate cancer led to the discovery that ketoconazole is a weakly competitive antagonist of the GnRH receptor.[201] Its affinity lies in the micromolar range. Thus, a nonpeptide lead structure is available for the first time, the receptor affinity of which can still be improved.

4.7. Angiotensin II (A II)

The renin–angiotensin system plays an important role in the regulation of blood pressure. The enormous interest in

this system has come about because of the high incidence of cardiovascular diseases, for example hypertension and heart failure.

The biosynthesis of angiotensin II starts from angiotensinogen, a protein with a mass of about 60 kDa, which is largely synthesized in the liver and then passes into the blood. In the kidneys it is cleaved by the aspartyl protease renin into the decapeptide angiotensin I, which in turn is converted by the angiotensin-converting enzyme (ACE), a carboxypeptidase found primarily in the lungs, into the biologically active angiotensin II (**127**). Its inactivation results from C-terminal cleavage of a further amino acid and leads to angiotensin III. The brain is also capable of synthesizing angiotensin II. This octapeptide was the most potent substance known for increasing the blood pressure until the discovery of endothelin-1. It affects the blood pressure directly by constriction of the blood vessels and indirectly by release of aldosterone through the cortex of the adrenal gland.

In addition to its action on the blood pressure, angiotensin II transmits numerous other effects,[202] for example release of catecholamines from the adrenal medulla and stimulation of glycogenolysis in the liver. In the kidneys it stimulates the synthesis of prostaglandins and the resorption of sodium ions, and inhibits the release of renin and, thereby, its own biosynthesis. Angiotensin effects contraction of the uterus and stimulates ovulation, and in the brain it stimulates the secretion of vasopressin and adrenocorticotropic hormone (ACTH) by the pituitary gland and also functions as a neuromodulator.

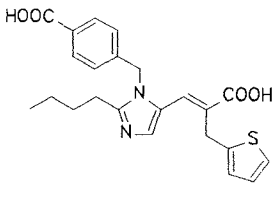
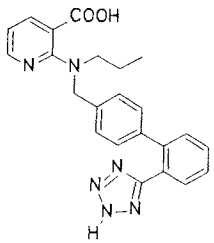
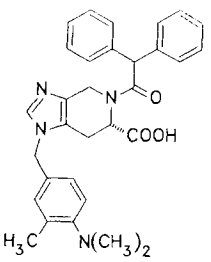
129



130



131



132

Based on the variable selectivity of synthetic ligands, two receptor subtypes, AT-1 and AT-2, could be differentiated.[203] Recently, with the help of an oligonucleotide primer derived from AT-1, an additional receptor subtype, AT-3, from the adrenal cortex of the rat, was cloned, sequenced, and expressed in COS cells and in xenopus oocytes.[204]

All known physiological effects of angiotensin II have hitherto been attributed to the AT-1 receptor, which has been demonstrated in several tissue types (adrenal cortex, liver, kidney, brain, and smooth muscles of blood vessels, bronchi, and the digestive tract), and whose c-DNA has been cloned from various species (cow,[205] rat,[206] humans[207]) and expressed in COS cells. A G protein-mediated action through various second-messenger systems, including the inhibition of adenylate cyclase activity, increase in the intracellular calcium concentration by mobilization of intracellular reserves or by opening of calcium channels, and hydrolysis of phosphatidylinositol-4,5-bisphosphate could be demonstrated. In comparison with AT-1, the receptor subtype AT-2 is found predominantly in the adrenal cortex and in the uterus. Unlike AT-1, AT-2 is not deactivated by reaction with disulfide-reducing agents and is apparently not coupled to a G protein. Its biological function is unknown.

There are indications that angiotensin II plays a role in embryonic development. A growth-factor-like effect of angiotensin II is possibly mediated by the AT-2 receptor.[208] A development-dependent differential expression of the two receptors AT-1 and AT-2 has been observed in the aorta[209] and the brain[210] of the rat.

In principle there are numerous possibilities for the pharmacological influence of the renin–angiotensin system, for example, by application of renin inhibitors, ACE inhibitors, or of antagonists of the A II receptor. ACE inhibitors have proven to be useful in the treatment of hypertension. In addition to the development of effective, orally active renin inhibitors, dramatic activity has taken place most recently in the development of angiotensin II analogues. While A II agonists are of interest for biochemical and pharmacological investigations (e.g. characterization and localization of the various A II receptors), the A II antagonists are of high therapeutic potential. One of the newer peptide-based ligands of the A II receptor is [Sar^1,(2′,3′,4′,5′,6′,-Br_5)Phe^8]-A II, a strong noncompetitive antagonist with a long-lasting effect in vivo.[211] Derivatives of [Sar^1]-A II, in which Phe^8 is replaced by β,β'-diphenylalanine (**3**), are potent agonists of the A II receptor, whereas [Sar^1]-A II analogues with 2-naphthylalanine (**4**) and 2-amino-2-indanecarboxylic acid (**5**) in place of Phe^8 are antagonists. Global restriction of the conformational flexibility of A II led to the agonist [$HCy^{3,5}$]-A II as well as the agonist [Sar^1,$HCy^{3,5}$,Ile^8]-A II, both with higher affinity for the receptor (HCy = homocysteine).[212] Peptide antagonists with selectivity for the AT-2 receptor include [*p*-aminophenylalanine^6]-A II[213] and nicotinic acid-Tyr-(*N*-Z-Arg)-Lys-His-Pro-IleOH.[214]

The first potent, orally active nonpeptide antagonist of the AT-1 receptor and prototype of a series of further compounds of similar structure[202] is DuP 753 (MK-954, **128**)[215] (IC_{50} = 19 nM). Compound **128** was developed by superpositioning the lead structure of S-8308 (**129**), a weak

but specific antagonist of the AT-1 receptor,[216] with the structure of angiotensin II, assisted by the use of molecular modeling. In clinical trials the blood pressure of volunteers could be reduced as a function of the concentration used. This discovery spurred intensive research in this area which culminated in the design of more potent and selective antagonists of the AT-1 receptor such as SK & F 108566 (**130**, $IC_{50} = 1$ nM)[217] and A-81988 (**131**, $K_i = 0.76$ nM; K_i for AT-2 > 10000 nM).[218] Selective antagonists of the AT-2 receptor were also discovered: PD-123319 (**132**), a nonpeptide antagonist of the AT-2 receptor ($IC_{50} = 34$ nM)[219] is representative here of other compounds with similar structures.

Investigations with **128** and other nonpeptide ligands suggest that angiotensin III is taken up into the cell and then inhibits cGMP-phosphodiesterase, resulting in opposite effects (relaxation of smooth muscle) to those of angiotensin II.[220] Since controlled clinical studies with nonpeptide A II antagonists are not yet available, the suitability of such agents for the treatment of cardiovascular diseases cannot be judged at this time.

4.8. Endothelins

Endothelin-1 (**133**),[221] a peptide consisting of 21 amino acids which has a marked blood vessel contracting action (10 times stronger than angiotensin II), was first isolated in 1988 from cultivated endothelial cells.[222] Later, two other related peptides were found, endothelin-2 (**134**) and endothelin-3 (**135**).[223] They are related to the sarafotoxins (snake toxins) in terms of structure and also from the pharmacological viewpoint. The endothelins belong to a series of substances that can be secreted from endothelial cells (cells of the inner walls of blood vessels) and which transmit a regulatory effect of the endothelial cells on the vascular tonus and thereby on the blood pressure (Fig. 5).[221] In addition to the endothelins[224] other substances belong to this class, including prostacyclins and the endothelium-derived relaxing factor (EDRF-NO), recently identified as nitrogen monoxide. The endothelins cause a long-lasting contraction of arteries and veins, minimize the excretion of sodium ions by the kidneys, and mediate a series of other biological effects, for example contraction of smooth bronchial, intestinal, and uterine muscles.[221] In the central nervous system the endothelins appear to be involved in the regulation of GnRH secretion.[225]

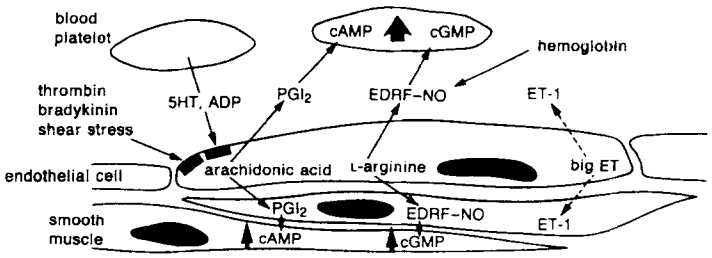


Fig. 5. Production of prostacyclin (PGI2), endothelial-derived relaxing factor nitrogen monoxide (EDRF-NO) and endothelin-1 (ET-1) in cells of the interior walls of blood vessels (endothelial cells). The blood platelets (thrombocytes) release serotonin (5HT) and adenosine diphosphate (ADP) through the influence of thrombin and bradykinin, or from the application of shear stress. The stimulation of the cell receptors by serotonin or adenosine diphosphate leads to the release of vessel-active mediators. Prostacyclin, formed from arachidonic acid, relaxes the smooth muscles of the blood vessels and inhibits the aggregation of blood platelets by increasing the concentration of *cyclo*-adenosine monophosphate (cAMP). EDRF-NO, formed from L-arginine, has the same effect but by increasing the *cyclo*-guanosine monophosphate (cGMP) level. Prostacyclin and EDRF-NO thereby function synergistically in inhibiting blood platelet aggregation by the simultaneous increase of the cAMP and cGMP concentration. Hemoglobin inactivates EDRF-NO. Endothelin-1 is generated in the endothelial cells by proteolysis of big endothelin (big ET). After exocytosis it binds to the membrane receptors of the smooth muscle cells and causes a contraction of the blood vessel muscles[224].

139

cyclo(-D-Glu-Ala-allo-D-Ile-Leu-D-Trp-) **137**

cyclo(-D-Trp-D-Asp-Pro-D-Val-Leu-) **138**

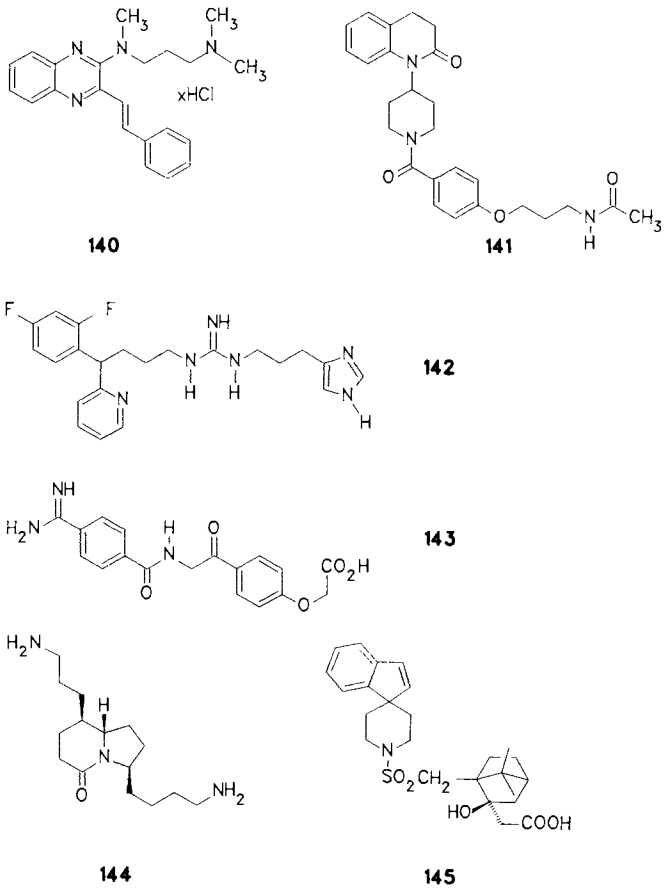
The biosynthesis of the most investigated member, endothelin-1, occurs by way of a preproendothelin (203 amino acids) and a proendothelin (39 amino acids). This peptide, also known as "big endothelin", is cleaved by the endothelin-converting enzyme, which can be inhibited by the metalloprotease inhibitor phosphoramidon (**136**).[226] So far two endothelin (ET) receptor types have been isolated: ET_A with selectivity for endothelin-1 and ET_B without selectivity for the isopeptides. They have subsequently been sequenced, cloned, and expressed.[227] The receptors display seven transmembrane regions. They are coupled by G proteins to the phosphatidylinositol-4,5-bisphosphate second-messenger system and effect the mobilization of calcium ions from intracellular stores. Interestingly, after endothelin is bound to its receptor (Swiss 3T3 cells), a tyrosine kinase is also stimulated.[156a] Endothelins and their receptors occur in peripheral tissues and also in various regions of the brain.[228]

A linear endothelin-1, in which all four cystein residues are replaced by alanine, acts as a selective agonist for the ET_B receptor.[229] If the outer of the two disulfide bridges in endothelin-1 is exchanged for an amide bond between di-

aminopropionic acid and aspartic acid in position 15 (the position of the outer cysteine residue), a specific, potent antagonist for the ET_A receptor is obtained.[230] The authors discuss a direct participation of the outer disulfide bridge in the recognition of endothelin-1 by its receptor, possibly by a disulfide exchange between ligand and receptor.[231]

Screening revealed another selective ET_A antagonist,[232] the cyclopeptide **137**. Structure–activity analysis based on this compound led to **138**, which has improved affinity and selectivity for the ET_A receptor.[233] Apparently this compound acts as a noncompetitive antagonist.[234] IRL-1038 [Cys^{11}-Cys^{15}]-endothelin-1(11-21) was recently described as a selective antagonist for the ET_B receptor,[235] and the anthraquinone derivative **139** was described as the first nonpeptide antagonist of the ET receptor.[236]

Apart from pharmacological and pathophysiological aspects, the main therapeutic potential of ET_A-selective antagonists lies in the treatment of elevated blood pressure. Other possible applications for ET_A antagonists include the treatment of arteriosclerosis, vasospasms in brain and heart, asthma, and malfunction of the kidneys. No concrete hypothesis concerning the potential of the ET_B receptor antagonists can be made at present, especially as the physiological significance of the ET_B receptor is still not clear. An opposite action to that of the ET_A receptor (relaxation of the vessel muscles and thereby a reduction in blood pressure) is being discussed.[237]



4.9. Miscellaneous

A series of other long-known agents have been shown recently to be mimetics of endogenous peptide ligands. In addition to the examples discussed above the following can be mentioned:

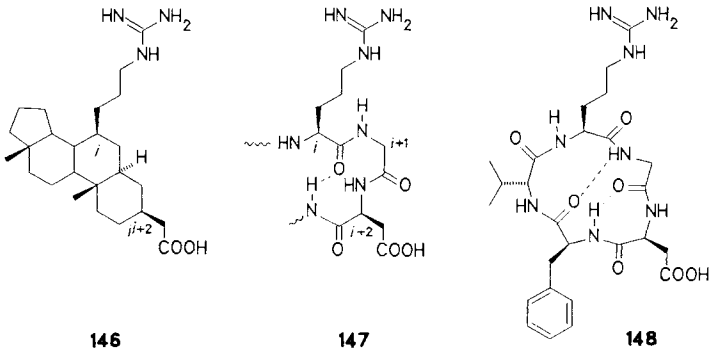
a) The antibiotic erythromycin has been shown to be an agonist of the polypeptide motilin, which is responsible for the coordination of the contraction of the gastrointesinal tract.[238] This observation led to the successful application of erythromycin for the treatment of the delayed emptying of the stomach caused by diabetes, thereby extending its indication area.[239]

b) Drugs based on sulfonylurea, long used for treatment of diabetes mellitus type II, are mimetics of the endosulfines, the endogenous peptide ligands of the sulfonylurea receptor.[240]

c) The endogenous ligands of the benzodiazepine receptor—an integral component of the $GABA_A$ receptor (GABA = γ-aminobutyric acid)[241]—are peptide based.[242]

Other nonpeptide ligands for peptide receptors include the glucagon receptor antagonist CP-99711 (**140**),[243] the vasopressin V1 receptor antagonist OPC-21268 (**141**),[244] the neuropeptide Y antagonist He-90481 (**142**),[245] and the glycoprotein (GP) IIb-IIIa antagonist (**143**) (highly potent inhibitor of thrombocyte aggregation),[246] the antagonist **144**[247] of the immune-stimulating tetrapeptide tuftsin (Thr-Lys-Pro-Arg), and the first nonpeptide oxytocin antagonist **145**.[248]

The steroid derivative **146**[249] was recently synthesized as an analogue of a postulated typeI β turn **147** of the glycoprotein GpIIb-IIIa-bound sequence Arg-Gly-Asp (RGD) of fibrinogen. Compound **146** binds to the GpIIb-IIIa receptor and shows an IC_{50} value of 100 μM when fibrinogen is used as ligand. In comparison the peptide *cyclo*(Arg-Gly-Asp-Phe-D-Val) (**148**, IC_{50} = 2 μM) is much more potent.[250] The RGD conformation relevant for the binding of the glycoprotein GpIIb-IIIa is apparently imitated better by **148**. According to NMR spectroscopic investigations, the Arg residue of this cyclopeptide in the position $i + 2$ takes up a βII′ turn, whereas the Asp residue in the central position adopts a γ turn.[251]



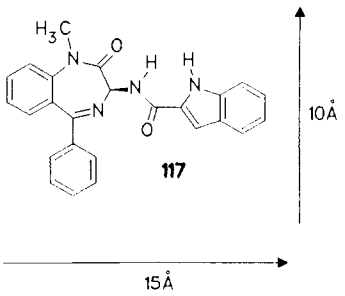
5. Summary and Outlook

Despite the disadvantages referred to at the beginning of this article, the development of peptide-based receptor lig-

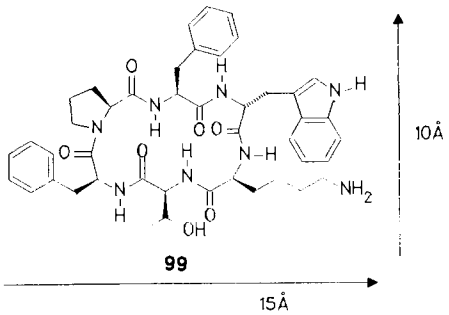
ands will certainly remain of interest in the future.[252] The successes in this area cannot be denied. The marked trend of the last few years is the design of effective, orally active nonpeptide ligands for peptide receptors. Of significance in this regard is the fact that it is possible, in principle, to imitate or to block the function of a relatively large peptide at the receptor level with low molecular mass compounds. The opioid alkaloids are excellent examples here. The peptidomimetic character of other drugs such as ketoconazole, erythromycin, the sulfonylureas, and benzodiazepines have only recently been discovered.

Most of the peptide receptors known to date are coupled with proteins that bind guanine nucleotides (G proteins).[253] If one then contemplates the structures of the previously mentioned nonpeptide ligands, it is noticeable that they frequently contain hydrophobic and in particular aromatic structure elements. This suggests the existence of lipophilic domains at the ligand binding site of these receptors. Aromatic groups on the ligand appear generally to play a central role in recognition and in subsequent receptor activation. The elimination of such groups often leads to an inversion of the action at the receptor.[254] This is shown quite impressively, for example, by a comparison of structures **100a** (substance P agonist) and **100b** (substance P antagonist).

A major problem in the design of ligands for peptide receptors with favorable pharmacalogical properties was and remains the discovery of a lead structure. That this can also take place rationally is shown unequivocally by the example of **119**: The correct spatial positioning of the pharmacophores of a peptidal CCK agonist provided a "peptoid" with high affinity and antagonistic properties to a CCK receptor. In this case an endogenous peptide served as a lead compound. The importance of the appropriate spatial arrangement was also demonstrated in studies of immunoglobulin mimetic **59**, the development of which was based on the X-ray crystallographic analysis of an antigen–antibody complex. This compound, as well as the somatostatin agonist octreotide (**98**), the GnRH agonist **65**, and the thrombin inhibitor **67**, demonstrates unequivocally the value of the concept of conformative restriction and the application of secondary structure mimetics in the development of ligands that imitate the conformation of a peptide bound to a receptor. NMR spectroscopy has been shown to be increasingly useful in the investigation of bioactive peptide conformations. Of great importance here is the fact that receptor proteins are becoming available in larger quantities with the help of molecular biology—for example, by expression in foreign cells. In this way the production of isotopically labeled receptor proteins is also possible. The importance of NMR spectroscopy in studies of peptide–receptor complexes[17b] under physiological conditions was demonstrated recently for the example of cyclosporin A and its interaction with the protein cyclophilin.[17c, d] A general method for the application of such knowledge to conformational design[255] is, nevertheless, not yet available. In conformational design the aim is often the conception of suitable scaffolds that carry the functional groups required for binding to the receptor in a suitable spatial arrangement. Structure–activity investigations have shown that only a relatively small peptide sequence of four to eight amino acids is responsible for the biological activity, and that the amide backbone is not involved in occupation of the receptor and its activation.[12, 254] In addition, conformation–activity investigations show that these sequences of folded and compact bioactive conformations are generally 10×15 Å in size. These are the same dimensions of a benzodiazepine like **117** (MK-329) or a cyclic hexapeptide such as **99**.[9]



117



99

The benzodiazepine skeleton has proven to be versatile and leads not only to neuropeptide mimetics like tifluadom (**81**), MK-329 (**117**), and L-365260 (**118**) but also to HIV protease inhibitors (HIV = human immunodeficiency virus).[256] Thus, it would appear that benzodiazepines[257] and related structures will provide years of research for both chemists and physicians.

The biochemical and pharmacological properties of the compounds **100a** and **100b** finally suggest the potential of the carbohydrate skeleton in the design of nonpeptide ligands. Carbohydrates offer advantages of structural diversity and the facile derivatization with a multitude of functional groups.[260]

Ultramicroelectrodes in Electrochemistry

By Jürgen Heinze*

Dedicated to Professor Herbert Zimmermann on the occasion of his 65th birthday

In the 1950s and 1960s fundamental developments in electrochemical methods included voltammetry and low signal techniques. A generation later, the discovery of the unusual properties of ultramicroelectrodes has opened new possibilities of analyzing electrode processes. The changes in mass transport conditions bring about extremely high current densities at ultramicroelectrodes, whereas the currents themselves become very small. This little-noticed phenomenon allows for many electroanalytical applications that are not possible with conventional electrodes, especially experiments in solutions with very low electrolyte concentrations, in nonpolar solvents, in solids, and even in gases. In addition, two factors—changes in the experimental time scale at low scan rates because of the size of the electrode, and insignificant *iR* effects at very high scan rates—make it possible to study very fast homogeneous and heterogeneous electrode processes.

1. Introduction

Electrodes are systems of coupled electrically conducting phases, which are usually in electrochemical equilibrium. An exchange of charges takes place across the interfaces between the phases. The reaction at the phase interface is known as an electrode reaction, and the exchange of charged particles across the phase interface is a charge transfer reaction. As a rule, one phase conducts electrons and at least one phase ions (metal or semiconductor electrode). In principle, an electrode can also consist of two ion-conducting phases.

In textbooks, some such definition will introduce the electrode as the crucial instrument of electrochemistry. Accordingly, almost all our knowledge in this field concerns electrodes directly or indirectly. In basic research, electrode kinetics[1] and electrochemical thermodynamics provide comprehensive theories that are continually being extended to explain the properties of electrodes and the processes at or through them. Hence, it comes as a surprise to learn that in the past electrochemists paid little attention to the influence that size and geometry of the electrode surface have on electrochemical processes, apart from the direct proportionality between size and the measured signal.[2]

The development of polarography[3] made the relatively small spherical Hg drop electrode widely known as early as 1922. Initially, however, no one appears to have obtained theoretical or experimental findings that indicated a direct relationship between the size of the drop and its electrochemical properties. In 1937 MacGillavry and Rideal[4] set up a current–time equation for the stationary, spherical electrode for the first time, which predicted that the course of the diffusion-controlled current over time depended on the size of the radius. Two years later, Laitinen and Kolthoff were unable to verify this relationship experimentally.[5a] In 1941 the same authors reported the results of voltammetric experiments using thin wire electrodes.[5b] They interpreted the stationary currents they observed as a consequence of natural convection, and did not relate them to surface size or geometry of the electrode. Only in the mid 1960s, when current–time measurements at small stationary disk electrodes excluded the influence of convection, was it accepted that the results did not agree with the theory of planar diffusion. These phenomena were interpreted as edge effects due to surface size, for the most part the result of quasi-spherical diffusion processes.[6] At about this time, almost twenty-five years after it had been theoretically predicted, experiments confirmed for the first time that the current response in chronoamperometric experiments with spherical electrodes becomes time-independent and stationary. The time lapse before the stationary value is attained depends on the electrode radius.[7] Although the subject attracted some interest in the following years,[8–7] only at the end of the 1970s did Fleischmann and co-workers at the University of Southampton[18] establish beyond question that diminishing electrode surface size has not only quantitative effects, but also—and always—unusual qualitative effects.[19, 20] For instance, chronoamperometric measurements at electrodes with μm dimensions (≤ 20 μm) showed that, in contradiction of Cottrell's theory,[21] even with planar electrodes a time-independent stationary state is reached very rapidly. Other conspicuous phenomena included high current densities in spite of small measuring currents, the possibility of measuring transients at considerably shorter time scales as well as a drastic decrease in the ohmic drop caused by the resistance of the solution. In 1981 Wightman provided a first comprehensive survey of the special properties and perspectives of microvoltammetric electrodes.[22]

These discoveries have encouraged numerous research groups to study the properties and applications of ultramicroelectrodes in theory and practice.

The concept of ultramicroelectrodes (UME) is now a widely accepted term in the literature. However, unlike in the field of electrophysiology, in electrochemistry it is not necessary for all dimensions of probes to be extremely small. In principle, only one, the characteristic dimension that is given by the geometry of the electrode, must be very small. For instance, a very narrow, but long band electrode makes a suitable ultramicroelectrode.

In their enthusiasm, electrochemists should not forget that microelectrodes with diameters of 25 μm have long been

[*] Prof. Dr. J. Heinze

Albertstrasse 21, D-79104 Freiburg (FRG)
Telefax: Int. code + (761)203-2815

used in medical and biological research.[23] They were initially developed to determine the oxygen content of living tissue and tissue liquids.[24, 25] Accordingly, the electrodes had to be as small as possible. The users either did not notice the unconventional properties of these electrodes, or did not think anything of it.

Electrochemists are interested in ultramicroelectrodes mainly because their application in accordance with the general principles of practice used in voltammetry and chronoamperometry opens totally new possibilities for studying electrode reactions. The results of dynamic measurements in solvents with low electrolyte concentrations or in poorly conducting media,[26] or in the solid state,[27] or even in the gas phase[28] have been particularly spectacular. This will ensure that in future electrochemical data will be obtained under similar experimental conditions as, for example, in spectroscopy.

Moreover, using microelectrodes expands the time scale for measurements by several orders of magnitude, which makes it much easier to study rapid homogeneous or heterogeneous reactions with microelectrodes than with, for example, rotating electrodes. Over and above this, the combination of exceptionally high current densities and low measuring currents promises new applications in the fields of analysis, sensors, and scanning electrochemical microscopy.[29] At the same time, the small dimensions of the electrodes guarantee that the experiment will not alter or destroy the object measured, a very important aspect in, for instance, biophysical examinations.

A growing number of communications, progress reports,[30] and books[31] indicates that the above-mentioned set of examples is by no means complete. As ultramicroelectrodes become commercially available, this technique will soon find new friends outside specialized electrochemical laboratories. It is hoped that this survey will encourage this development.

2. Electrochemistry at Ultramicroelectrodes

2.1. Mass Transport

In principle, experiments using ultramicroelectrodes are similar to those using conventional electrodes. A stationary electrode immersed in an unstirred electrolytic solution is given either a constant potential or one that changes linearly over time. Provided there is an electroactive substance, that is, one that can undergo oxidation or reduction, in the electrolytic solution, a heterogeneous charge transfer will occur at the metal/liquid interface, during which, in the case of reduction, for example, electrons will be transferred from the electrode to the electroactive substance.[1, 32] At the same time, the concentrations at the electrode surface start to change, which sets off diffusive mass transport to and from the electrode.

Depending on the size of the electrode and the volume of electrolytic solution used, one can distinguish between three limiting cases of diffusion. The simplest case is an electrode in a thin-layer cell with a very low ratio of cell volume to electrode surface. Under these conditions, mass transport within the cell is negligible, and no diffusion gradient develops.[33] By reducing the ratio between the electrode surface and the electrolyte volume, one approximates the normal situation of a voltammetric experiment with semi-infinite planar diffusion.[34] With the transition to extremely small electrode surfaces, the conditions change yet again, and the diffusion process becomes dependent on the size and geometry of the electrode[2, 30, 31] (Fig. 1).

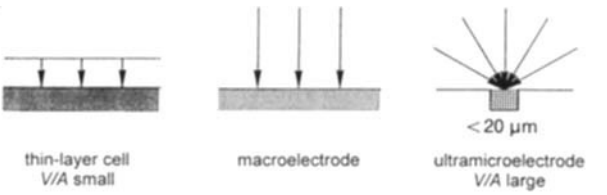

Fig. 1. Limiting cases of diffusive mass transport in electrochemical cells. Left: Thin-layer cell; the available transport paths are short, and no diffusion gradient develops. The ratio between electrolyte volume (V) and electrode area (A) is very low. Center: Macroelectrode (for example, disk with diameter ≥ 0.01 m); mass transport perpendicular to electrode is in form of a semi-infinite planar diffusion. In mathematical terms, the process corresponds to mass transport in a one-dimensional diffusion field [Eq. (1)]. Right: Ultramicroelectrode; the diffusion process depends on the shape of the electrode. A spatial diffusion field develops (hemispheric in the case of a disk electrode) [Eqs. (2–6)]. The V/A ratio is extremely high.

As one might expect, the voltammetric current–voltage curves of these three cases differ markedly. In the case of a thin electroactive layer, the cathodic and anodic waves appear as perfect mirror images. Normal electrodes produce the characteristic cyclic voltammograms,[34] and extremely

Jürgen Heinze was born in Dresden in 1939. He studied chemistry in Cologne and Munich from 1960 to 1966. After obtaining his Diploma, he completed a PhD under Herbert Zimmermann in Freiburg in 1971 on the synthesis and physical properties of azole systems. In 1980 he habilitated in Physical Chemistry with studies on microelectrodes and was appointed professor in 1987. Since 1991 he has been a member of the newly founded Freiburger Materialforschungszentrum. He is chairman of the Baden-Württemberg priority research program, "Electroactive Materials for Sensor Technology". His main research subjects are mechanistic investigations of electron-transfer-induced processes and their coupled chemical reactions, and the development of new and improved methods of electrode kinetics (cyclic voltammetry), in particular, those involving microelectrodes. Further interests include electroactive materials, such as conductive polymers, and the development of electrochemical sensors.

small electrodes (ultramicroelectrodes) yield steady-state current–voltage curves, which resemble the classic polarograms as well as the current–voltage curves of rotating electrodes (Fig. 2).

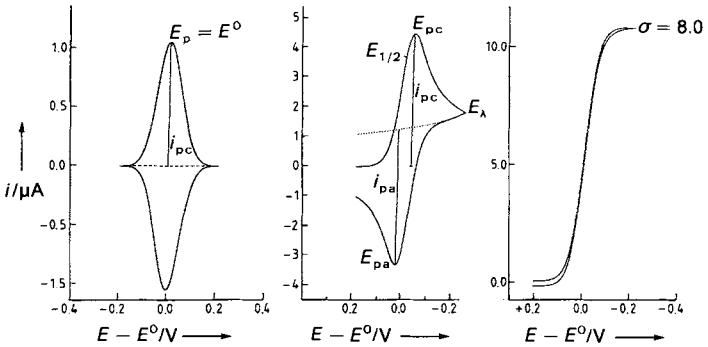

Fig. 2. Voltammetric current–voltage curves. Left: for the thin-layer cell; center: for semi-infinite planar diffusion ($\sigma = 0$) to a macroelectrode; right: for semi-infinite hemispheric diffusion to a microdisk electrode ($\sigma = 8.0$). E_λ = switching potential, $E_{\frac{1}{2}}$ = half-wave potential, E_p = peak potential, E_{pa} = anodic peak potential, E_{pc} = cathodic peak potential, i_{pa} = anodic peak current, i_{pc} = cathodic peak current. The V/A ratio increases from left to right.

The phenomena at ultramicroelectrodes are caused by time-dependent changes in mass transport, in which one-dimensional diffusion fields transform into spatial fields. In the case of planar electrodes, besides the usual axial diffusion, an additional, radial diffusive component becomes effective parallel to the electrode surface. In the case of curved electrode surfaces, spherical or cylindrical diffusion fields form over time at rates that depend on electrode size.

In mathematical terms, the diffusion is described by Fick's Laws, which vary for spatial fields [Eqs. (1–5)] according to the electrode geometry.[35]

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} \quad \text{(planar diffusion)} \tag{1}$$

$$\frac{\partial c}{\partial t} = D\left(\frac{\partial^2 c}{\partial r^2} + \frac{1}{r}\frac{\partial c}{\partial r}\right) \quad \text{(cylindrical electrode)} \tag{2}$$

$$\frac{\partial c}{\partial t} = D\left(\frac{\partial^2 c}{\partial r^2} + \frac{2}{r}\frac{\partial c}{\partial r}\right) \quad \text{(spherical electrode)} \tag{3}$$

$$\frac{\partial c}{\partial t} = D\left(\frac{\partial^2 c}{\partial r^2} + \frac{1}{r}\frac{\partial c}{\partial r} + \frac{\partial^2 c}{\partial z^2}\right) \quad \text{(disk)} \tag{4}$$

$$\frac{\partial c}{\partial t} = D\left(\frac{\partial^2 c}{\partial x^2} + \frac{\partial^2 c}{\partial z^2}\right) \quad \text{(band)} \tag{5}$$

The introduction of further boundary conditions determines whether the diffusion will be finite (thin-layer cell) or semi-infinite and whether the electrode reaction will proceed galvanostatically (constant current), potentiostatically (constant potential), or potentiodynamically (variable potential). When ultramicroelectrodes are used, measurements are generally potentiostatic (chronoamperometry) or potentiodynamic (cyclic voltammetry).

The planar disk is the most popular electrode in experiments (Fig. 3). It is constructed relatively easily by encasing a metal wire or a carbon fiber in glass or embedding it in

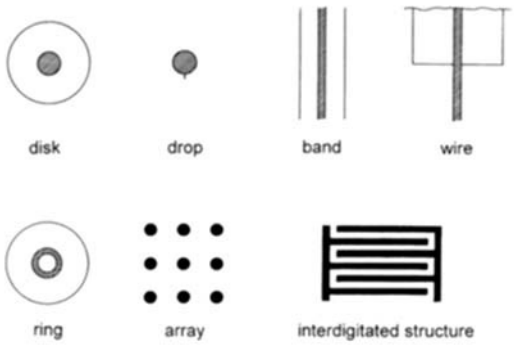

Fig. 3. Typical configurations of ultramicroelectrodes.

plastic; the flat surface of the end of the insulated wire serves as the active electrode surface.[6, 36–38] Recently, greater use has been made of band[39–42] and ring electrodes,[43, 44] whose surface areas can be enlarged by altering the length of the band or the circumference of the ring without losing the specific properties of ultramicroelectrodes. The same objective can be achieved with electrode arrays,[45–47] that is, several electrodes arranged, for example, in the form of an interdigitated structure. However, with arrays the diffusion conditions change depending on the arrangement of the electrodes. This means that, during very long experiments, the diffusion field eventually returns to a planar form.[48, 49] From a theoretical point of view, spherical (Hg drop)[49] and cylindrical (wire) electrodes[17, 41, 51] are particularly interesting, as they allow for one-dimensional solutions to the diffusion problem.[2, 4, 35]

2.2. Chronoamperometry

Notwithstanding different diffusion equations, when the surface area is reduced, qualitatively similar changes take place in the current response of all electrodes, irrespective of shape. This is because at electrodes generally the particle flux per surface unit increases as the distance from the electrode surface decreases. A study of chronoamperometric experiments reveals the details of this phenomenon.

In the simplest case of a chronoamperometric (potential step) experiment, a working electrode is given a potential sufficient to completely reduce or oxidize at the electrode surface a dissolved electroactive substance of concentration c^*. The corresponding initial and boundary conditions are compiled in Equations (6)–(8).

$$c(x,0) = c^* \qquad (t = 0) \tag{6}$$

$$\lim_{x \to \infty} c(x,t) = c^* \quad (t > 0) \tag{7}$$

$$c(0,t) = 0 \tag{8}$$

Experiment and theory show that under these conditions a diffusion-controlled, faradaic current i flows over the electrode. Its value (in A, proportional to j, the flux in $\mathrm{mol\,s^{-1}\,m^{-2}}$) is directly proportional to the concentration gradient at the electrode surface [Eq. (9), where F is the faradaic constant, D the diffusion coefficient, and A the area

$$\frac{i}{nFA} = j(0,t) = -D\left[\frac{\partial c}{\partial x}\right]_{x=0} \quad (9)$$

of the electrode]. This gradient causes the formation of a diffusion layer in front of the electrode, which gradually spreads into the solution (Fig. 4, top). For a purely planar

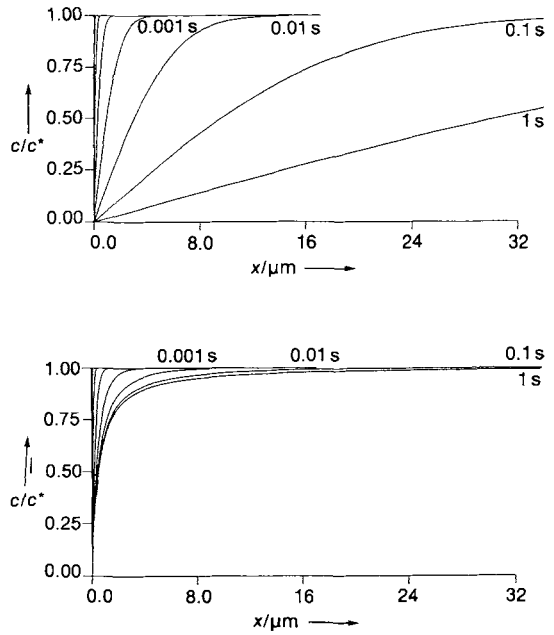

Fig. 4. Concentration profiles of diffusion layers (diffusion coefficient $D = 1 \times 10^{-9}\ m^2 s^{-1}$) in a chronoamperometric experiment for different times t after application of a potential step (concentration of the electroactive species at electrode surface is zero). Top: semi-infinite planar diffusion; bottom: spherical diffusion for a spherical microelectrode with $r_0 = 0.5$ μm. c/c^* = normed concentration, x = distance from electrode.

diffusion, the time-dependent current obeys the Cottrell equation [Eq. (10)],[21] which predicts that the current in

$$\frac{it^{1/2}}{nFAD^{1/2}c^*} = \frac{1}{\pi^{1/2}} \quad (10)$$

the chronoamperometric experiment is inversely proportional to $t^{\frac{1}{2}}$.

The conditions for planar diffusion are properly fulfilled only if the electrode surface is very large. In the case of a disk electrode, edge effects become increasingly noticeable as surface area decreases: in addition to the mass transport perpendicular to the electrode, mass transport also develops parallel to the electrode. The size of the edge effects depends on duration of the measurement and electrode radius. Figure 5 shows computed concentration profiles at disk electrodes with different radii recorded after 1 s of measuring.

From this it is clear that as the electrode radius decreases, semi-infinite planar diffusion gradually transforms into semi-infinite hemispherical diffusion. Longer experiment duration produces the same phenomenon. Due to the time-dependent change in the diffusion profile, the solid angle occupied by the diffusion layer in front of the electrode increases, and hence, grows considerably relative to the electrode surface. As a consequence, many more electroactive particles per unit time and area reach the electrode than in

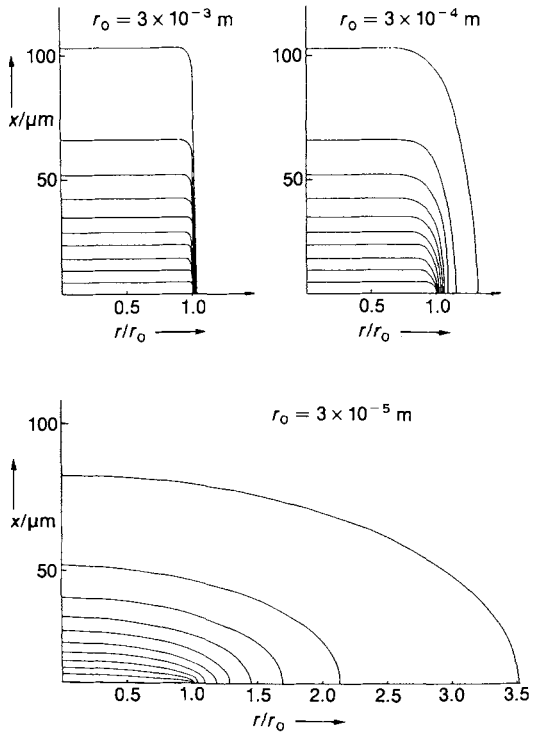

Fig. 5. Normalized calculated concentration profiles c/c^* calculated for disk electrodes with different radii ($r_0 = 3 \times 10^{-3}$, 3×10^{-4}, 3×10^{-5} m; $D = 1 \times 10^{-9}\ m^2 s^{-1}$) 1 s after start of a chronoamperometric experiment; concentration of the electroactive species at the electrode is zero because of a high potential pulse. Concentration curves are separated by 0.1 of a concentration unit. x = distance perpendicular to the electrode.

the case of pure planar diffusion. On the other hand, the growing volume within the prescribed solid angle means that the particle flux in and out of the volume eventually becomes stationary (Fig. 4b) and the diffusion layer stops growing. The mass transport rate in the stationary case is given by the mass transport coefficient m (in $m s^{-1}$). Its value in a (hemi)spherical field is indirectly proportional to the electrode radius r_0 [Eq. (11)]. Consequently, for extremely small electrodes the diffusion rate can be extraordinarily high.

$$m = Dr_0^{-1} \quad (11)$$

Hence, the calculation of the current–time curve produces a modified Cottrell equation [Eq. (12)]. For the disk elec-

$$\frac{it^{1/2}}{nFAD^{1/2}c^*} = \frac{1}{\pi^{1/2}}\left(1 + b\left(\frac{Dt}{r_0^2}\right)^{1/2}\right) \quad (12)$$

trode,[6, 13, 52] $\pi^{\frac{1}{2}} \leq b \leq 4\pi^{-\frac{1}{2}}$. The value of the prefactor b changes in the transition from the planar to the hemispherical diffusion field. Approximate formulas for this intermediate case may be found in the literature.[53, 54] By analogy, Equation (13) is valid for the spherical electrode.[2, 4] As long

$$\frac{it^{1/2}}{nFAD^{1/2}c^*} = \frac{1}{\pi^{1/2}}\left(1 + \pi^{1/2}\left(\frac{Dt}{r_0^2}\right)^{1/2}\right) \quad (13)$$

as planar diffusion dominates and the measuring time is short, the second term on the right-hand side of Equations (12) and (13) can be neglected, which results in the

limiting case of Equation (10). By contrast, if the measuring time is very long, the first term on the right-hand side becomes negligible, and the result is a stationary current. The smaller the electrode surface, the shorter the time lapse before the stationary state is established. The parameter (14)

$$\eta = \left(\frac{Dt}{r_0^2}\right)^{1/2} \tag{14}$$

characterizes the extent of the nonplanar diffusion. For values of η greater than 6, the current becomes stationary; for smaller values, one approximates the limiting case of planar diffusion. Oldham's comprehensive theoretical studies[55-57] have shown that one can set up an identity for the stationary limiting currents i_{Gr} (in A) for the spherical, hemispherical, and disk electrodes by introducing a surface diameter d [Eq. (15)]. For the sphere, $d = 2\pi r_0$, for the hemi-

$$i_{Gr} = 2nFc^*Dd \tag{15}$$

sphere $d = \pi r_0$, and for the disk electrode $d = 2r_0$. The attainable stationary limiting currents for the different electrode forms are listed in Table 1.[41,56-59] In contrast to

Table 1. Limiting currents for ultramicroelectrodes.

Sphere
$i_{Gr} = 4\pi r_0 nFDc^*$

Hemisphere
$i_{Gr} = 2\pi r_0 nFDc^*$

Disk:
$i_{Gr} = 4r_0 nFDc^*$
is identical with the sphere when $= (\pi/2)r_0$ (hemisphere)

Cylinder (approximate)
$i = 2nFADc^* \dfrac{1}{\ln[4(Dt)/r_0^2]}$
where A = cylinder surface area ($2\pi r_0 l$) or
hemicylinder surface area ($\pi r_0 l$), l = length of the cylinder

Band electrode (approximate)
$i = 2\pi nFDc^* l \dfrac{1}{\ln[4(Dt)/r_0^2]}$
l = length of the band

Ring
$\dfrac{\lim_{t\to\infty} i(t)}{nFDc^*} = \dfrac{\pi^2(a+b)}{\ln[16(b+a)/(b-a)]}$
where $a - b \ll a$ and
b = inner radius of the ring, a = outer radius of the ring

macroelectrodes, with microelectrodes current and electrode surface are not proportional for diffusion-controlled processes; instead current is proportional to the characteristic electrode diameter or radius. Thus, with microelectrodes under diffusion control, the current density is larger the smaller their diameter, whereas with macroelectrodes it is usually independent of surface area.

The time lapse before a stationary state is reached depends both on the size of the electrode and on the diffusion coefficient of the electroactive system. Calculations of Oldham et al.[57] show that for an average diffusion coefficient of $10^{-9}\,m^2s^{-1}$, a 10 μm disk electrode takes approximately 1.3 s and a 1 μm electrode 0.01 s to reach a stationary state, with a deviation $\varepsilon = 5\%$. (According to Equation (12), stationary states can, in theory, also form at macroelectrodes. This would take about 360 h in the case of a 1 cm disk electrode, so that in any event convection influences would dominate.) As it is obvious that several parameters determine the specific properties of such electrodes—the influence exerted by iR will be discussed in Section 2.5—it is very difficult to define an "ultramicroelectrode" in terms of a precise limit for its characteristic dimension. It has become practice to use the term UME for disk electrodes with a diameter smaller than or equal to 20 μm. The term nanode is used for electrodes with a diameter of less than 1 μm.

As expected, the influence of electrode shape is greatest for spherical diffusion fields. The comparison with planar diffusion (Fig. 6) shows that already after 1 s, despite a small

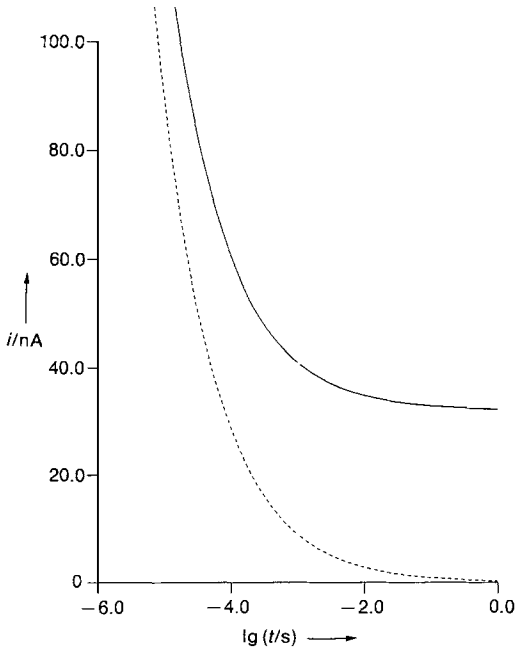

Fig. 6. Simulated current–time curve in chronoamperometry (Cottrell experiment) ($D = 1 \times 10^{-9}\,m^2s^{-1}$, $c^* = 5.4 \times 10^{-2}$ M, $c(0,t) = 0$) for planar (——) and spherical (- - - -) diffusion ($r_0 = 0.5$ μm).

absolute current, the current density at a spherical microelectrode with a diameter of 1 μm is nearly 100 times greater than that at a normal electrode [Eq. (16)].

$$\frac{i_{spher}}{i_{plan}} = 1 + \left(\pi \frac{Dt}{r_0^2}\right)^{1/2} \tag{16}$$

The calculations for cylindrical, band, and ring electrodes prove that these attain only a quasi-stationary state, as the equations for their currents contain time-dependent terms. On the other hand, the current response can be considerably increased by altering band length or ring circumference without changing the diffusion field. This opens interesting perspectives for analytical applications.

2.3. Voltammetry

Whereas in chronoamperometry the potential at the electrode is constant after a single step from the initial to the

final value, in voltammetry the potential changes linearly over time. Starting from an initial potential E_i, a linear potential sweep (potential ramp) is applied to the electrode. After reaching a switching potential E_λ, the sweep is reversed and the potential returns linearly to its initial value,[32, 34] which explains the term *cyclic* voltammetry. The experimental time scale is determined by the potential scan rate (also known as the sweep rate) $v = \Delta E/\Delta t$. This popular electrochemical method was presented in a previous issue of *Angewandte Chemie*.[34]

Ultramicroelectrodes in cyclic voltammetry produce, in principle, the same phenomena as in chronoamperometry. The transition to the stationary state is achieved by reducing the scan rate—and the smaller the characteristic radius of the electrode, the faster the transition. Initially the cyclic voltammograms at "high" v values are wave-shaped; as v declines they become sigmoid polarograms (Fig. 7). As such, they are

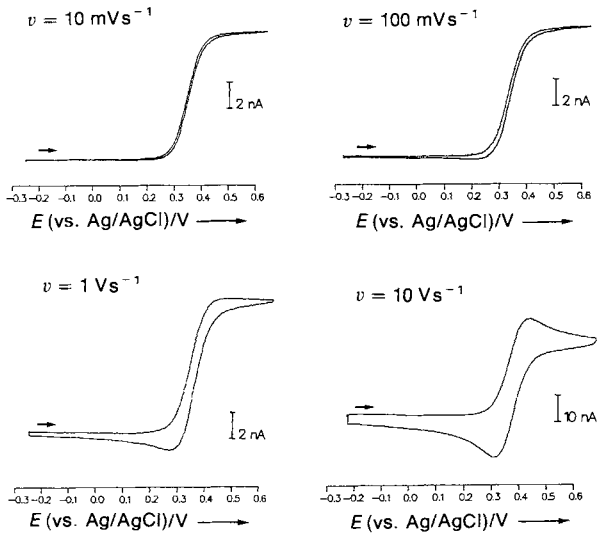

Fig. 7. Experimental cyclic voltammograms of the oxidation of ferrocene ($c = 3.2$ nM) in CH_2Cl_2/0.1 M [TBA]PF_6 (TBA = tetra-*n*-butylammonium) at different scan rates. Measurements taken with a Pt microdisk electrode ($r_0 = 6$ μm).

comparable with the steady-state voltammograms at rotating disk electrodes. This resemblance is due to the formation of stationary (Nernst) diffusion layers, which in the case of rotating electrodes are caused by rapid convectional mass transport, and in the case of microelectrodes are a result of the particular shape of the diffusion field and the high diffusive mass transport rate.

In the stationary state, the currents are time-independent, and the scan rate no longer affects the shape and size of the voltammetric wave. The conditions for the formation of a steady-state differ according to the geometry of the electrodes used. Whereas the diffusion-limited current or the current density corresponds to the values obtained for the stationary state in chronoamperometry (Table 1), theoretical modeling of the entire current–voltage curve has to be done numerically.[60, 61] The only exception is the case of the simple reversible redox process during spherical diffusion to a spherical electrode. For this, Reinmuth[62] has developed a correction formula that can be used to calculate the dimensionless current function $\pi^{\frac{1}{2}}\chi^s(at)$ (which corresponds to a normalized current—s stands for spherical) from the known current function $\pi^{\frac{1}{2}}\chi^p(at)$ (p stands for planar) for planar diffusion [Eq. (17), where σ is the sphericity (17b) and Φ the spherical correction factor (17c)]. The factor a is the normal-

$$\pi^{1/2}\chi^s(at) = \pi^{1/2}\chi^p(at) + \sigma\Phi(at) \tag{17a}$$

$$\sigma = \sqrt{\frac{D}{ar_0^2}} \tag{17b}$$

$$\Phi = \frac{1 - e^{-at}}{1 + e^{\eta - \eta^0}} \tag{17c}$$

ized scan rate in cyclic voltammetry (defined as $a = vnF(RT)^{-1}$) and $\eta^{(0)} = E^{(0)}nF(RT)^{-1}$ is a normalized potential. The sphericity σ characterizes the extent of the spherical diffusion. For $\sigma = 0$, the limiting case of normal planar diffusion ($r \to \infty$) characterized by the typical transient voltammogram is observed, whereas from $\sigma > 1$ the stationary state ensues (Fig. 8). The transition to the stationary

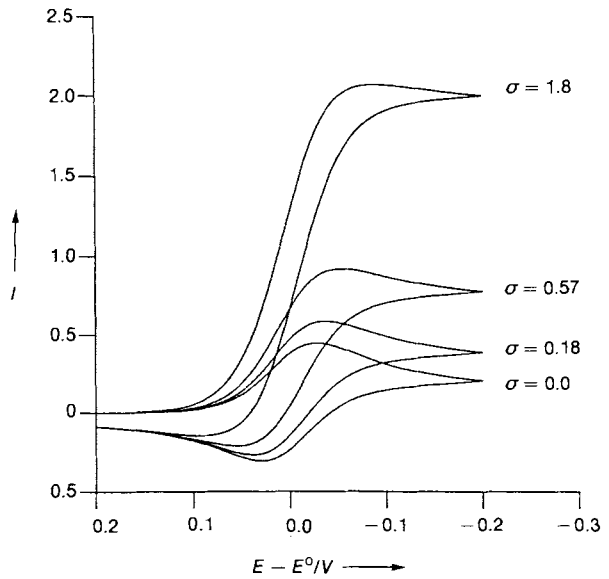

Fig. 8. Simulated cyclic voltammetric diagrams for spherical electrodes with different sphericities. The ordinate gives the current function $\pi^{\frac{1}{2}}\chi(at)$ (= normalized current i) [8].

state takes place at somewhat higher σ values for other electrode geometries.

Larger σ values, usually a consequence of smaller electrode radii, imply higher transport coefficients m (Eq. 11) and therefore higher current densities. A comparison with rotating electrodes (RDE) reveals that the transport coefficient of a spherical electrode with a diameter of 10 μm corresponds to a speed of 10000 rpm. Whereas this is the maximum speed for rotating electrodes, the dimensions of ultramicroelectrodes can be considerably smaller.

One property that distinguishes ultramicroelectrodes from stationary electrodes of conventional size is the increase in the transport rate of the electroactive particles as the electrode radius decreases. The high transport rates mean that with very small electrodes this process can take place as fast or even faster than heterogeneous charge transfer; that is,

instead of being diffusion-controlled, the process becomes kinetically controlled. Unlike the diffusion-controlled case, which is in thermodynamic (Nernst) equilibrium at the electrode, the corresponding stationary current–voltage curves shift and change their shapes depending on the rate of electron transfer (Fig. 9). Thus, ultramicroelectrodes are very

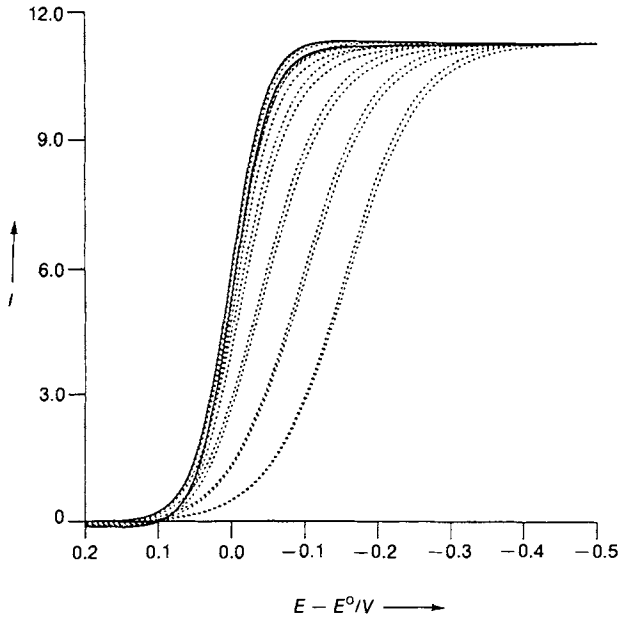

Fig. 9. Steady-state cyclic voltammograms with an ultramicrodisk electrode ($\sigma = 11.1$, ($D = 1 \times 10^{-10} m^2 s^{-1}$, $r = 0.5$ μm, (hemi)spherical diffusion field). k_s^0: (——) > 1, (----) 0.011, 0.0035, 0.0011, 0.00035, 0.00011, 0.000035, 0.000011 ms^{-1}. For $k_s^0 > 1\ ms^{-1}$ and a mass transport coefficient of $m = 0.002\ ms^{-1}$, the electrode process is diffusion-controlled (Nernst case). For $k_s^0 \leq 0.002\ ms^{-1}$, the reaction is kinetically controlled, and the steady-state voltammograms shift with simultaneous minor changes in shape along the potential axis. With the help of theory [63], k_s^0 can be determined from the curves' potential shift.

elegant instruments for determining kinetic parameters of rapid electron transfer reactions. As theoretical considerations show,[63] rapid transfer processes with heterogeneous rate constants of the order of $10^{-2}\ ms^{-1}$ can be analyzed by disk electrodes with a diameter of between 5 μm and 0.05 μm. For slower processes, electrodes with significantly larger diameters are adequate. By applying a suitable set of ultramicroelectrodes of different sizes to obtain steady-state voltammograms, one can determine the kinetic parameters of the heterogeneous charge transfer (the transfer coefficient α and the transfer rate k_s^0) as well as the thermodynamic standard redox potential.[63, 64]

There is also another reason why ultramicroelectrodes can accurately determine standard redox potentials. As a result of the high transport rates, the homogeneous chemical processes associated with the heterogeneous charge transfer in the experimental time scale—the latter expressed by the σ value [Eq. (17b)] or the mass transport coefficient m [Eq. (11)]—take place only partially or not at all (Fig. 10). Because the diffusion rates rise with decreasing electrode radius while the rates of homogeneous chemical processes do not change, the effect of diffusion rates on the shape and position of the voltammetric current–voltage curves decreases continuously. Provided that the heterogeneous

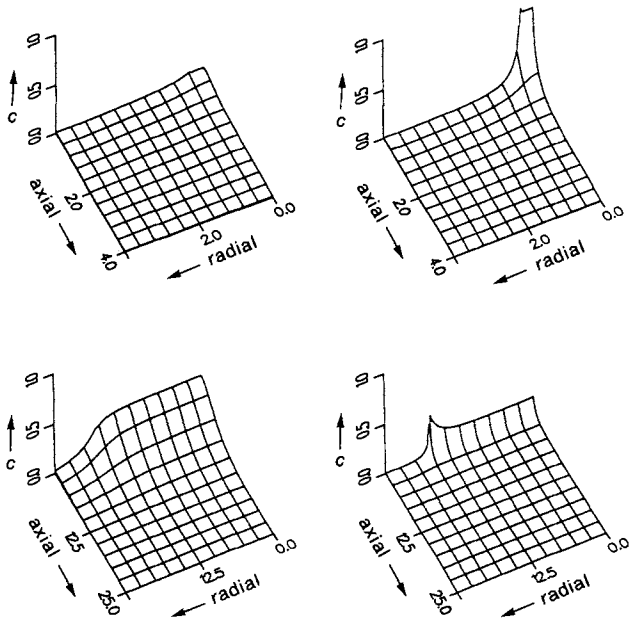

Fig. 10. Two-dimensional concentration profiles for an electron transfer reaction ($R \rightarrow R^-$), to which an irreversible dimerization is coupled ($2R^- \rightarrow R_2^{2-}$, EC_{2irr}, $k_f c/a = 20.0$). Top: microdisk electrode, $\sigma = 5.0$, for the dimer (left) and the anion (right); bottom: macrodisk electrode, $\sigma = 0.1$, for the dimer (left) and the anion (right). The formation of the dimer close to the macroelectrode is very clear; in the case of the microelectrode, the concentration profile of the first anion formed predominates.

charge transfer is very fast, appropriately small electrodes enable the direct determination of the formal redox potential of an electrode reaction by measurement of the half-wave potential $E_{\frac{1}{2}}$.[64] As shall be seen in Section 3.1.1, the relationship between diffusion rate, on one hand, and the reaction rate of the associated chemical reactions, on the other, can be applied to quantitative analysis of the kinetics of such chemical processes.

2.4. The Influence of the Capacitive Current

As with all dynamic electrochemical experiments, chronoamperometry and cyclic voltammetry have to take account of the faradaic current as well as the capacitive current i_c that flows along the electrode when the electrical double layer is charged. The simplest way of simulating the capacitive current is by applying an electrical equivalent circuit, with a resistance that corresponds to the resistance of the solution R_u and a capacitance in series that corresponds to the double layer capacitance C_d. For a single potential step ΔE, i_c (in A) is given by Equation (18), which shows that

$$i_c = \frac{\Delta E}{R_u} \exp\left(-\frac{t}{R_u C_d}\right) \tag{18}$$

the capacitive charging current falls exponentially over time. The smaller the corresponding time constant for charging the double layer (contained in the term RC), the faster the process. According to the expression (19), the drop-off time

$$R_u C_d \sim r_0 \tag{19}$$

for the charging current for ultramicroelectrodes becomes extremely short; they, therefore, hold great potential for measurements in very small time domains.

Because of continual potential sweep, the capacitive current in cyclic voltammetry has two components, one transient, the other steady-state [Eq. (20)]. As the latter predominates at medium and low scan rates, as a rule (20) simplifies to (21).

$$i_c = \left[\left(\frac{E_a}{R_u} - vC_d\right)\exp\left(-\frac{t}{R_uC_d}\right)\right] + vC_d \tag{20}$$

$$i_c = vC_d \tag{21}$$

The capacitive current component i_c disturbs studies on electrochemically induced electron transfer reactions (the faradaic processes), because voltammetric measurements always give the sum of both currents. The capacitive current increases linearly with the scan rate v, whereas the faradaic current i_f changes at $v^{\frac{1}{2}}$. Moreover, when the concentrations of the active redox system are low ($< 10^{-5}$ M), i_f and i_c cannot be adequately separated. Although there is some capacitive effect when ultramicroelectrodes are used in the stationary state, the current ratio i_f/i_c improves drastically as the faradaic component of the current density increases with r_0^{-1}, whereas the capacitive component is independent of the radius. The relationship (22) holds either exactly or approximately for most geometric shapes.

$$\frac{i_F}{i_c} \approx \frac{1}{r_0C_dv} \tag{22}$$

The smaller the characteristic dimension of the electrode and the lower the scan rate, the better the current ratio i_f/i_c in the stationary state of a voltammetric measurement.

2.5. The Ohmic *iR* Drop

As a consequence of the ohmic resistance in an electrolyte, in every electrochemical experiment involving current flow, any prescribed (time-dependent) potential $E_a(t)$ (in V) will be incorrect because of an ohmic potential drop [Eq. (23)]. The

$$E_{eff}(t) = E_a(t) - iR_u \tag{23}$$

lower the conductivity of the electrolyte system and the larger the total current, the larger this effect will be. This influence is particularly conspicuous when the faradaic current is accompanied by a strong capacitive component, as observed, for instance, at high scan rates in cyclic voltammetry (Fig. 11). Moreover, as the combination of R and C_d acts as a low pass filter on the current response (its properties are given by the time constant RC_d), sudden changes in current are more or less strongly distorted.[64b, 65] Because of all these effects, current and potential are mutually dependent in voltammetric analysis, and instead of the set potential scan rate v, an effective rate v' is operative [Eq. (24), Fig. 12].

$$E_{eff}(t) = E_{start} - v't + R_u(C_dv' + i_f) \tag{24}$$

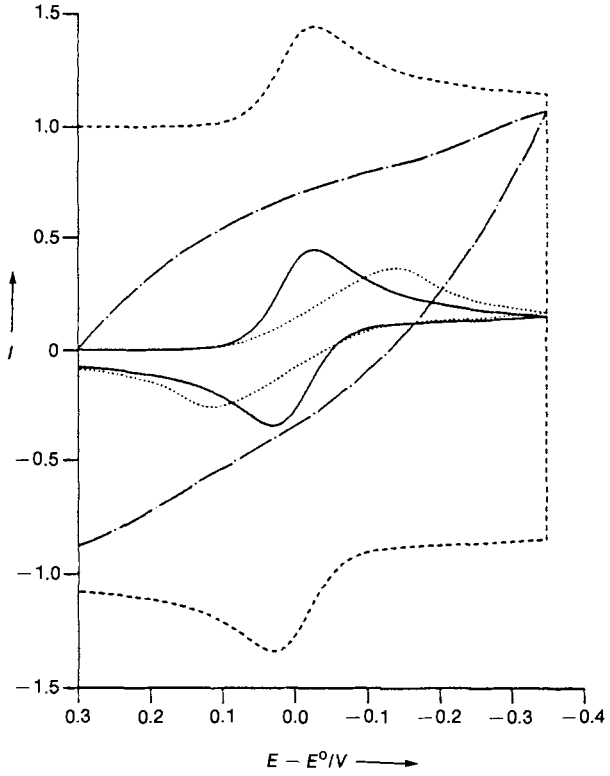

Fig. 11. Simulated cyclic voltammogram for a reversible charge transfer with planar diffusion (——). Presence of a normalized capacitance [65] $\gamma = 1$ (– – –), of a normalized uncompensated solution resistance $\rho = 10$ (· · · ·), and of a combination of these properties (—·—·—) [80b].

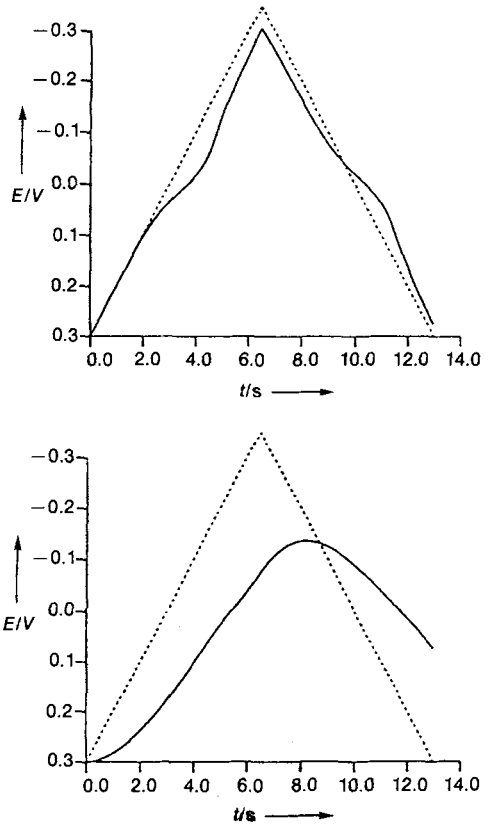

Fig. 12. Potential–time curves for the cyclic voltammograms in Figure 11; measured (effective) potential (——), applied potential (· · · ·). Top: only resistance $\rho = 10$; bottom: resistance $\rho = 10$ and capacitance $\gamma = 1$ [65].

Hence, even in electrolytic solutions with high conductivity, the maximum scan rate for ordinary electrodes with a radius greater than 1 mm is approximately 400 Vs^{-1}.[2, 32] In solutions with low conductivity, this value falls drastically. For example, in benzene the current–voltage curves measured at scan rates of less than 0.1 Vs^{-1} are so distorted that they cannot be interpreted, even though the time constant is negligible, and the only effect is the ohmic potential drop.

In the past one attempted to reduce the iR drop by improving equipment, usually by including a potentiostat in combination with a three-electrode configuration.[32, 66] Through the potentiostat, a reference electrode with high impedance provided a correction signal large enough to compensate for most of the loss of potential at the working electrode. The remaining uncompensated solution resistance was further reduced by electronic feedback,[67] which resulted in possible scan rates of greater than 1000 Vs^{-1} for systems with high conductivity electrolytes and conventional electrodes.

Using ultramicroelectrodes reduces the iR drop so much that it is possible to interpret the results of measurements taken even in extremely diminished electrolytic solutions. Several limiting cases must be distinguished, depending on the experimental conditions. Theoretical[68] and experimental[69] studies show that in the stationary state with a diffusion-controlled limiting current, the ohmic potential drop is no longer dependent on the size and geometry of the microelectrode, but solely on the properties of the electrolyte [Eq. (25), $\varkappa$ = conductivity of the electrolyte system].

$$iR = nFc^{*}D\varkappa^{-1} \tag{25}$$

The iR drop in the case of a low conductivity electrolyte ($\varkappa = 10^{-2}\,Sm^{-1}$, $D = 10^{-9}\,m^2s^{-1}$, $c^{*} = 0.1\,mol\,m^{-3} = 10^{-4}$ M, concentration of an electroactive system) is, according to Equation (25), then 1 mV.

The situation becomes more complicated when the level of the conducting electrolyte in the solution is reduced, for then, in addition to the diffusive mass transport, migration effects can also play a role.[70] As Oldham's calculations and experiments show,[36, 71] the quantitative ratio of conducting electrolyte to electroactive substance can fall to 1:1 without any significant distortion of the current–voltage curve in the stationary state. One reason for this is that the charge transfer at the solution/metal interface raises the ionic density immediately in front of the electrode, which improves the local conductivity $\varkappa$.

The relationship (26) is valid for purely planar diffusion, as exists in the case of high scan rates. Accordingly, as electrode size decreases, so does the ohmic potential drop. As, according to Equation (19), the time constant of the cell decreases parallel to iR, the smaller the radius of the ultramicroelectrode, the more suitable it is for measurements at high scan rates.

$$iR \sim r_0 \tag{26}$$

3. Applications of Ultramicroelectrodes

3.1. Reaction Mechanisms

3.1.1. *Voltammetry under Steady-State Conditions*

As shown in Section 2.3, the magnitude of the diffusion-limited current depends not only on the simple charge transfer, but on whether chemical reactions also take place, possibly coupled with further charge transfer steps. If one uses "large" UMEs ($r_0 < 100\,\mu m$) for the analysis of a three-step reaction[34] comprising one charge transfer followed by a chemical step and subsequently a second charge transfer (ECE reaction), the diffusion-limited current as a rule corresponds to the transfer of two electrons. With smaller microelectrodes, the rate of the chemical step decreases relative to that of the diffusive mass transport (Fig. 10). As a result, the time scale used in steady-state voltammetry is too short for the overall reaction, and therefore n_{app}, the number of electrons measured by the limiting current, gradually declines to 1. This change in the current as a function of the electrode radius can be used to determine the rate constant and the activation parameters of chemical steps in reactions of this nature.[64, 72, 73]

The stationary limiting current's dependence on electrode size can also be used to determine the rate constants of the chemical step in the catalytic EC′ mechanism,[73–77] in which the starting species is regenerated in a chemical step after the heterogeneous charge transfer, and of the reactions preceding the charge transfer. By contrast, in pure EC mechanisms —only a chemical step after the charge transfer—the limiting current is independent of the rate of the next step. Information on the kinetics can only be obtained from the shifts of steady-state voltammograms as a function of the electrode radius.[73]

The use of microelectrodes in steady-state voltammetry to determine rate constants of homogeneous processes has been described several times.[64, 72, 74–79] This method has the advantage that by measuring the diffusion-limited currents with a set of microelectrodes of varying size, the rate constant of a chemical step can quickly be determined. However, this assumes that the precise relationship between the characteristic electrode radius and the kinetics is known, which was as yet only partly the case.

Apart from the catalytic EC′ mechanism,[75–78] the classical ECE mechanism has also been studied in detail. A typical example is the dimerization of triphenylamine (TPA)[80, 81] after its radical cation formation. Under the given experimental conditions ($E_1^0 > E_2^0, E_3^0$), the product tetraphenylbenzidine (TPB) is oxidized to its dication. Overall, a two-electron transfer has apparently taken place [Eq. (27)].

$$2\,TPA \xrightarrow{E_1^0} TPB^{2+} + 2e^{-} + 2H^{+} \tag{27}$$

Figure 13 shows the change in the number of electrons n_{app} at an 8 μm disk electrode as a function of the concentration of TPA. Because the dimerization is a second-order reaction, the rate of the coupling step, and thus the number of electrons transferred, decreases as the concentration of TPA diminishes. A comparison between the experimental data and computer simulations[80] gave a rate constant of

$2.2 \times 10^3\ M^{-1} s^{-1}$, which is in very close agreement with values in the literature.[81] There was some difficulty in interpreting the finding that, in high concentrations of TPA, measurements at microdisk electrodes give rate constants greater than $10^4\ M^{-1} s^{-1}$ on account of the significantly higher n_{app} values (Fig. 13).[72] However, the results did not support the

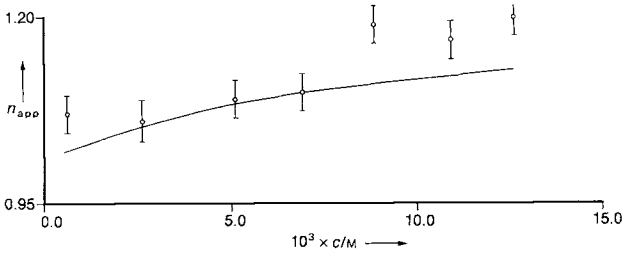

Fig. 13. Numbers of electrons transferred (n_{app}) for the oxidation of triphenylamine for different concentrations in CH_2Cl_2/0.1 M [TBA]PF_6. Experimental points (o) and simulated curve (——). Diffusion-controlled limiting currents measured at a Pt microdisk electrode with diameter 8 μm.

initial assumption that the changes in current density at a microdisk electrode, obtained using a spherical diffusion model with uniform current density over the entire electrode surface, would be false.[72] Rather, it turns out that TPA electropolymerizes to a conducting polymer at a microelectrode[64] (Fig. 14).

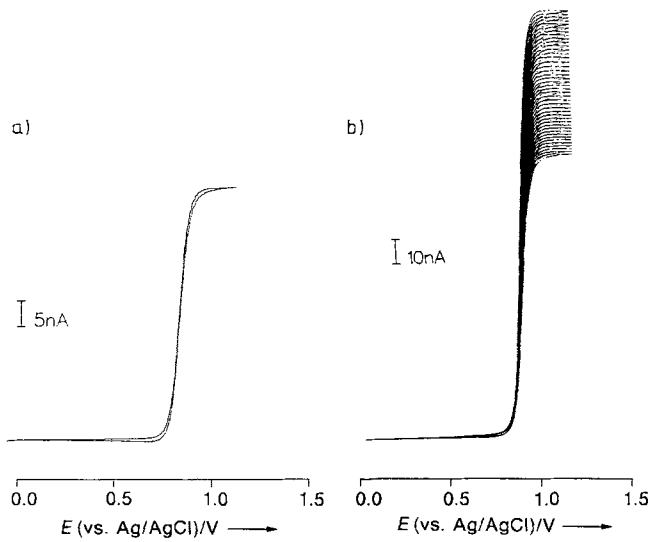

Fig. 14. Experimental steady-state voltammograms for the oxidation of triphenylamine. a) $c = 2.3 \times 10^{-3}$ M, b) $c = 1.2 \times 10^{-2}$ M in CH_2Cl_2/0.1 M [TBA]PF_6, measured at an 8 μm microdisk electrode. The rise in the current in b) is due to electropolymerization effects.

The mechanisms of a whole series of processes used in industrial electrosynthesis have been analyzed.[82] The chief advantage of microelectrodes is the absence of *iR* distortion in the current–voltage curves, even in extremely high concentrations of the reactants, which, of course, enables kinetic and thermodynamic data to be accurately evaluated. For instance, steady-state measurements revealed the experimental conditions under which hydrodimerization of acrylonitrile to adiponitrile (Monsanto process) dominates over the simple reduction of acrylonitrile to propionitrile.[83] Other examples include the catalytic mechanism to methoxylize furane by indirect anodic oxidation in the presence of bromide and methanol[84] and the reductive hydrodimerization of formaldehyde to ethyleneglycol.[85]

Finally, reports on microelectrodes with modified surfaces include studies on electrocatalytic effects of simple redox systems[86] as well as charging processes at conducting polymers or their formation mechanisms.[87, 88] Microelectrodes can also be used in the analysis of slow homogeneous chemical reactions of redoxactive compounds in a reactor to determine the rate constants of the chemical step directly from the time-dependent changes in the diffusion limited currents.[89]

As pointed out above, as the mass transport coefficients *m* increase (that is, as the electrode radius decreases), the diffusion rate may exceed the rate of the associated heterogeneous charge transfer. This makes it possible to determine the rate constants directly from the shift and change in slope in steady-state voltammograms relative to the reversible case.[63] Steady improvements in the construction of ultramicroelectrodes have reduced their characteristic dimensions.[30a, 36, 58a, 90, 91] There have already been reports of microelectrodes with radii of 1–100 nm.[92–94] Hence, theoretically, it should be possible to determine standard rate constants k_s^0 smaller than 1 ms^{-1}. Recent results published by Penner et al.[94] appear to confirm this. Using nanodes ($r_0 = 1-2$ nm), they measured a series of outer-sphere redox couples, for example, $[Ru(NH_3)_6]^{2+/3+}$ (H_2O, 0.5 M KCl) and ferrocene ($Fc^{0/+}$)(CH_3CN, 0.3 M [nBu$_4$N]ClO_4), and obtained k_s^0 values of 0.79 ± 0.44 ms^{-1} and 2.2 ± 1.2 ms^{-1}. Somewhat earlier studies by Bond et al.[95] on ferrocene with 0.3 and 0.5 μm Pt electrodes also produced an unusually high k_s^0 value of 0.064 ms^{-1}. Such high standard rate constants could not be measured in the past. These new results compare surprisingly well with the values predicted by the electron transfer theory of Marcus.[96] Hitherto, standard rate constants of charge transfers obtained with conventional electrodes had produced much lower values, which had raised doubts about the reliability of the theoretical predictions. Apparently, the high transport rates hinder the formation of passivating films, which would otherwise retard the charge transfers in proportion to their thickness and electrode coverage. On the other hand, Penner's results have drawn a lot of criticism. Baranski[97] has shown that relatively large electrodes that are in contact with the electrolyte (through a hollow lagoon left by imperfect fusing and subsequently filled with solution) produce current–voltage curves that are almost identical to those obtained with nanodes. In these circumstances, the theoretical predictions for nanodes are certainly no longer valid; thus the postulated high rate constants have not been unequivocally substantiated.

3.1.2. *Voltammetry with High Scan Rates*
