[a] The appropriate coordination number N was derived from the Kim and Rees model, averaging over both P and M clusters. [b] The relative amplitude N' was obtained by fixing $\sigma_{tot.}$ at the value derived from the solution fit and optimizing N'. This is not a coordination number, since the appropriate polarization effects have not been taken into account. [c] Crystallographic value ref. [4]. [d] Crystallographic value ref. [6]. [e] Total standard deviation $\sigma_{tot.} = \sigma_{stat.} + \sigma_{thermal}$. [f] Statistical standard deviation.

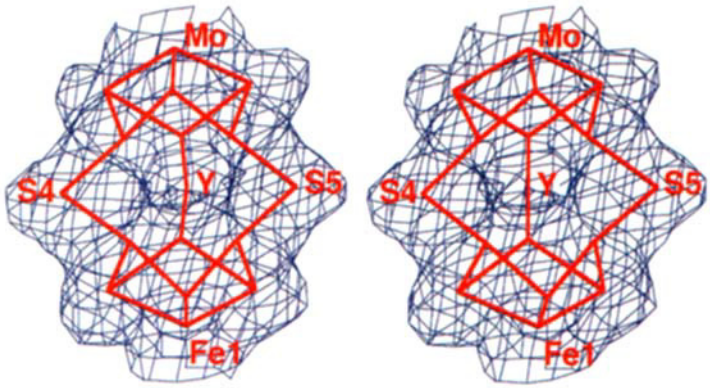

Fig. 2. Comparison of the refined EXAFS model for the M cluster in MoFe protein (red) and electron density map (blue). This stereoplot is oriented so that the Fe-Y-Fe bridge is towards the viewer. The electron density map is from a map with 2.3 Å resolution calculated with experimentally determined phases (model unbiased). The contour level of the map is set at the root mean square value of the electron density in the asymmetric unit.

(174). Clearly, the positions of atoms in our model are in excellent agreement with the electron density map and in fact fit the map as well as those in the crystallographic model.

In conclusion, the structure of the intact MoFe protein has been studied by single-crystal Mo and Fe EXAFS spectroscopy. We observed orientation dependence not only for the "well-known" Mo–Fe interaction at 2.7 Å but also for a new Mo–Fe component at 5.1 Å. Fe–Fe components at 2.6 and 3.7 Å are also stronger in the single-crystal data. Combining the Mo and Fe EXAFS results with crystallographic information allows us to propose a more symmetrical structure for the M cluster with unprecedented precision.

Experimental Procedure

Nitrogenase MoFe protein was purified from *A. vinelandii* at Louisiana State University by methods previously described [13]. Specific activities were 1800 nmol C_2H_2 reduced $min^{-1} mg^{-1}$ protein. MoFe protein crystals were prepared and mounted at Purdue University [3]. The crystals have the space group $P2_1$ with unit cell parameters $a = 69.9$, $b = 151.2$, $c = 121.8$ Å, and $\beta = 110.3°$. The experiments were performed on beamlines 7-3 and 10-2 at SSRL, X10C and X19A at NSLS. The X-ray absorption spectra were measured at 4 K in the fluorescence excitation mode using a 13-element Ge solid-state array detector [14]. The EXAFS fits were calculated using FEFF5 curved-wave multiple-scattering (MS) analysis software [15]. The geometry information was taken from the crystallographic results [4, 6]. In the capped-prismane model compound, multiple scattering is significant for the feature at approximately 3 Å because of the focusing effect arising from three almost linear Mo-C-O (ca. 177°) interactions. However, FEFF5 calculations found that multiple scattering is not significant for the Fe EXAFS in the nitrogenase cluster.

De Novo Design of a Novel Heterodinuclear Three-Helix Bundle Metalloprotein**

By *M. Reza Ghadiri** and *Martin A. Case*

Proteins, the epitome of molecular form and function, remain the most challenging targets for molecular design. Despite the substantial advances in the design of "small-molecule" models of enzyme active sites,[1] little progress has been made toward the construction of "large-molecule" systems that can mimic both the structural and functional properties of natural proteins.[2] Here we report the design, synthesis, and characterization of a novel three-helix bundle Ru^{II} metalloprotein which is capable of functioning as an efficient type-II copper binding protein.

The foremost problem in the de novo design of functional proteins is the availability of structurally well-defined scaffolds onto which the desired functionalities of the active site may be elaborated. Recently, we have developed a series of metal ion assisted, self-organizing processes for the design and convergent synthesis of topologically predetermined metallopeptides and artificial metalloproteins.[3] One such design, a three-helix bundle structure,[3a] was the starting point in the present study for rational modification into a heterodinuclear $Ru^{II}Cu^{II}$ metalloprotein. Our strategy is illustrated in Figure 1. As in our previous studies, the key design feature in directing the self-assembly process is the incorporation of a bipyridyl (bpy) moiety at the N-terminus of the polypeptide subunit. Metal ion complexation to the bipyridyl moieties is thought to initially sequester three peptide chains to form the putative intermediate shown. The higher coil density and the dramatically increased effective molarity of hydrophobic moieties in the intermediate species strongly bias the system toward formation of a parallel three-helix bundle ensemble. Moreover, it was hypothesized that by placing a second ligand in an appropriate position within each polypeptide sequence, a new composite metal binding site may be formed.

Schiffer for his contribution to the early stages of this project, Dr. D. Goodin for EPR measurements, and Drs. M. Griffith, S. Kent, and G. Siuzdak for their assistance in mass spectrometric analyses.

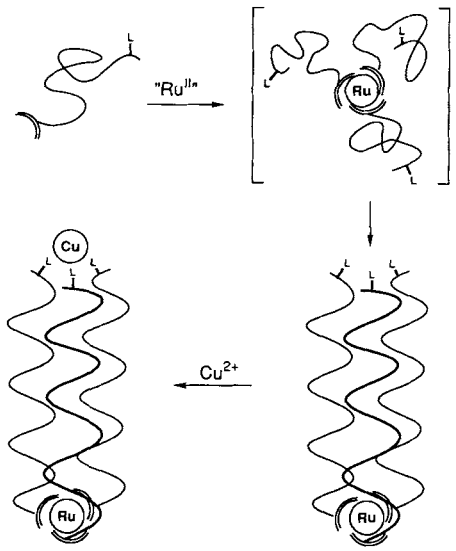

Fig. 1. Schematic representation of the hypothetical folding in the ruthenium(II)-assisted self-assembly of the three-helix bundle metalloprotein (double arcs represent the bipyridyl moieties). The peptide is designed such that upon complexation of Ru^{II} the ligands L are arranged to form a novel copper binding site.

The polypeptide sequence was designed according to previously described principles (Fig. 2).[3a] Histidine was chosen as the potential ligand in the design of the type-II copper binding site based on its natural affinity for a variety of transition metal ions as well as its high frequency of occurrence in natural copper-binding metalloproteins.[4] The optimal position for the histidine moiety within the peptide subunit was determined by the analysis of a structural model. The second metal binding site was placed near the C-termini of the peptides in the helix bundle in order to take advantage of favorable charge–helix dipole interactions and enhance the metal ion binding propensity.[5] A tyrosine residue was placed near the putative Cu^{II} binding site in order to facilitate spectroscopic analysis of copper binding.[6] Despite the simplified folding pathway illustrate in Figure 1, there are two potential ligands (imidazolyl (imd) and bpy) within each peptide subunit, thus various side reactions during the ruthenium(II)-assisted assembly process are possible. It is therefore essential that the imidazolyl side chain functionalities not interfere, in either inter- or intramolecular fashion, with the key bpyRu^{II} complex forming reaction. In other words, *the formation of the Ru^{II} complex must be exquisitely chemo- and regioselective.*

The 19-residue amphiphilic polypeptide used in this study, when reacted with the $Ru_5Cl_{12}^{2-}$ cluster anion,[7] was shown to undergo an unprecedented chemo-, regio-, and diastereoselective reaction to form the desired parallel three-helix bundle Ru^{II} metalloprotein.[8] The remarkably high selectivities observed in forming $[Ru(peptide)_3]^{2+}$, which is kinetically inert to ligand exchange, may be attributed to the following factors. The high affinity of nitrogen-containing aromatic heterocycles for ruthenium ions was expected to bias the chemical activity of the ruthenium reagent toward the bipyridyl and imidazolyl moieties.[3a, c, 9] However, the higher kinetic stability of bipyridyl- versus imidazolyl-Ru^{II} complexes may have played a significant role in the chemo- and regioselectivity of the process. Furthermore, the lack of any observable intramolecular complexation, in which the histidine and bipyridine moieties of a single subunit are both coordinated to a ruthenium ion, may be attributed to the unfavorable geometrical constraints imposed by the helical structure as well as the noncovalent interactions between the subunits of the protein. This assumption is borne out by the observed high diastereoselectivity of the process in which the *fac* isomer is formed in >95% yield suggesting strong interhelical interaction during the complex formation.[10]

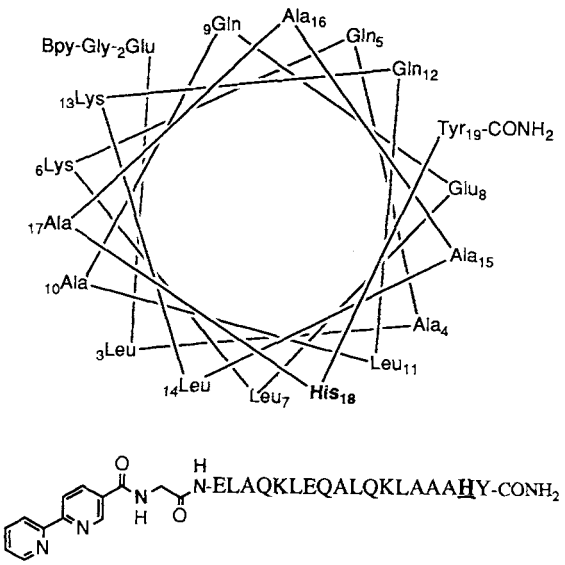

Fig. 2. Peptide sequence and the corresponding helical wheel diagram emphasizing the amphiphilic helical structure of the subunit.

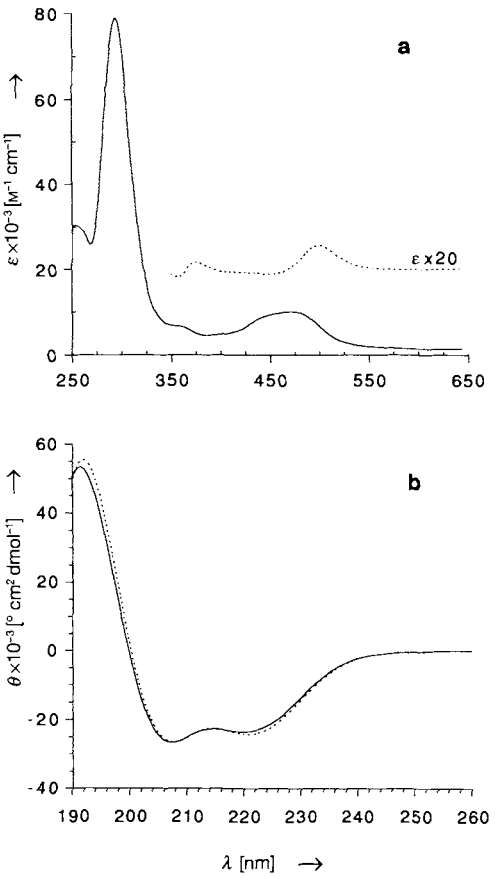

Fig. 3. UV/VIS absorption and CD spectra of the Ru^{II} and $Cu^{II}Ru^{II}$ metalloproteins. a) Room-temperature absorption spectrum of the Ru^{II} metalloprotein (solid line) and the difference spectrum (dotted line) after addition of one equivalent of Cu^{2+} (baseline is offset for clarity). b) CD spectra of the Ru^{II} (solid line) and $Cu^{II}Ru^{II}$ metalloproteins (dotted line) (1.5×10^{-6} M in 20 mM MES, pH 6.0 at 25 °C).

The overall three-helix bundle topology of the ensemble was supported by the following experimental observations. The protein displays absorption bands at $\lambda = 289$ and 475 nm characteristic of $[Ru(bpy)_3]^{2+}$ complexes (Fig. 3a).[3a, 11] Electrospray mass spectrometric analysis unequivocally establishes the trimeric nature of the ensemble (Fig. 4a). In addition, the solution properties and the hydrodynamic behavior of the complex, as judged by gel permeation chromatography, are not only consistent with the expected molecular weight, they are also indicative of the monomeric nature of the Ru^{II} metalloprotein in aqueous solutions. The absence of intermolecular aggregation is also corroborated by the lack of dependence of circular dichroism (CD) spectra on protein concentration in the measured range of 2–500 μM. Moreover, the Ru^{II} metalloprotein exhibits a CD spectrum consistent with the expected helical secondary structure of the ensemble ($\theta_{222} = -23000°\,cm^2\,dmol^{-1}$, Fig. 3b). Furthermore, the metalloprotein displays a cooperative guanidine hydrochloride (Gnd · HCl) denaturation curve with a free energy of stabilization of $\Delta G_{H_2O} = 2.0 \pm 0.2$ kcal mol^{-1} (Fig. 5).

The ruthenium(II)-assisted self-assembly of the peptide into a three-helix bundle metalloprotein has been shown to create, as anticipated, a new high-affinity type-II copper

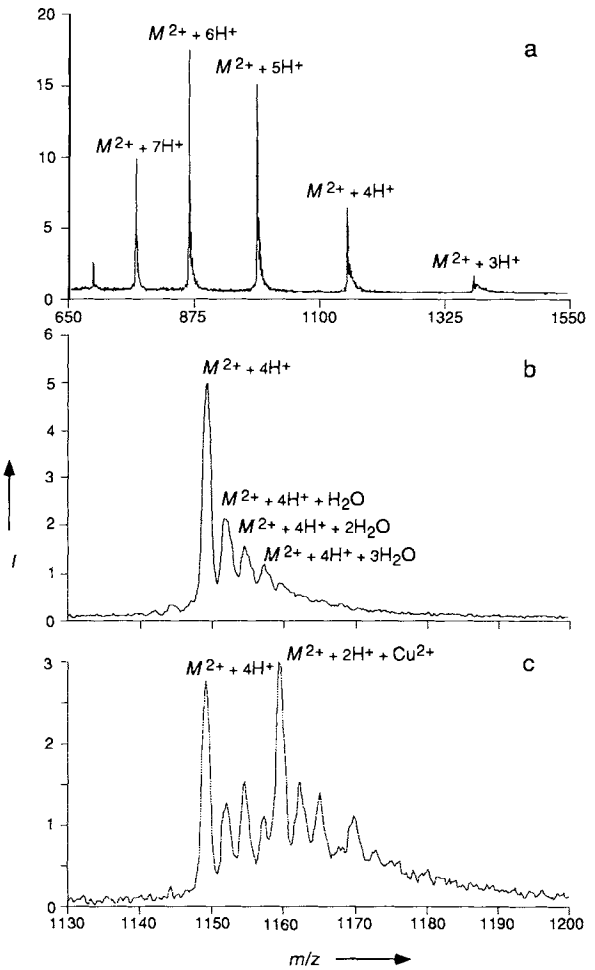

Fig. 4. Electrospray ionization mass spectra of a) the Ru^{II} metalloprotein (each peak corresponds to a detected charged state of the protein ($M_{found} = 6887 \pm 2$, $M_{calcd.} = 6887$)); b) a single charged state of the Ru^{II} metalloprotein and its hydrated forms; c) a single charged state of the dinuclear $Ru^{II}Cu^{II}$ metalloprotein. The peak corresponding to the Ru^{II} metalloprotein arises from dissociation during the gas-phase ionization process and is dependent on the applied orifice potential. Spectra were collected on Perkin-Elmer SCIEX API-3 mass spectrometer at applied orifice potential of 100 V.

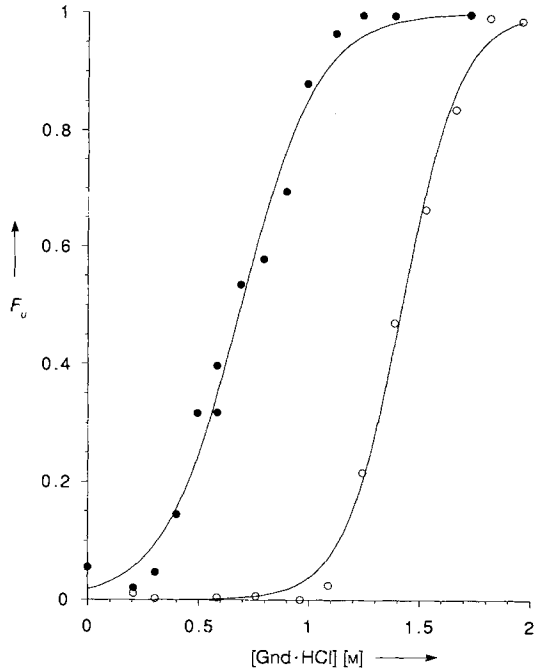

Fig. 5. Guanidine hydrochloride denaturation curves for the Ru^{II} (•) and $Cu^{II}Ru^{II}$ metalloproteins (○) (8.0×10^{-6} M, 25 mM MES, pH 6.0, 25 °C) measured by luminescence spectroscopy. Solid lines are based on parameters obtained by a nonlinear least-squares fit [3a]. F_u = proportion of denatured protein.

binding site. Site-specific Cu^{II} binding was studied spectrophotometrically by monitoring the fluorescence emission of the nearby tyrosine chromophore as a function of the concentration of Cu^{2+} ions. Least-squares fit as well as Scatchard analysis of the titration curves indicate a 1:1 copper:protein complex with an apparent dissociation constant of $K_d = 3.0 \pm 0.1 \times 10^{-7}$ M. No appreciable dimunition of the tyrosine fluorescence emission was observed under identical conditions when a control Ru^{II} metalloprotein was employed.[12] Interestingly, copper binding does not appreciably change the CD spectrum of the metalloprotein ($\theta_{222} = -24000°\,cm^2 \cdot dmol^{-1}$, Fig. 3b). Lack of a significant structural change upon copper binding as well as the high affinity of the Ru^{II} metalloprotein for copper ions suggest formation of a highly preorganized metal binding site upon assembly of the three-helix bundle. Formation of the $Ru^{II}Cu^{II}$ metalloprotein was also monitored by electrospray mass spectrometry (Fig. 4c). Interestingly, even when a 20-fold excess of Cu^{2+} was employed, a 1:1 $Ru^{II}Cu^{II}$ metalloprotein was formed, further supporting the existence of a unique high-affinity copper binding site. Moreover, the binding of Cu^{2+} at the designated site is expected to reinforce the three-helix bundle geometry by constraining the protein at both ends and further enhance the stability of the ensemble toward denaturation.[3c–d, 16a] Indeed, the $Ru^{II}Cu^{II}$ metalloprotein displays a free energy of stabilization $\Delta G_{H_2O} = 3.5 \pm 0.2$ kcal mol^{-1}, which is 1.5 kcal mol^{-1} greater than that of the corresponding uncomplexed protein (Fig. 5).

Information concerning the ligand arrangement and the environment of the copper binding site was provided by UV/VIS and EPR spectroscopy. Analysis of the difference absorption spectrum of the Ru^{II} metalloprotein before and after copper complexation reveals a $\pi(imH) \rightarrow Cu^{II}$ charge transfer band centered at $\lambda = 375$ nm ($\varepsilon = 100$ M^{-1} cm^{-1}) and a ligand field band centered at $\lambda = 495$ nm ($\varepsilon = 300$ M^{-1} cm^{-1}) consistent with tetragonal or square-planar

geometry of the copper complex (Fig. 3a).[13] Moreover, the EPR spectrum is indicative of a type-II copper binding site in a similar ligand environment with $g_{\parallel} = 2.27$ and $A_{\parallel} = 173\,(cm^{-1} \times 10^4)$. Peisach and Blumberg analysis[14] is consistent with the complexation of Cu^{II} to three nitrogen and one or more oxygen ligands which are presumably donated by water and/or buffer.

In summary, we have presented a novel approach in which two different metal ions and three peptide subunits ultimately join, through a highly selective self-assembly process, to form the first de novo designed heterodinuclear metalloprotein (Fig. 6).[15, 16] The availability of such a convergent

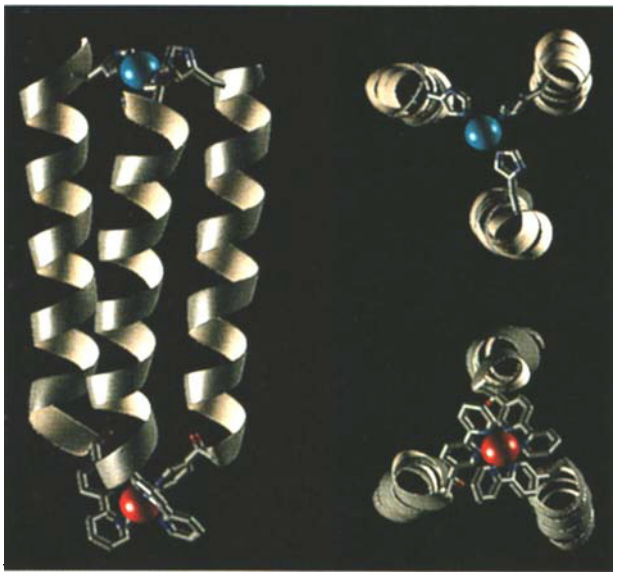

Fig. 6. Computer-generated model of the parallel three-helix bundle $Cu^{II}Ru^{II}$ metalloprotein.

synthetic process holds considerable promise for the future design of redox-active and artificial light-harvesting metalloproteins.

[8] The Ru^{II} metalloprotein was synthesized by the addition of a solution of the peptide subunit (130 mg, 13 μmol) in 300 μL of degassed water under an Ar atmosphere to a 50 °C blue solution of the $Ru_2Cl_7^{2-}$ cluster anion (prepared from 0.86 mg of $RuCl_3 \cdot xH_2O$ in a final volume of 200 μL EtOH) and refluxed for 30 min. The product is formed in 70% yield and separated from the unreacted starting peptide by C_{18} RP-HPLC according to standard procedures [3a].

Octaethyltetraoxaporphyrin Dication—Counterpart of Octaethylporphyrin in the Tetraoxaporphyrin Series

By *Emanuel Vogel,* Joachim Dörr, Adalbert Herrmann, Johann Lex, Hans Schmickler, Peter Walgenbach, Jean Paul Gisselbrecht,* and *Maurice Gross**

The recently discovered tetraoxaporphyrin dication (as the perchlorate **1a**),[1] has a very promising chemistry, as shown by its conversion to tetraoxaisophlorin,[2] the tetraoxaporphyrin dianion,[2] and the 5-hydroxytetraoxaporphyrin dication.[3] The possibilities for the development of this new porphyrinoid become particularly obvious when one considers that as an oxonium/carbenium ion this species is related to the pyrylium ion as porphyrin is to pyridine.

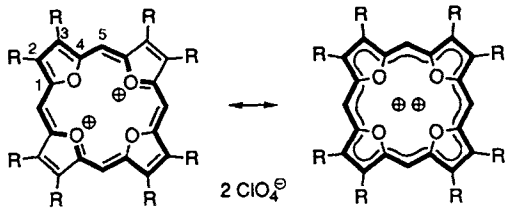
As the reaction spectrum of **1a** is impaired because of its insolubility in organic solvents, the need arose to prepare derivatives of the dication possessing solubilizing alkyl or aryl groups. Mindful of the important role played by octaethylporphyrin[4] and *meso*-tetraphenylporphyrin[5] as model compounds in porphyrin chemistry, we attempted to synthesize the corresponding tetraoxaporphyrin dications. We report here on a preparative access to the 2,3,7,8,12,13,17,18-octaethyltetraoxaporphyrin dication (as the perchlorate **1b**).



1a: R = H; **1b**: R = C_2H_5

The production of **1b** by the acid-catalyzed cyclic condensation of 2-hydroxymethyl-3,4-diethylfuran (**5**) and subsequent oxidation of the anticipated product tetraoxaporphyrinogen **6** was suggested by the routes to **1a**,[1c] as well as to porphyrin[6] and its octaethyl derivative.[4]

3,4-Diethylfuran (**4**), required as starting material and for which surprisingly no suitable preparative method existed,[7] was conveniently made by the inverse Diels–Alder reaction of 4-phenyloxazole (**2**)[8] with 3-hexyne (**3**), followed by in situ cleavage of the resulting adduct.

Heating 40 g (0.5 mol) of **3** and 91.8 g (0.65 mol) of **2** in a 500 mL autoclave (Teflon lined) for 3 d at 250 °C gave a brown, liquid mixture, from which **4** was easily separated by distillation in vacuum (colorless liquid, b.p. 51–52 °C/20 Torr; yield 43.4 g, 70%). Vilsmeier formylation of **4**, carried out by addition of the furan to a mixture of *N*,*N*-dimethylformamide (DMF) and phosphorus oxychloride in dichloromethane at 0 °C followed by heating under reflux (1 h), smoothly gave 3,4-diethyl-2-formylfuran (b.p. 96–97 °C/15 torr; yield 70%; see also Table 1), from which **5** was obtained by conventional reduction with sodium borohydride in tetrahydrofuran/water (9:1) (b.p. 108–110 °C/12 torr; yield 90%).

Based on experience in the biomimetic synthesis of porphyrins, it was anticipated that the acid-catalyzed condensation of **5** to octaethylporphyrinogen **6** could be accomplished with better yields than that of furfuryl alcohol to the parent tetraoxaporphyrinogen (hitherto only 1–2%), as the ethyl groups promote ring closure to form the macrocycle on conformational grounds (helical effect).[9] In fact, **5** could be condensed with *p*-toluenesulfonic acid in nitromethane to give **6** in 16% yield (colorless rhomboids from ethanol, m.p. 138–140 °C). Remarkably, this result was only obtained when the acid was used in equimolar (based on **5**), not catalytic amounts (see Experimental Procedure). Unlike the behavior of the pyrrole analogue, the "porphyrinogen cyclocondensation" with **5**, at least under the given reaction conditions, does not take place selectively. In addition to **6**, homologous cyclocondensation products with five or more furan components (total amount about 2–3%) are formed.

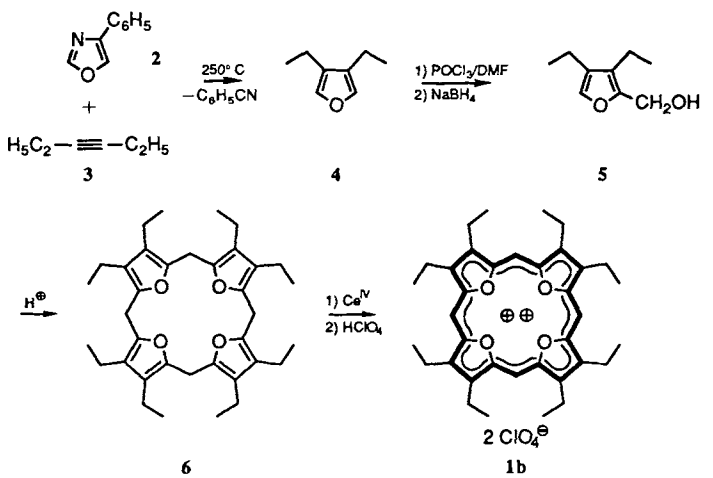


Table 1. Selected physical and spectroscopic data for 3,4-diethyl-2-formylfuran, **5**–**7**, **1b**, **8d**[a] and **9d**[a].

3,4-Diethyl-2-formylfuran: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 9.66 (s, 1H; CHO), 7.32 (s, 1H; H-5), 2.69 (q, 2H; H-3a), 2.37 (q, 2H; H-4a), 1.17 (t, 3H; H-4b), 1.14 (t, 3H; H-3b); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 177.9 (CHO), 148.4, 144.0, 139.2, 129.7, 16.6, 16.2, 14.8, 13.5; MS (EI, 70 eV): *m/z* (%): 152 (100) [M^+], 151 (36), 137 (42), 123 (42), 95 (30); IR (film): $\tilde{\nu}$ = 3363, 3134, 2969, 2936, 2875, 2771, 1674, 1599, 1520, 1463, 1416, 1379, 1341, 1299, 1263, 1222, 1144, 1116, 1058, 958, 930, 781, 762, 602 cm^{-1}.

5: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.06 (s, 1H; H-5), 4.47 (s, 2H; CH_2OH), 2.53 (s, 1H; OH), 2.37 (m, 2H; H-3a), 2.35 (m, 2H; H-4a), 1.16 (t, 3H; H-4b), 1.09 (t, 3H; H-3b); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 149.1, 137.5, 127.4, 123.8, 55.3, 16.8, 16.4, 15.4, 13.5; MS (EI, 70 eV): *m/z* (%): 154 (73) [M^+], 139 (25), 136 (60), 125 (100), 110 (25), 92 (30), 78 (10); IR (Film): $\tilde{\nu}$ = 3350, 2960, 2930, 2870, 1555, 1460, 1375, 1280, 1210, 1125, 1005, 908, 760 cm^{-1}.

6: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 3.69 (s, 8H; H-5,10,15,20), 2.29 (q, 16H; H-2a,3a,7a,8a,12a,13a,17a,18a), 1.04 (t, 24H; H-2b,3b,7b,8b,12b,13b,17b,18b); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 145.1, 120.7, 23.1, 16.9, 15.6; MS (EI, 70 eV): *m/z* (%): 544 (100) [M^+], 529 (6), 515 (14), 409 (8), 273 (20), 137 (18); IR (CsI): $\tilde{\nu}$ = 2962, 2928, 2870, 1583, 1462, 1408, 1374, 1230, 1124, 1060, 957, 856, 795, 692 cm^{-1}; UV/VIS (CH_2Cl_2): λ_{max} (ε) = 224 nm (22500).

1b: ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 11.57 (s, 4H; H-5,10,15,20), 4.08 (q, 16H; H-2a,3a,7a,8a,12a,13a,17a,18a), 2.16 (t, 24H; H-2b,3b,7b,8b,12b,13b,17b,18b); ^{13}C NMR (75.5 MHz, CD_2Cl_2): δ = 155.6, 154.0, 98.3, 21.3, 18.0; MS (FAB): *m/z* (%): 541 (100) [(M + H$^+$ − 2 ClO_4^-)$^+$], 540 (29), 539 (12); IR (CsI): $\tilde{\nu}$ = 2976, 2938, 2877, 1505, 1451, 1084, 625 cm^{-1}; UV/VIS (CH_2Cl_2): λ_{max} (ε) = 317 (10900) sh, 351 (16500) sh, 363 (22100) sh, 377 (66000), 397 (844100), 424 (840 sh), 476 (830), 515 (2400) sh, 543 (24300), 562 (6100) sh, 589 nm (2100) sh.

7: ^{1}H NMR (300 MHz, [D_8]THF): δ = 0.16 (m, 40H; H-2a,2b,3a,3b,7a,7b,8a,8b,12a,12b,13a,13b,17a,17b,18a,18b), −0.13 (s, 4H; H-5,10,15,20); ^{13}C NMR (75.5 MHz, [D_8]THF): δ = 160.3, 133.0, 91.9, 14.6, 13.1; MS (EI, 70 eV): *m/z* (%): 540 (100) [M^+], 270 (36); IR (CsI): $\tilde{\nu}$ = 2965, 2933, 2870, 1751, 1508, 1466, 1397, 1372, 1319, 1294, 1260, 1235, 1132, 1071, 1057, 952, 902, 876, 788, 734, 670, 486 cm^{-1}; UV/VIS (THF): λ_{max} (ε) = 323 (87300) sh, 334 (107100), 351 (128400), 417 (7500) sh, 432 (9000) sh, 462 (7700), 497 (5000), 623 (460), 692 (550), 710 (550), 751 nm (510).

8d [a]: M.p. 114–120 °C (ethanol); yield 28%; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 5.91 (m, 8H; H-2,3,7,8,12,13,17,18), 3.77 (t, 4H; H-5,10,15,20), 1.88 (m, 8H; H-5a,10a,15a,20a), 1.27 (m, 8H; H-5b,10b,15b,20b), 1.23 (m, 8H; H-5c,10c,15c,20c), 0.84 (m, 12H; H-5d,10d,15d,20d); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 154.3, 105.3, 38.5, 30.6, 29.5, 22.4, 14.0; MS (EI, 70 eV): *m/z* (%): 544 (40) [M^+], 487 (100), 430 (10), 373 (45), 316 (44); IR (KBr): $\tilde{\nu}$ = 3106, 2954, 2930, 2868, 1560, 1466, 1181, 1015, 971, 947, 772, 738 cm^{-1}; UV/VIS (Cyclohexane): λ_{max} (ε) = 223 (41400), 237 nm (12900) sh.

9d: Violet needles from hot 50% $HClO_4$, yield 30%, m.p. > 300 °C (decomp.); ^{1}H NMR (300 MHz, CF_3CO_2D, CH_2Cl_2 int.): δ = 11.12 (s, 8H; H-2,3,7,8,12,13,17,18), 5.63 (t, 8H; H-5a,10a,15a,20a), 2.89 (m, 8H; H-5b,10b,15b,20b), 2.11 (Sextett, 8H; H-5c,10c,15c,20c), 1.35 (t, 12H; H-5d,10d,15d,20d); ^{13}C NMR (75.5 MHz, CF_3CO_2D, CH_2Cl_2 int.): δ = 160.9, 138.4, 124.3, 42.7, 38.7, 25.3, 14.3; MS (FAB): *m/z* (%): 541 (48) [(M + H$^+$ − 2 ClO_4^-)$^+$], 540 (100), 539 (58); IR (CsI): $\tilde{\nu}$ = 3133, 2959, 2929, 2871, 1541, 1507, 1456, 1340, 1190, 1085, 907, 816, 788, 624 cm^{-1}; UV/VIS (HCOOH): λ_{max} (ε) = 367 (15900) sh, 387 (75800) sh, 401 (715000), 423 (8200) sh, 497 (900) sh, 527 (2750) sh, 563 (15100), 571 (10900) sh, 609 nm (23500).

[a] The *n*-butyl compounds **8d** and **9d** are given as typical examples of *meso*-alkylated tetraoxaporphyrinogens **8** and tetraoxaporphyrin dications **9**. For the appropriate data for **8a–c**, **8e**, **9a–c**, and **9e** see ref.[18]. Because **8d** exists as a stereoisomeric mixture, the ^{1}H and ^{13}C NMR data are averaged.

Oxidation of **6** to the octaethyltetraoxaporphyrin dication **1b** was achieved (under anhydrous conditions) with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), as described for the synthesis of **1a**,[1c] or with cerium(IV) ammonium nitrate in acetonitrile, in both cases with subsequent addition of perchloric acid. The cerium(IV) oxidation was given preference because of easier workup; **1b** is obtained after crystallization from formic acid or acetonitrile, each containing 1% perchloric acid, as red needles that decompose above 300 °C (yield 65 and 60%, respectively). In agreement with the intention of this work, the eight ethyl groups provide the salt **1b** with sufficient solubility in organic solvents (in particular in acids like formic and trifluoroacetic acid, or in dichloromethane, acetonitrile, and nitromethane) that the compound can be studied as a model tetraoxaporphyrin dication in homogeneous media.

In comparison with the spectra of **1a**[1a] those of **1b** show only qualitative differences (Table 1), so that further comment is unnecessary.

An X-ray crystallographic analysis of **1b**,[10] which shows the dication to be centrosymmetric in the crystal (Fig. 1), provides insight into the molecular structure. The ring

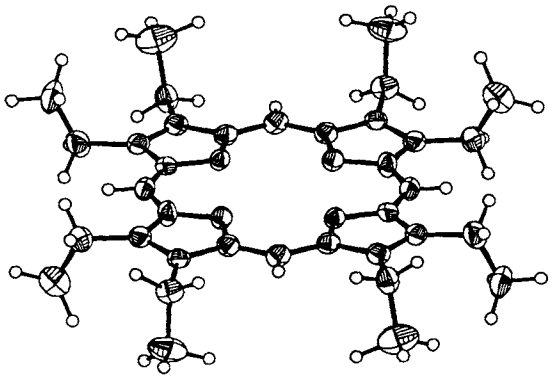

Fig. 1. Structure of **1b** in the crystal: perspective view.

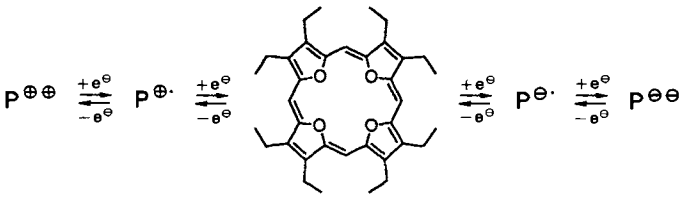
framework of **1b** is planar, similar to that of the parent dication **1a**.[1a] The structural parameters of **1b** are in close agreement with those of **1a**, except for the lengths of the C_β–C_β bonds of the furan units, which are stretched (on average by 0.035 Å) as a result of the influence of the substituents. A slight deviation of the framework from the ideal D_{4h} symmetry affects the dimensions of the inner cavity in such a way as to distort the O_4 nucleus towards a rectangle (O···O distances: 2.842 and 2.944 Å). The spatial arrangement of the ethyl substituents corresponds to the situation in octaethylporphyrin.[11]

An electrochemical study of the octaethyltetraoxaporphyrin dication **1b** confirmed the existence of the tetraoxaporphyrin redox system, consisting of the 18 π dication, the radical cation, the neutral molecule ([20]annulene tetraoxaisophlorin), the radical anion, and the 22 π dianion, which was hitherto deduced mainly from chemical reduction[2] of the dication **1a** (insoluble in organic solvents) in combination with ESR studies. Polarographic investigation of **1b** in DMF with 0.1 M tetraethylammonium perchlorate (TEAP) as supporting electrolyte (accessible potential range + 0.4 to −2.9 V vs. SCE)[12] gave four half-wave potentials at + 0.24, −0.01, −1.46, and −1.73 V vs. SCE, which, as corroborated by cyclic voltammetric measurements in the same solvent, are attributable to reversible, one-electron transitions. Cyclic voltammetry of **1b** in dichloromethane with 0.1 M tetrabutylammonium hexafluorophosphate ($TBAPF_6$)[13] also shows that the compound can be reduced in four distinct one-electron steps, namely at + 0.20, −0.21, −1.63, and −1.93 V vs. SCE. The first two of these processes again are reversible transitions, whereas the third is pseudo-reversible and the fourth lies too close to the cathodic limit of measurement to be investigated in more detail.[14] Comparison of the potentials in DMF with those in dichloromethane shows that the first step in the reduction takes place at almost the same potential, whereas the three following steps are shifted to more positive potential (+ 200 mV) in DMF. This finding can be attributed to the solvating properties of this solvent. According to the results presented here, the electrochemical reduction of the dication **1b** takes place in four separate (in terms of electric potential) one-electron transitions, as shown in Scheme 1.

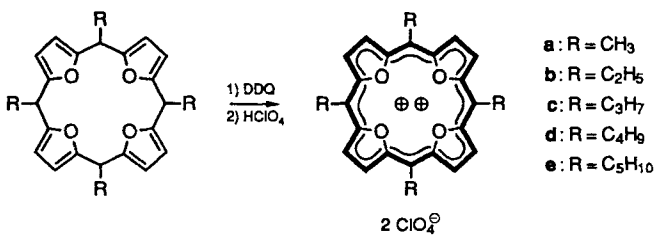


7

Scheme 1. Octaethyltetraoxaporphyrin redox system: $P^{\oplus\oplus}$ (dication **1b**), $P^{\oplus\cdot}$ (radical cation), **7** (octaethyltetraoxaisophlorin), $P^{\ominus\cdot}$ (radical anion), $P^{\ominus\ominus}$ (dianion).

The preparation of the electrochemically detected octaethyltetraoxaisophlorin (**7**) was accomplished—as for the parent compound[2]—by reduction of **1b** with potassium in THF to give the dianion, followed by partial oxidation with atmospheric oxygen. Chromatographic workup (with cooling) and crystallization from THF (−78 °C) gave **7** as a black, microcrystalline powder (yield 30%, decomposition above 0 °C).

The easy access to the 5,10,15,20-tetraalkyltetraoxaporphyrinogens **8a–e** (as stereoisomeric mixtures by the acid-induced condensation of 1,1-difurylalkanes with the appropriate aldehyde), suggested conversion of these compounds into the corresponding *meso*-alkyl-substituted tetraoxaporphyrin dications by the same process of oxidation and treatment with perchloric acid. Compounds **8a** and **8b** were already known,[15] and **8c–e** were prepared analogously here. As anticipated, the dications **9a–e** were obtained (yield 25–31%) without difficulty. The compounds were characterized by their spectra and, in the case of **9a**, moreover, by an X-ray structure analysis. All of these dications, which are stable in the crystalline state, are very soluble in formic and trifluoroacetic acid, but solubility in dichloromethane and acetonitrile is found to be adequate only for **9c–e** (the solubility increases markedly with increasing size of the alkyl group).



8 **9**

In striking contrast to the octaethyltetraoxaporphyrin dication **1b**, the *meso*-alkylated tetraoxaporphyrin dications **9c–e** are not stable in dichloromethane or other inert organic solvents (stability in acids, however, is retained). Relatively rapid decomposition occurs (half-lifetimes in the range 0.5–2 h), which starts, according to ^{1}H NMR experiments, by deprotonation in the side chain. Precedents for such a deprotonation exist in the case of *meso*-alkylated diprotonated porphyrins.[16] The greater stability of **1b** relative to **9c–e**, which makes **1b** a more suitable model compound for the tetraoxaporphyrin dication,[17] can be ascribed to the different substitution pattern and also to the higher degree of alkylation.

Experimental Procedure

6: To a solution of *p*-toluenesulfonic acid (4.42 g, 25 mmol) in boiling nitromethane (160 mL) was added 3,4-diethyl-2-hydroxymethylfuran (**5**, 3.85 g, 25 mmol) in nitromethane (20 mL), and the mixture heated under reflux for 15 min. After neutralization with saturated sodium bicarbonate solution the reaction mixture was extracted three times with 200 mL ether. The combined organic extracts were washed with water, dried over Na_2SO_4, and the solvent was then removed under vacuum. Chromatography of the resulting product on silica gel (3 × 70 cm column) with toluene/hexane (1:1) gave **6** as a pale yellow solid, which crystallized from ethanol as colorless rhombic crystals; m.p. 138–140 °C, yield 545 mg (16%).

1b: Porphyrinogen **6** (268 mg, 0.5 mmol) was dissolved in absolute acetonitrile (40 mL) and stirred with cerium(IV) ammonium nitrate (1.5 g, 4 mmol) at room temperature. After 45 min 0.5 mL of a 70% solution of perchloric acid was added to the reaction mixture, and the solvent removed under vacuum. The remaining amorphous residue was washed first with a little water and then with ether, and crystallized from formic acid containing 1% of a 70% perchloric acid solution. The dication **1b** was obtained as red needles, which decompose above 300 °C; yield 242 mg (65%).

[11] J. W. Lauher, J. A. Ibers, *J. Am. Chem. Soc.* **1973**, *95*, 5148.

[12] The polarographic and cyclic voltammetric experiments in DMF were carried out with a dropping mercury electrode (flow rate 0.61 mg s^{-1}) at a scan rate of 5–100 V s^{-1}. Purification of DMF and the supporting electrolyte TEAP was as previously described: H. J. Callot, A. Giraudeau, M. Gross, *J. Chem. Soc. Perkin Trans. 2* **1975**, 1321.

[13] Dichloromethane was both dried and stored over molecular sieves (4 Å) under argon. $TBAPF_6$ (Fluka, electrochemical grade) was used without further purification as supporting electrolyte. The cyclic voltammetric measurements in dichloromethane were carried out at a Pt electrode with a scan rate of 10 mV s^{-1} - 20 V s^{-1}. The potentials were measured against a saturated calomel electrode as reference; under the prevailing experimental conditions,ferrocene (internal standard) was oxidized in dichloromethane and 0.1 M $TBAPF_6$ at + 0.4 V vs. SCE.

[14] A scan rate of 10 mV s^{-1} to 10 V s^{-1} was used for peak analysis: For the first two reductions $I_p = f(v^{1/2})$ passes through the zero point and is linear; ΔE_p varies between 60 (at rate of 10 mV s^{-1}) and 80 mV (10 V s^{-1}). For the third redox process ΔE_p increases with increasing scan rate from 80 (at 10 mV s^{-1}) to 200 mV (at 10 V s^{-1}), whereas $I_p = f(v^{1/2})$ is linear and passes through the origin.

New Porphycene Ligands: Octaethyl- and Etioporphycene (OEPc and EtioPc)—Tetra- and Pentacoordinated Zinc Complexes of OEPc

By *Emanuel Vogel,* Peter Koch, Xue-Long Hou, Johann Lex, Michael Lausmann, Michael Kisters, Mohamed Ally Aukauloo, Philippe Richard,* and *Roger Guilard**

The 2,7,12,17-tetrapropylporphycene ligand (TPrPc), conceived as the counterpart of octaethylporphyrin (OEP) in the porphycene series, has proved its value in metalloporphycene research on numerous occasions.[1] Although the cavity of the N_4 coordination center in porphycenes is smaller than that in porphyrins, and the lone electron pairs on the pyrrolenine nitrogen atoms as well as the N–H bonds are not strictly oriented towards the center of the molecule, TPrPc readily forms stable complexes with the common metal ions Ni^{II}, Cu^{II}, Co^{II}, Co^{III}, Fe^{III}, Mn^{III}, Al^{III}, and Sn^{IV} (each have small to medium crystal ionic radii[2]). In contrast to previous experience, TPrPc can even form complexes with the comparatively large osmium(II) ion, as recently reported by the groups of C.-M. Che and C. K. Chang.[1j]

In the light of these findings, it seemed remarkable that TPrPc shows only a relatively low tendency to coordinate to a zinc ion to form porphycenatozinc. Given the importance of zinc complexes in porphyrin chemistry, whether as photo-

sensitizers,[3] as model compounds for the study of photosynthesis,[4] or as components in enzyme models,[5] there is considerable interest in porphycene ligands that are more able than TPrPc to bind zinc(II) and larger ions.

We report here on 2,3,6,7,12,13,16,17-octaethylporphycene and 2,7,12,17-tetraethyl-3,6,13,16-tetramethylporphycene (OEPc **1** and EtioPc **4**, respectively), and on the readily obtained four- and five-coordinate zinc complexes of **1**[6] (Table 1).

Table 1. Selected physical and spectroscopic data for the new compounds. ^{1}H NMR: 300 MHz; ^{13}C NMR: 75.5 MHz, $CDCl_3$; MS: EI, 70 eV; IR: CsI; UV/VIS: CH_2Cl_2.

1: M.p. 181–183 °C (methanol/chloroform); ^{1}H NMR ($CDCl_3$): δ = 9.48 (s, 4H; H-9,10,19,20), 4.02 (q, 8H; H-3a,6a,13a,16a), 3.87 (q, 8H; H-2a,7a,12a,17a), 1.65 (t, 12H; H-2b,7b,12b,17b), 1.58 (t, 12H; H-3b,6b,13b,16b), 0.65 (br. s, 2H; NH); ^{13}C NMR: δ = 143.27, 142.02, 137.23, 136.72, 109.82, 21.39, 19.94, 18.08 (2 C atoms); MS: *m/z* (%): 534 (100) [M^+], 267 (14) [M^{2+}]; IR: $\tilde{\nu}$ = 2964, 2930, 2869, 1518, 1471, 1060, 989, 946, 929, 856 cm^{-1}; UV/VIS: λ_{max} (ε) = 385 (144000), 576 (35200), 625 (19700), 665 nm (30700).

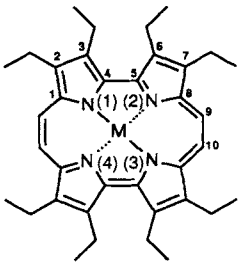
2: M.p. 263–265 °C (hexane/chloroform); ^{1}H NMR ($CDCl_3$): δ = 9.80 (s, 4H; H-9,10,19,20), 4.15 (q, 8H; H-3a,6a,13a,16a), 4.04 (q, 8H; H-2a,7a,12a,17a), 1.84 (t, 12H; H-2b,7b,12b,17b), 1.78 (t, 12H; H-3b,6b,13b,16b); ^{13}C NMR: δ = 146.91, 142.69, 140.78, 137.44, 109.78, 21.06, 20.31, 18.74, 18.69; MS: *m/z* (%): 596 (100) [M^+], 298 (19) [M^{2+}]; IR: $\tilde{\nu}$ = 2963, 2930, 2869, 1488, 1314, 1301, 1132, 1013, 994, 948 cm^{-1}; UV/VIS: λ_{max} (ε) = 375 (77500) sh, 393 (161000), 590 (21900), 638 nm (94600).

3: M.p. 243–245 °C (pyridine/dioxane); ^{1}H NMR ($CDCl_3$): δ = 9.61 (s, 4H; H-9,10,19,20), 6.49 [m, 1H; H-γ (pyridine)], 5.74 [m, 2H; H-β (pyridine)], 4.06 (q, 8H; H-3a,6a,13a,16a), 3.96 (q, 8H; H-2a,7a,12a,17a), 3.59 [m, 2H; H-α (pyridine)], 1.76 (t, 12H; H-2b,7b,12b,17b), 1.69 (t, 12H; H-3b,6b,13b,16b); ^{13}C NMR: δ = 145.87, 144.64, 142.68, 141.60, 136.51, 135.65, 122.27, 109.19, 21.04, 20.29, 18.81, 18.71; MS: *m/z* (%): 596 (100) [$M^+ - C_5H_5N$], 298 (24) [$M^{2+} - C_5H_5N$]; IR: $\tilde{\nu}$ = 2963, 2930, 2868, 1484, 1277, 1225, 1134, 1009, 995, 948 cm^{-1}; UV/VIS: λ_{max} (ε) = 371 (81000) sh, 395 (146400), 598 (22400), 644 nm (91900).

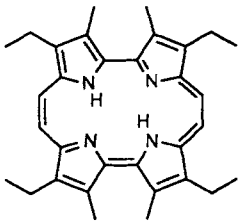
4: M.p. 268–270 °C (hexane/chloroform); ^{1}H NMR ($CDCl_3$): δ = 9.52 (s, 4H; H-9,10,19,20), 3.85 (q, 4H; H-2a,7a,12a,17a), 3.57 (s, 12H; H-3a, 6a, 13a, 16a), 1.70 (t, 12H; H-2b,7b,12b,17b), 0.86 (br. s, 2H; NH); ^{13}C NMR: δ = 143.88, 142.13, 137.32, 130.46, 109.84, 19.96, 17.23, 16.19; MS: *m/z* (%): 478 (100) [M^+], 239 (19) [M^{2+}]; IR: $\tilde{\nu}$ = 2960, 2928, 2867, 1466, 1196, 1083, 1057, 982, 938, 864, 806 cm^{-1}; UV/VIS: λ_{max} (ε) = 382 (144200), 570 (34200), 617 (18400), 657 nm (30000).

6a: M.p. 103–105 °C (ethanol); ^{1}H NMR ($CDCl_3$): δ = 9.10, 4.34, 2.75, 1.96, 1.33, 1.08. **6b**: M.p. 97–99 °C (ethanol); ^{1}H NMR ($CDCl_3$): δ = 8.87, 4.30, 2.74, 2.37, 1.33, 1.12, 1.06. **7a**: Subl. >170 °C (hexane/dichloromethane); ^{1}H NMR ($CDCl_3$): δ = 8.68, 4.33, 2.77, 2.04, 1.34, 1.14. **7b**: M.p. 161–163 °C (hexane/dichloromethane); ^{1}H NMR ($CDCl_3$): δ = 8.78, 4.28, 2.76, 2.44, 1.33, 1.17, 1.05. **8a**: decomp. >218 °C; ^{1}H NMR ([D$_6$]DMSO): δ = 10.96, 2.69, 2.49, 1.05. **8b**: decomp. >260 °C; ^{1}H NMR ([D$_6$]DMSO): δ = 11.94, 11.11, 2.69, 2.30, 1.09, 0.88. **9a**: M.p. 76–78 °C (sublimation); ^{1}H NMR ($CDCl_3$): δ = 7.68, 6.55, 2.49, 2.02, 1.22. **9b**: M.p. 90–92 °C (sublimation); ^{1}H NMR ($CDCl_3$): δ = 7.68, 6.54, 2.51, 2.42, 1.24, 1.06. **10a**: decomp. >245 °C (hexane/dichloromethane); ^{1}H NMR ($CDCl_3$): δ = 9.85, 9.65, 2.75, 2.10, 1.23. **10b**: decomp. >227 °C (hexane/dichloromethane); ^{1}H NMR ($CDCl_3$): δ = 9.64, 9.47, 2.76, 2.50, 1.26, 1.05.

Consideration of models[7] which predict that the introduction of alkyl groups to the 3,6- and 13,16-positions of the porphycene structure would cause an increase in the N1···N4 and N2···N3 distances as a result of van der Waals repulsion, was decisive for the choice of **1** and **4** as ligands. Thus with these ligands, in addition to a weakening of the N–H···N hydrogen bonds, the pronounced rectangular N_4 coordination center in the parent compound[8] and in TPrPc[1a] would now adopt an almost square arrangement. An improved tendency toward complex formation should result in both cases. The assumed deviations from planarity of the ring framework in 3,6,13,16-alkyl-substituted porphycenes, caused by steric interactions,[7] which had originally prevented us from considering **1** as a model ligand, should—as concluded from structural results with the nickel complex of TPrPc[1a]—largely if not completely cancel in the conversion of such porphycenes to metal complexes.

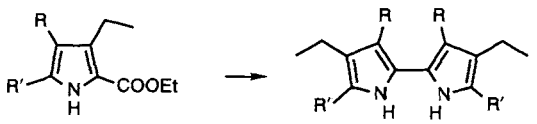


1: M = 2H **2**: M = Zn **3**: M = Zn(C_5H_5N)



4

The synthesis of octaethylporphycene **1** was achieved according to the general method of preparation for porphycenes,[1a, 7] by subjecting 3,3′,4,4′-tetraethyl-5,5′-diformyl-2,2′-bipyrrole (**10b**), made as described in Scheme 1, to reductive carbonyl coupling with low valent titanium. After standard workup and recrystallization of the product from methanol/chloroform (5:1), **1** was obtained as violet needles (blue, nonfluorescent solutions), which melt without decomposition at 181–183 °C (yield 15%, see Experimental Procedure).



a: R = CH_3
b: R = C_2H_5

5a/5b: R′ = H[23]
6a/6b: R′ = I

7a/7b: R′ = COOEt
8a/8b: R′ = COOH
9a/9b: R′ = H
10a/10b: R′ = CHO

Scheme 1. **5a/5b** → **6a/6b**: I_2/HIO_3, CCl_4/dilute acetic acid, reflux, 45 min (85–90%); **6a/6b** → **7a/7b**: Cu, dimethylformamide (DMF), 110 °C, 3 h (45–50% for **7a**, 35–40% for **7b**); **7a/7b** → **8a/8b**: NaOH in C_2H_5OH/H_2O, reflux, 2 h (90–95%); **8a/8b** → **9a/9b**: sublimation at 195 °C/0.01 Torr (85–90%); **9a/9b** → **10a/10b**: $POCl_3$/DMF; CH_3COONa, H_2O (90–95%). For physical and spectroscopic data, see Table 1.

The ^{1}H NMR spectrum (300 MHz, $CDCl_3$) shows that **1** is an aromatic porphycene. Comparison with the signals of the corresponding protons in TPrPc reveals that the signal of H9,10,19,20 occurs at almost the same field (singlet at δ = 9.48 versus 9.62 in TPrPc), whereas that of the *N*-protons (δ = 0.65 versus 3.04) experiences a marked shift to higher field ($\Delta\delta$ = 2.39), which could be foreseen in view of the increase in the N1···N4 and N2···N3 distance (weakening of the N–H···N hydrogen bonds). The IR spectrum of **1** shows, analogous to that of TPrPc, no stretching vibration in the range 3300–3600 cm^{-1}, which indicates that the hydrogen bonds are weakened only gradually.

According to an X-ray crystallographic analysis,[9] **1** exists in the crystal as a molecule with C_2 symmetry (Fig. 1). The crystal exhibits a statistical distribution of the two *N*-hydrogen atoms with half occupancy of the four possible positions. The porphycene skeleton of **1**, in contrast to that of TPrPc, is no longer planar, but experiences a slight twist because of the van der Waals repulsions of the ethyl groups in the 3,6-

and 13,16-positions (maximum distance of the C and N atoms from the central plane of the porphycene ring structure: ±0.27 Å). Deviation of the structure from the planar arrangement is accompanied by angle deformations, in particular by contraction of the bond angles in the NCCN segments (118.5° versus 121.8° in TPrPc). Consequently, in accordance with the prediction, the N_4 coordination center adopts an approximately square arrangement. Remarkably, the N···N distance of the hydrogen bonds in **1** is now slightly larger than that between the nitrogen atoms within the bipyrrole units.

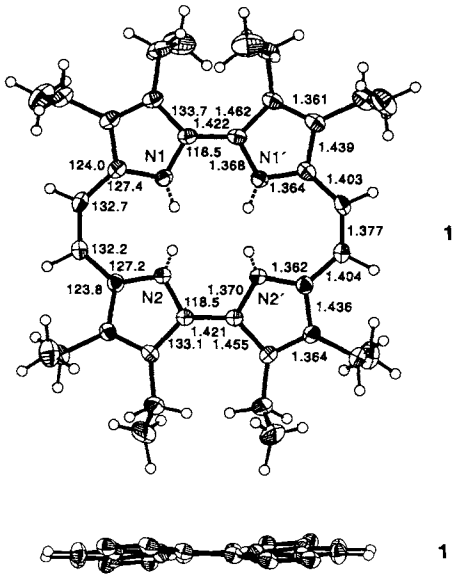


Fig. 1. Structure of **1** in the crystal (top: viewed from above; bottom: side view). Vibrational ellipsoids represent 40% probability. Also shown are selected bond lengths [Å] and angles [°] (standard deviations about 0.002 Å or 0.2°, respectively); inner hydrogen atoms in **1** disordered. The ethyl groups are not shown in the side view. N1···N2 2.799, N1···N1′ 2.732 Å.

The expectation that **1** is more suitable than TPrPc as a complexing agent for the zinc(II) ion is borne out by experiment. The new ligand can be converted quantitatively into complex **2** within 15 min by treatment with methanolic zinc acetate solution in refluxing chloroform, whereas in the case of TPrPc even extensive heating in DMF at 150 °C does not lead to complete reaction.[10] Simple workup gave **2** in the form of violet needles (from hexane/chloroform, m.p. 263–265 °C; yield 87%).[11]

Compared to that of **1**, the ^{1}H NMR spectrum (300 MHz, $CDCl_3$) of **2** exhibits a slight downfield shift for the signal of H9, 10, 19, 20 ($\Delta\delta = 0.32$) as well as for the signals of the ethyl protons. The main reason for this may be ascribed to the fact that metalation of **1** enhances the ring current effect due to the increase in symmetry of the molecular framework.[12] Apart from that, an electron transfer from the porphycene π system to the metal ion, operative in the same direction, is likely to be involved.[13] The UV/VIS spectrum shows a Soret band that is almost congruent with that of the free ligand in addition to two absorption bands in the visible range. The band positions are solvent dependent, which is linked to the ability of the zinc ion to enter into axial pentacoordination;[14] donor solvents such as pyridine cause bathochromic shifts.

According to an X-ray structural analysis,[15] complex **2** is centrosymmetric (Fig. 2); moreover, the porphycene ring system is shown to be planar (maximum distance of the heavy atoms from the central plane: ±0.05 Å). From the structural parameters of **2** it follows that the metalation of **1** with zinc profits if the bond angles in the NCCN segment—in the interests of a better alignment of the nitrogen electron pairs and bonds towards the center of the molecule—undergo further contraction (relative to TPrPc and **1**). The formation of a rectangular N_4 center must be tolerated here. The average Zn–N distance in **2** is 2.007 Å and is thus somewhat shorter than that found in tetracoordinated zinc porphyrinates (Zn–N: 2.024–2.06 Å).[16] As the metalation of **1** is associated with a considerable reduction in the nonbonding substituent interactions, the unusual situation arises that a nonplanar porphyrinoid ligand experiences a flattening effect on the incorporation of metal ions.[17]

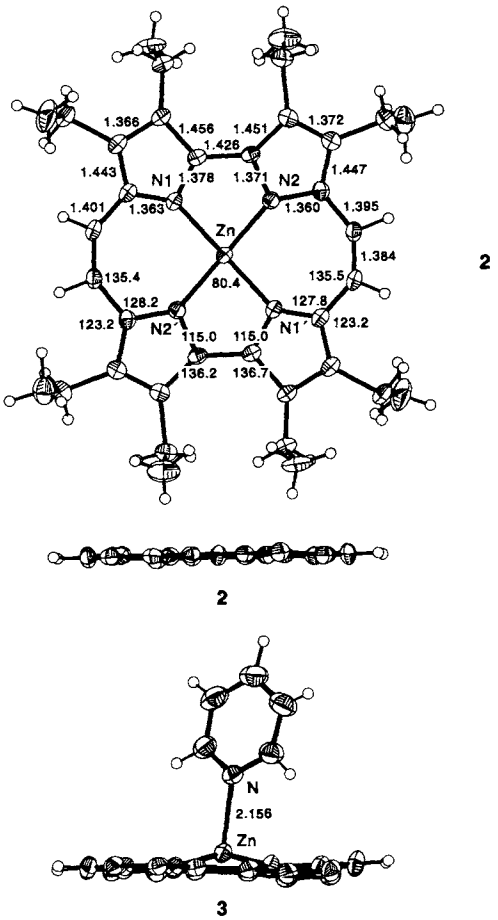

Fig. 2. Structure of the zinc complexes **2** and **3** in the crystal (top: **2** viewed from above; center: side view of **2**; bottom: side view of **3**). Vibrational ellipsoids represent 40% probability. Selected bond lengths [Å] and angles [°] are also given (standard deviations ca. 0.003 Å or 0.2°, respectively). The ethyl groups are not shown in the side views. N1···N2′ 3.066, N1···N2 2.588 Å in **2**.

By analogy with the corresponding zinc porphyrinates, **2** also shows a tendency to increase the coordination number of zinc by adding an axial donor ligand. A typical example is the formation of pyridine(octaethylporphycenato)zinc(II) (**3**) by crystallization of **2** from pyridine/dioxane (1:1). On the strength of an X-ray crystal structure analysis[18] (Fig. 2 bottom), the new complex shows great similarity with **2** in terms of bond lengths and angles, but the zinc atom resides 0.39 Å above the N_4 plane as a result of the axial ligand (corresponding distance in quinquidentate zinc porphyrin-

ates: 0.22–0.39 Å).[19] The other distances involving the zinc atom lie within normal range.

The idea of increasing the complex-forming ability of porphycenes by alkyl substitution in the 3,6,13,16-positions was followed not only in Cologne but also in Dijon. Considering the fact that many porphyrins possess the alkyl substitution pattern of etioporphyrin-II,[20] the French coauthors chose 2,7,12,17-tetraethyl-3,6,13,16-tetramethylporphycene (etioporphycene) (**4**) rather than **1** as model compound. The synthesis of **4**, using the same route as that employed for **1** (Scheme 1), is somewhat more advantageous because the Ullmann coupling of the 3,4-dialkyl-2-ethoxycarbonyl-5-iodopyrrole to afford the bipyrrole derivative gives a better yield, on evident steric grounds. Analogous to **1**, a solution of **4** is intense blue and nonfluorescent. Compound **4** is obtained as violet crystals [needles from hexane/chloroform (1:1), m.p. 268–270 °C, yield 15%].

The spectra of **4** show only slight changes relative to those of **1**, so it could not be determined whether the exchange of the 3,6,13,16-ethyl groups for methyl groups had a noticeable effect on the conformation of the ring skeleton. This is, in fact, the case. According to an X-ray crystal structure analysis,[21] the planarity of the ring framework in TPrPc is almost restored in **4** (maximum distance of the heavy atoms from the central plane of the porphycene macrocycle: ±0.15 Å, Fig. 3). As far as the other geometric features are concerned there is no major difference between **4** and **1**.

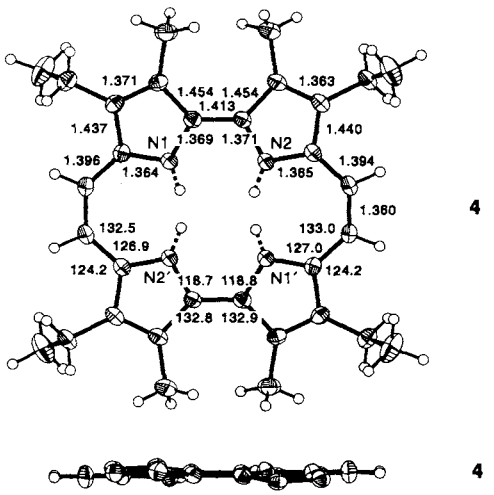

Fig. 3. Structure of **4** in the crystal (top: viewed from above; bottom; side view). Vibrational ellipsoids represent 40% probability. Selected bond lengths [Å] and angles [°] are also shown (standard deviations about 0.002 Å or 0.1°, respectively); inner hydrogen atoms in **4** disordered. The ethyl and methyl groups are not shown in the side view. N1 ··· N2' 2.791, N1 ··· N2 2.737 Å.

The two new alkyl-substituted porphycenes **1** and **4** complement TPrPc (representing the porphycene parent compound) as ligands that, on the grounds of "optimized coordinating ability", should encourage research into the metalloporphycenes—especially as they invite comparison with the corresponding metalloporphyrins.

Experimental Procedure

10a/10b: The bipyrrole dialdehydes **10a**[22]/**10b** were obtained as shown in Scheme 1.

1/4: Activated zinc (13.1 g, 200 mmol) and CuCl (2.0 g, 20 mmol) were placed in tetrahydrofuran (800 mL), $TiCl_4$ (11.0 mL, 100 mmol) added dropwise, and the resulting mixture heated at reflux for 3 h. Within 4 min (for **1**) or 15 min (for **4**) a solution of **10b** (1.5 g, 5 mmol) or **10a** (1.4 g, 5 mmol) in THF (200 mL) was added dropwise, and the reaction mixture stirred at reflux for 3 min. Finally, the resulting product was hydrolyzed with 200 mL of 10% K_2CO_3 solution and worked up.

1: After chromatography on neutral aluminum oxide (activity III, column 3 × 30 cm) with hexane/dichloromethane (1:1), **1** was obtained as the first fraction. Crystallization from methanol/chloroform (5:1) gave octaethylporphycene (**1**) as violet needles, m.p. 181–183 °C; yield 200 mg (15%).

4: After chromatography on silica gel (column 4 × 15 cm) with dichloromethane, **4** was obtained as the first fraction. Crystallization from hexane/chloroform (1:1) gave etioporphycene (**4**) as violet needles, m.p. 268–270 °C; yield 180 mg (15%).

2: Compound **1** (106 mg, 0.2 mmol) in chloroform (60 mL) was heated at reflux for 15 min with 2 mL of a saturated solution of zinc acetate in methanol. The solvent was then removed, the resulting zinc complex taken up in chloroform, and the solution filtered. Crystallization from hexane/chloroform (4:1) gave **2** as violet needles, m.p. 263–265 °C; yield 104 mg (88%).

The Nature of the 7-Norbornyl Cation and its Rearrangement into the 2-Norbornyl Cation**

By *Stefan Sieber, Paul von Ragué Schleyer,* Hrvoj Vančik, Milan Mesić*, and *Dionis E. Sunko*

The structure of the 7-norbornyl cation has always been an enigma.[1, 2] The exceptionally slow solvolysis rates of 7-norbornyl derivatives first suggested the absence of anchimeric assistance and the intervention of a classical cationic intermediate. However, a symmetrical C_{2v} structure (**1**, see Fig. 1) was later ruled out by the demonstration that the substitution product *retains* its stereochemistry.[1c–e] While this is also consistent with a C_s formulation (**2**), more recent interpretations favor a nonclassical, bridged structure (**3**) (Fig. 1).[1d] This is consistent with the formation of small, but significant amounts of 2-bicyclo[3.2.0]heptyl rearrangement products, as well as extensive evidence from, for example, D and CH_3 labeling experiments.

Before the present study, attempts at direct observation of the 7-norbornyl cation in superacid media all failed. In one of the earliest papers on studies in superacids, Schleyer, Olah et al. reported that ionization of 7-norbornyl derivatives led only to the 2-norbornyl cation.[1a] Subsequent attempts in our laboratories led to similar results.

Earlier computational studies were not definitive.[2] These were carried out at lower levels of theory, known now to give inadequate descriptions of such electron deficient species.[3] As part of a comprehensive examination of the $C_7H_{11}^+$ potential energy surface, we now report computations[4, 5] on the C_{2v} (**1**) and C_s (**2**) structures of the 7-norbornyl cation, the bridged ion **3**, as well as other stationary points related to the conversion into the 2-norbornyl cation (**4**)[6, 7] at the MP4(sdq,fc)/6-31G*//MP2(full)/6-31G* + ZPE(MP2(full)/6-31G*) level.[*] The vibrational frequencies, computed at the correlated level given, assist in the unambiguous identification of the $C_7H_{11}^+$ ion that we have now been able to observe experimentally.

Early ab initio calculations favored **1**, but this was due to the use of inadequate basis sets (STO-3G, 3-21G, 4-21G). Adequate searches of the carbocation potential energy surface require[3] the use at least of polarized double-ξ (DZ or split valence) basis sets with electron correlation. Thus, whereas at the HF/6-31G* level, **2** is favored over **1** by 0.4 kcal mol^{-1} and over **3** by 0.7 kcal mol^{-1}, the order changes with correlation. The (central) bridge flipping barrier (**2** ⇌ **1** ⇌ **2'**) increases to 2.3 kcal mol^{-1} at our final theoretical level. The relative stability of **2** and **3** reverses; the

unsymmetrically bridged structure **3** is favored over **2** by 2.9 kcal mol^{-1} (Table 1); structure **2** is identified as transition state for the same-side bridge-flipping process by frequency analysis (Scheme 1).

It is difficult to observe carbocations (like the 7-norbornyl cation) that have low rearrangement barriers.[1a] The recently developed cryogenic SbF_5 matrix IR technique[8, 9] enables otherwise elusive carbocations to be investigated. We have used this procedure to generate the 7-norbornyl cation by codepositing 7-chloronorbornane and a large excess of SbF_5 (1:500) on a CsI window at 10 K. The first spectrum, recorded at 10 K (Fig. 2a), was that of the starting chloride. During slow warming of the matrix to 100 K the signals of the chloride disappear and at the same time new signals of the 7-norbornyl cation appear (Fig. 2b). The IR spectrum at 200 K (Fig. 2c) is the same as that of the 2-norbornyl cation reported earlier.[8b]

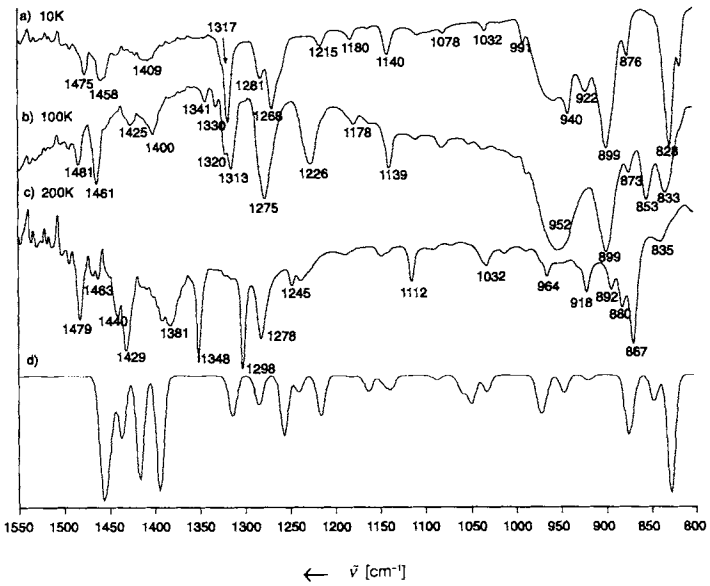

Fig. 2a)–c). Experimentally obtained spectra of 7-norbornyl chloride at 10 K, the 7-norbornyl cation **3** at 100 K, and the 2-norbornyl cation **4** at 200 K; d) the computed spectrum of **3** at the MP2(full)/6-31G* level (frequencies scaled by 0.939).

The experimental spectrum recorded at 100 K (Fig. 2b) is in very good agreement with the calculated frequencies for **3** (correlation coefficient cc = 0.9993, cf. Fig. 2d and Table 2). The intensities are reproduced with less accuracy.[10] The

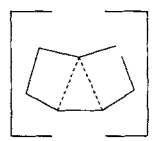
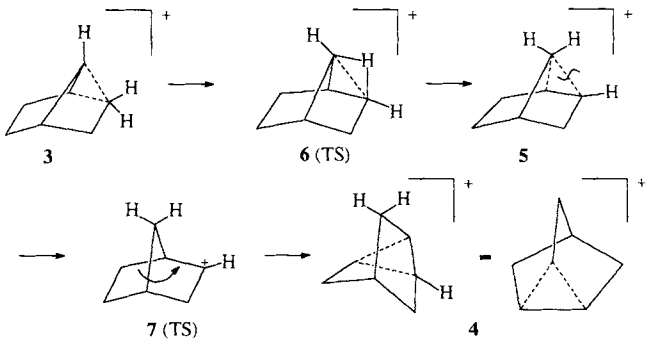
[a] The assignment of experimental vs. calculated frequencies is based on the best numerical agreement. Calculated frequencies outside the range of the experimental spectrum are omitted. [b] w: weak, m: medium, s: strong, vs: very strong, sh: shoulder.

slope of the correlation line (m = 0.939) is that expected, since the harmonic approximation was used in the computations.[4, 11] Although the experimental frequencies (Fig. 2b) also correlate reasonably to those computed for other isomers containing multicenter bonds (**2**, **5**, **8**;[12] $cc \approx 0.99$), these are excluded by theoretical considerations: The sym-



8

metrical structure **2** is a transition state; the barrier for rearrangement of the 2-norpinyl cation **5** into the 2-norbornyl cation is much too low (1.25 kcal mol^{-1}, see below) to

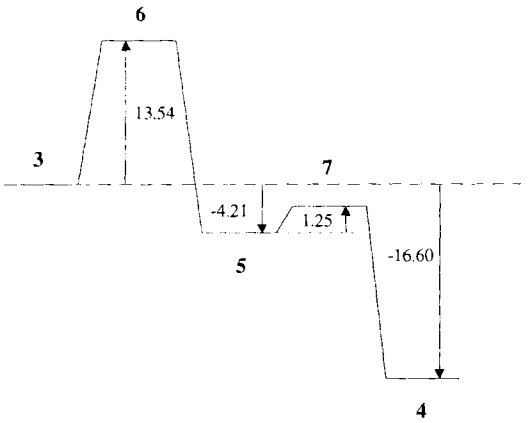


Scheme 2. Mechanism of the isomerization **3** → **4**. TS = transition state.

permit experimental detection under these conditions; the related structure **8** has been generated by Kirmse under short-lived conditions.[12] The IR spectra exclude **1** and **7** (and other isomers we have investigated).[13]

Our minimum energy reaction pathway for the rearrangement, first observed some time ago,[1a] of the 7-norbornyl cation to the 2-norbornyl cation (**4**), involves the 2-norpinyl cation **5** whose intermediacy has been postulated by Kirmse (Scheme 2).[1e]

The crucial step for the interconversion of the 7-norbornyl into the bridged 2-norbornyl cation (**4**), a 1,3 H shift from C2 to C7 (transition state **6**, Fig. 1), has a barrier of 13.5 kcal mol^{-1} to form the bridged 2-norpinyl intermediate **5**. Although **5** is 4.2 kcal mol^{-1} more stable than **3**, the high barrier between **3** and **5** allows the experimental detection of the 7-norbornyl cation. Only a 1.3 kcal mol^{-1} barrier (transition state **7**)[14] separates the 2-norpinyl cation from the global minimum of the $C_7H_{11}^+$ potential energy surface, the 2-norbornyl cation **4**. The low barrier of the latter reaction



Scheme 3. Energy barriers and reaction energies associated with the isomerization **3** → **4**.

makes the experimental detection of the 2-norpinyl cation **5** (for example, in stable superacid solutions) unlikely.

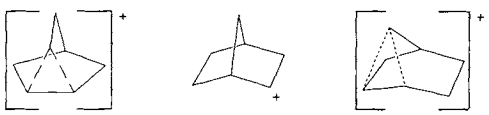
[13] The details of the $C_7H_{11}^+$ potential energy surface will be published later.

[14] This structure, which resembles the classical 2-norbornyl cation closely, is discussed comprehensively in the following communication: P. von R. Schleyer, S. Sieber, *Angew. Chem.* **1993**, *105*, 1676; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1606.

The Classical 2-Norbornyl Cation Rigorously Defined Ab Initio**

By *Paul von Ragué Schleyer** and *Stefan Sieber*

While extensive experimental and computational data have now firmly established that the 2-norbornyl cation is the symmetrically bridged (C_s) minimum energy structure **1**,[1] most of the other intriguing features of the $C_7H_{11}^+$ potential energy surface have not been elucidated fully.[2] This applies in particular to the "classical" structure[3] of the 2-norbornyl cation (**2**). We have now been able to locate a



1 **2** **3**

stationary point at an adequately high ab initio level, which corresponds to the structure **2**: its geometry optimized at MP2(full)/6-31G* level is compared with that of norbornane (**3**) in Figure 1. The structures correspond well.

Earlier attempts to compute energies and bond lengths and angles for a classical 2-norbornyl geometry were either inadequate or unsuccessful. Structures have been assumed, based on the structure of the parent hydrocarbon, norbornane (**3**).[4] The classical geometries computed by semiempirical molecular orbital theory (e.g. MINDO/3, MNDO, AM1, and PM3) are artifacts arising from the failures of these methods to describe the energies of the 2-norbornyl cation and its bridged nature properly (Table 1).[2, 5] Ab initio computations with inadequate basis sets (e.g., STO-3G,

Fig. 1. The optimized geometries (at the MP2/6-31G* level) of transition structure **2** (model for the "classical" 2-norbornyl cation) and norbornane (**3**). Note the close correspondence between the structural parameters for **2** and **3**. See also structures **4** and **5** in the preceeding communication [14] for the geometries of **1** and **4**, respectively.

3-21G, 4-21G, 4-31G) find only partially bridged minima.[6, 7] The reliable investigation of carbocation potential energy surfaces require the use of flexible, basis sets that include polarization functions and electron correlation.[6-8] Searches for a minimum corresponding to a classical 2-norbornyl cation structure at such levels prior to this paper have failed.[6, 8] Optimization leads (correctly) to the symmetrical C_s minimum **1** instead.[8]

Table 1. Relative energies for the structures of **1**, **2**, and **4**, optimized with ab initio and the semiempirical MINDO/3 methods (kcal mol^{-1}).

Method	1	2	4
MP2(full)/6-31G*//MINDO/3	5.7	16.7	20.9
MP2(full)/6-31G*//MP2(full)/6-31G*	0.0	17.6	13.8
MP4(sdq,fc)/6-31G**//MP2(full)/6-31G* [a]	0.0	13.6	12.4

[a] Corrected for zero point energy at the MP2(full)/6-31G* level, scaled by 0.93 [9].

Indeed, the new $C_7H_{11}^+$ stationary point **2** that we located with considerable effort[9] is not a minimum, but rather a transition state in the rearrangement of **1** into the bridged 2-norpinyl cation, **4**.[2] The somewhat elongated C1–C7 bond (1.671 Å) in **2** reflects this character. The C–C bonds to the tricoordinated carbocation center are shortened, as expected, but the other geometric parameters differ little from those of **3** (Fig. 1). Despite the increased C1–C7 bond length, this bond may still be termed classical in the sense of a two-center, two-electron bond. According to the NPA (NPA = orbital population analysis), the natural bonding orbital for C1–C7 is occupied with 1.8 electrons, about 92% of a "normal" bond like, for example, C1–C6. Consequently, **2**, a rigorously defined stationary point, can be taken as a model for the classical 2-norbornyl cation. At the theoretical level employed, MP4sdtq/6-31G**//MP2(full)/6-31G* + ZPE(MP2(full)/6-31G*),[10] the energy of classical **2** is 13.6 kcal mol^{-1} higher than that of nonclassical **1** (see Table 1). This value is in remarkably good agreement with earlier, rough gas-phase estimates.[6, 11]

The MP2(full)/6-31G* energies computed for the MINDO/3 geometries of **1** and **4** (Table 1) are in good agreement with those obtained for the MP2(full)/6-31G* geometries, which indicates that they are similar. The energy for the MINDO/3 structure of **2** (relative to MP2(full)/6-31G*//MINDO/3 energy of **1**) is somewhat lower than that for the transition state structure calculated with ab initio methods. The MINDO/3 structure might be assigned to a point on the reaction path between **2** and **1**. (The MINDO/3, MNDO, AM1, and PM3 methods also give very similar classical minima for 2-norbornyl cations. These differ from **2** by having normal C1–C2 distances, but slightly elongated C1–C6 bonds (1.582–1.593 Å)).

Structure **2** can also be employed to predict the ^{13}C chemical shifts of the classical 2-norbornyl cation. Table 2 summarizes this data, not only for **2**, but also for **1** and **4** for comparison with the experimental measurements. Schindler's best computed (IGLO) NMR chemical shifts for a model of a classical 2-norbornyl cation[4] are provided for comparison, as are those computed using the MINDO/3 minimum energy geometry. The IGLO chemical shifts for **2** deviate considerably from those of the classical 2-norbornyl cation models of Schindler (see his "best" values in Table 2), but are much more in line with those expected for a classical carbocation (cf. the value for C2, which is close to C1 of the isopropyl cation).[12] The comparison of the chemical shifts for **1** and **2** with the experimental data confirms once again the symmetrical nonclassical structure of the 2-norbornyl cation.[1, 6-8, 12]

Although it has not been observed directly in super acidic media, the 2-norpinyl cation (**4**) also is an intriguing nonclassical species, which has been generated by solvolysis and by deamination.[7] The computed chemical shifts for **4** (Table 2) reveal shielding characteristic of hypercoordinate carbocat-

Table 2. Computed (IGLO and MP2-GIAO) ^{13}C chemical shifts for **1**, **2**, and **4** and for comparison, the experimental NMR data, for the 2-norbornyl cation (vs. TMS).

[a] DZ = double ζ basis, Tz = triple ζ basis, P with polarization functions, II = triple ζ basis with polarization functions. [b] The difference in the sums of all the ^{13}C chemical shifts between a carbocation and its corresponding alkane (norbornane: $\Sigma(\delta^{13}C) = 233$) provides an index of carbocation structure. Large differences indicate classical carbocations (e.g. **2**); values for nonclassical cations (e.g. **1** and **4**) are much smaller (200 or less): P. von R. Schleyer, D. Lenoir, P. Mison, G. Liang, G. K. S. Prakash, G. A. Olah, *J. Am. Chem. Soc.* **1980**, *102*, 683. [c] R. M. Jarret, M. Saunders, *J. Am. Chem. Soc.* **1987**, *109*, 3366. [d] MP2-GIAO calculations by J. Gauss, cf. S. Sieber, P. von R. Schleyer, J. Gauss, *J. Am. Chem. Soc.* **1993**, *115*, 6987. [e] M. Schindler's best geometry (evidently partially optimized; details were not given in ref. [3]).

ions.[2, 8, 13] The reason for the difficulty in observing **4** is now clear: the barrier to rearrangement into **1** (as represented by the energy difference between **2** and **4** is only 1.2 kcal mol^{-1}. Structure **4** also functions as a stationary point during the rearrangement of the 7-norbornyl into the 2-norbornyl cation. This has been described in the preceding communication along with other intriguing features of the $C_7H_{11}^+$ potential energy surface.[14]

Our decade-old conclusion[6] is worth repeating: "The symmetrically bridged (C_s) 2-norbornyl cation structure is expected to be the only minimum... As no minima with C_1 symmetry are found, *'classical' and partially bridged 2-norbornyl cations are not expected to exist*, at least as isolated (gas-phase) entities. The extra stabilization due to bridging of the C_s 2-norbornyl cation (the 'classical–nonclassical energy difference') is estimated approximately in two ways to be about 15 kcal mol^{-1}." We will explain in a subsequent communication why the difference in transition state energy for 2-*exo* and 2-*endo*-norbornyl solvolysis (only about 5 kcal mol^{-1})[3] is reduced to such a large extent.

[9] Optimization to the C_1-point-group transition structure **2** must be carried out directly at the MP2/6-31G* level, as it is not a stationary point at the HF/6-31G* level. Its nature was confirmed by frequency analysis at the MP2(full)/6-31G* level; an imaginary frequency of 347i cm^{-1} was found. This type of calculation uses about 100 MByte of memory, 2 GByte of disk space and 35 hours on a Cray YMP-EL.

[10] If not given otherwise, all data (energies and structure parameters) apply to MP4(sdq·fc)/6-31G**//MP2(full)/6-31G* + ZPE(MP2(full))/6-31G* (for an explanation of abbreviations, see ref. [14]); ZPE's are scaled by 0.93. This level of theory has been shown to be adequate even for demanding electronic structures: S. Sieber, P. Buzek, P. von R. Schleyer, W. Koch, J. W. M. Carneiro, *J. Am. Chem. Soc.* **1993**, *115*, 259. Larger basis sets result only in slightly different structures and energies. For a description of methods and basis sets employed, see W. J. Hehre, L. Radom, P. von R. Schleyer, J. A. Pople, *Ab Initio Molecular Orbital Theory*, Wiley Interscience, New York, **1986**, Chapter 7, and J. B. Foresman, E. Frisch, *Exploring Chemistry with Electronic Structure Methods: A Guide to Using Gaussian*, Gaussian Inc., Pittsburgh, **1993**. Absolute energies (MP4(sdq·fc)/6-31G**//MP2(full)/6-31G*) are: **1**: −272.24562, **2**: −272.22283, **4**: −272.22589 Hartree; zero point energies (MP2(full)/6-31G*, unscaled); **1**: 105.5, **2**: 104.8, **4**: 105.5 kcal mol^{-1}. All calculations were performed with the program GAUSSIAN 92 (M. J. Frisch, G. W. Trucks, M. Head-Gordon, P. M. W. Gill, M. W. Wong, J. B. Foresman, B. G. Johnson, H. B. Schlegel, M. A. Robb, E. S. Replogle, R. Gomperst, J. L. Andres, K. Raghavachari, J. S. Binkley, C. Gonzalez, R. L. Martin, D. J. Fox, D. J. Defrees, J. Baker, J. J. P. Stewart, J. A. Pople, Gaussian Inc., Pittsburgh, PA, **1992**).

[11] The estimates of the **1**/**2** energy difference in superacidic media (6–8 kcal mol^{-1}) gave lower values (see P. von R. Schleyer, J. Chandrasekhar, *J. Org. Chem.* **1981**, *46*, 225); these were, however, based on equations involving model carbocations that were assumed (erroneously) to be "classical" [6].

Tris(chlorodimethylstannyl)amine, a Molecule with a Planar Sn_3N Skeleton Stabilized by Intramolecular Sn-Cl-Sn Bridges**

By *Christian Kober, Jürgen Kroner, and Wolfgang Storch**

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

Structural information about the few known tristannylamines is contradictory. IR spectroscopic investigations on tris(trimethylstannyl)amine indicate a pyramidal Sn_3N skeleton,[1] electron diffraction studies in the gas phase, however, reveal a trigonal-planar arrangement of the tin atoms around the nitrogen center.[2] Especially interesting is the comparison of $N(SnR_3)_3$ compounds with the lighter homologues $N(MR_3)_3$ (M = Si, Ge), whose planar NM_3 skeleton is due in part to the π-acceptor properties of the M atoms,[3] whereas the planarity of the region around the N atom in triisopropylamine is forced by steric overcrowding.[4] Which structure tristannylamines have is of primary importance, because this determines whether or not a Sn–N π interaction can be deduced. Consequently, we are investigating the chemistry and structure of tristannylamines with varying substituents.

Tris(chlorodimethylstannyl)amine **2**,[5] the first tristannylamine functionalized at the tin atom, is synthesized by the complete exchange of the $(CH_3)_3Sn$ groups of tris(trimethylstannyl)amine **1** with $(CH_3)_2SnCl_2$ [Eq. (a)]. The NMR

$$\underset{\mathbf{1}}{[(CH_3)_3Sn]_3N} + 3(CH_3)_2SnCl_2 \longrightarrow \underset{\mathbf{2}}{[Cl(CH_3)_2Sn]_3N} + 3(CH_3)_3SnCl \qquad (a)$$

spectra of **2** (Table 1) clearly show changes in the molecular skeleton in comparison to that of the permethylated compound **1**. The exchange of one methyl group on each tin atom of **1** for a chlorine atom results in reduced shielding of the ^1H, ^{13}C, and ^{15}N nuclei in **2**. The better shielding of the ^{119}Sn nuclei is, however, unusual and indicates a higher coordination number of the Sn centers. The ^{119}Sn CP-MAS NMR spectrum of **2** in the solid state shows an even clearer high-field shift of the signal.[6] In contrast, the $\delta(^{15}N)$ signal gives no clear indication about the geometry at the nitrogen atom.[7] Due to the −I effect of the chlorine substituents and probably also due to the changed geometry at the tin atoms, the values of the coupling constants $^1J(^{119}Sn, ^{13}C)$ and $^2J(^{119}Sn, ^1H)$ are significantly larger than those of **1**. Further information about the structure of **2** is obtained by estimat-

[a] To conform with previous work we assume a negative sign for $^2J(^{119}Sn,^{117}Sn)$ for **2**.

ing the C-Sn-C angle by using the $^1J(^{119}Sn, ^{13}C)$ coupling constants. Many investigations have confirmed a linear correlation between these values.[8] According to calculations based on this work,[8] the C-Sn-C angle in **2** is 122.5°, which implies a trigonal-bipyramidal geometry at the Sn atom.

Noticeable are also the very different geminal $^2J(^{119}Sn, ^{117}Sn)$ coupling constants of **1** and **2**.[9a] The value of $|^2J|$ decreases by about 150 Hz for **2**. If one assumes that the coupling constant is negative, as in **1**,[9b] the decrease in the value of the scalar coupling means an increase of the s contribution in the Sn−N bonds, which should be linked to a bond shortening and a widening of the Sn-N-Sn angle.[10, 11] This assumption is supported by the significantly smaller value of the $^1J(^{119/117}Sn, ^{15}N)$ coupling constant in **2** in comparison to that found for **1**. For the latter compound and for a large number of other mono- and distannylamines a negative sign has been observed for the ^1J value.[11] Thus here too a smaller negative value for the ^1J coupling corresponds to a larger s contribution in the Sn−N bonds.[11a] These interpretations of the NMR data of **2** are supported completely by the crystal structure (Fig. 1).[12]

The crystal data support the almost undistorted D_{3h} symmetry of **2**. The planar NSn_3Cl_3 molecular skeleton is noteworthy. The sum of the angles at the nitrogen atom is 360°. The intramolecular, almost symmetrical Sn-Cl-Sn bridges, which lead to pentacoordination of the Sn atoms are typical for **2**. The assumption, according to the Bent rule,[13] that the equatorial bonds should have more s character than the axial is supported by a clear shortening of the Sn−N bonds to 199 pm. This leads to smaller values for the $^1J(^{119/117}Sn, ^{15}N)$ and $^2J(^{119}Sn,^{117}Sn)$ coupling constants. To our knowledge **2** has the shortest Sn−N bonds observed to date.[10] The sum of the covalent atomic radii of both elements is calculated as 203.3 pm.[14] Similarly, the Sn−C bonds at 208 pm are shortened in comparison to those in tetracoordinate Sn compounds (210 pm in $(o\text{-}iPr_2C_6H_3)N[Sn(CH_3)_2Cl]_2$[15] and 213 pm in $tBuN[Sn(CH_3)_2Cl]_2$[15]). The sum of the bond angles (360°) in the equatorial region of the tin centers confirms the planar arrangement of these substituents. The observed C-Sn-C angles in **2** agree with the value calculated from the NMR data (e.g. C1-Sn1-C2 121.8°).

The Cl−Sn bonds alternate between 270 and 280 pm. The intramolecular bridging function of the Cl atoms on the one hand leads to significantly longer Sn−Cl bonds than found in pentacoordinate, nonionic Sn compounds (e.g. $(CH_3)_3SnCl\cdot py$: 246.0 pm[16]), but on the other hand it causes a distortion of the trigonal-bipyramidal coordination polyhedron of the tin atoms in **2**. The Cl-Sn-Cl bond angle is thus only 164 instead of 180°. Thus, the chlorine bridges can also partially cause the shortening of the Sn−N bonds. The molecular structure of **2** is the first example of an intramolecularly bridged tin−nitrogen compound and a further example of the importance of the Sn-Cl-Sn bridges in determining the structure. These bridges, which also exist in solution, have previously only been confirmed[17b] for the

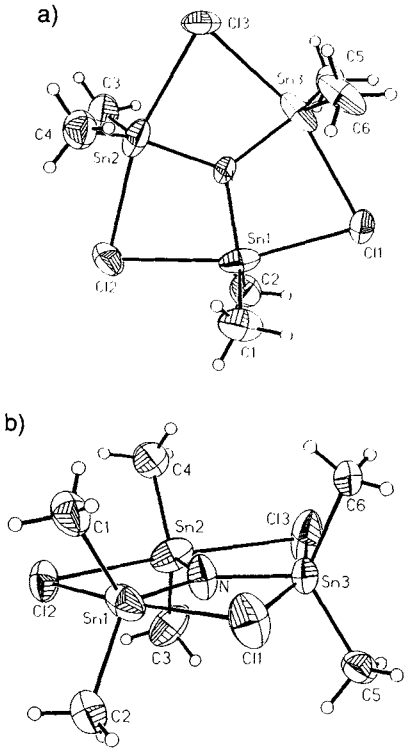

Fig. 1. a) Molecular structure of **2** (ORTEP representation). b) Structure of **2** side view. Thermal ellipsoids correspond to a 25% probability level. Selected bond lengths [pm] (standard deviations in parentheses) and angles [°]: Sn1-N 201(1), Sn2-N 198(1), Sn3-N 197(1), Sn1-C1 208(2), Sn1-C2 207(2), Sn1-Cl1 269.6(6), Sn1-Cl2 282.4(5), Sn2-Cl2 272.3(5), Sn2-Cl3 279.3(6), Sn3-Cl3 275.5(6), Sn3-Cl1 280.7(5); Sn1-N-Sn2 118.3(7), Sn1-N-Sn3 119.5(6), Sn2-N-Sn3 122.1(6), N-Sn1-C1 118.0(6), N-Sn1-C2 119.9(6), Sn1-Cl1-Sn3 77.3(1), Sn1-Cl2-Sn2 76.3(1), Sn2-Cl3-Sn3 77.2(1), Cl1-Sn1-Cl2 163.7(2), C1-Sn1-C2 121.8(7).

cyclodimeric distannylamine $[CH_3N\{Sn(CH_3)_2Cl\}_2]_2$[10] and the corresponding distannoxane $[\{Cl(CH_3)_2Sn\}_2O]_2$.[17a]

The analytical results of the unusual structure of **2** are also confirmed by geometry-optimized approximate calculations. AM1 calculations[18] for the parent compound $N(SnH_2Cl)_3$ show that a Sn-Cl-Sn bridged structure is around 104.5 kJ mol^{-1} less energetic than an unbridged structure. The potential energy surface for 13 various Sn−Cl distances and 10 N-Sn-Cl angles (Fig. 2) shows that for a simultaneous lengthening of the Sn−Cl bonds and a decrease in the N-Sn-Cl bond angles only a small barrier of <4 kJ mol^{-1} needs to be overcome to leave the extremely flat hollow of the minimum of the unbridged form and to proceed with a steady energy gain to the bridged form. The barrier to rotation about the N−Sn bond for the unbridged form is only 8.4 kJ mol^{-1} according to AM1 calculations. Compound **2**, according to these model calculations, has a trigonal-planar nitrogen center with a lone pair in a p type orbital. A planarization of the region around the nitrogen atom has been structurally confirmed for trisilyl-[3a, b] and trigermyl-

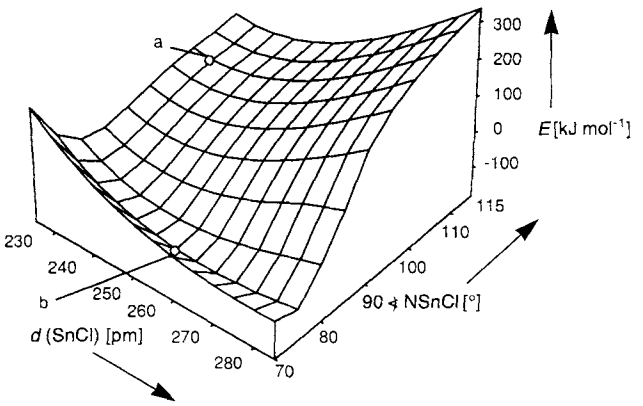

Fig. 2. AM1 potential energy surface of Sn-Cl-Sn bridged and unbridged $N(SnH_2Cl)_3$ (a: unbridged, b: bridged).

amines.[3c] The p character of the lone pair at the trigonal-planar nitrogen center was first documented for the sterically demanding triisopropylamine.[4]

A comparison of the structural data determined for **2** and the results of the AM1 calculations for $N(SnMe_2Cl)_3$ shows good agreement between the Sn–N bond lengths as well as between the Sn-N-Sn angles.[19] The energy difference between the bridged and unbridged forms is 143.5 kJ mol^{-1} according to AM1 calculations. The experimentally observed asymmetry of the Sn-Cl-Sn bridges could not be confirmed by calculations. An approximate value for the Sn-Cl-Sn bridge bond energies of about 46 kJ mol^{-1} can be estimated from the calculated energy differences. Indications of (pd)π interactions between the nitrogen and the tin atoms cannot be inferred from spectroscopic investigations (NMR and Mössbauer data[20]) or from the quantum mechanical model calculations, since these confirm the structure and bonding without including the d orbitals.

[5] *Experimental Procedure*: To a solution of $(CH_3)_2SnCl_2$ (68.9 g, 314 mmol) in CH_2Cl_2 (120 mL) was added dropwise at 0 °C with stirring 50 vol% of a solution of $[(CH_3)_3Sn]_3N$ **1** (52.8 g, 105 mmol) in CH_2Cl_2 (70 mL). The rest of this solution (50 vol%) was added at −35 °C. After slow warming and 12 h stirring at room temperature the solvent was condensed at about 25 °C/12 Torr into a cold trap cooled to −78 °C. Subsequently, $(CH_3)_3SnCl$ (59.5 g, 95%) was sublimed off. This process was completed by repeated dissolution of the residue in CH_2Cl_2, followed by removal of the solvent, and renewed sublimation. After recrystallization from CH_2Cl_2 53 g (90%) tris(chlorodimethylstannyl)amine **2** (m.p. 164–166 °C) was obtained. Crystals suitable for the X-ray structure analysis were obtained by slow diffusion of petroleum ether into a saturated solution of **2** in CH_2Cl_2 at room temperature. NMR data see Table 1. MS (15 eV; based on ^{120}Sn, ^{35}Cl): *m/z* (assignment), %: 567 (M^+), 1; 552 ($M^+ - CH_3$), 100; 332 ($M^+ - (CH_3)_2SnCl_2 - CH_3$), 12; 302 ($M^+ - (CH_3)_2SnCl_2 - C_2H_6 - CH_3$), 31; 282 ($M^+ - (CH_3)_2SnCl_2 - C_2H_6 - CH_3Cl - CH_3$), 22.
[6] We thank Dr. Dr. habil. A. Sebald, Universität Bayreuth, for recording the CP-MAS solid-state NMR spectra.
[7] For example the region around the N atom, according to the spectroscopic data, is planar for $(CH_3)_2B-N[Sn(CH_3)_3]_2$, $\delta(^{14}N) = -272$ [9a] and pyramidal for $CH_3N[Sn(CH_3)_3]_2$, $\delta(^{15}N) = -358.2$ [11a].

Nitrosyl Azide, N_4O, an Intrinsically Unstable Oxide of Nitrogen**

By *Axel Schulz, Inis C. Tornieporth-Oetting,** and *Thomas M. Klapötke**

Dedicated to Professor Paul von Ragué Schleyer

Nitrogen is able to form no fewer than six molecular oxides (N_2O, NO, N_2O_3, NO_2, N_2O_5, NO_3). Two (NO and NO_2) form π*–π* bound dimers, and all are thermodynamically unstable with respect to decomposition into N_2 and O_2.[1, 2] Although they all possess positive heats of formation, they are not intrinsically unstable with the exception of

[**] This work was supported by the Deutsche Forschungsgemeinschaft (KL 626/2-2), the Fonds der Chemischen Industrie, and the Bundesministerium für Bildung und Wissenschaft (Graduiertenkolleg). We thank Prof. Dr. Dr. R. Hoppe for stimulating information.

the paramagnetic radical NO_3, which has not been isolated as a pure compound.[1] Moreover, prior to our work there had been some evidence for nitryl azide (NO_2N_3) and the substantially less stable nitrosyl azide (NON_3).[3] However, the identification of NON_3 was essentially based on the identification of its decomposition products (N_2 and N_2O) and four IR bands, three of which can definitely *not* be assigned to NON_3.[4, 5] The objective of our work was to establish the existence of this intriguing tetranitrogen monoxide and to elucidate its structure by a combination of low-temperature Raman spectroscopy and high-level quantum mechanical ab initio computations. As N_4O is intrinsically unstable, low-temperature techniques are more suitable than room-temperature gas-phase IR or electron diffraction studies to characterize this compound.

Reaction of activated, anhydrous NaN_3 and NOCl, followed by low-temperature vacuum sublimation, produced solid, pale yellow N_4O [Eq. (a)]. N_4O was unambiguously identified by its low-temperature Raman spectrum (Fig. 1) and, in agreement with earlier work,[4] was shown to decompose yielding N_2O and N_2 (identified by Raman spectroscopy and mass spectrometry and gas discharge—Teslar coil) [Eq. (b)].

$$NaN_3\ (\text{excess}) + NOCl \xrightarrow{-196 \le T \le -55\,^{\circ}C} NaCl + N_4O \qquad (a)$$

$$N_4O \xrightarrow{T \ge -50\,^{\circ}C} N_2O + N_2 \qquad (b)$$

To support our Raman data of N_4O, the structure and vibrational frequencies were computed with ab initio methods. The calculations were carried out with the Gaussian 92 program and the 6-31 + G* basis set.[6, 7] The geometries

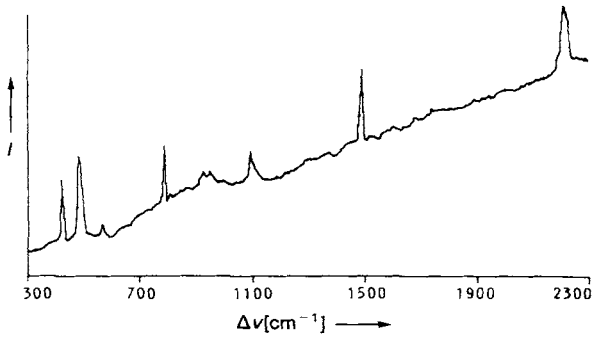

Fig. 1. Raman spectrum of N_4O in the range of 300–2300 cm^{-1} (647 nm, 30 mW, −110 °C, 3 scans, 1 s/p, 1 s integration time).

were fully optimized at the HF level and at correlated level according to Møller-Plesset second order perturbation theory (MP(FC)). Since the HF calculation predicted an unreliable, short terminal N2–N3 bond length of 1.088 Å,[8] the vibrational frequencies were computed on the correlated MP2 level (6-31 + G*). Table 1 shows the computed, scaled,[7] and observed frequencies and their assignments.

In agreement with the experimental spectroscopic results, the ab initio computation also shows a (planar, C_s) chainlike N_4O structure for nitrosyl azide. The optimized geometry and the computed structural parameters of N_4O, as well as the most likely Lewis representation, are shown in Figure 2.

As indicated by NBO analysis,[9] there is a significant interaction of one of the lone pairs on oxygen with the unoccupied, antibonding σ* orbital of the N1–N4 bond. This LP(O) → σ*(N1–N4) (negative) hyperconjugation[10] accounts for the rather long N1-N4 bond of 1.48 Å (cf. N_2F_4, d(N–N) = 1.49 Å).[11] Moreover, the ON–N_3 bond has a polarity $ON^{\delta+}$–$^{\delta-}N_3$ (cf. Fig. 2) that resembles the situation of the polarized covalent azides BrN_3 and IN_3.[12] The N_4-O distance of 1.20 Å is 0.07 Å longer than that in NOCl (1.13 Å),[1] corresponding to a bond order (b) slightly less than 2 (usual values for d(N–O): b = 1, 1.36 Å, b = 2, 1.16 Å).[1] Finally, all structural parameters of the (*trans*-bent) azide unit are in good agreement with other covalent azides.[13]

Table 1. Computed (MP2) and experimentally observed vibrational frequencies [cm^{-1}] of N_4O.

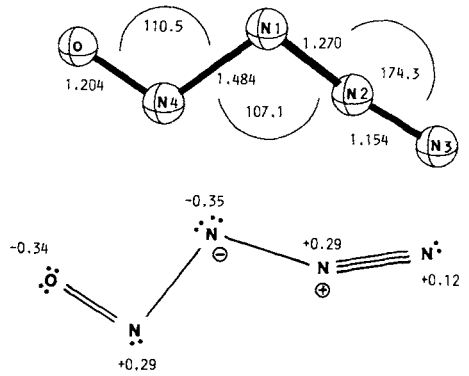

Fig. 2. Top: MP2-optimized geometry (distances in Å, angles in °); bottom: Lewis representation with natural bond order (NBO) charges for N_4O.

The dissociation of isolated, gaseous N_4O molecules into N_2O and N_2 according to Equation (b) was calculated to be strongly exothermic (after temperature correction for H by means of C_p and inclusion of the work term): ΔH^0_{298} [Eq. (b), MP2] = −91 kcal mol^{-1}.[14] It is interesting to note that N_4O is one of the few examples of an intrinsically unstable molecule that has been isolated as an essentially pure compound.

The cyclic, aromatic, 6π isomer of ON–N_3 (isoelectronic to N_5^-) was computed to be 13 kcal mol^{-1} more favorable than the observed chainlike species (MP2(FC)/6-31 + G*). The preference for the *trans*-chain form[15] can easily be explained by the reaction mechanism. The *trans* isomer formed in the first step could easily convert into the *cis* isomer (1 kcal mol^{-1} less stable); however, the cyclization requires a high activation energy (49 kcal mol^{-1}) because of the necessary bending of the azide unit.

We intend to report on the theory of the bonding in nitrogen oxides in a full paper.[16]

Experimental Procedure

Caution: Covalent azides are potentially hazardous and appropriate safety precautions should be taken.

N_4O was prepared by condensing gaseous NOCl (purified by distillation; 0.36 g, 5.54 mmol) from the calibrated, stainless steel, vacuum apparatus (the quantities of the materials were determined by volume changes at constant pressure) at −95 °C onto anhydrous NaN_3 (3.60 g, 55.38 mmol, excess) activated by recrystallization from SO_2. After the mixture was warmed to −55 °C (cf. m.p. (NOCl) = −59.6 °C) and allowed to react for 4 h, the product was sublimed into a 5 mm Raman capillary (−196 °C). Traces of N_2 and N_2O (b.p. (N_2O) = −88.5 °C) were pumped off at −85 °C leaving behind N_4O as a pale yellow solid in approximately 20% yield (0.08 g, 1.1 mmol). A mass spectrum of the sublimed and decomposed product (EI, 70 eV, 25 °C) showed N_2O to be present (m/e = 44; most intense signal beside N_2 and O_2). Subliming cold N_4O into the vacuum within an IR gas cell held at room temperature only gave evidence for the decomposition product N_2O.

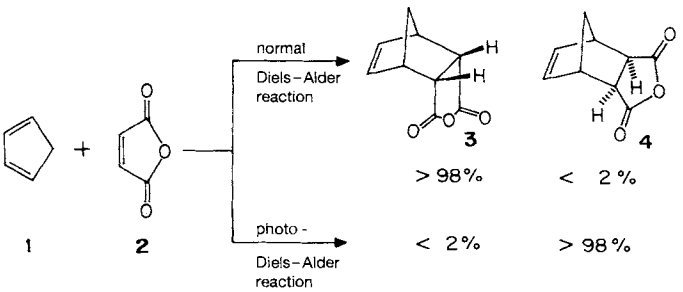
Photo-induced *exo*-Selective Diels–Alder Reactions**

By *Bipin Pandey** and *Pramod V. Dalvi*

Dedicated to Professor Manapurathu Verghese George on the occasion of his 65th birthday

The 65-year-old Diels–Alder reaction[1] and its intramolecular,[2] inverse-electron demand,[3] hetero,[4] and asymmetric[5] variants offer many synthetic advantages in view of their simplicity and versatility. The chemo-, regio-, and stereoselectivity associated with these reactions, besides proving to be a productive testing ground for theoretical organic chemists,[6] have widely been exploited in the synthesis of natural products.[2–5, 7] Of the various levels of stereoselectivity, a particularly important feature is the predominant formation of the *endo* isomer in the thermal reaction of cyclic dienes with cyclic dienophiles.[8] The alternative possibility of exclusive *exo* selectivity is usually not achieved by conscious modification of reaction conditions,[8] although some substrate-specific exceptions are known.[9] We now report some examples, in which exclusively the *exo* isomer is obtained in Diels–Alder reactions by a suitable choice of reaction conditions.

It is known that when cyclopentadiene (**1**) is warmed with maleic anhydride (**2**), the selectivity is >98% for the *endo* isomer **3**.[8] In marked contrast, the photolysis of **1** (6.6×10^{-4} mol) and **2** (5.7×10^{-4} mol) in 5% triethylamine in dry ethanol (20 mL) furnished essentially (>98% selectivity) *exo* isomer **4** (38%) (Scheme 1 and Table 1, entry 1). The generality of *exo*-selective photo-Diels–Alder reactions is indicated in Table 1.



Scheme 1. *endo*- and *exo*-selective Diels–Alder reactions of **1** with **2**.

Table 1. Photo-induced, *exo*-selective Diels–Alder reactions.

Entry no	Dienophile	Molar ratio [a]	Reaction condition [b]	Photolysis duration [h]	Product (yield [%]) [c, d]
1	**2**	1:1.2	A	1	**4** (38)
2	**2**	1:1.2	A	0 [e]	**4** (0)
3	**2**	–	A	1	**2** (90)
4	**11**	1:1.2	C	2	**5a** (34) [f]
5	**12**	1:5	D	6	**6a** (26) [g]
6	**12**	1:2.3	C	6	**6a** (42) [f, g]
7	**13**	1:10	E	5	**6b** (35) [h]
8	**13**	1:5	D	5	**6b** (81)
9	**13**	1:12	B	5	**6b** (25)
10	**14**	1:10	B	4	**6c** (68)
11	**15**	1:1.3	A	2	**5b** (64) [i]
12	**15**	1:1.3	A	0 [e]	**5b** (0)
13	**2**	1:1.2	A	1	**8** (44)
14	**12**	1:2.2	B	6	**7a** (54)
15	**13**	1:2.5	C	6	**7b** (42)
16	**16**	1:1.1	C	2	**9** (70)
17	**17**	1:1	C	2	**10** (48)

[a] The molar ratio of dienophile: diene is presented. Cyclopentadiene **1** (entries 1–12 as well as 16 and 17) and cyclohexadiene (entries 13–15) were used as diene. [b] The photo-Diels–Alder reactions were carried out in the presence of different quantities of triethylamine in dry ethanol (% volume): A = 5%, B = 10%, C = 20%, D = 50%, and E = 98%. [c] The yield is for isolated pure adduct and is based on consumed dienophiles [10, 11]. The conversion of dienophiles was invariably greater than 90%. [d] The absence of *endo* isomer (i.e. >98% *exo* selectivity) was confirmed by thin-layer and/or gas chromatography [12]. [e] Control experiments (entries 2 and 12) were carried out in dark and at room temperature for the same length of time as in the corresponding photochemical experiments (entries 1 and 11). No *endo* or *exo* isomer was observed. [f] Side products due to triplet-sensitized diene dimerization, for example *exo* and *endo* dimers of **1** [13, 18]. [g] 1,4-Dihydronaphthalene as side product. [h] 1,4,5-Trihydroxynaphthalene as side product. [i] 2-Methyl-4-hydroxyphenol as side product.

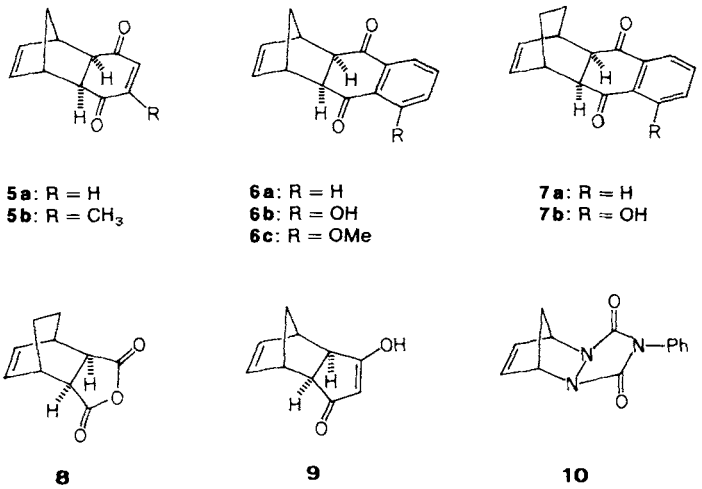
[**] NCL Communication No. 5746. This work was supported by the Director of the National Chemical Laboratory, Dr. R. A. Mashelkar (Senior Research Fellowship for P. V. D. and a Kite Flying Grant for B. P.) and by the Department of Science & Technology, India (instrumentation support).

The *exo*-products **4**–**10** (Scheme 2)[10] have been obtained by reacting either **1** or 1,3-cyclohexadiene (CHD) with common cyclic dienophiles, for example maleic anhydride (**2**), 1,4-benzoquinone (**11**), 1,4-naphthoquinone (**12**), 5-hydroxy-1,4-naphthoquinone (**13**), 5-methoxy-1,4-naphthoquinone (**14**), 2-methyl-1,4-benzoquinone (**15**), 4-cyclopentene-1,3-dione (**16**), and 4-phenyl-1,2-dehydro-1,2,4-triazole-3,5-dione (**17**) under various photochemical conditions (Table 1).



Scheme 2. *exo* Products that were prepared under different photochemical reaction conditions (see Table 1).

Several characteristic features of these reactions are summarized in the following: 1) Photo-Diels–Alder reactions are highly *exo* selective. 2) Photolysis is essential for the success of the reaction (entries 2 and 12). 3) The duration of photolysis is short, that is 1–6 h. 4) The yield of *exo* isomer ranges between 25–81%.[10, 11] 5) With naphthoquinone-type dienophiles, 20–50% of Et_3N in ethanol gives satisfactory yields of *exo* isomers (entries 6, 8, and 15). Very high concentration of Et_3N furnishes reduced products, for example 1,4-dihydroxynaphthalene and 1,4,5-trihydroxy naphthalene (entries 5 and 7). 6) Et_3N, as such, does not react with **2** under photolytic conditions (entry 3). 7) *exo*-Selective transformations can also be carried out on a gram scale (see Experimental Procedure). 8) Normally, our methodology is suitable for dienophiles containing carbonyl groups. However, photolysis of pure **1** under the reaction condition C (see Table 1) for 5 h gave a 60:40 mixture of the *exo*/*endo* dimers.

The present study unequivocally establishes the ability of triethylamine to reverse the *endo* selectivity of Diels–Alder reactions. However, one can only speculate on the electronic origin of this effect. *Endo* selectivity is generally believed to be due to secondary orbital overlap between the diene HOMO and the dienophile LUMO.[6, 14] The electron-rich Et_3N seems to disturb this secondary orbital overlap interaction in the transition state of the Diels–Alder reaction,[15] perhaps by complexing with the dienophile in the excited state.[16] An alternative explanation could be the selective isomerization of *endo* isomer under photolytic conditions.[17] But this possibility is partially valid only with highly reactive dienophiles for example **2**, **11**, and **17**. With other, less reactive dienophiles, no *endo* product was observed in control experiments. Another control experiment in which **1** and 1,4-naphthoquinone **12** in 20% Et_3N/EtOH were heated under reflux did not lead to the formation of the *exo* isomer **6a**. Additionally, photolysis of diene **1** and dienophile **12** without Et_3N is known to give triplet-sensitized diene dimers and [2 + 2] photocycloaddition products.[18, 19]

In summary, a novel photochemical methodology for *exo*-selective Diels–Alder reactions with dienophiles containing carbonyl functionality has been developed. We are currently investigating the role of triethylamine and generality of our *exo*-selective procedure for inter-, and intramolecular, asymmetric and as well as hetero-Diels–Alder reactions.

Experimental Procedure

6a (large-scale preparation): To a solution of 1,4-naphthoquinone **12** (4.0 g, 31.6×10^{-3} M) in ethanol/triethylamine (50/50; this ratio usually gave the best yield for large-scale preparations, although the 80/20 ratio led to a similar yield for small-scale reactions, see entry 6 Table 1) (800 mL) in a pyrex tube, freshly cracked cyclopentadiene **1** (3.8 g, 72.0×10^{-3} M) was added, and the reaction mixture was purged with a slow stream of nitrogen for 10 min. The solution was then irradiated at 300 nm with a Rayonet photochemical reactor with constant stirring and cooling at room temperature for 6 h. Progress of the reaction was monitored by thin-layer and gas chromatography, until more than 95% of the dienophile was consumed. After removal of the solvent and triethylamine under reduced pressure, the residue was chromatographed on a silica gel column by eluting with 5% acetone/hexane to give **6a** (2.44 g, 43%). M.p. 160 °C; IR (nujol): $\tilde{\nu}[cm^{-1}] = 1650\ cm^{-1}$ (C=O); ^1H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta = 1.5$ (m, 2H, CH_2), 2.35 (m, 2H, CH), 4.15 (m, 2H, CH), 6.8 (m, 2H, vinylic H), 7.5–7.7 (m, 2H, aromatic H), 7.9–8.1 (m, 2H, aromatic H); ^{13}C NMR (50.32 MHz, $CDCl_3$): $\delta = 181.23$ (s), 162.66 (s), 142.25 (d), 132.91 (d), 132.53 (d), 125.82 (d), 73.02 (d), 48.44 (t); MS (70eV): *m/z* 224 (90%) [M^+]; correct analysis (C,H) for $C_{15}H_{12}O_2$.

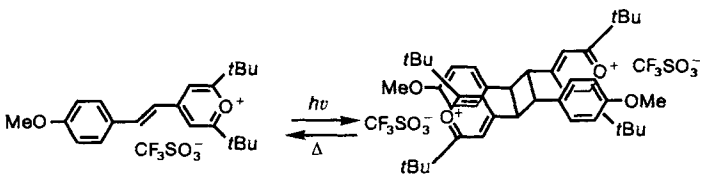
Crystallographic Study of a Single Crystal to Single Crystal Photodimerization and Its Thermal Reverse Reaction**

By *Kathleen Novak, Volker Enkelmann,* Gerhard Wegner,* and *Kenneth B. Wagener*

Topochemical reactions proceed in crystals under the strict control of the crystal lattice. The best studied topochemical reactions are [2 + 2] photocycloadditions[1] and the solid state polymerization of diacetylenes.[2] In their pioneering work on the [2 + 2] photodimerization of cinnamic acid derivatives, G. M. J. Schmidt et al. observed that of many possible dimers, only the one whose symmetry is already preordained in the crystal packing of the monomers is formed.[3] Photodimerizations of this type proceed heterogeneously, as do most topochemical reactions; that is, at a certain extent of conversion, phase separation occurs. This destroys the monomer crystal and results in the formation of microcrystalline aggregates. The driving force is the anisotropic changes in the lattice that occur when van der Waals forces are transformed into chemical bonds in particular directions. In contrast, homogeneous topochemical reactions, for example the solid state polymerization of diacetylenes, are characterized by the persistence of the crystal throughout the whole conversion range.[4] The monomer and polymer form a substituted mixed crystal in which monomer and polymer are statistically distributed when conversion is incomplete and occupy identical lattice positions. This is possible, because the accompanying chemical reactions, which in part involve substantial atomic shifts, are limited to only a few atoms in the center of the molecule, while the substituents form a matrix that, as a first approximation, does not alter its position during the reaction.

The system shown in Scheme 1 and first described by Hünig and Hesse,[5] does not only undergo the [2 + 2] photodimerization homogeneously, as described for individual cases in the literature,[4] but also returns thermally to a pure crystal of the monomer. It is thus possible in this case to switch between monomer and dimer state without loss of crystal quality.



Scheme 1. Reversible [2 + 2] photodimerization in the crystal.

The key to this behavior lies in the choice of a suitable wavelength for the photodimerization. If the wavelength of the absorption maximum of the styrylpyrilium chromophore (λ_{max} = 420 nm) is used, the heterogeneous reaction typical for cinnamic acid derivatives is observed: Initially yellow microcrystalline aggregates of the dimer form on the surface of the red crystals. On further irradiation the original monomer crystals break up completely. This behavior persists for monochromatic irradiation with wavelengths up to λ = 540 nm. However, if the wavelength corresponds to the flank of the absorption, more than 150 nm longer than λ_{max} (λ > 570 nm), the crystal is preserved over the whole reaction. Nevertheless, the choice of wavelength does not influence the crystal structure of the incipient dimer. The position of the reflections and their intensities in the X-ray powder diffractogram of the microcrystals obtained on UV irradiation correspond to those from single-crystal structure analyses. Figure 1 shows projections of views of the crystal structures of the monomer and the dimer, as well as of two monomer–dimer mixed crystals that were isolated after different irradiation times.[6] In the mixed crystals, separate

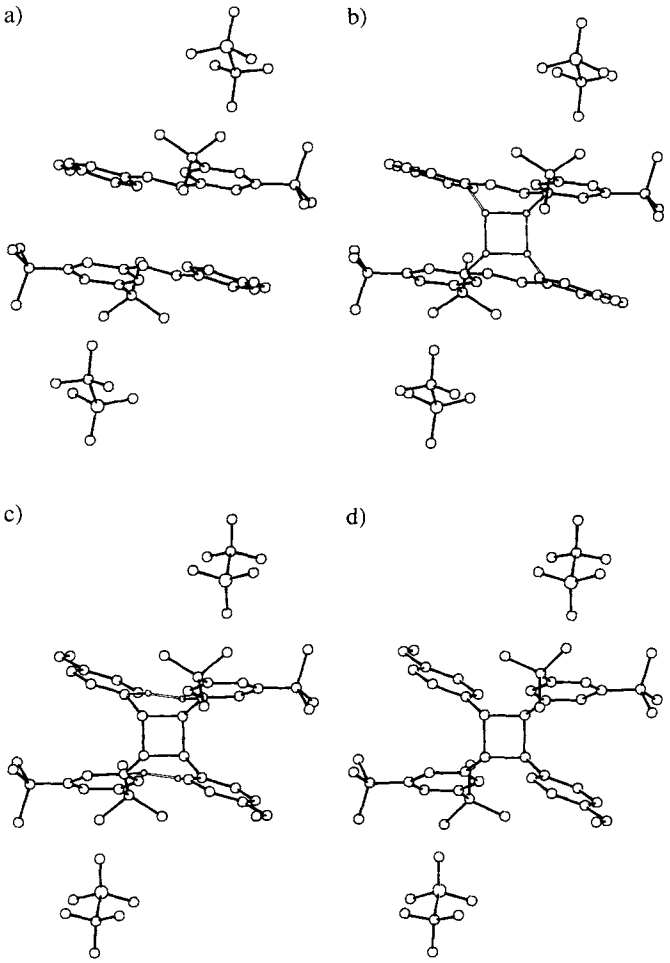


Fig. 1. Sections of the crystal structures of a) the monomer, b) a monomer–dimer mixture after 13% conversion, c) a monomer–dimer mixture after 67% conversion, and d) the dimer for the reaction in Scheme 1.

atomic coordinates are found only for those C atoms directly involved in the reaction. The occupation parameters of these atoms were optimized in the refinement and agree with the values obtained by IR spectroscopy.[7] The positions of other atoms in the mixed crystal are identical within the error limits of the structure analysis. The comparison of the crystal structures depicted in Figure 1 reveals that in the course of the reaction the positions of these atoms change substantially. For instance, the phenyl ring twists during the reaction by 18°. Similar movements of the pyrilium ring and the counterion can also be detected. The change in conformation appears to be continuous, since the dihedral angle determined from the mixed crystals lies between the two end states.

The counterion and the *tert*-butyl groups are disordered in the monomer at room temperature, and their two orientations are statistically occupied. This is probably caused by a dynamic process. The solid state ^{13}C MAS NMR spectrum contains only one peak for the *tert*-butyl groups at room temperature.[8] Accordingly we assume that the dynamic process is a jump rotation between the two sites. This is frozen at low temperature. If the crystal structure is determined at 165 K, all disordered groups are present in only one of the two orientations. Surprisingly, in the dimer the disorder no longer occurs at room temperature. Apparently the cavities in the monomer in which these groups rotate are changed to such an extent that the movement is no longer possible after the reaction, although in the dimer no significantly smaller C–H contacts are observed.

The photochemically generated dimer is apparently in a metastable state. At temperatures greater than 100 °C the crystals of the monomer are reformed in a smooth reaction during which the unexpectedly small heat of reaction of 1.8 kcal mol^{-1} is released.[9] Preliminary experiments show that this is a reversible photochromic system. It is possible to store holograms photochemically in several cycles with a He–Ne laser (633 nm), to read them, and subsequently to delete them thermally.[10]

On recrystallization of the dimer from organic solvents another modification of the crystal is obtained. A view of the crystal structure of this form is illustrated in Figure 2.[6] In this modification of the dimer, the disorder described for the monomer is detected at room temperature. The dimer crystals formed on recrystallization can no longer be transformed back into the monomer, in contrast to the "as dimerized" form, but are stable at temperatures at which the latter are cleaved within a minute.

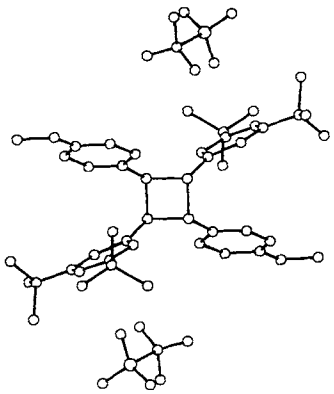

Fig. 2. Section of the crystal structure of the recrystallized dimer of the reaction in Scheme 1.

The ability to initiate a homogeneous topochemical photoreaction by irradiation into the outer absorption flank is not restricted to the system described here. Crystals of the oligomer of distyrylpyrazine have already been obtained in the same way.[4d] Some salts of styrylpyrilium monomers with counterions like ClO_4^-, BF_4^-, ReO_4^-, SbF_6^-, $AuCl_2^-$, or $SnCl_5^-$ likewise form photoreactive crystals that can be dimerized homogeneously in the same way. Preliminary experiments with α-*trans*-cinnamic acid indicate that here, too, a dimerization can take place while the crystal is retained.[11] It seems possible that further photoreactions in crystals that are heterogeneous under the usual irradiation conditions may be single crystal to single crystal transformations on irradiation into the outermost absorption flank.

It should be emphasized that topochemical control of the reaction is not affected by the homogeneous or heterogeneous course of the reaction. Every solid-state reaction is associated with anisotropic lattice changes. A steep concentration profile develops on irradiation into the absorption maximum, and the photoreaction takes place in only a thin layer on the crystal surface. As the lattices of monomer and dimer are not identical, the crystallites of the dimer detach from the surface of the crystal under these conditions. The observation of the crystal surface of heterogeneous systems therefore enables no conclusions about the mechanism of the photoreaction. The directed material transport observed by Kaupp[12] on the surface of cinnamic acid crystals under the atomic force microscope during irradiation describes the necessary structure of the crystallites under the chosen irradiation conditions, but does not support deductions on a violation of the topochemical principle.

Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für

wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57343, the names of the authors, and the journal citation.
[7] The monomer was prepared as described in [5]. The photodimerization was performed with a Coherent Innova ^{90}Kr laser. Eight to nine crystals 0.3–0.5 mm long were oriented so that the (100) surface was irradiated and slowly turned within a surface that was uniformly illuminated by means of a beam expander. Two to three of these crystals were subjected to crystallographic analysis, while the rest were used for IR spectroscopic studies. The calibration was achieved by irradiation of a mixture of monomer and dimer with a Xe lamp followed by establishment of the degree of conversion by ^{1}H NMR spectroscopy.
[8] The solid-state ^{13}C NMR spectra were recorded with a Bruker MSL 300 spectrometer at 75.47 MHz. The MAS (*m*agic *a*ngle *s*pinning) frequency was 3 kHz, and the CP (*c*ross *p*olarization) time 2 ms. A TOSS (*t*otal *s*uppression of *s*pinning *s*ide bands) pulse sequence was used. The detection time was 35 ms for a 90° pulse length of 4.5 μs. For a spectral width of 29.411 Hz, 2048 data points were collected.
[9] Thermoanalytical experiments were performed on a Mettler DSC 30 instrument at a heating rate of 5 K min^{-1}.
[10] A thick sinusoidal phase grating with a period of 17.3 μm was recorded on the (100) face of a crystal with two interfering beams from a 30 mW He–Ne laser. Between writing periods, one of the writing beams was blocked, and the intensity of the diffracted reading beam measured with a photomultiplier tube. After the desired diffraction intensity had been reached, the reading beam was attenuated by a factor of 2000 to avoid bleaching, and the thermal decay of the grating was monitored continuously.
[11] V. Enkelmann, G. Wegner, K. Novak, K. B. Wagener, *J. Am. Chem. Soc.*, in press. The dimerization of α-*trans*-cinnamic acid was performed at a wavelength of 360 nm and under these conditions is quantitative as a single crystal to single crystal transformation.

[Ni(P*t*Bu)$_6$] and [Ni(SiH$_2$)$_6$] Are Isolobal, Related to [In{Mn(CO)$_4$}$_5$]$^{2-}$, and Have 16-Electron Counts**

By *Huang Tang, David M. Hoffman,* Thomas A. Albright,* Haibin Deng,* and *Roald Hoffmann**

Recently Ahlrichs, Fenske et al.[1] reported the isolation, structure determination, and calculations of the unique compound **1**. The nickel and six phosphorus atoms in this com-

[Ni(P*t*Bu)$_6$] **1**

plex lie nearly in a plane. There is an interesting ambiguity in the electron counting for **1**.[1, 2] In one extreme, the P*t*Bu groups can be counted as two-electron (2e) donors, leading to a 22 electron count around the metal. Alternatively, the normal P–P distances lead one to think of two-center two-electron P–P bonds (i.e., (P*t*Bu)$_6$ is electronically saturated). But then what holds the Ni(0) within the cavity of the (P*t*Bu)$_6$ ring? There are also lone pairs on the phosphorus atoms of the (P*t*Bu)$_6$ ring, sites for potential metal coordination. But these do not point to the ring center.

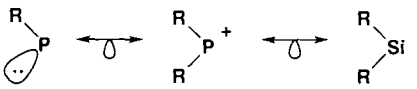
H. is a 1992–1994 Alfred P. Sloan Research Fellow.

The reason why **1** is stable and does not violate electron counting rules is symmetry-based. Consider first the hypothetical molecule **2** with a D_{6h} geometry. This is isolobal[3, 4]

[Ni(SiH$_2$)$_6$] **2**

with **1** because of the relationship between PR and SiR$_2$, as shown in Scheme 1. An idealized orbital interaction diagram



Scheme 1.

for **2** is present in Figure 1. The frontier orbitals of a carbenoid SiH$_2$ fragment consist of a radial sp^2 hybrid orbital pointing directly toward the Ni and a tangential p orbital.[4] Let us assume that intermixing between radial and tangential combinations of the same symmetry is minimal. The twelve resulting symmetry-adapted orbitals for the Si$_6$H$_{12}$ ligand are those shown on the right side of Figure 1. Three radial

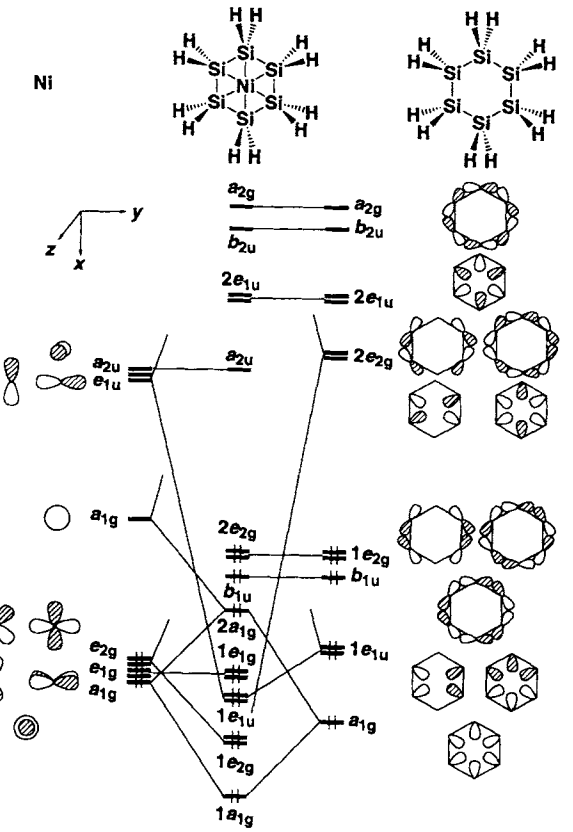


Fig. 1. An idealized orbital interaction diagram for [Ni(SiH$_2$)$_6$] (**2**) (D_{6h} symmetry).

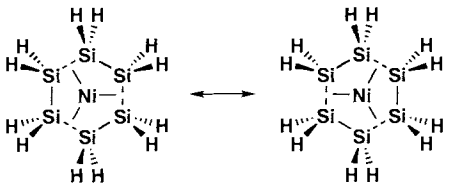
($a_{1g} + 1e_{1u}$) and three tangential ($b_{1u} + 1e_{2g}$) combinations are Si–Si bonding and thus are at low energies. These molecular orbitals (MOs) are the delocalized equivalent of six localized Si–Si σ bonds.

When the (SiH$_2$)$_6$ MOs are interacted with the valence atomic orbitals (AOs) of a Ni atom, a simple picture emerges. The Ni s and z^2 orbital[5] interact with the Si$_6$H$_{12}$ a_{1g} orbital to form a typical three orbital pattern,[4] with the

bonding $1a_{1g}$ and nonbonding $2a_{1g}$ MOs filled. Note that the topology of the $2a_{1g}$ orbital strongly resembles that found in square- or trigonal-planar complexes;[4] namely, the $2a_{1g}$ orbital is primarily Ni z^2 and Ni s mixed in an antibonding and bonding way, respectively, with the Si_6H_{12} a_{1g} orbital. The Ni xy and $x^2 - y^2$ orbitals overlap strongly with the $2e_{2g}$ Si–Si antibonding orbital set, and are stabilized. This interaction was also noted by Ahlrichs, Fenske et al. for $[Ni(PR)_6]$ (R = *t*Bu or Me).[1] The $1e_{1u}$ orbital set on Si_6H_{12} is stabilized by interactions with the Ni x and y orbitals. All other Ni and $(SiH_2)_6$ fragment orbitals remain nonbonding. In particular, the filled b_{1u} Si_6H_{12} orbital has no symmetry match with the Ni AOs. The $1e_{2g}$ Si_6H_{12} orbital set is comprised of tangential combinations in which the electron density is concentrated at the periphery of the Si_6 ring. Therefore, the overlap with the Ni $x^2 - y^2$ and xy orbitals is small (0.11 vs. 0.23 with the $2e_{2g}$ set).

The important result from Figure 1 is that three MOs of the $(SiH_2)_6$ fragment with six electrons remain Si–Si bonding and Ni–Si nonbonding. The other eight occupied MOs are either Ni–Si bonding orbitals or nonbonding Ni orbitals. Thus, $[Ni(SiH_2)_6]$ is effectively a 16-electron complex; a valence bond construction would include the resonance structures shown in Scheme 2:[6]



Scheme 2.

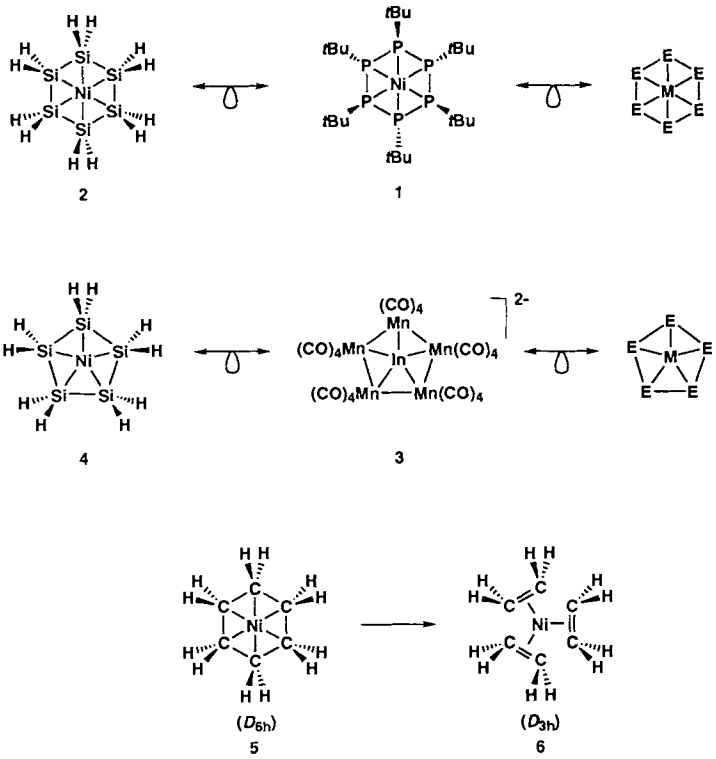
A detailed inspection of the bonding for $[Ni(SiH_2)_6]$ (**2**) and $[Ni(PH)_6]$ at the extended Hückel level[7] confirms our qualitative analysis and clearly shows that the electronic structures of both molecules are quite similar.[8] Note that the same result would be obtained for any isolobal analogue of **1** and **2**, including those with lower symmetry because the basic orbital topology does not change.

Equally interesting is the complex dianion **3**, whose potassium salt was recently synthesized by Ziegler et al.[9] In **3** the

$[In\{Mn(CO)_4\}_5]^{2-}$ **3**

indium atom and five manganese atoms lie almost in a plane. Assuming that indium is in the oxidation state III, each $[Mn(CO)_4]^-$ group could be considered a 2e donor,[3, 4] and the electron count around the indium atom would be 10 electrons. The formation of two-center two-electron Mn–Mn bonds would preclude the existence of any covalent bonding to the indium center. The relationship between the bonding in **1** and **3** is provided by the isolobal analogy (Scheme 3). $d^{10}s^0$ Ni^0 is isolobal to In^{3+}, and $[Mn(CO)_4]^-$ is isolobal to PR and CH_2.[3, 4] Thus, on the basis of the isolobal analogy, a series of compounds, such as $[Ni(PR)_5]$, $[In\{Mn(CO)_4\}_6]^{3-}$, etc., can be formulated. Moreover, because a PR fragment is isolobal to SiH_2, CH_2, S, etc., the series can be extended further. These compounds, on the surface, appear to be very electron rich and are rare examples of hexagonal- and pentagonal-planar coordinated metal centers. An interaction diagram for **3** and the isolobal **4** reveals

$[Ni(SiH_2)_5]$ **4**



Scheme 3. The molecules considered in this study. M = d^{10} metal or metalloid. E = PR, CH_2, S, etc.

a situation analogous to that in $[Ni(SiH_2)_6]$ (**2**). There are six electrons shared between In and Mn in the former molecule and 16 electrons either localized at Ni or shared between Ni and Si for the latter molecule. There are two inter-ring orbitals, topologically identical to the $2e_{2g}$ MOs of **2** (Fig. 1), which remain nonbonding to the central atom.

To further explore the generality of this class of complexes with a hexagonal- or pentagonal-planar coordinated central atom, we have carried out a series of ab initio MO calculations[10] with basis sets at three increasing levels of complexity (BS I–III).[11] The geometry optimizations and computations of the harmonic frequencies were done at the Hartree-Fock (HF) level with BS I. For $[Ni(SiH_2)_6]$ (**2**) (Scheme 3), a D_{6h} structure is found to be a minimum on the potential energy surface. The optimized Ni–Si and Si–Si distances are 241 pm. These are 7 pm longer than the experimentally observed values for Si_6Me_{12}.[13] In **1** the P–P bond lengths are 8 pm longer than those computed for the free cyclophosphane $(PtBu)_6$.[11] The binding energies of **2** relative to the ^1S ($3d^{10}$) state of Ni and the geometry optimized Si_6H_{12} ligands (D_{3d} symmetry, chair conformation) are given in Table 1). These values also include an estimate of the basis set superposition error.[14] The values at the electron-correlated MP2 and QCISD (quadratic configuration

Table 1. The calculated binding energies [kJ mol^{-1}] for **2** and **4** which include an estimate of the basis set superposition error.

interaction with single and double substitutions) levels are similar to those found in **1**.[1] In $[Ni(SiH_2)_5]$ (**4**), a minimum with D_{5h} structure is found. The binding energies, again relative to the ^1S state of Ni and to the geometry-optimized Si_5H_{10} ligands (C_s symmetry, envelope conformation), are only slightly smaller than those in **2**. Interestingly the Ni–Si and Si–Si distances are calculated to 220 and 259 pm, respectively. The Si–H bond lengths (147 pm) in **2** and **4** are identical. Several attempts were made to locate a D_{3h} structure as a minimum on the potential energy surface for **2**. In each instance the optimization collapsed back to the D_{6h} minimum. Note that the binding energies for **2** and **4** are greatly underestimated at the HF level; a similar situation exists for **1**.[1] Dynamical electron correlation apparently plays a critical role in setting the magnitudes.

The situation for the congener $[Ni(CH_2)_6]$ is quite different. The geometry-optimized D_{6h} structure, **5** (Scheme 3), possesses five imaginary frequencies. Furthermore, this structure lies 544 kJ mol^{-1} higher in energy than the tris-ethylene complex (**6**)[15] with D_{3h} symmetry at the HF level (BS I). The problem here is geometrical. The Ni–C and C–C distances in **5** are 185 pm. This is somewhat short for a Ni–C bond, and is much too long for an effective C–C bond; note in Figure 1 that six electrons remain in three intra-ring bonding MOs. Although geometric factors dominate, there is also an electronic component at work. That there is a striking difference in the balance between σ and π bonding for **5** and **6** on the one hand and the Si analogues on the other is not surprising—recall the similar difference between *cyclo*-O_6 and $3O_2$, and *cyclo*-S_6 and $3S_2$.

$[NiS_6]$ highlights another problem. For the D_{6h} geometry, the Ni–S and S–S bond lengths were found to be 237 pm, the latter of which is elongated by 31 pm compared to a free S_6 ring.[16] There are four imaginary frequencies associated with $[NiS_6]$. The complication here is due in part to the filled lone pairs on sulfur at the D_{6h} geometry which show both intra-ring repulsion and repulsion with the filled Ni xz, Ni yz orbitals.

In conclusion, we have shown that complexes with hexagonal- and pentagonal-planar coordinated transition metals should be regarded as 16-electron complexes. Compounds in this class will be stable provided that the interatomic distances in the ring are not too elongated in comparison to those of the free ligand and repulsions between lone pairs on the ring and filled metal d orbitals are minimized. In particular, the large binding energies associated with $[Ni(SiH_2)_6]$ (**2**) and $[Ni(SiH_2)_5]$ (**4**) strongly suggest that these compounds or their substituted derivatives should be stable. Experimental work on alkyl derivatives of **2** and **4** as well as theoretical studies on compounds with different ring sizes and atomic compositions are in progress.

[8] There is some intermixing between the tangential $1e_{2g}$ and radial $2e_{2g}$ sets of orbitals on the Si_6H_{12} ligand and between the orbital counterparts on P_6H_6. This leads to a three orbital mixing pattern with Ni $x^2 - y^2$ and xy orbitals, but the middle molecular orbital (analogous to $2e_{2g}$ in Fig. 1) is still nonbonding. There are repulsive interactions between the filled lone pairs on P with the Ni xz and yz orbitals in $[Ni(PH)_6]$. We also find there to be a rather small stabilizing interation between the Ni xz and yz orbitals with Si–H or P–H σ antibonding orbitals. This interaction would increase if there were a substituent more electronegative than hydrogen or alkyl on Si or P.

[11] BS I employed an effective core potential (ECP) [12a] on Ni, Si, S, and an associated double zeta basis set for the valence orbitals 3s, 3p, 3d, 4s, and 4p on Ni, 3s and 3p on Si and S. For C and H, BS I adopted the 3-21G basis set [12b]. In BS II the same ECPs were used for Ni and Si, while the valence 3d and 4p orbitals on Ni were further split into triple zeta, and *d* polarization functions with the zeta value taken as 0.395 [12c] were added onto the Si basis set. BS III is the same as BS II except for Si where the valence 3p orbital was split into a triple zeta set.

Computer-Assisted Design of Chiral Boron Enolates: A Novel, Highly Enantioselective Aldol Reaction for Thioacetates and Thiopropionates**

By *Cesare Gennari,* Daniela Moresca, Siegfried Vieth,* and *Anna Vulpetti*

It is well known that the enantioselective synthesis of *syn* aldols can be achieved nowadays with high efficiency by using a plethora of methods.[1] In contrast, the methods available for the synthesis of either *anti* or unsubstituted aldols are significantly less effective.[1–3] Here we describe a new chiral boron reagent for highly enantioselective synthesis of *anti* and unsubstituted aldols.

In boron enolate chemistry, *syn* aldols are easily obtained with good enantioselectivity from chiral *Z*(OB) enolates[4] because *Z*(OB) enolates have access to a single transition structure, the chair conformation **1**.[5] High selectivity for *anti* or unsubstituted aldols is more difficult to achieve because unsubstituted enolates and (partly) *E*(OB) enolates have access to a variety of transition structures, namely the chair conformation **1**, and the boat conformations **2** and **3** (Scheme 1).[5] This competition among transition structures

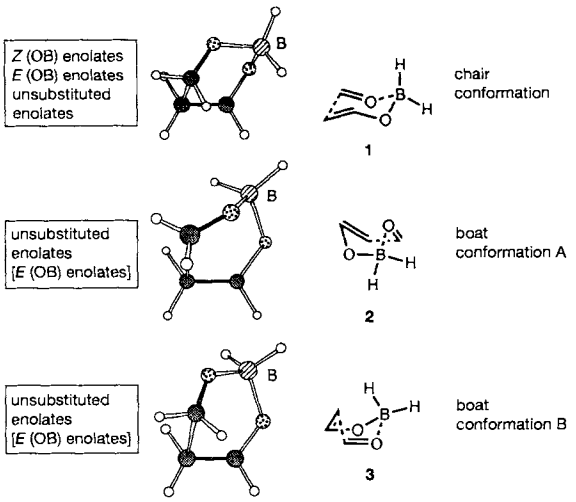
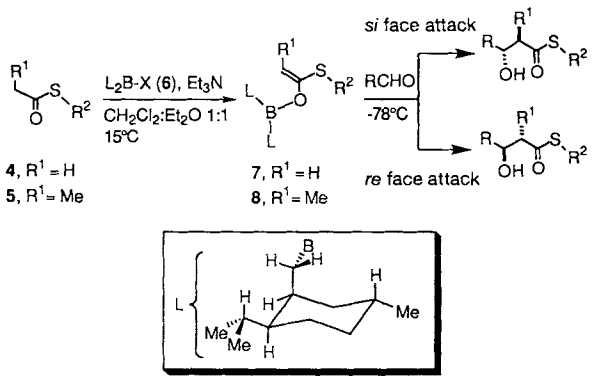
Goodman (Cambridge University, UK) for helpful discussions.

of similar energy (usually many conformers for each transition structure core-conformation **1**–**3**) makes the stereochemical control of the reaction much more difficult to obtain.



Scheme 1. Structures of the transition states (all-hydrogen substituted) determined by ab initio calculations for boron enolate aldol addition (see ref. [5a–c]).

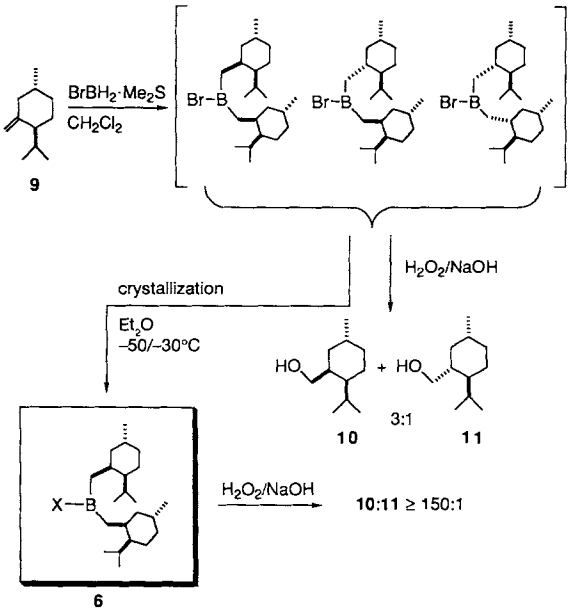
We have recently exploited transition state computer modeling to develop a new boron reagent (**6**, X = Cl) that allows the enantioselective synthesis of *anti* and unsubstituted aldols derived from ketones.[6] The chloroborane **6** (X = Cl) is efficient and selective in the enolization of methyl and ethyl ketones at −78 °C,[6] whereas it behaves poorly (0–15% yield) in the enolization of thioesters even at room temperature (Scheme 2), although the difference in pK_a between the two substrates is quite modest (CH_3COCH_3: $pK_a = 19.0$; $CH_3COSCH_2CH_3$: $pK_a = 20.4$–21.5).[7]



Scheme 2. Enantioselective synthesis of unsubstituted β-hydroxy thioesters and *anti* α-methyl-β-hydroxy thioesters.

Therefore a new reagent possessing a stronger Lewis acidity (**6**, X = Br) was synthesized (Scheme 3), starting with a Wittig reaction ($Ph_3P{=}CH_2$) on (−)-menthone to give (−)-(**9**) in high yield (≥90%).[6, 8] Hydroboration ($BrBH_2 \cdot Me_2S$) of (−)-(**9**) gave a mixture of diastereoisomers with a moderate preference for axial vs. equatorial -CH_2B- (**10**:**11** ≈ 3:1). Recrystallization (Et_2O, −50°/−30 °C) gave pure (**6**, X = Br) (28–30% yield; **10**:**11** ≥ 150:1).

Enolization of thioesters (**4** and **5**) proceeded smoothly at +15 °C with **6** (X = Br) and Et_3N in CH_2Cl_2/Et_2O



Scheme 3. Synthesis of reagent **6** (X = Br).

(Scheme 2). Addition of aldehydes at −78 °C gave the aldol products with good to excellent selectivity (Table 1). The following points are worth noting: a) The enolization of thiopropionates (**5**) preferentially results in the formation of *E*(OB) enolates **8**, as implied from the high *anti*:*syn* ratios observed in the aldol products. This preference is particularly strong for bulky substituents at sulfur (R^2) (see Table 1, entries 10, 13 (R^2 = *t*Bu) vs. 17, 18 (R^2 = Ph)). b) In the aldol reaction of thioacetates (**4**), the enantiomeric ratio is enhanced by the use of bulky substituents at sulfur (R^2) (see Table 1, entries 3 and 6 (R^2 = *t*Bu and $R^2 = CEt_3$) vs. 16 (R^2 = Ph)). Contrary to other reagents,[2o,p,r] there is no advantage in the use of the extra-large $R^2 = CEt_3$ (entries 4–

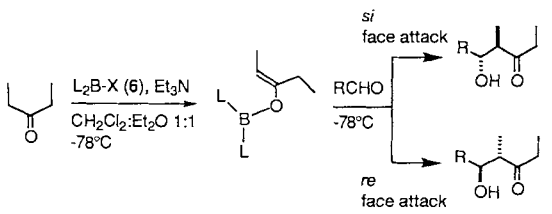
[a] For $[\alpha]_D$ value and absolute configuration of this compound, see ref. [3s]. [b] The aldol product was reduced ($LiAlH_4$, Et_2O/THF) to the corresponding diol for correlation, according to the supplementary material of ref. [2o]. [c] Absolute configuration of this product assumed by analogy. [d] The aldol product was transformed into the corresponding β-hydroxy acid (1. LiOH, H_2O_2, H_2O/THF 2. HCl) and methyl ester (CH_2N_2), according to ref. [3k], for $Eu(hfc)_3$ NMR analysis, and optical comparison with the known methyl ester (R = Ph). [e] The ratio can be improved to 97:3 by using iPr_2EtN instead of Et_3N for the enolization.

6) over the more readily accessible *t*Bu (entries 1–3). c) The absolute configuration of the aldol products is consistent with chair transition structures featuring preferential attack on the *re* face of the aldehyde, as suggested by the computer model.[6] The boat transition structures are probably irrelevant for both the *E*(OB) enolates (**8**) and the unsubstituted enolates (**7**). d) The role of SR^2 steric hindrance in enhancing the enantioselectivity is also consistent with the computed transition state model.[6] The model suggests a distinct steric interaction between SR^2 and the pseudo-axial chiral boron ligand in the chair transition structure for the disfavored attack on the *si* face of the aldehyde.

The new bromoborane **6** (X = Br) is a very good reagent also for the enolization of ketones (Scheme 4). Diethyl ketone gave with methacrolein the aldol product with a 97.5:2.5 *anti*:*syn* ratio (enantiomeric ratio of the *anti* aldol = 7.0:1), compared to the 93:7 *anti*:*syn* ratio (enantiomeric ratio = 7.0:1) of the chloroborane **6** (X = Cl).[6] Our bromoborane is also more selective than Brown's reagents[9] in the diethyl ketone aldol addition to benzaldehyde: *anti*:*syn* 90:10 (enantiomeric ratio of the *anti* aldol = 6.1:1) vs. *anti*:*syn* 70:30 (Chx_2BBr) (Chx = cyclohexyl)[9] and 79:21 (Chx_2BCl).[9]



R	*re*:*si* ratio	*anti*:*syn* ratio	yield [%]

Ph	6.1:1	90:10	70

Scheme 4. Enantioselective synthesis of *anti* aldols derived from ketones.

In conclusion, we have shown that the new borane **6** (X = Br), conceived by transition state computer modeling, is an excellent reagent for the enantioselective synthesis of *anti* and unsubstituted aldols.

Experimental Procedure

6 (X = Br): A solution of (−)-(**9**) (98%, 4.2 g, 27.1 mmol) in freshly distilled dichloromethane (13.0 mL) was treated with $BrBH_2$-SMe_2 (95%, Aldrich) (1.52 mL, 13.5 mmol) at 0 °C, under argon, with stirring. The reaction mixture was stirred at room temperature (RT) overnight. The solvent dichloromethane and dimethyl sulfide liberated during hydroboration were removed under vacuum (ca. 0.1 Torr) and the residue (a thick liquid or a low melting solid) was dissolved in dry diethyl ether (7.3 mL) under argon. The solution was cooled to −50 °C and left to crystallize for 1.0 h. The solvent was removed with a double-tipped needle (cannula) under argon at −50 °C; the remaining white crystals were washed with cold diethyl ether (1.0 mL) and the solvent removed again with a cannula. The crystals were then dissolved in dry diethyl ether (4.0 mL) at RT and cannulated off of a small amount of insoluble residue (white powder) into another flask. The solution was cooled (slowly!) to −45 °C and after 1.0 h the mother liquor was removed with a cannula from the crystals formed. The solid was washed with cold diethyl ether (1 mL) at −45 °C, the solvent removed again with a cannula, and the crystals redissolved in dry ether (4.0 mL) at RT. The solution was cooled (slowly!) to −30 °C and after 1.0 h the mother liquor was removed with a cannula from the crystals formed. The crystals were weighed under argon (1.62 g, 30%). The ratio between the diastereoisomers was determined by decomposition with hydrogen peroxide and VPC analysis (OV-1 column, 70–150 °C) of alcohols **10** and **11** (≥150:1) [6]. **6** (X = Br): ^{11}B NMR (200 MHz, $CDCl_3$, 25 °C, relative to BF_3-Et_2O): δ = 78.83. Methanolysis gave **6** (X = OMe): ^{11}B NMR (200 MHz, $CDCl_3$, 25 °C, relative to BF_3-Et_2O): δ = 55.05; ^{13}C NMR ($CDCl_3$): δ = 53.30 (OCH_3), 48.39, 42.26, 35.85, 31.38, 29.57, 26.17, 24.54, 22.74, 21.41, 20.69, 16.3 (broad, C-B). Treatment of **6** (X = OMe) with $HOCH_2CH_2NH_2$ in Et_2O gave **6** (X = $OCH_2CH_2NH_2$) [6]: ^{13}C NMR ($CDCl_3$): δ = 65.52 (OCH_2), 48.86, 42.62, (CH_2NH_2), 41.93, 35.98, 31.82, 29.41, 26.24, 24.51, 22.76, 21.45, 20.71, 16 (broad, C-B). Correct C,H,N analysis.

A 0.4 M stock solution was prepared by dissolving **6** (X = Br) (1.62 g) in dichloromethane (8.4 mL) and kept for weeks in the refrigerator at 0 °C without any appreciable decomposition.

General procedure for the aldol reaction: To a stirred solution of *tert*-butyl thioester (0.40 mmol) in diethyl ether (1.41 mL for **4**; 1.80 mL for **5**) at 0 °C (ice cooling), under an argon atmosphere a solution of **6** in dichloromethane (0.4 M; 1.41 mL, 0.56 mmol for **4**; 1.80 mL, 0.72 mmol for **5**), and then Et_3N (0.084 mL, 0.60 mmol for **4**; 0.156 mL, 1.12 mmol for **5**) were added dropwise. Enol borinate was generated with concurrent formation and precipitation of $Et_3N \cdot HBr$. After 5 min at 0 °C and 2.5 h at +15 °C (for **4**; 5.0 h at +15 °C for **5**), the mixture was cooled to −78 °C and the aldehyde (1.2 mmol) was added dropwise. The resulting mixture was stirred at −78 °C for 15 h, and then quenched with Et_2O (2 mL) and pH 7 phosphate buffer (2 mL). The aqueous phase was extracted with Et_2O (3 × 5 mL), and the combined organic extracts were dried (Na_2SO_4) and evaporated. The residue was dissolved in MeOH (3.5 mL) and phosphate buffer (1 mL) at 0 °C, and treated with 30% H_2O_2 (1 mL). After 20 min stirring at RT, the mixture was diluted with water and extracted with CH_2Cl_2 (3 × 5 mL). The organic phase was washed with a pH 7 phosphate buffer solution, dried (Na_2SO_4) and evaporated. The crude product was flash chromatographed to give the desired aldol compound. The enantiomeric excesses were determined by ^{1}H NMR spectroscopy ($CDCl_3$) in the presence of Eu(hfc)$_3$, splitting the R^2 = *t*Bu singlet (Table 1, entries 1–3 and 7–15), the vinylic methyl singlet (entries 3, 6, 13, 16, 17), and the R^1 = Me doublet (entries 10–15, 17, 18), in comparison with racemic samples. Enantiomeric ratios were confirmed in selected cases (entries 4–6, 11, 12) by reaction with (*R*)-(−)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride and analysis of the resulting MTPA-esters by ^{19}F and ^{1}H NMR spectroscopy. Absolute configuration was determined by comparison with known optical rotation values (Table 1, entries 1, 7), and by chemical correlation (see footnotes of Table 1). *Anti*:*syn* ratios were determined by ^{1}H NMR spectroscopy ($CDCl_3$) (Table 1, entries 10–15, 17, 18) and by capillary VPC analysis (OV-1 column, 60–160 °C) (Table 1, entries 11, 12, 14) in comparison with authentic samples.

[4] *It is more convenient to use the same stereodescriptors for the boron enolates derived from different substrates. As sequence-rule-priority changes passing from ketones (OB > alkyl) to esters (OB < O alkyl) to thioesters (OB < S alkyl), we like to define the enolates as Z(OB) enolates or E(OB) enolates, conventionally attributing to the OB substituent the highest priority.*

$[Mo_2(S)_2(\mu\text{-}S)(syn\text{-}Me_8[16]aneS_4)_2]^{2+}$, a Novel Sulfidomolybdenum Complex Containing a Linear S=Mo–S–Mo=S Linkage**

By *Toshikatsu Yoshida,* Tomohiro Adachi, Kazuhiko Matsumura*, and *Katsumi Baba*

Despite the extensive chemistry of transition metal sulfides, the only three 18-electron complexes containing terminal sulfido ligands known are *trans*-$[Mo(S)_2(syn\text{-}Me_8[16]aneS_4)]$, *trans*-$[W(S)_2(PMe_3)_2L_2]$ (L = PMe_3, *t*BuNC), and *trans*-$[Mo(S)(O)(dppe)_2]$.[1] The long M=S distances of these complexes compared to those of 16-electron sulfido Mo^{IV} and W^{IV} complexes suggest the significant reduction in the $p_\pi(S) \rightarrow d_\pi(M)$ interaction, which promises high nucleophilicity for the terminal sulfido ligand. However, the nucleophilicity of the terminal sulfido ligand of these electronically saturated complexes has remained virtually unexplored. Recently we reported that one of the terminal sulfido ligands in **1** is readily alkylated with alkyl halides to give sulfido(thiolato) complex *trans*-$[Mo(SR)(S)(syn\text{-}Me_8[16]aneS_4)]^+$ (R = Me, CH_2Ph).[2] We have now found that the protonation of **1** with HBF_4 proceeds with evolution of H_2S to give the salts **2** and **3**. The former contains a novel dimolybdenum

trans-$[Mo(S)_2(syn\text{-}Me_8[16]aneS_4)]$ **1**

$[Mo_2(S)_2(\mu\text{-}S)(syn\text{-}Me_8[16]aneS_4)_2](BF_4)_2$ **2**

trans-$[Mo(S)(F)(syn\text{-}Me_8[16]aneS_4)](BF_4)$ **3**

tris(sulfido) complex as cation. The X-ray structural study of **2** reveals the presence of a linear S=Mo–S–Mo=S linkage. In view of the strong propensity of sulfido ligands to bridge M-S-M in a bent fashion, linear μ-sulfido complexes are extremely rare except the well-characterized cumulated systems of the types M=S=M and M≡S≡M.[3] The cation in **2** also represents the first example of the sulfur analogue of the linear O=M–O–M=O complexes with d^0–d^2 metal centers.[4]

Addition of an equimolar amount of $HBF_4 \cdot Et_2O$ to a suspension of **1**[1a] in toluene at room temperature and subsequent recrystallization of the precipitate from acetone/toluene gave grayish green crystals of **2** together with green crystals of **3** in 7 and 40% yield, respectively. When the reaction is carried out in CH_2Cl_2, **2** was obtained as the sole product (65%). In both reactions the evolution of H_2S was detected. The ^1H NMR spectra of both compounds indicate that the $Me_8[16]aneS_4$ ligand adopts the *syn*-conformation, suggesting the retention of the *syn*-form of the macrocyclic ligand upon the protonation of **1**. The presence of both terminal (S_t) and bridging sulfido ligands (S_b) in **2** are confirmed by the observation of one IR active ν_{as} (Mo=S_t) band at 468 cm^{-1} and two Raman active ν_s (Mo=S_t) and ν_s (Mo–S_b–Mo) bands at 486 and 335 cm^{-1}, respectively. The high ν (Mo=S_t) stretching frequency in **2** compared to that found in **1** (436 cm^{-1})[1a] is consistent with the 16-electron d^2 complex in **2** and the weaker *trans* influence of a bridging sulfido ligand over a terminal sulfido ligand.

The cation in **2** (Fig. 1)[5] consists of two [Mo(S)(*syn*-$Me_8[16]aneS_4$)] moieties which are connected through the S_b atom in a face-to-face fashion. In both moieties the S_t atom occupies the congested axial site surrounded by the ring carbon atoms. The two moieties are staggered with the torsion angle S1(1)-Mo1–Mo2–S2(1) of 45.0(4)°. The angles S_t-Mo-S_b and Mo1-S_b-Mo2 are respectively 178.1(4) (average) and 177.3(3)°, thus, the S_t1-Mo-S_b-Mo-S_t2 framework is essentially linear and the cation possesses approximately D_{4d} symmetry. The mean Mo–S_t separation (2.149(9) Å) may be compared with those found for 16-electron sulfido Mo^{IV} complexes (2.126–2.149 Å),[6] but is significantly shorter than that found in **1** (2.238(9) Å). Because of the strong *trans* influence of terminal sulfido ligands, the Mo–S_b distances (average 2.407(9) Å) are considerably elongated; they are even longer than the corresponding value (2.23–2.35 Å) found for binuclear Mo^{IV} complexes with bent μ-sulfido ligands.[7] The mean nonbonded distance (4.17(5) Å) between the C atoms of axial methyl groups of the face-to-face macrocyles is comparable with twice the van der Waals radius of a methyl group (4.00 Å). Thus, the linearity of the S=Mo–S–Mo=S backbone may be rationalized by steric effects, since the van der Waals repulsions between the methyl groups should increase substantially when the molecular framework is bent.[8]

The structure of the cation in **3** (Fig. 2)[5] shows that the terminal sulfido ligand again occupies the congested axial site with the fluoro anion at the opposite readily accessible uncongested site. The results of structural studies of **2** and **3** suggest that the protonation of **1** took place stereoselectively at the sulfido ligand located on the uncongested axial site. A similar discrimination of the two sulfido ligands at the stereochemically different axial sites was observed for the monoalkylation of **1** with alkyl halides, which gave *trans*-[Mo(SR)(S)(*syn*-Me_8[16]aneS_4)]$^+$ (R = Me, CH_2Ph), in which the thiolato ligand is located at the uncongested axial site.[2]

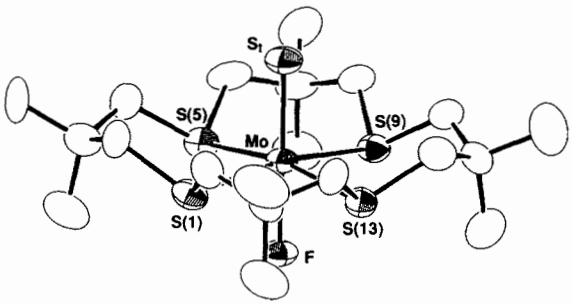

Fig. 2. Molecular structure of the cation of **3** (ORTEP, thermal ellipsoids at the 50% probability levels). Selected bond lengths [Å] and angles [°]: Mo-S_t 2.118(3), Mo-S1 2.445(4), Mo-S5 2.459(4), Mo-S9 2.451(4), Mo-S13 2.464(4), Mo-F 1.969(6); S_t-Mo-F 179.0(3), S_t-Mo-S1 95.6(1), S_t-Mo-S5 95.8(1), S_t-Mo-S9 95.3(1), S_t-Mo-S13 96.3(1), S1-Mo-S5 90.4(1), S1-Mo-S9 169.1(1), S1-Mo-S13 88.2(1), S5-Mo-S9 89.0(1) S5-Mo-S13 167.9(1), S9-Mo-S13 90.2(1), S1-Mo-F 84.3(2), S5-Mo-F 83.2(2), S9-Mo-F 84.8(2), S13-Mo-F 84.8(2).

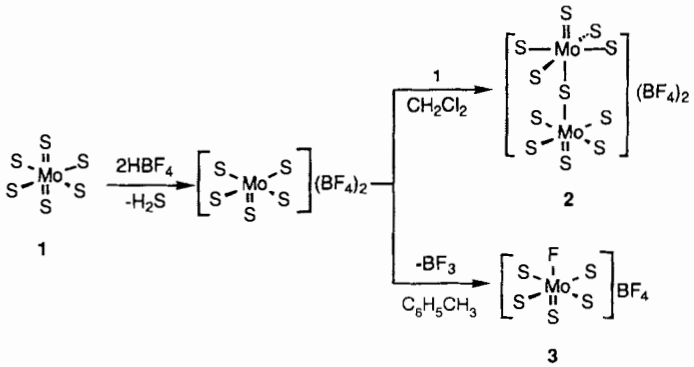
A plausible mechanism for the protonation of **1** to afford **2** and **3** is shown in Scheme 1. The protonation of the terminal sulfido at the uncongested axial site may produce a hydrogensulfido(sulfido) species [Mo(SH)(S)(*syn*-Me_8[16]aneS_4)]$^+$, followed by a second, more facile protonation at the hydrogensulfido ligand, affording a coordinatively unsaturated monosulfido complex [Mo(S)(*syn*-Me_8[16]aneS_4)]$^{2+}$ with concomitant evolution of H_2S. The complete



Scheme 1. Possible mechanism for the formation of **2** and **3** from **1** ($CH_2CMe_2CH_2$ units of *syn*-Me_8[16]aneS_4 were omitted for clarity).

absence of the hydrogensulfido species in the reaction mixture contrasts sharply to the alkylation of **1**, in which *trans*-[Mo(SR)(S)(*syn*-Me_8[16]aneS_4)]$^+$ is formed.[2] Subsequently the coordinatively unsaturated intermediate abstracts a F^- ion from the counterion BF_4^- to give the cation in **3**; a nucleophilic attack by **1** at the terminal sulfido ligand on the uncongested axial site produces the cation in **2**. The proposed extremely facile diprotonation of one of the terminal sulfido ligands in **1** to give the coordinatively unsaturated species is supported by the results of the protonation of **1** with 1.1 equivalents of CF_3SO_3H, which afforded **4** together

trans-[Mo(O_3SCF_3)(S)(*syn*-Me_8[16]aneS_4)](O_3SCF_3) **4**

with a recovery of unreacted **1** in 35 and 40% yields, respectively. If the reaction pathway in Scheme 1 is assumed, the solvent effect on the observed product ratio of **2** and **3** can be explained in terms of the difference in solubility of **1** in toluene and CH_2Cl_2. In the latter solvent, in which the concentration of **1** is high due to its high solubility, the coordinatively unsaturated intermediate once formed reacts preferentially with **1** to give **2**. By contrast, in toluene the concentration of **1** is low and the intermediate therefore abstracts a F^- ion from the weakly coordinating counterion BF_4^-. This is a well-documented reaction.[10] The difference in solvent polarity may also affect the product ratio. In nonpolar toluene the vacant axial site of the coordinatively unsaturated cationic species is probably blocked by the formation of a contact ion pair with BF_4^-, whereas solvent-separated ion pairs exist in CH_2Cl_2.[11]

Finally it is worth noting that the cationic 16-electron d^2 metal complex **2** is inert toward protonation with HBF_4. This was expected because the terminal sulfido ligands in **2** are less nucleophilic than that in **1**, the net charges of the former and latter assessed by Extended Hückel MO calculations are −0.81 and −1.03, respectively.[8] Two-electron reduction of the cation in **2** should give the analogous neutral 17-electron d^3 metal complex,[12] whose terminal sulfido ligands are expected to be more nucleophilic than those in the cation of **2**.

Experimental Procedure

2 and **3**: To a suspension of **1** (60 mg, 0.107 mmol) in toluene (30 ml) was added 85% ether solution of $HBF_4 \cdot Et_2O$ (22 mg, 0.115 mmol) at room temperature. The yellow suspension immediately turned orange with evolution of H_2S, which was confirmed by its characteristic odor. After the mixture was stirred for 1 h, the precipitate was filtered and recrystallized from acetone/toluene to give a mixture of **2** and **3** as grayish green and emerald green crystals, respectively. Analytical pure samples of both complexes were obtained by mechanical separation of the above crystals followed by recrystallization from acetone/toluene; the yields of **2** and **3** were 7 and 40%, respectively. When the above reaction was carried out in CH_2Cl_2, **2** was obtained as the sole product in 65% yield. **2**: M.p. 260 °C (decomp); ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 1.29$ (s, 3H; Me), 1.44 (s, 3H; Me), 2.51 (d, $^2J(H,H) = 11.5$ Hz, 2H, CH_2) 3.72 (d, $^2J(H,H) = 11.5$ Hz, 2H; CH_2); UV/VIS (acetone): λ_{max} (ε) = 304 (5820), 366 (7200), 4888 (37900), 672 (688), 821 nm (653); FAB-MS (3-nitrobenzyl alcohol): m/z 1106 [M^+].

3: M.p. 235 C (decomp); ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 1.36$ (s, 3H; Me), 1.40 (s, 3H; Me), 3.01 (br, 2H; CH_2), 3.66 (br, 2H; CH_2); IR (CsI): $\nu = 494$ cm^{-1} (Mo=S); FAB-MS (3-nitrobenzyl alcohol): m/z 557 [M^+], 538 [$M^+ - F$].

4: Treatment of **1** (33 mg, 0.058 mmol) with CF_3SO_3H (18 mg, 0.115 mmol) in toluene (10 ml) and recrystallization of the precipitate from CH_2Cl_2/toluene gave **4** as pale yellow crystals (68%). M.p. 279 °C (decomp); ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 1.45$ (s, 3H; Me), 3.01 (d, $^2J(H,H) = 11.6$ Hz, 2H; CH_2), 3.66 (d, $^2J(H,H) = 11.6$ Hz, 2H; CH_2); IR (CsI): $\tilde{\nu} = 519$ cm^{-1} (Mo=S). FAB-MS (3-nitrobenzyl alcohol): m/z 687 [M^+]. The reaction with 1.1 equivalents of CF_3SO_3H under the similar conditions afforded **4** (35%) together with the recovery of **1** (40%).

[8] Extended Hückel MO calculations on the model compound of the cation in **2**, $[Mo_2(S)_2(\mu\text{-}S)\{syn\text{-}(SH_2)_4\}_2]^{2+}$ with D_{4d} symmetry, where vacant sulfur d orbitals are included, indicate that the amount of electrons transferred from the occupied $p_x(p_y)$ orbital of the S_b^{2-} ion to each Mo atom is 0.337, while the corresponding value calculated for the terminal sulfido ligand is 0.791. Note that the electrons transferred through σ donation are comparable, 0.503 for each Mo–S_b bond and 0.547 for the Mo–S_t bond. The H_{ij} values and the orbital exponents for the Mo atom were taken from the reference [9], while those of other atoms are standard values. The bond lengths and angles were the average values of those found in the cation of **2** except the strict linearity of the S_t=Mo–S_b–Mo=S_t linkage and the S–H distance of 1.33 Å. Extended Hückel MO calculations of *trans*-$[Mo(S)_2\{syn\text{-}(SH_2)_4\}]$, a model compound of **1** were carried out similarly.

[11] We thank one of the referees for suggesting that we investigate the effect of solvent polarity on the reaction.

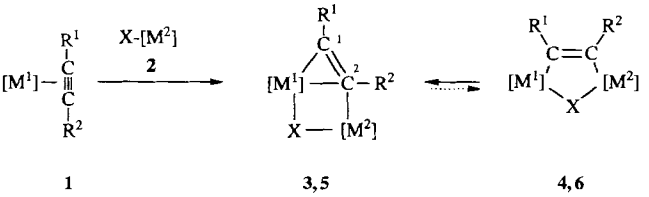
[12] The cyclic voltammogram of **2** (0.2 M nBu$_4$NBF$_4$ in CH_2Cl_2) shows two quasi-reversible redox potentials at -0.95 and -1.66 V (vs. Cp_2Fe^+/Cp_2Fe).

The Energetic Stabilization Caused by a Planar-Tetracoordinate Carbon Atom: A Dynamic NMR Spectroscopic Study of the Dimetallabicycle $[(Cp_2Zr)_2(\mu\text{-}C{\equiv}CCH_3)(\mu\text{-}H_3CCCCH_3)]BPh_4$**

By *Gerhard Erker** and *Dirk Röttger*

Dedicated to Professor Carl Krüger to the occasion of his 60th birthday

We recently described a new class of highly stable heterodimetallic complexes containing planar-tetracoordinate carbon atoms.[1] These compounds **3** arise, in general, by the reaction of the (η^2-alkyne)metallocene **1** generated in situ, with halide, alkyl, or alkynyl compounds of boron, aluminium, or gallium (**2**) (Scheme 1). An analogous dizirconocene complex **5a** ($R^1 = CMe_3$, $R^2 = CH_3$, $X = C{\equiv}C{-}CMe_3$) was also reported recently.[2–4]



Scheme 1. $[M^1] = Cp_2Ti$, Cp_2Zr, Cp_2Hf; **3**, **4**: M^1 = Ti, Zr, Hf; M^2 = B, Al, Ga; **5**, **6**: $[M^1] = Cp_2Zr^+$, $[M^2] = Cp_2Zr$. The M^1-C-M^2 bonds in **3** and **5** are three-center, two-electron bonds.

Theoretical calculations indicate that the structures of the metallabicycles **3** with a planar-tetracoordinate carbon atom are 30–50 kcal mol^{-1} more stable than their isomers **4** with "normal" olefin structure.[5] This large difference in energy means that it is rather unlikely that **4** could be detected experimentally starting from **3**. In contrast, in compounds of type **5**, if two identical substituents were introduced at the alkyne bridge (e.g. **5b**: $R^1 = R^2 = CH_3$; $X = C{\equiv}C{-}CH_3$), the thermally induced opening of the central Zr^1–C^2 bond would then lead to a C_{2v}-symmetric dimetallamonocycle **6b**. Thus, it should be possible to detect the equilibration

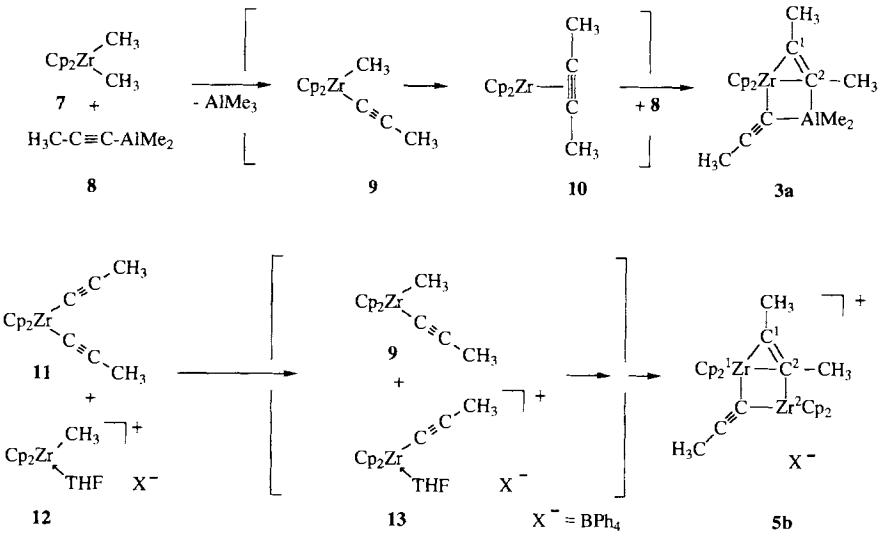
5b⇌**6b**, in contrast to that of **3**⇌**4**, by dynamic NMR spectroscopy.

Unfortunately, the synthetic procedure described by Horton et al.[2] can only be used for the preparation of the very complex **5a**, which exhibits a specific substitution pattern. With starting materials bearing different substituents, other products are obtained, rather than compounds of type **5**.[2] We have therefore prepared **5b** by a new synthetic route based on our method for the synthesis of the planar-tetracoordinate carbon compounds **3** (Scheme 2). Thus, bis(propynyl)zirconocene (**11**)[6] was allowed to react at room temperature with the methylzirconocene cation (introduced as $[Cp_2Zr(CH_3)(thf)]BPh_4$ (**12**)[7]). The σ-ligand exchange leads presumably to the intermediate **9**, which, in the presence of the intermediate (propynyl)zirconocene cation generated in the first step, affords the product **5b** in 85% yield, following reductive coupling and addition of **13**.[8]

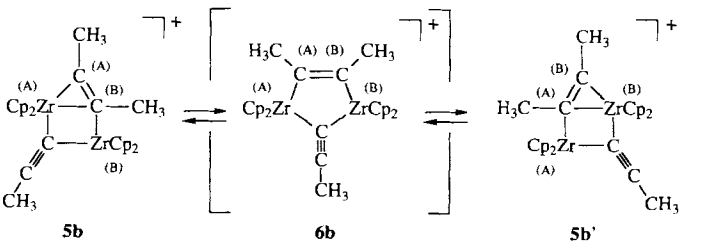


Scheme 2. Synthesis of compound **5b** in accordance with our method for the preparation of **3** with a planar-tetracoordinate C atom; $X^- = BPh_4^-$. The Zr-C-Al bonds in **3a** and the Zr-C-Zr bonds in **5b** are three-center, two-electron bonds.

Compound **5b** shows IR bands at 2070 (C≡C) and 1580 cm^{-1} (C=C). In the ^{13}C NMR spectrum at 213 K two signals are observed for the Cp ligands at $\delta = 109.8$ and 108.4. The μ-η^1:η^2-$(H_3C)CC(CH_3)$ unit gives rise to signals at $\delta = 210.4$ (C^1), 28.9 (CH_3 at C^1), 124.3 (planar-tetracoordinate C^2 atom), and −25.6 (CH_3 at C^2). In the ^1H NMR spectrum of **5b** at 200 K, two singlets are observed for the Cp ligands at $\delta = 5.84$ and 5.70 in addition to three signals at $\delta = 2.48$ (CH_3 at C^1), 2.29 (μ-C≡C-CH_3), and −0.16 (CH_3 at planar-tetracoordinate C^2) corresponding to the methyl groups.[9] Compound **5b** displays dynamic NMR spectra. Upon raising the temperature, the ^1H and ^{13}C NMR signals of the Cp ligands as well as those of the C^1CH_3 and C^2CH_3 groups rapidly broaden and pairwise coalescence is observed. The signals of the BPh_4 anion and the μ-C≡C-CH_3 ligand remain unaffected. At a sufficiently high temperature, simplified spectra are obtained, showing only one signal each for the Cp ligands [$\delta = 5.85$ (^1H NMR, 300 K), $\delta = 109.8$ (^{13}C NMR, 280 K)] and the methyl groups at C^1 and C^2 [$\delta = 1.25$ (^1H NMR, 300 K)], which have become symmetry-equivalent. It can be assumed that the observed intramolecular equilibration of **5b** is initiated by a thermally induced opening of the central Zr^1-C^2 bond (Scheme 3), which leads inevitably to the formation of the C_{2v}-symmetric compound **6b**. Starting from **6b**, it is now possible to form a stable ground-state structure by restoring an additional central Zr–C interaction. In this process, the connection of $Zr^{(A)}$ with $C^{(B)}$ and $Zr^{(B)}$ with $C^{(A)}$ is of equal probability (Scheme 3), which leads ultimately to the observed thermally induced automerization of the original compound **5b**. We have estimated a Gibbs activation energy of $\Delta G^{\ddagger}_{autom}$ (250 K) = 11.8 ± 0.5 kcal mol^{-1}[10] for this degenerate rearrangement of **5b**, based on the analysis of the temperature-dependent line shape of the ^1H NMR signals of the Cp ligands and the methyl substituents at C^1 and C^2.

Theoretical analysis of the planar-tetracoordinate Zr/Al compound **3** reveals that the dimetallamonocycle **4** is unlikely to correspond to a local minimum on the hypersurface of these systems, but is instead transformed into **3** with continual gain in energy.[5] If the **5**/**6** system behaves analogously, the activation barrier determined for the thermally induced automerization of **5b** provides an estimate of the energetic stabilization caused by the introduction of a planar-tetracoordinate carbon atom, starting from a "normal" metal-substituted olefin. However, it certainly cannot be ruled out that the cationic dimetallacycle **6** (in contrast to **4**[5]) does, in fact, correspond to a local minimum; in this case, the determined energy value of about 12 kcal mol^{-1} constitutes merely an upper limit for the stabilization of the structure containing the planar-tetracoordinate sp^2-hybridized carbon atom compared with the "normal" olefinic structural alternative of these compounds. It is evident that the value determined for the cation **5b** [$\Delta\Delta G_{plan.C}$ (obs) ≤ 12 kcal mol^{-1}] is lower than that predicted from the calculations for **3**: the Cp_2ZrX moiety is a poorer σ-donor substituent than $XAlR_2$.[11]

We have demonstrated that for specific model compounds (e.g. **5b**) with a planar-tetracoordinate sp^2-carbon atom, the



Scheme 3. The Zr-C-Zr bonds in **5** are three-center, two-electron bonds.

degree of energetic stabilization relative to that of their "conventional" isomers with trigonally planar carbon atoms can easily be approximated by experiment. This should provide a good basis from which to assess the results of quantum mechanical calculations carried out on such systems, and thus help us to obtain a realistic picture of the common factors which lead to the formation of stable compounds containing planar-tetracoordinate carbon atoms.

Lithium Di-*tert*-butylmethylsilylhydrazide, a Hexamer with Li^+ Ions Bound Side-on and End-on**

By *Sven Dielkus, Christian Drost, Regine Herbst-Irmer,* and *Uwe Klingebiel**

The only monosilylhydrazine known is $Ph_3SiNHNH_2$, described by Wannagat et al. in 1958. At 90 °C it readily condenses to *N,N'*-bis(silyl)hydrazine, while releasing N_2H_4.[1] This class of compounds is better kinetically stabilized by the use of *tert*-butylsilyl groups.[2]

By treating di-*tert*-butylmethylfluorosilane with lithiated hydrazine, we prepared the thermally stable monosilylhydrazine **1**, which can be converted into the lithium derivative **2** by *n*BuLi. When **2** reacted with trifluorosilylbis(trimethylsilyl)amine, we observed the formation of the *N,N'*- or *N,N*-bis(silyl)hydrazines **3** and **4**, respectively. The NMR data of these compounds are compiled in Table 1.

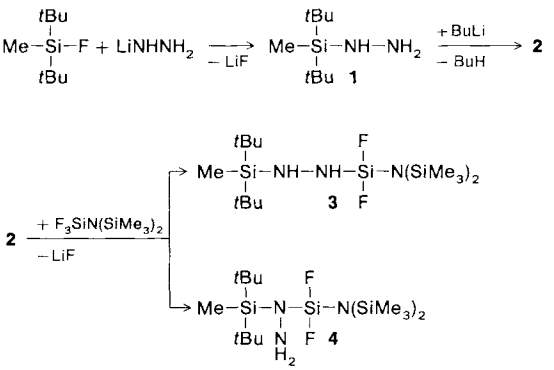

Table 1. NMR data of compounds **1**–**4**. All measurements were made at 25 C with a 250 MHz spectrometer (except ^{19}F NMR: 80 MHz instrument). Standard for ^1H, ^{13}C, and ^{29}Si NMR: TMS int., for ^{19}F NMR: C_6F_6 ext., for ^7Li NMR: LiCl ext.

1 (all measurements in $CDCl_3$): ^1H NMR: $\delta = -0.14$ (SiMe, 3H), 0.85 ($SiCMe_3$, 18H); ^{13}C NMR: $\delta = -9.44$ (SiC), 20.23 ($SiCC_3$), 28.25 ($SiCC_3$); ^{29}Si NMR: $\delta = 8.74$.

2 (measurements in C_6D_6/THF): ^7Li NMR: $\delta = 0.55$; ^{29}Si NMR: $\delta = 9.13$, 10.65.

3 (all measurements in $CDCl_3$): ^1H NMR: $\delta = 0.11$ (SiMe, 3H), 0.22 (t, ^5J(H,F) = 0.8 Hz, $SiMe_3$, 18H), 0.98 ($SiCMe_3$, 18H), 2.98 (t, ^3J(H,F) = 3.3 Hz, NH, 1H), 2.99 (NH, 1H); ^{13}C NMR: $\delta = -9.40$ (t, ^5J(C,F) = 1.2 Hz, SiC), 3.62 (t, ^4J(C,F) = 1.6 Hz, SiC_3), 20.49 ($SiCC_3$), 28.27 ($SiCC_3$); ^{19}F NMR: $\delta = 25.82$; ^{29}Si NMR: $\delta = -66.12$ (t, ^1J(Si,F) = 219.8 Hz, SiF_2), 6.27 (t, ^3J(Si,F) = 1.0 Hz, $SiMe_3$), 10.85 ($SiCMe_3$).

4 (all measurements in $CDCl_3$): ^1H NMR: $\delta = 0.04$ (t, ^5J(H,F) = 2.2 Hz, SiMe, 3H), 0.26 (t, ^5J(H,F) = 0.8 Hz, $SiMe_3$, 18H), 1.07 ($SiCMe_3$, 18H), 2.68 (NH_2, 2H); ^{13}C NMR: $\delta = -7.55$ (t, ^4J(C,F) = 3.9 Hz, SiC), 3.74 (t, ^4J(C,F) = 1.8 Hz, SiC_3), 21.14 ($SiCC_3$), 28.92 ($SiCC_3$); ^{19}F NMR: $\delta = 37.04$; ^{29}Si NMR: $\delta = -60.37$ (t, ^1J(Si,F) = 236.8 Hz, SiF_2), 5.93 (t, ^3J(Si,F) = 1.4 Hz, $SiMe_3$), 9.22 (t, ^3J(Si,F) = 1.5 Hz, $SiCMe_3$).

Formation of the isomers **3** and **4** requires prior coordination of the Li^+ ion with the two N atoms of the hydrazine unit. Side-on coordination of Li^+ has so far been predicted

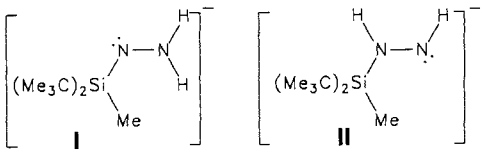
[+] Crystal structure analysis.

[**] This work was supported by the Fonds der Chemischen Industrie.

only by ab initio calculations for lithiated hydrazine.[3] To prove our point, we isolated single crystals of **2** and carried out an X-ray structural analysis.[4]

The crystal structure of **2** (Fig. 1)[4] exhibits two different silylhydrazide units **I** and **II**, which are bound by six Li^+ ions to form a hexameric entity. The Li^+ ions are bound to three



different structural units: Li1 is coordinated with one N atom and two NH groups, Li2 with one N atom, one N_2, and one NH unit, and Li3 with one NH, one N_2, and one NH_2 unit. Thus four Li^+ ions are bound side-on.

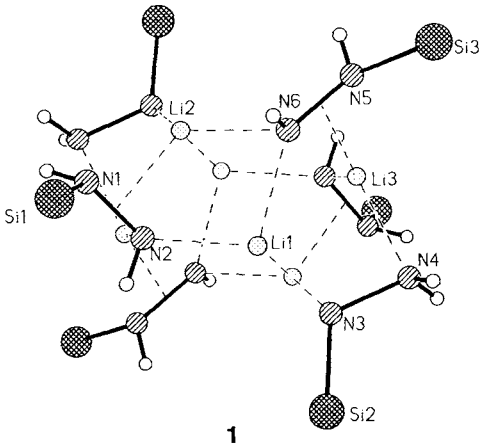


Fig. 1. Crystal structure of **2** (Me and *t*Bu groups were omitted for clarity). Selected bond lengths [pm] and angles [°]: Li1-N1 199.5(14), Li1-N3 201.6(13), Li1-N6 201.8(14), Li2-N2 200.8(14), Li2-N6 203.6(13), Li2-N3 [a] 204.0(13), Li2-N1 210.4(13), Li3-N4 201.3(14), Li3-N6 202.3(13), Li3-N5 202.4(14), Li3-N2 [a] 202.7(13), N1-N2 149.3(8), Si1-N1 174.4(6), Si2-N3 173.0(6), N3-N4 149.3(9), N5-N6 147.7(8), Si3-N5 174.4(6); N2-Li2-N1 42.5(3), N6-Li3-N5 42.8(3), N2-N1-Li2 65.3(5), N1-N2-Li2 72.2(5), N4-N3-Si2 115.4(4), N4-N3-Li1 108.4(5), Si2-N3-Li1 112.7(5), N5-N6-Li3 68.6(5), N6-N5-Li3 68.5(5); symmetry transformation for the equivalent atoms [a]: $-x+1, -y+1, -z$.

Unlike unit **II**, in the solid state **I** does not coordinate Li^+ ions side-on. The side-on bond lengths for the atoms Li2 and Li3 were determined to be 192 and 188 pm, respectively. The angles at N5 and N6, which bind Li3 side-on, are nearly identical; the angles at N1 and N2, which coordinate Li2, deviate by 7° (N5-N6-Li3 68.6, N6-N5-Li3 68.5; and N1-N2-Li2 72.2, N2-N1-Li2 65.3°). Thus Li3 is positioned centrosymmetrically above the N–N bond.

As X-ray structural analyses of Li derivatives of silyl-substituted hydrazines had been unknown so far, the structural analysis of **2** was compared with ab initio calculations for lithium hydrazide.[3] Table 2 shows a comparison of the data for the calculated $(NHNH_2)Li^+$ system (**A**) with that for the side-on units N1-N2-Li2 and N5-N6-Li3 (**B**) in **2**, derived from the X-ray structure determination.

The stuctural analysis confirms the ab initio calculations,[3] according to which Li^+ ions in hydrazides can be

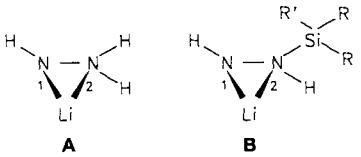

Table 2. Calculated and measured parameters in $Li(HN\text{-}NH_2)$ **A** and **2** (**B**), respectively.

Bond lengths [pm]	A	B	Bond angles [°]	A	B
N-N	145	149.3; 147.7	N-Li-N	56	42.5, 42.8
N^1-Li	161	200.8, 202.3	Li-N^1-N^2	49	72.2, 68.6
N^2-Li	189	210.4, 202.4	Li-N^2-N^1	76	65.3, 68.5

coordinated equally by both N atoms of the hydrazine. This phenomenon also accounts for the isomerizations during the secondary substitutions.

Experimental Procedure

1: N_2H_4 (0.02 mol, 0.64 g) in hexane (50 mL) was metalated with an equimolar quantity of BuLi (15% in hexane). When release of butane had ceased, THF (50 mL) and tBu_2MeSiF (0.02 mol, 3.52 g) were added. After the mixture was heated to reflux for 36 h the solvent was distilled off, and the residue was heated to 90 °C for 36 h. LiF was removed, and **1** was purified by distillation. Yield: 65%. B.p. 36 °C/0.01 mbar; MS (70 eV): *m/z* 188 (M^+, 6%).

2: To **1** (0.01 mol, 1.88 g) in hexane (20 mL) was added BuLi (0.01 mol, 15% in hexane). The suspended matter was dissolved by addition of THF at boiling temperature, and **2** was obtained in a crystalline form by slow cooling to room temperature. Yield: 95%, m.p. 68 °C (decomp) **3** and **4**: **1** (0.01 mol, 1.88 g) in hexane/THF (50 mL) was lithiated with BuLi (0.01 mol, 15% in hexane). An equimolar quantity of the fluorosilane was added rapidly to the Li derivative at −30 °C. The reaction mixture was slowly warmed to room temperature and heated to reflux for 1 h. The crude products were purified by distillation; a separation of the structural isomers was not accomplished. Yields (according to integration of the ^1H NMR data): 70% (**3**), 5% (**4**). B.p. 79 °C/0.01 mbar. MS (FI): *m/z* 413 (M^+, 100%).

New As–S Cage Structures with Organometallic Components Formed by Complex-Induced Realgar Fragmentation**

By *Henri Brunner, Bernhard Nuber, Ludwig Poll,* and *Joachim Wachter**

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

Substituent-free ligands from the elements of groups 15 and 16 are interesting primarily because of their vast structural diversity.[1, 2] Similarities exist above all in the formation of multinuclear complexes. However, the ability of P and As ligands to form ring systems is unusual; these ring systems show remarkable parallels to cyclic hydrocarbon ligands through the isolobal relationship P(As) $\leftrightarrow$ CH. Relatively little is known to date about complexes with ligands that contain elements from groups 15 and 16. A simple route to such compounds is the fragmentation of As_4S_4 with reactive transition metal complexes. Mixed realgar fragmentation products that have so far been structurally characterized are complexes with *cyclo*-As_2S,[1c] As_2S_3,[3] and As_3S_3 ligands.[4] The AsS_3 building block,[5] the first molecular example from the extensive class of sulfo salt minerals, is of particular significance.[6] Since the investigations were carried out on complexes with different structures and with various metal centers, nothing is known as yet about the fragmentation mechanism of realgar.[3, 7] We report here on the synthesis and structure determination of bi- and trinuclear Cp^xCo complexes ($Cp^x = \eta^5$-C_5Me_4Et) with AsS and As_2S_3 ligands in new modes of coordination and their reactivity relationships with one another.

The reaction of **1** with stoichiometric quantities of As_4S_4 (toluene, 80 °C) affords complexes **2**–**5** in yields between 6 and 13%. All compounds were characterized analytically[8] and conclusions about the symmetry can be drawn from the ^{1}H NMR spectra (Table 1). X-ray structure determinations were carried out for **2** and **5**. Since the properties of **3** are very similar to those of the structurally characterized complex **6** ($Cp^* = C_5Me_5$),[3] this suggests that also in **3** a chain, in which S and As atoms alternate, bridges the two Co centers. In contrast, the structure of **4** remains open because of the numerous possible isomers.

Table 1. ^{1}H NMR spectroscopic data [a] of compounds **2**–**5**.

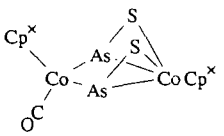
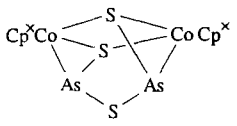
$[\{Cp^xCo(CO)\}_2]$ **1**



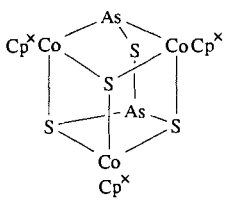
2



3

$[Cp^x_3Co_3As_4S_2]$

4



5

$[Cp^*_2Co_2As_2S_3]$ **6**

The most important feature of the crystal structure of **2**[9] is the two Co centers *syn* bridged by two $\eta^1:\eta^2$-AsS ligands (Fig. 1). A terminal CO group at Co2, also evident by an IR absorption at 1987 cm^{-1}, is responsible for the formal saturation of the two Co centers. The two As atoms come remarkably close to each other (2.717(2) Å),[10] whereas the S–S distance (3.278 Å) is greater than that for bonding interactions. The Co–S distances in the frameworks of **6** and **2** are the same length; of the two different Co–As distances ($\Delta = 0.08$ Å) in **2**, however, even the shorter ones are about 0.06 Å longer than those in **6**. The As–S distance (mean 2.169 Å) is about 0.07 Å shorter than that in the minerals As_2S_3 and As_4S_4[11] and other complexes which contain the $\eta^2:\eta^2$ AsS ligand.[7, 12]

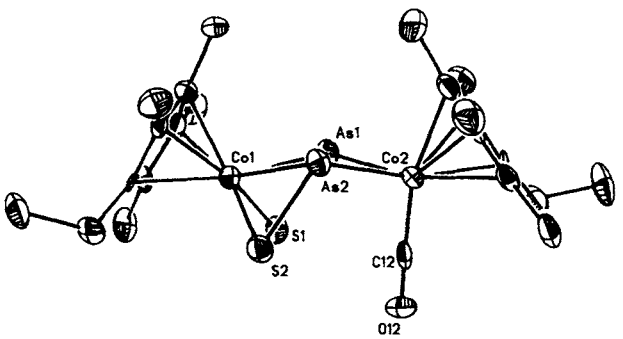


Fig. 1. Crystal structure of **2**. Selected distances [Å] and angles [°]: Co1-As1 2.473(2), Co1-As2 2.465(2), Co1-S1 2.275(4), Co1-S2 2.279(4), Co2-As1 2.383(3), Co2-As2 2.381(3), As1-S1 2.174(4), As2-S2 2.164(4), As1···As2 2.717(2), S1···S2 3.278(4); As1-Co1-As2 66.7(1), As1-Co1-S1 54.3(1), As1-Co1-S2 102.3(1), S1-Co1-S2 92.1(2), As1-Co2-As2 69.5(1), As1-Co2-C12 93.3(4), As2-Co2-C12 97.3(4), Co1-As1-Co2 107.7(1), Co1-As1-S1 58.2(1), Co2-As1-S1 110.7(1).

The crystal structure of **5**[13] is characterized by a $Co_3As_2S_4$ cage, in which one μ_3-S and one μ_3-As_2S_3 ligand form the main constituents of a distorted cube (with As1 above a plane) (Fig. 2). The construction of the As_2S_3 bridge can be seen as a molecular section from the As_nS_{2n+1} chain

[**] We thank Prof. Dr. G. Huttner, Heidelberg, for providing the facilities for the structure determination.

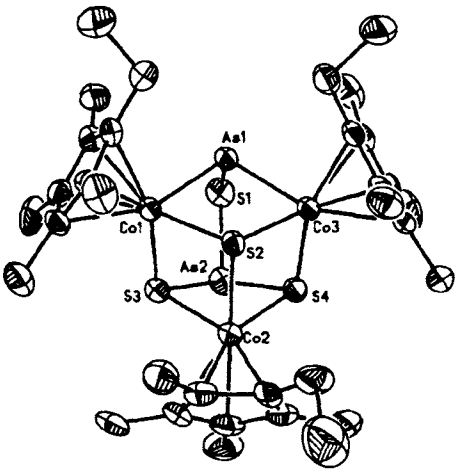

Fig. 2. Crystal structure of **5**. Selected distances [Å] and angles [ ]: Co1-As1 2.342(3), Co1-S2 2.266(4), Co1-S3 2.209(4), Co2-S2 2.274(4), Co2-S3 2.272(4), Co2-S4 2.274(4), Co3-As1 2.341(3), Co3-S2 2.263(4), As1-S1 2.318(4), As2-S1 2.196(1), As2-S3 2.292(4), As2-S4 2.292(4); As1-Co1-S2 78.5(1), Co1-As1-Co3 98.1(1), Co1-S2-Co3 102.7(1), S3-Co2-S4 89.0(1), S3-As2-S4 88.1(1), As1-S1-As2 98.0(1).

with trigonal pyramidal AsS_3 subunit[6] typical for sulfo salts; at the As1 atom two Co atoms replace two S atoms. Correspondingly, the As–S distances also vary between 2.195 and 2.318 Å. Of the noble gas-configurated Co centers, Co1 and Co3 are symmetry equivalent, which is also in accordance with the ^{1}H NMR spectrum (Table 1).

Since the reaction of **1** with As_4S_4 in boiling xylene (15 h) only affords **3** and **5** in 11 and 51% yield, respectively, it appears likely that **2** and **4** are intermediate products. Indeed, warming solutions of **2** to 110 °C affords **3** (25% yield), **4** (10%), and **5** (18-28%). Interestingly, the addition of sulfur does not cause the linkage of the two AsS ligands, rather, only the isolation of a small quantity of $[Cp^x_2Co_2S_4]$.[15]

It can be concluded that AsS units play an important role in the construction of new cage structures which are characterized by the As_2S_3 framework. A comparison with the fragmentation of the As_4 tetrahedron by **1** seems appropriate,[16] although the apparently rapid opening of the edges of the As_4S_4 framework has not been proven to date. Compound **2** is, however, structurally analogous to [Cp*Co-(μ-η^4:η^1:η^1-As_4)Co(CO)Cp*], an intermediate from this reaction, when the two S-"wing tips" are replaced by an As–As building block. Also this complex is thermally unstable. However, it rearranges into a Co_3As_6 framework, which can be described as a strongly distorted As_6 prismane constructed from three As_2 units.

Experimental Procedure

The suspension from **1** (902 mg, 1.91 mmol) and As_4S_4 (817 mg, 1.91 mmol) in toluene (50 mL) was stirred for 15 h at 80 °C. After the solvent had been removed, the oily brown residue was taken up in toluene and prepurified on SiO_2 (column 10 × 3 cm). With toluene/ether 10:1 first a very broad red-brown zone was eluted and then a brown zone which contained **2** in 10% yield. The first zone was then chromatographed on SiO_2 (column 84 × 2.5 cm). With toluene/pentane 1:1 a series of compounds was eluted: orange-red $[Cp^*Co(CO)_2]$, green-brown **4**, red-brown **5**, and finally violet **3** (yields: 13 (**4**), 11 (**5**), 6 (**3**)%). Recrystallization at −20 °C from toluene/pentane mixtures afforded brown (**2**.**4**.**5**) and dark violet (**3**) crystals, respectively.

The First Heteroallyl Metal Complexes of Arsenic with the Coordination Number 2**

By *Uwe Wirringa, Herbert W. Roesky,** *Mathias Noltemeyer,* and *Hans-Georg Schmidt*

Dedicated to Professor Helmut Werner on the occasion of his 60th birthday

The chemistry of low-coordinate group 15 elements of the periodic table has already been the subject of numerous investigations. Particular emphasis was focused on phosphorus compounds such as phosphaalkynes and -alkenes,[1] diphosphenes,[2] and iminophosphanes.[3] These compounds have already been used as synthetic building blocks.[1–4] In contrast, the chemistry of compounds containing low-coor-

[*] Prof. Dr. H. W. Roesky, Dipl.-Chem. U. Wirringa, Dr. M. Noltemeyer, H.-G. Schmidt

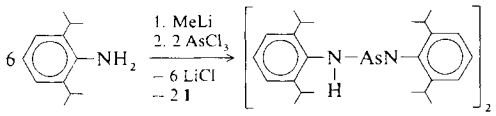
Tammannstrasse 4, D-37077 Göttingen
Telefax: Int. code + (551)393373

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

dinate arsenic and higher homologues is only in its infancy.[5–9] Attempts to synthesize heteroallyl metal complexes by deprotonation were only partially successful.[10–12] Structural investigations of corresponding arsenic systems were completely unknown. Our aim was to coordinate metal atoms to aryl imides of arsenic by deprotonation reactions, and, moreover, to use these systems for additional metal complexation.

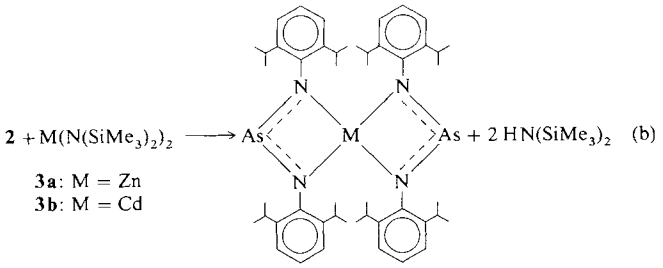
The starting material **2** was prepared by using the method described by M. F. Lappert et al.[7] Instead of 2,4,6-tri-*tert*-butylaniline, we used 2,6-diisopropylaniline **1**, which yielded the dimeric arsazene **2** [Eq. (a)]. Mass spectrometric investigations confirmed the dimeric nature of the product ((FI MS): *m/z* 853).



(a)

1 **2**

The reactions of **2** with bis(bis(trimethylsilyl)amido)zinc **3a**[13] and bis(bis(trimethylsilyl)amido)cadmium **3b**[13] led to the heteroallyl complexes **4** and **5**, respectively, which formed orange powders [Eq. (b)]. This indicates that the nitrogen-bonded hydrogen atom of **2** is reactive enough to generate the readily separable hexamethyldisilazane. It is expected that the method described here is generally suitable for the synthesis of heteroallyl metal complexes.



(b)

The structures of compounds **4** and **5** are isotypical (Fig. 1), which was already to be expected based on the spectroscopic data and the almost identical melting points (304 °C (**4**) and 302 °C (**5**)). The molecules of both complexes are arranged chainlike in the crystal (Fig. 2). The intermolecular As–As distances (**4**: 387.4; **5**: 382.5 pm) are, however, too long to assume interactions between the molecules.

The molecules consist of two four-membered rings spirocyclically linked through the central atom.[14] In contrast to **4**, the rings in **5** have different sizes. The NMR data in solution are in agreement with the structures in the solid state. The rings consisting of arsenic, nitrogen, and the corresponding metal are planar, forming a torsion angle of 62.9° in **4** and one of 51.8° in **5**. The more distorted tetrahedral geometry at the metal center in **5** cannot be explained by steric influences; similar tendencies are observed in aluminum-, gallium-, and indium–nitrogen systems.[15] This might be explained by the decreasing degree of hybridization, parallel to the increasing atomic number within a group.

The remarkably strong exposition of the arsenic atoms can be deduced from the N-As-N angles (**4**: 92.47(14) and 92.73(14)°; **5**: 94.7(3) and 91.9(2)°). As a result of this, a strong nucleophilic character for these centers can be assumed. This can only be explained by a reduction of the electron density at the central atom. In contrast, the steric influence of the 2,6-diisopropylphenyl substituents is very small. This is already demonstrated by the dimeric structure of compound **2**.

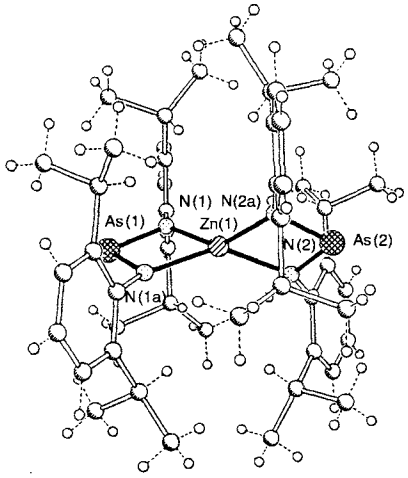


Fig. 1. Crystal structure of **4**, which is isotypical to that of **5**. Selected bond lengths [pm] and angles [°] of **4**: Zn(1)-N(2) 203.5(2), Zn(1)-N(2a) 203.5(2), Zn(1)-N(1a) 204.0(2), Zn(1)-N(1) 204.0(2), As(1)-N(1) 174.4(2), As(1)-N(1a) 174.4(2), As(2)-N(2a) 174.2(2), As(2)-N(2) 174.2(2); N(2)-Zn(1)-N(2a) 76.36(12), N(2a)-Zn(1)-N(1a) 116.32(9), N(2a)-As(2)-N(2) 92.47(14), As(2)-N(2)-Zn(1) 95.58(9), N(1)-As(1)-N(1a) 92.73(14), N(1a)-Zn(1)-N(1) 76.42(12); of **5**: Cd(1)-N(1a) 219.7(4), Cd(1)-N(1) 219.7(4), Cd(1)-N(2) 222.9(4), Cd(1)-N(2a) 222.9(4), As(1)-N(1) 169.5(3), As(1)-N(1a) 169.5(3), As(2)-N(2) 173.9(4), As(2)-N(2a) 173.9(4); N(1a)-Cd(1)-N(1) 67.4(2), N(1)-Cd(1)-N(2) 122.51(14), N(1)-Cd(1)-N(2a) 145.7(2), N(2)-As(2)-N(2a) 94.7(3), As(2)-N(2)-Cd(1) 97.6(2), N(2)-Cd(1)-N(2a) 70.0(2), N(1)-As(1)-N(1a) 91.9(2), As(1)-N(1)-Cd(1) 100.4(2).

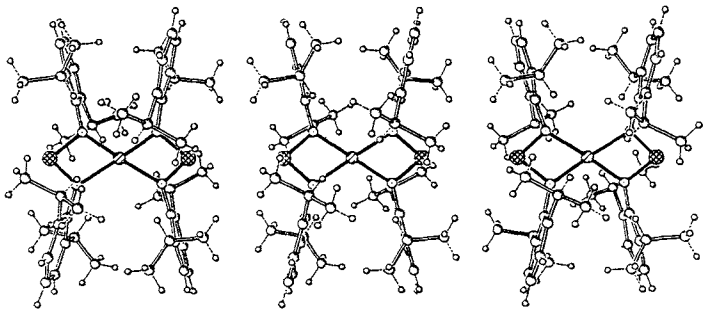

Fig. 2. Representation of the arrangement of the molecules of **4** and **5** in the crystal.

The metal–nitrogen bond lengths in both compounds are in the range of those expected for single bonds (**4**: 203.5(2) and 204.0(2) pm; **5**: 219.7(4) and 222.9(4) pm). The As–N distances within the heteroallyl ligands of the two compounds are the same (**4**: 174.4(2) and 174.2(2) pm, **5**: 169.5(3) and 173.9(4) pm). M. F. Lappert et al. determined As–N bond lengths of 174.5(7) and 171.4(7) pm[7] for their arsazene. According to L. Pauling's calculations the length of an As–N double bond is 173 pm and that of an As–N single bond 195 pm.[16]

Interestingly, in both compounds, the phenyl rings are arranged almost parallel, and perpendicular to the As-M-As axis. This arrangement leads to a tube formed by the organic substituents enclosing the As-M-As axis and results in unprotected As atoms. This becomes important if metal fragments are to be coordinated to the arsenic atoms.

Experimental Procedure

2: **1** (15.9 g, 90 mmol) was dissolved in hexane (100 mL) and subsequently treated with methyllithium (2.0 g, 90 mmol) dissolved in diethyl ether (57 mL) at room temperature; thus, the reaction mixture heated up to almost boiling. After the addition of MeLi was completed, the mixture was stirred at room temperature for about 1.5 h. Subsequently, arsenic trichloride (5.4 g, 30 mmol) was added dropwise; again the reaction mixture heated to almost boiling. The solution turned orange immediately. The reaction mixture was then heated under reflux for 14 h. The lithium chloride was recovered by filtration. The remaining deep red solution was concentrated in vacuo and the product was precipitated at −18 °C. To separate **2** from adhesive **1**, after filtration, the solid was washed three times with hexane (ca. 10 mL). Yield 8.4 g (23 mmol, 77%). M.p. 164 °C; MS(FI): *m/z* (%): 853 (100) $[M^+]$; ^{13}C NMR (63 MHz, [D$_8$]toluene, 25 °C, TMS): δ = 22.5 (Me), 28.2 (*C*HMe$_2$), 119.0 (aryl-C), 123.1 (aryl-C), 132.4 (aryl-C), 140.8 (aryl-C); ^1H NMR (250 MHz, [D$_8$]toluene, 25 °C, TMS): δ = 1.15 (d, ^3J(H,H) = 7 Hz, 48 H; CH*Me*$_2$), 2.63 (sept., ^3J(H,H) = 7 Hz, 8 H; *CH*Me$_2$), 3.21 (s, 2H; NH), 6.99 (m, 12 H; aryl-H); IR (nujol): $\tilde{\nu}$ = 3397 cm^{-1} (N–H).

4: **2** (0.856 g, 2 mmol) was dissolved in toluene (30 mL) and treated with **3a** (0.385 g, 1 mmol). Subsequently, the mixture was heated under reflux for 14 h. The solution turned red and an orange solid precipitated. Some of the solvent was removed in vacuo, the solid was filtered off and finally recrystallized from hot toluene. Yield: 0.61 g (67%). M.p. 304 °C; MS(FI): *m/z* (%): 914 (30) $[M^+]$, 739 (100) $[M^+ - C_{12}H_{17}N]$; ^{13}C NMR (63 MHz, [D$_8$]toluene, 25 °C, TMS): δ = 22.5 (Me), 28.2 (*C*HMe$_2$), 118.9 (aryl-C), 123.0 (aryl-C), 132.2 (aryl-C), 140.7 (aryl-C); ^1H NMR (250 MHz, [D$_8$]toluene, 25 °C, TMS): δ = 1.15 (d, ^3J(H,H) = 7 Hz, 48 H; CH*Me*$_2$), 2.63 (sept., ^3J(H,H) = 7 Hz, 8 H; *CH*Me$_2$), 7.02 (m, 12 H; aryl-H); correct elemental analysis.

5: The experimental procedure was similar to that for the synthesis of **4**. Compound **2** (0.856 g) was treated with **3b** (0.433 g). The orange product **5** was obtained in 83% yield (0.80 g). M.p. 302 °C; MS(FI): *m/z* (%): 964 (10) $[M^+]$, 788 (100) $[M^+ - C_{12}H_{17}N]$; ^{13}C NMR (63 MHz, [D$_8$]toluene, 25 °C, TMS): δ = 22.5 (Me), 28.2 (*C*HMe$_2$), 118.9 (aryl-C), 123.0 (aryl-C), 124.0 (aryl-C), 132.2 (aryl-C), 140.8 (aryl-C), 144.3 (aryl-C); ^1H NMR (250 MHz, [D$_8$]toluene, 25 °C, TMS): δ = 1.08 (d, ^3J(H,H) = 7 Hz, 24 H; CH*Me*$_2$), 1.15 (d, ^3J(H,H) = 7 Hz, 24 H; CH*Me*$_2$), 2.63 (sept., ^3J(H,H) = 7 Hz, 4 H; *CH*Me$_2$), 3.33 (sept., ^3J(H,H) = 7 Hz, 4 H; *CH*Me$_2$), 7.02 (m, 12 H; aryl-H); correct elemental analysis.

Comparison of the Electrophilicities of Cationic Metal π Complexes and of Ordinary Carbenium Ions**

By *Herbert Mayr*,* *Karl-Heinz Müller*, and *Doris Rau*

The terms nucleophilicity and electrophilicity play a central role in the discussion of reaction mechanisms, and there have been numerous attempts to gauge these kinetic quantities.[1, 2]

Kane-Maguire, Sweigart et al. elaborated one of the most extensive sets of data by kinetic investigation of the reactions of cationic metal π complexes with phosphanes, phosphites, and amines.[2] The relative reactivities of these electrophiles were independent of the nature of the reference nucleophiles, and it was thus possible to formulate a uniform electrophilicity scale. From kinetic investigations of the reactions of these π complexes with electron-rich arenes it has been deduced that carbon nucleophiles do not obey these so-called "constant selectivity relationships", and the electrophilicity scale of Kane-Maguire, Sweigart et al. appeared to be applicable only to *n*-nucleophiles (*n* = amines, phosphanes).[2]

We have now studied the kinetics of the reactions of the three electrophilic metal complexes (**1a–c**)[3] with electron-rich vinyl derivatives and the hydride donor tributylstannane, and we found also in these reactions the relative reactivities of **1a–c** to be independent of the nature of the nucleophile. Since the rates of the reactions of these nucleophiles with diarylcarbenium ions are already known,[6] one can now link the electrophilicity scale of the metal π complexes to that of ordinary carbenium ions.

The dienylium complexes **1a–c** react with silylated enol ethers[7a, b] and allylstannes[7c] in the typical way to give the 5-*exo*-substituted cycloalkadiene complexes regio- and stereoselectively (Scheme 1). Some of these products had already been synthesized in different ways.[8, 9] The cycloheptadienylium complex **1c** also reacts with carbon nucleophiles in this way, though it has been reported that under certain circumstances triphenylphosphane initially attacks these complexes at the metal atom and finally ends up at the 5-

endo position of the seven-membered ring.[10] The reaction of **1a–c** with tributylstannane proceeds with hydride transfer to yield the cycloalka-1,3-diene complexes, from which **1a–c** is usually generated by hydride abstraction.

Table 1. Rate constants (20 °C, acetone) and activation parameters for the reactions of tricarbonyl(dienylium)iron complexes with various nucleophiles.

Nucleophile	Electrophile	k_2 [L mol^{-1} s^{-1}]	$\Delta H^{\neq}$ [kJ mol^{-1}]	$\Delta S^{\neq}$ [J mol^{-1} K^{-1}]
	1a	9.16×10^{-3}	58.4 ± 3.2	-84 ± 11
	1a	8.56×10^{-2}	49.3 ± 1.0	-97 ± 4
	1a	2.55×10^{-2}	50.5 ± 1.5	-103 ± 5
	1b	3.35×10^{-3}	51.6 ± 0.7	-116 ± 3
	1c	2.78×10^{-3}	-	-
	**1a**	2.36×10^{-1}	44.7 ± 1.0	-104 ± 4
	1b	5.50×10^{-2}	42.3 ± 0.5	-124 ± 2
	1c	4.58×10^{-2}	33.1 ± 0.3	-158 ± 1
	**1a**	6.59	31.6 ± 0.2	-121 ± 1
	1b	7.66×10^{-1}	37.9 ± 0.8	-118 ± 3
	1c	2.05×10^{-1}	31.2 ± 1.5	-152 ± 6
	1a	4.87	43.8 ± 0.9	-82 ± 3
$HSnBu_3$	**1b**	8.31×10^{-1}	44.1 ± 1.0	-96 ± 4
	1c	5.98×10^{-1}	46.9 ± 0.7	-89 ± 1

Photometric monitoring of the reaction kinetics, as described for the reactions of diarylcarbenium ions with alkenes,[11] revealed a second-order rate law. Eyring activation parameters were determined from the temperature dependence of the rate constants (Table 1); for the reactions of **1a** and **1b**, the activation entropies were of similar order of magnitude as for the corresponding reactions of diarylcarbenium ions.[6d] Considerably more negative values of $\Delta S^{\neq}$ were observed for the reactions of **1c** with π systems possibly because of steric shielding of the reaction center in the seven-membered ring.

According to Figure 1 the reactivities of all nucleophiles toward the cyclohexadienyl complex **1a** correlate linearly with their reactivities toward the bis(*p*-dimethylaminophenyl)carbenium ion.[6d] Accordingly Sweigart et al. reported that the reactivity order of *n*-nucleophiles toward metal π complexes is also valid toward ordinary carbenium ions.[12] Figure 1 unambiguously proves that C-nucleophiles behave analogously.

Figure 2 shows for five selected nucleophiles that the nucleophilicity order $PPh_3 > Me_2C{=}C(OMe)OSiMe_3 \approx HSnBu_3 > H_2C{=}C(Me)CH_2SnBu_3 > H_2C{=}C(Ph)OSiMe_3$ holds for all electrophiles examined. The small differences of the slopes of the various correlations imply that a reversal of relative reactivities of nucleophiles upon variation of electrophiles only has to be taken into consideration when nucleophiles with very similar reaction rates are compared.

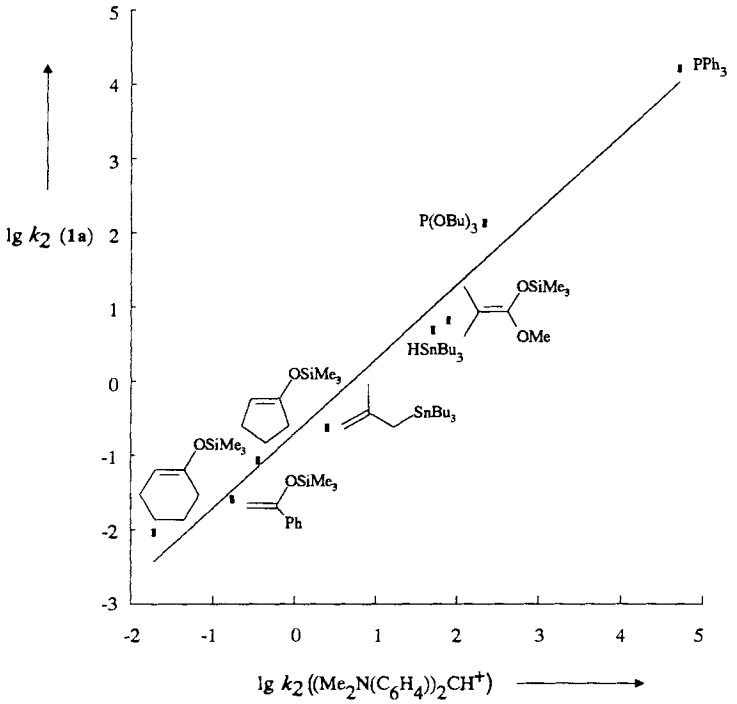

Fig. 1. Correlation of the reactivities of tricarbonyl(η^5-cyclohexadienyl)iron (1+) (**1a**, 20 °C, acetone) toward various nucleophiles with the corresponding reactivities of the bis(*p*-dimethylaminophenyl)carbenium ion [6d] (20 °C, CH_2Cl_2). Data for **1a** + PR_3 from ref. [2].

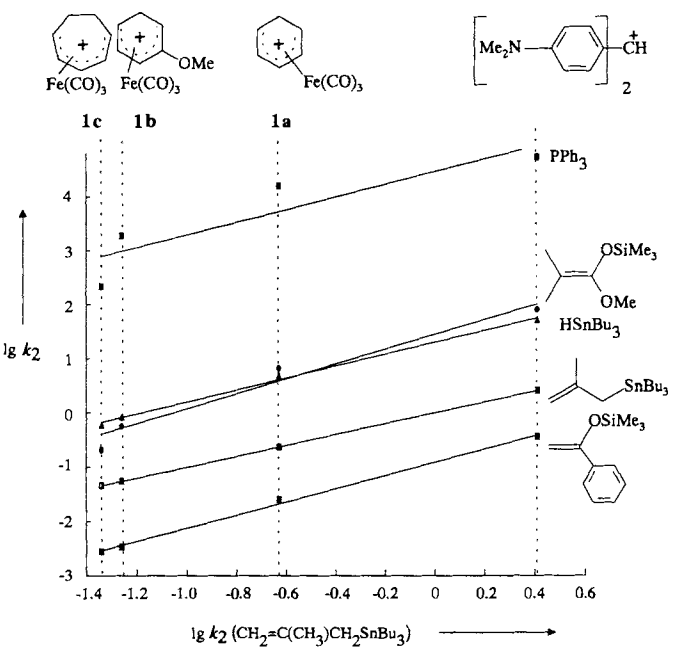

Fig. 2. Correlation of the reactivities of π-, σ-, and *n*-nucleophiles toward various electrophiles with the corresponding reactivities of the tributyl(2-methylallyl)stannane.

Knowing rate constants for the reactions of three electrophiles from the listing of Sweigart, Kane-Maguire et al.[2] with some nucleophiles whose reactivities towards diarylcarbenium ions we had determined previously,[6] we can now combine these two electrophilicity scales to render a direct comparison of the electrophilicities of metal π complexes and of ordinary carbenium ions (Fig. 3). In combination with the reactivity scale for nucleophiles published recent-

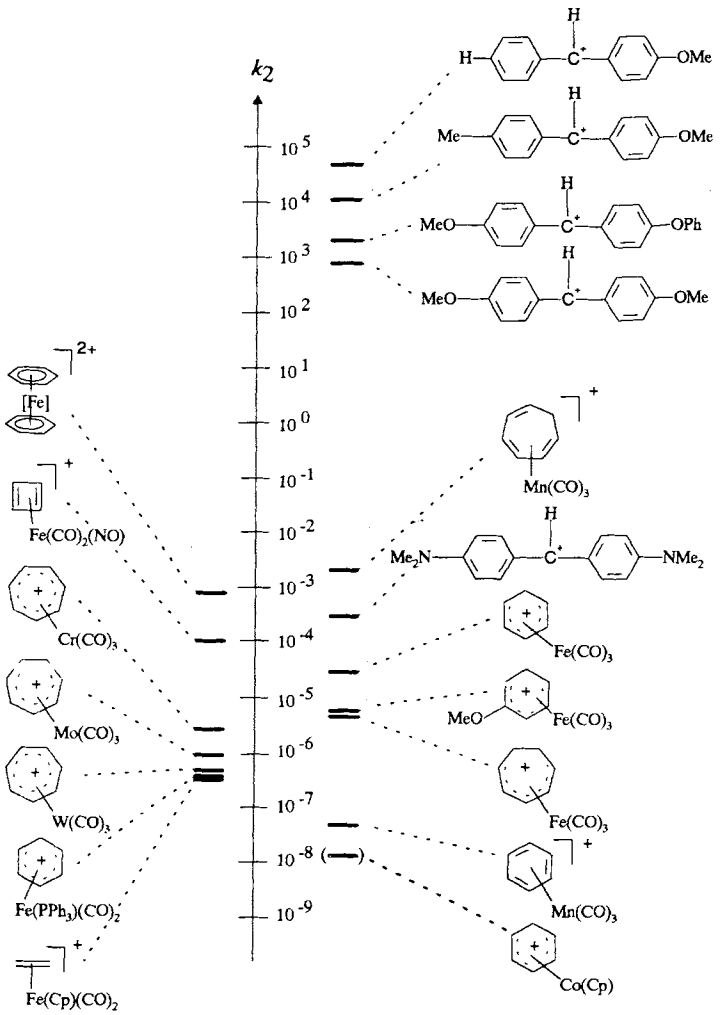

Fig. 3. Averaged reactivities of diarylcarbenium ions [6] and metal π complexes [2] toward nucleophiles (20 °C). Values in parentheses indicate electrophiles that have only been investigated with respect to one nucleophile.

ly,[13] predictions of reactivities in a wide field of organometallic chemistry are now possible.

Bromine Bromate Br_2O_3**

By *Raimund Kuschel* and *Konrad Seppelt**

Dedicated to Professor Wolfgang Sundermeyer on the occasion of his 65th birthday

Oxides of the halogens have been known for a long time.[1] However, much of the knowledge about them has only been gained over the past few years. Chloryl chloride (ClO_2–Cl)[2] and solid Cl_2O_6 as $ClO_2^+ClO_4^-$,[3] for example, were described only recently, as were the structure of solid Cl_2O_7[4] and the paramagnetic-diamagnetic transformation of ClO_2 in the solid state.[5] Whereas also most of the oxygen fluorides and the iodine oxides are well characterized, our knowledge about bromine oxides is limited. The only bromine oxide which could be identified with certainty, and of which the structure could be determined, is Br_2O.[6, 7]

There have been reports of another bromine oxide ("BrO_2"), which supposedly forms in a Br_2/O_2 gas (1:3) high-voltage discharge,[8] as well as during the ozonization of bromine in $CFCl_3$ at low temperatures.[9] In both cases, a yellow powder is obtained which decomposes when warmed to room temperature. From its Raman spectrum, "BrO_2" produced by ozonization was assumed to be $O_2Br–BrO_2$ with a $S_2O_4^{2-}$ or hydrazine structure.[10] Recently, "BrO_2" produced by the discharge route was reported to be really $Br–O–BrO_3$.[11] The main arguments for this assignment were 1) the EXAFS (*E*xtended *X*-ray *A*bsorption *F*ine *S*tructure) data 2) the Raman spectrum (though distinctly different from the one described in ref. [10]), and 3) the fact that BrO_4^- can be identified as one of the hydrolysis products.

It was our aim to characterize the "BrO_2" products unambiguously by single-crystal structure investigations. Ozonization of bromine in $CFCl_3$ yields a lemon-yellow precipitate which dissolves partly in CH_2Cl_2, forms an orange solution, and leaves an insoluble colorless solid. From the solution, orange needles crystallize at −90 °C. The crystals decompose above −40 °C and detonate if warmed rapidly to approximately 0 °C. The crystal structure investigation gave $Br–O–BrO_2$ **1** as the molecular composition (Fig. 1). Bromine bromate **1** is formally the anhydride of hypobromous and bromic acid. Some covalent hypobromites such as $BrO–SO_2F$,[12] $BrOSeF_5$,[13] $BrOTeF_5$,[13] $(BrO)_2TeF_4$,[14] $BrONO_2$,[15] $BrO–ClO_3$,[16] and only very

few covalent bromates like O_2BrONO_2,[16] $O_2BrOClO_3$,[17] and $C_6F_5BrO_2$[18] are known. Crystal structure analyses of these compounds have not yet been reported.

The new bromine oxide **1** has bond lengths and bond angles in accord with the formula $Br-O-BrO_2$, that is, **1** has Br^V in a pyramidal environment with two short Br=O bonds and an angled Br-O-Br unit. The two crystallographically different but chemically identical molecules both have a *syn* conformation. Of particular note are the dimers of **1** in the crystalline solid with a Br···Br distance of 299.5(1) pm. This distance is even somewhat shorter than the intramolecular Br···Br distance of 305.0(1) pm. The directionality of this interaction is also indicated by the angles in the -O-Br···Br-O- bridge, which are 175.9(2) and 86.4(2)°.

A comparison between the structural data of **1** and those of the compound recently described as $Br-O-BrO_3$[11] reveals a striking resemblance. The latter was prepared with the discharge method and characterized by EXAFS as $BrO-BrO_3$. The EXAFS method determines fairly accurate bond lengths only if multiple scattering effects can be excluded or if they are properly considered. Moreover, the determination of the number of neighboring backscatterers (which is generally not very accurate) becomes impossible if perhaps polymorphic products or even product mixtures are investigated. A comparison of the Raman spectra also fails to decide if we have identical or different products. If we restrict ourselves to the prominent bands above 400 cm^{-1}, **1** absorbs at 449, 588, and 849 cm^{-1}. The postulated[11] $BrOBrO_3$ absorbs at 453, 582, and 842 cm^{-1}. If it is assumed that the local C_{3v} symmetry of the BrO_3 part of the molecule dominates the Raman spectrum, the spectra of the compounds could be indeed very similar. The detection of BrO_4^- among the hydrolysis products is only meaningful for a uniform product. The existence of $BrOBrO_3$ is therefore questionable.

None of our experiments resulted in a product with a prominent Raman band at $\tilde{\nu} = 205\ cm^{-1}$. The occurrence of this band had been the main argument for the existence of a bromine oxide formulated as $O_2Br-BrO_2$, which should now be regarded as a totally hypothetical entity.[10]

For the colorless residual bromine oxide, which precipitates on dissolution in CH_2Cl_2, we have as yet not found a suitable solvent. Its Raman spectrum shows it to be a new compound, and it seems to be more strongly oxidized, since the colorless-residue/Br_2O_3 ratio increases with increasing ozonization time. Its lack of coloration excludes the presence of a hypobromite group. We refrain from speculating about its structure at this point.[19] At any rate, if $Br-O-BrO_2$ **1** is the first traceable product during ozonization, it is fascinating to think that it might have been formed by a bimolecular reaction $Br_2 + O_3 \rightarrow Br_2O_3$.

Experimental Procedure

Ozone adsorbed on silica gel at −78 °C was passed very slowly between −50 − −60 °C through a solution of Br_2 in $CFCl_3$ with a stream of argon, until the brown color of the bromine in solution had almost disappeared. The lemon-yellow solid was freed from solvent and ozone under vacuum and dissolved in a little CH_2Cl_2 at −78 °C. The undissolved colorless bromine oxide was removed by low-temperature centrifugation. When the orange solution was cooled to −90 °C, Br_2O_3 crystallized in needles of the same color. Raman spectrum (solid, krypton ion laser, 647.0 nm): $\tilde{\nu}$ = 156, 167 m, sh, 325 $\delta_s(BrO_2)$ s, 387 w, 449 ν(BrOBr) s, 588 ν(BrOBr) s, 849 $\nu_s(BrO_2)$ s, 890 $\nu_{as}(BrO_2)$ w cm^{-1}. Crystal structure analysis: a = 1186.6(2), b = 762.9(1), c = 869.3(2) pm, β = 106.4(1)°, T = −145 °C, $P2_1/c$, Z = 8, μ = 208 cm^{-1}, 3029 measured reflections in the range θ = 2–35°, $\pm h, +k, +l$, 2800 unique reflections. R_{int} = 0.020, 2302 reflections with $I \geq 3\sigma(I)$. R = 0.046, R_w = 0.039. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-57429, the names of the authors, and the journal citation.

Double Lewis Acid Activation in Phosphate Diester Cleavage**

By *Mark Wall, Rosemary C. Hynes*, and *Jik Chin**

It has recently been shown that a number of important enzymes that hydrolyze phosphate diesters are activated by two metal ions. They include 3′-5′ exonuclease from DNA polymerase[1] as well as RNase H from HIV reverse transcriptase.[2] In order to investigate the cooperativity between adjacent metal ions for cleaving phosphate diesters, we compared the reactivities of a simple mononuclear and a simple dinuclear copper(II) complex, using 2-[bis(2-benzimidazolylmethyl)aminomethyl]-4,6-dimethylphenol (HL-1) and 2,6-bis[bis(2-benzimidazolylmethyl)aminomethyl]-4-methylphenol (HL-2), which are mono- and dinucleating ligands respectively (Fig. 1).[3] Here we report on the reactivity of the

mononuclear copper (II) complex **1** and the dinuclear copper (II) complex **2** for cleaving 2-hydroxypropyl-*p*-nitrophenylphosphate (HPNP).

[(L-1)CuCl] **1**
[(L-2)Cu_2Cl_2]Cl **2**

There is considerable interest in developing catalysts that hydrolyze RNA. Many artificial enzymes that hydrolyze RNA or simple RNA models (e.g. HPNP) have been reported to date. They include nonmetallic compounds,[4] as well as mononuclear transition metal[5] complexes and lanthanide complexes.[6] In nature there are many DNases and RNases that are activated by two metal ions. Crystal structures reveal that both 3′-5′ exonuclease[1] and RNase H from HIV reverse transcriptase[2] contain two metal ions at the active site. There is evidence that the *Tetrahymena* ribozyme is also activated by two metal ions.[7] Site-directed mutagenesis may shed some light into the role of each metal ion in the enzymes. However, it would be easier to evaluate whether two metals could be better than one as catalysts in simple chemical systems rather than in complex biological systems. Interestingly, **2** is more reactive than **1** for cleaving HPNP. The pseudo first-order rate constants for cleavage of HPNP (50 μM) catalyzed by **1** or **2** (1 mM) at 25 °C and pH 7 are $4.0 \times 10^{-5}\,s^{-1}$ and $2.1 \times 10^{-3}\,s^{-1}$, respectively. The dinuclear **2** cleaves HPNP by intramolecular transesterification rather than by oxidation. The products of the cleavage of HPNP catalyzed by **2**, as detected by ^1H and ^{31}P NMR, are *p*-nitrophenol and the cyclic phosphate.

To gain some insight into the mechanistic role of the dinuclear complex in cleaving HPNP we obtained a crystal structure of dibenzyl phosphate (DBP) coordinated to the copper complex **3**.[8] The crystal structure reveals that both oxygen atoms of the phosphate diester are coordinated to metal centers of the dinuclear complex to form a bridged structure (Fig. 2). The distance between the two metal centers in **3** (3.67 Å) is comparable to that in 3′-5′ exonuclease (3.8 Å) and HIV RNase H (4 Å). We propose that the key to the reactivity of **2** for cleaving HPNP is double Lewis acid activation of the phosphate diester (Fig. 3). Double Lewis acid activation should be particularly effective for cleaving phosphate diesters bound to a nucleophile (for instance, RNA or HPNP).[9] Single Lewis acid activation in combination with intramolecular metal hydroxide activation has been shown to be effective for hydrolyzing phosphate diesters not bound to a nucleophile (dimethyl phosphate, bis(*p*-nitrophenyl)phosphate).[10] Intramolecular metal-hydroxide activation should not provide much rate-acceleration for cleaving phosphate diesters that are already bound to a nucleophile.

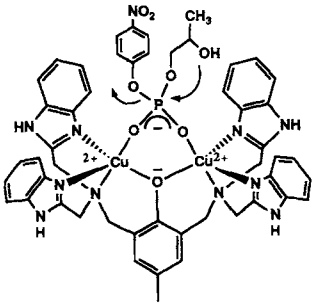

Fig. 3. Proposal for the mechanism of double Lewis acid activation for HPNP cleavage.

([(L2)Cu_2(DBP)]$(ClO_4)_2$ **3**

Over the years, many elegant dinuclear metal complexes with bridging carboxylates or phosphates have been synthesized as spectroscopic models for dimetallic enzymes.[11] In contrast, functional models of dimetallic enzymes are scarce. Dinuclear **2** is not only more reactive for cleaving HPNP than mononuclear **1**, but also significantly more reactive than previously reported nonmetallic catalysts,[4e] and than mononuclear transition metal complexes[5g] and lanthanide complexes.[6c, d]

Experimental Procedure

Compound **3** was prepared by adding sodium dibenzyl phosphate (10 μmol) to an ethanolic solution of HL-2 (10 μmol) and $Cu(ClO_4)_2$ (20 μmol). The crude product was recrystallized from ethanol by slow evaporation to yield thin greenish plates.

The cleavage of the barium(II) salt of HPNP was followed by monitoring the increase in the visible absorbance at 400 nm caused by release of the *p*-nitrophenolate ion. In a typical kinetic experiment, 5 mL of a 0.01 M stock solution of HPNP in water was added to 1 mL of a solution of **1** or **2** (0.5 to 1 mM) at 25 °C and pH 7.0. The rate constants were obtained by fitting the first three half-lives of the reaction to a first-order rate low (correlation coefficient >0.996). Each kinetic run was reproducible to within 3% error. The pH of the reaction solution did not change appreciably during the course of the hydrolysis as a result of the buffering effect of the metal complex solution. In water, the coordinated

chloride atoms are replaced by solvent molecules. Potentiometric titration reveals that the pK_a values of the two bound water molecules in $[(L\text{-}2)Cu_2(H_2O)_2]^{3+}$ are 6.7 and 7.2. The pK_a value of the bound water molecule in $[(L\text{-}1)Cu(H_2O)]^+$ is 6.6.

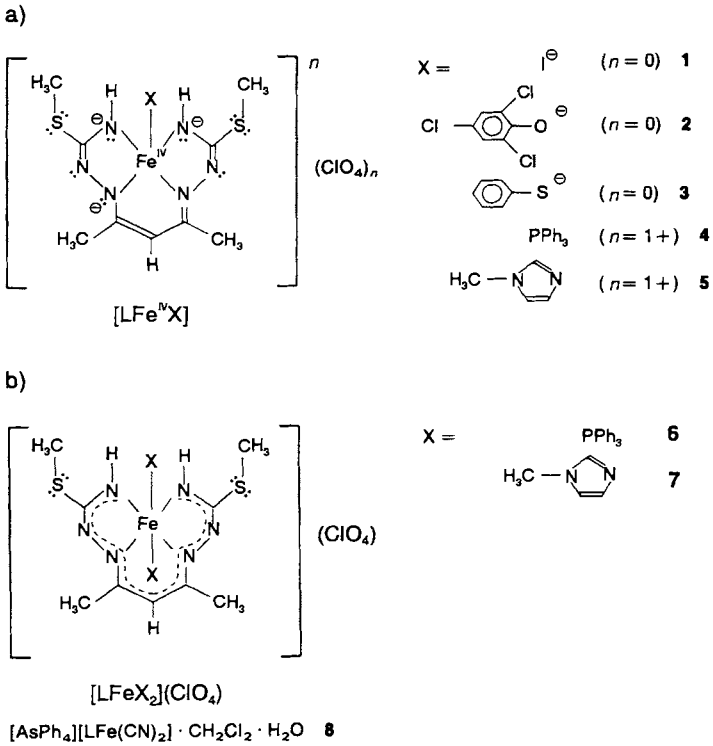
catalytic cycle of iron-containing heme peroxidases.[4] Notably all structurally characterized iron(IV) model complexes to date have the t_{2g}^4 low-spin configuration with a triplet ground state ($S = 1$) regardless of the coordination number at the iron(IV) center (five or six).[11]

Inspired by the work of Gerbeleu et al. and Leovac et al.,[3] who showed that the trianionic pentane-2,4-dione-bis(*S*-alkylisothiosemicarbazonate), a porphyrin-like, four-coordinate ligand L^{3-}, can form stable square-pyramidal iron(IV) complexes $[Fe^{IV}(L^{3-})X]$ (X = Cl, Br, I, NCO, NCS[3a]) and $[(Fe^{IV}L)_2(\mu\text{-}O)]$,[3b] we determined the crystal structure of the *S*-methyl derivative $[Fe^{IV}(L^{3-})I]$ (**1**, Scheme 1 and Fig. 1, top). The structure is very similar to the



Scheme 1. Synthesized square-pyramidal (a) and octahedral (b) iron complexes **1**–**8**.

How "Innocent" Are Pentane-2,4-dione-bis(*S*-alkylisothiosemicarbazonato) Ligands in Biomimetic Fe^{II} and Fe^{IV} Complexes?**

By *Ulrich Knof, Thomas Weyhermüller, Thomas Wolter, Karl Wieghardt,* Eckhard Bill, Christian Butzlaff,* and *Alfred X. Trautwein*

In recent years a few square-pyramidal and octahedral iron(IV) complexes have been isolated and structurally characterized.[1–3] Complexes of this type have been studied in detail, as compounds with iron in the +IV oxidation state have been shown by spectroscopy to be intermediates in the analogous S-ethyl complex.[3a, 5] The iodide ion in **1** was then exchanged for the biomimetic ligands, thiophenolate and *N*-methylimidazole, as well as 2,4,6-trichlorophenolate and triphenylphosphane, to form **2**–**5** (Scheme 1). The new five-coordinate complexes **2**–**5** were isolated as analytically pure species; as expected they have an $S = 1$ ground state (see Table 1).

We then noticed that the reaction of $[(Fe^{IV}L)_2(\mu\text{-}O)]$[3b] in $CHCl_3$ with a large excess of PPh_3 or *N*-methylimidazole gave the octahedral complexes **6** and **7** after the addition of some aqueous $HClO_4$ [Eq. (a)]. Treatment of **1** with KCN in

$$[(LFe^{IV})_2(\mu\text{-}O)] + 4X + 2H^+ \longrightarrow 2[FeL(X)_2]^+ + H_2O \qquad (a)$$

6: X = PPh_3
7: X = $CH_3\text{–}C_3H_3N_2$ (in CH_2Cl_2)

a two-phase CH_2Cl_2/H_2O mixture, followed by addition of $[AsPh_4]Cl$, gave black crystals of **8**, the structure of which has been determined by X-ray crystallography (Fig. 1 bottom).[5]

The complexes **6** and **7** can also be obtained from solutions of **4** and **5** in CH_2Cl_2 with an excess of PPh_3 or *N*-methylim-

idazole. The formation constants of **6** ($K(\mathbf{6}) = 200\ \mathrm{M}^{-1}$) and **7** ($K(\mathbf{7}) = 1400\ \mathrm{M}^{-1}$) [Eq. (b)] were determined spectrophotometrically at 20 °C (inset, Fig. 2). The cyanoiron complex **8** is so stable in CH_2Cl_2 that no dissociation could be detected by spectrophotometry.

$$\underset{\mathbf{4,5}}{[FeLX]^+ + X} \rightleftharpoons \underset{\mathbf{6,7}}{[FeL(X)_2]^+} \qquad \text{(b)}$$

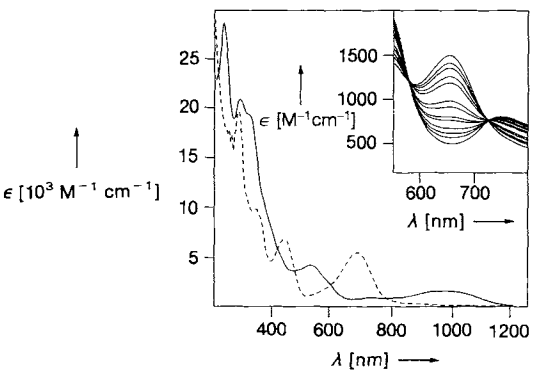

Fig. 2. Electronic spectra of **1** (–) and **8** (···) in CH_3CN. The inset shows the conversion **4** + PPh_3 ⇄ **6**, monitored by spectrophotometry ([**4**] = 3×10^{-4} M, [PPh_3] = $(0.08 \cdots 6.9) \times 10^{-2}$ M).

Magnetic susceptibility values (Fig. 3) measured as a function of temperature, as well as Mössbauer spectra (Fig. 4) recorded with and without an applied external field (4.96–2.45 T) clearly show that complexes **1**–**5** have a triplet ground state ($S = 1$). Adjusted calculations for **1** for both

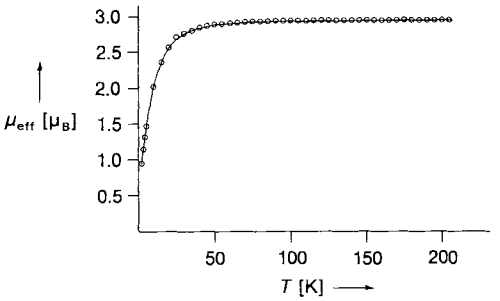

Fig. 3. Temperature dependence of the effective magnetic moment (μ_{eff}) of **1**. The curve represents the fitted ligand-field model described in the text for a $3d^4$ electron configuration ($S = 1$).

methods by using the spin-Hamiltonian operator $\mathcal{H}_e = D[S_z^2 - {}^2/_3 + E/D(S_x^2 - S_y^2)] + \mu_{Bohr}\vec{S}g\vec{B}$ for $S = 1$ gave the following parameters: zero-field splitting $D = +30\ \mathrm{cm}^{-1}$ and rhombicity $E/D = 0.28$. Due to the size of the zero-field splitting the g values of iron are correlated with the zero-field parameters in the spin-Hamiltonian simulation. On the basis of the ligand-field model for the low-spin t_{2g}^4 ($S = 1$) configuration,[6] the g values are found to be (2.19, 2.35, 1.99) if a one-electron spin-orbit coupling constant $\zeta = 500\ \mathrm{cm}^{-1}$ is assumed.

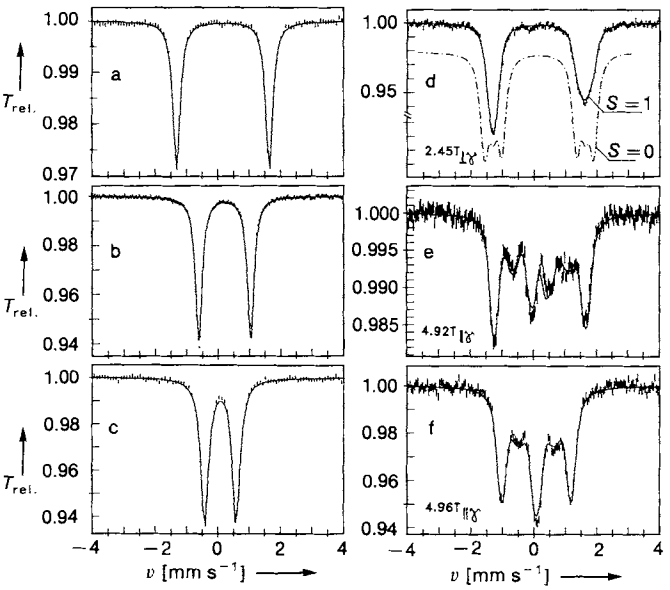

Fig. 4. Mössbauer spectra of **1** (a, d), **6** (b, e) and **8** (c, f) at 4.2 K with (d, e and f) and without (a, b, and c) an external field. The solid lines in a, b, and c are fitted Lorentz curves. In d the solid line is obtained from a simulation with the spin-Hamiltonian operator with $S = 1$ and the parameters given in the text and in Table 1, together with the asymmetry parameter $\eta = 1$ and the hyperfine coupling constant $A = (-20, -12, -20)$ T. The dashed line in d and the solid lines in e and f fit the usual nuclear-Hamiltonian operator for an external field with quadrupolar splittings as in Table 1 ($\eta = 0.8$ for e and $\eta = 1$ for f); in this case the valence shell of the iron center does not contribute to the magnetic splitting. The simulation in f was calculated with an effective outer field of 4.6 T, which is reduced by 0.36 T compared to the actual applied field of 4.96 T [7].

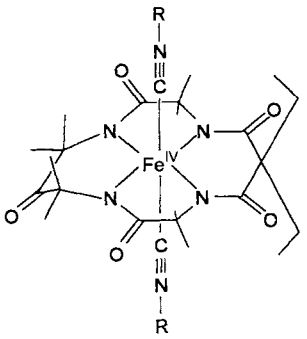
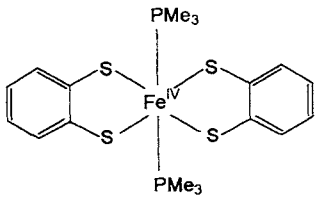
In stark contrast to this, the six-coordinate complexes **6**, **7**, and **8** have a singlet ground state ($S = 0$) and are diamagnetic (a small residual magnetism remains, which is caused either by small amounts of an impurity that is five-coordinate ($S = 1$), or by a weak orbital moment). The Mössbauer spectra measured with an externally applied field prove that **6**–**8** have singlet ground states[7] (Fig. 4).

The quadrupolar splitting of all complexes is practically temperature independent, which rules out energetically low-lying excited electron states; the splitting is smaller for the more symmetric octahedral complexes **6**–**8** than for the square-pyramidal complexes **1**–**5**. The low isomer shifts, similar for all complexes, in the region 0.06–0.18 mm s^{-1} are in agreement with known Fe^{IV} complexes.[1–3]

Although it seems theoretically possible for the complexes **6**–**8** to have a diamagnetic ground state with an iron(IV) t_{2g}^4 electron configuration (low low spin), which would be in agreement with the Mössbauer spectra and magnetic properties, the fact that the neutral octahedral Fe^{IV} complexes **9** of Collins et al.[2b] and also Sellmann's complex **10**[1b] have a triplet ground state must cast some doubt on this. Instead of Fe^{IV} complexes, **6**–**8** might be low-spin Fe^{II} complexes with $S = 0$. The question then is whether L^{3-} is an electronically 'innocent ligand', or whether it can also be thought of as the monoanion L^-.[8]

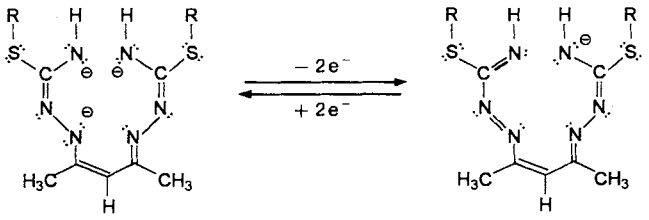


9



10

The two resonance forms L^{3-} and L^- in Scheme 2 show that L^{3-} is a 14π-electron system, and L^-, its oxidized form, is a 12π electron system. The trianion L^{3-} has four delocalized double bonds, whilst the monoanion L^- has five. It is therefore to be expected that the sum of the C–N, N–N, and C–C bond lengths of the ligand π-electron system in ML^{3-} and ML^- complexes will be different; the sum for the former should be somewhat greater than the sum for the latter. For calibration we used the complex $[Cu^{III}(L^{3-})]$,[9] which we recently reported and which is diamagnetic with an essentially square-planar CuN_4 coordination geometry. Formulation as $[Cu^{I}(L^-)]$ is out of the question, as this would be expected to have tetrahedral CuN_4 geometry. The sum of the distances $\Sigma[6(C-N) + 2(N-N) + 2(C-C)]$ comes to 13.546 Å for this complex. For **1**, its *S*-ethyl derivatives,[3a] and $[\{Fe^{IV}(L^{3-})\}_2(\mu\text{-O})]$,[3b] these sums are 13.503, 13.491, and 13.495 Å, respectively, and for the two crystallographically independent anions in **8**, the average value is 13.470 Å. Remarkably, **8** has the smallest and $[Cu^{III}L]$ the largest total. We therefore suggest that **8** may be written as $[Fe^{II}(L^-)(CN)_2]^-$. A similar trend is found on considering only the C–NH bond lengths, which should have more single-bond character in L^{3-} than in L^-. In $[Cu^{III}L]$, **1**, its *S*-ethyl derivatives, and $[\{Fe^{IV}(L^{3-})\}_2(\mu\text{-O})]$, these distances are 1.319, 1.314, 1.332 and 1.318 Å, respectively, whilst in **8** this distance is significantly shorter (1.285 Å).



Scheme 2. Resonance forms of the trianion L^{3-} and the monoanion L^-.

These considerations all suggest that the structures **1**–**5** are correctly described as Fe^{IV} complexes, whilst **8** (and because of their similar electronic spectra (Table 1) **6** and **7**, too) should be considered to be octahedral, low-spin Fe^{II} complexes.

Cyclic voltammetry and coulometry of **8** gave further evidence for the validity of the above hypothesis.[10] A quasi-reversible one-electron *oxidation* is observed at a redox potential of 0.30 V vs. the standard hydrogen electrode (SHE), which is attributed to the redox pair $[Fe^{II}(L^-)(CN)_2]^-/$

[a] UV/VIS spectra: solvent CH_2Cl_2. [b] Mössbauer spectra: measured at 4.2 K in zero-field; the isomer shift δ is relative to α-Fe at 298 K; ΔE_Q = quadrupolar splitting; Γ = line width at half height. [c] CN = coordination number. [d] Not measured.

$[Fe^{III}(L^-)(CN)_2]$. However complexes **9**[2b] and **10**[1b] showed quasi-reversible *reductions* at 1.16 V and −0.28 V vs. SHE, as did **1**–**5**[10] ($E_{1/2}(Fe^{IV}/Fe^{III})$: **1**, −0.37; **2**, −0.33; **3**, −0.66; **4**, −0.10; **5**, −0.19 V vs. SCE).

If **6**, **7**, and **8** are indeed Fe^{II} complexes and **4** and **5** Fe^{IV} complexes, then the formation (b) of octahedral complexes from square-pyramidal substrates can be described as reductive addition and the reverse reaction as oxidative elimination. Finally, in answer to the question posed in the title we have shown that the ligand can coordinate as a 14π- or 12π-electron system; it is therefore definitely not electronically 'innocent'.

Experimental Procedure

Complex **1** and $[(FeL)_2(\mu\text{-}O)]$ were synthesized according to literature methods [3]. All following syntheses were carried out in an argon atmosphere. All complexes gave good elemental analyses for C, H, N and Fe.

2 and **3**: A solution of $[(FeL)_2O]$ (0.10 g; 0.15 mmol) in $CHCl_3$ (10 mL) was treated with either 2,4,6-trichlorophenol (0.30 mmol) or thiophenol (0.75 mmol) and stirred for 3 h at 20 °C, whereupon the green solution turned red-brown. After separation of the $CHCl_3$ layer and overlaying with *n*-pentane (10 mL) for 12 h at −20 °C, red-brown microcrystals of **2** or **3** separated (56 and 38% yield, respectively). IR(KBr): ν(N–H) [cm^{-1}]: **2**, 3310(s); **3**, 3330(s).

4 and **5**: To a solution of $[(FeL)_2O]$ (0.10 g, 0.15 mmol) in $CHCl_3$ (10 mL) were added either PPh_3 (0.30 mmol) or *N*-methylimidazole (0.30 mmol). After addition of 5 mL of a 6 mM aqueous solution of $HClO_4$ containing $NaClO_4$ (0.20 g), the solution was stirred vigorously for 1 h at 20 °C. The resulting red-brown $CHCl_3$ layer was separated off, overlaid with *n*-pentane (10 mL), and left to stand for 12 h at −20 °C, whereupon red-brown microcrystals formed (yield: **4**, 51%; **5**, 45%). IR(KBr): ν(N–H) [cm^{-1}]: **4**, 3340(s); **5**, 3300(s).

6 and **7**: Both complexes were synthesized similarly to **4** and **5**, by addition of PPh_3 or *N*-methylimidazole, respectively, (5 mmol) and enough 6 mM $HClO_4$ solution to make the aqueous phase slightly acidic. Green microcrystals formed in 42% (**6**) and 68% (**7**) yield. IR(KBr): ν(N–H) [cm^{-1}]: **6**, 3350(s) and 3340; **7**, 3350(s).

8: A solution of **1** (0.20 g; 0.44 mmol) in CH_2Cl_2 (100 mL) was overlaid with H_2O (50 mL) and treated with KCN (1.0 g, 15 mmol) with vigorous stirring at 20 °C. Initially the organic layer, and then after a few minutes, also the aqueous layer, turned dark green. After 30 min the aqueous layer was separated off and treated with $[AsPh_4]Cl$ (0.5 g, 1.2 mmol), whereupon black-green microcrystals of **8** separated in 72% yield. The CH_2Cl_2 layer could be extracted further by addition of H_2O. Single crystals were obtained by slow diffusion of *n*-pentane into a CH_2Cl_2 solution of **8**. IR(KBr) [cm^{-1}]: $\nu(OH_2)$: 3440, 3527; ν(NH) = 3366; ν(CN) = 2098. ^1H NMR (80 MHz, $CDCl_3$): δ = 6.17 (s, 2H), 5.26 (s, 1H), 2.53 (s, 6H), 2.47 (s, 6H).

[7] For a satisfactory simulation of the 4.96 T spectrum of **8** we had to assume a small, internal field of 0.36 T acting in the opposite direction to the applied field (Fig. 4). We presume that this field is due to the orbital moment of the diamagnetic iron center, in accord with the observed weak residual magnetism of **8** (Table 1).

Metallacyclic Interconversions in the Chemistry of Palladium with Phenyl Isocyanate**

By *Frédéric Paul, Jean Fischer, Philippe Ochsenbein,* and *John A. Osborn**

The palladacycle **1** was isolated[1] from solutions of the homogeneously catalyzed palladium/*o*-phenanthroline carbonylation of nitrobenzene, which yields phenyl carbamate in excellent yield (90%) when ethanol is present (Scheme 1).[2] We proposed that **1** and similar metallacyclic

$$PhNO_2 \longrightarrow PhNHCO_2Et$$

Scheme 1. Carbonylation of introbenzene. Reaction conditions: 1 equiv $[Pd(OAc)_2]_3$ + 3 equiv *o*-phen, 8 equiv CF_3COOH, 180 °C, 120 bar CO, EtOH, 30 min. $c(PhNO_2)/c(Pd)$ = 360; 100% conversion; 90% selectivity.

species may be involved as intermediates in this multistep catalytic process.

Using conditions similar to those previously[1] described, $[Pd(OAc)_2]$, *o*-phen (3 equiv), CO (40 bar, 80 °C, 1 h) but with only nitrobenzene (200 equiv) as solvent (thus omitting alcohol), we obtained a yellow complex **2** (40% yield) along with **1** (30% yield). In the presence of protons (8 equiv of 2,3,5,6-tetramethylbenzoic acid), the yield of **2** after several hours is nearly quantitative. Analysis and spectroscopic studies indicate that **2** contains, in addition to a Pd(*o*-phen) moiety, two C_6H_5NCO units. Thus, the FAB-MS analyses (*o*-nitrobenzyl alcohol as matrix) of **2** shows peaks at

m/z (%) 525 ($M+1$), 497 ($M+1-CO$), 406 ($M+1-C_6H_5NCO$), 377 ($M-C_6H_5NCO-CO$), and 286 ($M-2C_6H_5NCO$). The IR spectrum shows two intense absorptions at 1675 and 1610 cm^{-1}, characteristic of carbonyl groups. A five-membered metallacyclic structure resulting from an *apparent* head-to-tail coupling of two isocyanate molecules was indicated (Scheme 1), which has been confirmed in an X-ray structure determination[3, 4] (Fig. 1).

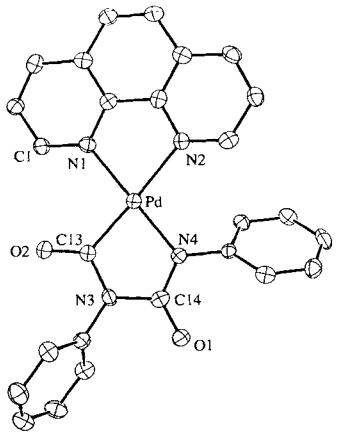

Fig. 1. ORTEP plot of **2** (50% probability level), showing part of the labeling scheme used. Hydrogen atoms are omitted for clarity. Selected distances [Å] and angles [°]: Pd–N1 2.062(4), Pd–N2 2.169(3), Pd–C13 1.963(4), Pd–N4 1.996(3), N3–C13 1.383(6), N3–C14 1.420(6), N4–C14 1.327(6), O1–C14 1.230(5), O2–C13 1.213(5), O2–C1 2.976(5), N1–Pd–N2 78.9(1), C13–Pd–N4 80.1(2), N2–Pd–N4 102.3(1), N1–Pd–C13 99.8(2).

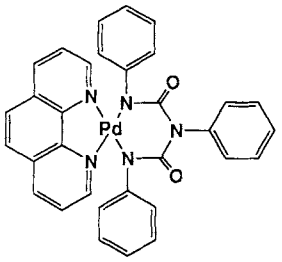
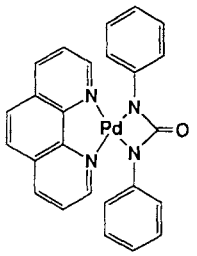
Compound **2** is extremely stable (decomposition only at 290 °C) and unlike **1** does not react with alcohol in the presence or absence of protons. We surmised that **2** might be formed in the reaction of **1** with C_6H_5NCO, but heating **1** with C_6H_5NCO (40 equiv) at 140 °C for 7 h in nitrobenzene or *o*-dichlorobenzene yields a orange-yellow complex **3** in about 90% yield. Spectroscopic studies (^1H NMR, FAB-MS) indicate that **3** contains a six-membered metallacyclic structure. The X-ray structure[5] of the *p*-tolyl derivative **3a** is very similar to that of an analogous nickellacycle,[6] which has been isolated from the reaction of Ni^0 with C_6H_5NCO. Indeed, we find that on refluxing [Pd(*o*-phen)(dba)] (dba = dibenziliden acetone), with C_6H_5NCO (20 equiv) in benzene, **3** is formed in about 30% yield. Under milder conditions (25 °C, CH_2Cl_2) and a large excess of C_6H_5NCO, **2** is formed in approximately 50% yield along with extensive formation of the cyclic trimer of C_6H_5NCO, triphenylisocyanurate.

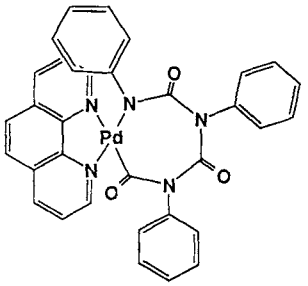
However, **2** is unexpectedly neither a catalyst for this trimerization process nor an intermediate in the formation of **3**; no reaction occurs on prolonged heating on **2** with excess C_6H_5NCO at 140 °C. Although **3** is quite stable (decomposition in the solid only at 250 °C), it undergoes two reactions of note: a) treatment with CO (1 bar) in $C_6H_5NO_2$ at 140 °C for 5 h produces **2** along with the precipitation of some Pd metal and b) heating **3** in solution with a labeled isocyanate (e.g. *p*-tolyl isocyanate) causes total exchange of the phenyl isocyanate groups to yield quantitatively the *p*-tolyl analogue (**3a**) of **3**.



3



4



5

Since a sequence of ring expansion and contraction (or the reverse) could be envisaged for these reactions, we heated **3** in *o*-dichlorobenzene at 140 °C for 1 h. The ^1H NMR, IR ($\nu = 1615\ cm^{-1}$ (C=O)), and FAB-MS data of the resulting red compound showed that a four-membered metallacycle **4** was formed with the concomitant extrusion of C_6H_5NCO.[7] The structure determined by X-ray methods is shown[8] (Fig. 2) and will be described in detail elsewhere.[9] Further, mild treatment of **4** with excess C_6H_5NCO (50 equiv) regenerates **3** quantitatively (80% yield). Thus we propose that the isocyanate exchange reaction occurs by a reversible six- to four- to six-membered palladacycle interconversion. Furthermore, since **4** also reacts with CO (40 bar) in CH_2Cl_2 to yield **2** (85% yield), formation of **2** from **3** is thus seen to result from a six- to a four-membered ring contraction with

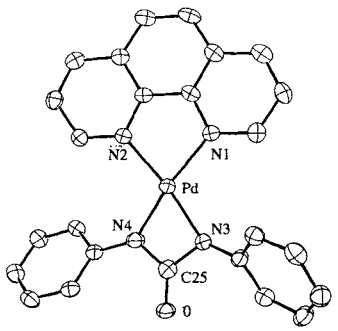


Fig. 2. ORTEP plot of **4** (50% probability level) showing part of the labeling scheme used. Hydrogen atoms are omitted for clarity. Selected distances [Å] and angles [°]: Pd–N1 2.066(3), Pd–N2 2.034(3), Pd–N3 1.992(3), Pd–N4 2.001(3), N3–C25 1.376(5), N4–C25 1.373(5), O–C25 1.238(5), N1–Pd–N2 80.3(1), N3–Pd–N4 65.6(1), N2–Pd–N4 107.1(1), N1–Pd–N3 107.2(1).

loss of isocyanate followed by a four- to a five-membered ring expansion upon insertion of CO. The detailed mechanism of formation of **3** (as well as **2**) from aryl isocyanate and Pd^0 is not evident, although decarbonylation of the 7-membered palladacycle **5**, formed by the head to tail coupling of three isocyanates and Pd^0, is probably the last step. Note, however, that a classical coupling process of two C_6H_5NCO ligands on Pd^0 to form a five-membered palladacycle such **2**, followed by a further insertion of isocyanate to give **5**, can be excluded since **2** does not react with isocyanate.

Although the above reactions are not directly implicated in the catalytic carbonylation of nitrobenzene[11], the pervasiveness and stability of the palladacycles **1**–**4** and their interconversions would offer credence to the intermediacy of analogous cycles in this catalytic process, particularly if the isoelectronic and isolobal nature of certain entities involved, e.g. RNCO and CO_2, are considered.[10] Furthermore, considering the relationship of **2** and **3** to diphenylurea and triphenylbiuret, which are undesirable by-products[12] in the carbonylation process, our results indicate that such metallacycles, however, may indeed play a subsidiary perhaps even detrimental, role in this catalytic reaction. Finally the formation of both **1** and **2** under the catalytic conditions described above in the absence of a proton source or alcohol would seem to argue against the existence of intermediates such as aniline in the formation of carbamates in this palladium system.[10b]

Tautomer-Specific Anti-(N-3-Substituted)-Adenine Antibodies: New Tools in Molecular Dosimetry and Epidemiology**

By *Karl-Heinz Glüsenkamp,* Kai Krüger, Gertrud Eberle, Wolfgang Drosdziok, Eckhard Jähde, Oliver Gründel, Andrea Neuhaus, Roland Boese, Peter Stellberg,* and *Manfred F. Rajewsky*

Mutagenic and carcinogenic substances are found in the environment (including foodstuffs) and are produced endogenously within organisms.[1] Such compounds cause structural modifications of the deoxyribonucleic acid (DNA) in exposed cells, often leading to the formation of covalent DNA-base adducts.[1–8] Of particular importance in this context is the class of alkylating agents, which includes many N-nitroso compounds,[2, 3, 6] polycyclic hydrocarbons,[7] some fungal metabolites,[8] and numerous chemotherapeutic agents.[4] Among the functional groups of DNA that are reactive towards alkylating agents, the nucleophilic N-3 atom of deoxyadenosine is of special interest, because its alkylation destabilizes the N-glycosidic bond[9] and may thus lead to the release of N-3-substituted adenines, resulting in the formation of apurinic ("abasic") sites. In addition, 3-alkyladenines are removed from DNA by DNA-repair enzymes (3-alkyladenine-DNA-glycosylase).[10] Many modified bases are not further metabolized and hence appear unchanged in the body fluids (urine, blood plasma).[11] Besides DNA, RNA is a potential target for alkylating agents, too; however, after exposure of cells to alkylating agents 3-alkyladenines are formed mainly in DNA.[12]

[**] This work was supported by the European Community as part of the program "Science and Technology for Environmental Protection (S. T. E. P.)" (EV5V-CT91-0012), and by the Kind-Phillipp-Stiftung für Leukämieforschung im Stifterverband für die Deutsche Wissenschaft.

A variety of N-3-substituted adenines may be produced in cellular DNA, depending on the molecular nature of the alkylating reactant. Many alkyl and allyl substituents, some bearing aromatic groups, have been found at the N-3 position of adenine in vivo and in vitro.[13] To determine N-3-adenine adducts by immunoanalytical methods in cellular DNA for "molecular dosimetry" of a broad spectrum of endogenous and exogenous DNA-reactive compounds, we have produced novel anti-(N-3-*R*-adenine) monoclonal antibodies (mab). These mabs bind to modified adenines with high affinity, regardless of the size of the substituents at position N-3.

We describe here the design and synthesis of the haptens used for coupling to carrier proteins for the immunization of BALB/c mice.[11b] The aim of our studies was the production of antibodies with very high specificity for the entire family of N-3-substituted adenines and with very low cross-reactivity with other, naturally occurring purine derivatives.

AM1-calculations[14] and spectroscopic studies[15] on the tautomerization equilibria (Fig. 1) of several N-3-substituted adenines revealed that the tautomeric structure **1** is energetically preferred, regardless of the substituent at the position N-3. Analogous considerations for the parent

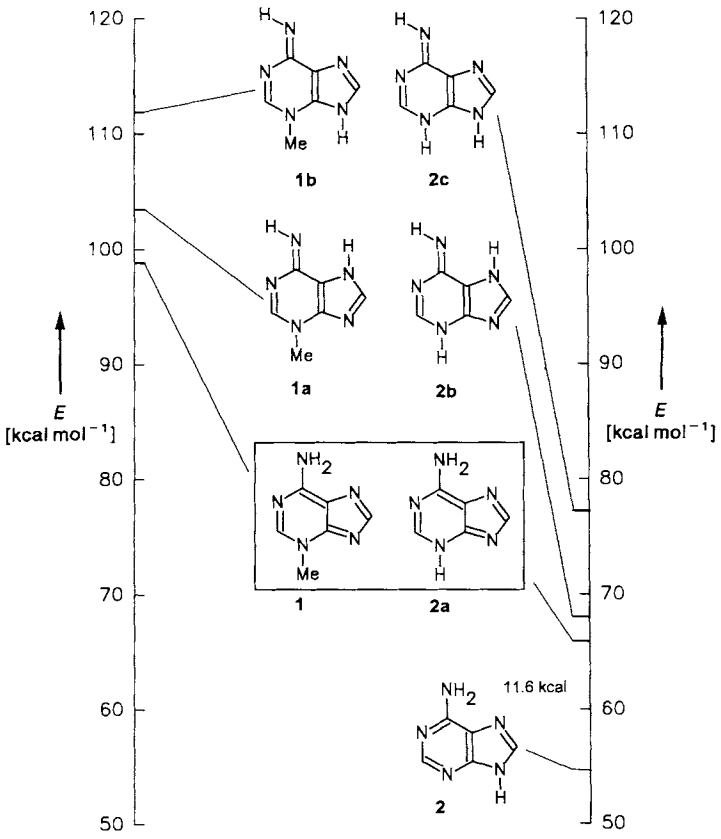

Fig. 1. Comparison of the enthalpy of formation for selected tautomeric structures of 3-methyladenine (**1**) (left) and adenine (**2**) (right), determined by using the AM1 method[14-16]. Structures **1** and **2a** show the tautomeric forms of the adenine skeleton (in the box), which are recognized by mab EM-6-47. In the case of unsubstituted adenine, the tautomeric form **2** is 11.6 kcal mol^{-1} lower in energy.

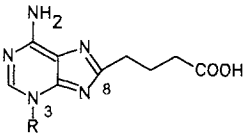
compound, adenine, show that the tautomeric structure **2** is 11.6 kcal mol^{-1} more stable than the tautomer **2a**, which represents the lowest energy structure of the family of N-3-substituted adenines. Based on this large energy difference, it seemed possible to develop mabs that would specifically recognize the favored tautomeric structure **1** induced by a substituent at the N-3 position.

For the production of mabs directed against low molecular weight compounds these must first be conjugated to an immunogenic carrier protein (e.g., keyhole limpet hemocyanin[11b]). To obtain tautomer-specific anti-(N-3-R-adenine) mabs, the tautomerization equilibrium of the 3-substituted adenines must remain unaffected by the coupling of haptens to carrier proteins. By using AM1-calculations on 3,8-disubstituted adenines we were able to show that the tautomer equilibria of N-3-substituted adenines are not influenced significantly by 8-alkyl substituents.[14c] For the production of a tautomer-specific anti-(N-3-R-adenine) mabs the key haptens **3**–**5** were synthesized in three steps.[17]



3: R = Me
4: R = Et
5: R = *n*Bu

The carboxypropyl substituent in position 8 served both as a coupling group to the carrier protein and as a spacer for optimal presentation of the antigen on the protein surface.[19]

Figure 2 shows the result of an X-ray structure analysis[20] of 3-methyl-8-(3-carboxypropyl)adenine (**3**), which crystallized with four molecules of water per formula unit.

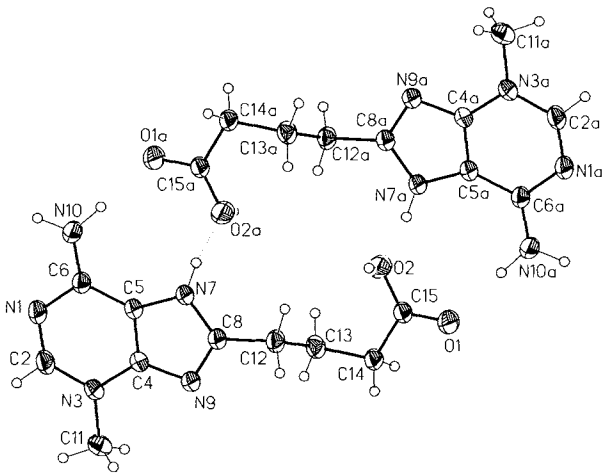


Fig. 2. The crystal structure of **3**. The thermal ellipsoids are drawn at the 50% probability level.

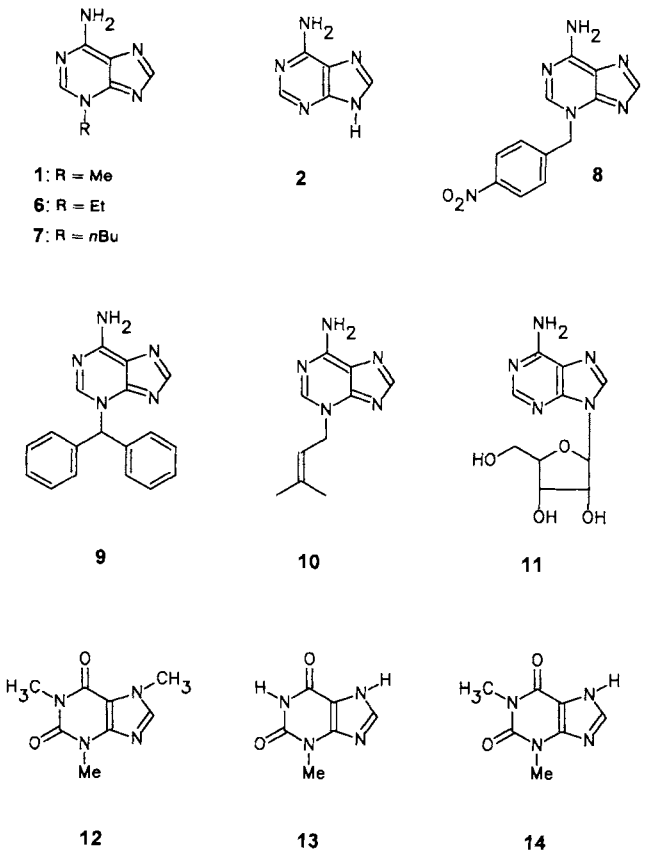
Whereas the protein conjugates of **3** and the corresponding *n*-butyl derivative **5** gave no satisfactory immune response, the conjugate bearing an ethyl substituent in the 3-position induced a large number of high-affinity mabs (affinity constants for 3-ethyladenine of the order of 10^{10} L mol^{-1}[11a, b]). As expected, binding studies with these mabs and the purine derivatives shown in Scheme 1 revealed high specificity and affinity for 3-substituted adenines. The adenine N-3 substituents can range from methyl to sterically demanding diphenylmethyl groups without causing significant changes in the affinity. In contrast, the observed binding constants of naturally occurring purine derivatives such as adenine (**2**), adenosine (**11**), and theophylline (**14**) is more than five orders of magnitude lower. Table 1 shows a selec-



Scheme 1. 3-Substituted adenines and naturally occurring purines as competitors of 3-ethyladenine (**6**) in the radioimmunoassay with mab EM-6-47.

tion of purines tested and summarizes the binding characteristics of a representative mab (mab EM-6-47). In accordance with the earlier theoretical considerations, the binding studies indicate tautomer-specific, high-affinity, antigen–antibody binding.

Table 1. Cross-reactivity[a] of the monoclonal antibody EM-6-47 with alkylated adenines and naturally occurring purines (competitors).

Competitor		Binding of competitor relative to **6** in competitive radioimmunoassays [a]
3-ethyladenine	**6**	1
3-methyladenine	**1**	0.04
3-methyl-8-(3-carboxypropyl)adenine [17]	**3**	0.05
3-ethyl-8-(3-carboxypropyl)adenine [17]	**4**	0.6
3-butyl-8-(3-carboxypropyl)adenine [17]	**5**	5.2
3-butyladenine	**7**	2.5
triacanthin [23]	**10**	0.2
3-(*p*-nitrobenzyl)adenine	**8**	0.9
3-(diphenylmethyl)adenine	**9**	0.1
adenine	**2**	<0.00001
adenosine	**11**	<0.00001
coffeine	**12**	<0.00001
3-methylxanthine	**13**	<0.00001
theophylline	**14**	<0.00001

[a] The competitive radioimmunoassays were carried out as described in ref. [21]. All compounds except **3**–**5** are described [22].

Until now, we have been able to quantify 3-methyladenine and 3-ethyladenine at fmol levels in the urine of experimental animals and human individuals.[11b] On the basis of a recently developed conjugation method,[24] immunoaffinity columns have been prepared with anti-(N-3-R-adenine) mabs, allowing the quantitative isolation of 3-substituted adenines from body fluids.[25] By using these mabs as an efficient tool in combination with separation by HPLC (HPLC = high-performance liquid chromatography) we will be able to measure individual exposures to environmental alkylating agents and hence gain access to novel markers for exposure studies.

Another potential application for anti-(N-3-adenine) mabs is in monitoring during chemotherapeutic treatment with anti-cancer drugs. These mabs can be employed for dosimetry at the level of target cell DNA by measuring the rate of formation of N-3-substituted adenines, which can vary dramatically among individuals.

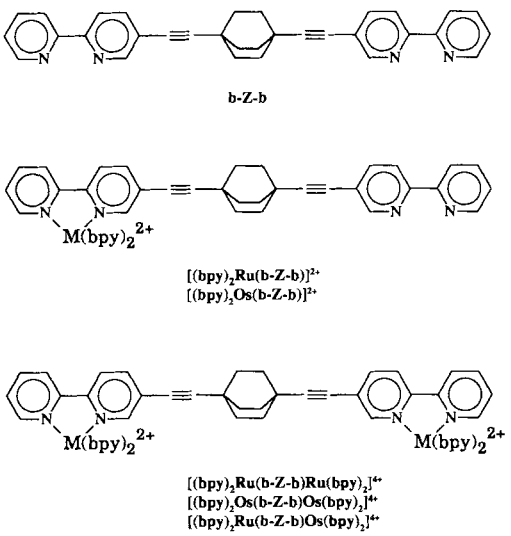
Rigid Rodlike Metal Complexes of Nanometric Dimension: Synthesis, Luminescence Properties, and Long-Range Energy Transfer**

By *Fritz Vögtle,* Michael Frank, Martin Nieger, Peter Belser,* Alex von Zelewsky, Vincenzo Balzani,* Francesco Barigelletti, Luisa De Cola,** and *Lucia Flamigni*

The development of photochemical molecular devices[1–3] for a variety of applications (e.g., artificial photosynthesis[3–7] and information processing[8–11]) is largely based on the design of supramolecular species in which photoinduced energy or electron transfer processes can take place over a long distance with high efficiency. An important requirement for the usefulness of such supramolecular species is their degree of spatial organization. Species in which the active components are linked by nonrigid bridges are of little applicative interest because practical devices require vectorial energy or electron transfer over long distances. Furthermore, when the geometry of the system is not strictly defined, the results obtained are of limited basic interest since they cannot be compared with the predictions of energy and electron transfer theories.[3–5, 12–17]

Because of their outstanding excited state and redox properties,[18] Ru^{II} and Os^{II} bpy-type complexes (bpy = 2,2′-bipyridine) are excellent components for building supramolecular species capable of exhibiting photoinduced energy and electron transfer processes.[3, 19] For synthetic reasons, however, it is difficult to assemble these metal-containing building blocks in *extended and rigid* supramolecular structures.[20]

We have synthesized the novel bridging ligand 1,4-bis[2-(2,2′-bipyridine-5-yl)ethynyl]bicyclo[2.2.2]octane (hereafter indicated by b-Z-b, in which two bipyridine units (b) are separated by a 1.0 nm long spacer (Z) made of a rigid bicyclooctane component and two linear acetylene-type units. Such a rigid bridging ligand has allowed us to prepare the mono- and dinuclear complexes of Ru^{II} and Os^{II} shown in Scheme 1. In the dinuclear species, the distance between the two metal centers (ca. 1.7 nm) changes only slightly on rotation around the single bonds that connect the bridge (spacer) to the bpy units. These rodlike, nanoscale supramolecular species exhibit interesting excited state and redox properties.



Scheme 1. Structural formulas of the bridging ligand b-Z-b and of the complexes it has been used to prepare.

The novel ligand b-Z-b has been synthesized via the corresponding bis-alkene **3** (Scheme 2). Phosphonate ester **1** was readily obtained by an Arbuzov rearrangement from 5-bromomethyl-2,2′-bipyridine.[23] Bicyclo[2.2.2]octane-1,4-dicarboxaldehyde **2**[24] and **1** were coupled by a Wadsworth–Emmons reaction to give the (*E*,*E*) diene **3**. Bromination at room temperature gave **4** and subsequent dehydrobromination by refluxing with excess potassium hydroxide yielded the diyne b-Z-b, which was isolated as a colorless, crystalline solid. An X-ray structure of the bridg-

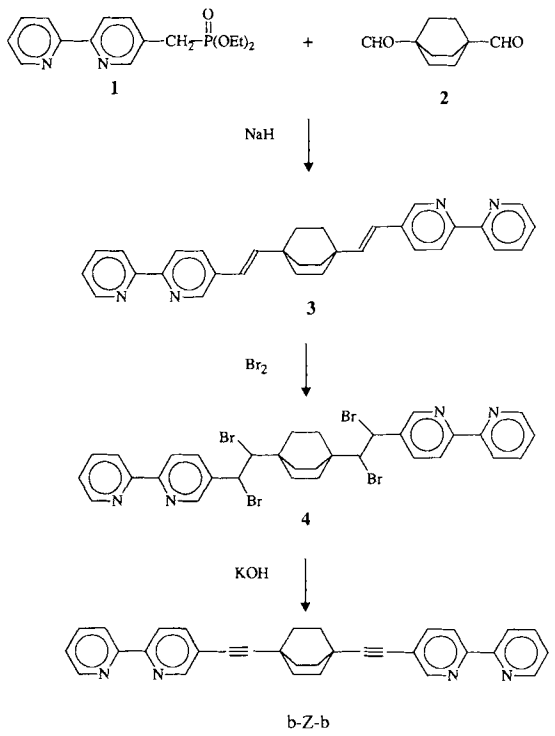

Scheme 2. Synthesis of the ligand b-Z-b.

ing ligand b-Z-b proved the assumed, rodlike structure (Fig. 1).[25]

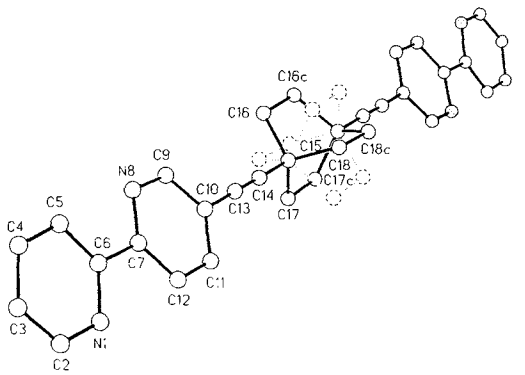

Fig. 1. Crystal structure of the bridging ligand b-Z-b; the bicyclooctane unit is disordered.

The mono- and dinuclear complexes of the bridging ligand b-Z-b were prepared and purified according to a previously reported procedure.[26] Characterization was performed by elemental analysis, FAB mass spectrometry, ^{1}H NMR, UV/VIS, spectroscopy. The equipment used to measure the absorption spectra, luminescence properties, and oxidation potentials have been previously described.[26] Some of the results obtained have been gathered in Table 1, in which data on the "parent" $[Ru(bpy)_3]^{2+}$ and $[Os(bpy)_3]^{2+}$ compounds[18] are also shown for comparison purposes.

The absorption spectra in the visible region and the luminescence spectra of the dinuclear compounds are displayed in Figure 2. Particularly noteworthy are the isosbestic

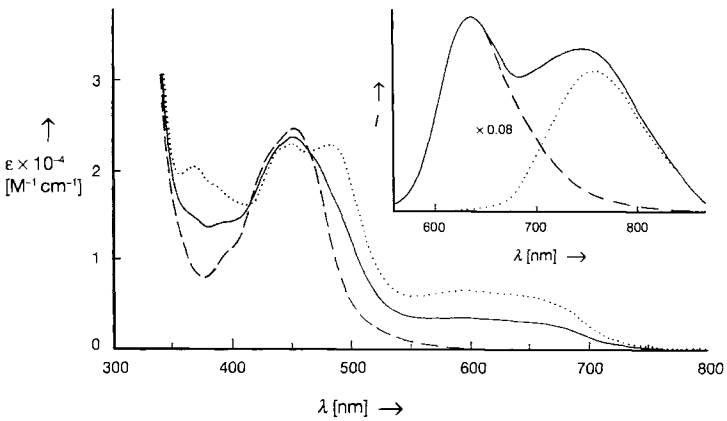

Fig. 2. Absorption and (inset) uncorrected luminescence spectra of $[(bpy)_2Ru(b\text{-}Z\text{-}b)Ru(bpy)_2]^{4+}$ (– –) multiplied by 0.08, $[(bpy)_2Os(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ (· · ·), and $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ (–).

points at 416 and 466 nm. When excitation is performed at one of these wavelengths on the Ru–Os complex (as was the case for the luminescence experiments), each metal-based unit absorbs 50% of the incident light.

From Table 1 and Figure 2 one can see that in the novel compounds each metal-based unit displays its own electrochemical properties and absorption spectrum regardless of the presence and nature of a second metal-based unit. Furthermore, the dinuclear homometallic compounds exhibit the same luminescence properties as the corresponding mononuclear species (Table 1). These results indicate that the electronic interaction between the metal-containing units in the dinuclear compounds is very weak.

Table 1. Spectroscopic and electrochemical data of Ru and Os(bpy) complexes [a].

	Absorption [b]	Luminescence [c]			Electrochemistry [d]
	λ_{max}	λ_{max}	τ	$\Phi \times 10^2$ [e, f]	$E_{1/2}$ [V]
$[(bpy)_2Ru(b\text{-}Z\text{-}b)]^{2+}$	453	635	226	1.5	+1.25 (1)
$[(bpy)_2Os(b\text{-}Z\text{-}b)]^{2+}$	484	787	28	0.18	+0.84 (1)
$[(bpy)_2Ru(b\text{-}Z\text{-}b)Ru(bpy)_2]^{4+}$	452	635	231	1.5	+1.28 (2)
$[(bpy)_2Os(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$	484	787	29	0.18	+0.84 (2)
$[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$	452/(484) [g]	638/787	22 [h]/29 [i]	0.13/0.18 [h]	+1.27 (1)/+0.84 (1)
$[Ru(bpy)_3]^{2+}$	452	615	170	1.5	+1.26 (1)
$[Os(bpy)_3]^{2+}$	478	743	49	0.32	+0.83 (1)

[a] Acetonitrile solution, room temperature; λ_{max} in nm, τ in ns. For $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ the first value is for the Ru-based and the second for the Os-based units. [b] Maximum of the lowest energy spin-allowed charge-transfer band. [c] Air-equilibrated acetonitrile solution. Excitation was performed at $\lambda = 466$ nm, which is an isosbestic point between the Ru-based and Os-based units. λ_{max} has been corrected for photomultiplier response. [d] $E_{1/2}$ values vs SCE and, within parentheses, relative current intensities. All the oxidation peaks are reversible. [e] Standard: $[Ru(bpy)_3]^{2+}$ in deaerated CH_3CN, $\Phi = 0.062$ (J. M. Calvert, J. V. Caspar, R. A. Binstead, T. D. Westmoreland, T. J. Meyer, *J. Am. Chem. Soc.* **1982**, *104*, 6620). [f] Standard: $[Os(bpy)_3]^{2+}$ in deaerated CH_3CN, $\Phi = 0.005$ (E. M. Kober, J. V. Caspar, R. S. Lumpkin, T. J. Meyer, *J. Phys. Chem.* **1986**, *90*, 3722). [g] Shoulder, see Figure 2. [h] 1:1 mixture of $[(bpy)_2Ru(b\text{-}Z\text{-}b)Ru(bpy)_2]^{4+}$ and $[(bpy)_2Os(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ having the same concentration of $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ shows the luminescence properties expected in the absence of any interaction. [i] Part of the luminescence signals shows a rise time of 21 ns.

In the dinuclear heterometallic species $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ the quantum yield of the Ru-based luminescence (after correction for the 50% light absorption by the Os-based unit) is about ten times smaller than that of the reference compounds $[(bpy)_2Ru(b\text{-}Z\text{-}b)]^{2+}$ and $[(bpy)_2Ru(b\text{-}Z\text{-}b)Ru(bpy)_2]^{4+}$, whereas the quantum yield of the Os-based luminescence is about the same as that observed for the reference compounds $[(bpy)_2Os(b\text{-}Z\text{-}b)]^{2+}$ and $[(bpy)]_2Os(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ (Table 1; Fig. 2, inset). Under the experimental conditions used (complex concentration 1×10^{-5} M), intermolecular energy transfer can be excluded. Therefore the results demonstrate that in $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ an *intramolecular* (intercomponent) energy transfer process takes place, which quenches the luminescent excited state of the Ru-based unit and sensitizes the luminescent excited state of the Os-based one. This is confirmed by the decrease in the excited state lifetime of the Ru-based unit (from 231 nm in $[(bpy)_2Ru(b\text{-}Z\text{-}b)Ru(bpy)_2]^{4+}$ to 22 ns in $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$) and by the rise time (21 ns) observed for part of the luminescence of the Os-based unit (Table 1).

The rate constant for energy transfer from the Ru-based to the Os-based unit of $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ can be obtained from Equation (a), in which τ and τ^0 are the luminescence lifetimes of the Ru-based component in $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ and $[(bpy)_2Ru(b\text{-}Z\text{-}b)Ru(bpy)_2]^{4+}$, respectively (Table 1). Energy transfer processes can take place by Förster-type (dipole–dipole resonance)[27] and/or Dexter-type (electron exchange)[28] mechanisms.[3] The expected rate constant for energy transfer according to the Förster mechanism can be estimated on the basis of spectroscopic quantities by Equation (b).

$$k_{en} = \frac{1}{\tau} - \frac{1}{\tau^0} = 4.1\times10^7\ s^{-1} \qquad (a)$$

$$k_{en} = 5.9\times10^{-25}\,(\Phi_D/n^4\tau_D r^6)\int_0^\infty F_D(\tilde{\nu})\varepsilon_A(\tilde{\nu})d\tilde{\nu}/\tilde{\nu}^4 \qquad (b)$$

For $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$, $\Phi_D = 0.015$, $\tau_D = 226$ ns, $r = 1.7$ nm (n = refractive index of the solvent, $\tilde{\nu}$ = wavenumber, ε_A = molar extinction coefficient) and the value of the overlap integral is $4.7\times10^{-14}\ M^{-1}\,cm^{-3}$. The value obtained for k_{en} ($2.4\times10^7\ s^{-1}$) is somewhat smaller (but of the same order of magnitude) than the experimental value ($4.1\times10^7\ s^{-1}$). In view of the approximations involved, it could well be that the Förster mechanism can account for most of the observed energy transfer. It cannot be excluded, however, that exchange energy transfer is also involved and even plays a major role. For an exchange energy transfer mechanism, the rate constant in the nonadiabatic limit can be expressed as in Equation (c);[3, 14, 17, 29] ν_{en} and $\Delta G^{\neq}$ can be obtained from Equations (d) and (e), respectively.

$$k_{en} = \nu_{en}\exp(-\Delta G^{\neq}/RT) \qquad (c)$$

$$\nu_{en} = \frac{2(H_{en})^2}{h}\left(\frac{\pi^3}{\lambda_{en}RT}\right)^{1/2} \qquad (d)$$

$$\Delta G^{\neq} = \left(\frac{\lambda}{4}\right)\left(1+\frac{\Delta G^0}{\lambda}\right)^2 \qquad (e)$$

Following usual assumptions,[29–31] the free energy change ΔG^0 can be expressed by the difference between the spectroscopic energies of the donor and acceptor (− 0.33 eV, as estimated from the energy of the emission maxima of the Ru-based and Os-based luminescence at 77 K), and the reorganizational energy λ (ca. 0.2 eV) can be obtained from the spectroscopic Stokes shift.[29–31] This yields a value of about 0.4 for the exponential term of Equation (c), which means than ν_{en} must be about $1\times10^8\ s^{-1}$ to account for the experimental rate constant. From Equation (d) a value of $0.4\ cm^{-1}$ can thus be obtained for the through-bond electronic interaction energy H_{en} between the two metal-containing units, under the assumption that the observed energy transfer process only takes place by an exchange mechanism.[32]

In conclusion, we have synthesized a rigid bis(bipyridine) bridging ligand, b-Z-b, which has been used to construct rodlike dinuclear metal complexes of nanometric dimension. In spite of the long metal–metal distance (1.7 nm), in the dinuclear, heterometallic $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$ compound light excitation of the Ru-based unit is followed by a very efficient (>90%) energy transfer process ($k_{en} = 4.1\times10^7\ s^{-1}$), which causes the sensitized emission of the Os-based unit. To our knowledge, the b-Z-b ligand described here is the first example of a bis(bipyridine) bridging ligand in which two chelating units are separated by a rigid rodlike spacer. The new ligand might be used to build up rigid, dendrimer-type polymetallic compounds,[33] and self-assembled multicomponent supramolecular structures.[34] More generally, this novel rodlike ligand represents a useful component for the construction of nanodevices[35] based on transition metal complexes.

Experimental Procedure

(*E,E*)-1,4-Bis[2-(2,2′-bipyridine-5-yl)ethenyl]bicyclo[2.2.2]octane **3**: Under an argon atmosphere a solution containing phosphonate **1** (5.52 g, 18 mmol) in dry THF (100 mL) was added at room temperature to a suspension of sodium hydride (0.57 g, 19 mmol, 80% in an oil suspension) in dry THF (50 mL). The mixture was stirred for 10 min. Aldehyde **2** (1.36 g, 8.2 mmol) was dissolved in dry THF (50 mL) and added dropwise over a period of 1 h. The mixture was stirred for a further 2 h, ice (200 g) was added and a solid precipitated. The crude product was filtered off and washed with water and *n*-hexane. For purification the residue was chromatographed on silica gel (eluent: $CHCl_3/CH_3OH$/aqueous ammonia, 300:10:1; R_f value: 0.55) and recrystallized from toluene. Yield of **3**: 2.9 g (76%), m.p. 310–312 °C. ^1H NMR (200 MHz, $CDCl_3$): $\delta = 1.7$ (s, 12H, CH_2), 6.3 (s, 4H, CH), 7.28 (ddd, 2H, CH), 7.78 (td, 2H, CH), 7.8 (td, 2H, CH), 8.35 (m, 2H, CH), 8.36 (m, 2H, CH), 8.6 (d, 2H, CH), 8.66 (dm, 2H, CH). MS (70 eV): m/z 470.2467 $[M]^+$ (calcd. 470.2470). Satisfactory C,H,N analysis for $C_{32}H_{30}N_4$.

1,4-Bis[2-(2,2′-bipyridine-5-yl)ethynyl]bicyclo[2.2.2]octane (b-Z-b). To the diene **3** (2.35 g, 5.0 mmol) in CCl_4 (200 mL) bromine (11 mmol) in CCl_4 was added. The reaction mixture was stirred for 12 h and evaporated to dryness. The crude product was washed with diluted aqueous $NaHSO_3$ and ether. The stereoisomeric mixture of the tetrabromide **4** was directly used in the subsequent dehydrobromination. Tetrabromide **4** (1.6 g, 2.12 mmol) was dissolved in dry ethanol (100 mL) and anhydrous dioxane (50 mL); excess potassium hydroxide (ca. 25 g) was added. The mixture was allowed to reflux for 40 h, poured on ice water and extracted with dichloromethane. The combined extracts were treated with diluted aqueous NH_4Cl and water and dried over magnesium sulfate. After evaporation of the solvent the residue was chromatographed on silica gel (eluent: $CHCl_3/CH_3OH$/aqueous ammonia, 300:10:1; R_f value: 0.78) and recrystallized from toluene. Yield of b-Z-b: 0.50 g (51%), m.p. 290–293 °C. ^1H NMR (200 MHz, $CDCl_3$): $\delta = 1.95$ (s, 12H, CH_2), 7.3 (ddd, 2H, CH), 7.79 (dd, 2H, CH), 7.8 (td, 2H, CH), 8.3–8.42 (m, 4H, CH), 8.6–8.7 (m, 4H, CH); MS (70 eV): m/z 466.2157 $[M]^+$ (calcd. 466.2158).

The metal complexes were prepared by using $[M(bpy)_2Cl_2]$ (M = Ru, Os) and the ligand b-Z-b in refluxing methoxyethanol. Upon addition of excess NH_4PF_6, the PF_6^- salts of the complexes were precipitated and purified as previously described [26]. Characterization for $[(bpy)_2Ru(b\text{-}Z\text{-}b)Os(bpy)_2]^{4+}$: Elemental analysis: (calcd. for $C_{73}H_{66}Cl_2F_{24}N_{12}O_3OsP_4Ru$ including 3 mol water and 1 mol dichloromethane): C, 43.02 (43.18); H, 3.23 (3.28); N, 7.91 (8.28). FAB-MS: m/z = 1817 (75%) $[M^+PF_6^-]$, 1672 (100%) $[M^+ - 2PF_6^-]$. ^1H NMR (300 MHz, CD_3CN): $\delta = 1.73$ (s, 12H, CH_2), 7.26–8.51 (m, 46H, bpy and (b-Z-b)-H). UV/VIS spectral and electrochemical data: see Table 1. The homometallic complexes gave similar results in accordance with the expected values.

[20] Linear rigid structures can more easily be obtained by using the tridentate 2,2′:6′,2″-terpyridine (tpy) ligand [21]. However, the Ru^{II} complexes of tpy-type ligands are only weakly or not at all luminescent at room temperature and the lifetime of their lowest excited state is very short [22].

Electrochemical Synthesis of New Sb–Te Zintl Anions by Cathodic Dissolution of Sb_2Te_3 Electrodes: Structures of $[Sb_4Te_4]^{4-}$ and $[Sb_9Te_6]^{3-}$**

By *Christopher J. Warren, Douglas M. Ho, Robert C. Haushalter,** and *Andrew B. Bocarsly**

Dedicated to Professor Josef Zemann on the occasion of his 70th birthday

In the early 1930s Eduard Zintl showed that the electrolysis of certain main group, main group alloy, and intermetallic phases could produce metal polyanions in the catholyte.[1] Through the use of potentiometric titrations of liquid ammonia solutions of these saltlike intermetallic compounds, and exhaustive extractions of alkali metal alloys of the heavier elements of groups 14 and 15, Zintl et al. were able to deduce the existence of Sn_9^{4-}, Pb_9^{4-}, Pb_7^{4-}, As_3^{3-}, As_5^{3-}, As_7^{3-}, Sb_7^{3-}, Sb_3^{3-}, Bi_7^{3-}, Bi_5^{3-}, and Bi_3^{3-}, but were unable to isolate and structurally characterize corresponding crystalline salts to confirm their findings. Since the initial report by Kummer and Diehl[2] on the ethylenediamine (en) extraction of Na_4Sn_9 and isolation of Sn_9^{4-} from Na_4Sn_9, many homopolyatomic[3] and heteropolyatomic anions[3] have been isolated by the solvent extraction of Zintl phases. The electrolytic generation of Zintl anions, however, has not been thoroughly investigated and is limited to the early work of Zintl himself and two more recent, brief communications.[4, 5] We previously reported the novel electrochemical synthesis of the gold tellurides $(n\mathrm{Bu_4N})_3[Au_3Te_4]$[6] and $(Ph_4P)_2[Au_2Te_4]$[6] by the cathodic dissolution of $AuTe_2$ alloy electrodes. This technique, which was inspired by the early electrolyses of Zintl, has allowed us to prepare and structurally characterize solids that may not be accessible by standard hydrothermal and high-temperature elemental fusion techniques. In many cases our technique, which relies on the constantly increasing concentration of polyanions as they are discharged from the cathode to crystallize with cations of the electrolyte, provides single crystals suitable for X-ray analysis in three to four days. Here we report the electrochemical synthesis of two new antimony tellurides **1** and **2**, both of which contain discrete polyanions in the solid

$(TPA)_4[Sb_4Te_4]$ **1**
$(TPA)_3[Sb_9Te_6]$ **2**
$TPA = (n\text{-}C_3H_7)_4N^+$

state and are synthesized concurrently from the cathodic dissolution of a Sb_2Te_3 alloy electrode.

In contrast to the numerous known antimony sulfides[7] and selenides,[8] only very few antimony telluride compounds are found in the literature. Apart from the known binary phase Sb_2Te_3, there appears to be only four other known compounds containing Sb–Te polyanions: $BaSbTe_3$,[9] $LiSbTe_2$,[10a] K_3SbTe_3,[10b] and $AgSbTe_2$.[11] Several mixed antimony germanium telluride compounds such as $GeSb_4Te_7$,[12] $GeSb_2Te_4$,[12] and $Ge_2Sb_2Te_5$[12] also exist and have been studied for their potential semiconduct-

ing properties. All of these compounds have been prepared by the high-temperature fusion of the elements.

Tellurides **1** and **2** were prepared by the cathodic dissolution of a Sb_2Te_3 electrode, which was made by melting stoichiometric amounts of the elements under N_2 in a quartz tube. The resulting silver solid was then crushed into a fine powder and fabricated into electrodes in accordance with the procedure reported for the Au–Te system.[6] The synthesis was conducted in a two-compartment, liquid junction, airtight electrochemical cell equipped with a nickel plate counter electrode. The use of nickel as a counter electrode is advantageous, since an insoluble purple precipitate (the qualitative microprobe analysis of which showed Ni and Br in a 1:2 molar ratio) is then generated in the anode chamber. Cross-contamination of the cathode chamber with oxidation products from the anode chamber is thus prevented, allowing longer reaction times. The cell was filled with a 0.56 M solution of tetrapropylammonium bromide (TPABr) in ethylenediamine (en) which served as both the supporting electrolyte and a source of cations for the crystallization process. The ethylenediamine was purified by distillation from a red solution of K_4Sn_9, and all manipulations were performed in a high-purity (<1 ppm O_2) He atmosphere.

The cathodic dissolution of a Sb_2Te_3 alloy electrode running at a current density of approximately 300 $\mu A\,cm^{-2}$ immediately gave rise to a deep brown stream of anions which surrounded the cathode and then slowly sank to the bottom of the cathode chamber. After one day a red-brown crystalline solid, which was later identified as **1**, was observed growing on the Sb_2Te_3 cathode. After approximately two days the deep brown catholyte solution also yielded brown spear-shaped crystals of **2**, which were found growing on the bottom of the chamber. The reaction was halted after five days to yield **1** and **2** in an approximately 80:20 ratio. The chemical and electrochemical yields calculated based on moles of Sb were 29% and 17% for **1**, and 12% and 2% for **2**.[13] These two compounds appear to be the only solid products of the electrochemical dissolution reaction and are not obtained from a control experiment with powdered Sb_2Te_3 and TPABr in en. Independent experiments have also shown that **1** is not converted into **2** on standing in the electrolyte solution, which suggests that the anions are formed independently during the dissolution of the electrode.

Telluride **1** crystallizes in space group *Pbcn* with eight $[Sb_4Te_4]^{4-}$ anions in the unit cell.[14] The structure of the anion is shown in Figure 1. The anion displays approximate, but not crystallographically imposed, *2mm* point group symmetry in the solid state and consists of a folded Sb_4 ring to which four terminal Te atoms are attached in the equatorial positions. This geometry is quite different from that of the bare, square-planar Sb_4^{2-} anion[15] but more closely resembles that of $(t\mathrm{Bu})_4Sb_4$,[16] in which the *t*Bu groups are bonded to a folded Sb_4 ring in equatorial positions. The Sb–Sb distances in **1** are in the range 2.836(4)–2.883(4) Å and can be compared to those in the *t*Bu-substituted Sb_4 ring (2.814(2)–2.821(2) Å). The average transannular nonbonded Sb–Sb distance in **1** is 3.916 Å. For comparison the average Sb–Sb distance in the Sb_4^{2-} anion is 2.750 Å, and it has an average transannular nonbonded Sb–Sb distance of 3.889 Å. The Sb–Te bond lengths in $[Sb_4Te_4]^{4-}$ are in the range 2.722(4)–2.761(4) Å. Paucity of structurally characterized Sb–Te compounds makes extensive comparisons with these Sb–Te bond lengths difficult. The ternary Zintl phase compound K_3SbTe_3 contains discrete, trigonal-pyramidal, anionic units having three equivalent Sb–Te bond lengths of 2.7831(7) Å. The Sb–Te bond length in the solid-state phase Sb_2Te_3 is 2.974 Å, and Sb–Te distances in $BaSbTe_3$ are in the range 2.832–3.090 Å.

Telluride **2** crystallizes in the monoclinic space group $P2_1/c$ with four $[Sb_9Te_6]^{3-}$ anions in the unit cell.[14] The structure of the $[Sb_9Te_6]^{3-}$ anion is shown in Figure 2. The assignment of Sb and Te atoms in this anion was based on their chemically reasonable connectivities and a microprobe analysis, which yielded an Sb:Te ratio of 1.5:1. The $[Sb_9Te_6]^{3-}$ anion can be thought of as the fusion product of two well-known structure types: a bicyclic Sb_6Te_2 moiety (Fig. 3a) with a Sb–Sb transannular closure and a geometry closely resembling that of Se_8^{2+},[17] and an Sb_6Te_2 cage, (Fig. 3b), which resembles the cages found in X_4N_4 (X = As, S, Se),[18–20] X_4S_4 (X = P, Te),[21, 22] and As_4Se_4.[23]

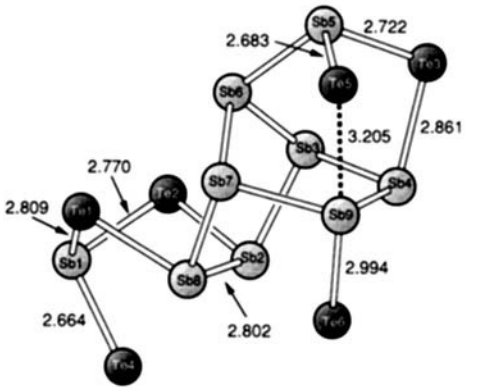

Fig. 2. Structure of the $[Sb_9Te_6]^{3-}$ anion in **2** [14]. The dashed line represents a long Sb–Te contact of 3.205(6) Å. Some other Sb–Sb and Sb–Te distances [Å] are noted.

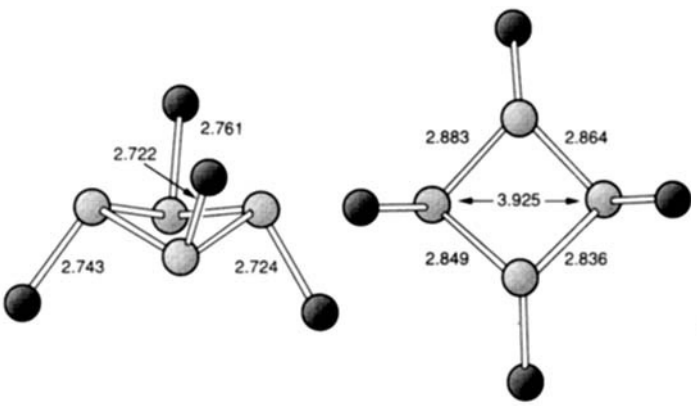

Fig. 1. Two views of the structure of the $[Sb_4Te_4]^{4-}$ anion in **1** [14]. Left: projection approximately down one of the two transannular Sb–Sb vectors in the molecule; right: view perpendicular to the plane defined by the four Sb atoms. The Te atoms have darker shading.

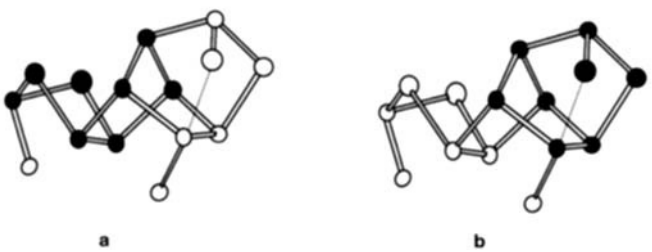

Fig. 3. Structure types found in the $[Sb_9Te_6]^{3-}$ anion in **2**.

An interesting feature of the structure of $[Sb_9Te_6]^{3-}$ is the pseudo-four-coordinate Sb9 atom, which is bonded to Sb4 and Sb7 (2.756(5) and 2.803(5) Å, respectively), but displays an abnormally long Sb9–Te6 contact of 2.994(5) Å. The other two terminal Te–Sb contacts in the anion are much shorter (Sb5–Te5 2.683(6) Å, Sb1–Te4 2.664(5) Å). The lengthening of the terminal Sb9–Te6 contact is most likely due to the weak coordination of Sb9 to Te5 (distance 3.205(6) Å) making Sb9 pseudo-four-coordinate. It is interesting to note that all three terminal Sb–Te bonds are *"endo"* relative to the cluster. It is not clear if this is simply due to packing forces in the crystal, or if the effect is driven by weak Sb–Te interactions like those involving Te4 and Sb2 and Sb8 (corresponding Te–Sb distances 3.671 and 3.720 Å, respectively) or Te6 and Sb4 (3.327 Å). Sb–Sb distances in $[Sb_9Te_6]^{3-}$ are in the range 2.756(5)–2.871(5) Å, and internal Sb–Te distances vary from 2.722(7) to 2.878(5) Å; these separations are all comparable to those in the $[Sb_4Te_4]^{4-}$ anion and in other structurally characterized antimony tellurides.

Our continuation of the early investigations of Zintl has shown that polyanion synthesis from the cathodic dissolution of alloy electrodes is very useful for the preparation of a wide variety of solids. In addition to the novel Sb–Te polyanions described here, we have also prepared and structurally characterized others such as $[GaTe_2(en)_2]^-$[24] and $[In_2Te_4]^{4-}$,[25] as well as tellurides from the As and Hg systems.

[13] The yield calculations were based on 0.2475 g (0.3952 mmol) of Sb_2Te_3 electrode which dissolved after five days giving 0.1255 g of crystals that were collected from the cathode chamber. The percent yields were based on the assumption that the product was 80% **1** (0.1004 g, 0.0576 mmol) and 20% **2** (0.0251 g, 0.0137 mmol), and were calculated based on moles of Sb. Electrochemical yield = moles product per moles e^- passed. The deep brown color of the catholyte suggests that some fraction of the polyanions produced are soluble and remain in solution. The difference in stoichiometry of the reactant and products requires the existence of excess Te, which could also be present in the catholyte solution in the form of soluble polytellurides.

[14] Crystal data for **1**: orthorhombic, *Pbcn* (no. 60), $a = 41.790(9)$, $b = 17.978(2)$, $c = 18.132(4)$ Å, $V = 13{,}623(5)$ Å^3, $Z = 8$; 8964 unique reflections, 2671 with $F > 3.0\,\sigma(F)$, 281 parameters. $R(R_w) = 0.0692$ (0.0612). **2**: monoclinic, $P2_1/c$ (no. 14), $a = 23.580(5)$, $b = 13.446(3)$, $c = 20.427(4)$ Å, $\beta = 92.87(2)^\circ$, $V = 6{,}468(2)$ Å^3, $Z = 4$; 11455 unique reflections, 2503 with $F > 3.0\,\sigma(F)$, 292 parameters. $R(R_w) = 0.0629$ (0.0574). The data for both samples was collected on a Siemens P4 diffractometer ($Mo_{K\alpha}$ radiation) at 235 K. Structures were solved by direct methods and refined by full-matrix least-squares using the Siemens SHELXTL PLUS program package. Substrate-Specific Catalysis by Ion Pairs**

By *Paul J. Smith, Eun-il Kim*, and *Craig S. Wilcox**

The electrostatic fields associated with charged and dipolar functional groups in the active sites of enzymes may well be essential to the rate accelerations achieved by these complex molecules. The electric fields generated by the spatially fixed polar groups of the protein can be properly positioned to complement the field of the transition state and in this way lower the activation energy for reaction.[1] To evaluate the magnitude of such effects and to contribute to current efforts to develop selective molecular recognition based catalysts,[2] we have examined the effects of ion pairs on the reactivity of some simple molecules in chloroform. Those

experiments have shown that covalently attached ion pairs can substantially accelerate chemical reactions in nonpolar solvents.[3] This suggests that the reversible binding of ion pairs to organic reactants could lead to significant rate enhancements in processes whose rate-determining step proceeds through a polar transition state (Fig. 1).[3b, 4] In this paper we illustrate the idea and confirm that the noncovalent binding of ion pairs can be used for selective and reversible activation of functional groups.

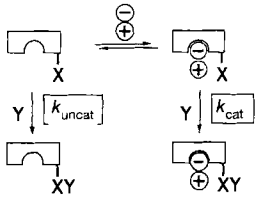

Fig. 1. Generalized example of ion pair catalysis. k_{cat} = rate constant for the catalyzed reaction, k_{uncat} = rate constant for the uncatalyzed reaction.

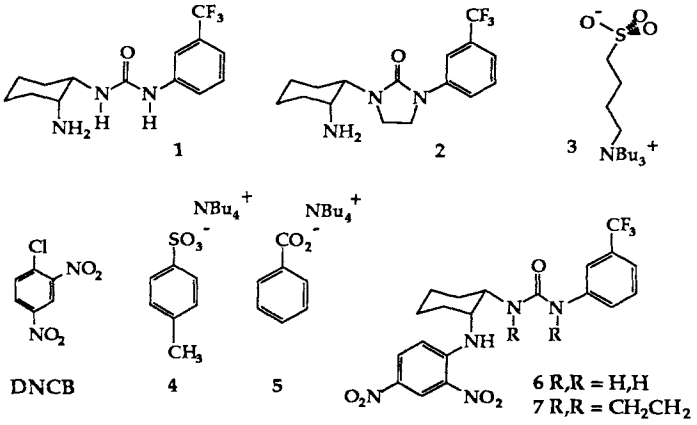
Amine **1** was synthesized because the urea group can serve as a strong binding site for ion pairs in chloroform.[5] Imidazolidinone **2** was prepared to serve as a control compound for **1** containing a blocked binding site. The measured association constant for **1** with zwitterion **3** in chloroform (determined by UV spectroscopic methods) is $1350 \pm 240\ M^{-1}$. Binding to ion pairs was also evaluated: tetrabutylammonium tosylate (**4**, $K_a = 1290\ M^{-1}$) and tetrabutylammonium benzoate (**5**, $K_a = 5800\ M^{-1}$) both bind to the urea derivative **1**.



The reactions of amines **1** and **2** with 1-chloro-2,4-dinitrobenzene (DNCB) in the presence of various concentrations of ionic compounds **3**–**5** were examined. This reaction was chosen because its rate-determining step proceeds through a polar transition state, and it can be conveniently followed by UV/VIS spectrophotometry.[6] The initial rates for the reaction of 1.0 mM amine **1** or **2** with 20.0 mM DNCB in the presence of 0 to 5 mM **3** were measured in chloroform at 298 K. Absorbance at $\lambda = 420$ nm was used to monitor the appearance of products **6** or **7**, and data up to 2.0% conversion were used.

The results from the reactions of **1** and **2** with **3** are shown in Figure 2. The rate of reaction of **1** increased with increasing salt concentration, asymptotically approaching a limiting value. The initial rates for imidazolidinone **2**, which contains a blocked binding site, were found to increase only slightly and linearly in the range of zwitterion concentrations employed, as is usually the case for an intermolecular salt effect.[3b, 7] The binding site is therefore required for significant catalysis of this reaction by **3** in chloroform. Similar results were obtained with ion pairs **4** and **5**.

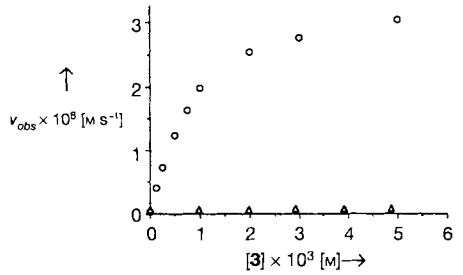


Fig. 2. Initial rates for the reactions of 1.0 mM **1** (○) and **2** (△) with 20.0 mM DNCB as a function of the concentration of added **3**. Each point represents the average value of two determinations. The measured initial rate in the absence of **3** is 2.64×10^{-10} M s^{-1}. The equation of the regression line (least squares) for these data is: reaction rate $v = 6.4 \times 10^{-10} + 3.0 \times 10^{-8} \times [3]$. All experiments were conducted in chloroform at 298 ± 1 K.

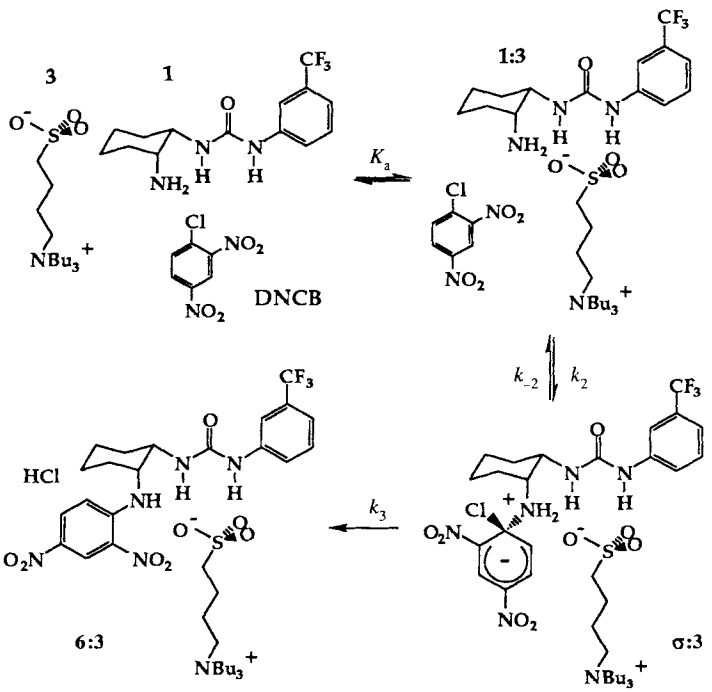
The observed catalysis of the reaction of **1** and DNCB by **3**, **4**, and **5** may be analyzed in terms of the Michaelis–Menten model for enzyme kinetics. The reaction process is mathematically equivalent to the "random BI-BI" enzyme reaction mechanism.[8] Nucleophilic attack is the rate-determining step for the reaction of DNCB with aliphatic amines in solvents with low dielectric constants ($k_3 \gg k_{-2}$, Scheme 1).[9] The absence of base catalysis by the nucleophile and by added bases is evidence that conversion of the σ complex to products is much faster than the back-reaction of this intermediate to give starting materials.[9] If this were the case for the catalyzed reaction (or more explicitly, if



Scheme 1.

$k_3 + k_{-2}$ were much larger than [DNCB] · k_2), then the value of K_M^{-1} (K_M = Michaelis constant) obtained from this plot should equal our measured value of K_a. A plot of $(v_{obs} - v_{uncat})^{-1}$ versus the reciprocal of concentration of the unbound salt (Fig. 3) allows K_M and k_{cat} to be determined. Since

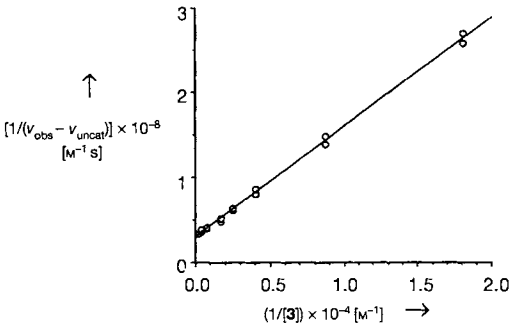

Fig. 3. Another plot of the data used in Figure 2. The reciprocal of the observed rate minus the uncatalyzed rate for the reaction of **1** and DNCB is plotted as a function of the reciprocal of initial concentration of unbound salt [14]. Sixteen data points are included. The equation of the regression line (least squares) for these data is: $(v_{obs} - v_{uncat}^{-1})^{-1} = 3.01 \times 10^7 + 1.30 \times 10^4$ ($[\mathbf{3}]^{-1}$).

k_{uncat} is known, the rate acceleration due to the presence of the ion pair ($k_{cat} \cdot k_{uncat}^{-1}$) can be calculated. For **4**, $K_M = 6.76 \times 10^{-4}$ M ($K_M^{-1} = 1480$ M^{-1}) and $k_{cat} \cdot k_{uncat}^{-1} = 84$; for **5**, $K_M = 1.85 \times 10^{-4}$ M ($K_M^{-1} = 5400$ M^{-1}) and $k_{cat} \cdot k_{uncat}^{-1} = 390$; and for the zwitterion **3**, $K_M = 4.33 \times 10^{-4}$ M ($K_M^{-1} = 2300$ M^{-1}) and $k_{cat} \cdot k_{uncat}^{-1} = 130$. Because the association constants K_a are used to calculate the concentration of unbound salt for the double-reciprocal plot, if the catalyst and substrate do not aggregate or follow alternative kinetic pathways under the reaction conditions, then the value of K_M^{-1} for these ion pairs will be in agreement with the measured association constants. Ion pairs **4** and **5** are freely soluble in chloroform (>1 M). At present we think that the discrepancy between K_M^{-1} and K_a observed for zwitterion **3** is best explained by aggregation of this marginally soluble species. In any case, the value of $k_{cat} \cdot k_{uncat}^{-1}$ would not be much affected by errors in K_a: for **4**, using the observed value of $K_a = 1290$ M^{-1}, $k_{cat} \cdot k_{uncat}^{-1} = 84$; using $K_a = 2590$ M^{-1}, $k_{cat} \cdot k_{uncat}^{-1} = 90$; using $K_a = 645$ M^{-1}, $k_{cat} \cdot k_{uncat}^{-1} = 110$.

What is the mechanism of catalysis? For the addition step, the bound salt would stabilize the polar intermediate reaction states and lower the standard free energy of the σ complex. Coulombic forces, including hydrogen bonding and dipole–dipole interactions, are likely to be the dominant forces. General base catalysis of this step by bound sulfonate is not possible, because the sulfonate is not basic enough to deprotonate the σ complex.[10] (The equilibrium constant for formation of a hydrogen-bonded ion pair between methanesulfonic acid and *n*-butylamine in chloroform is 4.5×10^9 M^{-1}.[11]) In aqueous solutions, Meisenheimer complexes of 1,3,5-trinitrobenzene and primary and secondary amines are 100–400 times less basic than the amines from which they are formed.[12]) These experiments cannot reveal the role the bound ion may have in the transformation of the intermediate σ complex to the product. The pathway from the σ complex to product could follow any of three pathways: 1) a direct loss of chloride ion, 2) a concerted general base mechanism, or 3) a nonconcerted general base/general acid mechnism in which bound sulfonic acid promotes the rate-determining loss of chloride ion.[6, 13]

The rate accelerations caused by these simple ion pairs are substantial and approach levels of catalysis that could afford practical control of reaction rates and selectivity. This work demonstrates that a simple ion pair can act as a potent substrate-specific catalyst for a complex chemical reaction in chloroform. The potential utility of ion pair catalysis for any given reaction may be reasonably predicted based on knowledge of the ground state and transition state character for the reaction. Enantioselective and diastereoselective processes can be proposed based on such ion pair catalysis, and experiments to demonstrate such selectivity are underway.

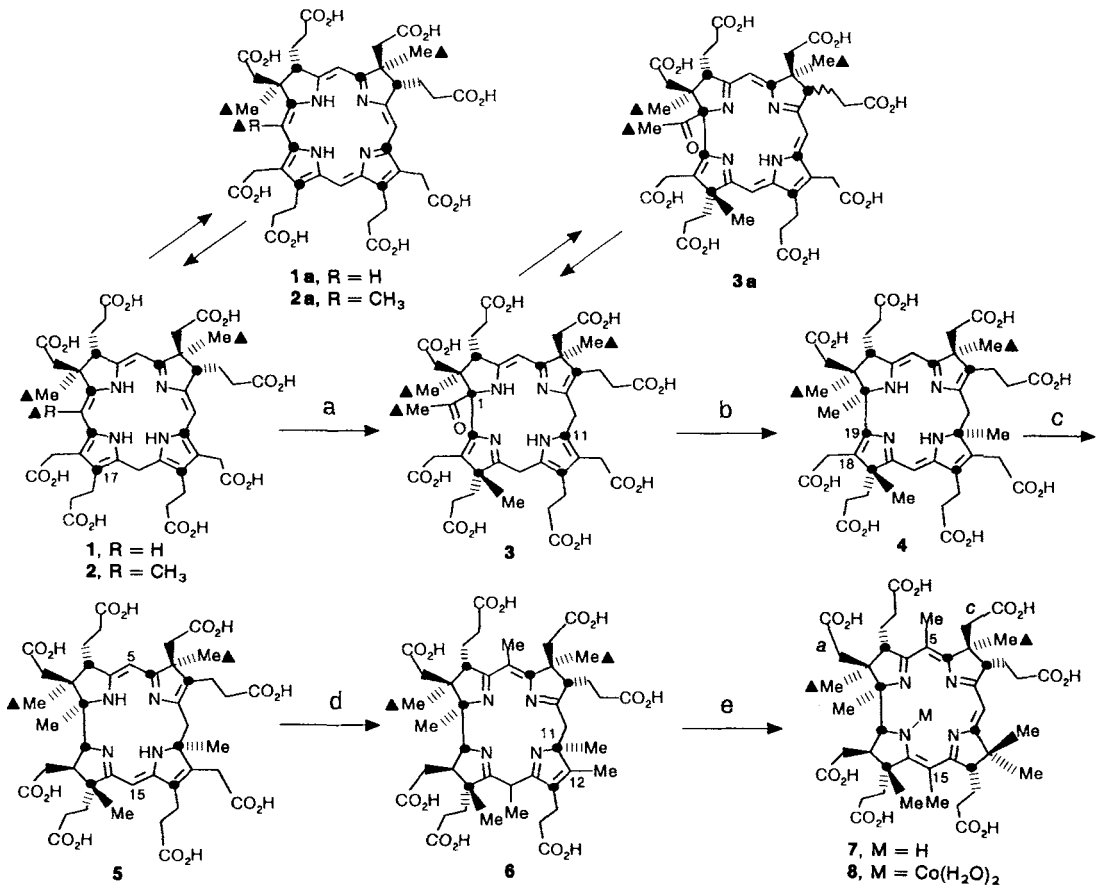
Parallels and Decisive Differences in Vitamin B_{12} Biosyntheses**

By *Francis Blanche,** *Dennis Thibaut, Laurent Debussche, Ralf Hertle, Franz Zipfel,* and *Gerhard Müller**

Studies on the chemical nature of the microbial biosynthesis of vitamin B_{12}[1,14] have revealed that the organization of the individual reactions in the aerobe *Pseudomonas denitrificans* and the anaerobe *Propionibacterium shermanii* differs significantly, and that these differences could be evolutionary in their origins. The work of Blanche, Crouzet et al.[1a-c] has provided deep insight into the molecular nature of vitamin B_{12} synthesis. Their construction and efficient application of recombinant strains of *P. denitrificans* led to the discovery and isolation of new and spectacular vitamin B_{12} precursors with the responsible cloned enzymes.

It was shown that the tetrapyrrolic vitamin B_{12} ligand hydrogenobyrinic acid **7**[2] is synthesized without cobalt via the precorrins 2(**1**) and 3(**2**)[2a,14] as well as the newly discovered ring-contracted precorrins 4(**3**)[3], 6x(**4**),[4] 6y(**5**),[5] and 8x(**6**)[6] (Scheme 1). After two obligatory amidations leading to **7**-*a*,*c*-diamide,[7] cobalt is inserted by the cobaltchelatase responsible for vitamin B_{12} formation.[8] In the case of *P. shermanii* neither **7** nor **7**-*a*,*c*-diamide are precursors of vitamin B_{12}.[2,9a] Instead cobyrinic acid (**8**), the cobalt-containing analogue of **7**, and **8**-*a*,*c*-diamide appear in the biosynthetic pathway.[9a,10] Enzyme preparations from *P. shermanii* are able to transform in vitro not only the oxidized and aromatized precorrins 2(**1a**) and 3(**2a**)[2a,14] (known as factors II and III, respectively) into **8**, but also the cobalt complexes of **1a** and **2a**.[9] In contrast, the enzyme systems from *P. denitrificans* that produce **7** are able to use only **1a** and **2a** but not the corresponding cobalt complexes.



Scheme 1. Reaction steps and individual reactions of the biosynthetic pathway precorrin 3(**2**) → hydrogenobyrinic acid (**7**) and the gene products responsible [1c] (in brackets) in *Pseudomonas denitrificans*: a) ring contraction, C17 methylation (CobG and CobJ); b) elimination of the C20 acetate group and C11-, C1-methylation (CobM and CobF); c) NADPH-dependent C18/C19 reduction (CobK); d) C5-, C15-methylation + C12-acetate decarboxylation (CobL); e) C12-methylation by C11 → C12 methyl group migration (CobH), as well as regiospecific $^3H/^{14}C$ labeling via precorrin 3(**2**), biosynthesized from [4-^{14}C]5-aminolevulinate and *S*-adenosyl-L-[methyl-$^3H_3$]methionine • = ^{14}C and ▲ = ^{3}H. **1a**, **2a**, and **3a** are oxidation products or isolates from the corresponding precorrins 2–4 and can be channeled into the pathway of **7** [2a, 3]. **1a** and **2a** are utilized in the formation of **8** [2a, 14].

These and other results demonstrated that in *P. shermanii* cobalt insertion must occur at the latest after the third methylation step.[9a,b] Our latest investigations using $^{57}Co^{2+}$ have shown then that weakly enriched enzyme preparations from *P. shermanii* catalyze a cobalt insertion after the addition of either **1a** or **2a**. However, if the incubation conditions are such that [edta] ≫ [Co^{2+}], then the enzymatic insertion of cobalt is only observed with **1a**. As expect-

ed in in-vitro investigations into the formation of **8** at high concentrations of edta, only **1a** (and not **2a**) is converted to **8**. From these results it is concluded that in *P. shermanii* the true substrate for the relevant cobaltchelatase must be a dimethylated precursor. Interestingly, Co^{III}-**1a** has been previously converted into Co^{III}-**2a** under in-vitro conditions.[9a, b] Additional precursors of **8** or the enzymes responsible for their formation are not known. However, the sequence of methylation that begins with uroporphyrinogen III is the same in both organisms.[2a] To try and answer the question of the role the ring-contracted precursors of **7** (formed by *P. denitrificans*) play in the synthesis of **8**, incorporation studies based on tried-and-true procedures using $^3H/^{14}C$ doubly labeled substrates **3a**, **4**, **5**, and **6** and the enzyme systems from *P. shermanii* leading to **8** were carried out.[2, 9] Although with the known substrates **2a** and Co^{III}-**1a** (experiments 1 and 2) markedly higher levels of incorporation were achieved, the results summarized in Table 1 demonstrate unequivocally that precursors **4**, **5**, and **6** from the pathway leading to **7** can be converted into **8** by enzyme preparations from *P. shermanii*.

Table 1. Formation of cobyrinic acid (**8**) with enzyme preparations from *P. shermanii* [2] and the radioactively [$^3H/^{14}C$] doubly labeled substrates factor III (**2a**), Co^{III} factor II (Co^{III}-**1a**), precorrin 6x(**4**), precorrin 6y(**5**), and precorrin 8x(**6**) [a].

[a] In each case the same enzyme preparation was used: 70 g (wet weight) of bacterial cells in 140 mL of 52 mM phosphate buffer (pH 7.7) per experiment [2] + 285 μM *S*-adenosyl-L-methionine + 58 μM Co^{2+} + 70 μM reduced nicotinamide-adenine dinucleotide phospate (NADPH) + 42 μM ethylenediaminetetraacetic acid (edta) + 500 nmol [$^3H/^{14}C$] doubly labeled substrate [g]. [b] Synthesized by in-vitro biosynthesis from [4-^{14}C]5-aminolevulinate + *S*-adenosyl-L-[methyl-$^3H_3$]methionine [2]. [c] In the same manner as [b] followed by chemical incorporation of cobalt. [d] Synthesized by in-vitro biosyntheses from **2a** via **3** + *S*-adenosyl-L-methionine: **4** [4a], **5** [5a], **6** [6b], and **3a** [3]. [e] Based only on ^{14}C radioactivity. [f] Based on radiochemical yields of the substrate/product transformation. [g] Refers to the regiospecific labeling, see Scheme 1. [h] Incorporation rates based on the radioactive substances used. [i] Control experiments with known substrates.

A plausible explanation based on these and earlier results[9] is that cobalt complexes of the tetrapyrrolic ligands **4**, **5**, and **6** occur in the biosynthesic pathway of **8**, and that these formed spontaneously from added substrates during the incorporation experiments. Indeed, this would explain the relatively low levels of incorporation observed. Direct evidence that cobalt-coordinated ligands were present during the in-vitro transformations to **8** came from the additional results of these experiments. Because of low substrate specifity of the mutase in *P. shermanii* responsible for the transfer of a methyl group from C11 to C12 (reaction step e in Scheme 1), enzyme preparations of *P. shermanii* convert **6** not only into **8** but also into **7** (e.g. 10 nmol **7** in experiment 5, isolated and analyzed as the heptamethyl ester[2]), which is not a precursor of **8** and in fact inhibits its formation.[2] But considering that **6** is the only substrate investigated that was transformed into **7**, cobalt complexes of **4** and/or **5** must have been present during the in-vitro transformation into **8**. In this context the results achieved with **4** and **5** (experiments 3 and 4) are of special interest. With these two substrates it was possible for the first time to biosynthetically prepare the 5-noranalogue of **8**[11] (10 nmol in experiment 3 and 4.2 nmol in experiment 4), whose cobalt-free ligand does not occur in *P. denitrificans*. Since the order of the *meso* methylation in *P. shermanii* is C5 > C15,[2a] the occurrence of this norcobyrinate, which has been shown not to be a precursor of **8**,[9a, 12] must be attributed to a regiospecifically incorrect primary methylation at C15 of **5**.

The conclusions based on the results can be summarized as follows: a) the pentamethylated ligand **4** with its characteristic structural features also occurs in *P. shermanii*; b) the individual reactions in the synthesis of **7** outlined in c, d, and e in Scheme 1 are also carried out in principle in the synthesis of **8**; c) in *P. shermanii*, however, cobalt-coordinated ligands are used instead; and d) the mutase enzyme from *P. shermanii* responsible for a sigmatropic 1,5 methyl shift is not very specific with respect to the central ion and *meso*-methyl groups already present.

Experiments with the didehydroisolate of unstable **3**, factor IV (**3a**), were negative. Although **3a** was transformed into **7** by means of reaction steps b, c, d, and e by using the enzyme systems from *P. denitrificans* leading to **7**, it proved impossible to convert $^3H/^{14}C$ doubly labeled **3a**[3] into **8** with the corresponding enzyme preparations from *P. shermanii*. It remains unclear if the reaction steps following the third methylation, for example the C17 methylation and/or the nature of the ring contraction, differ in *P. shermanii* and *P. denitrificans*. Experiments to clarify this point will be undertaken as soon as the corresponding substrates become available. Of special interest is a tetramethylated cobalt corphinoid that was recently isolated in minute quantities from *P. shermanii* and was found to be protein bound.

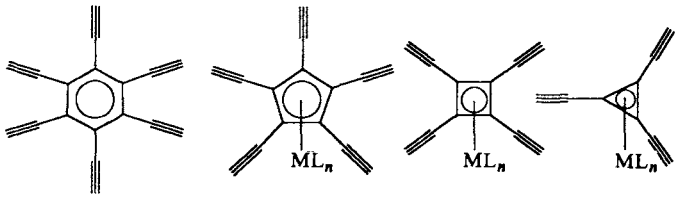
The First Complex with a Tetraethynylcyclobutadiene Ligand**

By *Uwe H. F. Bunz** and *Volker Enkelmann*

Dedicated to Dr. Manfred Kämper on the occasion of his 60th birthday

Perethynylated arenes and π perimeters such as **1**–**4** have not been widely investigated. The benzene derivative **1** was synthesized in 1986 by Vollhardt et al. by reacting hexabromobenzene with trimethylsilylacetylene in the presence of a palladium catalyst.[1] The interest in compounds such as **1**–**4** arises from their aesthetic structure, their potential applicability as multidentate ligands in organometallic chemistry,[2] and their use as potential building blocks for carbon-rich molecular entities.[3] Compound **1** was used as starting material for the synthesis of triangulane.[4] The multiple alkynylation of arenes was demonstrated by Whitesides et al., Stille et al., and Präfcke et al.; they found that some polyalkynylated arenes form discotic phases[5] or, as in the case of tetraethynylthiophene, produce glassy carbon fibers upon controlled pyrolysis.[4a, b]

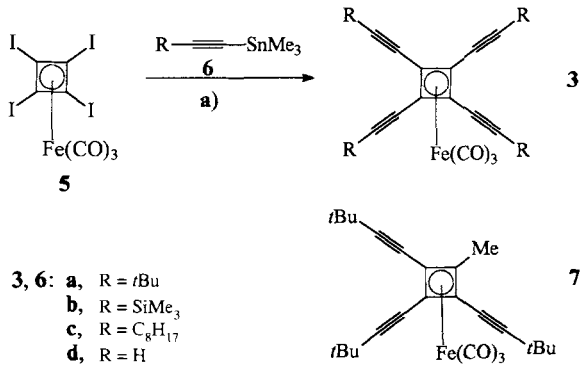


1 **2** **3** **4**

In contrast to **1**, nothing is known about the complexed smaller homologues **2**–**4** and perethynylcyclooctatetraene. In view of their high density of functional groups as well as the ease of derivatization and the complexing ability of the alkyne groups, such compounds are attractive synthetic targets. We report here the preparation of several derivatives of **3** [$ML_n = Fe(CO)_3$].

To synthesize a tetraalkyne such as **3**, its inherent sensitivity has to be taken into consideration. Neither the starting material **5** nor the expected product would survive heating with CuI and amine at 100 °C for several days, the conditions used by Vollhardt[1] to prepare **1**. An alternative approach, based on the coupling of stannylated alkynes with iodoarenes and iodocyclopentadienyl complexes, was successfully applied by Stille; this reaction leads to complete conversion of the corresponding starting materials within a day at room temperature under neutral conditions.[6] However, it was not clear if this method was suitable for multiple substitution of the tetraiodide **5**.[7]

We first attempted to react **5** with an excess of *tert*-butyl(trimethylstannyl)acetylene **6a** in dimethylformamide (DMF) using the catalyst system described by Farina et al.[8] (Scheme 1). Removal of the solvent under high vacuum fol-



Scheme 1. a) 5 equivalents of stannane, 5.5 mol% $[Pd_2(dba)_3]$, 22 mol% triphenylarsine, about 60 mL DMF, 18 h at 20 °C, column filtration over Al_2O_3. **3a**: 40%; **7**: 20%; **3b**: 83%; **3c**: 25%.

lowed by flash chromatography on silica gel (pentane/dichloromethane 95:5) afforded the two compounds **3a** and **7** as pale yellow, somewhat light-sensitive, but otherwise stable crystalline powders in 40 and 20% yields, respectively. We assume that **7** was formed by the transfer of a methyl group from **6a** to **5**, because the high steric demand of the *t*Bu substituent at the alkyne should reduce its reactivity.

If the trimethylsilyl-protected stannylacetylene **6b** is used, **3b** can be isolated after filtration of the crude product over neutral aluminum oxide in 83% yield. In this reaction no methyl derivative analogous to **7** can be detected. The octyl-substituted tin alkyne **6c** can be used to give **3c** in 25% yield after chromatography over aluminum oxide. While solid **3b** is only slightly sensitive to light, the oil **3c** has to be stored under exclusion of light in a freezer.

Treatment of **3b** with potassium carbonate in methanol gave the parent compound **3d** in 79% yield. The complex with unprotected tetraalkyne ligand is stable in chloroform at −30 °C for several weeks; however, it can only be isolated for a short period of time at low temperature (below 0 °C) and under an inert atmosphere. Solid **3d** polymerizes at room temperature even with the exclusion of air within minutes to give an insoluble dark brown material.

The structures of the compounds **3a**–**d** and **7** follow from spectroscopic data (Table 1). The NMR spectrum of **3d**, which as a result of the high molecular symmetry only has a few lines, will serve as an example. The ^{13}C NMR spectrum

[**] We thank BASF for a generous donation of cyclooctatetraene and trimethylstannyl chloride. U. H. F. B. thanks the Fonds der Chemischen Industrie for a Justus-von-Liebig-Stipendium and Prof. Dr. Klaus Müllen for generous support. According to the IUPAC rules the compound **3d** would be named tricarbonyl [(1,2,3,4-η)-1,2,3,4-tetraethynyl-1,3-cyclobutadiene]iron.

Table 1. Physical data of **3a–d** and **7** [a].

3a: M.p. 137 °C; IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2970, 2217, 2045, 1992; ^{1}H NMR ($CDCl_3$): δ = 1.28 (s, 36H; *t*Bu); ^{13}C NMR ($CDCl_3$): δ = 28.41 (s, $C(CH_3)_3$), 30.67 (q, $C(CH_3)_3$), 68.46, 69.12, 103.99 (3 s, ring-C/alkyne-C), 212.48 (s, CO); MS (70 eV): *m/z* 512 (M^+, 2%), 484 (M − CO, 12%), 456 (M − 2CO, 7%), 427 (M − 3CO, 100%); correct elemental analysis.

7: Sublimation 60 °C, 0.001 Torr; IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2972, 2952, 2931, 2215, 2039, 1991, 1960, 1920; ^{1}H NMR ($CDCl_3$): δ = 1.22 (s, 18H; *t*Bu), 1.24 (s, 9H; *t*Bu), 1.85 (s, 3H, Me); ^{13}C NMR ($CDCl_3$): δ = 10.43 (q, Me), 28.35, 28.51 (2 s; $C(CH_3)_3$), 30.70, 30.75 (2 q, $C(CH_3)_3$), 65.22, 67.32, 69.20, 69.39, 88.33, 103.31, 103.48 (7 s, ring-C/alkyne-C), 213.18 (s, CO); MS (70 eV): *m/z* 446 (M^+, 2%), 418 (M − CO, 6%), 390 (M − 2CO, 5%), 362 (M − 3CO, 100%); high-resolution MS: *m/z* 444.1599 (found for M^+) 444.1591 (calcd).

3b: M.p. 128 °C; IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2961, 2155, 2055, 2006, 1251; ^{1}H NMR ($CDCl_3$): δ = 0.19 (s, 36H; $SiMe_3$); ^{13}C NMR ($CDCl_3$): δ = −0.31 (q, $SiMe_3$), 67.37 (s, ring-C), 94.05, 102.11 (s, alkyne-C), 210.95 (s, CO); MS (FD): *m/z* 576 (M^+, 28%), 548 (M − CO, 75%), 492 (M − 3CO, 100%); high-resolution MS: *m/z*: 574.1146 (found for M^+) 574.1138 (calcd).

3c: Yellow oil; IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2955, 2928, 2856, 2227, 2048, 1988, 1983, 1953, 1466; ^{1}H NMR ($CDCl_3$): δ = 0.86 (t, ^3J(H,H) = 6.6 Hz, 3H; CH_3); 1.26–1.40 (m, 10H; 5 CH_2), 1.53 (quint, ^3J(H,H) = 7.3 Hz; 2H; CH_2), 2.30 (t, ^3J(H,H) = 7.0 Hz, 2H; propargyl-H); ^{13}C NMR ($CDCl_3$): δ = 14.07 (q, CH_3), 19.89, 22.66, 28.34, 28.77, 29.07, 29.20, 31.84 (t, $(CH_2)_7$), 68.28, 70.57, 96.29 (3 s, ring-C/alkyne-C), 212.19 (s, CO).

3d: IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3296, 3283, 2075, 2063, 2024, 2016, 1997, 1965, 1223, 833.94; ^{1}H NMR ($CDCl_3$): δ = 3.27 (s, 4H; alkyne-H); ^{13}C NMR ($CDCl_3$): δ = 65.51 (s, ring-C), 72.64 (s, -*C*≡C-H), 83.58 (d, -C≡*C*-H), 209.91 (s, CO).

[a] The ^{1}H NMR spectra were recorded at 300 MHz, the ^{13}C NMR spectra at 75 MHz.

of **3d** has a characteristic signal at δ = 209.91 for the CO groups bonded to the iron center and other signals at δ = 83.58 and 72.64 for the alkyne carbon atoms. A singlet shifted to high field at δ = 65.51 can be assigned to the C atoms in the four-membered ring. This interpretation is supported by the value of the J(C,H) coupling constants. The ^{1}H NMR spectrum shows, as expected, one singlet at δ = 3.27. In the IR spectrum only bands in the region around 3300 and from 1900 to 2100 cm^{-1} are observed.

The remarkable tetragonal topology was verified by the crystal structure of complex **3b**[9] (Fig. 1). It is noteworthy

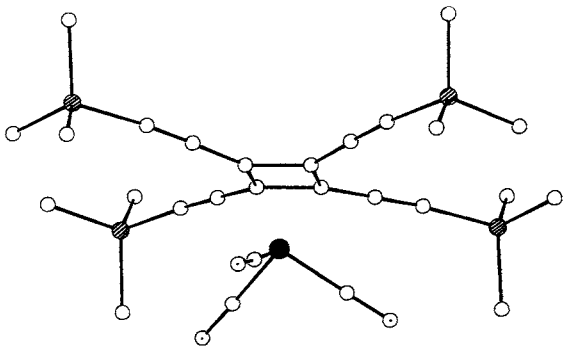

Fig. 1. Crystal structure of **3b**. The hydrogen atoms are omitted for clarity. Important bond lengths [pm]: C–C bonds in the four-membered ring: 144.2(7), 145.5(6), 147.4(7), 148.3(6). C(four-membered ring)–Fe: 203.2(9); -C≡C- (average): 121.0(7). White circles are C atoms, hatched circles are Si atoms, circles with a dot are O atoms, and the black circle is the Fe atom.

that the structure **3b** has a distinctly lower symmetry than that of the unsubstituted tricarbonyl (cyclobutadiene) iron **8**:[10] the four C–C bonds of the cyclobutadiene ligand

$(C_4H_4)Fe(CO)_3$ **8**

lie in the range 144–148 pm and are therefore about 4 pm longer than those obtained for the parent compound **8**. The average length of the triple bonds is 121 pm and thus consistent with reported values.[11] Also noteworthy is the distortion of the expected square arrangement of the alkyne substituents: the distances of the silicon atoms from one another lie in the range 690–850 pm, and are therefore not equidistant. This distortion results from packing effects; a trimethylsilyl and a tricarbonyliron group of neighboring molecules lie between two acetylene arms each of the molecule considered and thus widen the corresponding bond angles (Fig. 2). Such a ring distortion was not observed in the hexaethynylbenzene **1**.[1]

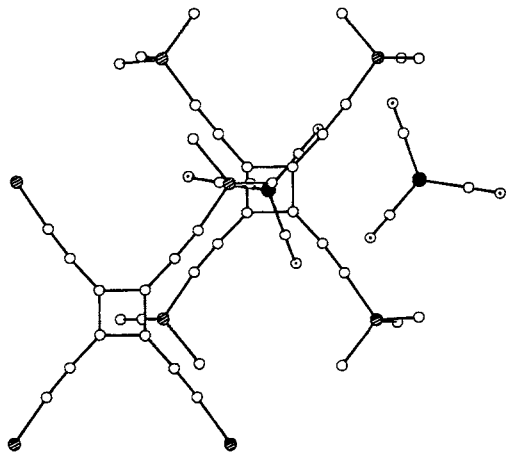

Fig. 2. The interaction of a Me_3Si and a $Fe(CO)_3$ group with the alkyne substituents in **3b** causes an unexpected distortion (labeling of the atoms as in Fig. 1).

We describe here the synthesis of new tetraethynylated-cyclobutadiene iron tricarbonyl complexes by palladium-catalyzed fourfold Stille coupling. These perethynylated compounds are fascinating monomers for the construction of carbon networks.

Experimental Procedure

3b: Tetraiodide **5** (936 mg, 1.35 mmol), stannane **6b** (1.76 g, 6.73 mmol), $[Pd_2(dba)_3]$ (68.7 mg, 75.0 μmol), and triphenylarsine (91.9 mg, 300 μmol) were dissolved in anhydrous DMF (60 mL) with exclusion of air and moisture. After the mixture had been stirred for 18 h, DMF was removed under high vacuum and the residue was filtered over neutral aluminum oxide. In this manner 641 mg (83%) of **3b** were obtained. Analogous reactions of **6a, c** gave **3a** (40%) and **7** (20%) as a mixture as well as **3c** (25%).

3d: Silane **3b** (205 mg, 355 μmol) was dissolved in methanol (20 mL), potassium carbonate (400 mg, 2.89 mmol) was added, and the mixture was stirred for 15 min. Partition between water and diethyl ether, drying of the organic phase and removal of the solvent at −10 °C/0.01 Torr gave 81 mg (79%) of **3d**.

Decamethylaluminocenium, a π-Stabilized R_2Al^+ Cation**

By *Carsten Dohmeier, Hansgeorg Schnöckel,* Christian Robl, Uwe Schneider*, and *Reinhart Ahlrichs**

Numerous reactions of organoaluminum compounds and their IR and NMR spectroscopic investigations have given hints for the existence of π complexes containing a three-coordinate aluminum center and three unsaturated organic ligands.[1] However, only a small number of these compounds could be characterized by X-ray or electron diffraction methods. Among these are complexes with π interations between Al and one C atom of an unsaturated ligand[2] with the structural unit **A**[3] and with η^3-bound Cp* groups (Cp* = C_5Me_5).[4]

A

Only recently η^5-bound Cp* ligands could be identified in both $[(Cp^*Al)_4]$ (**1**)[5] and in $[(Cp^*AlCl_2)_2]$.[6] This coordination type is especially suited for stabilizing Al^I centers because of a strong π bond.[7] This stabilization raises the questions whether even the strongly Lewis-acidic aluminum atom of an R_2Al^+ cation can be stabilized by Cp* ligands, and if the small central ion in a $[Cp^*_2Al]^+$ complex leads to a ferrocene-like sandwich structure.[8] We report here on the synthesis and characterization of a compound containing cation **2**.

$[(\eta^5\text{-}Cp^*)_2Al]^+$ **2**

A solution of **1** was heated in toluene at 110 °C for 20 days then cooled to room temperature to provide (apart from metallic aluminum) a colorless substance, which shows a sharp signal in its ^{27}Al NMR spectrum at $\delta = -114.5$ ($\omega_{1/2} = 50$ Hz, benzene). Comparison of these results with those from the ^{27}Al NMR investigations of a reaction product formed from $AlCl_3$ and Cp*Li implies that the observed signal arises from an Al^{III} compound.[9] This NMR chemical shift, which is the furthest upfield yet reported for an Al^{III} compound (diamagnetic ring current effect of the aromatic rings), indicates η^5-bound Cp* groups with enhanced Al–Cp* bonding as a result of π contributions.[10] The narrow peak-width, which results from a highly symmetric charge distribution at the aluminum nucleus, is in accordance with the proposed ferrocene analogue $[(\eta^5\text{-}Cp^*)_2Al]^+$ **2**.

To check this hypothesis we performed ab initio calculations for **3** and **2**. The SCF geometry optimization[11] yielded

$[Cp_2Al]^+$ **3**

the following results (X denotes the center of the C_5 rings): **3**: $d(Al\text{–}C) = 220.4$, $d(Al\text{–}X) = 184.3$, $d(C\text{–}C) = 142.1$ pm; **2**: $d(Al\text{–}C) = 220.8$, $d(Al\text{–}X) = 183.6$, $d(C_{ring}\text{–}C_{ring}) = 142.9$, $d(CH_3\text{–}C_{ring}) = 151.0$ pm. The conformer of **2** with staggered Cp* ligands (D_{5d}) is more stable than that having eclipsing ligands by 1.9 kJ mol^{-1}. The rotational barrier is even smaller for **3** (0.47 kJ mol^{-1}[12]). In addition we performed MP2 calculations[13] for **3** to investigate the influence of electron correlation on the structure. Configuration interaction leads to a shortening of the Al–C distance by 3 pm and to an elongation of the C–C bond by 1 pm. We expected similar trends for the homologous compound **2**: **2** ["MP2"]: $d(Al\text{–}C) = 217.4$ pm and $d(C_{ring}\text{–}C_{ring}) = 143.9$ pm.

Subsequent calculations of the ^{27}Al NMR chemical shifts by the GIAO-SCF method[14, 15] provided a value of $\delta = -130.0$ for the MP2 geometry of **3** and $\delta = -119.8$ for the corrected structure of **2**.[16] The expected maximum error amounts to $\Delta\delta \approx 15$.[10] We thus obtained close agreement between the measured signal ($\delta = -114.5$) and the predicted value, which confirms our structural hypothesis.

Since the product of the thermal disproportionation of **1**[17] was not suitable for X-ray structure determination, we attempted to isolate cation **2** with other counterions. The reaction of [Cp*Al] with $AlCl_3$ leads to precipitation of Al and formation of the colorless, extremely air- and moisture-sensitive complex **4** [Eq. (a)]. The mass spectrum (positive and negative ions) confirms the reaction product. Compound **4** forms triclinic crystals in the space group $P\bar{1}$ with two formula units per unit cell. The $[(\eta^5\text{-}Cp^*)_2Al]^+$ ions occupy two crystallographically independant inversion cen-

$$3[Cp^*Al] + AlCl_3 \longrightarrow 2\,Al + [(\eta^5\text{-}Cp^*)_2Al][\eta^1\text{-}Cp^*AlCl_3] \quad \text{(a)}$$

ters. The X-ray structure[18] is shown in Figure 1. The average Al–C distance in the staggered conformation found here amounts to 215.5 pm, in good agreement with the MP2-corrected value of 217.4 pm. Even the calculated structure of the Cp* groups is confirmed by the X-ray results. Both predict a slight bend of the methyl groups out of the ring plane and away from the metal atom (expt. $\approx 1.8°$, calc. $= 4.0°$).

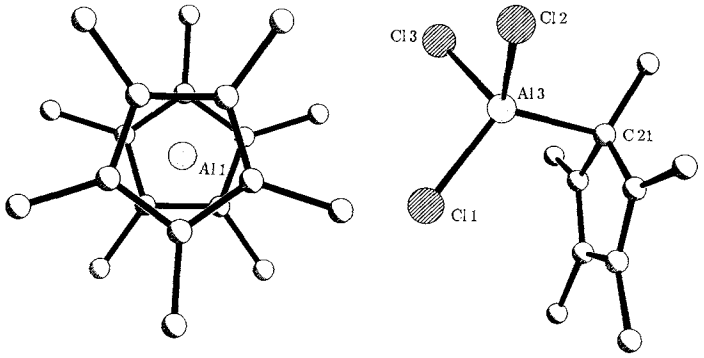

Fig. 1. Molecular structure of one of the two crystallographically independant $[(\eta^5\text{-Cp*})_2\text{Al}]^+$ (left) and $[\eta^1\text{-Cp*AlCl}_3]^-$ (right) ions in **4**. Selected distances and angles ([pm] and [°], $(d_{min}|d_{max}|\bar{d})$, standard deviations in parentheses): $[(\eta^5\text{-Cp*})_2\text{Al}]^+$: (X denotes the center of the C_5 ring) Al-C_{ring} (213.7(8)|218.4(8)|215.5), CH_3-C_{ring} (150.7 (11)|153.4(9)|152.0), C_{ring}-C_{ring} (140.9(11)|145.0(9)|142.9); X-Al-X (180.0(1)), CH_3-C-X (0.8|2.6|1.8). $[\eta^1\text{-Cp*AlCl}_3]^-$: Al3-C21 202.0(6), Al3-Cl1 214.2(3), Al3-Cl2 217.2(3), Al3-Cl3 217.1(3).

The anion $[\eta^1\text{-Cp*AlCl}_3]^-$ in **4** is nearly C_s symmetric. The η^1-coordination of the Cp* ligand to the Al center seems reasonable when one considers the increased negative charge on the metal atom compared to that in the dimer $[(\eta^5\text{-Cp*AlCl}_2)_2]$.[6] The Al–C bond length in **4** amounts to 202.0 pm; the Al–Cl distances are all nearly the same (217.2 and 214.2 pm) and lie within the range observed for $AlCl_4^-$ ions.

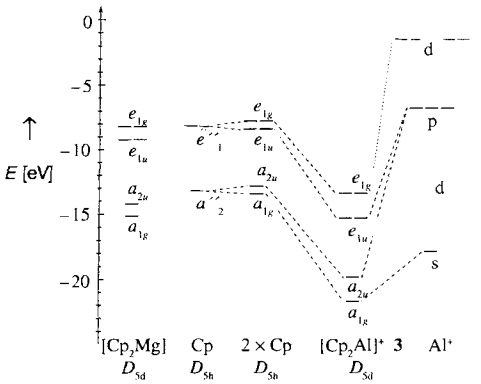

Fig. 2. MO diagram of **3** compared to Cp, Al^+ and $[Cp_2Mg]$ [26].

The π interactions that contribute to Al–Cp* bonding in the decamethyl aluminocenium ion **2** are a new contribution to stabilizing cationic aluminum compounds. The MO diagram in Figure 2 shows the energetic order of the high-lying molecular orbitals of **3**, which arise from linear combinations of the π orbitals of the C_5H_5 rings and 3s, 3p, and 3d atomic orbitals of the Al^+ ion. In comparison with the MOs of the isoelectronic complex $[Cp_2Mg]$,[19] the pronounced stabilization of all MOs in **3** by the net positive charge is evident. The splitting of ligand group orbitals in **3** ($a_{1g} + a_{2u}$ from $2a_2''$ and $e_{1u} + e_{1g}$ from $2e_1''$) is determined by the energetic position of the Al atomic orbitals: the stabilizing influence of the 3s orbital is greater than that of the 3p AOs, and the high-lying 3d AOs contribute even less to bonding. The MO diagram is in accordance with the Mulliken population analysis (MPA)[20] applied to **3**, which ascribes to the Al^+ ion a 3s occupation of 0.55, a $3p_{x,y}$ population of 0.34 each, a $3p_z$ occupation of 0.17 and a total d population of only 0.45.

If one considers the Al–Cp bond based on the purely ionic formulation $[Al^{3+}(Cp^-)_2]$, the charges are equalized by both σ-type bonding (0.76 electrons in 3s, $3p_z$, and $3d_{z^2}$) and π-type bonding (1.08 electrons in $3p_{x,y}$ and $3d_{xz,yz}$). The resulting net charges ($Al^{+1.14}$, $Cp^{-0.07}$) indicate strongly covalent contributions to the Al–Cp bonding.

Until now R_2Al^+ ions were known only in the gas phase[21] or as Lewis acid/base complexes. The latter can be donor-stabilized either intermolecularly as in $[AlMe_2 \cdot [15]\text{crown-5}]^+$ [22] or intramolecularly as in $[Al\{2\text{-C}(SiMe_3)_2C_5H_4N\}_2]^+$.[23] The boron-containing cation $[Cp_2^*B]^+$ prepared by Jutzi et al. was found to have the structure $[(\eta^5\text{-Cp*})(\eta^1\text{-Cp*})B]^+$ in NMR spectroscopic studies.[24] This means that **2** is as yet the only known sandwich complex of an element from the third main group. The higher positive charge on the Al center in **2** leads to a pronounced decrease in the metal–ring distance relative to that in $[Cp_2^*Mg]$ ($d(Mg-C) = 234.1$ pm[25]). This forces the Cp* rings closer together, and the energetic gap between eclipsed and staggered conformations increases ($\Delta E(Cp_2Mg) = 0.13$ kJ mol^{-1};[26] $\Delta E(\mathbf{3}) = 0.47$ kJ mol^{-1}; $\Delta E(\mathbf{2}) = 1.9$ kJ mol^{-1}).

Experimental Procedure

All reactions were carried out under nitrogen in pre-dried vessels. NMR spectra were recorded on a Joel GSX-270 spectrometer, TMS (^{1}H) and $[Al(H_2O)_6]^{3+}$ (^{27}Al, 70.4 MHz) served as external standards. MS: (CI, isobutane, Finnigan (MAT 90)), fragments with intensities less than 5% not listed.

4: [Cp*Al] (50 mg, 0.309 mmol) and $AlCl_3$ (15 mg, 0.115 mmol, resublimed prior to use) were suspended in 3.5 mL toluene, whereupon elimination of aluminum began. The originally yellow solution faded after the starting materials had completely dissolved. After 3 d the reaction tube was heated to 100 °C for 15 h. By slowly cooling, colorless extremely air- and moisture-sensitive **4** was obtained (29 mg, ≈ 50%). M.p. 232 °C (decomp). – Since **4** is poorly soluble in aromatic hydrocarbons, NMR spectra were recorded in $CDCl_3$. This solvent reacts with **4**, and $[Cp_2^*Al][AlCl_4]$ is formed. ^{1}H NMR ($CDCl_3$): $\delta = 2.20$ (br.); ^{27}Al NMR ($CDCl_3$): $\delta = 103.0$ ($\omega_{1/2} = 8$ Hz), $\delta = -115.2$ ($\omega_{1/2} = 8$ Hz). MS [*m/z* (%)]: positive ions: 429 $[Cp_2^*Al_2Cl_3]^+$ (5.4), 297 $[Cp_2^*Al]^+$ (100); negative ions: 367 $[Cp_2^*AlCl_2]^-$ (15.8), 267 $[Cp^*AlCl_3]^-$ (100).

[8] Until now our attempts to prepare $[Cp^*_2Al]^-$ with an Al^I central atom, which is isoelectronic to $[Cp^*_2Si]$, have not been successful.
[9] When 1.0 mmol $AlCl_3$ and 1.0 mmol Cp*Li were allowed to react at 25 °C in toluene/diethyl ether, the following ^{27}Al NMR signals were observed after 4 d: $\delta(C_6D_6) = 101.2$ and 115.0. The sample thus contains the previously described compound among others.
[10] J. Gauss, U. Schneider, R. Ahlrichs, C. Dohmeier, H. Schnöckel, *J. Am. Chem. Soc.* **1993**, *115*, 2402.
[11] All calculations were performed with TURBOMOLE program package (R. Ahlrichs, M. Bär, M. Häser, H. Horn, C. Kölmel, *Chem. Phys. Lett.* **1989**, *162*, 165) on IBM RISC/6000 workstations. Basis sets for geometry optimization: Al: (10s7p)/[4s3p] + d ($\eta = 0.30$); C: (7s3p)/[3s2p] + d ($\eta = 0.80$); H: (3s)/[2s]. All basis sets were fully optimized (A. Schäfer, H. Horn, R. Ahlrichs, *J. Chem. Phys.* **1992**, *97*, 2571). SCF total energy: **2**: −1015.49175 a.u.; **3**: −625.66939 a.u.
[12] For **3**, the D_{5d} structure was proved to correspond to a local minimum on the potential energy surface by calculating the geometry hessian of the SCF energy.
[13] In MP2 calculations electron correlation is treated with second-order perturbation theory (C. Møller, M. S. Plesset, *Phys. Rev.* **1934**, *46*, 618).
[14] GIAO (Gauge-Including Atomic Orbitals): R. Ditchfield, *Mol. Phys.* **1974**, *27*, 789.
[15] M. Häser, R. Ahlrichs, H.-P. Baron, P. Weis, H. Horn, *Theor. Chim. Acta* **1992**, *83*, 455.
[16] For GIAO-SCF calculations the basis sets must have more flexibility than for structure calculations. Following ref. [10] we chose the following contraction schemes: Al: (11s7p1d)/[6s5p1d], C: (8s4p1d)/[4s3p1d], and H: (4s1p)/[2s1p]. The conversion from the calculated nuclear shieldings to NMR chemical shifts is done according to the formula $\delta_{subst} = \delta_{ref} + \sigma_{ref} - \sigma_{subst}$, which implies that the results depend on the choice of the reference molecule. We chose AlH_4^- as a standard, because it can easily be treated with theoretical methods, and its chemical shift has been measured several times (see, for example, H. Nöth, *Z. Naturforsch. B* **1980**, *35*, 119 and referenes therein).
[17] The hitherto obtained spectroscopic results indicate a multistep reaction. Probably [Cp*Al] first forms $[(Cp^*_2Al)Cp^*]$, which reacts to give a compound with the structural element $[Cp^*(C_5Me_4CH_2)Al]$ and to Cp*H. To clarify this reaction sequence further experiments will be necessary.
[18] X-ray structure analysis: $C_{30}H_{45}Al_2Cl_3$, $M = 566.0$, triclinic, space group $P\bar{1}$, $a = 910.6(3)$, $b = 970.5(3)$, $c = 1872.7(5)$ pm, $\alpha = 99.73(2)$, $\beta = 90.76(2)$, $\gamma = 92.24(2)°$, $V = 1629.5 \times 10^6$ pm^3, $Z = 2$, $\varrho_{calcd.} = 1.153$ g cm^{-3}, F(000) = 604, $\mu = 3.5$ cm^{-1} ($Mo_{K\alpha}$), 295 K, ω-Scan, $\theta_{max} = 22°$, scan velocity 1.30–14.65° min^{-1}, scan width 1.3°, Siemens R3m/V diffractometer, graphite monochromator, 4398 reflections recorded, of which 4002 were symmetry-independant, $R_{int} = 0.0206$; 2439 reflections with $|F| > 3\sigma_{|F|}$ classified as observed. Calculations with SHELXTL-Plus, 320 parameters, hydrogen atoms geometrically positioned. Non-hydrogen atoms anisotropically refined, numerical absorption correction; $R = 0.0789$, $R_w = 0.0505$, $R_g = 0.0365$, $w = \sigma^{-2}_{|F|}$. Extremes of the final difference Fourier synthesis: +0.37/−0.32 e × 10^{-6} pm^3. Further details of the crystal structure determination may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen on quoting the depository number CSD-57426, the names of the authors, and the journal citation.
[19] If no Al basis functions of d type are included in the calculation, then **3** is destabilized by 81 kJ mol^{-1}. Calculations without valence p functions lead to an increase in energy by 216 kJ mol^{-1} (see: H. Horn, R. Ahlrichs, *J. Am. Chem. Soc.* **1990**, *112*, 2121).

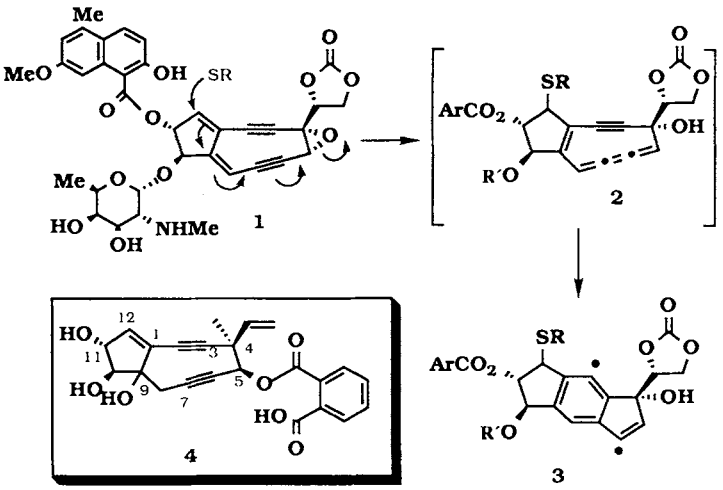
Synthesis of a Nine-Membered Cyclic Analogue of the Neocarzinostatin Chromophore and Its DNA-Cleaving Activity**

By *Takashi Takahashi,* Hiroshi Tanaka, Yoshimasa Hirai, Takayuki Doi, Haruo Yamada, Takashi Shiraki,* and *Yukio Sugiura*

Neocarzinostatin (NCS)[1] is a naturally occurring antitumor antibiotic complex consisting of a protein component (NCS apo-protein) and a chromophoric molecule (NCS-chr, **1**). The antitumor activity of NCS is attributed primarily to the NCS-chr **1**, which is proposed to undergo a thiol-triggered epoxide opening followed by a Myers' type cyclization[2] of enynecumulene **2** leading to a highly reactive biradical **3**, which abstracts hydrogen atoms from the sugar phosphate backbone of DNA[3] (Scheme 1).



Scheme 1. Mechanism for the generation of the biradical of the NCS-chr **1** and the structure of the nine-membered analogue NCS analogue **4**. The $ArCO_2$ group corresponds to the substituted naphthoic acid residue, R'O the sugar residue in **1**.

The design and synthesis of DNA-cleaving molecules is currently a topic of intense research.[4] So far, four groups[5] have succeeded in synthesizing nine-membered analogues of NCS-chr **1**. Of these, two groups[5a,b] have demonstrated cycloaromatization of their analogues, but no group has achieved DNA cleavage. In this communication we report the first synthetic nine-membered analogue **4** which is sufficiently stable at ambient temperature to allow its handling and shows strong DNA-cleaving activity.[6]

In our synthetic plan, the first key reaction is the transannular [2,3]-Wittig rearrangement[7] of the twelve-membered cyclic ether **6**, prepared by the intramolecular O-alkylation of bromoalcohol **7** (Scheme 2). In this way we are able to construct a highly strained nine-membered diyne **5**, in which

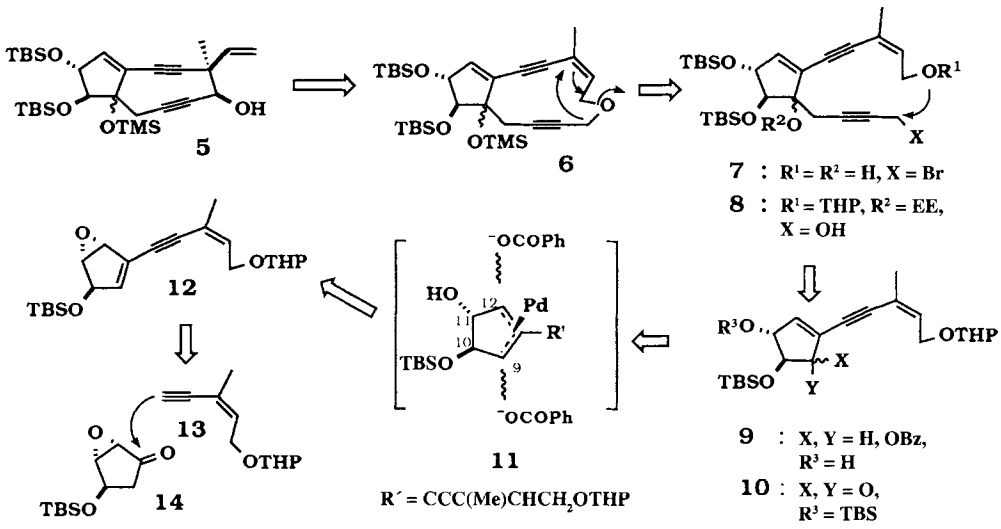
[**] We would like to thank Dr. Nancy I. Totah (Columbia University) for helpful discussions that have made this publication possible.



Scheme 2. The strategy for the synthesis of diyne **5**. TBS = tBuMe$_2$Si, TMS = Me$_3$Si, THP = tetrahydropyranyl, EE = ethoxyl ethyl. In Pd complex **11** only one of the two benzoate groups are bound at either C9 or C12.

the newly formed secondary alcohol and vinyl groups can be used to introduce a phthalic acid "trigger" and a cyclic carbonate group, respectively. MM2 calculations[8] of the possible conformations of **6** (Fig. 1) suggest that its [2,3]-Wittig rearrangement should proceed smoothly.

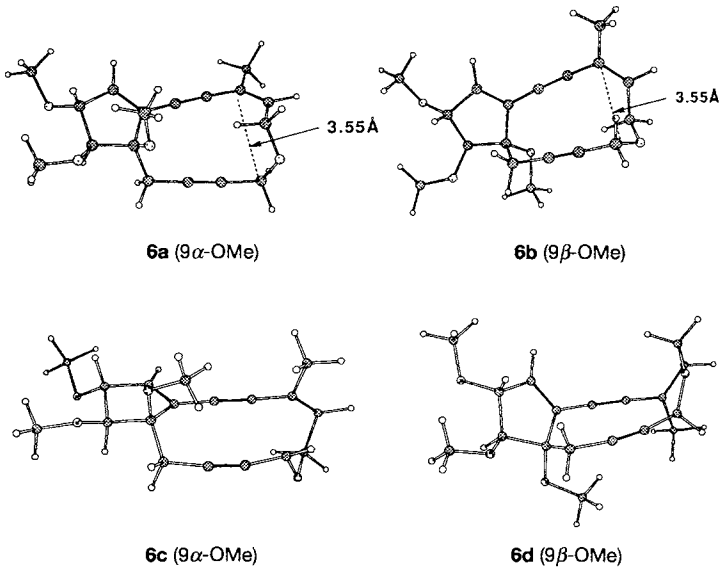


Fig. 1. Conformational analyses of the twelve-membered cyclic ether **6** based on MM2 models of the ground state (**6a**, **6b**) and MM2 models (**6c**, **6d**) of the transition state.

A second key reaction is the nucleophilic ring-opening of the unsaturated epoxide **12** with benzoic acid, which is promoted by a palladium complex.[9] This process results in a "*trans*" relative stereochemistry between the siloxy groups at C10 and C11, and introduces the $\Delta^{1(12)}$ double bond in **9** at the same time. While this palladium-catalyzed reaction could produce up to four possible regio- and stereoisomers via the π-allyl palladium complex **11** (α and β displacement at C9 and C12), all isomers can be converted into enone **10** in three steps. This methodology, if successful, offers an enantioselective approach to **4** starting from the optically active epoxide **14**, which is easily derived from the (4*S*)-hydroxy-2-cyclopentenone.[10] We describe herein a route to racemic **4**.

Molecular modeling based on MM2 calculations and MM2 transition state models[11] has proven to be useful in the design of key synthetic intermediates as well as in the prediction of stereoselectivity in reactions of macrocyclic compounds.[12] Initial conformational analyses of **6** were conducted using MacroModel[13] to predict whether the [2,3]-Wittig reaction of **6** would be likely to proceed. These analyses showed that in all lower energy conformers[14] of **6** (Fig. 1) the two reactive centers are separated by only a short distance (about 3.5 Å) and the orbitals at the reactive centers overlap well with the π orbitals oriented horizontally to the plane of the ring. Moreover, MM2 models of the transition state[15] based on Houk's ab initio calculations for the reactive centers and MM2 calculations for the rest of the molecule suggest[16] that the product of the [2,3]-Wittig reaction of **6** should have a "*cis*" relative stereochemistry between the newly formed vinyl and hydroxy groups.

The synthesis of the cyclic ether **6** was carried out as follows. Addition of the lithium derivative of **13** (*n*-BuLi/THF, −70 °C; 71 %) to ketone **14**, which is prepared from (±)-4-*tert*-butyldimethylsiloxy-2-cyclopentenone, and dehydration of the resultant tertiary alcohol ($(CF_3SO_2)_2O$/2,6-lutidine; 60 %) afforded the unsaturated epoxide **12**. Palladium-catalyzed epoxide opening of **12** ($[Pd(OAc)_2]$/PPh_3, benzoic acid, THF, 25 °C) gave a 85:15 mixture of C9-benzoate **9** (α:β benzoate = 80:20) and its C12 isomer in 80 % combined yield. The allylic alcohols thus obtained were used without separation; protection of the allylic alcohol (TBSCl/imidazole), hydrolysis of the benzoate group (K_2CO_3/MeOH), and oxidation (pyridinium chlorochromate) provided enone **10** in 50 % overall yield. 1,2-Addition of propargylmagnesium bromide to **10** (80 % yield), protection of the resultant tertiary alcohol (ethyl vinyl ether/H^+), and condensation of metalated terminal alkyne (EtMgBr/THF) with paraformaldehyde afforded the propargyl alcohol **8** in 40 % yield for the three steps. Alcohol **8** was then converted into its propargyl bromide derivative in 74 % yield by mesylation and displacement with lithium bromide. Simultaneous removal of the tetrahydropyranyl and ethoxy ethyl ethers under mild acidic conditions (AcOH:THF:H_2O = 4:1:1, at 25 °C) gave bromoalcohol **7** in 54 % yield. Cyclization of **7** was achieved under high-dilution conditions. A solution of diol **7** (10^{-2} M in THF) was added with a syringe pump to a suspension of NaH and HMPA at room temperature to give the cyclized product in 54 % yield. This compound was converted into trimethylsilyl ether **6**.[17]

The [2,3]-Wittig rearrangement of **6** promoted by *tert*-butyllithium at −100 °C in THF was complete within

10 min, and the product **5**[18] was isolated in 62% yield. In this rearrangement, as expected, a high degree of "*cis*" stereoselectivity (>99%)[19] between the newly formed vinyl and hydroxy groups was observed. Neither the corresponding *trans* isomer nor the 1,2-rearrangement product were obtained. Esterification of **5** (phthalic anhydride, pyridine, dimethylaminopyridine, room temperature; 51%) and acid hydrolysis (40% aq. HF:CH_3CN = 5:95, room temperature; 60%) gave the desired diyne **4**.[20] At ambient temperature diyne **4** was sufficiently stable for purification on silica gel and characterization.

The DNA-cleaving activity of **4** was analyzed with supercoiled pBR322 DNA (Form I) in the presence of methyl thioglycolate, and clean scission was observed. As shown by gel electrophoresis (Fig. 2), incubation of **4** (200 μM, 1 mM) with DNA Form I (0.4 mg) and methyl thioglycolate (20 mM) in 10% DMF/Tris-HCl buffer (pH 7.5) for 18 h at 37 °C cleanly produced a nicked circular Form II and finally the linear Form III. As expected, in the absence of methyl

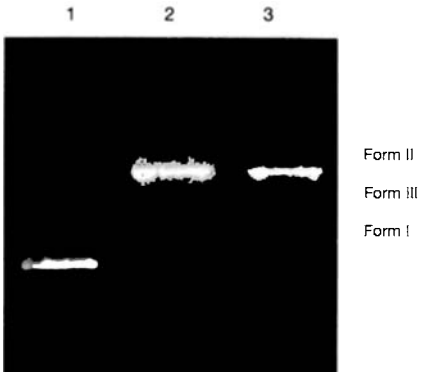

Fig. 2. Agarose gel electrophoretic patterns of DNA before and after nicking by the NCS-chr analogue **4** (lane 2, 200 μM; lane 3, 1 mM). Lane 1 shows intact DNA.

thioglycolate, incubation of **4** with Form I did not cause any cleavage. At present, the mechanism for thiol-triggered cycloaromatization of **4** is not clear. Further studies to elucidate the mechanism are currently underway in our laboratory.

In summary, we have succeeded in synthesizing the first nine-membered NCS-chr analogue possessing DNA-cleaving activity. The introduction of sugar and naphthoic acid residues at C10 and C11, respectively, as found in natural NCS-chr **1** is currently under investigation in our laboratory.

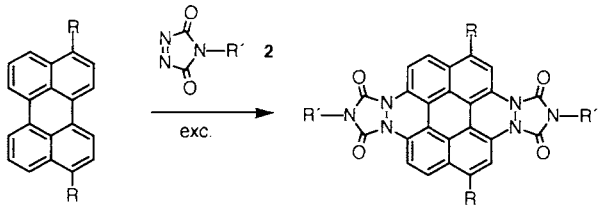
Liquid-Crystalline Perylene Derivatives as "Discotic Pigments"**

By *Christine Göltner, Dietmar Pressner, Klaus Müllen,** and *Hans Wolfgang Spiess**

Pigments based on perylene are industrially important.[1] The wider application of their chromophoric properties, however, is often restricted by their poor processibility, for example, because of their high melting and softening temperatures. Our aim was to synthesize liquid-crystalline derivatives based on the planar perylene molecule. We expected these to show advantages in terms of good solubility and meltability as well as to exhibit the ability to self assemble into columnar superstructures of discotic mesogens. In the following we report on the twofold cycloaddition of 3,5-dioxotriazoles to alkyl-substituted perylenes and the characterization of the liquid-crystalline perylene derivatives thus obtained.

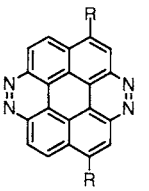
Attempts to carry out cycloadditions of dienophiles at the "bay" positions of **1** (R = H), reported so far, have resulted in the addition of a single dienophile only.[2] A diaddition product was obtained in low yields only under more drastic reaction conditions.[3] This observation can be explained by the low enophilicity of the respective monoaddition products as well as their poor solubility. Treating 3,10-dialkyl perylenes **1**[4] with an excess of commercially available 4-phenyl-3,5-dioxotriazole (**2**), however, yields the aromatized diaddition product, 2,9-dialkyl-5,6,11,12-tetraaza-5,6,11,12-tetrahydrocoronene-5,6,11,12-tetracarboxylic acid bisphenylimide **3** (R = phenyl), quantitatively. Since the basic structure of this compound is disc-shaped (discoid), it seemed obvious that the reaction of 3,10-dialkyl perylenes with alkyl-substituted 3,5-dioxotriazoles might afford discotic mesogens.



1 R = *n*-C_5H_{11}, *n*-$C_{12}H_{25}$, *n*-$C_{18}H_{37}$ **3**

R' = C_6H_5, *n*-C_5H_{11}, *n*-$C_{11}H_{23}$, *n*-$C_{17}H_{35}$, *n*-$C_{21}H_{43}$

The reaction of **1** with 4-*n*-alkyl-3,5-dioxotriazoles of different chain length also resulted in soluble compounds **3** in excellent yields. For simplicity these are defined in the following as **Px-y** (x = length of the alkyl chain attached to the perylene ring and y = length of the alkyl chain linked with the urazole unit). The materials obtained are thermally stable up to 350 °C and also stable to protonic acids (e.g. trifluoroacetic acid, 1 d reflux). Treatment with NaOH at temperatures above 90 °C causes cleavage of the imide moiety. On acidification, spontaneous decarboxylation yields the previously unknown, readily soluble tetraazacoronene **4**.[3]



4

R = *n*-$C_{12}H_{25}$

Comparing the UV spectra of **3** with the ones obtained from the corresponding perylenes (λ_{max} = 453 nm), the longest wavelength absorption is found to be bathochromically shifted by 130 nm. The typical line shape of the UV spectra of **3** indicate that despite chemical modification the perylene chromophore is intact.

As expected, the derivatives **3** form mesophases, which qualitatively was detected by optical microscopy. The materials show birefringence and shearability, both typical of liquid crystals. The structure of the mesophases, however, could not be assigned, because the derivatives **3** show diffuse textures, and the extraordinarily high phase width generally did not allow for heating the substances above their clearing temperatures (e.g. **P11-12**: c – 20 °C D_{ho} 373 °C i). The transition temperatures could be determined by calorimetric (DSC) measurements. The clearing temperatures (T_c) significantly depend on the substitution pattern of **3**. The higher the symmetry of the molecule, that is, the more similar the chain lengths ($x \approx y$) of the alkyl substituents R(x) and R'(y), the higher is the clearing temperature (Table 1).

Table 1. Influence of the molecular shape on the phase transition temperatures [°C] of selected perylene derivatives.

Compound	Phase transition temperatures	Shape
P18-05	c 69 D_{col} 261 i	⬯
P18-17	c 45 D_{ho} 305 i	◯
P12-11	c -20 D_{ho} 373 i	◯
P05-17	c 85 D_{col} 202 i	⬭

Small-angle X-ray diffractograms allowed for an unambiguous elucidation of the phase structures of most derivatives of **3**. Long-chain substituted, symmetrical derivatives show an ordered columnar alignment of the molecules with a hexagonal superstructure (D_{ho}),[5] while more unsymmetrically substituted compounds exhibit a strong disturbance of the hexagonal lattice. The latter corresponds qualitatively to the observed decrease of the clearing temperatures determined by calorimetric measurements. As an example, Figure 1 shows the diffractogram of **P18-17**, in which the reflections, which prove the columnar, hexagonal structure of the mesophase, are labeled.

The number of lateral alkyl chains attached to the skeleton of **3** is surprisingly low in comparison to that of the "classical" discotic mesogen hexabutyloxy triphenylene **5a** (c 88 °C D_{ho} 145 °C i). The latter is the liquid-crystalline derivative of the series of hexaalkyloxy triphenylenes with the shortest possible length of alkyl chains, and it shows a significantly smaller width of the mesophase than **P5-5**, the "shortest" derivative of **3** synthesized so far. The ratio of aliphatic to aromatic carbon atoms in the triphenylene **5a** is 8:6, while it

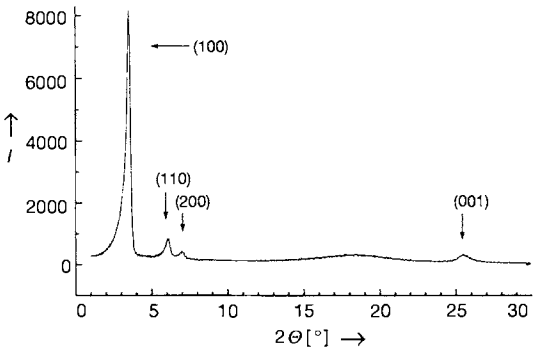

Fig. 1. X-ray diffractogram of the **P18-17** derivative at 130 °C.

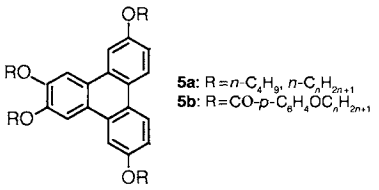
is 5:6 for **P5-5**, which nevertheless forms a mesophase of more than 250 °C width (c 27 °C D 319 °C i). It can be expected that even further shortening of the lateral alkyl chains in **3** will not obstruct the formation of a mesophase.



The mesophases of compounds **3** with longer alkyl substituents, however, still are extraordinarily stable (**P18-17**: c 45 °C D_{ho} 305 °C i; **P12-17**: c 15 °C D_{ho} 316 °C i). In contrast to this, triphenylenes with side chains longer than 14 carbon atoms are not liquid crystalline any more.[6] The mesophases of the parent triphenylene core can be stabilized by substitution with alkoxyaryl esters, but the hexaalkyloxy triphenylene benzoates of the type **5b** still exhibit clearing temperatures far below the ones of **3**, as shown in Figure 2.[7]

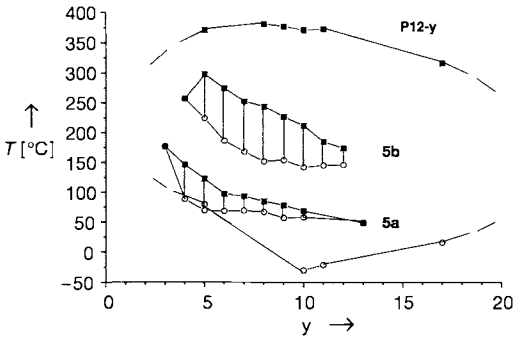


Fig. 2. Phase transition temperatures (melting point T_m (—○—) and clearing temperatures T_c (—■—) °C) of **3** compared with classical discotic mesogens [6, 7].

Since the unusual stability of the mesophases of **3** cannot only be explained by the ratio of aliphatic to aromatic carbon atoms, more specific interactions must be taken into account. Decisive indications of those and the mechanisms of dynamic processes can be obtained from solid-state ^{2}H NMR spectra. For this purpose, three derivatives of **P12-17**, selectively deuterated at different positions (**6a**, **6b**, and **6c** in Fig. 3) were synthesized. In all cases, the degree of deuteration was determined by ^{1}H NMR spectroscopy to be higher than 85%.

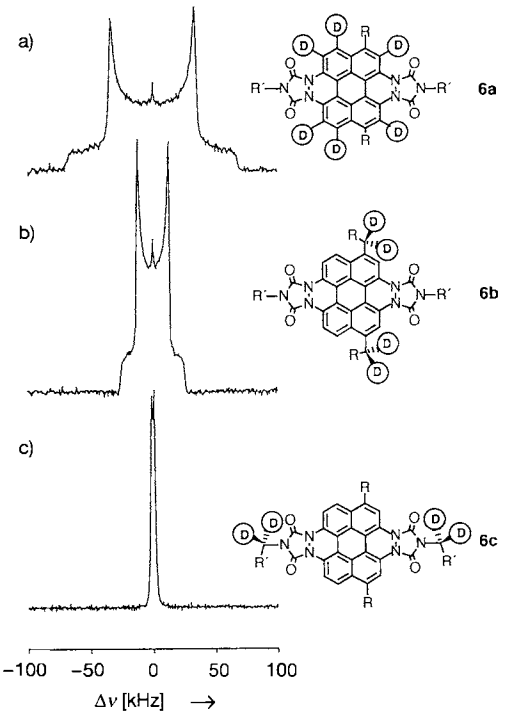

Fig. 3. Solid-state ^{2}H NMR spectra of **6a–c** at 130 °C.

In many cases reported previously, one- and two-dimensional ^{2}H NMR spectroscopy has proven to be a successful method for the elucidation of dynamic processes and structural properties of columnar mesophases.[8] The ^{2}H NMR spectra of the isotropic solid, recorded under conditions, in which the molecules can be considered rigid on the NMR time scale (rigid Pake spectra), show characteristic changes of the line shape during the transition into the mesophase. Defined motions result in defined spectra. Especially the uniaxial rotation of the disc-shaped molecule around the main columnar axis causes a characteristic, motion-averaged spectrum, the quadrupolar splitting of which is reduced by a factor of 2. This could be shown for the derivative **6a**, deuterated in the aromatic positions (Fig. 3; 131 kHz at −70 °C, 66 kHz at 130 °C). The nature of the main dynamic process of the mesogen could thus be determined unambiguously.

For the alkyl chains attached to the perylene core and to the urazole unit, respectively, a remarkably different dynamic behavior was found (cf. Figs. 3b, c). The motion-averaged, reduced spectrum observed for **6b** corresponds to the ones obtained from α-deuterated triphenylene side chains.[9] These indicated a planar *trans* conformation at the α-carbon atom of the alkyl chain. In the ^{2}H NMR spectrum of **6c** a further reduction of the quadrupolar splitting by a factor of 5 is observed. This change in the width of the spectrum is ascribed to the internal mobility of the molecule, which could be caused by a flip process of the urazole rings between the two nonplanar conformations relative to the perylene skeleton as well as an enhanced conformational freedom of the adjacent alkyl chain. The results of the ^{2}H spectra indicate that the five-membered, heterocyclic ring clearly deviates from a coplanar conformation. This nonplanarity could cause an "entanglement" between neighboring perylene

units, resulting in an increased phase width of **3**. In fact, such an entanglement was found to be the reason for the increased stability of the mesophases formed by ester-substituted triphenylenes.[10]

Further investigations will reveal, if additional dynamic processes or electronic interactions among the molecules are responsible for the extraordinary stability of the mesophases formed by **3**.

The synthesis and characterization of the novel discotic mesogen **3** allowed for the assembly of perylene as a liquid-crystalline material, not just in a liquid-crystalline matrix.[11] This extends the possibilities of processing and application of perylene pigments, and in fact, preliminary experiments show that some derivatives of **3** can be oriented in a magnetic field and that highly oriented fibers can be drawn.

Experimental Procedure

P5-17: 3,10-dipentylperylene (250 mg, 0.5 mmol) was dissolved in xylene (30 mL) under gentle heating. This solution was treated with 4.4 equivalents of 4-*n*-heptadecyl-3,5-dioxotriazole (750 mg, 2.2 mmol) [12] and heated to reflux for two minutes. Additional small portions of dioxotriazole were then added until neither the yellow starting material nor the red monoaddition product could be detected by chromatography (tlc). The reaction mixture was worked up by first pouring it into cold methanol (150 mL) followed by filtration. The residue was purified by column chromatography on silica gel (petroleum ether/toluene), yield: 470 mg (82%).

^{1}H NMR (300 MHz, [D$_2$]tetrachloroethane, 110 °C): δ = 7.93 (d, J = 9 Hz, 2H, Ar-H), 7.86 (s, 2H, Ar-H), 7.17 (d, br., 2H, Ar-H), 3.65 (t, J = 7 Hz, 4H, 2 α-urazole chains-CH$_2$), 2.58 (m, 4H, 2 benzylic CH$_2$), 1.77 (m, 4H, 2 CH$_2$), 1.56 (m, 4H, 2 CH$_2$), 1.59–1.10 (m, 64H, 16 CH$_2$), 0.93–0.82 (m, 12H, 4 CH$_3$); ^{13}C NMR (75 MHz, [D$_2$]tetrachloroethane, 110 °C): δ = 144.70, 144.64, 144.46, 141.13, 129.96, 129.81, 126.40, 125.02, 124.94, 113.85, 113.68, 113.14, 110.90, 41.34, 40.15, 32.88, 32.11, 29.90, 29.50, 29.15, 28.10, 28.00, 27.62, 27.19, 26.71, 22.84, 22.71, 14.23. IR(KBr): $\tilde{\nu}$ = 2905, 2830, 1740, 1685, 1580, 1410, 1385 cm^{-1}; UV(CHCl$_3$): λ_{max} (log ε):586 (4.01), 541 (3.94), 505 (3.64); FD-MS (70 eV): m/z (rel. intensity): 1062.98 (100%).

4: **3** (R′ = Ph, R = n-C$_{12}$H$_{25}$) (500 mg, 0.54 mmol) was suspended in benzyl alcohol (30 mL) and heated to 90 °C. This mixture was treated with solid NaOH (500 mg, 12.5 mmol) and stirred at this temperature until the solution became homogeneous and no longer showed red fluorescence. The reaction mixture was then added dropwise to a well-stirred mixture of methanol (200 mL) and concentrated hydrochloric acid (5 mL). After filtration the crude product was purified by recrystallization from isopropyl alcohol; yield: 300 mg (87%).

4: ^{1}H NMR (200 MHz, CDCl$_3$): δ = 9.00 (d, 2H, J = 9 Hz, Ar-H), 8.80 (s, 2H, Ar-H), 8.66 (d, J = 9 Hz, 2H, Ar-H), 3.52 (t, J = 8 Hz, 4H, 2 α-CH$_2$), 2.06 (m, 4H, 2 β-CH$_2$), 1.68–1.26 (m, 36H, 18 CH$_2$), 0.86 (t, J = 8 Hz, 6H, 2 CH$_3$); ^{13}C NMR (50 MHz, CDCl$_3$): δ = 142.22, 141.83, 141.48, 129.98, 128.42, 127.34, 125.53, 115.07, 111.35, 109.75, 39.38, 33.57, 31.96, 31.16, 31.16, 29.97, 29.76, 29.70, 29.40, 22.70, 14.10; IR (KBr) $\tilde{\nu}$ = 3471, 3449, 3432, 3418, 2849, 1041, 8287 cm^{-1}; UV (CH$_2$Cl$_2$): λ_{max} (log ε): 453 (4.27), 426 (3.95), 403 (3.58); EI-MS: m/z (rel. intensity): 640.38 (4.3%).

Preparative Enantiomer Separation of the Anesthetic Enflurane by Gas Inclusion Chromatography**

By *Volker Schurig*,* *Heiko Grosenick*, and *Bernard S. Green*

Chiral enflurane [C*HFCl–CF$_2$OCF$_2$H] is used as an inhalation anesthetic in clinical practice. The achiral chemical synthesis yields a racemate, which is clinically administered as a 1:1 mixture of enantiomers. Because enantiomers generally have different pharmacological and toxicological properties and may differ greatly in their spectrum of activity, the preparation of the pure enantiomers is of considerable interest. A multistep enantioselective synthesis of enflurane has been described,[1] and approaches to the resolution of the racemate by formation of inclusion complexes have been presented ((−)-brucine, 8% *ee*;[1] tri-*o*-thymotide (TOT, cyclic trilactone of 3-isopropyl-6-methylsalicylic acid), 38% *ee*[2]). The analytical enantiomer separation of enflurane by gas chromatography has also been achieved.[2, 3]

We describe here the preparative-scale separation of the enflurane enantiomers by inclusion gas chromatography on octakis-(3-*O*-butanoyl-2,6-di-*O*-*n*-pentyl)-γ-cyclodextrin (**1**)[4] diluted with polysiloxane SE-54 [(poly(dimethylsilanol-*ran*-phenylmethylsilanol-*ran*-vinylmethylsilanol *ran* = random)(0.94:0.05:0.01 mol%)];[5] the antipodes are obtained in almost enantiomerically pure form (*ee* ≥ 99%, cf. Fig. 1 b,c).

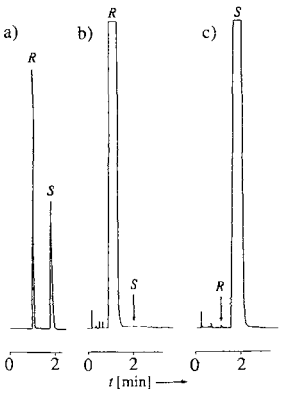

Fig. 1. Analytical enantiomer separation of enflurane on **1** [4] in OV-1701 (38 wt%) [5]. Quartz capillary column (6 m × 0.25 mm internal diameter), 25 °C, 55 cm s^{-1} hydrogen (flame ionization detector, FID). a) racemic; b) (*R*)-(−)-enflurane 99.9% *ee*; c) (*S*)-(+)-enflurane 99.9% *ee*.

Enflurane is separated into its enantiomers on an analytical capillary column coated with **1** in OV-1701, as shown in Figure 1 a. The surprisingly high separation factor $\alpha > 2$ permits a quantitative enantiomer separation in only 20 s (50 °C, 60 cm s^{-1} hydrogen). The transfer of this procedure to a preparative scale is achieved by using a 4 m × 7 mm (internal diameter) packed column filled with 10 wt% (**1**) in SE-54 (20 wt% on Chromosorb) (Fig. 2). Enflurane can be separated from the carrier gas helium without any difficulty. Since the enantiomer separation is achieved in 45 min, larger quantities of separated enantiomer can be recovered by re-

peating the separation cycle. The amount of mobile phase consumed during this process can be minimized by recycling, and the time required for separation can be reduced further by using hydrogen as carrier gas. The absolute configuration of the enantiomers were assigned according to published data.[1] Although the separation factor is smaller, the preparative separation of 8 mg of isoflurane into its enantiomers can be achieved by using the above set-up. Halothane, on the other hand, cannot be resolved on a preparative scale.

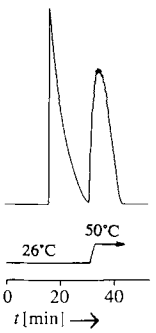

Fig. 2. Preparative enantiomer separation of 47 mg of enflurane (for conditions see Experimental Procedure).

Whereas the application of cyclodextrin derivatives in gas chromatograpy has mainly been in analytical enantiomer separations,[6, 7] our investigations demonstrate their potential in preparative separations. Native α-cyclodextrin in aqueous formamide was previously suggested as a possible stationary phase for this purpose in 1983,[8] and camphene was later separated on a preparative scale by using this system.[9] The dilution of derivatized cyclodextrins with polysiloxanes that has proved to be especially valuable in analytical work[5] is also the method of choice for preparative-scale separations, since it combines chemical selectivity with chromatographic efficiency in an optimal way.

Experimental Procedure

Polysiloxane SE-54 (WGA, Düsseldorf) (22.95 g) was placed in a round-bottomed flask and dissolved under reflux in anhydrous chloroform (600 mL). The γ-cyclodextrin derivative **1** [4] (2.55 g) was added to this mixture. Chromosorb P-AW-DMCS (80/100 mesh, Alltech, Arlington Heights, Ill., USA) (100 g) was then added to the resulting solution. The flask was shaken until the Chromosorb formed a slurry with the solution. The resulting suspension was carefully concentrated on a rotary evaporator over several hours by rotating the flask at a moderate speed, at 40 °C, and under a weak vacuum. Finally, the granular, impregnated Chromosorb was dried at 70 °C and 0.004 Torr for 24 h (the Chromosorb impregnated in this way is coated with a 20.3 wt% layer of the enantioselective stationary phase; the stationary phase itself consists of 10.0 wt% **1** in SE-54).

A glass column (4.04 m × 7 mm internal diameter) was filled with the stationary phase (ca. 95 g). In order to ensure a compact, uniform, dead-volume-free packing, the column was tapped and shaken continuously and was then placed in an ultrasonic bath for 1 min. A modified gas chromatograph (MEGA, Fisons, Mainz, FRG) was used for the preparative-scale separation of the enflurane enantiomers (carrier gas helium (4.6), inlet pressure 4 bar, 8.4 $cm\,s^{-1}$; injector block: 150 °C, on-column injection; detector: FID). Enflurane was supplied by a local clinic. The eluate from the column was led through a splitter (1:1500) into two parallel lines, one leading to the FID and the other to a U-shaped cold trap. The connection to the cold trap (dry ice/acetone) can be heated and was maintained at the column temperature. The enflurane enantiomers were recovered by condensation. The enantiomeric purity was determined by analytical enantioselective capillary gas chromatography, by using the same separation phase as above (Fig. 1). The column temperature was held constant at 26 °C until elution of the first peak and was then raised to 50 °C. A quantitative (base-line separation) resolution of 31 μL = 47 mg of racemic enflurane into its antipodes was achieved in an analysis time of 45 min (cf. Fig. 2) by using the above set-up. The percentage recovery (not optimized) was: first peak: (*R*)-(−)-enflurane (enantiomeric purity $ee \geq 99.9\%$, chemical purity: 99.5%), yield 60% with respect to the *R* enantiomer in the racemate (isolated and transferred into an ampoule); second peak: (*S*)-(+)-enflurane (enantiomeric purity $ee \geq 99.9\%$, chemical purity: 99.7%), yield 52% with respect to the *S* enantiomer in the racemate (isolated and transferred into an ampoule). The enflurane enantiomers were characterized by NMR spectroscopy and by their chiroptical data (cf. ref. [1]).

Synthesis, Structure, and Optical Properties of Cd_4S^{6+} Clusters Encapsulated in an Aluminate Cage**

By *Matthew E. Brenchley* and *Mark T. Weller**

Small-particle semiconductors that demonstrate a blue shift from the bulk (macrocrystalline) material in the optical spectra have been the subject of intense recent interest as a result of their physical properties.[1] Several preparative techniques have been used to prepare small-particle semiconductors including colloidal[2] and porous host methods;[3] however, with these techniques the particle size and distribution is not easily controllable. The size of the particles controls the extent of the blue shift and, hence, a preparative technique which provides greater control of particle size has been sought.

Wang and Herron[4] found that zeolites with various-sized cavities and channels could be used to entrap II–VI semiconductor units of known dimension and composition. Later Moran et al.[5] found that discrete M_4X^{6+} units could be prepared in situ within borate and beryllosilicate frameworks possessing the sodalite structure. With precise control of semiconductor unit stoichiometry and the inter-connectability of these units through the sodalite cage, exceedingly sharp absorption edges in the optical sepctrum could be obtained. However, Moran et al. were not able to synthesize the ZnS/borate sodalites in a pure form, and structural results for the cadmium sulfide helvite were not presented. We report here on the discovery of a compound of the aluminate sodalite family[6] with discrete Cd_4S^{6+} units.

$Cd_8[AlO_2]_{12}S_2$ was prepared by a two-stage process[7] via a parent sulfate sodalite synthesized at high temperatures. First CdO, $CdSO_4$, and Al_2O_3 in the molar ratio 3:1:3 were finely ground and sealed under vacuum in a silica glass tube. The tube was fired at 1000 °C for two days and then cooled to yield a white crystalline powder. The product was shown

to be a single phase by powder X-ray diffraction (Siemens D5000, $Cu_{K\alpha 1}$) and all reflections were indexed on a body-centred cubic cell, sodalite structure, with $a = 9.0994(1)$ Å. IR spectroscopic measurements helped confirm this product as cadmium sulfate aluminate sodalite, $Cd_8[AlO_2]_{12}(SO_4)_2$.

The sulfate sodalite was then reduced under pure hydrogen at 600 °C for 8 hours to yield a bright yellow material. Powder X-ray diffraction measurements showed this to be a single-phase body-centred sodalite with $a = 8.8181(1)$ Å except for a very minor contribution from Al_2O_3 ($I/I_o = 0.05\%$). IR spectroscopic measurements showed no S–O vibrational modes, which is consistent with reduction of sulfate to sulfide and the formation of cadmium sulfide aluminate sodalite, $Cd_8[AlO_2]_{12}S_2$.

The powder X-ray diffraction data for the Rietveld refinement of the structure of $Cd_8[AlO_2]_{12}S_2$ were collected over the angular range 22–127° 2 θ with $Cu_{K\alpha 1}$ radiation on a Siemens D5000 diffractometer over 15 hours. The starting model for the refinement was the structure of the calcium analogue[7] in the space group $I\bar{4}3m$ adopted by sodalites with no ordering of the cage anions. Refinement was undertaken by using the DBWS-9006PC package of Wiles and Young.[8] The small amount of alumina found in the sample was included into the profile as a second phase. The refinement proceeded smoothly and final cycles included all profile and atomic parameters with χ^2 converging to 2.40. The final coordinates and isotropic temperature factors are listed in Table 1; Figure 1 shows the final profile fit to the data.

Table 1. The atomic coordinates and isotropic temperature factors of $Cd_8[AlO_2]_{12}S_2$ ($R_{wp} = 13.62$, $R_{ex} = 8.79$) derived from the powder X-ray data.

Atom	x	y	z	B_{iso}
Al	0.25	0.5	0.0	0.12(8)
O	0.1397(5)	0.1397(5)	0.4125(7)	0.24(16)
Cd	0.1660(1)	0.1660(1)	0.1660(1)	0.42(3)
S	0.0	0.0	0.0	0.55(16)

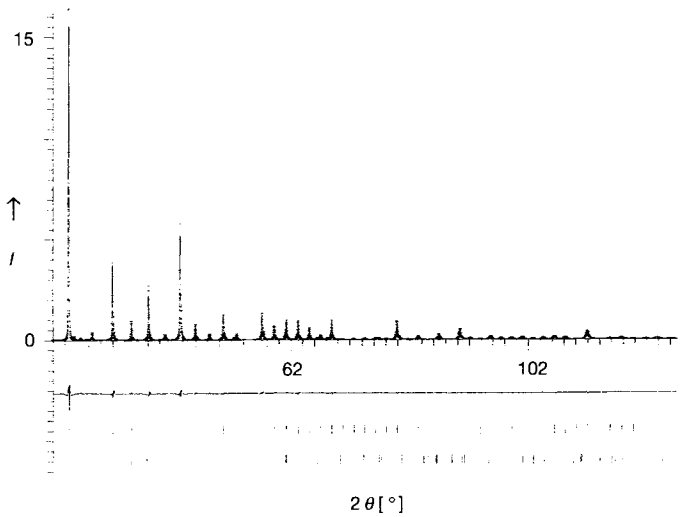

Fig. 1. Profile fit to the powder X-ray data from $Cd_8[AlO_2]_{12}S_2$. Horizontal bars are observed data and the upper full line the fit to the data. Lower full line is the difference; the upper tick marks show reflection positions for the sodalite and lower tick marks for Al_2O_3. I in units of 1 000 counts.

Bond lengths and angles calculated from the final parameters are presented in Table 2: the aluminate sodalite structure has been discussed in detail by Depmeier.[9] The central tetrahedral Cd_4S group has Cd–S bond lengths of 2.535(2) Å, somewhat larger than bulk CdS, which adopts the wurtzite structure. The next nearest neighbor cadmium to sulfide distances which represent the interaction of Cd_4S groups between cages is 5.101(4) Å. Figure 2 illustrates the relative orientations of the Cd_4S clusters to one another; the sodalite cages have been omitted for clarity.

Table 2. Bond lengths and angles of $Cd_8[AlO_2]_{12}S_2$ derived from the powder X-ray data.

Bond lengths [Å]		Bond	Angles [°]
Al-O	1.749(9)	Al-O-Al	126.1(12)
Cd-S	2.535(2)	O-Al-O (4 ×)	112.4(8)
Cd-S [a]	5.101(4)	O-Al-O (2 ×)	108.0(8)
Cd-O (3 ×)	2.198(10)		
Cd-O (3 ×)	3.297(10)		

[a] Next nearest neighbor.

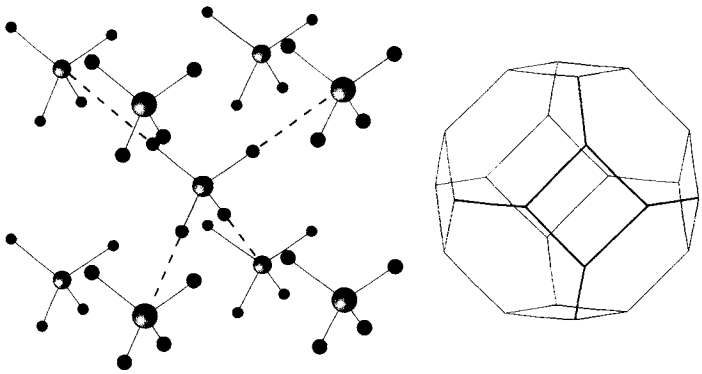

Fig. 2. Left: Spatial arrangement of the Cd_4S tetrahedra in $Cd_8[AlO_2]_{12}S_2$; interactions between the tetrahedra are shown by dotted lines. Right: The Al framework of the sodalite is shown to scale in the same orientation as the Cd_4S units.

A diffuse-reflectance UV/VIS spectrum obtained from the sodalite is shown in Figure 3. The sharp absorption edge at 505 nm is blue shifted by approximately 100 nm from the bulk material for which an absorption edge trail is observed. The sodalite does in fact behave much more like colloidal CdS with 1 μm particles which show a similar shift but preserve a gentle absorption edge. These colloid particles are some 2000 times larger than the individual Cd_4S units in the sodalite but the latter interact between cages over the so-

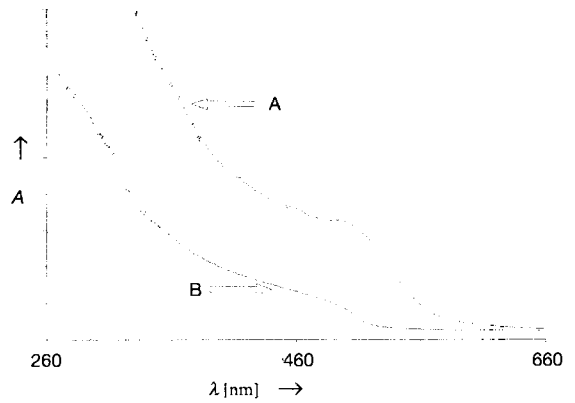

Fig. 3. UV/VIS diffuse-reflectance spectrum of bulk (macrocrystalline) CdS(A) and $Cd_8[AlO_2]_{12}S_2$ (B) in the wavelength range 260–660 nm. A = absorbance.

dalite particle size through the next nearest neighbor Cd–S interactions. The UV/VIS spectrum is not consistent with a small amount of surface CdS, since the intensity of the absorption observed for the sodalite is of a similar magnitude to that of pure bulk CdS. In addition any CdS particles would be lost from the surface at the high temperatures used in the synthesis of CdS–sodalite.

Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Book Reviews

The Organic Chemistry of Polycoordinated Iodine. By *A. Varvoglis*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. XII, 414 pp., hardcover DM 196.00.—ISBN 3-527-89538-8/1-56081-538-8

Iodine is the most polarizable, largest, but least electronegative, of the common halogens. As a consequence it can readily polycoordinate by forming bonds with 2–5 ligands and acquire an oxidation state of 3, 5, or 7. The first polycoordinated organic species, the stable crystalline $PhICl_2$, was reported by Willgerodt in 1886. Nearly one hundred years later polycoordinated organoiodine chemistry is undergoing a renaissance. This monograph is a welcome contribution by one of the major contributors and experts in the field. It is divided into eight chapters with extensive, up-to-date references to the original literature.

The first chapter deals with general aspects and discusses nomenclature, structural types, bonding, structure, spectra, preparation, stability, and reactivity patterns. The majority of organic polycoordinated iodine compounds are λ^3-iodanes and iodonium salts of various types: the most important, common and widely used being PhIO, $PhICl_2$, $PhI(OAc)_2$, $PhI(OOCCF_3)_2$, and PhI(OH)(OTs), along with diaryliodonium salts $Ar_2I^{\oplus}X^{\ominus}$.

The second chapter covers dichloro- and difluoroiodanes. Although such inorganic species as IF_3, IF_5, IF_7, and ICl_3 are stable and well known, this chapter focuses on organic iodine(III) compounds with at least one carbon ligand, i.e. RIX_2. $ArICl_2$ and $ArIF_2$, for example, are useful in chlorinations and fluorinations, respectively.

Chapter 3 discusses the properties and extensive chemistry of [bis(acyloxy)iodo]arenes, $ArI(O_2CR)_2$, and related compounds. The great majority of reactions of these compounds involve oxidations, many of which are analogous to the reactions of $Pb(OAc)_4$ without the concomitant toxic and environmental problems of lead.

Chapter 4, "Iodosyl Compounds and their Derivatives", deals with the chemistry and properties of derivatives of the nonisolable $ArI(OH)_2$, such as $ArI(OR)_2$, $ArI(ONO_2)_2$, $ArI(OSO_2R)_2$, ArI(OH)(OSO_2R), and the amorphous PhIO. Iodosylbenzene, PhIO, is an extensively employed, very useful, oxidant, both in the presence and absence of Lewis acids, including its extensive use in Cytochrome P-450 model studies. More recent examples include the widely used "Koser's reagent" $PhI(OH)(OSO_2C_6H_4CH_3)$ and "Zefirov's reagent" $PhI^{\oplus}$-O-$I^{\oplus}Ph \cdot 2X^{\ominus}$ (X = BF_4 or CF_3SO_3).

The longest and most extensive chapter (Ch. 5) treats iodonium salts. These include the classical diaryliodonium salts, $Ar_2I^{\oplus} \cdot X^{\ominus}$, as well as more recent members of the family such as alkynyl aryliodonium salts $RC{\equiv}CI^{\oplus}Ph \cdot X^{\ominus}$. These latter species are particularly useful as synthetic equivalents of "$RC{\equiv}C^{\oplus}$", namely electrophilic acetylenes, allowing for Umpolung of the more conventional and traditional acetylide, $RC{\equiv}C^{\ominus}$, chemistry. Alkynyl(phenyl)iodonium salts were successfully employed as progenitors to the hitherto unknown, novel alkynyl esters $RC{\equiv}COC(O)Ar$, $RC{=}COP(O)(OR')_2$, and $RC{\equiv}COSO_2Ar$. They also serve as alkynylating agents in reactions with a wide variety of nucleophiles including organometallic nucleophiles. Similarly, the perfluoroalkyl aryliodonium salts, $R_FI^{\oplus}Ph \cdot X^{\ominus}$, serve as a ready means of perfluoroalkylation and hence simple introduction of the R_F group into a variety of organic compounds.

The last three chapters cover: zwitterionic iodonium compounds (Ch. 6), including iodonium ylides as well as various dipoles; organoiodates (Ch. 7), i.e. anionic species of the type $IL_n^{\ominus}$ (where n may be 2, 4, 6, or 8) such as I_3, ICl_2 etc., and the compounds of pentavalent iodine (Ch. 8) dealing

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1993 0570-0833/93/1111-1665 $ 10.00+.25/0

with species such as $PhIO_2$, $PhIOF_2$, $PhIF_4$, $PhI(O_2CR)_4$, and related molecules.

What makes polycoordinated iodine chemistry particularly useful and attractive is that it closely parallels the chemistry of such familiar species as Pb^{IV}, Te^{IV}, Se^{II}, Se^{IV}, Hg^{II}, and Hg^{IV} without the problems associated with the handling and safety of these mostly toxic heavy metal analogues. Moreover, the chemistry of organic polycoordinated iodine compounds, along with other main group polycoordinated species, partly resembles that of transition metal complexes, making possible a wide variety of useful transformations like those known for transition metal compounds.

This is a superbly written monograph. It maintains a good balance between structural and mechanistic information and synthetic uses and applications of organic polycoordinated iodine compounds. The text is easy to read, well illustrated and well referenced. The book can be strongly recommended to connoisseurs of iodine chemistry as well as novices. It should also serve as a nice supplementary text in graduate courses in both mechanistic and synthetic organic chemistry, although its cost is unfortunately likely to discourage wide use in this area.

University of Utah
Salt Lake City (USA)

Homogeneous Catalysis. The Applications and Chemistry of Catalysis by Soluble Transition Metal Complexes. By *G. W. Parshall* and *S. D. Ittel*. Wiley, New York, 1992. XII, 342 pp., hardcover £ 39.95.—ISBN 0-471-53829-9

This book, now in its second edition, describes the current state of knowledge on homogeneous catalysis by transition metals. The subject matter is arranged according to reaction types, but the emphasis is mainly on the wide variety of applications of this chemistry rather than on mechanisms. The book not only gives a wealth of information on useful and elegant methods for the laboratory-scale synthesis of organic compounds that one could not easily prepare in other ways, but also includes an extensive compilation of all types of industrial applications of homogeneous catalysis.

The authors have the advantage of many years of experience in senior positions in Du Pont's central research laboratories. The benefits of this are evident in their coverage of the relevant patent literature, and in the almost encyclopedic treatment of commercial applications and assessment of their relative importance. These range from large-scale applications such as the SHOP process developed by Shell (ethene oligomerization, metathesis) and the Du Pont adiponitrile process (hydrocyanation of butadiene, isomerization), through processes for manufacturing intermediates such as 1,4-butandiol (hydroformylation of allyl alcohol by the Kuraray method), to those used for making specialty chemicals and pharmaceuticals, e.g. the synthesis of Vitamin A (by hydroformylation and isomerization, BASF), of L-menthol (enantioselective isomerization, Takasago Perfumery), or Monsanto's new method for *S*-Naproxen® (enantioselective hydrogenation).

The authors describe how homogeneous catalytic methods, following their spectacular successes for large-scale processes in the 1970s and 1980s, are now increasingly finding new applications in fine chemicals manufacture. They illustrate this trend by describing industrial processes for synthesizing pharmaceuticals, plant protection chemicals, fragrances, and chemicals for the electronics industry. Moreover, the armory of methods is being continually refined. Thus, enantioselective syntheses, especially those involving hydrogenations and isomerizations, have now developed to the status of routine methods, as also have homogeneously catalyzed reactions carried out in two liquid phases so that the catalyst can be removed by phase separation.

The book's most important contribution is in providing a broad overview of developments in this field. The extensive bibliographies attached to each chapter, with review articles and more specific papers listed separately, are a pleasing and very useful feature. They are not only comprehensive but also commendably up-to-date, covering publications up to the end of 1991. Also the keyword index provides an easy way into the contents, enabling one to quickly find a required reaction on the basis of educt, product, catalyzing metal, and reaction type.

The individual chapters are packed with information, are readable, and contain a wealth of useful hints. The lucid and well arranged text and clear formula diagrams will be much appreciated by the reader who wants a quick overview of one of the areas covered. On the other hand, the reader wishing to go into greater detail on a certain topic will find the background information and literature references a valuable resource.

This is a soundly written book which can be recommended unreservedly, not only for synthetic organic and organometallic chemists in universities and industry but also for advanced students who wish to learn about this increasingly important field.

Cycloaddition Reactions in Carbohydrate Chemistry. (ACS Symposium Series, Vol. 494. Series editor: *M. J. Comstock*.) Edited by *R. M. Giuliano*. American Chemical Society, Washington DC, 1992. X, 181 pp., hardcover $ 49.95.—ISBN 0-8412-2429-3

How many chemists immediately associate the word carbohydrates with cycloadditions? Probably very few, since from a synthetic standpoint carbohydrates, with their important structural and information-carrying roles in biological systems, are much more likely to be associated with ideas such as glycosidation, the chiral pool, and the use of protecting groups. Thus one cannot deny that this book has a certain degree of interdisciplinary character. In fact the use of cycloaddition reactions introduces some interesting novel aspects into carbohydrate chemistry. The converse is also true, of course: the field of cycloaddition reactions is already quite extensive, and the combination with carbohydrates increases the range of possibilities still further. Moreover, such reactions can have a very wide variety of uses: carbohydrates can serve either as chiral auxiliaries or as building blocks that are incorporated into the product molecule.

All these aspects are covered in the book reviewed here. The eleven articles are based on a symposium held by the American Chemical Society. In the introductory article R. M. Giuliano presents an overview of the topic, with separate sections on Diels–Alder reactions, hetero-Diels–Alder reactions, dipolar cycloadditions, and photochemical reactions, each including examples in which one of the partners in the cycloaddition is derived from a carbohydrate. The following articles treat individual topics in detail, in the form

of progress reports. R. W. Franck deals with the use of dienophiles derived from carbohydrates, describing cycloadditions involving both electron-rich and electron-deficient dienophiles. The preparation of α,β-unsaturated aldehydes and dienes from pyranoses and their use in cycloaddition reactions is described by J. C. Lopez et al. Such α,β-unsaturated aldehydes can act not only as dienophiles but also as diene components in hetero-Diels–Alder reactions. The article by M. Chmielewski describes the use of glycals in [2 + 2]-cycloadditions with isocyanates. The cycloadducts obtained in this way can serve as educts for the synthesis of β-lactam derivatives. D. Horton discusses the control of stereospecificity in the cycloaddition of cyclopentadiene to α,β-unsaturated esters prepared from aldopentoses. Not surprisingly, it is found that the facial selectivity in the cycloaddition reaction is controlled mainly by the allylic substituent. Y. Leblanc describes the hetero-Diels–Alder reaction of glycals with azodicarboxylates. This proceeds regiospecifically, yielding heterocyclic adducts that can be used for direct glycosidation with glycosyl acceptors. The effectiveness of this method has been demonstrated by synthesizing a number of complex 2-aminosaccharides. In the following article P. DeShong describes the use of glycosyl-manganese pentacarbonyl complexes for synthesizing C-glycosides. The glycosylmanganese pentacarbonyl complexes for this purpose can easily be prepared from a glycosyl bromide and a salt of the manganese pentacarbonyl anion. By means of insertion reactions these complexes can then be converted to C-glycosides in a wide variety of ways. However, this very interesting contribution has little relevance to the subject of cycloadditions. That criticism certainly does not apply to the next article, in which P. Herzegh et al. start by describing how a thiocarbonyl derivative prepared from a carbohydrate can undergo a hetero-Diels–Alder reaction with a 1,3-diene to yield a chiral thiopyran derivative. They then go on to describe intramolecular Diels–Alder reactions in which a diene and a dienophile are linked through a chain derived from a sugar, yielding various highly functionalized hexahydroindenes and octahydronaphthalenes. The next article, by H. Kunz, is concerned with a different application of carbohydrates, namely as chiral auxiliaries. For example, acrylates derived from carbohydrates can be reacted with 1,3-dienes in the presence of a Lewis acid catalyst to give the corresponding cycloadducts with a high degree of selectivity. Similarly, imines prepared from glycosyl amines can be reacted with electron-rich dienes, again with high selectivity. In all these cases it appears that the choice of the pivaloyl protecting group at the positions of the OH groups of the sugar is crucial. Next A. Lubineau discusses the effect of using water as the solvent for the Diels–Alder reaction between water-soluble dienes and electron-deficient dienophiles. Typical dienes that can be used here are 1,3-butadienylethers of carbohydrates without protecting groups. For these cycloaddition reactions the *endo*-selectivity is practically 100%, and the reaction rates are higher than in the usual organic solvents. In the last article L. Fisera describes 1,3-dipolar cycloadditions in which various nitrones derived from sugar aldehydes are reacted with *N*-aryl maleic imides. I feel that 1,3-dipolar cycloadditions could have been given more space in this book. One important topic, the de-novo synthesis of carbohydrates by means of cycloadditions, is even omitted entirely. However, this may have been a deliberate decision, as there is already a volume on this topic in the ACS Symposium Series.

In summary, this book offers a representative collection of articles on recent work in the area of cycloaddition reactions of carbohydrates. In each article the stereochemical aspects of the results are discussed in detail using appropriate transition state models. The book includes subject and author indexes which make it easy to locate a specific topic. However, one can also enjoy simply leafing through the book and admiring the illustrations. The way in which the book has come about inevitably means that there is some overlapping between individual articles. Also some readers may be somewhat displeased by the presentation, as there are differences in the typefaces used by the individual authors, and the line spacing is not uniform throughout. Despite this, the book can be recommended for everyone whose work is concerned with carbohydrates, cycloadditions, or stereoselective syntheses in general. It should provide many stimulating new ideas.

Catalytic Chemistry. By *B. Gates*. Wiley, Chichester, 1992. XXI, 458 pp., paperback £ 14.95.—ISBN 0-471-55914-8

The literature on chemical catalysis has up to now suffered from being divided, according to the catalytic principles used, into homogeneous and heterogeneous catalysis. Since it is, to a greater extent than any other area of chemistry, an interdisciplinary field between pure science and technology, the recent publication by Wiley of a textbook on "Catalytic Chemistry" for students and teachers is welcome news. This conveniently-sized book attempts to cover all the important aspects of catalysis, a difficult but worthwhile task, even if it cannot be fully achieved.

The division into chapters is essentially along the lines of types of catalysts and processes, which is sensible from a teaching standpoint. Thus the main chapters cover: catalysis in solutions (Ch. 2, 128 pp.), catalysis by enzymes (Ch. 3, 47 pp.), catalysis by polymers (Ch. 4, 71 pp.), catalysis in cavities of molecular dimensions (Ch. 5, 55 pp.), and catalysis at surfaces (Ch. 6, 106 pp.). The short first chapter (14 pp.) introduces some important concepts (amplified where necessary in a glossary at the end of the book), emphasizes the importance of the mass balance laws and kinetic relationships (which other textbooks usually neglect), discusses catalytic cycles taking as an example the production of 1,4-hexadiene by the ethylene–butadiene coupling reaction, and ends with a "Problems Section" aimed at involving the reader in some learning activity.

The merits of this book are that it gives a quick overview of the most important types of (industrially relevant) catalytic processes, discusses some problems that remain to be solved by further research, and frequently compares kinetic data with mechanistic models and hypotheses. All the important modern catalytic processes are treated and, wherever possible, discussed in the context of kinetics laws. The reader interested in the practical details of industrial catalytic processes should find the clearly set out flow schemes especially useful. The author has incorporated results from recently published work, and always makes a point of relating the discussions to practical situations; this is shown, for example, by the description in mechanistic terms of the osmium tetraoxide catalyzed *cis*-hydroxylation of olefins (p. 141 f.). Here his wide experience of catalytic research, particularly in the field of surface organometallic chemistry, shows up to advantage.

The boldness to attempt a comprehensive treatment, always a good feature in a textbook, inevitably involves the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1993 0570-0833/93/1111-1667 $ 10.00+.25/0

risk of shortcomings. Three examples of these are the following: 1) Hydroformylation (p. 91 ff.). Although the Halpern mechanism is shown by formulas, readers (who are likely to include advanced students of chemistry and process technology) are not told about the problem of regioselectivity. Consequently there is also no reference to the possibility of achieving stereoselective hydroformylation of prochiral olefins. It is pleasing that the highly topical two-phase hydroformylation process and the Aldox process are included, but there should also have been a brief discussion of the advantages and disadvantages of some more commonly used catalysts, such as the Shell and UCC systems. 2) Olefin metathesis. Leaving aside the fact that Eleuterio (1960) was not the discoverer of this reaction (it originated much earlier as a spin-off from work on olefin polymerization), no information is given about catalysts suitable for industrial use. Also the treatment of the reaction mechanism is dubious from the standpoint of organometallic chemistry. Here the description of important industrial processes (e.g., SHOP, Norsorex, Vestenamer, cf. *Kontakte* **1991** (3), 29 ff.) is quite unsatisfactory, and consequently this chapter is not convincing. 3) Propene oxidation (p. 403 ff.). The essentials of bimetallic catalysis, of which the Sohio process for the ammoxidation of propene is an important industrial example, are well described. However, although the discussion of the mechanism is up-to-date so far as the (meager) literature is concerned, it fails to convey a picture of the molecular reaction steps that might be involved. Here there was a good opportunity to relate heterogeneously catalyzed processes to organometallic model systems!

This book may well provide the advanced student of chemistry with an impression of the wide-ranging nature of chemical catalysis, but this is achieved at the cost of superficiality in some important areas. I therefore feel that work using this book needs to be accompanied, or still better preceded, by a good lecture course providing a thorough grounding in the fundamentals. Under these circumstances it would prove its worth, since a lecture course cannot include the same amount of detail on reaction kinetics and process technology. Thus the book can be recommended to everyone who has to spend a period of time concentrating on the study of catalytic chemistry and, as a chemist or chemical engineer in industry, needs to read up on the subject to extend or refresh his or her knowledge. The book is well worth its price.

Accurate Molecular Structures. Their Determination and Importance. (Series: IUCr Monographs on Crystallography, Vol. 1.) Edited by *A. Domenicano* and *I. Hargittai*. International Union of Crystallography, Oxford University Press, Oxford, 1992. XXI, 590 pp., hardcover £ 60.00.—ISBN 0-19-855556-3

With this book the International Union of Crystallography (IUCr) begins a series in which various special areas of crystallography will be treated in detail. However, rather than limiting the series strictly to crystallography, the editors (A. Domenicano and I. Hargittai) are sensibly extending the scope so as to acquaint readers with other methods of structure determination and their applications.

The determination and interpretation of the structures of molecules is an important area of chemical research, which is also interdisciplinary. To carry it out effectively it is essential to have a knowledge of the accuracy and limitations of the methods with regard to systematic and random experimental errors. This book summarizes the capabilities of the various methods used for precise molecular structure determination, as well as their use in combination and the significance of accurate structural data in modern chemical research (in the preface). The 22 chapters have been written by recognized experts. A bibliography is given at the end of each chapter, and the book concludes with author, subject, and formula indexes (although the last is very incomplete). The editors have set out to cover the whole of the field, but it is not possible for a single book to fulfill this ambitious aim. Nevertheless, it is a mine of information that will be of considerable interest to every structural chemist who wants to look beyond the immediate confines of his or her particular method.

The first chapter gives an excellent general introduction to the subject. After a short account of the historical background, experimental and theoretical methods used for structure determination are briefly sketched, and the importance of obtaining precise structural data is illustrated by a few well chosen examples.

Chapter 2 is concerned with the derivation and significance of potential functions for di- and polyatomic molecules; here the reader is assumed to have extensive mathematical knowledge in the area of group theory. Included here is a survey of the different ways of defining interatomic distances which is especially important. The chapter ends with a table listing experimentally measured data on equilibrium structures and anharmonic potential constants for polyatomic molecules; unfortunately, though, the literature references given here extend only to 1988, which does not entirely fulfill the book's declared aim of presenting "current chemical research".

Chapter 3 deals with microwave spectroscopy. The fundamental principles are derived and discussed, and their application is illustrated by describing a structure determination carried out using this method.

Chapter 4 is devoted to structure determination by vibrational-rotational spectroscopy. The author confines his discussion mainly to IR spectroscopy, and describes the mathematical formalism and procedures for di- and polyatomic molecules.

The treatment of gas phase electron diffraction (Chapter 5) begins with the development of the method, followed by the theoretical fundamentals and the experimental details. An example of a structural analysis is then described, together with a discussion of the uncertainties in the information yielded by the method. Chapter 6 gives an easily understandable introduction to the basic principles of single crystal structure analysis by X-ray diffraction. Subject matter which normally fills thick textbooks is here compressed into about 30 pages. One is prompted to wonder for whom this chapter has been written. The reader already familiar with these matters can either miss it out or use it as a source of ideas on how best to teach the subject. For the novice, however, it is so elementary that it requires too great a jump to Chapters 7–11 that follow. Even the ten-page glossary at the end of the chapter, a feature that is unfortunately missing from most textbooks, is not enough to put this right. For any structure determination by X-ray diffraction that is more than just a routine measurement, to obtain precise data one must not only have a suitable crystal, but must also make measurements at as many angles as possible, repeated as

risk of shortcomings. Three examples of these are the following: 1) Hydroformylation (p. 91 ff.). Although the Halpern mechanism is shown by formulas, readers (who are likely to include advanced students of chemistry and process technology) are not told about the problem of regioselectivity. Consequently there is also no reference to the possibility of achieving stereoselective hydroformylation of prochiral olefins. It is pleasing that the highly topical two-phase hydroformylation process and the Aldox process are included, but there should also have been a brief discussion of the advantages and disadvantages of some more commonly used catalysts, such as the Shell and UCC systems. 2) Olefin metathesis. Accurate Molecular Structures. Their Determination and Importance. (Series: IUCr Monographs on Crystallography, Vol. 1.) Edited by *A. Domenicano* and *I. Hargittai*. International Union of Crystallography, Oxford University Press, Oxford, 1992. XXI, 590 pp., hardcover £ 60.00.—ISBN 0-19-855556-3

With this book the International Union of Crystallography (IUCr) begins a series in which various special areas of crystallography will be treated in detail. However, rather than limiting the series strictly to crystallography, the editors (A. Domenicano and I. Hargittai) are sensibly extending the scope so as to acquaint readers with other methods of structure determination and their applications.

The determination and interpretation of the structures of molecules is an important area of chemical research, which is also interdisciplinary. To carry it out effectively it is essential to have a knowledge of the accuracy and limitations of the methods with regard to systematic and random experimental errors. This book summarizes the capabilities of the various methods used for precise molecular structure determination, as well as their use in combination and the significance of accurate structural data in modern chemical research (in the preface). The 22 chapters have been written by recognized experts. A bibliography is given at the end of each chapter, and the book concludes with author, subject, and formula indexes (although the last is very incomplete). The editors have set out to cover the whole of the field, but it is not possible for a single book to fulfill this ambitious aim. Nevertheless, it is a mine of information that will be of considerable interest to every structural chemist who wants to look beyond the immediate confines of his or her particular method.

The first chapter gives an excellent general introduction to the subject. After a short account of the historical background, experimental and theoretical methods used for structure determination are briefly sketched, and the importance of obtaining precise structural data is illustrated by a few well chosen examples.

Chapter 2 is concerned with the derivation and significance of potential functions for di- and polyatomic molecules; here the reader is assumed to have extensive mathematical knowledge in the area of group theory. Included here is a survey of the different ways of defining interatomic distances which is especially important. The chapter ends with a table listing experimentally measured data on equilibrium structures and anharmonic potential constants for polyatomic molecules; unfortunately, though, the literature references given here extend only to 1988, which does not entirely fulfill the book's declared aim of presenting "current chemical research".

Chapter 3 deals with microwave spectroscopy. The fundamental principles are derived and discussed, and their application is illustrated by describing a structure determination carried out using this method.

Chapter 4 is devoted to structure determination by vibrational-rotational spectroscopy. The author confines his discussion mainly to IR spectroscopy, and describes the mathematical formalism and procedures for di- and polyatomic molecules.

The treatment of gas phase electron diffraction (Chapter 5) begins with the development of the method, followed by the theoretical fundamentals and the experimental details. An example of a structural analysis is then described, together with a discussion of the uncertainties in the information yielded by the method. Chapter 6 gives an easily understandable introduction to the basic principles of single crystal structure analysis by X-ray diffraction. Subject matter which normally fills thick textbooks is here compressed into about 30 pages. One is prompted to wonder for whom this chapter has been written. The reader already familiar with these matters can either miss it out or use it as a source of ideas on how best to teach the subject. For the novice, however, it is so elementary that it requires too great a jump to Chapters 7–11 that follow. Even the ten-page glossary at the end of the chapter, a feature that is unfortunately missing from most textbooks, is not enough to put this right. For any structure determination by X-ray diffraction that is more than just a routine measurement, to obtain precise data one must not only have a suitable crystal, but must also make measurements at as many angles as possible, repeated as

many times as possible, as slowly as possible, and at the lowest possible temperature. Chapter 7 explains all this in an impressive way, together with the necessary systematic procedures and corrections that can be applied.

It cannot be emphasized too often that the refinement of structural parameters from X-ray diffraction data can yield as an extra bonus valuable information about the dynamics of molecules and of the crystal lattice. Too few research groups make use of this capability, even though suitable programs are available and the information is obtainable at no extra cost, in the form of the anisotropic temperature parameters (or, better still, displacement parameters). Although Chapters 8 and 9 describe the background and methematical formalism of procedures such as the "rigid body test" and the determination of rotational barriers, they are not sufficient to save the user the bother of consulting the original literature. More detail and more examples would have been useful here.

The next chapter explains clearly that experimentally determined distribution functions for deformation density and residual electron density are greatly dependent on the method used and on how one defines the pro-molecule. However, the objective seems to be always that of bringing the experimental deformation density distribution into as close agreement as possible with that calculated from theory, and this must always come up against difficulties in view of the wide variety of methods. Unfortunately not enough attention is given here to the importance of the integrity or self-sufficiency of the chosen method, despite the fact that the author of this chapter, who has since died, was a leading pioneer in this field. Neutron diffraction excels where X-ray diffraction is weakest, namely in determining the positions and anisotropic displacement factors of hydrogen atoms. Consequently Chapter 11 is concerned not only with comparing the two methods but also especially with hydrogen bonding. The subject of hydrogen bonds is in turn closely related to the effects of crystal packing, and this leads one into making comparisons with quantum mechanical calculations. Many examples are presented to show that, despite the high cost of neutron diffraction experiments, this method will continue to have a secure place among methods of structure determination. Chapter 12 deals with NMR spectroscopy in liquid crystalline solvents. The basic principles and experimental details are explained, an example of a structure determination by this method is described, and factors affecting the accuracy of the measurements are discussed.

Quantum mechanical methods for calculating static and dynamic structures are described in Chapter 13 in a clearly understandable way. Chapter 14 is concerned with the methods of molecular mechanics. However, the discussion is mainly confined to the basic principles, which are generally well known, whereas relatively little space is given to applications and problem areas. Chapter 15 is mainly concerned with the Cambridge Structural Database (CSD) and with its design features, the search strategies used, and examples of applications. An updated account is given of examples that are already familiar from the author's earlier publications.

Chapters 16 and 17 use selected examples to illustrate how results from structure determinations can be applied to chemical problems. As well as describing stereoelectronic effects, examples are given to show the importance of structural correlations for determining reaction pathways and energy hypersurfaces.

Chapter 18 reviews numerous studies on the effects of substituents in distorting the benzene ring, comparing and interpreting experimental and theoretical methods of structure determination. The following chapter discusses the difficulties in estimating the packing effect, which describes the extent to which the molecular conformation in a single crystal departs from that corresponding to a global energy minimum. Here considerations based on polymorphic structures are useful, and so especially are theoretical methods. Up to this point one might have the impression that insufficient attention is devoted to structure determinations for inorganic molecules. This is remedied in Chapters 20 to 22, which discuss the particular role of structure determination in inorganic chemistry and the special problems that arise, especially with regard to single crystal structural studies. The examples described illustrate that when one attempts to determine the positions of light atoms adjacent to heavy atoms or to determine space groups or occupancy numbers, one quickly comes up against the limitations of the method.

The level of previous knowledge that is assumed varies greatly from chapter to chapter, due to the difficulty of coordinating the work of such a team of authors. However, it is pleasing to find that there are cross-references between the chapters.

This book can be emphatically recommended for the structural chemist who cannot afford to simply restrict himself to his own method, but must instead seek opportunities for interdisciplinary collaboration. However, it is less suitable for students owing to the wide differences between chapters in the level of previous knowledge needed. Further volumes in this series should, if possible, be more correctly matched to the needs of the intended readership.

The Unique Antithrombin III Binding Domain of Heparin: A Lead to New Synthetic Antithrombotics

By Constant A. A. van Boeckel* and Maurice Petitou*

Heparin, a sulfated glycosaminoglycan, is well known for its anticoagulant effect mediated by the serine protease inhibitor antithrombin III (AT III). Heparin has been used clinically for more than half a century for the prophylaxis and treatment of venous thrombosis and thromboembolism. Up until the 1980s it was assumed that the biological activity of heparin was mainly caused by its polyanionic character. However, this paradigm was contradicted when it was discovered that part of the heparin polysaccharides contains a well-defined pentasaccharide domain that specifically binds and activates AT III. The specificity of the interaction between the characteristic pentasaccharide and AT III has become more obvious after the synthesis and biological testing of various heparin analogues. This article reviews the synthesis of the heparin pentasaccharide, some closely related counterparts, and some highly modified analogues. With the aid of molecular modeling and through "tailored" molecular modifications of the pentasaccharide, much knowledge has been gained concerning structure–activity relationships. On this basis not only have more potent and simplified derivatives been developed, but also the recognition between heparin and AT III can now be understood in greater detail at the molecular level.

1. Introduction[**]

The chemically closely related polysaccharides heparin and heparan sulfate are present in many living organisms.[1–3] Whereas heparan sulfate is widely distributed in different cell types and tissues, heparin is confined to one cell type only, the mastocytes, where it is complexed to histamine. Heparin has attracted considerable attention because of its anticoagulant properties, which are at the origin of its clinical use in preventing venous thrombosis (the clotting of blood in veins).[3]

From a chemical standpoint, heparin is a glycosaminoglycan. This family of complex anionic polysaccharides includes glucosaminoglycans (heparin, heparan sulfate), galactosaminoglycans (chondroitin 4-sulfate, chondroitin 6-sulfate, dermatan sulfate), hyaluronic acid, and keratan sulfate. The structure of heparin[4] is shown schematically in Figure 1. It consists of a carbohydrate backbone made up of alternating 1,4-linked uronic acid (D-glucuronic or L-iduronic) and glucosamine residues. A standard heparin preparation consists of a mixture of linear polysaccharides composed of approximately 20 to 100 monosaccharides. Most of the monosaccharides bear one or several substituents at different positions, as shown in Figure 1.

Heparin inhibits blood coagulation[5] through activation of antithrombin III (AT III), a physiological inhibitor of coagulation. AT III belongs to the serin protease inhibitors superfamily (serpins). This glycoprotein constructed of 432

[**] All = allyl, Ac = acetyl, Bn = benzyl, Bz = benzoyl, Z = benzyloxycarbonyl, MCA = monochloroacetyl, Lev = levulinoyl, Tf = trifluoromethylsulfonyl, TBDMS = *tert*-butyldimethylsilyl.

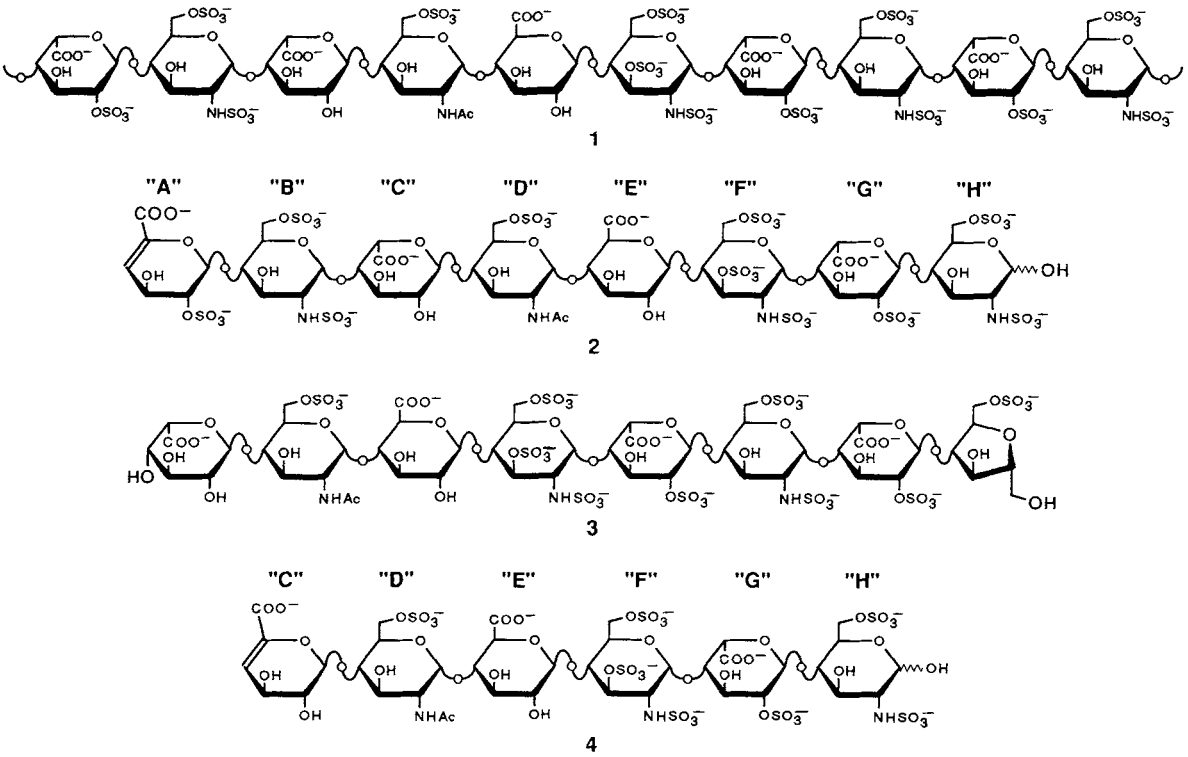

Fig. 1. Oligosaccharide **1** in the top row represents a hypothetical fragment of a heparin molecule. Heparin chains consist of alternating 1 → 4 linked uronic acid and glucosamine residues. The former may be β-D-glucuronic acid (e.g., unit E), α-L-iduronic acid (e.g., unit C), or α-L-iduronic acid-2-sulfate (e.g., unit G), while the latter may be *N*-acetyl-α-D-glucosamine-6-sulfate (e.g., unit D), α-D-glucosamine-N-sulfate-6-sulfate (e.g., unit H; see the footnote on p. 1673 for the term N-sulfate), or α-D-glucosamine-N-sulfate-3,6-disulfate) (e.g., unit F). Glucosamine units can also be present as counterparts not sulfated at position 6. The largest part of the structure of a heparin preparation is accounted for by the repeating unit consisting of the disaccharide sequence α-L-iduronic acid-2-sulfate(1 → 4)α-D-glucosamine-N-sulfate-6-sulfate (e.g. disaccharide moiety GH), which forms "regular regions" [4]. The rest of the structure contains in various proportions the other monosaccharide residues that form "irregular regions" which could be of major importance for the biological function of these complex molecules. Octasaccharides **2** and **3** result from controlled degradation of heparin by heparinase or nitrous acid, respectively [12]. Hexasaccharide **4** was obtained in the same way after prolonged enzymatic digestion [12]. The pentasaccharide sequence DEFGH (the variant in which unit D is N-sulfated), shared by all these biologically active oligosaccharides, was selected as the first target for total synthesis.

amino acids (in humans) forms tight complexes with several blood coagulation factors—we will focus here on blood coagulation factors Xa and IIa (also called thrombin)—which are thereby inactivated (see Figs. 2a, 2b). The rate of protease inactivation is increased by several orders of magnitude when ATIII is bound to a heparin molecule.[6]

Constant A. A. van Boeckel was born in 1956 in Brunei (formerly British Borneo) and studied chemistry at the University of Leyden. He received a doctorate in chemistry in 1979 and his Ph.D. degree in 1982 under J. van Boom. He then moved to the pharmaceutical industry (Organon Int. B. V., Oss). In 1988 he was appointed part-time Professor at the University of Leyden. He was awarded the Unilever Chemistry Prize (1978), the Professor Oosterhoff Prize (1981), the Akzo Chemistry Prize (1988), and the Golden Medal of the Royal Dutch Chemical Society (1988). Presently he is departmental head of the Medicinal Chemistry Department at Organon Int. His areas of interest include carbohydrate chemistry, nucleotide chemistry, protease inhibitors, and drug design.

Maurice Petitou was born in 1949 in France and studied chemistry in Clermont-Ferrand and Orléans, where he received a master's degree in 1971 and a doctorate in chemistry in 1974. He then worked for three years as a Fellow of the Ligue Nationale Française Contre le Cancer (LNFC) studying membrane glycoproteins of leukemic cells. In 1978 he joined the Institut Choay, the research branch of Laboratoires Choay, to work on the chemistry of heparin; he received his Ph.D. in 1984. He received the Groupe Français des Glucides Prize in 1985 and the Galien Prize for Pharmaceutical Research in 1986. He was appointed Research Associate Director of the Centre National de la Recherche Scientifique (CNRS) in 1988. Since 1989 he has been head of the Carbohydrate Chemistry Department at Sanofi Recherche, where he is in charge of research on the chemistry of glycosaminoglycans.

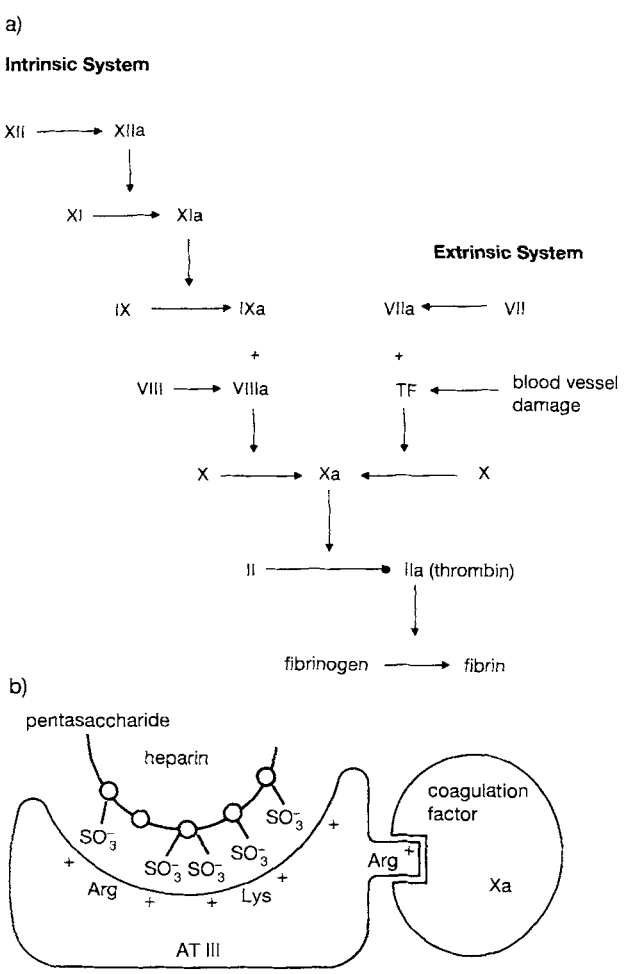

Fig. 2. a) Overview of the blood coagulation system. Blood coagulation is a complex process involving several enzymes (activated coagulation factors) present in plasma as their precursors (zymogens). Activation of these proenzymes occurs in a cascade and can be initiated by contact of blood with foreign surfaces and presumably also by subendothelial structures exposed during blood vessel damage (intrinsic pathway). These proenzymes can also be activated by thromboplastin and tissue factor (TF) excreted or released by injured cells (extrinsic pathway). The two pathways converge at the level of factor X activation. An imbalance in the system leads to a prohemorragic or to a prothrombotic state. Natural inhibitors like AT III are supposed to oppose prothrombotic states. When it is complexed to heparin, AT III can inhibit several activated blood coagulation factors, but when it is bound to a pentasaccharide it selectively inactivates factor Xa. b) A characteristic pentasaccharide domain of heparin selectively binds to AT III. During the interaction, AT III changes its conformation and a remote loop fragment of AT III becomes exposed to facilitate the inactivation of blood coagulation factor Xa.

Owing to its anticoagulant properties, heparin has been used in clinics since 1937. However, its true mechanism of action is not necessarily connected to its whole anticoagulant activity, but, possibly, to its ability to catalyze the inactivation of a particular serin protease in blood coagulation. This was recognized when clinicians began to use low doses of heparin that hardly affected the coagulation parameters (e.g. blood coagulation time) but nevertheless sufficed to prevent thrombosis. Pharmacologists then proposed that inhibition of blood coagulation factor Xa could be more relevant than inhibition of thrombin (factor IIa) for achieving optimal clinical efficacy (i.e. the best benefit/risk ratio). Since then, the scientific community has devoted efforts to obtaining heparin preparations with increased factor Xa activity and/or decreased anti-factor IIa activity, in other words, with an increased anti-Xa/anti-IIa ratio.[7]

2. Background

2.1. Fractionation and Degradation of Heparin

Following the above hypothesis that heparin preparations with increased anti-factor Xa/anti-factor IIa ratios could be better antithrombotic drugs than standard heparin itself, programs were launched aiming at the preparation of such drugs. Two crucial observations were made in 1976. The first was that only some of the heparin molecules bind to AT III when heparin is fractionated by affinity chromatography on immobilized AT III.[8-10] The second finding was that heparin molecules having affinity for AT III achieved the same degree of factor Xa inhibition, whatever their size, while thrombin inhibition was size dependent.[8] (A rational explanation based on chemical structure is discussed in Section 7.) In summary, any heparin preparation contains at least three kinds of molecules: those that can promote AT III inhibition of factor Xa and of thrombin (type 1), those that can only promote inhibition of factor Xa (type 2), and those that are unable to promote any significant inhibition (type 3). Standard heparin preparations are made up of about one-third of type 1 molecules and two-thirds of type 3. The simplest way to favor inhibition of factor Xa over that of factor IIa is to decrease the molecular weight of the preparation. This has been achieved both by chemical as well as enzymatic cleavage of heparin chains and has led[7, 11] to the widely used "low molecular weight heparin" class of drugs.[12]

2.2. Discovery of a Characteristic Antithrombin-Binding Pentasaccharide Domain

Since the ability of heparin fragments to reinforce AT III mediated inhibition of factor Xa appeared independent of their size, it was logical to look for the smallest fragments able to catalyze inhibition of factor Xa. The experimental approach consisted in controlled cleavage of heparin by chemical (nitrous acid) or enzymatic (heparinase from *flavobacterium heparinum*) means, separating the fractions having AT III affinity by affinity chromatography, and finally gel filtration of these fractions. By using this approach biologically active octasaccharides were identified, and their structures determined (Fig. 1).[*] Comparison of **2** and **3** suggests that the common hexasaccharide CDEFGH **4** contains the active sequence. This was proved after isolation of the corresponding hexasaccharide after treatment of **2** by heparinase. In hexasaccharide **4** the molecular identity of unit C has been altered without loss of biological activity. This strongly suggested that the pentasaccharide sequence DEFGH is the active sequence. It is particularly noteworthy that the active structures contain the trisaccharide sequence DEF—*N*-acetyl-6-sulfated glucosamine (D) (note that an N-sulfated glucosamine[**] has also been found in this position), glucuronic acid (E), and N-sulfated, 3,6-disulfated glucosamine (F)—since all three monosaccharides are minor

[*] The same sequences were independently found to correspond to the AT III binding site of heparin.

[**] In this review the $NHSO_3^-$ group is referred to as N-sulfate and the OSO_3^- group as sulfate.

constituents of heparin. Most remarkable is the sulfate group at position 3 of the central glucosamine unit.[13, 14] The presence of these structural features together in a short active oligosaccharide sequence suggests that DEFGH is the most characteristic domain of heparin. This hypothesis is supported further by studies of the interaction of well-defined synthetic analogues of pentasaccharide DEFGH with AT III. It is worth mentioning that in vivo studies in animals provided evidence that heparan sulfate in endothelial cells contains similar pentasaccharide domains which probably contribute to the nonthrombogenic properties of the vessel wall[15] (Fig. 3).

Since no biochemical tool for further controlled degradation has been available to obtain the pentasaccharide DEFGH, chemical synthesis has been required. Moreover, organic synthesis is the only way to obtain well-defined counterparts and simplified analogues.

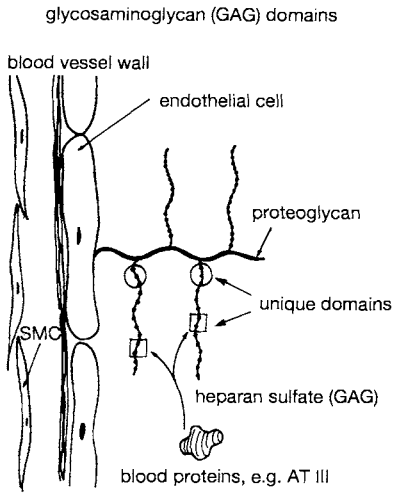

Fig. 3. There is much evidence that heparan sulfate proteoglycans are present on the luminal surface of endothelial cells of blood vessels. Heparan sulfate has been shown to endow the blood vessels with nonthrombogenic properties [15]. Furthermore this heparan sulfate contains unique domains that closely resemble the active pentasaccharide sequence of heparin. So it is assumed that a fraction of plasma ATIII is activated by heparan sulfate glycosaminoglycans located close to the surface of the blood vessels. This means that the characteristic pentasaccharide fragment of heparin is also an endogenous antithrombotic agent. SMC = smooth muscle cell.

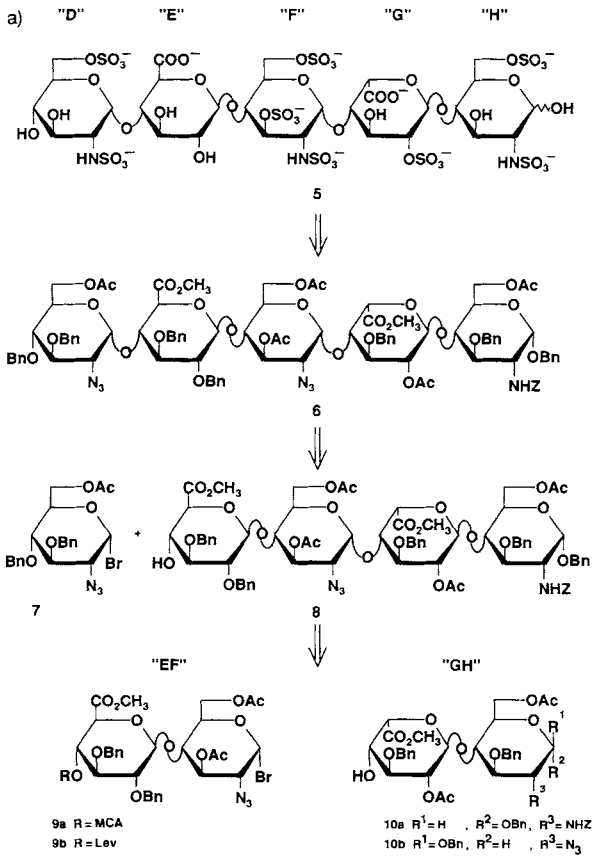
3. Synthesis of Antithrombin-Binding Pentasaccharides

3.1. Initial Syntheses of Pentasaccharides with a Natural Sequence

In the early 1980s the synthesis of the biologically active pentasaccharide **5** was carried out according to the strategy depicted in Figure 4a, in which a fully protected pentasaccharide **6** was first prepared and then converted into **5**.[17, 18] In the selection of the protective groups of **6** the following factors were considered: 1) the need for introduction of sul-



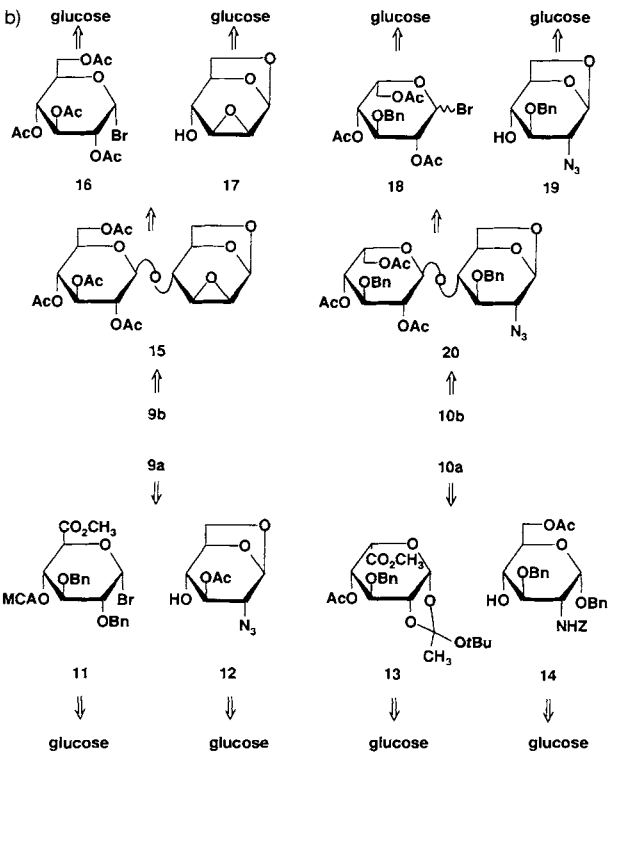


Fig. 4. a) Retrosynthetic pathway for pentasaccharide **5**. Two strategies were developed for the preparation of and the disaccharide building blocks **9** (EF) and **10** (GH), as shown in Figure 5a. b) In one route (lower part) glucose and idose derivatives, both obtained from glucose, are oxidized at the monosaccharide level to provide the corresponding uronic acid derivatives **11** and **13**, which are then coupled to glucosamine derivatives **12** and **14**, respectively. In the other route (upper part) the glucose and idose derivatives **16** and **18**, respectively, are first coupled with glucosamine derivatives or precursors yielding disaccharides **15** and **20**, respectively. Final functionalization and oxidation to give building blocks containing uronic acid is then performed at the disaccharide stage (for details see Fig. 5a and b).

fate and N-sulfate substituents, and the presence of carboxylate and hydroxyl groups in the proper positions on the target molecule **5**, and 2) the state of the art in oligosaccharide synthesis at the time, for instance the use of 2-azido glucose derivatives[16] to introduce 1,2-*cis*-linked glucosamine units (such a glycosylation requires a nonparticipating group at position 2 of the glycosyl donor) and the use of glycosyl donors having a participating group at position 2 to control the introduction of 1,2-*trans* interglycosidic bonds (as required for the two uronic acid units.)

In the first reported synthesis[17] the disaccharide building blocks **9a** and **10a**, the respective precursors of the EF and GH parts of the molecule, were obtained by condensing suitably protected glucuronic acid and iduronic acid monosaccharide derivatives with glucosamine precursors. All the monosaccharide units were obtained from glucose or from glucosamine, as illustrated in Figure 4b.

In another synthesis,[18] following a different approach but applying the same protective group strategy, similar building blocks **9b** and **10b** were prepared by condensation of the glucose and idose derivatives **16** and **18**, respectively, with the Cerny epoxide **17** and the glucosamine precursor **19**, respectively (Fig. 4b). Subsequent Jones oxidation of the function at the 6'-position then yielded disaccharides containing the corresponding uronic acids (Fig. 5b).

The protected pentasaccharide **6** was converted into **5** with the following sequence of reactions (Fig. 4a)[17]: 1) saponification of the ester groups of the molecule, 2) sulfation of the resulting free hydroxyl groups, 3) hydrogenolysis to generate the amino groups of the glucosamine units and to liberate

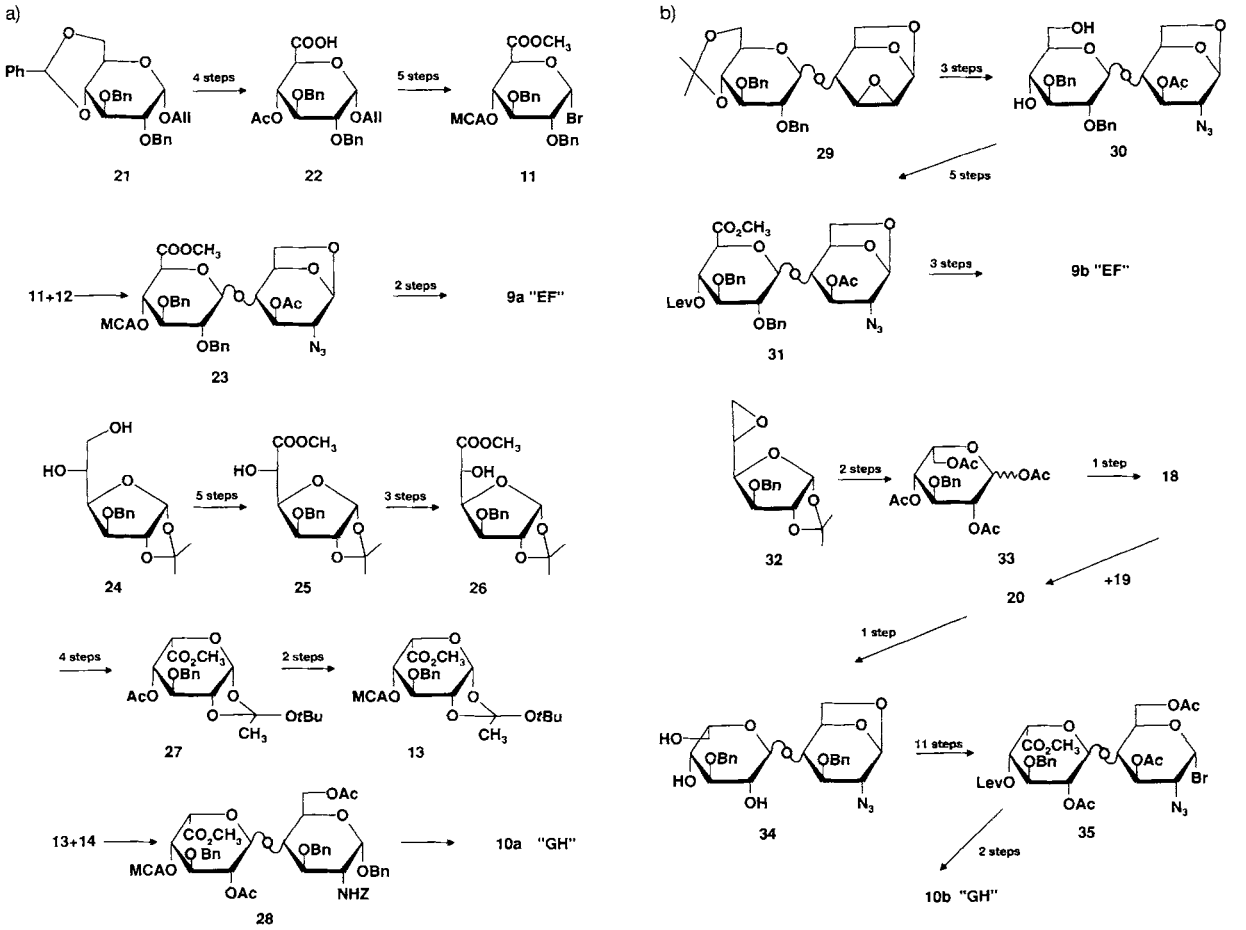

Fig. 5. a) Preparation of the disaccharide building blocks **9a** (EF), and **10a** (GH), by coupling monosaccharide derivatives of uronic acid and glucosamine, respectively [17]. 1-*O*-allyl-4,6-*O*-benzylidene-α-D-glucopyranoside [34] was benzylated to give **21** (71%, crystalline), which was converted to the glucuronic acid derivative **22** (acid hydrolysis, tritylation, acetylation, Jones oxidation; 50% overall yield). The potassium salt of compound **22** was isomerized to the prop-1'-enylglycoside (*t*BuOK, dimethyl sulfoxide (DMSO)), methylated, and monochloroacetylated. Cleavage of the glycoside and bromination using the Vilsmeier reagent then gave **11** (57% from **22**). Condensation with **12** (easily obtained from 1,6-anhydroglucose) gave **23** (70% from **11**), which was transformed into **9a** (acetolysis, bromination; 52%). For the preparation of **10a**, 3-*O*-benzyl-1,2-*O*-isopropylidene-D-glucofuranose (**24**) [33] was converted into **25** (tritylation, acetylation, Jones oxidation, saponification, methylation; 35% overall yield). Compound **25** was epimerized to provide **26** (Tf_2O, CF_3COONa or HCOONa, MeOH or $KHCO_3$; 90% overall yield), which was converted into **27** (acid hydrolysis, acetylation, bromination, formation of the ortho ester; 41% overall yield). Replacement of the acetyl group at position 4 by a monochloroacetyl group provided **13** (K_2CO_3/MeOH then MCACl/pyridine; 79%). Coupling of **13** and **14** (45% from **13**) and removal of the monochloroacetyl group gave the GH building block **10a**. b) Preparation of the disaccharide building blocks **9b** (EF) and **10b** (GH) by oxidation at the disaccharide stage [18]. Acetobromoglucose **16** was condensed with the Cerny epoxide **17** (see Fig. 4b) to give disaccharide **15** (62%, see Fig. 4b), which was converted in three steps (deacetylation, isopropylidenation, benzylation; 70% overall yield) into **29**. Compound **29** was converted into **30** (lithium azide/*N*,*N*-dimethylformamide (DMF), acetylation, acid hydrolysis; 95% overall yield). Compound **31** was obtained from **30** (dimethoxytritylation of the primary hydroxyl group, levulinoylation, acid hydrolysis, Jones oxidation, methylation; 43% overall yield) and converted into **9b** (acetolysis, removal of the acetate group at the anomeric center, bromination; 92% from **31**). For the preparation of **10b**, 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose (**24**) [33] was converted into **32** (dimesylation, selective substitution at C6 by an acetate, epoxidation; 71% from **30**). Compound **32** was converted into **33** (acid hydrolysis, acetylation; 54%), which was then brominated at C1 to give **18** (see Fig. 4b) and condensed with the glucosamine derivative **19** to give, after deacetylation of **20**, compound **34** (41% from **33**). **34** was converted into bromide **35** (essentially as described for the preparation of **9b** from **30**; 38% yield over 11 steps) which then was transformed into **10b** (two steps, 54%).

hydroxyl groups, and 4) selective N-sulfation of amino groups.

Other syntheses of **5** or similar compounds using either cellobiose[19] or maltose[20] as starting material have been described but again the same protective group strategy was adopted.

3.2. Synthetic Analogues of the Naturally Occurring Pentasaccharide

The conversion of the previously mentioned fully protected pentasaccharides, for example conversion of compound **6** into **5**, requires hydrogenolysis (step 3). However, under these conditions amino groups are generated very rapidly and may react with the reducing end of the pentasaccharide (aldehyde function), which is obtained after cleavage of the benzyl group at the anomeric position. The side reaction yields stable products (particularly after reduction of the intermediate Schiff base) corresponding to a mixture of dimers and trimers of the initial pentasaccharide.[21] In order to circumvent this undesired side reaction, the corresponding methyl glycoside derivative is used. Here, the reducing end is protected and the α linkage present at this position in heparin is mimicked, thus yielding analogue **39**[21] (Fig. 6). Compound **39** displays the same biological properties as **5**. Initially pentasaccharide **39** was prepared in the same way described for **5**; however, more recently the synthesis has been improved by using the trisaccharide imidate **36**[22] as a precursor for the DEF part of the molecule (Fig. 6). This reduced the amount of intermediate **37**, the expensive iduronic acid containing building block, required for the synthesis.

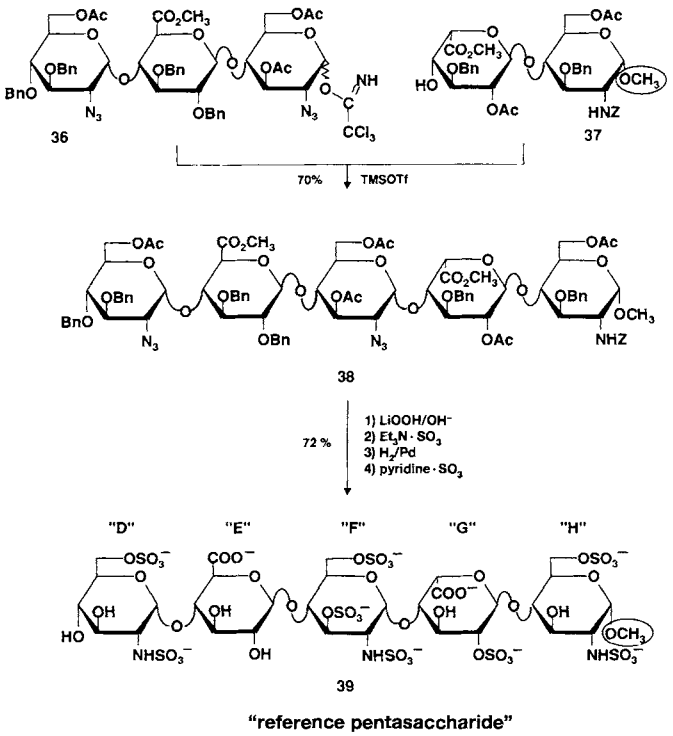

Fig. 6. In the synthesis of **39**, the α-methyl glycoside derivative of **5**, a 3 + 2 coupling approach is employed. In our studies compound **39** is referred to as the "reference pentasaccharide" or "natural product".

The preparation of **39** has been scaled up, and this synthetic heparin fragment is now the reference for studies of the series of antithrombotic oligosaccharides that selectively inhibit blood coagulation factor Xa through activation of AT III. Compound **39** displays a potency of 700 anti-Xa units (U) mg^{-1} in the Sanofi/Organon reference assay.[44]

We mentioned in Section 2.2 that in the pentasaccharide sequence responsible for the binding of heparin to AT III the D unit could be either an N-sulfated or an *N*-acetylated glucosamine residue. In the first syntheses, the N-sulfated variant was chosen because of the simpler chemistry; however; the approach starting from trisaccharide **40** (Fig. 7) allowed differentiation of the D unit at the trisaccharide level. The key reaction was the selective reduction of the azido group at position 2 of the nonreducing terminal monosaccharide unit of **40**, which could be performed by catalytic hydrogenation using either the Lindlar catalyst or hydrogen transfer conditions.[23] Afterwards the methyl glycoside analogue **42** of the natural *N*-acetylated pentasaccharide sequence could be obtained following the procedures used for the preparation of **39**. Surprisingly pentasaccharide **42** was a less potent stimulator of AT III than its N-sulfated counterpart **39** (350 anti-Xa U mg^{-1} versus 700 anti-Xa U mg^{-1}).

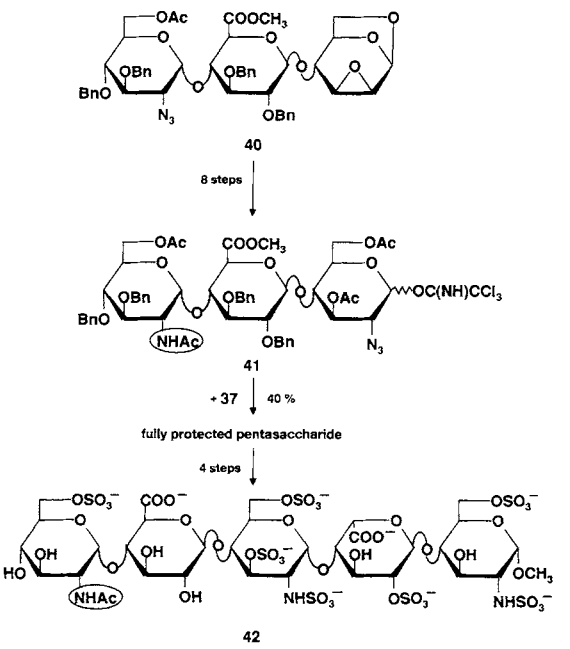

Fig. 7. Synthesis of the *N*-acetylated pentasaccharide representing the AT III binding site of porcine heparin. The azido group of **40** was reduced to give an amine which could be selectively acetylated. Further processing delivered the trisaccharide donor **41**, which was coupled with **37** to give compound **42**, following the standard transformations.

4. Conformational Analysis of the Pentasaccharide

The interaction of heparin oligosaccharides with antithrombin requires, at the level of the oligosaccharide, a

precise three-dimensional positioning of the sulfate and carboxylate groups involved (see Section 7). The orientation of these groups is mainly governed by the conformation of the carbohydrate backbone of the molecule, which in turn depends on the conformation adopted by the individual sugar residues and the conformational relationships between adjacent residues. We will first examine the conformational behavior of individual monosaccharides.

In all the heparin oligosaccharides studied so far,[17] the glucosamine and glucuronic acid residues have invariably been found to adopt the $^4C_1$ conformation[*] (Fig. 8), as supported by analysis of the coupling constants in their ^{1}H NMR spectra. In contrast, the conformation of the iduronic acid residues is highly dependent both on the substitution pattern (e.g. sulfate groups at the 2-position) and on the precise nature of the adjacent residues. Calculations on the conformational behavior of iduronic acid showed that the three conformations $^1C_4$, $^4C_1$, and $^2S_0$ (skew boat con-

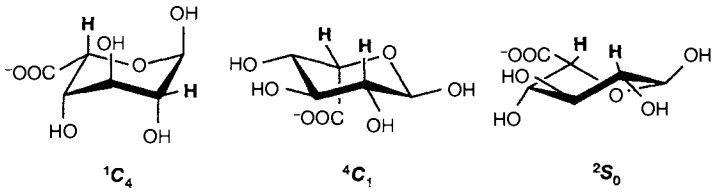

Fig. 8. The three conformers ($^1C_4$, $^4C_1$, $^2S_0$) of L-iduronic acid that may be present in heparin-like pentasaccharides. Protons H2 and H5 are close to each other in the $^2S_0$ conformer as indicated by ^{1}H NMR NOE experiments.

formation) must be considered, not just $^1C_4$ and $^4C_1$ as was previously assumed (Fig. 8). The occurrence of the third conformation, $^2S_0$, similar in energy to the other two, was also confirmed by the observation of a nuclear Overhauser enhancement (NOE) effect between protons H2 and H5, which only in this particular conformation are in close proximity (2.3 Å). Comparison of ^{1}H NMR data, particularly vicinal coupling constants (Fig. 9A), obtained for pentasaccharide **39** and its analogue **45**[25] (in which the N-sulfated, 6-sulfated glucosamine unit F is present) reveals differences in the conformations of the 2-sulfated α-L-iduronic acid residues.[26, 27] For example, replacement of the terminal reducing unit of **39** (i.e. N-sulfated, 6-sulfated glucosamine) by an N-sulfated, 3,6-disulfated glucosamine residue (**57**) favors the $^2S_0$ conformation.[28] Different conformations for iduronate residues, depending on their location in the oligosaccharide chains, were also observed in isolated heparin fragments. Similar observations were made for model trisaccharides (Fig. 9B). In these studies[29] it was also observed that at high salt concentrations (3 M NaCl) iduronic acid relaxes fully into the $^1C_4$ conformation. This phenomenon led us to postulate that the $^1C_4$ conformation predominates when the pentasaccharide is bound to ATIII.[29]

The conformations of the synthetic pentasaccharides **39** and **45** have been studied[30–32, 66] by combining computational techniques (using force fields) and NMR experiments.

[*] For pyranoses in the chair conformation, $^4C_1$ refers to the conformation in which C1 is below and C4 is above the plane formed by C2, C3, C5, O5; in the inverse $^1C_4$ conformation, C1 is above and C4 below this plane. See R. E. Reeves, *Adv. Carbohydr. Chem.*, **1951**, *6*, 107.

Fig. 9. Conformational analysis of a series of synthetic pentasaccharides (A) and trisaccharides (B) by ^{1}H NMR spectroscopy revealed that the conformational behavior of α-L-iduronic acid-2-sulfate is governed by substituents on the neighboring D-glucosamine units. The conformations of the α-L-iduronic acids can be differentiated best by their 2,3 and 3,4 vicinal coupling constants (^3J), as can be seen from the corresponding calculated coupling constants (lower part). An ammonium or *N*-acetyl (R^1) group on the neighboring glucosamine unit (B) stabilizes the $^1C_4$ conformation of α-L-iduronic acid. Sulfate groups (R^2) in the same unit destabilize the $^4C_1$ conformation, thereby allowing a considerable contribution of the $^2S_0$ (skew boat) conformer in the equilibrium. As a consequence of this last conformational change, the distances among various sulfate groups increase and their mutual electrostatic repulsions decrease. When both glycosamine neighbors have sulfate substituents, the $^2S_0$ conformation is almost exclusively present.

As previously mentioned, glucosamine and glucuronic acid residues adopt the $^4C_1$ conformation, whereas iduronic acid moieties exist in an equilibrium between $^1C_4$ and $^2S_0$ conformers. Sulfate substituents bound to tertiary carbon atoms by either an O or a N atom adopt a conformation in which the sulfur atom is in an eclipsed arrangement with respect to the ring proton. When linked to secondary carbon atoms (6-position of glucosamines), the sulfate group prefers the *trans* conformation at the C6–O6 bond; force field calculations reveal *gt* and *gg* conformations, but *gg* is strongly predominant according to ^{1}H NMR data. Free hydroxyl groups may adopt three conformations, whereas the carboxylate groups of uronic acids show great rotational freedom. In the most stable conformations of pentasaccharides **39**, **45**, and **57** (Fig. 17) the iduronic acid residues have either the $^1C_4$ or the $^2S_0$ conformation (Fig. 10).

Inspection of the models depicted in Figure 10 reveals an asymmetric distribution of the charges that are relevant for the interaction with ATIII (see Fig. 16 and Section 7). The

effect of a conformational change at the iduronic acid residue during the binding and activation of ATIII is not yet known.

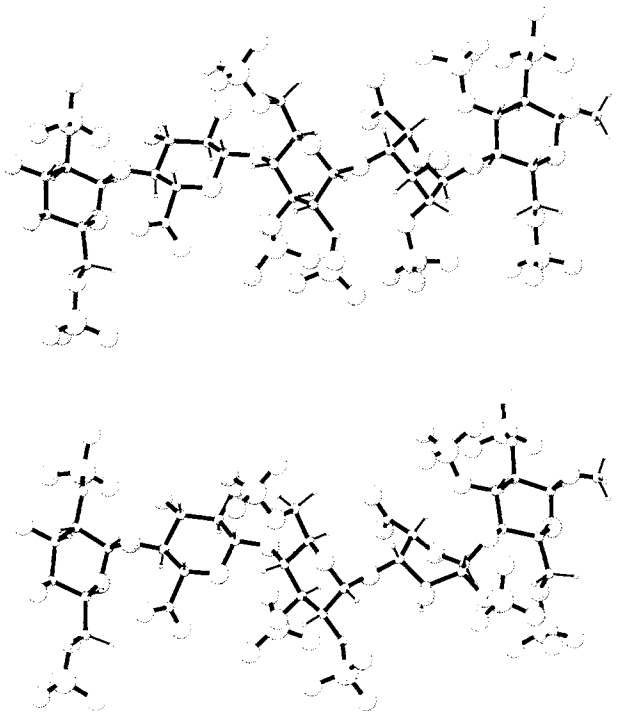

Fig. 10. Three-dimensional representation of compound **57** with an iduronic acid residue in $^1C_4$ (top) and $^2S_0$ (bottom) conformation.

5. Other Synthetic Analogues

5.1. Synthetic Analogues Lacking Charged Groups at Defined Positions

5.1.1. Analogues Lacking Certain Sulfate Groups

After the synthesis of the synthetic counterparts of the naturally occurring pentasaccharide, compounds **5** and **39**, a major question was whether all the charged groups of the pentasaccharide are required for ATIII activation. Although some important information about the role of sulfate groups was available from studies[35b] with (bio)chemically modified heparin fragments, the ultimate answer to this question was obtained by the synthesis of analogues lacking charged groups at defined positions (Fig. 11). For instance, the definitive proof that the characteristic 3-sulfate group at unit F is essential for ATIII activation came after synthesis[36] of the biologically inactive analogue **45** which lacked only this particular sulfate group. Obviously, the synthesis of analogue **45** closely resembles that of our lead compound **39**. The major difference is in the preparation of the EF disaccharide building block **43** which, according to our strategy, should contain a 3-*O*-benzyl group at unit F instead of the 3-*O*-acetyl group (as in EF building block **9b**). Apart from the 3-sulfate group at unit F it was also established[37] that the 6-sulfate group of the nonreducing D unit is absolutely required for biological activity. A similar strategy provided two synthetic pentasaccharides[38] lacking the 6-sulfate

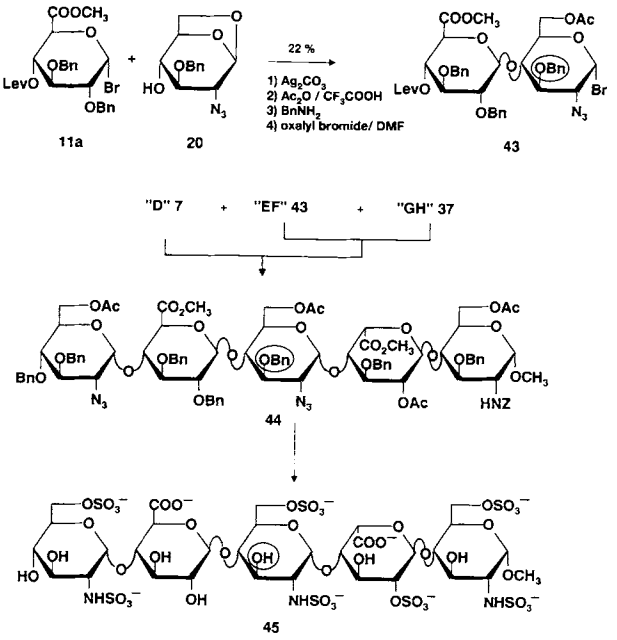

Fig. 11. Preparation of analogue **45**, which lacks the characteristic 3-sulfate group (circled) at glucosamine unit F. Compound **45** is biologically inactive, thus proving the importance of this particular sulfate group in the activation of ATIII.

group at unit H and the 2-sulfate group at unit G, respectively. Both analogues displayed about 25% of the activity of the reference pentasaccharide **39**, pointing to the importance of the sulfate groups at units G and H.

Surprisingly, a pentasaccharide lacking both the 2-sulfate group in unit G and the 6-sulfate group in unit H was almost as active as the two analogues in which only one sulfate group is absent.

The analogue without the 6-sulfate group at unit F has not yet been synthesized, but studies with naturally occurring heparin fragments lacking this group revealed that this substituent does not contribute considerably in the activation of ATIII.

5.1.2. Analogues Lacking Certain N-Sulfate Groups

With regard to the role of the N-sulfate groups at units D, F, and H, Riesenfeld et al.[39] demonstrated that removal of this substituent in either unit F or H gives rise to inactive heparin fragments. In contrast, heparin fragments with an *N*-acetyl instead of an N-sulfate group at unit D are still active. More precise information was obtained from synthetic derivatives. The synthetic analogue **42**, *N*-acetylated in unit D (see Section 3.2), which represents the most widespread ATIII binding domain of porcine heparin, was only half as active in an anti-factor Xa assay as the corresponding N-sulfated derivative **39**. The activity of a synthetic analogue with a 2-hydroxyl group at unit D was virtually the same as that of the pentasaccharide with an *N*-acetyl group (**42**).[43]

The very low activity (ca. 5%) of the synthetic analogue **46**[43] containing a 2-hydroxyl group at unit H is consistent with the studies of Riesenfeld et al.,[39] who found that the N-sulfate group at this position is essential. For the synthesis of the hydroxyl analogue **46** (Fig. 12) the suitably protected

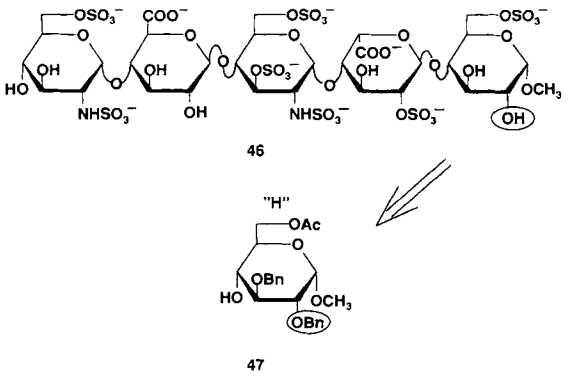

Fig. 12. In analogue **46** the N-sulfate functionality at the reducing end (H) is replaced by a hydroxyl group. According to the general strategy, the 2,3-di-*O*-benzyl-protected glucose unit **47** is required as the building block for the reducing terminal unit.

H building block **47** containing a 2-*O*-benzyl protective group had to be incorporated.[40]

5.1.3. *Analogues Lacking Certain Carboxylate Groups*

Synthetic model compounds were also used to examine the role of the two carboxylate groups in the active heparin fragment. Compound **51**, the first synthetic analogue prepared for this purpose, lacks the carboxylate group of iduronic acid; a 2-sulfate-β-D-xylopyranose unit is present instead of a 2-sulfate-α-L-idopyranuronate unit. Consequently, the GH disaccharide **49** had to be synthesized from

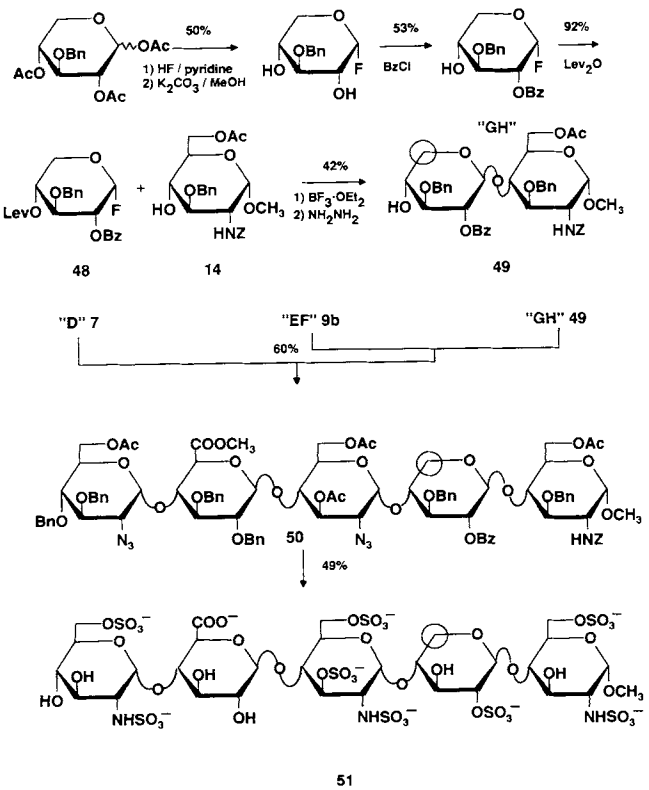

Fig. 13. Synthesis of analogue **51**, which lacks the essential carboxylate group (circled) of α-L-iduronic acid. For the preparation of compound **51** a properly protected D-xylopyranosyl derivative (compound **48**) had to be prepared as the G unit. The carboxylate group of α-L-iduronic acid is not only required for interaction with ATIII, but also governs the conformation of the G unit.

the xylopyranosyl donor **48** and the known acceptor **14** (Fig. 13). The fully protected pentasaccharide **50** was assembled by coupling **49** with the known disaccharide **9b** and monosaccharide **7**. Subsequent deprotection and sulfation delivered the inactive analogue **51**. Most likely this sharp decrease in biological activity should be ascribed to the loss of an essential carboxylate group that interacts with the protein; however, we also found[41] that the xylopyranosyl moiety in the analogue has a different conformation than that of the iduronic acid moiety ($^4C_1$ conformation instead of the $^2S_0/^1C_4$ equilibrium found for iduronic acid).

The carboxylate group of the glucuronic acid moiety (unit E) was also shown[42] to be a key charged group in the activation process, since pentasaccharide **52** (Fig. 14), which has a methyl carboxylate group at unit E, elicits only 5% of the activity of the natural product. Pentasaccharide **52** was not the result of a planned total synthesis but merely a side product that occurred during the preparation of the reference compound **39**.

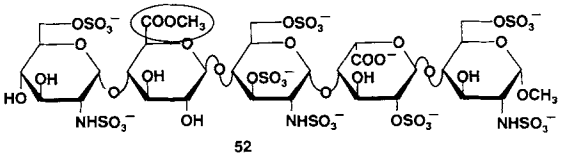

Fig. 14. Compound **52**, which contains a methyl ester at the D-glucuronic acid moiety, is hardly active, thus showing that the carboxylate group at this position plays an important role in the activation of ATIII.

The very low activity of pentasaccharides **51** and **52** indicates that the two carboxylate groups of the uronic acid moieties (units E and G) are essential for ATIII activation. In Section 5.5 it will be demonstrated that replacement of the charged group at C5 of uronic acid by another charged functionality ($CH_2SO_3^-$ instead of COO^-) is also detrimental.

In conclusion, the role of all sulfate and carboxylate groups of the active heparin pentasaccharide in ATIII activation is known from studies with well-defined synthetic analogues. The influence of the individual charged groups on the biological activity is indicated schematically in Figure 15.

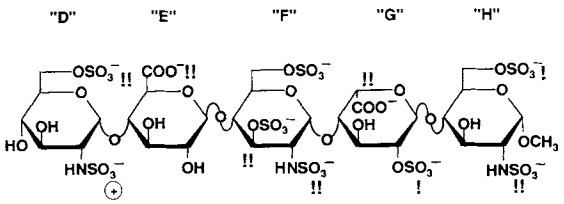

Fig. 15. The role of the individual charged groups in the activation of ATIII. Exclamation marks denote groups that are crucial, since their removal leads to loss of anti-Xa activity by more than 95% (!!) or by about 75% (!). The N-sulfate group marked with + contributes significantly (about 50% loss of anti-Xa activity after removal).

5.2. The Discovery of More Potent Derivatives

By 1987 we had assessed the role of the individual charged groups of the heparin pentasaccharide (see Section 5.1), and a reliable molecular model was available from ^{1}H NMR

spectroscopic studies and molecular modeling (see Section 4). Most remarkably, two distinct ATIII binding sites were implicated[43] based on the molecular model of the pentasaccharide as shown in Figure 16. It can be seen that

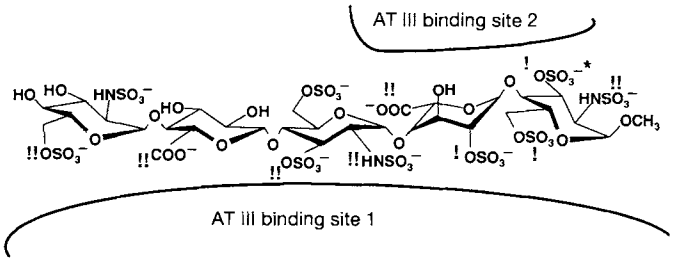

Fig. 16. When the role of the essential charged groups (!! and !) became known, the interaction model depicted, which has two ATIII/pentasaccharide binding sites, was postulated. Based on this model it was decided to introduce an extra sulfate group at the 3-position of the reducing terminal unit (*). Indeed, this "supersulfated" analogue **57** proved to be more active and to interact more strongly with the ATIII protein than the natural compound. Other supersulfated analogues were less active.

the potential interaction points should be located on the top ("north") face and the bottom ("south") face of the pentasaccharide. The essential charged groups of the DEF fragment are directed towards the southern binding region, whereas the important carboxylate and N-sulfate groups of the GH fragment are pointed towards the northern binding region. This ATIII heparin interaction model inspired us to synthesize an analogue (**57** in Fig. 17) containing an extra 3-sulfate group at unit H (see starred group in Fig. 16) which according to the model should enhance the binding capacity in the northern binding site. Indeed the derivative with the additional sulfate group (**57**) displayed a higher ATIII

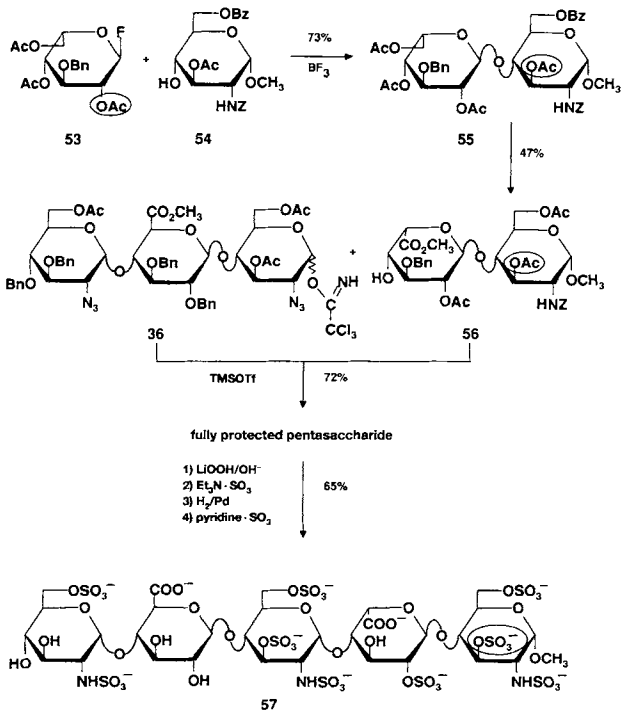

Fig. 17. Synthesis of the more active analogue **57** containing an extra 3-sulfate group at the reducing end. Following the general synthetic strategy, a suitably protected GH moiety (**56**) is required containing a 3-*O*-acyl instead of a 3-*O*-benzyl protective group (circled groups).

mediated anti-factor Xa activity than the reference compound **39** (1250 U mg^{-1} versus 700 U mg^{-1}), and analogue **57** binds to ATIII one order of magnitude stronger (see Section 7.1). Moreover, in pharmacokinetic studies[44] it was found that **57** displays a longer biological half-life, probably due to a stronger interaction with ATIII in circulation.

The synthesis of the "supersulfated" pentasaccharide **57** was based on the general strategy outlined previously. The additional 3-sulfate group at unit H required a glucosamine building block containing a 3-*O*-acetyl group instead of a 3-*O*-benzyl group. To this end, monosaccharide acceptor **54** was synthesized (Fig. 17). Coupling of **54** with the idopyranosyl fluoride donor **53** gave the fully protected disaccharide **55**, which was processed further in analogy to the preparation of **35** from **20** (see Fig. 5 b) to deliver the desired GH building block **56**.

Preparation of the fully protected pentasaccharide could be achieved most conveniently by coupling the GH acceptor **56** with an equimolar amount of the imidate-activated DEF donor **36**. However, the first attempts to convert the fully protected pentasaccharide into the required product **57** were disappointing. In the first deprotection step, saponification with sodium hydroxide, approximately 40% cleavage occurred owing to a 4,5-elimination at iduronic acid. Fortunately, this undesired side reaction could be suppressed by conducting the saponification with lithium hydroperoxide. The subsequent sulfation and deprotection steps could be conducted with good yields.

The potency of the supersulfated analogue **57** led us to turn our attention to some of its analogues. We wondered whether introduction of additional sulfate groups would render the pentasaccharide even more active, as the interaction with the positively charged ATIII may strengthen when the negative charge of the carbohydrate increases. However, the opposite was found. For instance, analogues **58** and **59** (Fig. 18) which contain an extra 3-sulfate group at glucuronic acid[45] and iduronic acid,[46] respectively, are less active than compound **57** by roughly 35% and 60%, respectively.

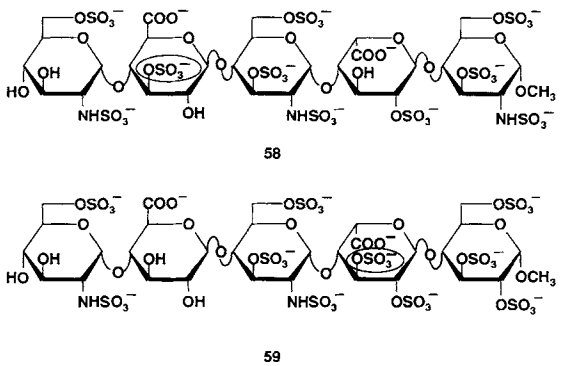

Fig. 18. Other supersulfated analogues such as compounds **58** and **59**, which contain 3-sulfated uronic acid moieties, are considerably less active than their counterpart **57** which lacks these extra sulfate substituents. This phenomenon indicates that the interaction between pentasaccharide and ATIII cannot be explained simply by the electrostatic attraction of two oppositely charged entities.

Analogues with extra sulfate groups at the D unit are approximately 10% less active.[46] At the extreme, the fully sulfated pentasaccharide is not active.[47] Apparently the in-

teraction between the characteristic heparin fragment and the protein is much more complex in nature than just the simple electrostatic attraction of two oppositely charged biomolecules.

5.3. Some Flexible Analogues

As described in Section 5.1, the carboxylate functions of the uronic acid residues E and G are strictly required for AT III activation. The next question was whether the pyran rings of the uronic acid moieties are essential. To answer this question we synthesized[48] the "ring-opened" analogues **63** and **64** (Figs. 19–21). In analogue **63** the α-L-iduronic acid

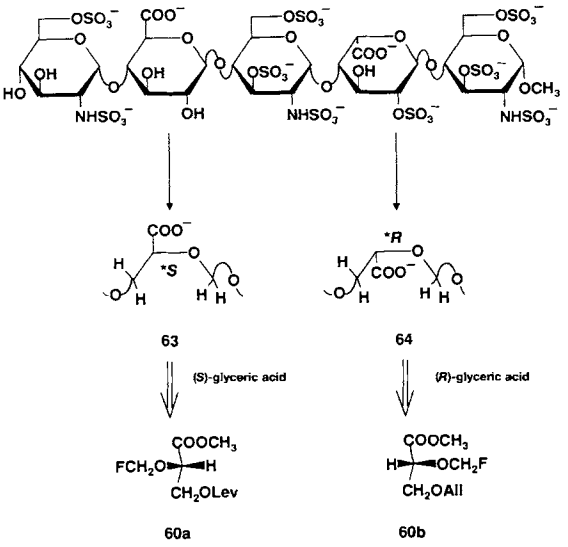

Fig. 19. We wondered if the uronic acid moieties of the pentasaccharide could be replaced by flexible "opened" pyranose moieties containing the essential carboxylate groups in the appropriate configuration. To this end the suitably protected (*S*)- and (*R*)-glyceric acid building blocks **60a** and **60b**, respectively, were synthesized.

unit is replaced by an (*R*)-glyceric acid-2-O-CH_2 moiety, while in analogue **64** the β-D-glucuronic acid unit is replaced by an (*S*)-glyceric acid-2-O-CH_2 moiety (Fig. 19). These analogues still comprise the essential carboxylate substituents in the appropriate configuration, but obviously their conformational flexibility is increased.

The key steps in the synthesis of these analogues were the preparation and incorporation of the glyceric acid-O-CH_2 residues. To this end, two suitably protected and activated building blocks **60a** and **60b** were prepared from (*S*)- and (*R*)-glyceric acid, respectively. In Figure 20 the synthesis of **63** is outlined; analogue **64** was prepared in a similar fashion (Fig. 21). Analogue **63** with the ring-opened α-L-iduronic acid unit displays about 25% of the activity of the reference compound, thus proving that the ring structure of α-L-iduronic acid is not strictly required. This phenomenon is not that surprising when one takes into account that this part of the molecule displays considerable conformational freedom[49] (see Section 4).

In contrast, analogue **64** (Fig. 21) with the ring-opened β-D-glucuronic acid moiety is virtually inactive, although all essential charged groups are present in the molecule. Probably, the rigid D-glucuronic acid moiety (unit E) is necessary in arranging the essential charged groups appropriately in space. Highly simplified analogues with two ring-opened iduronic acid moieties at positions E and G are biologically inactive.[50]

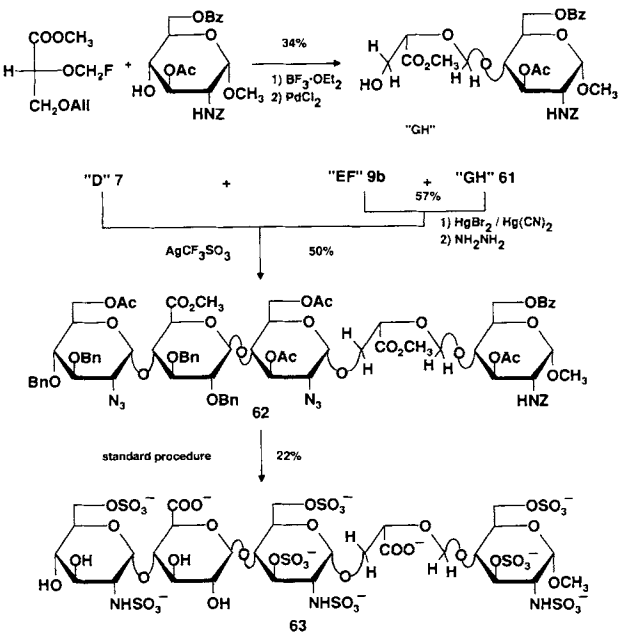

Fig. 20. Synthesis of analogue **63** containing "ring-opened" α-L-iduronic acid moiety. Analogue **63** elicits about 25% of the biological activity of the reference compound **39**. Apparently the flexible α-L-iduronic acid moiety (G) may be substituted by a linear chain exposing the carboxylate group in the appropriate configuration.

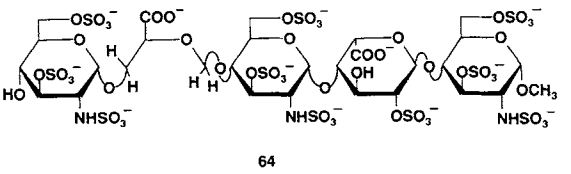

Fig. 21. Analogue **64** containing a ring-opened D-glucuronic acid moiety is not active although all essential charged groups are present. It may be concluded that the rigid D-glucuronic acid moiety (in $^4C_1$ conformation) is necessary for the activation of AT III.

5.4. Some Epimeric Analogues

In order to understand the specificity of the heparin/AT III interaction in even greater detail we examined some synthetic analogues containing all essential charged groups but in which only one of the twenty-five chiral centers has been inverted, in other words, epimeric analogues.

Compound **65** (Fig. 22) contains a β-coupled glucosamine (unit D) and is hardly active,[47] whereas compound **66** contains a β-D-glucuronic acid moiety instead of an α-L-iduronic acid residue (unit G) and is not active at all.[47] In the latter analogue, epimerization at C5 of α-L-iduronic acid to give β-D-glucuronic acid is accompanied by a drastic change in the conformational behavior of unit G, since the flexible iduronic acid ($^1C_4$ and $^2S_0$ conformations occur) is converted into a rigid glucuronic acid, which adopts solely the $^4C_1$ conformation.

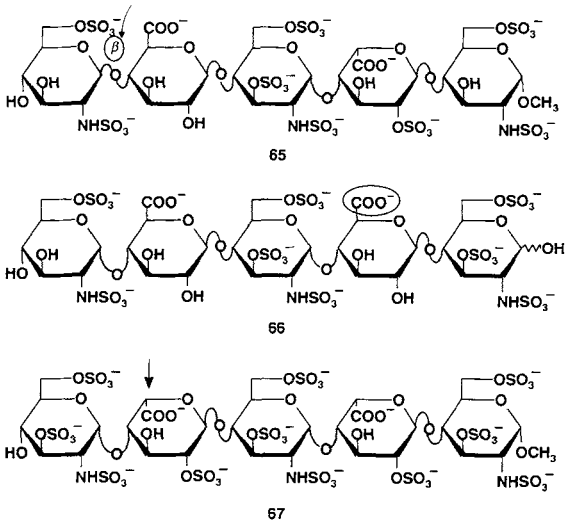

Fig. 22. The epimeric analogues **65** and **66** are hardly active, whereas analogue **67** displays about 10% of the activity of its epimer. Apparently the biological activity decreases drastically when the orientation of essential charged groups in space is changed.

Analogue **67**[51] in which D-glucuronic acid is epimerized at C5, contains two L-iduronic acid moieties, and still displays about 10% of the anti-factor Xa activity of the potent derivative **57**. From a synthetic point of view compound **67** is an attractive target molecule because it is constructed from an alternating sequence of saccharides. Units D, F, and H are alike, as well as units E and G, meaning that in principle only two building blocks are required. Interestingly, similar alternating sequences of the type [IdoA(2-SO_4)α1 → 4GlcNSO_3(3-SO_4)α1 → 4] have been identified in heparan sulfate of the glomerular basement membrane.[52]

Two epimeric analogues were also synthesized in a related series (see Section 6). One of them containing a nonreducing terminal D-mannopyranosyl unit (unit D) is only half as active as the corresponding pentasaccharide with the D-glucopyranosyl unit.[42] The other analogue with the D-galactopyranosyl unit[42] at the reducing end (unit D) had the same activity as the parent compound.

Another research group[19] showed that the biological activity of an analogue with a β-*O*-methyl group at the anomeric center (unit H) is identical to that of the reference compound. Since only a few of the possible epimeric analogues have been investigated so far, conclusions should not be drawn. Nevertheless, the results strongly suggest that the biological activity decreases when the location of essential charged substituents is changed.

5.5. Analogues with Other Charged Groups

Another aspect of the structure–activity studies of the characteristic heparin fragment is the significance of the type of charged groups in the molecule; in other words does the molecule need sulfate and carboxylate groups in the AT III activation process? We replaced,[53] for instance, the essential 6-sulfate group at unit D by a more highly charged phosphate group (compound **69** in Fig. 23). For the synthesis of this analogue a levulinoyl ester was employed for the temporary protection of the 6-position of unit D. After controlled hydrazinolysis of **68a**, the corresponding derivative **68b** with the free hydroxyl group was phosphorylated using standard phosphoramidite chemistry. Suitable phosphate protecting groups were required that are compatible with the subsequent deprotection and sulfation steps. In our hands a 2-cyanoethyl protective group in combination with a benzyl protective group gave the best results: the 2-cyanoethyl group is cleaved in the first deprotection step (saponification), and the benzyl group is removed during hydrogenolysis. To our surprise the monophosphorylated derivative **69** displays no significant activity. It is hard to explain that AT III does not recognize the phosphate group. It may be argued that the interaction of the phosphorylated derivative with AT III is weak because of the large free energy of dehydration of the phosphate group.

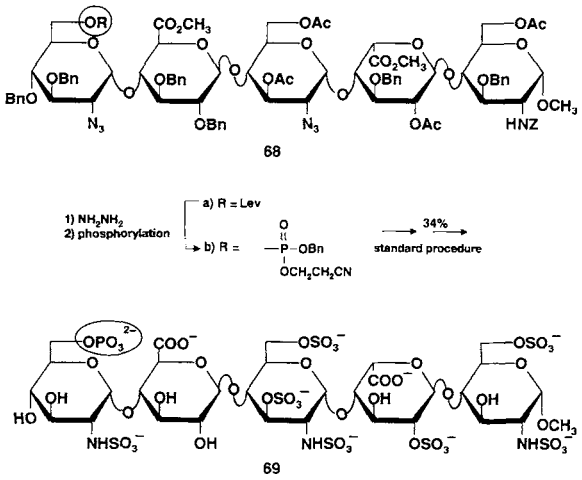

Fig. 23. Strategy for the synthesis of the 6-*O*-phosphorylated analogue **69**. To our surprise compound **69** is biologically inactive. This finding suggests that even the type of negatively charged groups of heparin (sulfate and carboxylate) is important in the specific recognition process between heparin and AT III.

Other groups[54] have found evidence that proteins may discriminate between phosphate and sulfate groups by different networks of hydrogen bonds (Fig. 24).

Since the two carboxylate groups of the pentasaccharide are involved in AT III activation, we sought to place other

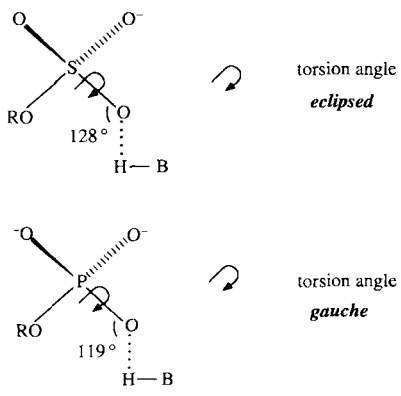

Fig. 24. X-ray crystal structures and ab initio calculations demonstrate that the formation of a hydrogen bond to a sulfate or a phosphate group results in markedly different orientations. The data shown were collected from crystal structure analysis [20a].

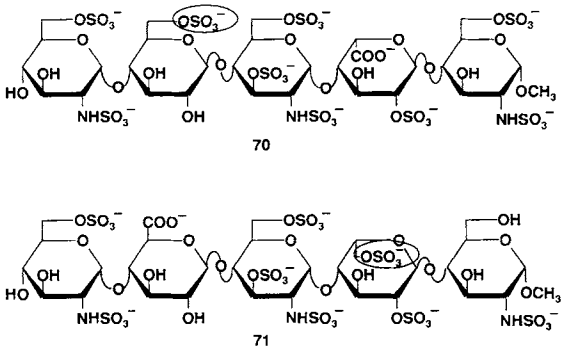
charged functionalities at these positions. For this purpose analogues **70** and **71**[55] (Fig. 25) were synthesized in which the COO^- groups are replaced by $CH_2OSO_3^-$ groups. Both analogues **70** and **71** are almost inactive, although they display similar conformational behavior to that of natural product. Thus, it should be concluded that also the type of charged group (i.e. carboxylate) at the 5-position of the uronic acid residue is crucial.



70

71

Fig. 25. Analogues **70** and **71**, containing methylsulfate instead of carboxylate groups, show only very low anti-Xa activity. This observation indicates that the carboxylate groups of the uronic acid moieties E and G have highly specific binding interactions with the positively charged complementary binding site of ATIII.

It is likely that the sulfate and carboxylate groups of heparin are deliberately selected in nature because of their distinct properties in molecular recognition. Presumably the protein–carbohydrate interaction involves highly ordered networks of hydrogen bonds (salt bridges),[54] in particular between defined, positively charged amino acid residues of ATIII and the essential charged groups of the characteristic heparin domain (see also Section 7).

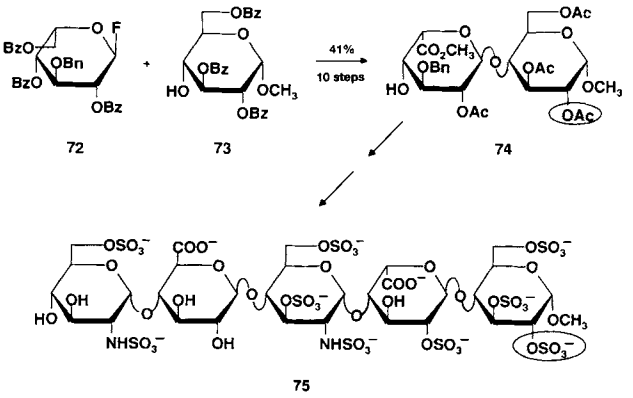
6. The Development of Biologically Active "Non-Glycosamino"glycan Analogues

6.1. Replacement of N-sulfate by Sulfate

Compound **75** (Fig. 26) is an analogue of the highly potent pentasaccharide **57** (see Section 5.2) and contains a glucose moiety (unit H) instead of a glucosamine unit.[56] Since this modification did not decrease the biological activity, we developed derivatives in which all N-sulfate groups are replaced by sulfate groups, which also allowed a much simpler synthesis. We achieved this goal with a completely new series of methylated heparin fragments (see Section 6.3), which we call "non-glycosamino"glycan fragments. For the preparation of analogue **75** the new GH acceptor **74** was synthesized by coupling idopyranosyl derivative **72** with acceptor **73** followed by further reactions.

6.2. *O*-Methylated Pentasaccharides

In order to broaden our scope of our studies on structure–activity relationships we synthesized several partially O-methylated derivatives and a fully *O*-methylated derivative



72 **73** **74**

75

Fig. 26. Strategy for the preparation of a supersulfated analogue containing a 2-sulfate group instead of N-sulfate group at the reducing end. This modification did not affect the anti-Xa activity (with respect to **57**), and therefore analogue **75** has been an important lead structure in the development of non-glycosaminoglycan analogues.

of the potent pentasaccharides **75** and **57** (Fig. 27).[57] Quite remarkably, these analogues were found to be almost as active as the corresponding nonmethylated pentasaccharides, indicating that the hydroxyl groups are not involved in the carbohydrate–protein interaction. However, in all protein–carbohydrate interactions studied so far at least a few "key polar" hydroxyl groups of the carbohydrate have been shown to interact strongly with the protein. Therefore it should be assumed that the most important feature of heparin is the exposure of key polar carboxylate and sulfate groups to AT III. This hypothesis is further supported by the biologically active analogues described in the next section.

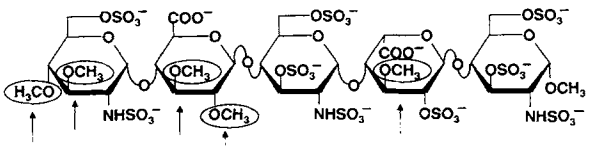


Fig. 27. Several synthetic *O*-methylated analogues have shown that no essential hydroxyl groups are present in the unique pentasaccharide domain of heparin. Subsequently non-glycosaminoglycan pentasaccharides were prepared containing solely sulfate and *O*-alkyl groups; some of these analogues have been found to be even more active than their natural counterparts.

6.3. *O*-Alkylated, Sulfated Pentasaccharides (Non-Glycosaminoglycan Analogues)

As neither methylation of free hydroxyl groups, nor replacement of the N-sulfate group of unit H by a sulfate group affected the biological activity, we prepared the non-glycosaminoglycan analogue **83** (Fig. 29), which contains solely sulfate esters and *O*-methyl ethers.[58] The synthesis of such analogues is much easier than that of heparin-like fragments (Sections 1–5), which is a distinct advantage in economically feasible drug development. The synthetic advantages of the non-glycosaminoglycans: 1) the synthetic strategy is more flexible because both acyl esters and benzyl ethers can be used to protect the hydroxyl groups to be sulfated; 2) no α-coupled glucosamines must be introduced, which would require elaborate synthetic routes towards azide-containing building blocks; 3) selective N-sulfation is

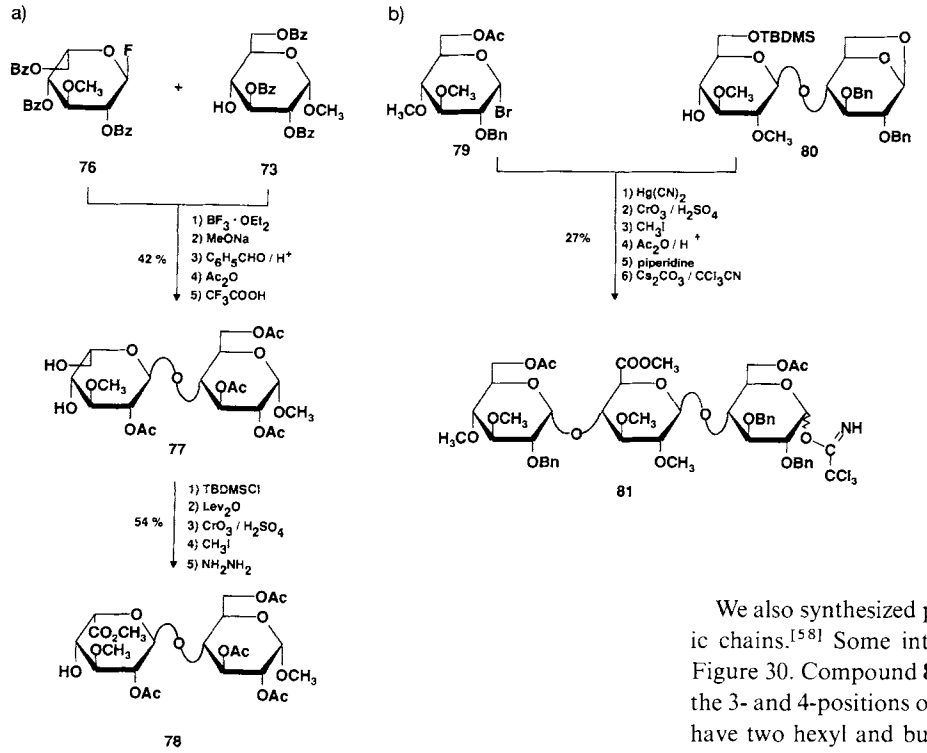

Fig. 28. a) Synthesis of the suitably protected GH disaccharide moiety **78** for the preparation of fully sulfated, *O*-methylated non-glycosaminoglycan analogues. b) Synthesis of the suitably protected DEF trisaccharide moiety **81** for the preparation of fully sulfated, *O*-methylated non-glycosaminoglycan analogues.

not necessary; 4) the scope of possible chemical modifications is broadened (carboxylates can be protected as benzyl esters, iduronic acid units can be epimerized, vide infra).

The first non-glycosaminoglycan analogue we synthesized[58] was compound **83**, which has a similar sulfation pattern as the potent derivative **57**. The syntheses of the methylated GH acceptor **78** and the methylated DEF donor **81** required for the preparation of **83** are shown in Figures 28a and 28b, respectively. The condensation of donor **81** with an equimolar amount of the acceptor **78** catalyzed by trimethylsilyl triflate afforded the required fully protected pentasaccharide in 70% yield (Fig. 29). Conversion of **82** into the final product **83** was achieved in 60% yield by a three-step procedure involving successive saponification, hydrogenolysis, and sulfation.

In order to circumvent side reactions (α,β-elimination, epimerization) at the uronic acid moieties during saponification of the protected pentasaccharide, we protected the carboxylate groups as benzyl esters;[42, 51] for example, pentasaccharide **84** was prepared instead of **82** (Fig. 29). The first deprotection step was hydrogenolysis to release (apart from the hydroxyl groups) the carboxylate groups, the presence of which suppresses α,β-elimination and epimerization in the subsequent saponification. Accordingly, the yields were higher (up to 96%), and the chemical purity of the end products was excellent. Consequently no ion-exchange chromatography was required to obtain pure final products. It should be stressed that this alternative protective group strategy is not possible in the synthesis of heparin fragments closely related to the natural product.

The sulfated, *O*-methylated analogue **83** displays even a somewhat higher ATIII mediated anti-factor Xa activity (1323 αXa U mg^{-1}) and a somewhat stronger binding with ATIII than the potent heparin analogue **57** (see Fig. 35).

We also synthesized pentasaccharides with longer aliphatic chains.[58] Some interesting examples are illustrated in Figure 30. Compound **85** has two linear tetradecyl groups at the 3- and 4-positions of unit D, while compounds **86** and **87** have two hexyl and butyl groups, respectively, at the same positions. To our surprise the introduction of tetradecyl groups is accompanied by a nearly complete loss of anti-factor Xa activity, whereas the corresponding butylated derivative **87** is even more active (1529 αXa U mg^{-1}) than the previously mentioned methylated pentasaccharide **83** (1323 αXa U mg^{-1}). Analogue **86** with two hexyl chains displays an intermediate activity (910 αXa U mg^{-1}).

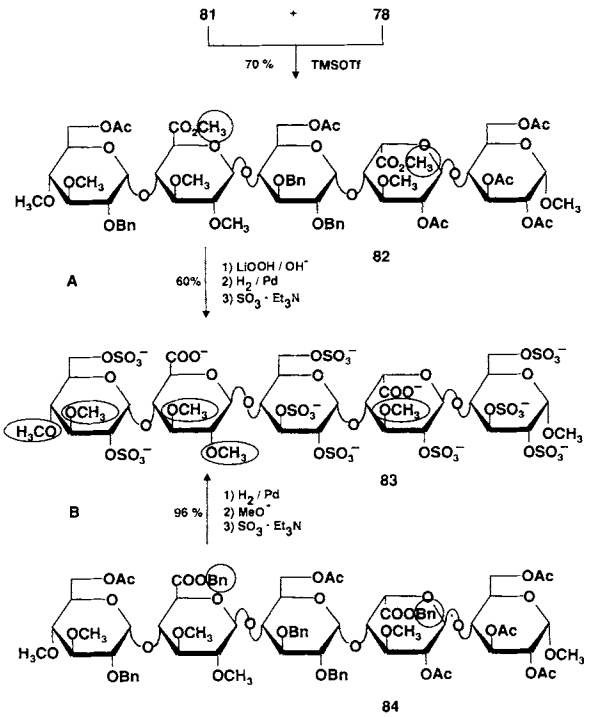

Fig. 29. Two strategies (A and B) for the preparation of non-glycosaminoglycan analogues **83**. For the synthesis of such analogues benzyl protection of the carboxylate groups is also possible (B). Deprotection of the benzyl esters by hydrogenolysis is more convenient than saponification of the corresponding methyl esters (A), because the latter deprotection conditions may cause elimination and epimerization.

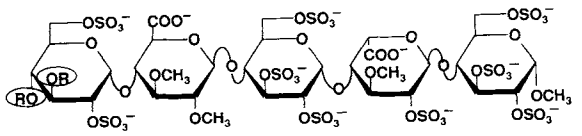

83 : R = CH_3 (1323 αXa U mg^{-1})
85 : R = $(CH_2)_{13}CH_3$ (<1 αXa U mg^{-1})
86 : R = $(CH_2)_5CH_3$ (910 αXa U mg^{-1})
87 : R = $(CH_2)_3CH_3$ (1529 αXa U mg^{-1})

Fig. 30. Some *O*-alkylated, sulfated analogues with longer alkyl chains at the D unit. When two hexyl or longer chain alkyl groups are present at the D unit, a drop in biological activity is observed. Presumably longer aliphatic chains hamper optimal interaction with AT III.

Thus, lipophilic groups of intermediate size (in the range methyl to butyl) at unit D increase the affinity of the pentasaccharide to AT III (see Fig. 35), probably owing to favorable hydrophobic interactions, but longer alkyl chains hamper an optimal binding. However, a stronger binding of an alkylated pentasaccharide with AT III does not necessarily imply increased specific activity (higher αXa activity); some hydrophobic interactions only strengthen the binding, while others also contribute to the AT III activation process (see example in Section 6.4). Furthermore, we observed that analogues with larger lipophilic groups readily adhere to other serum proteins as well, causing substantial loss of selectivity.[59]

6.4. Pentasaccharides with a "Pseudo-Alternating" Sequence; A Short Route to Simplified Analogues

The series of the sulfated, *O*-alkylated pentasaccharides provides promising candidates for drug development, because they are not only easier to synthesize, many of them display high AT III mediated αXa activity.

We wondered whether analogues could be designed for which even shorter synthetic routes could be devised. A particular appealing prospect was found[60] for derivatives with a semialternating sequence such as compound **88** in Figure 31. The EF and GH disaccharide fragments of this analogue have the same substitution pattern and differ only in configuration at C5 of the uronic acid moieties.

Taking into account the similarity between EF and GH, a route was developed in which an EF disaccharide is obtained by epimerization of a suitably protected GH disaccharide (Fig. 31). For instance epimerization of GH derivative **89** with sodium methoxide gave the corresponding EF moiety **90** in good yield. However, the EF disaccharide **90** thus obtained still contains a persistent methyl blocking group at its anomeric center. Conversion of **90** into an appropriate EF glycosyl donor requires (after protection of the 4'-hydroxyl group) acetolysis of the locked anomeric center to afford **91** in high yield. It should be stressed that both the 3-*O*- and 6-*O*-benzyl ethers were quantitatively cleaved during this last acetolysis step. One should note that this reaction sequence is only applicable in the non-glycosaminoglycan series and not in the series of heparin fragments. For the methanolate-catalyzed epimerization of GH, ether protective groups are required exclusively, whereas acetyl protective groups are required in the synthesis of heparin-like fragments. One should realize that after acetolysis of **90** to give **91** both acetyl and benzyl protective groups block the hydroxyl groups to be sulfated and that such a combination of different protective groups would not be applicable in the series of heparin-like compounds (Sections 1–5).

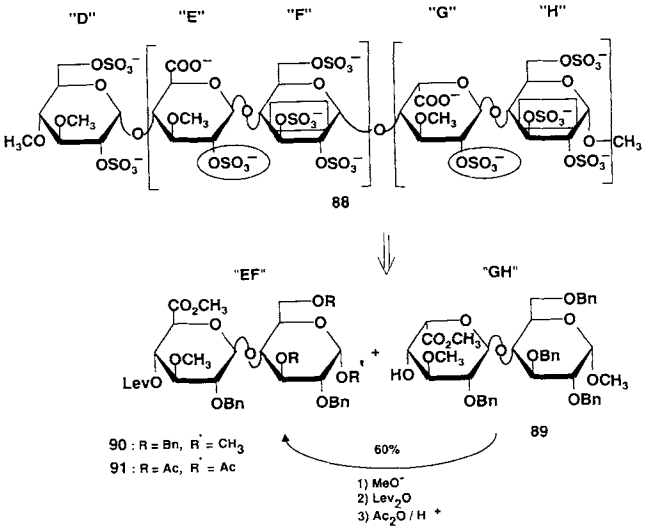

Fig. 31. By introduction of an extra 3-sulfate group at unit H and an extra 2-sulfate group at unit E, derivatives have been designed with a pseudo-alternating sequence. Thus units EF and GH of **88** are almost identical except for the configuration at C5 of the uronic acid moieties. Consequently, the suitably protected EF disaccharide building block **90** can be obtained by epimerization of the corresponding GH block **89**. This strategy can only be followed in the highly modified series of fully *O*-alkylated, sulfated analogues.

Analogue **88** displays an anti-factor Xa activity of 1150 U mg^{-1} implying that the presence of a 2-sulfate instead of 2-*O*-methyl group at glucuronic acid (unit E) reduces the activity slightly.

Another possibility for constructing a pentasaccharide with a pseudo-alternating sequence out of the lead compound **83** is the replacement of the 2-sulfate group of iduronic acid by a 2-*O*-methyl group, as seen in compound **92** (Fig. 32). Following a similar synthetic route as that described for pentasaccharide **88**, we prepared[61] several analogues methylated at the 2-O- and 3-O-positions of both uronic acid moieties (units E and G). We expected that the biological activity of these analogues would be less than half

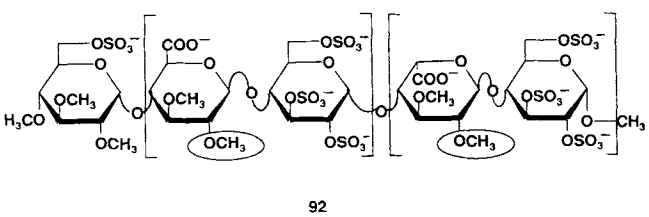

Fig. 32. In analogy to pentasaccharide **88**, a derivative with a pseudo-alternating sequence (**92**) can be designed by replacement of the 2-sulfate group of α-L-iduronic acid by a 2-*O*-methyl group. To our surprise compound **92** is the most active pentasaccharide found so far. Since removal of the 2-sulfate group of unit G in the natural compound would reduce the anti-Xa activity about fivefold, it may be concluded that methylation facilitates other favorable interactions, for example hydrophobic interactions.

of that observed for compounds in the series of heparin-like fragments lacking the 2-sulfate group of iduronic acid. However, quite unexpectedly, the methylated analogues turn out to be highly potent. Analogue **92**, which contains a 2,3,4-tri-*O*-methylated D unit, is the most active pentasaccharide identified so far with an anti-factor Xa of 1611 U mg^{-1}, notwithstanding the fact that two sulfate groups present in the natural product (at the 2-O-positions of units D and G) are lacking. The methyl groups at these positions may possibly interact even better with AT III than the corresponding sulfates, implying that the loss of electrostatic interactions may be compensated by favorable hydrophobic or van der Waals interactions. Alternative explanations for this phenomenon may be found in a reduced free energy of dehydration of permethylated analogues with respect to nonalkylated derivatives, or by assuming a decreased dielectric constant in the pentasaccharide binding region of AT III.

7. The Role of the Pentasaccharide in Antithrombin Activation

7.1. Kinetic Data and Binding Constants

As mentioned in Section 1 the characteristic heparin pentasaccharide and larger heparin fragments containing this sequence accelerate reactions of AT III with some serine proteases such as blood coagulation factor Xa. For the inactivation of other serine proteases, for instance thrombin, is not only the presence of the unique pentasaccharide a prerequisite but in addition the heparin chain should be at least 18 saccharides in length.[62] This phenomenon has been explained by a reaction that is composed of two distinct mechanisms: a conformational change of AT III (brought about by the pentasaccharide; see Figs. 2b and 34) and the bridging of AT III and thrombin by the same heparin chain (Fig. 33; a longer heparin chain is required as a bridge).[62, 63]

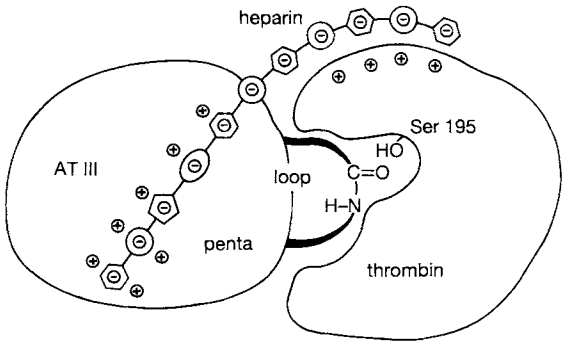

Fig. 33. For accelerating the AT III mediated inactivation of thrombin not only the unique pentasaccharide domain is required to interact with AT III but the heparin chain should also be long enough (about eighteen sugar units) to form a bridge between AT III and thrombin.

The mechanism of action of heparin was revealed by several kinetic studies.[62–64] In Figure 34 the role of the pentasaccharide in the AT III mediated inactivation of factor Xa is shown in greater detail. The pentasaccharide acts in a two-step process: first it binds to AT III (formation of the weak complex B) and achieves equilibrium quickly; then the protein undergoes a conformational change to give the activated form of AT III (C).[64] During this conformational change the interaction of the pentasaccharide with AT III strengthens. The activated form of AT III binds with factor Xa to give a stable AT III/Xa complex (D), while the pentasaccharide—the catalyst in this reaction—is released.

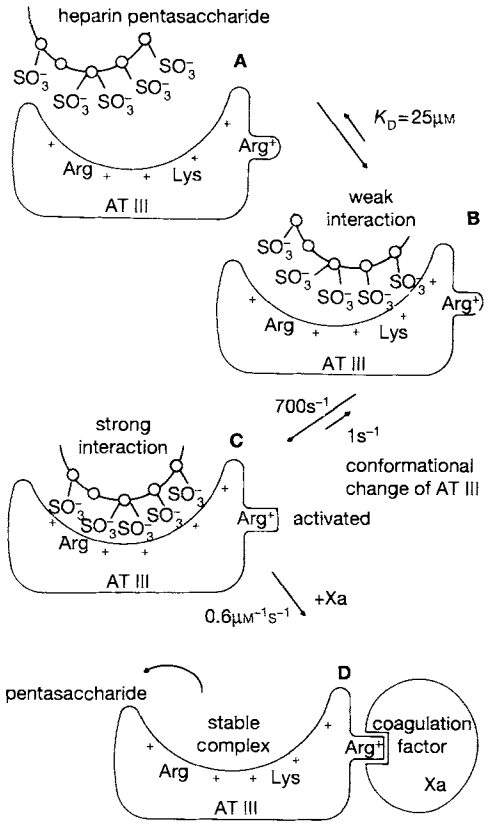

Fig. 34. Mechanism of action of the pentasaccharide as derived from kinetic studies. Initially the pentasaccharide binds to AT III (conversion of A to B), reaching equilibrium rapidly. The weak complex B changes conformation to deliver the activated pentasaccharide/AT III complex C. The active complex C then reacts with factor Xa to give a stable AT III/Xa complex D. During the formation of D another conformational change takes place, which amongst others causes the release of the pentasaccharide. When we discuss binding (dissociation) constants of the various AT III/pentasaccharide complexes, the formation of complex C is meant. In measurements of the anti-factor Xa activity, complex C and a chromogenic substrate (S2222) complete for binding with Xa.

The dissociation constant K_D for the AT III/pentasaccharide complex (C) has been determined by several groups with values between 36 and 300 nM. Obviously the value depends on the conditions, for example the pH value, and the type of AT III used. Similar studies performed with various pentasaccharide analogues have proved to be of great value in understanding the AT III activation process. For instance Atha et al. reported[35b] that tetrasaccharides comprising the DEFG and EFGH part of the pentasaccharide show 100-fold and 1000-fold lower affinity, respectively, for AT III than the pentasaccharide. These results are in line with the observation that the 6-sulfate at unit D is absolutely essential. Pentasaccharide **45**, which is not sulfated in the 3-position, binds AT III very weakly ($K_D = 5 \times 10^5$ nM), and shows essentially no capacity for effecting a conformational change in AT III.

Visser et al. studied[65] the influence of the sulfate groups at unit H (Fig. 35a). Introduction of an extra 3-sulfate group giving the potent analogue **57** leads to roughly 15-fold increase of the binding affinity for AT III, whereas removal of the 6-sulfate group from unit H (compound **93**) gives a four- to fivefold decrease. It was also shown that the decreased anti-factor Xa activity derivative **58**, which has an extra sulfate group at unit E, corresponds to a higher dissociation constant of the pentasaccharide/AT III complex.

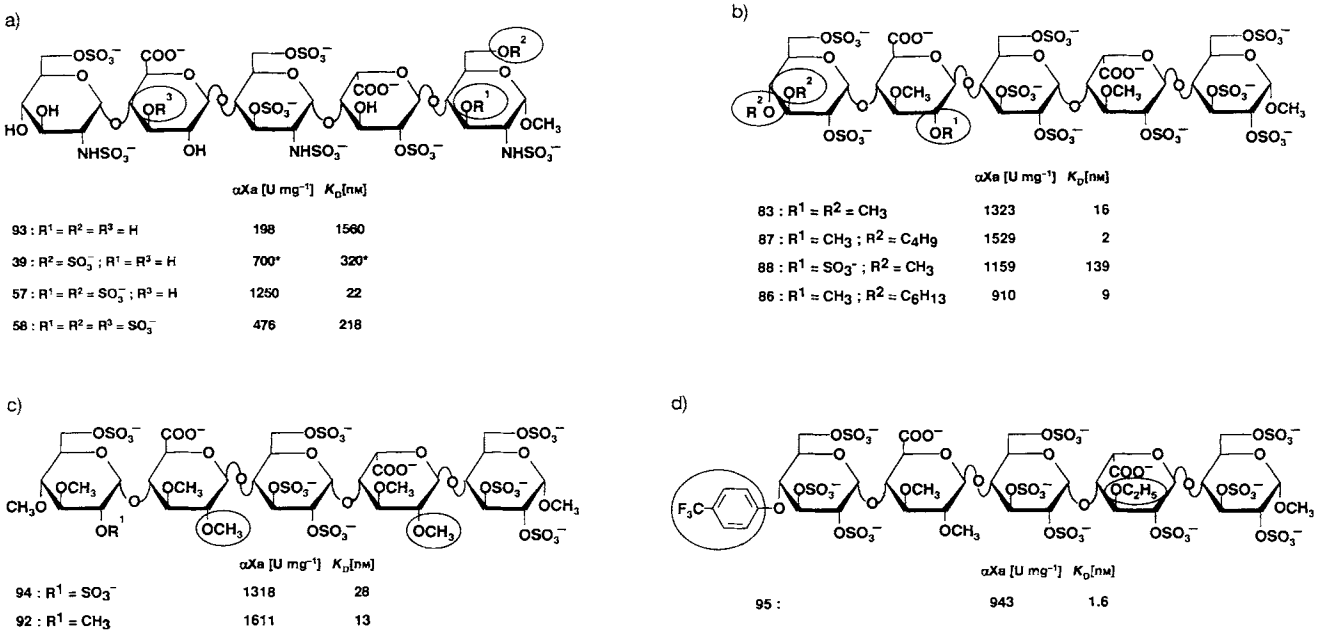

Fig. 35. Synthetic pentasaccharides and their anti-factor Xa activities and dissociation constants K_D with AT III. For a discussion see the text.

In Figures 35b and 35c the highly potent alkylated analogues **83**, **87**, **92**, and **94** are shown, which have not only improved anti-factor Xa activity but also increased affinity with AT III. Several non-glycosaminoglycan derivatives containing lipophilic, aliphatic, and aromatic residues (Fig. 35d) have also been synthesized. Most of these derivatives display strong binding with AT III (K_D up to 1.6 nM for compound **95**) but relatively low anti-factor Xa activity (< 1000 αXa U mg^{-1} for compound **95**). Moreover, the alkylated analogues also bind to other plasma proteins. These results may indicate that the derivatives are amphiphilic and therefore readily stick nonspecifically to positively charged domains of any protein.[59]

7.2. A Model of the Antithrombin–Pentasaccharide Complex

More detailed information about the interaction of the pentasaccharide with AT III was obtained after construction of a three-dimensional molecular model of the complex.[66] First a molecular model of AT III was built based on the crystal structure of cleaved α_1-antitrypsin (a member of the serpin superfamily to which AT III also belongs). Then the positively charged amino acid residues of AT III that have been identified to be essential in the interaction process (Lys 125, Arg 129, Arg 132, Lys 133, Lys 136, Arg 46, Arg 47) were highlighted. Since these amino acids display an asymmetric assembly of interaction points complementary to the essential charged groups of the pentasaccharide (Figs. 36b and 36c), the orientation of AT III and pentasaccharide toward each other could be established unambiguously in a docking trial. The model was optimized by molecular dynamics calculations in which water was assumed as solvent (Fig. 36d). The important AT III/pentasaccharide interactions are schematically depicted in Figure 37. Other reports also indicated the heparin binding region by using crystal structures of cleaved α_1-antitrypsin,[67] cleaved AT III,[68] and ovalbumin,[69] but neither the orientation of the pentasaccharide toward the binding region nor the possible interactions between complementary groups were outlined.

Recently, we performed a similar study using the crystal structure of intact AT III.[70] Although the two interaction schemes resemble each other closely, some binding characteristics differ significantly. It is interesting to note that in the crystal structure of AT III, Lys 125 and Arg 129 are located on one face of an α-helix denoted helix D, whereas the region Arg 132, Lys 133, Lys 136 possesses a coil-like conformation. During the molecular dynamics simulation in the presence of the pentasaccharide, helix D has a tendency to extend (or "elongate"). This coil–helix conformational change allows the basic side chains to interact better with the essential charged groups of heparin.

It should be recalled that there is much experimental evidence indicating that heparin stabilizes α-helical conformations by reducing detrimental electrostatic interactions between Lys and/or Arg side chains.[71] In this respect it is tempting to speculate that the pentasaccharide-induced elongation of helix D is the trigger for the well-known conformational change in AT III. Nevertheless, it is recognized that the overall conformational transition of AT III is much

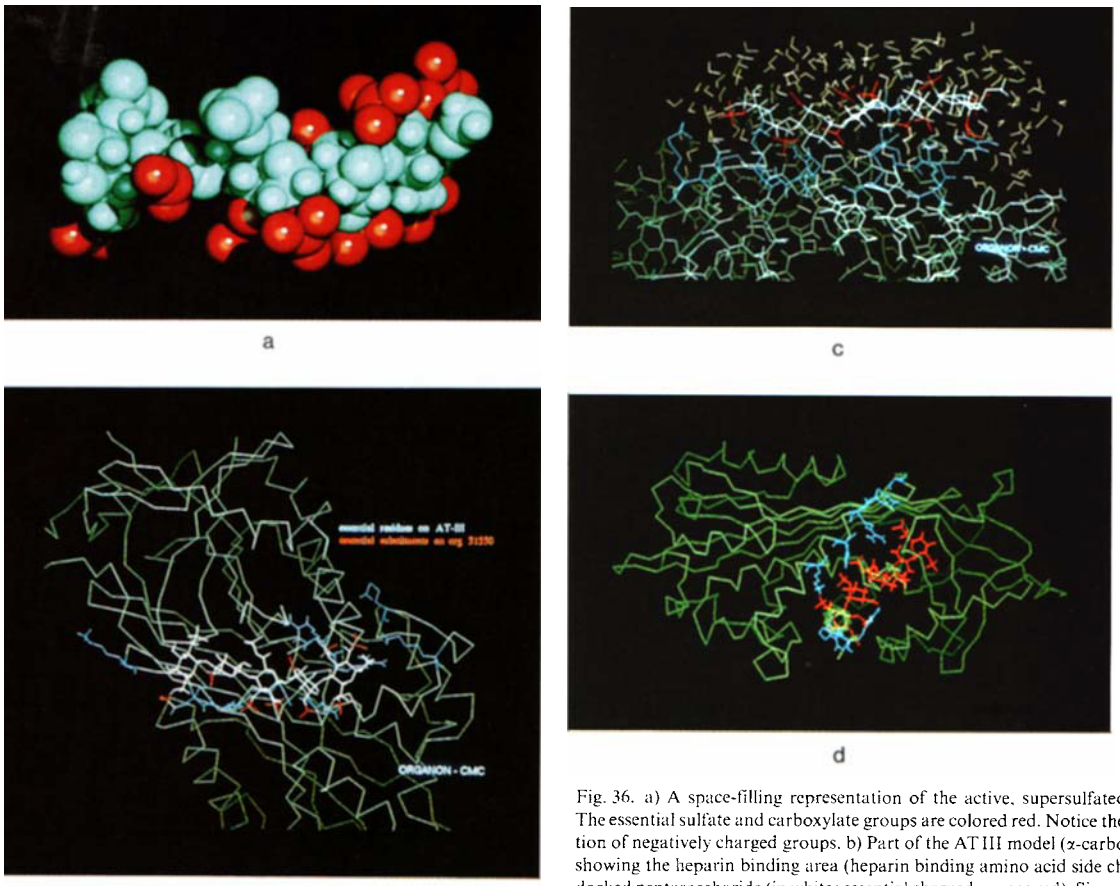

Fig. 36. a) A space-filling representation of the active, supersulfated pentasaccharide **57**. The essential sulfate and carboxylate groups are colored red. Notice the asymmetric distribution of negatively charged groups. b) Part of the AT III model (α-carbon backbone in green) showing the heparin binding area (heparin binding amino acid side chains in blue) with the docked pentasaccharide (in white; essential charged groups red). Since both the pentasaccharide and the protein have an unsymmetric assembly of interaction points, their relative orientation could be established unambiguously. c) Part of the complex of AT III and pentasaccharide **57** after hydration and further optimization by molecular dynamics calculations. d) Model of the complex of AT III and pentasaccharide **57** after molecular dynamics (30 ps). For the sake of clarity the water molecules have been omitted (pentasaccharide in red; essential amino acid side chains in blue). This complex is shown schematically in Figure 37.

more complex, since the protease binding loop of AT III becomes either more or less exposed by its partial insertion between strands S3 and S5 of "A" sheet of the protein.[71] A crystal structure of the AT III/pentasaccharide complex should give a definitive answer to the question as to how heparin activates AT III.

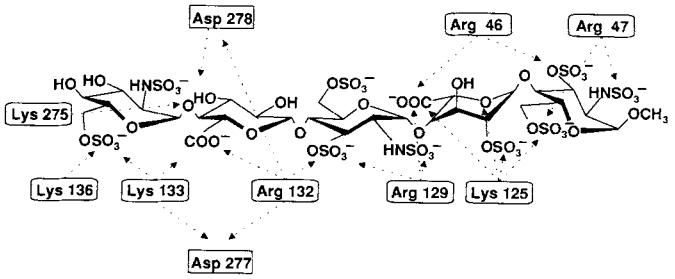

Fig. 37. Schematic diagram of the hydrogen-bonding network in an energy-minimized model of the complex of AT III and pentasaccharide **57**.

8. Summary

It is now assumed that the anticoagulant drug heparin interacts with various proteins through either cooperative or specific binding or both types of interactions. Numerous examples[2, 71a] have been described for heparin–protein interactions in which cooperative interactions appear to dominate; the longer the polysaccharide (and the higher the charge density), the higher the apparent affinity, because more positively charged areas can fit along the heparin chain. That highly specific interactions may occur became apparent when the heterogenous pentasaccharide domain of heparin was discovered, which accelerates the interaction of AT III with coagulation factor Xa. Indeed, other polyanions cannot substitute for the pentasaccharide in the binding and activation of AT III. In our opinion the discovery that a unique domain of a glycosaminoglycan, here the heparin pentasaccharide, is associated with a specific biological activity is a breakthrough in a hardly explored area of molecular biology. Unfortunately up to now only a few other examples of specific structural units in glycosaminoglycans are known.[72] For the AT III mediated inactivation of factor Xa the characteristic pentasaccharide represents the minimum chain length, but for the inactivation of thrombin (IIa) by the same serpin the heparin chain should be much longer (at least 18 carbohydrate units in length). Concerning the latter example there is good evidence that the heparin chain interacts specifically and strongly with AT III but only weakly and less specifically with thrombin.[63b]

A series of about fifty synthetic analogues of the unique pentasaccharide has provided significant advances in our

understanding of the heparin-mediated activation of AT III. The various aspects of this interaction and activation are summarized as follows:

1) The heterogenous pentasaccharide domain of heparin is the only polyanion identified so far that is able to trigger the conformational change in AT III.

2) The pentasaccharide possesses two essential sulfate groups, two essential N-sulfate groups, and two essential carboxylate groups. Removal of one of these key sulfate or carboxylate groups leads to a nearly complete loss of activity, while the presence of two to three more sulfate groups in the molecule appears to increase the activity.

3) The sulfation of the 3-hydroxyl group of the reducing unit (H) improves the biological activity, whereas sulfation of other hydroxyl groups is accompanied by a drop in activity. The persulfated pentasaccharide displays no significant activity.

4) The orientation of the key charged groups in space is important, since epimers display reduced activity.

5) The type of charge is crucial. Thus an essential sulfate group cannot be replaced by a phosphate group, and the carboxylate groups of the uronic acid moieties may not be exchanged for $CH_2OSO_3^-$ residues. These results suggest that the essential charged groups of heparin interact with the complementary residues of AT III through ordered hydrogen bonds.

6) The rigidity of some carbohydrate units such as glucuronic acid (unit E) is required, whereas flexibility of others such as iduronic acid (unit G) is allowed or even necessary.

7) AT III exposes also some negatively charged amino acid side chains in the heparin binding site which may repel charged residues of other polyanions, thereby increasing the selectivity.

8) The hydroxyl groups of the pentasaccharide do not function as hydrogen bond donors in the interaction process, since methylation of the hydroxyl groups does not reduce the activity. Neither are the hydrogen atoms of the sulfated amino groups important hydrogen bond donors, because N-sulfate can be replaced by sulfate.

9) Hydrophobic interactions may improve the binding and may increase the specific activity. In the most active derivative found so far, compound **92** (Fig. 32), two contributing sulfate ester groups are replaced by methoxy groups. However, larger hydrophobic substituents may hamper the AT III activation, while amphiphilic derivatives tend to bind nonspecifically with other proteins.

9. Outlook

The importance of the biological function of glycosaminoglycans in the control of key processes like cell growth, cell migration, cell differentiation, and cell adhesion is becoming more clearly recognized. For a long time investigation of these phenomena at the molecular level has been frustrated by a lack of suitable physico-chemical methods. Therefore it is not yet clear how many of these biological functions are associated with relatively short, well-defined domains of the complex, high molecular weight glycosaminoglycans. We feel that the example of heparin, in which a characteristic partial structure is associated with the known antithrombotic properties, should stimulate research in identifying the structures of other important domains of glycosaminoglycans. Finally, application of the preparative methods discussed in this article should offer opportunities for the development of new drugs.

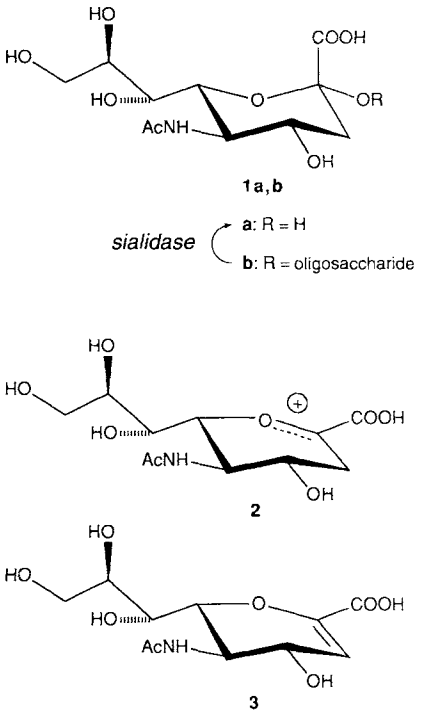
Got the Flu? Try a Designer Agent Derived from a Sugar

By *Carlo Unverzagt**

When we get the flu, all we can do besides reaching for the next handkerchief is hope that it will be over within a few weeks. Afterwards we are usually protected against a new infection for a while. However, the chances of catching the flu several times a year are high, even after an influenza vaccination. The flu caused by the influenza virus can be particularly dangerous for older people and those afflicted with diseases of the respiratory tract. A group of Australian researchers examined this problem and developed a synthetic antiinfluenza drug derived from *N*-acetylneuraminic acid (**1a**),[1] which is currently being tested as a nasal spray by Glaxo. This compound was designed based on the protein structure data from a complex of the influenza sialidase with an inhibitor.

Why doesn't our immune system give us permanent protection against influenza? The virus is capable of rapidly changing its surface antigens, thus outwitting the body's defense system which posesses no antibodies against the new virus forms. Animals can also contract influenza, and most likely the infection of an organism with two different types of influenza viruses leads to new highly pathogenic strains that may give rise to a pandemic.[2] Despite the variability of the two influenza surface antigens hemagglutinin and sialidase (neuraminidase), their functions remain conserved. Both proteins bind to the sugar *N*-acetylneuraminic acid (Neu5Ac, **1a**; Scheme 1), a member of the family of sialic acids. The sialic acids constitute an important part of the cell surface where they are mostly exposed at the termini of the carbohydrate chains on glycoproteins and glycolipids. Sialic acid (**1b**), located on the cell surface of the respiratory tract epithelium, is recognized by hemagglutinin. This allows the virus to adhere and promotes the following infection. With a function opposite to that of the hemagglutinin, sialidase enzymatically cleaves the glycosidic bond of sialic acid. It is thought that this allows release of the newly formed virus particles from the host cells. The cycle of infection and replication of the influenza virus is based on the recognition of terminal *N*-acetylneuraminic acid, thus offering a good lead in the development of a drug.

The X-ray crystallographic data of hemagglutinin and sialidase have been known for more than a decade; however, those data were unsatisfactory. Only recently X-ray structure analyses with good resolution have been published for complexes with the ligand *N*-acetylneuraminic acid.[3] A well-studied inhibitor of influenza sialidase is the glycal 2-deoxy-2,3-dehydro-*N*-acetylneuraminic acid (Neu5Ac2en) **3**,[4] which can be regarded as an analogue of neuraminyl cation **2**. In the sialidase reaction this type of cation has been proposed[5] for the conversion of the glycosidically bound (**1b**) into free *N*-acetylneuraminic acid (**1a**). Sialidase binds



Scheme 1.

to inhibitor **3** with higher affinity ($K_i \approx 1 \times 10^{-6}$ M) than to its natural substrate *N*-acetylneuraminic acid (**1a**) ($K_i = 6.9 \times 10^{-4}$ M). Glycal **3** is a competitive inhibitor, and it is slowly hydrated by sialidase to give **1a**,[6] which supports the assumption that **3** binds as a transition state analogue. Starting from **3** as a lead structure, von Itzstein et al. have now succeeded in designing a significantly more potent inhibitor.[1] They relied mainly on a crystal structure of the influenza sialidase carrying **3** in the binding pocket.[3a] By molecular modeling they screened the surface of the enzyme's binding pocket for sites that might allow additional interactions with the protein after replacement of functional groups in **3**. What they found was a groove next to OH-4 lined by acidic amino acids. According to this analysis, a particularly favorable interaction of the 4-amino group of 4-amino-Neu5Ac2en **4a** with the carboxylate of Glu-119 was predicted. An even stronger salt bridge was anticipated for 4-guanidino-Neu5Ac2en **4b** (Scheme 2).

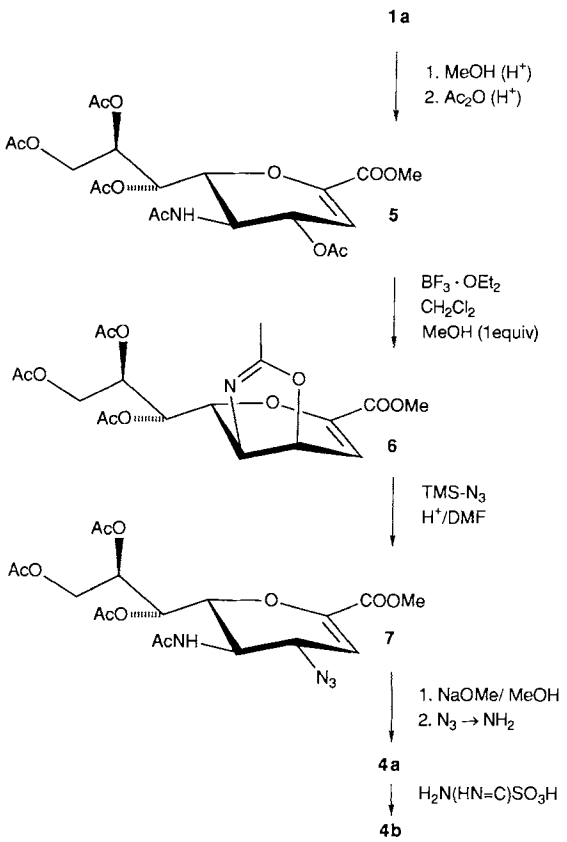
The inhibitors **4a, b** proposed in the preceding analysis were synthesized, and the crystal structure of their complexes with influenza sialidase showed that the predicted ionic interactions indeed formed. The 1-carboxylate residue keeps the molecule in place by contacts with the basic arginine residues 118, 292, and 371. The 4-amino group of **4a** is part of a salt bridge to Glu-119, whereas the 4-guanidino moiety of **4b** is bound by two glutamic acids (119 and 227). This additional ionic attraction of compounds **4a, b** through the substituents at C-4 explains their high potency as sialidase inhibitors. The amino compound **4a** has an inhibition constant of $K_i = 5 \times 10^{-8}$ M, **4b** has $K_i = 2 \times 10^{-10}$ M. Compounds **4a** and **4b**, which have in vitro activities in the nanomolar and subnanomolar range, are the most potent inhibitors of the influenza sialidase known to date.

How significant is the high activity of the new inhibitors? Will they stop an influenza infection in the organism? To answer these questions it is necessary to take a look at their selectivity. Sialidases are ubiquitous,[7] and interference of human sialidases as a part of influenza treatment might lead to complications. Probing of human and bacterial sialidases with the analogues modified at C-4 showed that those enzymes are inhibited only weakly.[8] It is likely that the high selectivity observed is related to the special groove within the binding pocket of the influenza sialidase. Large substituents at C-4 are tolerated by the influenza enzyme; this cleft is apparently not found on the other sialidases examined.

Initial experiments in tissue cultures and in the animal model (ferret) revealed that **4b** is much more active than amantadine and rimantidine; however, the latter inhibitors operate through a different mechanism of action. Interestingly, the parent compound **3** is nearly inactive in the animal model, but **4b** inhibits viral replication in the organism very efficiently.[1] It was thus shown for the first time that efficient and selective inhibition of influenza sialidase by the high affinity inhibitor **4b** can suppress an outbreak of influenza.

With their high rate of mutations, the influenza viruses might be selected by **4b** for sialidase variants lacking the groove for bulky substituents at C-4. In principle this cannot be ruled out entirely, but it would contradict the observed conservation of amino acids in the catalytic center and the scaffolding region surrounding it. Under conditions favoring the rapid occurrence of amantadine-resistant strains, no variants with resistance to **4b**[1] were observed. If the preliminary results are confirmed and the activity of **4b** proves to be equally high in humans as in animals, the question of availability arises before the drug goes into clinical trials. Chemical synthesis of **4b** (Scheme 3) begins with *N*-acetylneuraminic acid (**1a**),[9] an expensive starting material currently offered at a significantly lowered price of about \$35000 per kg.

N-acetylneuraminic acid (**1a**) is esterified with methanol followed by acetylation under acidic conditions to give the protected glycal **5**. In an intramolecular reaction, the allylic acetate moiety at C-4 is substituted by the neighboring acetamide. The conversion of **5** catalyzed by borontrifluoride–ether provides intermediate **6**[10] with an inverted configuration at C-4. Opening of the oxazoline ring activated by an allylic system readily occurs with nucleophiles such as azide, furnishing the 4-azido compound **7** with the configuration of 2,3-dehydro-*N*-acetylneuraminic acid. Starting



Scheme 3. DMF = *N*,*N*-dimethylformamide, TMS = trimethylsilyl.

from *N*-acetylneuraminic acid (**1a**), each reaction step can be performed in high yields. Subsequent cleavage of the acetate groups and the methyl ester, reduction of the azido group, and reaction of the resulting amine **4a** with aminoiminomethanesulfonic acid gives the guanidino compound **4b** in "reasonable" yield.[1, 10c] The synthesis, which appears laborious at first glance, leads to a compound whose price is likely to be high owing to the expensive starting material and the number of steps needed; nevertheless, economical production is mainly dependant on the cost of *N*-acetylneuraminic acid (**1a**) (vide supra).

For clinical trials and the approval of a compound it is crucial to produce "buckets" of inhibitor.[11] A pharmaceutical "glyco" industry has existed for only a few years, and solutions to such problems need to be developed. Other projects for pharmaceuticals based on carbohydrates are also promising and have stimulated the chemical industry.[11] Sugar chemistry, once considered too difficult to find application, has finally received the attention deserved, in part because of the rapidly increasing knowledge about the numerous biological functions of carbohydrates.[12]

In summary inhibitors **4a, b** of influenza sialidase are the results of more than a decade of work. Data obtained from protein crystallography led to the rational design of a tailor-made inhibitor with unequaled activity.

Electrochemical Production of Zintl Anions: Renaissance of a Synthesis Route**

By *Brigitte Eisenmann*

Among the three large classes of compounds, saltlike, covalent, and metallic, the intermetallic compounds are to a chemist's way of thinking the least accessible and developed. This holds true for both the conformity to stoichiometric laws, which so far have only be derived for a few compounds, and for the crystal structures, whose packing of large, interpenetrating coordination polyhedra do not allow for an obvious recognition of the distribution of valence electrons and thereby their bonding strength. Comparative analyses of the dominating structural elements, geometric factors, and valence-electron concentrations as well as model and band structure calculations, like that recently, comprehensively discussed by Nesper,[1] have led to a closer approach to this class of compounds.

The goal of the investigation that Haushalter et al. reported in the November issue of *Angewandte Chemie*[2] was to generate reactive intermetallic building units from which conducting or semiconducting films and solids for various applications could be constructed by chemical methods.

The preliminary attempts to find an experimental route to intermetallic phases starting from known terrain were carried out by Eduard Zintl. Already in the first communication about metals and alloys in 1931, the main emphasis was the transition between salts and metals, and dealt with saltlike and intermetallic compounds of sodium in liquid ammonia.[3] Zintl took into consideration the observations of Joannis in which solutions of sodium in liquid ammonia were found to react with a series of metals and semimetals such as lead or antimony to give intensely colored solutions.[4] According to the investigations by Kraus, the deep green Na–Pb solutions are electrolytes from which lead can be anodically deposited and anionically dissolved lead can be precipitated through the addition of Pb^{2+} salts, and in which lead can be cathodically dissoluted.[5]

Zintl took these individual observations and placed them in a wider context by performing these reactions systematically with the elements of the main and subgroups, starting with the chalcogenides and progressing to the left, and monitored the reactions by potentiometric titrations. The elements were initially placed in liquid NH_3, either as suspensions or in the form of the corresponding sulfides or iodides which dissolve. These were then titrated under rigorous exclusion of air with a solution of Na in liquid NH_3. Conversely, the latter can also be treated with solutions of the element halides. This experimental procedure gives the composition of the compounds formed in solution, detectable as the turning points of the titration curves, and leads to the formulation of polyanionic compounds such as Na_4Pb_9, Na_4Pb_7, Na_3Sb_3, Na_3Sb_7, or Na_3Bi_5. The finding that elements of the fourth main group are still anionically dissoluted but those of the third group are not, formed the basis for drawing a border between the anion and cation constituents; thus between the third and fourth main groups (Zintl border). Experiments concerning the cathodic dissolution of Pb, Tl, Sn, and Ge in solutions of alkali metal halides in water-free ammonia were successful only with lead as the cathode, already with Sn the electrodes remained clean, so this synthesis route was not further pursued.[6] In order to prevent the contamination of solutions with alkali metal halides, subsequently a reaction course was preferred in which alloys preprepared in fusion reactions were investigated with respect to their solubility in liquid NH_3.[7]

The polyanionic salts like $Na_4Pb_9 \cdot x NH_3$ are only stable as ammoniates. They separate from these solutions at low temperatures on concentration as X-ray amorphous, green-black residues. As the ammonia is removed, the salts lose solvent molecules and transform into alloy-like compounds such as $NaPb_{3-x}$, which correspond to the products of melt reactions.

The structure of these polyanions, which today are often termed as Zintl anions, remained unexplained at the time. In 1970, Kummer and Diehl first succeeded in preparing a crystalline compound, $[Na_4(en)_7]Sn_9$ (en = ethylenediamine).[8] The exchange of the solvent ammonia with en also proved to be a significant step with respect to the synthesis of other new compounds. The crystal structure determination of $[Na_4(en)_7]Sn_9$—reported for the first time in 1973—revealed that the cluster anion Sn_9^{4-} exists in the form of a square antiprism with one square face capped; the electron

count is consistent with Wade's rules for a *nido* cluster.[8] According to investigations by Corbett, the dissolution of such pre-prepared alloys is noticeably facilitated through the addition of macrobicyclic aminopolyethers, such as [2.2.2]cryptate. These exhibit high ionic selectivities and complex formation constants for alkali metal and alkaline earth cations. By using complexed cations as counterions, it became possible to crystallize and characterize additional Zintl anions such as Bi_4^{2-}, Pb_5^{2-}, Sn_9^{3-}, and Ge_9^{2-}, and others which are like Sn_9^{4-} cluster anions with multicenter bonds.[9]

The main route for the preparation of alkali metal and alkaline earth compounds with metals, semimetals, and heavy nonmetals of the third to sixth main groups, which comprise the class of Zintl compounds, proceeds through the reaction of mixtures of the elements in melts or high-temperature syntheses. The phase diagrams of the systems under consideration often consist of many phases, thus presenting problems for the production of single-phase products. The high heat of reaction can be controlled by meticulous regulation of the heating rates. If the starting materials show considerably different vapor pressures, the reactants can be placed in zones of differing temperatures, and the more volatile components can be slowly sublimed. This synthesis technique has proven effective, especially for the production of phosphides.[10]

The stoichiometries and structures of the intensely colored to metallic gray, air-sensitive compounds obtained by this method show considerable possibilities of variation. Their polarity and thus their classification in the transitional "ionic–metallic–covalent" domain with respect to structure, reactivity, and physical properties are clearly recognizable. The structures can be interpretated on the basis of an ionic approach (Zintl–Klemm concept), which is supported by results of Zintl's experiments. The anionic substructures obey the $(8-N)$ rule, in which N corresponds to the number of valence electrons, including those taken up. Each atom therefore reaches a complete shell of eight electrons by picking up electrons and/or through bond formation. The one-, two-, or three-dimensional atomic units are not limited to anions analogous to elemental entities like the P_4 analogue $[Si_4]^{4-}$, the As analogue $^2_\infty[Si^-]_n$, or the Se analogue $^1_\infty[As^-]_n$. Such units have been found in which the atoms exhibit different coordination numbers; these include chain fragments like $[As_4]^{6-}$ or nets with two- or three-coordinate atoms like $^2_\infty[Sb_3^{3-}]_n$ and many others.[11]

The existence of these anionic moieties containing atoms with various coordination numbers leads to the question of whether it is possible to prepare the corresponding alkali metal and alkaline earth compounds having heteroanions of metalloids. The structural characterization of such heteroanions is of special interest in cases in which the tendency towards the completion of an electron octet is not structurally determining in the binary parent compounds—as apparent from their structural organization. This applies to Sb_2Se_3, whose structure reveals both pseudo-tetrahedral and also pseudo-octahedral coordination for Sb, and to Sb_2Te_3 and Bi_2Te_3 (Fig. 1) as well as Sn_4As_3, whose atomic arrangement is dominated by octahedral and pseudo-octahedral coordination.

High-temperature reactions starting from mixtures of the elements have been shown to be the most suitable synthesis

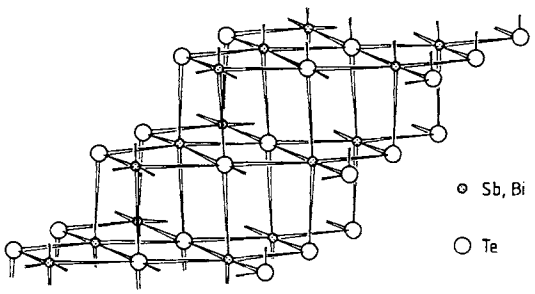

Fig. 1. A section of the crystal structure of Sb_2Te_3 and Bi_2Te_3.

route for these compounds. Difficulties arising from the strong formation tendencies and high melting points of some of the binary compounds formed, can be avoided, at least sometimes, by reacting suitable compounds with one another or with the appropriate element.

The structures of the compounds prepared by high-temperature reactions reflect the influence of the additional valence electrons and the different electronegativities. There is a clear tendency toward the formation of anionic subunits analogous to those anions of complex acids like silicates or phosphates, in which the less electronegative elements are saturated primarily through bonding and are either tetrahedrally or pseudo-tetrahedrally coordinated, as for example $[SnSb_4]^{8-} = [SiO_4]^{4-}$, $^1_\infty[SnAs_3^{5-}]_n = {}^1_\infty[SiO_3^{2-}]_n$, and $[SbTe_3]^{3-} = [AsO_3]^{3-}$.[11] Also groups in which the central atom is in a low oxidation state have been realized, such as $[As_2Te_4]^{4-}$ or $[Sn_2P_6]^{12-}$. Antimony and bismuth chalcogenide anions, like the $^2_\infty[BiTe_2]$ layer (Fig. 2) in $SrBiTe_3$, often show, corresponding to that observed in the binary compounds, high coordination numbers.[12]

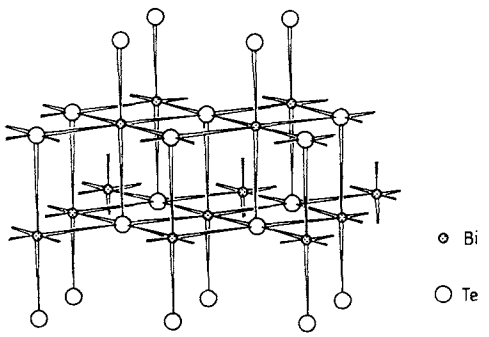

Fig. 2. A section of the $[BiTe_2]$ substructure in $SrBiTe_3$.

Here again the solubility of such compounds as well as the type and structure of solubilized species must be taken into account when considering their suitability as building units. By reacting an alloy of the net composition KTlTe with [2.2.2]cryptate and en, Corbett in 1981 was able to isolate for the first time the ternary compound $[K\text{-}([2.2.2]\text{cryptate})]_2Tl_2Te_2$ whose structure contains a $[Tl_2Te_2]^{2-}$ anion in the form of a folded four-membered ring.[9] Schäfer et al. demonstrated in 1983 that it is possible to react elements directly in en. The reaction of Ba, Sb, and Se in molar ratio 1:1:2 in boiling en afforded compounds possessing ortho anions of antimony in oxidation states of V and III, $[Ba(en)_x]_3(SbSe_4)_2 \cdot y\,en$ and $[Ba(en)_2]_3(SbSe_3)_2$, respectively. These compounds crystallize successively out of solution.

The reaction of Ba with Sb_2Se_3 in boiling en yielded, besides the two compounds mentioned above, an additional reaction product namely the polyselenidoantimonate(III) $[Ba(en)_4](SbSe_2)_2$.[13] The extraction of $Ba_4Sb_4Se_{11}$, a compound whose structure contains discrete $[SbSe_3]^{3-}$ and dimeric $[Sb_2Se_4]^{2-}$ anionic groups as well as Se_2^{2-} ions, with en at room temperature generated the same product mixture. These results show that the anionic or neutral groups present in the starting materials have little influence on the nature of the reaction products even under mild reaction conditions; the addition of cryptates also does not have any effect in the latter reactions. Since, as always, only the crystalline products are identified, the reactions are incompletely characterized. The influence of reaction parameters such as temperature and time have also not yet been analyzed. The complexity of the reactions, caused by, inter alia, differing solvating and binding energies, can be illustrated by several examples.

The reaction of the elements Ba, As, and Te in the ratio 1:1:2 under the same conditions as above, leads to a red crystalline compound $[Ba(en)_4]_2As_4Te_6$, whose anion is shown in Figure 3.[14] So far only the binary selenide [Ba-

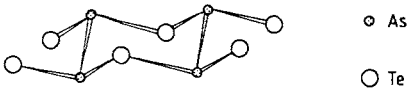

Fig. 3. The structure of the $[As_4Te_6]^{4-}$ anion.

([2.2.2]cryptate]η^1-en]Se_4[13] has been isolated from the extraction of $BaBiSe_3$ with en and addition of [2.2.2]cryptate, whereas the corresponding extraction of an alloy with the formal composition KPbSe yields the compound $[K\text{-}([2.2.2]\text{-cryptate})]_2Pb_2Se_3$.[15] These examples are not limited to chalcogenide anions. From KSnAs, whose structure is dominated by a $^2_\infty[SnAs^-]$ net, it is not possible to extract any soluble species with en. The soluble compound $[K\text{-}([2.2.2]\text{-cryptate})]_4SnAs_{14}$ can be produced, and deposited as dark orange crystals, only from a starting material obtained from a melt consisting of K_3As_7 and 2 Sn.[16] $[K\text{-}([2.2.2]\text{-cryptate})]_2Sn_2Bi_2$ is isolated from the solution reaction of "KSnBi", the composition of which does not correspond to a defined ternary compound. $[Sn_2Bi_2]^{2-}$ cluster anions analogous to P_4 exist in the crystal structure.[9]

The considerable number of fundamental and stimulating results is balanced by the number of unsolved problems. The amount of time necessary to obtain sufficiently crystalline products should also not be underestimated.

In this context, the synthesis of the new Zintl anions $[Sb_4Te_4]^{4-}$ and $[Sb_9Te_6]^{3-}$ by Haushalter et al. is especially relevant.[2] Not only the addition of two new Sb–Te anions in which antimony coordinates in different ways to tellurium, generating structures completely different from those previously reported for the handful of known Sb–Te compounds, deserves mention, but more importantly also the synthesis route. Here an "old" observation is adopted—in Zintl's experiments only the cathodic dissolution of Pb was successful—and in a cleverly simple way modified. The authors now use the binary compound Sb_2Te_3 as the cathode, and tetraalkylammonium ions in en solution serve as the counterions for the crystallization process. On the cathode as well as in the cathodic chamber, crystals of the two compounds grow, one after a short electrolysis time and the second after a short interval of a couple of days. It is evident that continuity of the cathodic process is decisive for crystal growth. The reaction route remains preparatively demanding, requiring the careful exclusion of O_2 and H_2O, since the products are sensitive to oxidation and hydrolysis. The cathodic reaction leads to anions—similar to those isolated by extraction reactions or reactions in en—which do not show any structural relationship to the starting materials, but in which for the first time besides heteronuclear Sb–Te bonds, homonuclear Sb–Sb bonds are also formed and even dominate the structure. The coordination numbers observed in the anions obey the $(8-N)$ rule, the moieties can be considered as low-valent units, like $[Sb_4Te_4]^{4-}$ or as mixed-valent units, like $[Sb_9Te_6]^{3-}$. The very recent publication by Haushalter et al. on the synthesis of a new Au–Te polyanion by cathodic dissolution of an $AuTe_2$ electrode,[17] as well as the results announced shortly thereafter concerning $[GaTe_2(en)_2]^-$ and $[In_2Te_4]^{2-}$ anions rouse expectations for the extended application of this electrochemical method.

Similar to the situation with the extraction reaction, the synthesis cannot be directed systematically with respect to the products at present, because the initially generated species are not yet known. Noteworthy is the discussion in reference [17] about the influence of the cations, up to now little has been said about the role of the composition of the cathodes. Here further investigations should certainly be initiated. The elegant and relatively quick synthesis approach presented here has, however, provided an entry to a group of highly sensitive anions, about which there is surprisingly little known concerning the potential for varying composition and structure, but which have fundamental meaning.

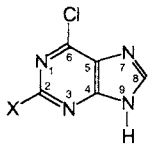
Regiospecific Alkylation of 6-Chloropurine and 2,6-Dichloropurine at N7 by Transient Protection of N3/N9 by Methylcobaloxime**

By *Christine Dalby, Christine Bleasdale, William Clegg, Mark R. J. Elsegood, Bernard T. Golding,** and *Roger J. Griffin*

We have found that protection by methylcobaloxime at N3 and N9 of 6-chloropurine and 2,6-dichloropurine enables regiospecific alkylation at N7. This is in contrast to direct alkylation of these purines, which gives a mixture of materials alkylated at N7 and (predominantly) N9. The 2- and 6-chloro-substituted purines are useful starting materials for preparing 2- and 6-substituted or 2,6-disubstituted analogues of adenine and guanine (e.g., 6-alkoxypurines), which are potential enzyme inhibitors.[1] We required an efficient route to such analogues that are specifically alkylated at N7.

Marzilli et al.[2] reported that selective alkylation at N7 of xanthine and hypoxanthine could be achieved by coordination of the purine as its anion to cobalt(III) of the cation bis(dimethylglyoximato)(tributylphosphane)cobalt ("tributylphosphinecobaloxime"). The resulting cobalt complex was either methylated or benzylated to give an alkylated xanthine or hypoxanthine. For seven examples studied, the structure of the only alkylated product obtained from each reaction was based on ^{1}H NMR analysis. Unfortunately, Marzilli et al. were not entirely confident about their structural assignments, because reference samples or literature NMR data were not available for all possible alkylation products. We have found that the Marzilli strategy applied to 6-chloropurine (**1**) and 2,6-dichloropurine (**2**) does indeed yield 7-alkylated products, usually exclusively, and therefore constitutes an excellent synthetic route to 7-alkylated purines.

Marzilli et al.[2] used the aqua(tributylphosphane)-cobaloxime cation (**3a**), prepared in situ (as its acetate) by treating the corresponding chloro complex (**3b**) with silver acetate, for protection of xanthine and hypoxanthine at N7. However, **3b**[3] is not as readily available as aqua(methyl)-cobaloxime (**3c**),[4, 5] which we have examined as an alternative reagent for purine complexation. Cobaloxime **3c** is soluble in weakly coordinating solvents like dichloromethane and acetonitrile, and its water ligand is easily displaced by other Lewis bases, including nitrogen heterocycles.[6] Thus, on stirring a solution of either chloropurine **1** or **2** with **3c** in acetonitrile a purine–cobaloxime complex soon precipitates.



1 X = H
2 X = Cl

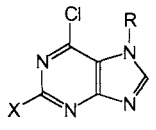
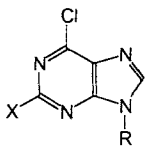
3b R = Cl, L = PBu_3
3c R = Me, L = OH_2



4a X = H, R = $PhCH_2$
4b X = H, R = $PhCOCH_2$
4c X = H, R = $CH_2CH{=}CH_2$
4d X = H, R = CH_2COCH_3

5a X = Cl, R = $PhCH_2$
5b X = Cl, R = $PhCOCH_2$



6a X = H, R = $PhCH_2$
6b X = H, R = $PhCOCH_2$
6c X = H, R = $CH_2CH{=}CH_2$
6d X = H, R = CH_2COCH_3

7a X = Cl, R = $PhCH_2$
7b X = Cl, R = $PhCOCH_2$

To the resulting suspension was added potassium carbonate and an alkyl halide, and the mixture was stirred at room temperature for several hours. Chromatography of the reaction mixture on silica led to decomposition of the alkylpurine–cobaloxime complex presumably present in the mixture and afforded the *N*7-alkylated purine (**4a–4d** from **1**, **5a–5b** from **2**) in excellent yield, obtained analytically pure after one recrystallization (Table 1). Reference samples of *N*7-alkylated purines **4a–4d**, **5a**, **5b**, and *N*9-alkylated purines **6a–6d**, **7a**, and **7b** were generated by direct alkylations[7] of **1** or **2** in acetonitrile (that is, essentially the same conditions as those just described, but with omission of the cobaloxime), which gave an approximately 1:2 ratio of *N*7- and *N*9-alkylated purine, separable by silica chromatography. The presence of (aquamethyl)cobaloxime **3c** therefore provides a remarkable control over the site of purine alkylation. (Alkylations in dimethylformamide (DMF) or dimethyl sulphoxide (DMSO)[7] give a lower *N*7- to *N*9-alkylation ratio than those in acetonitrile; we have determined a ratio of 1:9 for benzylation of **1** in DMF.)

Marzilli et al.[2] rationalized cobalt-mediated alkylation at N7 by postulating preferential ligation of N9 to cobalt in the intermediate purine–cobaloxime complex. They proved coordination of cobalt to purine N9 in the structure of bis(dimethylglyoximato)(tributylphosphane)(xanthinato)-cobalt(III) by X-ray analysis.[2] Coordination to purine N9 rather than N7 was ascribed to steric shielding of N7 by the O^6 atom. Combustion analysis of the crystalline complex isolated from mixing 6-chloropurine with **3c** supports its formulation as a 1:1 complex. The crystal structure determi-

nation[8] of this complex (Fig. 1) supports the hypothesis of Marzilli et al.[2] that the C6 substituent prevents cobalt ligation to N7. Coordination is not, however, to purine N9 in this case, but rather to N3. The complex also contains an intramolecular hydrogen bond from the hydrogen atom on the purine N9 atom to the dimethylglyoximato O1 atom. Thus, if this structure persists in acetonitrile N9 is not alkylated because of this indirect protection. The mechanism of the alkylation step could either involve direct attack at N7 (to give an intermediate that loses the N9 proton) or prior deprotonation at N9, followed by attack of alkylating agent. The latter possibility is supported by the observation that omission of potassium carbonate from a mixture containing **3c**, **1**, and benzyl bromide in acetonitrile gave no **4a** or **6a** (note: addition of base is preferred for alkylations done in the absence of **3c**, and without **3c** the chloropurine remains in solution).

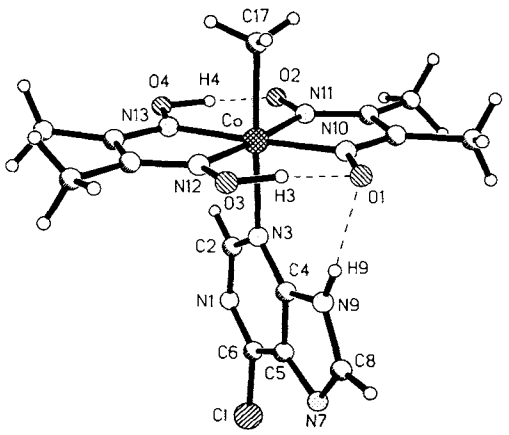

Fig. 1. Crystal structure of the methylcobaloxime complex of **1**.

Experimental Procedure

To a vigorously stirred solution of **3c** (500 mg, 1.55 mmol) in dry acetonitrile (10 mL), protected from light, was added the chloropurine (**1** or **2**, 1.55 mmol). An orange precipitate formed immediately. Dry acetonitrile (10 mL) was added followed by K_2CO_3 (214 mg, 1.55 mmol), and the mixture was stirred for 30 min. After adding the alkylating agent (1.55 mmol), the mixture was stirred at room temperature until no chloropurine remained [1–4 days, monitored by thin-layer chromatography (TLC)]. The solvent was removed and either aqueous 4 M sodium hydroxide (20 mL) (for 6-chloropurine reactions) or water (20 mL) for 2,6-dichloropurine reactions) was added. The product was extracted into dichloromethane (3 × 30 mL) and the combined extracts were washed with water and dried (Na_2SO_4). The solvent was removed and the crude product was chromatographed on silica, typically with ethyl acetate as eluent. The products were pure according to TLC and ^{1}H-NMR spectroscopy. Analytically pure samples were obtained by recrystallization, which gave white crystalline products.

A Novel Complex with Boat-Shaped, Synfacially Bound η^3:η^3-Benzene Bridges and the First μ_3-η^2:η^2:η^2-Arenetrirhodium Complex**

By *Jörn Müller,* Petra Escarpa Gaede,* and *Ke Qiao*

Dedicated to Professor Otto Scherer on the occasion of his 60th birthday

The number of molecular complexes in which an arene is bound in a π fashion to several metal atoms has increased greatly in recent years.[1] However, the structurally diverse examples, especially those with synfacial arrangement of metal atoms, remained at first restricted to a few transition metals. In the case of rhodium, such a coordination type was

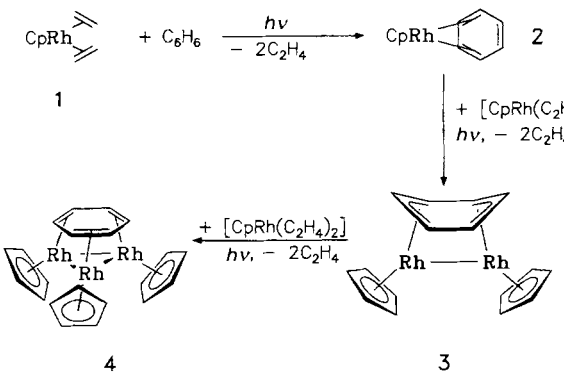
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

observed only in chemisorption of benzene, for example, on a (111) metal surface.[2] Now for the first time, we have been able to synthesize multinuclear rhodium complexes containing benzene bridges and characterize them by crystallography. At the same time we have realized a novel way of coordination for arenes.

In contrast to the analogous cobalt compound, cyclopentadienylbis(ethene)rhodium (**1**) is thermally quite stable, but eliminates the ethene ligands on illumination with UV light.[3] Irradiation of **1** in hexane in the presence of benzene gives rise to complexes **3** and **4**, probably via the intermediate **2**. Monitoring by mass spectrometry confirms the stepwise course of the reaction according to Scheme 1; with increasing irradiation times, the concentration of the trinuclear complex **4** increases at the expense of **3**; that is, the multinuclear complexes are formed by successive coordination of the photolytically generated [CpRh] fragments (Cp = η^5-C_5H_5) to the arene. The quite low overall yields are attributable to the formation of higher nuclearity decomposition products that prevent the photolysis of more **1** by absorbing UV light strongly. Consequently the formation of **4** also comes to a standstill. The actual presence of the intermediate **2** is indicated by an ion in the mass spectrum with $m/z = 246$. The concentration of **2**, however, always remains very low (no isolation was possible), from which one can deduce that the rate of the second reaction step in Scheme 1 is distinctly faster than that of the first. An additional pointer to the



Scheme 1.

possible role of **2** as intermediate is provided by the irradiation of **1** in the presence of [CpRh(η^4-C_6Me_6] synthesized along other routes, which produces analogous hexamethylbenzene complexes to **3** and **4** in substantially higher yields.[4]

The direct attack of [CpM] units on an arene, which leads to compounds like **3** and **4**, is restricted to M = Rh in the triad Co/Rh/Ir. In the case of cobalt, the thermal reaction of [$CpCo(C_2H_4)_2$] with benzene to form a complex analogous to **4** requires a suitable vinyl substituent on the benzene ring that directs the attack of the [CpCo] fragment; however, no intermediates of the type **2** or **3** can be detected.[5] The photolysis of [$CpIr(C_2H_4)_2$] in the presence of benzene, which we studied, took a different course; only with hexafluorobenzene could the successive formation of [$CpIr(C_2H_4)(\eta^2$-$C_6F_6)$] and [$CpIr(\eta^4$-$C_6F_6)$] be observed.[6]

The synfacial arrangement of the metal atoms relative to the benzene ligands and the presence of Rh–Rh bonds in **3** and **4** is deduced from the mass spectrum, because no [M^+ – CpRh] fragment appears; in both cases the loss of the benzene ligands is the preferred primary decomposition step. The base peak in the mass spectrum of **3** is the ion [$Cp_2Rh]^+$, formed by rearrangement; for **4** it is the [$M^+ - C_6H_6 - H_2$] ion.

The X-ray diffraction analysis of **3**[7] reveals that this compound is the first η^3:η^3-arene complex with a six-membered ring arranged synfacially over a metal–metal bond (Fig. 1); it therefore represents one of the few pieces still missing in the mosaic of the structural diversity of bridged arene complexes. The μ_2 benzene ligand is in boat form and can be

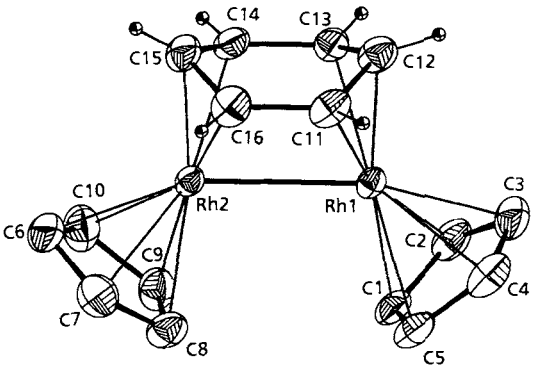


Fig. 1. Crystal structure of **3** (ORTEP). The H atoms of the Cp rings were omitted. Selected bond distances [pm] (standard deviations Rh-Rh 0.1, Rh-C 0.5, C-C 0.8): Rh1-Rh2 266.8, Rh1-C11 217.4, Rh1-C12 206.2, Rh1-C13 216.0, Rh2-C14 216.5, Rh2-C15 204.6, Rh2-C16 216.1, C11-C12 142.7, C12-C13 141.5, C13-C14 147.1, C14-C15 141.6,C15-C16 143.6, C16-C11 145.6.

described as a bis(enyl) ligand system. The angle between the two η^3-enyl planes is 127°. Within the ring the average bond lengths are shorter for the enyl structural units (142 pm) than for the remaining C13–C14 and C11–C16 distances (146 pm). The central atoms C12 and C15 of the enyl units lie closer to the rhodium atoms; these Rh–C distances of about 206 pm are distinctly shorter than the other bonds between rhodium and the benzene ring, whose length of about 216 pm lie within the usual range. The metal–metal distance (266.8 pm) is in accord with published values for Rh–Rh single bonds.[8]

Similar to the synfacial η^4:η^4-bridging arene ligands in [$(CpVH)_2(\mu$-$C_6H_6)$] and [$(CpFe)_2(\mu$-$C_6R_6)$][11], the benzene ring in **3** displays fluctional behavior. In the ^{1}H NMR spectrum (80 MHz, [D_6]acetone) at room temperature it yields only one signal at $\delta = 3.73$, a triplet with two equivalent ^{103}Rh couplings of 1 Hz. If the spectrum is recorded at lower temperatures, the signal broadens and finally splits into two resonance lines at $\delta = 4.00$ (4H) and 3.30 (2H); the coalescence temperature is −10 °C. Irrespective of the recording temperature, the Cp rings give rise to a common doublet at $\delta = 5.17$ ($J_{Rh,H} = 0.5$ Hz).

Also the trinuclear compound **4** is as first μ_3-η^2:η^2:η^2-arenerhodium complex a novelty. The crystal structure analysis[7] shows that the three Rh atoms span an equilateral triangle, which is approximately parallel to the benzene ring directly above it (Fig. 2). As in isostructural clusters,[11] the bond lengths within the arene ligands alternate slightly according to a Kekulé distortion. The crystallographically determined bending of the arene C–H bonds away from the metal centers is necessitated by the coordination and can be explained by MO theory.[9] The Rh–Rh distance of 262.5 pm is slightly less than in **3**. During the structure solution, the Cp ligand C9–C11 was found to be disordered in the crystal; this disorder is attributable to a statistical distribution of the Cp ring between two rotamers ($\Delta\phi = 36°$) in the ratio 1:1. Figure 2 depicts the ORTEP representation of one of the rotamers. The rotation of the arene ligand in

solution, already known for other compounds of this type,[1] can also be observed here; through equal coupling with the three ^{103}Rh nuclei, the isochronous benzene protons give rise to a quartet at $\delta = 4.06$, $J_{Rh,H} = 0.7$ Hz in the ^{1}H NMR spectrum (C_6D_6) at room temperature, whereas the Cp protons appear as singlet at $\delta = 5.11$.

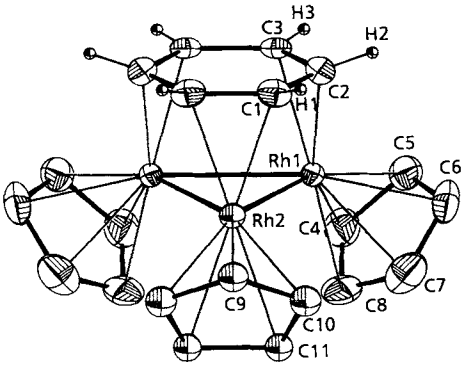

Fig. 2. Crystal structure of **4** (ORTEP). The H atoms of the Cp rings were omitted. Selected bond distances [pm] (standard deviations Rh-Rh 0.1, Rh-C 0.9, C-C 1.3): Rh1-Rh1′ 262.5, Rh1-Rh2 262.5, Rh1-C2 215.9, Rh1-C3 215.3, Rh2-C1 214.4, C1-C1′ 140.0, C1-C2 144.6, C2-C3 143.6, C3-C3′ 146.8.

As the ongoing experiments have already shown, the reactions according to Scheme 1 can be extended to other systems, for example condensed arenes. These results will be reported soon.

Experimental Procedure

All manipulations must be performed under inert atmosphere with dry solvents. Basic aluminum oxide (63–200 μm) with 7.5% water content was used as chromatographic medium.

$[CpRh(C_2H_4)_2]$ (**1**, 740 mg, 3.3 mmol) was dissolved in a mixture of hexane (170 mL) and benzene (30 mL) and irradiated by means of a mercury high-pressure lamp in a falling film apparatus for 5 h. A little Al_2O_3 was added, the solvent was removed under reduced pressure, and the mixture was transferred to the top of a chromatographic column. The separation was performed at −20 °C with hexane as eluent. First the broad, yellow band of unchanged starting material (255 mg, 1.14 mmol, 35%) was eluted. The next adjoining orange-red fraction contained, apart from very small amounts of **2**, a series of unidentified compounds. A clearly separated red zone followed, from which dark red, air-sensitive **3** (39 mg, 0.094 mmol, 8.7% based on converted **1**) was recovered after concentration of the solution and crystallization at −50 °C: m.p. 208 C (decomp.), correct elemental analysis. For further elution, 3% of ether was added to the eluent. A green zone was obtained, which yielded, when treated as above, dark green, crystalline **4** (11 mg, 0.019 mmol, 2.6% based on converted **1**), which is, to a large extent, stable to air in the solid state: m.p. 212 °C (decomp.), satisfactory elemental analysis. When the duration of irradiation is 3 h, 60% of **1** is recovered, and the yields are 15% (**3**) and 2% (**4**), in each case based on converted **1**.

A Synthetic Cavity Assembles Through Self-Complementary Hydrogen Bonds**

By *René Wyler, Javier de Mendoza*, and *Julius Rebek, Jr.**

Complementarity of shape, size, and chemical surface drives molecular recognition, and self-complementarity is the singular feature of biological molecules capable of assembly. Allosteric enzymes, palindromic nucleic acids, and viral capsids[1] all reveal an economy of information;[2] held together by weak intermolecular forces, these structures consist of interlocking, identical subunits. The instructions for assembly are written within the shapes of the subunits and the orientation of their recognition surfaces.[3] We have now synthesized a synthetic molecule that models these notional and structural features. The compound undergoes reversible dimerization to form a closed-shell cavity.

A tennis ball provides a minimalist, macroscopic analogy. Cut along its seam, the ball gives two identical pieces; in shape, the ends are complementary to the middle, and the subunits feature curvatures that dictate the overall spherical shape of the dimer (Fig. 1). Similar spacing and appropriate

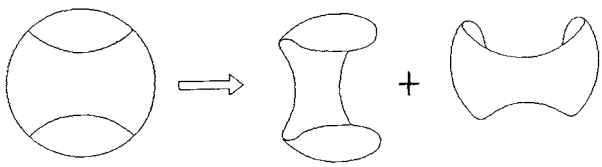

Fig. 1. Tennis ball assembly from self-complementary, interlocking subunits.

curvatures in the molecular subunit structure are required for the assembly to present a cavity.

Compound **1** (Fig. 2) presents these features at the molecular level. The lactam functions of **1** provide self-complementary hydrogen bond donors and acceptors (indicated by

Carolyn Knobler and William Davis for preliminary X-ray analysis, and to Mr. Edward Wintner for illustrations. Mass spectrometric data were provided by the MIT Mass Spectrometry Facility which is supported by the N.I.H. (grant. no. RR00317 to Prof. K. Biemann).

arrows). The curvature of the molecule along its length is a consequence of the folding caused by the 7-membered rings when the phenyl units are all on the same face of the structure. The curvature along its width is caused by the *cis* fusion of the 5-membered rings. The compound was prepared by condensing two molecules of diphenyl glycoluril[4] (**2**) with durene tetrabromide (**3**) using KOH in hot dimethyl sulfoxide[5] (DMSO). A congener (**5**) was prepared by similar methods for spectroscopic comparisons.

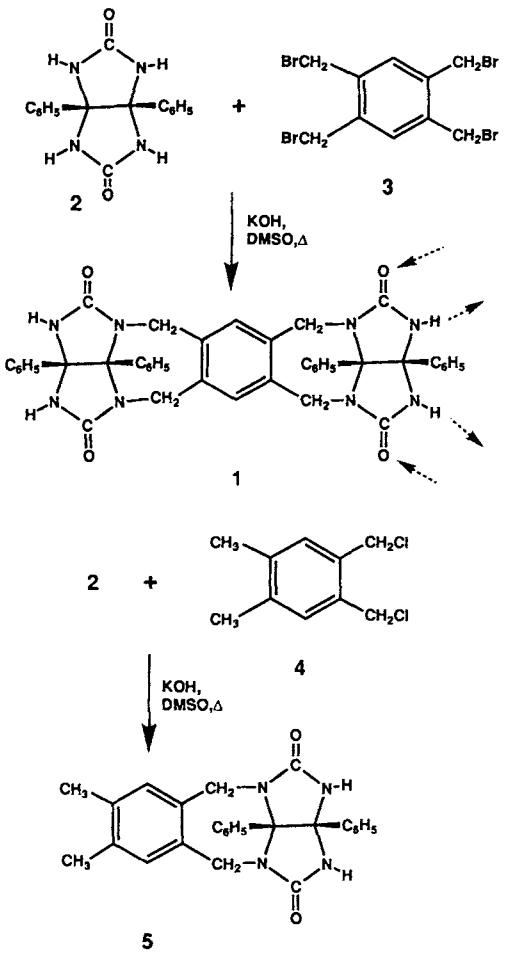

Fig. 2. Syntheses of the self-complementary compound **1** and structural congener **5**.

Two self-complementary molecules of **1** assemble to form a closed-shell, three-dimensional surface through a network of hydrogen bonds.[6] This behavior was established by the following physical measurements. Vapor pressure osmometry in $CHCl_3$ gave an average molecular weight of 1500–2000, a range which is in agreement with a dimeric structure containing a $CHCl_3$ guest. Electron impact (EI) mass spectrometry and fast atom bombardment (FAB) mass spectrometry (nitrobenzylalcohol matrix) gave sizable (25–30%) peaks at 1429 μ, while laser desorption mass spectrometry gave this value as the most intense peak. The calculated molecular weight of the dimeric structure (Fig. 3) is 1429.58.

The chemical shifts of the N–H resonances in the proton NMR spectrum in various media are recorded in Table 1. The downfield shifts indicate extensive intermolecular hydrogen bonding in $CDCl_3$ and benzene solutions when compared to the corresponding signals for **2** and congener **5**,

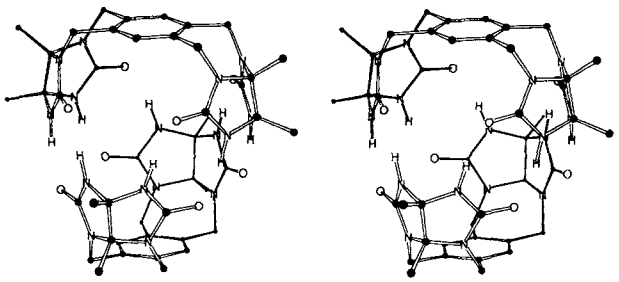

Fig. 3. Stereoscopic view of the assembly of **1** into the dimeric structure. Only those H, N, O atoms involved in the hydrogen bonding seam are labeled, and the eight phenyl groups have been replaced by carbon atoms for clarity.

which suggests the dimerization of **1**. The network of hydrogen bonds in $CDCl_3$ remains intact with up to 20% DMSO as cosolvent. These bonds are disrupted in 100% DMSO, in which the solvated monomeric **1** predominates.

Table 1. N–H Resonances (δ values) in various solvents

Compound	$CDCl_3$	$[D_6]$DMSO	C_6D_6
1	9.28	8.22	10.23
2	insoluble	7.74	insoluble
5	5.4–5.5	8.14	5.15

These data indicate an equilibrium between the dimer and its monomeric form **1**. Molecular modeling[7] suggests that the hydrogen bonds of the dimer (Fig. 3) can be nearly linear (164° for the N-H···O angles), have reasonable length (2.8 Å), and feature favorable secondary interactions.[8] In addition, one molecule of $CHCl_3$ is easily accommodated within the cavity when the Cl atoms of the guest are directed to the openings of the host. While the structure of **1** in the solid state (which may differ from that in solution) awaits X-ray crystallographic analysis, the dominant state in $CDCl_3$, benzene, and the gas phase appears to be dimeric.

Related modules that feature larger cavities have been identified, and we are pursuing their synthesis. It is perhaps not coincidental that self-complementarity is a key feature of self-replicating molecules;[9, 10] our intent is to provide chemical structures with interiors large enough to accommodate and transport synthetic replicators.

Experimental Procedure

A mixture of diphenylglycoluril **2** (26.4 g, 89.7 mmol), finely powdered KOH (10 g, 178 mmol), and DMSO (250 mL) was rapidly heated to 120 °C with vigorous stirring. Durene tetrabromide **3** (2.0 g, 4.44 mmol) was added in one portion, and stirring was continued for 1 h. The reaction mixture was poured into H_2O (3 L), and the precipitate filtered and thoroughly washed with water. The crude residue (26.2 g) was treated with boiling CH_2Cl_2 (500 mL) for 10 min. The suspension was filtered, and the treatment was repeated three more times. The combined CH_2Cl_2 extracts were evaporated to give crude **1** (1.05 g, 33%; m.p. >400 °C). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3400 (NH), 3200 (NH), 1713 (C=O); UV ($CHCl_3$): λ_{max} [nm] = 241, 254, 260, 265, 270. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 9.27 (s, 4H, NH), 7.50–7.00 (m, 22H, arom. H), 4.68 (d, J = 15.4 Hz, 4H, N–CH), 3.95 (d, J = 15.2 Hz, 4H, N–CH); ^{1}H NMR (250 MHz; d_6-DMSO): δ = 8.22 (s, 4H, NH), 7.28 (s, 2H, arom. H), 7.20–6.90 (m, 20H, arom. H), 4.71 (d, J = 15.7 Hz, 4H, N-CH), 3.96 (d, J = 15.5 Hz, 4H, N-CH); ^{1}H NMR (250 MHz, C_6D_6): δ = 10.23 (s, 4H, NH), 7.70–6.80 (m, 22H, arom. H), 4.74 (d, J = 15.6 Hz, 4H, N-CH), 3.70 (d, J = 15.6 Hz, 4H, N-CH); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 160.62 (s, 4C, C=O), 140–120 (m, 30C, arom. C), 87.84 (s, 4C), 79.59 (s, 4C), 43.79 (t, 4C, N-CH_2); MS (EI): m/z 1429 ($[2M]^{\cdot+}$, 22), 715 ($[M]^{\cdot+}$, 100); MS (FAB): m/z 1430 ($[2M]^{\cdot+}$, 26), 715 ($[M]^{\cdot+}$, 100); MS (laser desorption): m/z 1429 ($[2M]^{\cdot+}$, 100), 714 ($[M]^{\cdot+}$, 50). Elemental analysis: $C_{42}H_{34}N_8O_4 \cdot 1.5H_2O$: calcd. C 68.00, H 5.03, N 15.11, found C 68.18, H 4.94, N 15.14.

A Hexanuclear Organogallium Fluoride Oxide**

By *Bernhard Neumüller** and *Frank Gahlmann*

Dedicated to Professor Dietmar Seyferth on the occasion of his 65th birthday

Diorganogallium fluorides can be obtained by the reaction of triorganogallium compounds with $BF_3 \cdot OEt_2$.[1–4] The degree of association of diorganogallium fluorides, as indicated by spectroscopic data and molar mass determinations, is mainly dependent on the steric bulk of the substituents.[4] None of the derivatives had yet been structurally characterized, however.

We have now performed an X-ray structure analysis[5] of Mes_2GaF **1**[4] (Mes = 2,4,6-trimethylphenyl), the result of which confirms the degree of association, $n = 2$, that we had previously postulated. Compound **1** crystallizes with one THF molecule and lies on the intersection of the twofold symmetry axes. The GaF framework forms a planar, distorted rhombus with a Ga–F bond length of 194.7(2) pm (Fig. 1). The internal angles are 78.9(1)° (F1–Ga1–F1A) and 101.1(2)° (Ga1–F1–Ga1A).

After workup, the reaction of **1** with H_2O in the molar ratio 1:1 affords the hexanuclear gallium fluoride oxide $Mes_6Ga_6F_4O_4$ [**2**, Equation (a)], which also crystallizes with one THF molecule.[6] It can be seen from Equation (a) that, under the chosen conditions, only four equivalents of H_2O are required to react with six equivalents of **1**.

$$\underset{\mathbf{1}}{6\,Mes_2GaF} + 4\,H_2O \xrightarrow{THF,\ 25\,^{\circ}C} \underset{\mathbf{2}}{Mes_6Ga_6F_4O_4} + 2\,HF + 6\,MesH \quad (a)$$

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. W. Massa for the calculations and for his valuable contributions to discussions.

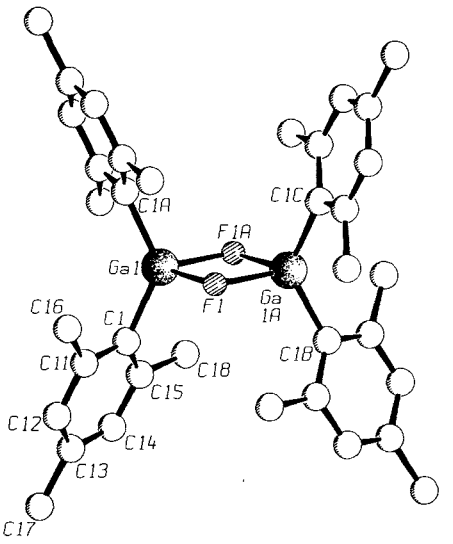

Fig. 1. Structure of **1** in crystals of **1**·THF (H atoms not shown.) Selected distances [pm] and angles [°]: Selected distances [pm] and angles [°]: Ga1-F1 194.7(2), Ga1-C1 194.9(5), Ga1···Ga1A 300.8(2); F1-Ga1-F1A 78.9(1), Ga1-F1-Ga1A 101.1(2), F1-Ga1-C1 104.5(2), F1-Ga1-C1A 113.1(2), C1-Ga1-C1A 130.8(2).

Little is known about the association of organogallium compounds to form larger aggregates,[7] although Barron et al. were recently able to demonstrate that $[t\mathrm{Bu_2GaOH}]_3$[8, 9] reacts in refluxing xylene to form $[t\mathrm{BuGaO}]_9$. The proposed structure for this oligomer was deduced mainly from ^{17}O NMR investigations. Analogously, $[t\mathrm{BuGaS}]_4$[10–12] can be converted to $[t\mathrm{BuGaS}]_n$ (n = 6-8) under the combined effect of base and heat.[8]

Hexanuclear **2** possesses threefold point symmetry, that is, the atoms O1 and F2 lie on a threefold axis (Fig. 2). The six

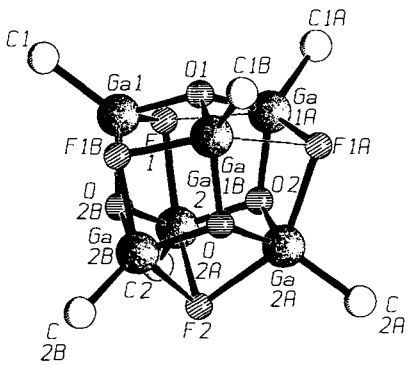

Fig. 2. Structure of **2** in crystals of **2**·THF (H atoms not shown.) Selected distances [pm] and angles [°]: Ga1-F1 197.3(3), Ga1···F1B 252.1(3), Ga1-O1 187.9(1), Ga1-O2B 186.9(3), Ga1-C1 193.0(4), Ga2-F1 222.3(2), Ga2-F2 221.9(2), Ga2-O2 186.6(3), Ga2-O2B 186.6(1), Ga2-C2 193.5(4); G1-Ga1-O1 87.2(1), F1-Ga1-O2B 84.0(1), O1-Ga1-O2B 104.3(2), F1-Ga1-F1B 144.7(1), F1-Ga2-F2 144.8(1), F1-Ga2-O2 81.6(1), F1-Ga2-O2B 77.4(1), F2-Ga2-O2 79.3(1), O2-Ga2-O2B 104.8(1), Ga1-F1-Ga2 90.3(1), Ga2-F2-Ga2A 88.0(1), Ga1-F1-Ga1A 86.5(1), Ga2-F1-Ga1A 84.5(1), Ga1-O1-Ga1A 111.5(1), Ga1A-O2-Ga2B 105.9(1), Ga1A-O2-Ga2 117.7(2), Ga2-O2-Ga2A 111.4(1).

Ga atoms form a distorted octahedron, all eight faces of which are capped by electronegative heteroatoms. The distortion arises because the Ga-O-Ga angles are larger than the Ga-F-Ga angles. The IR spectrum of **2** indicates quite clearly that the complex framework contains no OH groups. The assignment of the atomic positions of the electronegative heteroatoms can be carried out by a comparison of the

Ga–X distances, and by an estimation of the valency of X according to Donnay and Allmann.[13, 14] With the exception of F1 and its symmetry equivalent atoms, the O and F atoms are μ_3-bridging. F1 is pseudo μ_3-bridging. Two of the Ga–F distances are short (Ga1–F1 197.3(3) pm, Ga2–F1 222.3(2) pm); the remaining weaker Ga–F contact of 252.1(3) pm is between Ga1 and F1B. The solvent molecules in **1**·THF and **2**·THF are not coordinated to the metal atoms. The linking of the six Ga atoms through F and O atoms causes an approach of neighboring metal atoms to 298.05(9) pm (Ga1···Ga2) and 319.6(1) pm (Ga1···Ga2B); some 70 pm shorter than the sum of their van der Waal's radii (380 pm).[15] However, bonding Ga–Ga interactions in **2** can be discounted.[16]

Topologically related clusters can be found, for example, in organotitanium oxides: $[(MeC_5H_4)_6Ti_6Cl_4O_4]$,[17] $[Cp_6Ti_6Cl_2O_6]$,[17] and $[Cp_6Ti_6O_8]$[18] all have the same construction principle as **2**, regardless of the oxidation state of the titanium. As the space-filling model shows, the central gallium fluoride oxide unit is sterically shielded by the mesityl ligands, and this explains the kinetic inertness of **2** towards attack by water.

On the basis of cryoscopic molar mass determinations in benzene, and from NMR spectroscopic investigations, we assume that **2** does not dissociate in THF or toluene (1311, $n = 1.03$). The ^{19}F NMR spectrum shows two signals at $\delta = -90.7$ (three F) and -104.0 (one F). The ^1H and ^{13}C NMR spectra support this conclusion; two sets of signals were found, one for each of the groups of mesityl substituents in different environments, with an intensity ratio of 1:1.

Experimental Procedure

1: Synthesis according to ref. [4].

2: 0.54 g (1.65 mmol) of **1** was dissolved in a mixture of toluene (20 mL) and THF (2 mL). H_2O (0.02 mL, 1.10 mmol) were added. The solution was stirred at room temperature for three hours and then allowed to stand. The product **2**·THF separated from the solution in the form of colorless, rectangular prismatic crystals. Yield: 0.27 g (73% with respect to **1**; scaled-up reactions give corresponding yields). M.p. > 250 °C.

Cryoscopic molar mass determination (benzene, $c = 0.0054$ M): $M_r = 1311$, $n = 1.03$. ^1H NMR (C_6D_6, TMS ext.): $\delta = 2.09$, 2.15 (s, 18H, C4-CH_3), 2.51, 2.54 (s, 36H, C2/6-CH_3), 6.60, 6.67 (s, 12H, C3/5-H); ^{13}C NMR (C_6D_6, TMS ext.): $\delta = 21.0$, 21.2 (C4-CH_3), 24.5, 24.8 (C2/6-CH_3), 127.5, 127.7 (C3/5), 138.8, 139.0 (C4), 145.2, 145.4 (C2/6), 145.6, 145.7 (C1); ^{19}F NMR ([D$_8$]THF, $CFCl_3$ ext.): $\delta = -98.7$ (s, 3F), -104.0 (s, 1F). IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 2728, 1600, 1558, 1495, 1412, 1292, 1238, 1030, 948, 849, 843, 688, 634, 590, 492, 437, 407, 293. EI-MS (70 eV): *m/z* (%) 1238 (4) [$(M-2Me^+$], 1142 (3) [$(M-GaF_3)^+$], 1041 (10) [$(M-Mes-3O-4Me)^+$], 925 (16) [$(Mes_5Ga_5F_3O_2-C_8H_8)^+$], 819 (7) [$Mes_4Ga_4FO_3)^+$], 207 (7) [$(MesGaF)^+$], 119 (38) [$(Mes)^+$], 105 (100) [$(C_8H_9)^+$], 69 (20) [$Ga^+$]. Elemental analysis correct.

Dicyanononasulfane $S_9(CN)_2$—An Unbranched Chain of Thirteen Atoms**

By *Ralf Steudel*,* *Klaus Bergemann*, *Jürgen Buschmann*, and *Peter Luger*

Acyclic polysulfanes X–S_n–X form extensive homologous series.[1–7] Both ^1H NMR spectra[2] and HPLC analyses[1, 3, 7] show that n can have values of 35 and above. Only compounds of up to eleven S atoms have been isolated in pure form, however,[4] and structure determinations have only been carried out on sulfanes of up to six S atoms.[1, 5] This is because longer acyclic sulfanes are difficult to isolate and crystallize, since such compounds are thermally labile and tend to form oils, honeylike solids, and microcrystalline powders because of the many possible torsional isomers. We report here on the first synthesis of dicyanononasulfane $S_9(CN)_2$, as well as on its crystal packing and molecular structure, which shows a chainlike molecule of 13 atoms.

$S_9(CN)_2$ was prepared analogously to the synthesis of the short-chained members $S_n(CN)_2$ (n = 3-8)[6] from S_7Cl_2[7] and $Hg(SCN)_2$ [Eq. (a)]. Monoclinic crystals are formed,

$$S_7Cl_2 + Hg(SCN)_2 \longrightarrow S_9(CN)_2 + HgCl_2 \qquad (a)$$

which melt at 36–38 °C and decompose at 20 °C within 24 hours to form a red polymer, but which can be stored at −50 °C without decomposition. The X-ray analysis,[8] car-

ried out at −110 °C showed that the $S_9(CN)_2$ molecule has C_1 symmetry. The terminal SCN groups are almost antiparallel to each other (Fig. 1). The S_9 chain does not have the

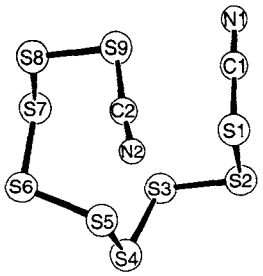

Fig. 1. Conformation of the $S_9(CN)_2$ molecule (the angle between the lines through S1 and N1 and through S9 and N2 is 170.7°). Nuclear distances [pm]: N1-C1 113(1), C1-S1 171.1(8), S1-S2 207.8(2), S2-S3 204.1(2), S3-S4 206.2(4), S4-S5 205.7(3), S5-S6 205.5(3), S6-S7 205.5(4), S7-S8 204.1(3), S8-S9 207.6(3), S9-C2 170.6(8), C2-N2 114(1); valence angles [°]: N1-C1-S1 177.2(8), C1-S1-S2 98.8(3), S8-S9-C2 100.1(3), S9-C2-N2 177.2(7); torsion angles [°]: N1-C1-S1-S2 −173(15), C1-S1-S2-S3 84.3(3), S1-S2-S3-S4 85.7(1), S2-S3-S4-S5 −80.2(1), S3-S4-S5-S6 −86.3(1), S4-S5-S6-S7 87.3(2), S5-S6-S7-S8 94.8(1), S6-S7-S8-S9 −94.2(1), S7-S8-S9-C2 82.1(3), S8-S9-C2-N2 −151(13).

expected stretched (helical) conformation, but resembles a part of the molecular structure of the S_{12} ring:[9a] the signs of the torsion angles τ of the S–S bonds, which would all be the same for a helix, are + + − − + + − + (S_{12}: + + − − + + − −...). The values of the torsion angles $|\tau|$ are in the usual region of 80–95°. The S_9 unit has approximate C_s symmetry; the S-S-S valence angles lie between 104.3(1) and 106.8(1)°. The S–S internuclear distances vary between 204.1 and 207.8 pm (average value 205.8 pm; average value for S_{12} 205.2 pm[9b]). Noticeable is that the "terminal" S–S bonds are the longest (207.7 pm) and the two neighboring ones are the shortest (204.1 pm). Similar observations were made for $S_4(CN)_2$, and the resonance structures shown in Scheme 1 were proposed.[10]

Scheme 1.

The low melting point $T_m = 310 \pm 1$ K of $S_9(CN)_2$ shows on the one hand that the intermolecular interactions can only be weak, but on the other hand that the melting entropy ΔS_m must be exceptionally large since $T_m = \Delta H_m/\Delta S_m$ (ΔH_m = melting enthalpy). The large entropy increase can be explained by the torsional isomerism of the S–S bonds, because each τ value can be about + 90° or −90° and thus for eight S–S bonds $2^8 = 256$ conformational isomers of similar energy (including enantiomers) exist.[11] The rotational barrier[12] for cumulative S–S bonds is only approximately 24 kJ mol^{-1}, so that a mixture of conformers can occur on melting.

The shortest contact distances in $S_9(CN)_2$ (S···N: 307, C···N: 318 pm) correspond roughly to van der Waals distances, yet all the SCN groups in the crystal arrange themselves parallel or antiparallel to the *b* axis of the monoclinic unit cell, which points to weak dipole–dipole interactions (Fig. 2). Since the CN groups are neither bulky nor particularly electronegative, the structure of $S_9(CN)_2$ can serve as model for the structure of other acyclic polysulfanes with small substituents, for example H_2S_n, S_nCl_2 or $(CH_3)_2S_n$, for which a compact structure in the solid state is possibly energetically more favorable than a helical conformation. Furthermore, the structure determination of $S_9(CN)_2$ yields for the first time information about the possible conformation of polymeric sulfur obtained by extraction from quenching of sulfur vapor or melts (random coil polymer). This sulfur is used in large quantities for rubber vulcanization.

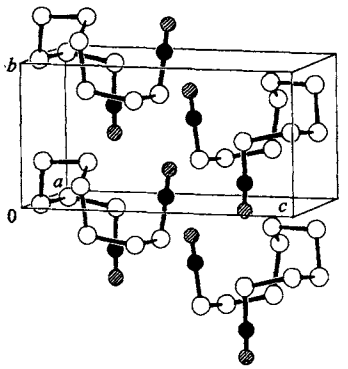

Fig. 2. Packing of $S_9(CN)_2$ molecules in the crystal. Open spheres correspond to the S atoms, solid spheres to the C atoms, and shaded spheres to the N atoms.

Experimental Procedure

Freshly prepared S_7Cl_2 [7] (1.25 mmol) was dissolved in 20 mL anhydrous CS_2, cooled to −10 °C, and $Hg(SCN)_2$ (1.56 mmol) was added with stirring. After 2 h the solvent was decanted from the $HgCl_2/Hg(SCN)_2$ mixture, cooled to −50 °C (12 h), decanted again, and warmed to 20 °C. *n*-Hexane was added until the mixture became cloudy. On cooling to −50 °C pure $S_9(CN)_2$ crystallizes (yield 21 %). Correct C, N, S analyses; ^{13}C NMR (67.69 MHz, $CDCl_3$, 25 °C): $\delta = 109.9$; FT Raman: $\tilde{\nu}$ [cm^{-1}] = 2153/2145 (C≡N), 666 (C–S), 483/466/454/438/427/402 (S–S and δ_{SCN}).

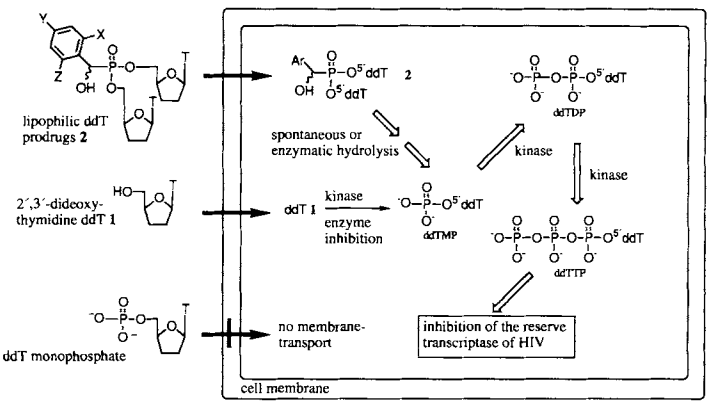
Lipophilic 5′,5′-*O*-Dinucleoside-α-hydroxybenzylphosphonic Acid Esters as Potential Prodrugs of 2′,3′-Dideoxythymidine (ddT)**

By *Chris Meier**

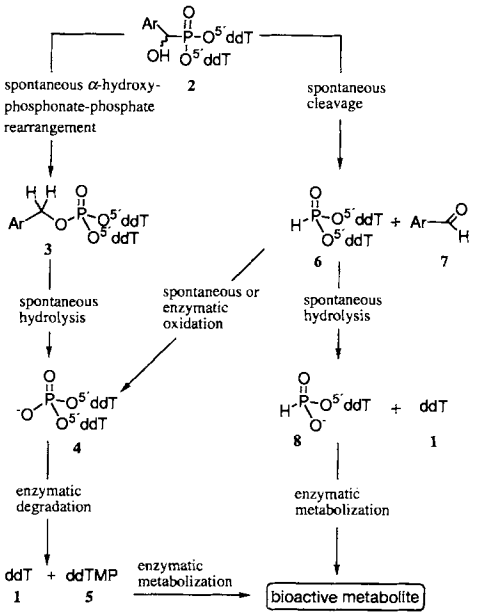
Nucleoside analogues are widely used in antiviral chemotherapy. Inside the cell the nucleoside analogues must be metabolized into their nucleoside triphosphates by three phosphorylation steps (Scheme 1),[1] since only the triphosphates act as inhibitors of the viral polymerases or initiate elongation termination after incorporation into a growing viral DNA chain.[2] The structural differences between the nucleoside analogues and the natural substrate could result in the inhibition of the phosphorylating enzymes (kinases). For this reason the conversion of the anti-HIV-active nucleoside analogue 2′,3′-dideoxythymidine (ddT **1**) into its 5′-monophosphate (ddTMP) by thymidine kinase is the rate limiting step: once the ddTMP is formed, the subsequent conversions are not inhibited.



Scheme 1. In vivo activation of 2′,3′-dideoxythymidine (ddT, **1**). Ar = aryl.

Hence, for nucleoside analogues like **1**, intracellular delivery as their 5′-monophosphates from prodrugs should bypass this metabolic limitation and consequently improve their biological activity. Lipophilic nucleoside phosphotriesters were studied with the aim of releasing the nucleoside monophosphate by spontaneous or enzymatic degradation.[3] In all reported cases the controlled cleavage of the masking groups of the prodrugs is not be satisfactorily solved. Apart from the controlled hydrolysis, the lipophilicity of the prodrugs is important for passive transport through biomembranes and through the blood–brain barrier. Only one prodrug form has been described for ddT recently.[4]

This communication reports on the synthesis of di-5′,5′-*O*-(2′,3′-dideoxythymidine)-α-hydroxybenzylphosphonate esters (**2**) with different substituents at the aromatic ring, on their partition coefficients in an octanol/water mixture, and on hydrolysis studies in phosphate buffer solution (pH 7.5) at 37 °C. Starting from **2**, two completely different mechanisms should lead to phosphorylated or phosphonylated products under alkaline conditions: a) α-Hydroxybenzylphosphonates (**2**) may undergo phosphonate–phosphate rearrangement to the corresponding phosphotriester derivatives (**3**) in alkaline medium. Carbanion-stabilizing substituents in the aromatic system promote this rearrangement.[5] In **3** the $ArCH_2$–O bond is the most labile phosphate ester bond, and hydrolysis leads to the nucleoside phosphodiester **4** (Scheme 2).[6] Diester **4** is enzymatically degradable into the 5′-monophosphate **5** and **1**. b) In competition with the phosphonate–phosphate rearrangement, a direct cleavage mechanism of the α-hydroxybenzylphosphonates (**2**) leading to the ddT-H-phosphonate diester **6** and the aldehydes **7** occurs. This direct cleavage should be dominant if the aromatic ring bears a carbanion-destabilizing, electron-donating substituent. The H-phosphonate diester **6** is easily hydrolyzable into the H-phosphonate monoester **8** and **1**.[7] Alternatively, **6** might be oxidized intracellularly to give the phosphodiester **4**[8] (Scheme 2).



Scheme 2. Hydrolytic degradation pathways of α-hydroxyphosphonate diesters (**2**). Ar = aryl.

Consequently, the two mechanisms would lead in three and two steps to phosphorylated or phosphonylated nucleoside analogues, respectively, and both precursors (the α-hydroxy-benzylphosphonates **2** as well as the benzylphosphotriesters **3**) could act as lipophilic prodrugs. Is it possible to control the two different reaction pathways under physiological conditions by changing the substituent at the aromatic ring?

The 5′,5′-*O*-(2′,3′-dideoxythymidine)-H-phosphonate diester **6**, used as starting material for the synthesis of **2**,[7] was obtained in 60–80% yield in a one-pot reaction with iPr_2NPCl_2 (**9**) and two equivalents of ddT (**1**) via the phosphoramidite **10** as intermediate, which was directly hydrolyzed by tetrazole activation (Scheme 3).[7] Alternatively, **6** was synthesized in the same yield by esterification of 5′-*O*-(2′,3′-dideoxythymidine)-H-phosphonate monoester (**8**) with a second equivalent of ddT **1** through the pivaloylchloride activation procedure described previously.[9] Precursor **8** was obtained by reacting phosphorus trichloride with imidazole to yield the phosphotriimidazolide, followed by reaction with **1** and subsequent hydrolysis (Scheme 3).[10]

h	H	NO_2	H	0.63	25	60	40
i	NO_2	H	H	0.58	12	15	85
j	NO_2	NO_2	H	0.86	0.5	2	98
1				0.23			

The first method allows the synthesis of the donor substituted compounds **2a–f** but failed to yield acceptor-substituted benzaldehydes **7g–k**. In all reactions the title compounds **2** were isolated as 1:1 diastereomeric mixtures with respect to the configuration at the C_α atom after purification by silica gel chromatography on a Chromatotron (Harrison Research). The diastereomers were not separable by chromatography but could be distinguished by ^1H, ^{13}C, and ^{31}P NMR spectroscopy. The use of the chiral base quinidine instead of triethylamine had no effect on the diastereomeric ratio formed in the reaction. In no reaction was the formation of the corresponding phosphotriester observed. Consequently, these reaction conditions avoid rearrangement as a side reaction during the synthesis.

The partition coefficients of the new compounds (**2**) in octanol/water mixture[13] allows an estimation of their lipophilic properties (Table 1). All compounds showed partition coefficients a factor 1.13 to 9 higher than that of **1** (0.23).[14] Consequently, the passive transport across a membrane should be easier for these compounds than for the free nucleoside.

In hydrolysis studies in which the disappearance of the α-hydroxybenzylphosphonates (**2**) in 10 mmolar phosphate buffer (pH 7.5) was monitored at 37 °C, a striking effect of the different substituents was observed (Table 1).[15] All α-hydroxyphosphonates disappeared following pseudo-first-order kinetics. Derivatives containing strong electron-withdrawing substituents in the aromatic residue rearranged in aqueous solution into the corresponding *O*-benzyl-*O*,*O*-dinucleosidephosphates **3** (Table 1, Scheme 2). To my knowledge, this is the first time that compounds of type **2** rearranged into **3** under aqueous, physiological conditions without enzyme mediation. Benzylphosphotriesters **3** showed further selective degradation into the 5′,5′-dinucleosidephosphodiester **4**. In this case the rate-determining step is the hydrolysis of the formed phosphotriester **3** to yield **4**. Phosphodiesters of type **4** are degraded in vivo enzymatically to yield the monophosphate **5** and ddT (**1**). Thus, α-hydroxyphosphonates (**2**) can, in principle, act as lipophilic prodrugs of 5′-nucleoside monophosphates.

Furthermore, it was shown that compounds **2a–2f** bearing weak electron-withdrawing groups or electron-donating substituents were selectively cleaved to form the 5′,5′-dinucleoside-H-phosphonate diesters **6** and the aldehydes **7** under the same conditions (Table 1, Scheme 2). The rate of this direct cleavage was controlled by the substituent: the stronger the electron-donating properties of the substituent, the faster the direct cleavage. Under the studied reaction conditions **6** was rapidly hydrolyzed into the 5′-ddT-phosphonate monoester **8** and ddT.[7] In this degradation pathway the direct cleavage is the rate-determining step. This pathway, which competes with the rearrangement, opens the possibility of the design of lipophilic prodrugs of 5′-nucleoside-H-phosphonate monoesters of type **8**. This result is important because recently it was shown that compounds of type **8** exhibit selectivity indices comparable with and even better than their parent nucleoside analogues in anti-HIV tests.[16]

In conclusion, these results show that it should be possible to deliver products with biological activity by spontaneous hydrolysis from **2a–j**. Furthermore, it is possible to control the reaction pathway (rearrangement versus direct cleavage) and the rate of the reaction with the substituents at the aromatic ring. Consequently, the new 5′,5′-dinucleoside-α-hydroxybenzylphosphonate esters **2** are potential prodrugs of phosphorylated or phosphonylated derivatives of antiviral nucleoside analogues like **1**. We are currently investigating the hydrolysis of **2** in 10% fetal calf serum (RPMI-culture medium) and their antiviral activity against HIV-1 and HIV-2.

Experimental Procedure

6: Dried 2′,3-dideoxythymidine (**1**, 4.0 mmol) was dissolved in anhydrous acetonitrile (60 mL). After addition of diisopropyl(ethyl)amine (6.0 mmol), the solution was cooled in an ice bath. iPr_2NPCl_2 (3.0 mmol) was added to the stirred solution within 5 min. After this mixture had been stirred at room temperature for 10 min, tetrazole (4.0 mmol) and water (80 μL) were added. After 15 min the solvent was evaporated under high vacuum. The reaction mixture was purified on a Chromatotron on silica gel plates (solvent gradient of ethyl acetate and methanol; 0% to 30% methanol). The 2′,3′-ddT-H-phosphonate diester **6** was isolated as a colorless solid in 80% yield.

2: **6** (1.6 mmol) and **7** (4.8 mmol) were dissolved in anhydrous THF (40 mL). While stirring freshly distilled triethylamine (20 μL) was added. After 4 h at room temperature no starting material **6** could be detected by TLC. The reaction mixture was neutralized by addition of acetic acid (20 μL), and the solvent was evaporated. The crude product was purified on a Chromatotron on silica gel plates (gradient of dichloromethane and methanol; 0% to 15% methanol).

The bis-(5',5'-*O*-2',3'-dideoxythymidine) α-hydroxybenzylphosphonate esters **2** were obtained after lyophilization, as colorless solids in 95% yield.

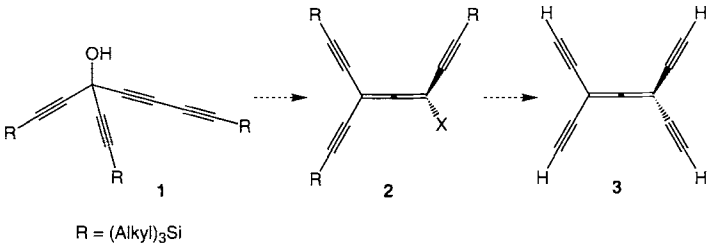
Tricyclo[6.2.0.0^{3,6}]deca-1,3,6,8-tetraene: A Remarkably Stable *para*-Quinodimethane from a Novel Rearrangement Reaction**

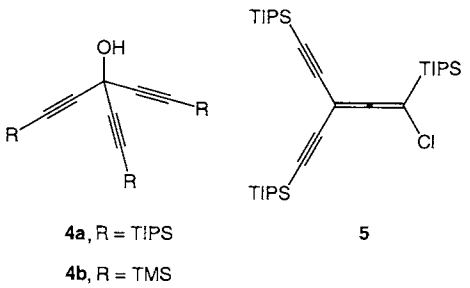
By *Jan-Dirk van Loon, Paul Seiler*, and *François Diederich**

In the course of our studies towards the development of new carbon networks,[1] we recently became interested in the synthesis of peralkynylcumulenes.[2] A possible route towards tetraethynylallene **3**, a molecule that could serve as a building block for a three-dimensional carbon lattice,[1] comprises the conversion of alcohol **1** into haloallene **2**, followed by a palladium-mediated coupling with a silyl-protected acetylene and exhaustive terminal deprotection (Scheme 1).

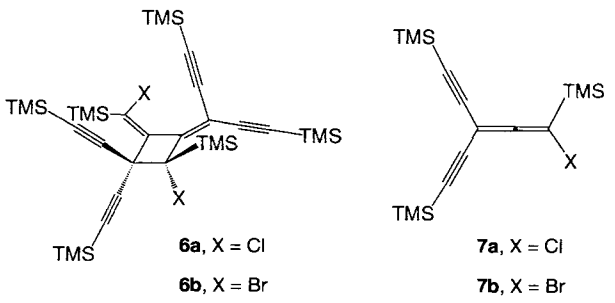


Scheme 1. Possible synthesis of tetraethynylallene **3**.

As a model for the first step, we investigated the reaction of the trialkynyl alcohols **4a**, **b**, which were readily prepared by treatment of the corresponding dialkynylketones with monoprotected lithium acetylides in hexane at 20 °C.[3] Reaction of triisopropylsilyl (TIPS)-protected **4a** with $SOCl_2$ in CH_2Cl_2 at −78 °C for 20 min afforded dialkynylchloroallene **5** in 86% yield. However, in a similar reaction with trimethylsilyl (TMS)-protected **4b**, the corresponding chloroallene **7a** could not be isolated because it rapidly dimerized to give **6a** in 76% yield. Similarly, reaction of **4b** with HBr in hexane at 20 °C (5 h) in the presence of one equivalent of CuBr[4] gave the brominated dimer **6b** in 70% yield. The different reactivity of **4a** and **4b** can be explained by the bulkiness of the TIPS groups, which prevent the dimerization of chloroallene **5**.



4a, R = TIPS
4b, R = TMS
5



6a, X = Cl
6b, X = Br
7a, X = Cl
7b, X = Br

In order to determine the structure of the dimer, a low-temperature X-ray analysis was performed on crystals of **6b** (Fig. 1).[5] All bond lengths and angles are within the expected range, except the very long C(1)–C(2) bond (1.626(5) Å) in the cyclobutane ring.[6] In the puckered four-membered ring the torsional angle between the two exocyclic C=C bonds is 44.3°. As a result the dienyne system C(18)=C(3)–C(4)=C(22)–C(23)≡C(24) is arranged in a helix, the handedness of which is determined by the configuration at the

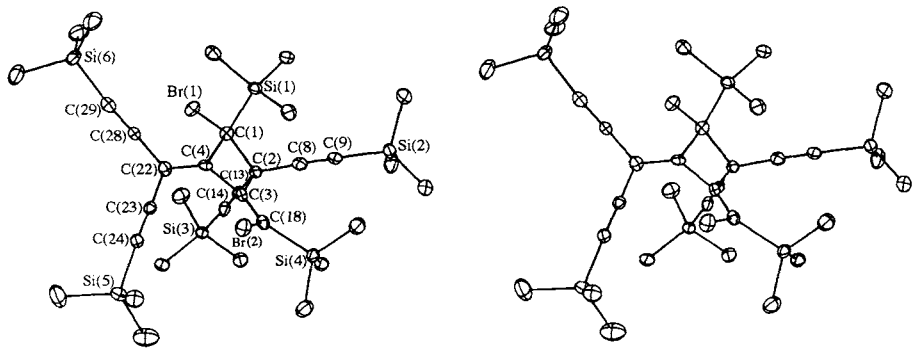

Fig. 1. X-ray crystal structure of **6b**. Selected bond lengths [Å] and angles [°]: C(1)-C(2) 1.626(5), C(1)-C(4) 1.505(5), C(2)-C(3) 1.564(6), C(2)-C(8) 1.471(6), C(2)-C(13) 1.464(5), C(3)-C(18) 1.336(6), C(4)-C(22) 1.363(5), C(8)-C(9) 1.203(6), C(13)-C(14) 1.215(5), C(22)-C(28) 1.432(5), C(22)-C(23) 1.431(6), C(23)-C(24) 1.200(6), C(28)-C(29) 1.213(5); C(1)-C(2)-C(3) 83.9(3), C(1)-C(2)-C(8) 116.8(3), C(1)-C(4)-C(3) 91.8(3), C(1)-C(4)-C(22) 134.5(4), C(2)-C(3)-C(4) 90.6(3), C(2)-C(3)-C(18) 130.8(4), C(2)-C(8)-C(9) 177.3(4), C(2)-C(13)-C(14) 178.9(4), C(4)-C(22)-C(28) 122.6(3), C(4)-C(22)-C(23) 121.6(4), C(22)-C(28)-C(29) 173.7(4), C(22)-C(23)-C(24) 179.2(4), Br(1)-C(1)-C(2) 114.7(3), Br(1)-C(1)-C(4) 116.8(3).

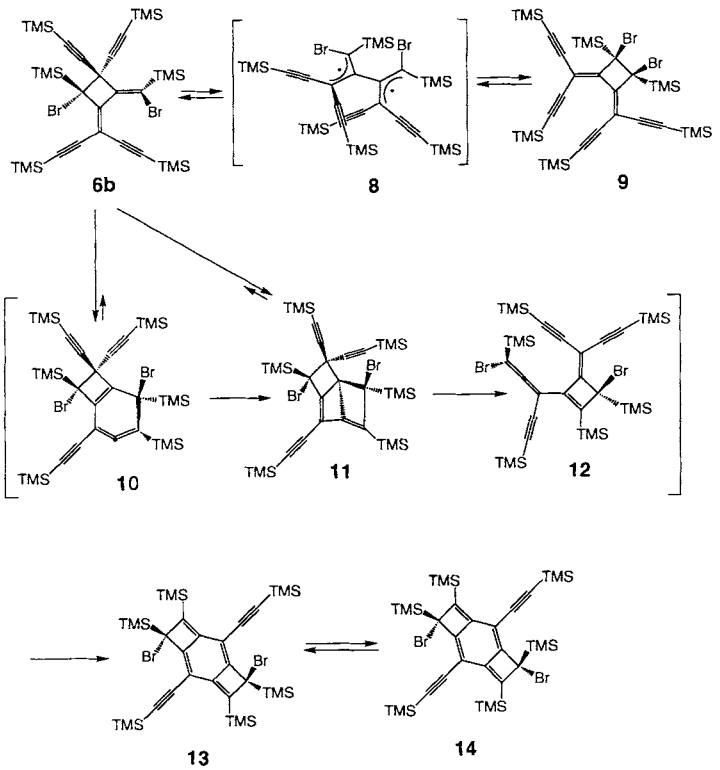
stereocenter. The formation of the racemic dimer **6b** can be explained by the reaction of two bromoallenes **7b** generated in situ, which approach each other orthogonally in the sterically most favorable manner.[7-9]

As the very long C(1)-C(2) bond in the cyclobutane ring of **6b** should be relatively weak, we were prompted to investigate the possible thermal rearrangement of **6b** to provide the more symmetrical cyclobutane **9** (Scheme 2). Compound **9** would be an interesting starting material for the synthesis of peralkynyl[4]radialenes by two Peterson olefination reactions. When a solution of **6b** in [D_8]toluene was heated at 90 °C, rapid rearrangement to give **9** indeed took place as was indicated by ^{1}H and ^{13}C NMR spectroscopy (Table 1). Surprisingly, however, before a thermodynamic equilibrium between **6b** and **9** could be established, **6b** reacted by a second pathway to yield the thermodynamically more stable *para*-quinodimethane **13**. The NMR signals of both **6b** and **9** disappeared, and an almost pure sample of **13** was obtained after 45 min (Scheme 2).[9] The kinetics for both pathways were followed by ^{1}H NMR spectroscopy and pseudo-first-order rate constants calculated as $k_{(\mathbf{6b}\rightarrow\mathbf{9})} = (5.7 \pm 0.5) \times 10^{-4}\ s^{-1}$, $k_{(\mathbf{9}\rightarrow\mathbf{6b})} = (2.2 \pm 0.2) \times 10^{-3}\ s^{-1}$, $k_{(\mathbf{6b}\rightarrow\mathbf{13})} = (9.8 \pm 0.8) \times 10^{-4}\ s^{-1}$, $k_{(\mathbf{13}\rightarrow\mathbf{6b})} \approx 0\ s^{-1}$ (Fig. 2).[10]



Scheme 2. Postulated mechanism of formation of **9** and **13** from **6b**.

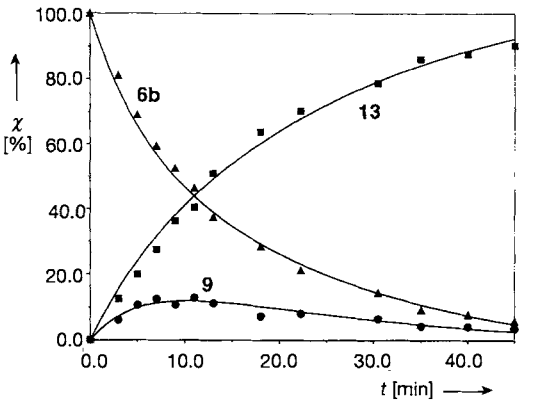


Fig. 2. Changes in the concentrations of **6b**, **9**, and **13** upon heating a solution of **6b** in toluene at 90 °C as a function of time. The fitting of the kinetic equations to the experimental data is shown.

Unambiguous structural proof of **13** was provided by a low-temperature X-ray analysis (Fig. 3).[5] The bond lengths and angles clearly show a *para*-quinodimethane bonding pattern. The inner bond angles of the four-membered rings in **13** are almost 90°, but in the six-membered ring the inner bond angles deviate significantly from 120°, with a value of 110.5° for the angle in fragment C(4A)-C(11)=C(3). The tricyclic ring system is almost planar (within 0.06 Å), and the crystal structure shows that **13** is the (*R,S*) or *meso* stereoisomer, in which the Br substituents adopt a *trans* orientation with respect to the planar ring system. The racemic mixture (*R,R*)- and (*S,S*)-**14**, in which the Br substituents adopt a *cis* orientation, eventually forms after prolonged heating of **13**, and gives ^{1}H and ^{13}C NMR spectra in which all resonances show only minor shifts compared to those in **13** (Table 1). Only after **13** is heated for several hours at 90 °C does decomposition take place, which is highly remarkable, since *para*-quinodimethanes are usually very reactive and stable only as transition metal complexes.[11,12] Compounds **13** and **14** possess the rare tricyclo[6.2.0.0^{3,6}]-deca-1,3,6,8-tetraene framework, of which only a few polyaryl-substituted derivatives have been reported so far.[13]

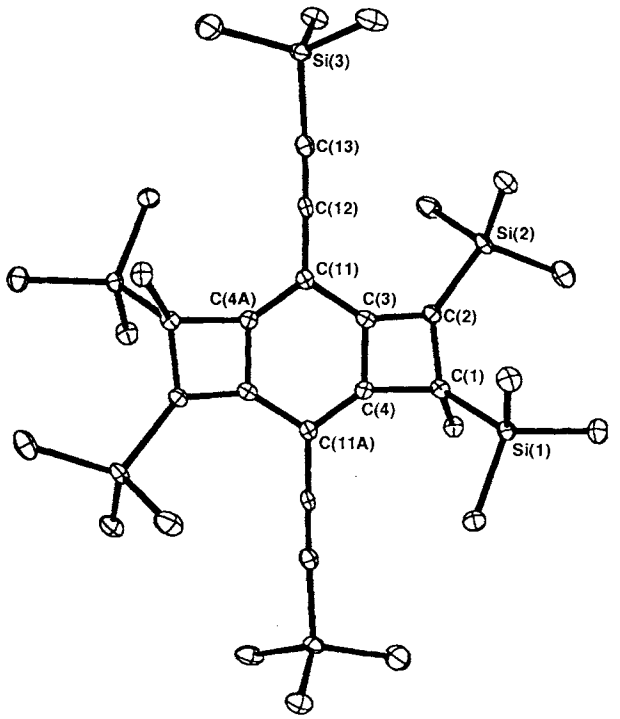

Fig. 3. X-ray crystal structure of **13**. Selected bond lengths [Å] and angles [°]: C(1)-C(2) 1.552(4), C(1)-C(4) 1.523(4), C(2)-C(3) 1.376(4), C(3)-C(4) 1.445(4), C(3)-C(11) 1.458(4), C(4)-C(11A) 1.366(4), C(11)-C(12) 1.425(4), C(12)-C(13) 1.212(4); C(1)-C(2)-C(3) 90.9(2), C(1)-C(4)-C(3) 89.5(2), C(2)-C(1)-C(4) 84.6(2), C(2)-C(3)-C(4) 94.4(2), C(2)-C(3)-C(11) 143.1(3), C(4)-C(3)-C(11) 122.3(3), C(1)-C(4)-(11A) 143.4(3), C(3)-C(11)-C(4A) 110.5(2), C(11)-C(12)-C(13) 178.0(3), Br(1)-C(1)-C(2) 114.2(2), Br(1)-C(1)-C(4) 111.8(2).

The reversible isomerization of **6b** to give **9** can be rationalized by assuming an orthogonal diradical intermediate **8**, which is formed from **6b** or **9** by a conrotatory opening of the cyclobutane ring,[7] in which one of the bulky TMS groups takes a sterically favorable inward position (Scheme 2). Diradical **8** presumably is also the intermediate in the dimerization of **7b** to give **6b**. In order to account for the selective formation of the *meso* stereoisomer **13** from **6b**, we propose a cascade pericyclic reaction mechanism. In the first step **6b** reacts in a $[2\pi_s + 2\pi_a]$ cycloaddition to provide the strained intermediate **11**. Alternatively, intermediate **11** can also be generated from **6b** by a 6π electrocyclic reaction to give the cyclic allene **10**,[14, 15] followed by a 4π conrotatory ring closure leading to **11**. In both pathways the stereochemistry at the newly formed stereocenters of **11** is controlled by the helical arrangement of the dienyne system in **6b** (vide supra), which in turn is induced by the stereocenter in the cyclobutane ring. The strained intermediate **11** opens by a $[2\pi_s + 2\pi_a]$ retrocycloaddition to give the chiral allene **12**, the configuration of which is determined by the fused ring system in **11**. Subsequent intramolecular $[2\pi_s + 2\pi_a]$ cycloaddition of the allene moiety in **12** with one of the C≡C bonds gives the *meso* form **13**. The epimerization of **13** to **14** most likely occurs through heterolytic rather than through homolytic C–Br bond cleavage, since a change of solvent from the less polar toluene to the more polar dimethylformamide accelerates the reaction significantly (roughly threefold).

Table 1. Yields and selected physical data of compounds **5**, **6b**, **9**, **13**, and **14**. ^{1}H and ^{13}C NMR spectra were recorded at 500 MHz and 125.6 MHz, respectively [a].

5: Yield 86%; yellow oil. IR (neat): $\tilde{\nu}$ = 2156 (C≡C), 1917 cm^{-1} (C=C=C); ^{13}C NMR ($CDCl_3$): δ = 216.9 (s, =C=), 97.9, 96.1 (2 × s, C=C), 96.8 (s, C=*C*Cl), 80.7 (s, *C*=C=CCl), 18.5, 18.3 (2 × q, CH_3), 11.5, 11.3 (2 × d, CH).

6b: Yield 70%. M.p. 125–126 °C; IR (KBr): $\tilde{\nu}$ = 2166 cm^{-1} (C≡C); ^{1}H NMR ([D$_8$]toluene): δ = 0.65, 0.57, 0.19, 0.18, 0.15, 0.13 (6 × s, 9H each); ^{13}C NMR ([D$_8$]toluene): δ = 157.1, 147.4 (2 × s, C=*C*-*C*=C), 130.4 (Br-*C*=C), 108.7 (s, (C≡C)$_2$*C*=C), 105.8, 104.4, 104.3, 103.5 (4 × s, Si-*C*≡C), 103.2, 102.2 (2 × s, (C≡*C*)$_2$C=C), 92.9, 91.8 (2 × s, (C≡*C*)$_2$*C*C$_2$), 62.5 (s, Br(TMS)*C*C$_2$), 50.5 (s, (C≡C)$_2$*C*C$_2$), 0.67, 0.38, 0.14, −0.19, −0.55, −0.57 (6 × q, CH_3).

9: ^{1}H NMR ([D$_8$]toluene): δ = 0.60, 0.24, 0.17 (3 × s, 18H each); ^{13}C NMR ([D$_8$]toluene): δ = 153.2 (s, C≡C-C=*C*), 107.6 (s, C≡C-*C*=C), 105.2, 105.2 (2 × s, Si-*C*≡C), 102.7, 101.6 (2 × s, Si-C≡*C*), 63.9 (s, CBr), 0.72, 0.40, −0.59 (3 × q, CH_3).

13: M.p. 219–220 °C (decomp); ^{1}H NMR ([D$_8$]toluene): δ = 0.50, 0.30, 0.29 (3 × s, 18H each); ^{13}C NMR ([D$_8$]toluene): δ = 159.3 (s, C≡C-C=*C*), 155.0 (s, Si-C=*C*), 152.3 (Si-*C*=C), 104.6 (s, Si-*C*≡C), 100.6 (s, C≡C-*C*=C), 99.2 (s, Si-C≡*C*), 62.2 (s, CBr), 0.78, −0.08, −1.36 (3 × q, CH_3); UV/VIS (hexane): λ_{max} [nm] = 399 sh (ε = 21400), 386 (27500), 373 sh (22400), 324 (6200), 264 (20500), 231 (32900).

14: ^{1}H NMR ([D$_8$]toluene): δ = 0.39, 0.26, 0.22 (3 × s, 18H each); ^{13}C NMR ([D$_8$]toluene): δ = 158.4 (s, C≡C-C=*C*), 155.5 (s, Si-C=*C*), 152.3 (Si-*C*=C), 104.3 (s, Si-*C*≡C), 100.2 (s, C≡C-*C*=C), 99.1 (s, Si-C≡*C*), 61.0 (s, CBr), 0.53, −0.07, −1.58 (3 × q, CH_3).

[a] All new compounds, except **9** and **14**, which were not isolated, were fully characterized by ^{1}H and ^{13}C NMR, IR, and UV spectroscopy, and high-resolution mass spectrometry or elemental analysis.

[5] Single crystals of **6b** ($C_{32}H_{54}Si_6Br_2$, M_r = 767.10) were first grown from methanol at 293 K. The scattering behavior of these crystals was very poor. Moreover, a phase transition occurred around 265 K, and cooling the compound below 260 K produced twinned crystals with a large mosaic spread; at very low temperature the crystals were transformed into a powder. Thus, a first data set was measured at 295 K using $Cu_{K\alpha}$ radiation and a nearly spherical crystal specimen with a diameter of ca. 0.6 mm. The structure could be solved by the Patterson method and refined by least-squares analysis to $R(F)$ = 0.08 (details are not given here). Owing to static and dynamic disorder of the TMS groups, the derived atomic parameters are very inaccurate. To avoid the phase transition and the disorder problem, a crystal specimen of good optical quality (size ca. 0.25 × 0.20 × 0.25 mm) was grown from methanol just below the transition temperature, mounted on the diffractometer without rewarming, and cooled slowly to 85 K. A second data set was then measured with $Mo_{K\alpha}$ radiation out to H = 1.19 Å^{-1} (7735 unique reflections, 4389 reflections with $I_o > 3\,\sigma(I_o)$). Crystal data: monoclinic space group $P2_1/c$ (No. 14), ϱ_{calcd} = 1.20 g cm^{-3}, Z = 4; a = 11.3870(10), b = 18.847(2), c = 22.468(4) Å, β = 118.27(2)°, V = 4247(1) Å^3. The structure was solved by the Patterson method (SHELXS86) and refined by full-matrix least-squares analysis (SHELXL 92), using a isotropic extinction correction and experimental weights. Final $R(F)$ = 0.024, $wR(F^2)$ = 0.061 for 416 variables and 4389 observed reflections (heavy atoms anisotropic, H atoms isotropic; H positions are based on stereochemical considerations, C–H = 0.96 Å, H-C-H = 109.5°). The results discussed in this paper are based only on this low-temperature analysis. – Single crystals of **13** ($C_{32}H_{54}Si_6Br_2$, M_r = 767.10) were grown from toluene at 293 K. A crystal specimen with linear dimensions of ca. 0.3 × 0.3 × 0.3 mm was cooled very slowly (ca. 3 K h^{-1}) to 85 K, in order to keep the mosaic spread as small as possible. A data set was measured with $Mo_{K\alpha}$ radiation out to H = 1.1 Å^{-1} (2803 unique reflections, 2203 reflections with $I_o > 3\,\sigma(I_o)$). Crystal data: monoclinic space group $P2_1/c$ (No. 14), ϱ_{calcd} = 1.26 g cm^{-3}, Z = 2; a = 12.868(3), b = 12.519(3), c = 12.905(3) Å, β = 103.15(3)°, V = 2024(1) Å^3. The structure was solved by the Patterson method and refined by full-matrix least-squares analysis (SHELXTL PLUS), using an isotropic extinction correction and a modified weight factor r = 5 Å^2 (J. D. Dunitz, P. Seiler, *Acta Crystallogr. Sect. B.* **1973**, *29*, 589–595). Final $R(F)$ = 0.027, $wR(F)$ = 0.032 for 210 variables and 2203 observed reflections (heavy atoms anisotropic, H atoms isotropic; H positions are based on stereochemical considerations, C–H = 0.96 Å, H-C-H = 109.5°). Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[6] In a seven-membered-ring allene dimer, an even longer C–C bond of 1.652(5) Å was observed in the cyclobutane ring: H. Jelinek-Fink, M.

[9] K. G. Migliorese, S. I. Miller, *Tetrahedron*, **1974**, *30*, 385–392. These authors reported on the stereospecific thermal isomerization of a tetraethynyldimethylenecyclobutane similar to **6a**. In light of our results, however, it is likely that as a product they had isolated a *para*-quinodimethane similar to **13** rather than the reported isomerized cyclobutane.
[10] The kinetic experiment was performed by addition of a solution of **6b** (100 mg) in [D_8]toluene (0.5 ml) to 20 mL of [D_8]toluene, that was thermostated at 90.0 ± 0.1 °C. Aliquots (0.5 mL) taken at this temperature were rapidly cooled and measured by ^{1}H NMR spectroscopy. The rate equations for the curve fitting were obtained by considering the equilibrium **9** ⇌ **6b** ⇌ **13**, with the corresponding (first-order) kinetic matrix which

$$\begin{pmatrix} k_{(9\to 6b)} & -k_{(6b\to 9)} & 0 \\ -k_{(9\to 6b)} & k_{(6b\to 9)}+k_{(6b\to 13)} & -k_{(13\to 6b)} \\ 0 & -k_{(6b\to 13)} & k_{(13\to 6b)} \end{pmatrix}$$

was solved by the program "Maple". We thank Ms. Tiziana Mordasini and Prof. Alfred Bauder, ETH Zürich, for their contributions.

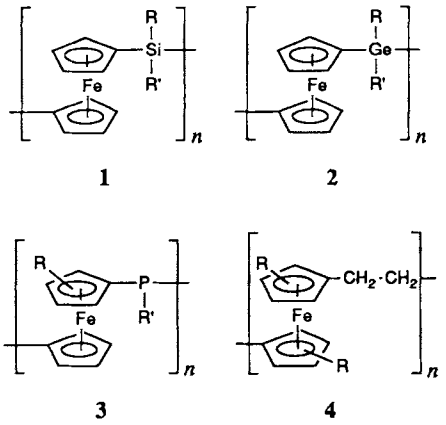
[15] *cis*-1,3-Hexadien-5-yne forms benzene via 1,2,4-cyclohexatriene at 274 °C with a half-life >90 min (H. Hopf, H. Musso, *Angew. Chem.* **1969**, *81*, 704; *Angew. Chem. Int. Ed. Engl.* **1969**, *8*, 680; we thank one reviewer for pointing out this reference to us.). The conversion **6b** → **10** occurs at a faster rate already at 90 °C since the reacting *cis*-1,3-hexadien-5-yne system in **6b** is perfectly preorganized for 6π electrocyclic ring closure.

Organometallic Ferrocenyl Polymers Displaying Tunable Cooperative Interactions between Transition Metal Centers**

By *Daniel A. Foucher, Charles H. Honeyman, James M. Nelson, Ben Zhong Tang,* and *Ian Manners**

Molecular or macromolecular materials which contain atoms of transition elements in close proximity are attracting increasing attention because of their potentially interesting electrical, redox, optical, and magnetic characteristics.[1] Organometallic polymers such as poly(vinylferrocene), which possess electroactive ferrocenyl side groups that are separated from one another by insulating organic units have been well studied. In such materials the ferrocenyl moieties are essentially noninteracting and a single oxidation wave is detected by cyclic voltammetry.[2] We have previously reported that the ring-opening polymerization of strained, ring-tilted [1]metallocenophanes provides a route to high molecular weight polymers **1**–**3** which possess backbones containing ferrocene groups alternating with either silicon, germanium, or phosphorus atoms.[3–5] We have also described an extension of this synthetic approach to the polymerization of [2]ferrocenophanes with a hydrocarbon bridge, which provided access to poly(ferrocenylethylene)s (**4**).[6] In this paper we present details of our comparative electrochemical studies of **1**–**4**, which show that they exhibit redox behavior which is markedly different from that of poly(vinylferrocene) and related polymers. Thus, we provide



evidence that in these materials the ferrocenyl units interact with one another and, moreover, that the extent of interaction is tunable, since it is dependent on the nature of the side groups and the bridge linking the adjacent ferrocenyl centers.

The poly(ferrocenylsilane)s **1** (R = R′ = Me, Et, *n*Bu, or *n*-hexyl) yield cyclic voltammograms in CH_2Cl_2 that show two reversible oxidation waves (Table 1).[7] Representative examples for polymer **1** (R = R′ = Me) at different scan rates are shown in Figure 1. The qualitative features of the cyclic voltammograms can be understood in the light of the extensive studies on low molecular weight compounds containing two or more ferrocenyl units linked together by a bridging group.[8] For example, biferrocene **5** ($x = 0$), in which the ferrocene units are in close proximity, shows two reversible oxidation waves at $E_{1/2} = 0.31$ V and $E_{1/2} = 0.64$ V as oxidation of the first ferrocenyl moiety makes subsequent removal of an electron from the other more difficult. The difference in these redox potentials ($\Delta E = 0.33$ V for biferrocene) is indicative of the extent of the interaction between the ferrocenyl units. Thus, as would be expected, the

[a] Molecular weights were determined by gel permeation chromatography (GPC) in THF containing 0.1% by weight of [NBu_4]Br using polystyrene standards. [b] $^1E_{1/2}$ and $^2E_{1/2}$ refer to the half-wave potentials for the first and second oxidation waves, respectively, and are relative to the ferrocene/ferrocenenium ion couple at 0.00 V, which was used as an internal reference. All potentials quoted refer to measurements at 250 mVs^{-1}. [c] The molecular weight was not determined because of adsorption to the GPC column.

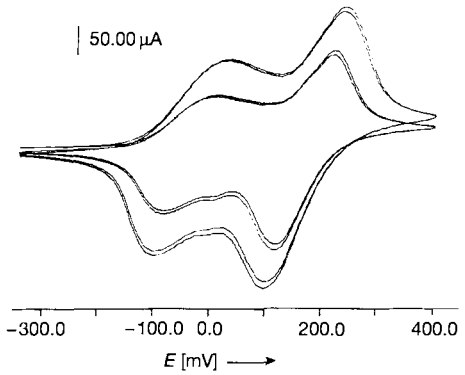

Fig. 1. Cyclic voltammogram of **1** (R = R′ = Me) in CH_2Cl_2 at scan rates of 500 and 1000 mVs^{-1}.

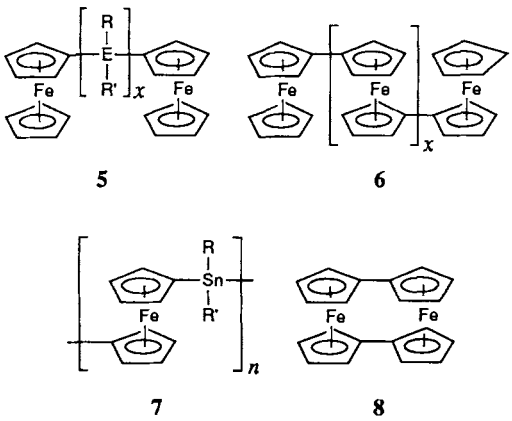
presence of an insulating CH_2 unit between the ferrocene groups as in diferrocenylmethane **5** (E = C, R = R′ = H, $x = 1$) leads to a decrease in ΔE to 0.1 V. Moreover, for species **5** (E = C, R = R′ = H, $x > 1$) with more than one CH_2 unit between the ferrocenyl groups, only one oxidation wave is detected ($\Delta E \approx 0$ V). Ferrocene oligomers without spacer groups such as terferrocene **6** ($x = 1$) and quaterferrocene **6** ($x = 2$) display cyclic voltammograms with a one-electron oxidation wave for each ferrocenyl unit present ($\Delta E \approx 0.2$ V).[9] These observations suggest that the first oxidations of poly(ferrocenylsilane)s occur randomly along the polymer chain at nonadjacent ferrocene sites. Subsequent oxidations would remove electrons from ferrocene groups that are adjacent to those already oxidized and would therefore be expected to occur at more positive potentials.[10] The difference (ΔE) in the oxidation potentials detected varies from 0.21 V (for **1**, R = R′ = Me) to 0.29 V (for **1**, R = R′ = *n*Bu or *n*-hexyl). For comparison, the value of ΔE for bis(ferrocenyl)dimethylsilane **5** (E = Si, R = R′ = Me, $x = 1$) is 0.145 V.[11] The results indicate that the extent of the interaction between the ferrocenyl units in poly(ferrocenylsilane)s depends significantly on the nature of the substituents at silicon. This may be caused by, for example, changes in the electronic structure of the bridge due to increased inductive effects as the length of the alkyl chain increases from Me to *n*Bu, or conformational effects which promote closer proximity of the metal centers in the case of the bulkier substituents.



To determine whether similar interactions would be present with other elements instead of silicon, the electrochemical behavior of a selected poly(ferrocenylgermane) (**2**, R = R′ = Me) and a selected poly(ferrocenylphosphane) (**3**, R = *n*Bu, R′ = Ph) was investigated. These polymers indeed showed similar electrochemical behavior to the poly(ferrocenylsilane)s **1**. For example, the cyclic voltammograms of **2** and **3** showed two reversible oxidation waves separated by 0.20 V and 0.19 V, respectively. The comparable values for the selected germanium-containing polymer and the analogous poly(ferrocenylsilane) (**1**, R = R′ = Me) indicate that the ferrocenyl groups interact to a similar extent. In order to investigate the effect of a tin bridge on the interactions, the low molecular weight poly(ferrocenylstannane) **7** (R = R′ = *n*Bu) was synthesized by the previously reported condensation route.[12] This material gave a cyclic voltammogram with two waves separated by 0.24 V, which is slightly less than for the silicon analogue **1** (R = R′ = *n*Bu) as might be expected from the larger size of the tin atom which would lead to a larger distance between the iron centers.

In contrast to the situation for organometallic polymers derived from the ring-opening polymerization of [1]ferrocenophanes, poly(ferrocenylethylene)s (**4**), prepared from [2]ferrocenophanes containing a hydrocarbon bridge, show electrochemical behavior indicative of minor interactions between the iron centers. Representative cyclic voltammograms for **4** (R = Me) show essentially one oxidation wave, which has an only partially resolved shoulder (Fig. 2, $\Delta E \approx 0.06$ V); this implies that only very weak interactions between the metallocene units are present. The behavior is in stark contrast to that recently reported for poly(ferrocenylene persulfide)s in which the ferrocene groups are linked by two sulfur atoms, for which a ΔE value of 0.32 V has been reported. This indicates that a disulfide bridge promotes much greater interactions between the ferrocene groups.[10]

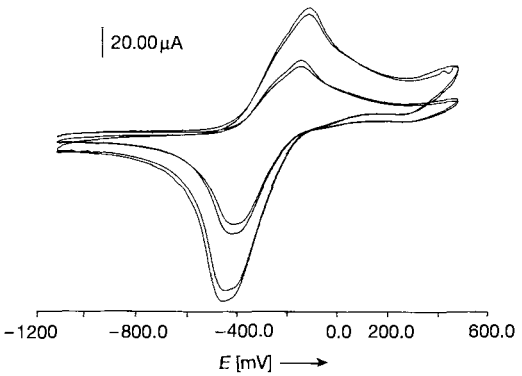


Fig. 2. Cyclic voltammogram of **4** (R = Me) in CH_2Cl_2 at scan rates of 500 and 1000 mVs^{-1}.

Further work will be directed towards obtaining a detailed understanding of the relationship between the structure of the polymer main chain and the type of side group, and the nature and extent of the interactions between the ferrocenyl groups. With this in mind, it is worth noting that in biferrocenylene **8**, which shows two reversible oxidation waves by cyclic voltammetry with $\Delta E = 0.63$ V, the extent of interaction between the ferrocene groups is so large that one-electron oxidation yields a radical cation with completely delocalized charge.[13] Clearly, an understanding of how the interactions between the ferrocenyl groups in organometallic polymers such as **1**–**3** can be maximized might allow the preparation of materials with appreciable electron mobility and therefore novel electrical and optical properties.

[5] Seyferth et al. have previously reported the synthesis of the poly(ferrocenylphosphane) **3**, (R = H, R' = Ph) by a condensation route: H. P. Withers, D. Seyferth, J. D. Fellmann, P. Garrou, S. Martin, *Organometallics* **1982**, *1*, 1283.

[6] J. M. Nelson, H. Rengel, I. Manners, *J. Am. Chem. Soc.* **1993**, *115*, 7035.

[7] Electrochemical experiments were carried out on a PAR model 273 potentiostat with a Pt working electrode, a W secondary electrode, and an Ag wire reference electrode in a Luggin capillary. The concentration of the polymer was 5×10^{-4} M in CH_2Cl_2; 0.1 M $[Bu_4N][PF_6]$ served as a supporting electrolyte. Peak currents were proportional to the square root of the scan rate over the range studied (25 mVs^{-1} to 1000 mVs^{-1}), which indicates that charge transfer is similar to a semi-infinite linear diffusion process. We attribute the slight difference in wave shapes to slight adsorption of the fully oxidized polymer to the electrode.

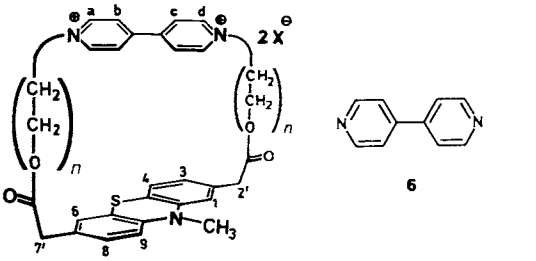
Phenothiazine–Bipyridinium Oligooxacyclophanes**

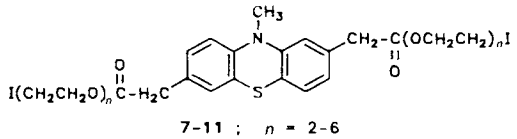
By *Christoph Petry, Martina Lang, Heinz A. Staab,* and *Helmut Bauer**

Intermolecular electron donor–acceptor interactions of phenothiazine with acceptors, for example 1,3,5-trinitrobenzene,[1] tetracyanoquinodimethane,[2] tetracyanobenzene,[3] tetracyanoethylene,[3] quinones,[3] pyromellitic dianhydride,[4] and 1,1'-dimethyl-4,4'bipyridinium dication (methylviologen),[5] have been known for some time. However, compounds in which a phenothiazine and a dicationic bipyridinium unit are covalently linked by an oligomethylene chain have been studied only in the last few years.[6–8] These investigations focused on complexation with cyclodextrins and the electron transfer between the phenothiazine and the bipyridinium components.

We report here on the first doubly bridged phenothiazine–bipyridinium diiodide systems **1**–**5** having an oligooxacyclophane structure and on the remarkable finding that the donor and acceptor groups in the 38-membered macrocycle **2** may approach each other in solvents like dichloromethane and acetonitrile. Oligoethyleneglycol fragments of various lengths were used as bridges in the cyclophanes. Since the compounds with a large cavity should be able to coordinate metal ions, a metal ion induced approach of the donor and acceptor should be possible.



1–5 : n = 2–6 , X = I



7–11 ; n = 2–6

Double alkylation of 4,4'-bipyridine (**6**) with the appropriate 2,7-bis(ω-iodo-oligooxaalkylcarbonylmethyl)-10-methylphenothiazines **7**–**11** in refluxing nitromethane (3–7 days) employing the dilution principle provided the oligooxa[3n + 2]cyclophanes **1**–**5** in yields of 8, 12, 20, 13, and 9%, respectively. Tetraoxa[8.8]cyclophane **1** was recrystallized from water to give small black plates (m.p. 262 °C, decomp), hexaoxa[11.11]cyclophane **2** forms fine black needles (m.p. 138–139 °C), and octaoxa[14.14]cyclophane **3** was recrystallized from methanol to furnish deep red plates (gradual softening starting at 75 °C). Decaoxa[17.17]- and dodecaoxa[20.20]cyclophanes **4** and **5** were purified by chromatography on P2-Gel (BIO-RAD) eluting with an aqueous buffer of 0.11 M acetic acid and 0.1 M triethylamine. After ion exchange on DOWEX 1 × 8 (iodide form), **4** and **5** were obtained as red-brown amorphous powders (softening starting at 70 and 60 °C, respectively). Each cyclophane takes up about two equivalents of triethylammonium iodide.

The syntheses of the phenothiazine cyclization components **7**–**11** all start with the known 2,7-diacetyl-10-methylphenothazine (**15**),[9] which is prepared from 2-acetyl-10-methylphenothiazine (**14**) by Friedel–Crafts acylation (Scheme 1). **Caution:** We recommend that compound **14** not be prepared as described by N-methylation of commercially available 2-acetylphenothiazine (**12**) with methyliodide in a sealed tube.[10] During one of the many reactions of this type that we carried out, tremendous pressure built up in the glass vessel leading to an **explosion**. The roundabout synthesis via ketal **13** followed by methylation at −20 °C is safer.

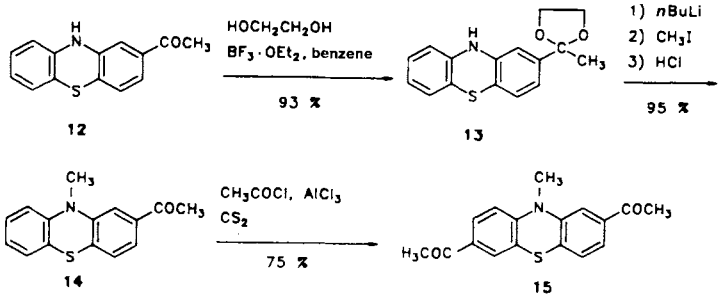
[**] Electron Donor–Acceptor Compounds, Part 49. Part 48: H. A. Staab, A. Döhling, C. Krieger, *Tetrahedron Lett.* **1991**, *32*, 2215–2218.



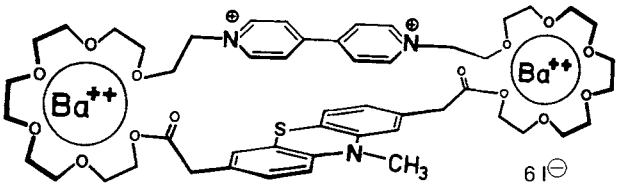
Scheme 1. Synthesis of 2,7-diacetyl-10-methylphenothiazine.

Linkage of phenothiazine with 4,4'-bipyridine by $(CH_2OCH_2)_n$ bridges could not be realized, since bis-(2,7-alkoxymethyl)-10-methylphenothiazine could not be prepared as a model compound and the ether groups of bis(2,7-methoxyethyl)-10-methylphenothiazine are cleaved even in water to give the diol. Thus, the oligooxa bridges were connected with the phenothiazine framework through ester functions. For this purpose, **15** was converted into dicarboxylic acid **16** by a Willgerodt–Kindler reaction, and the phenothiazine cyclization components **7**–**11** were subsequently obtained by two routes (Scheme 2). The first route proceeds via dimethylester **17** by transesterification with monochlorooligoethyleneglycols, the second route by esterification of **16** with monoiodo- or mono-*p*-toluenesulfonyloligoethyleneglycols employing the azolide 1,1-carbonylbis(methylimidazolium)trifluoromethanesulfonate[11] as condensation agent. Dichlorides **18**–**20** and ditoluenesulfonates **21** and **22** were readily converted into the more reactive diiodides **7**, **8**, **23**, and **10**, **11**, respectively, by reaction with sodium iodide. Diiodide **23** and bipyridine did not undergo cyclization.

In water and in acetonitrile cyclophanes **1**–**5** show only a weak, broad charge transfer (CT) absorption, but in dichloromethane this band is quite distinct: $\lambda_{CT}(\varepsilon)$ of **2** in CH_2Cl_2: 485 nm (1200), **3**: 477 nm (1000), **4**: 457 nm (920), and **5**: 475 nm (1050). A UV/VIS spectrum of [8.8]cyclophane **1** in dichloromethane could not be measured because of poor solubility. The CT absorptions can be attributed primarily to the CT interaction between the iodide ions and the bipyridinium components of the cyclophanes, since the red compound 1,1'-didodecyl-4,4'-bipyridinium diiodide[12] has a similar VIS spectrum ($\lambda_{CT}(\varepsilon)$ in CH_2Cl_2: 506 nm (1276)).

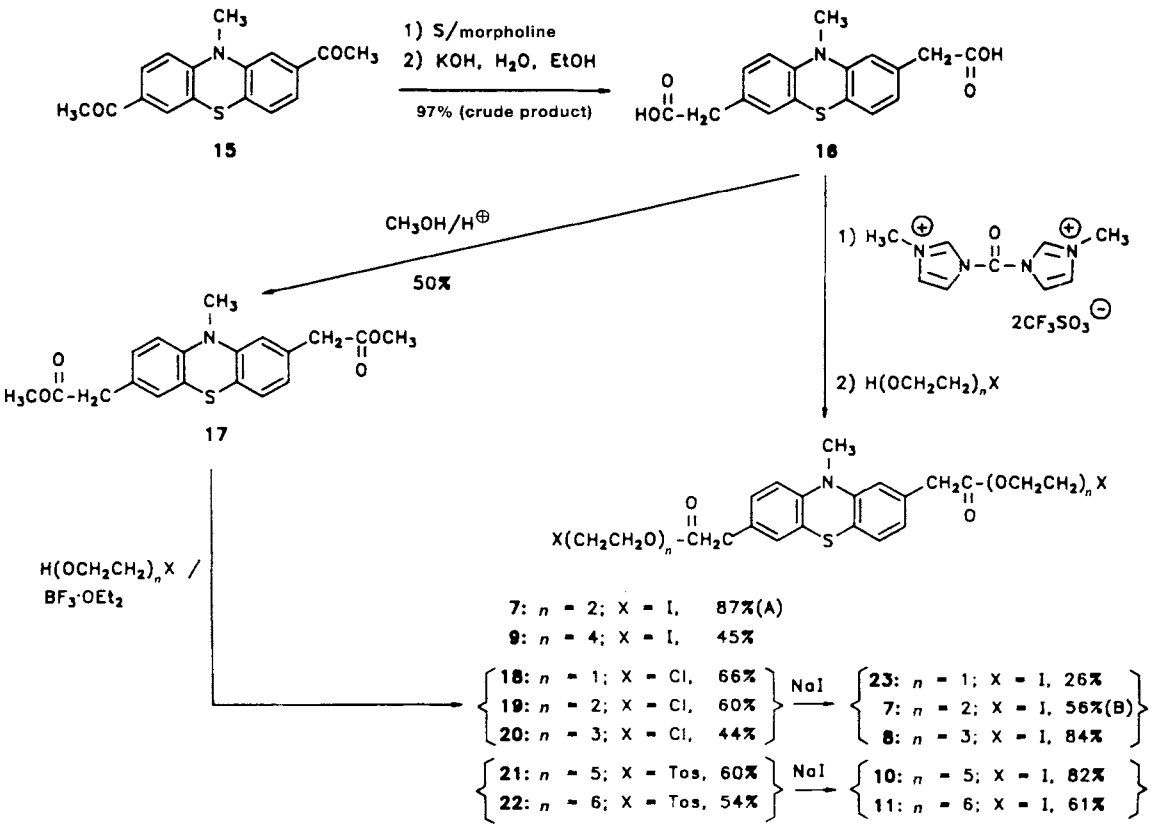
Fluorescence measurements of solutions of cyclophanes **1**–**5** in dichoromethane and acetonitrile show 95% quenching of the phenothiazine fluorescence relative to the reference compounds **17** and **11**.

The reaction of [20.20]cyclophane **5** with barium diiodide in acetone furnished the barium complex **24** as a red-brown powder in 22% yield. In analogy to previous findings[13] for cation complexes of donor–acceptor oligooxacyclophanes, the barium ion may be coordinated as shown in structure **24**.



24

The red-shift of the IR band for the ester by approximately 30 cm^{-1} relative to that of [20.20]cyclophane **5** indicates that this group is also coordinated to Ba^{2+}.



Scheme 2. Preparation of the phenothiazine cyclization components.

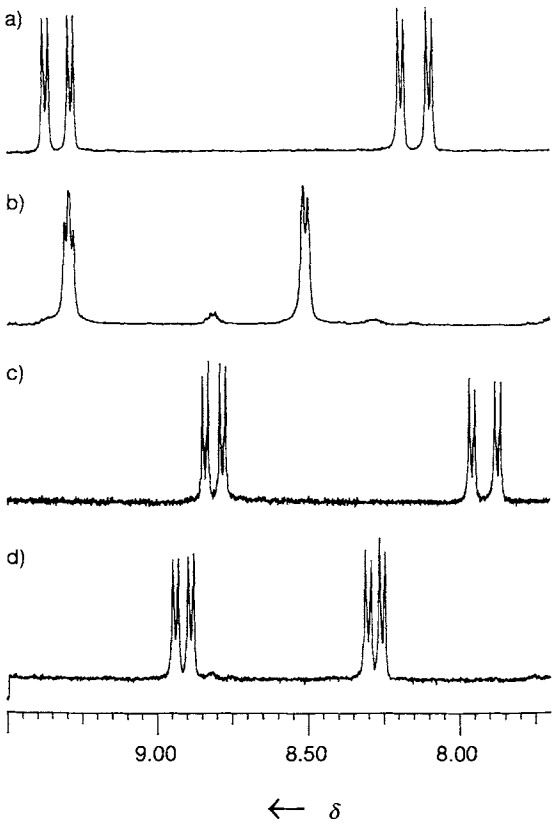


Fig. 1. Sections of the ^{1}H NMR spectra of a) **2** in CD_2Cl_2, b) **5** in CD_2Cl_2, c) **2** in CD_3CN, and d) **24** in CD_3CN.

In the ^{1}H NMR spectra of **2** and **5** in CD_2Cl_2 the signal patterns for the bipyridinium hydrogen atoms differ significantly (Fig. 1). In the spectrum of **2** the signals of both the inner and the outer hydrogen atoms of the bipyridinium unit are clearly resolved as two sets of doublets at $\delta = 9.39/9.37$, 9.29/9.27 and 8.18/8.16, 8.07/8.05, as would be expected owing to the proximity of the unsymmetric phenothiazine unit. In contrast, in the spectrum of the larger macrocycle **5** practically only the signals of the unperturbed bipyridinium unit are evident. The signal resolution observed for the Ba_2 complex **24** is similar to that for **2** (Fig. 1), which indicates that complexation brings the bipyridinium and phenothiazine units closer together.

The approach of the donor and acceptor units of cyclophane **2** in dichloromethane is proven unequivocally by rotating frame nuclear Overhauser effect (ROE) experiments (Fig. 2). Upon irradiation of the signals for the b and c hydrogen atoms of the bipyridinium component, not only the signals of the a/c and b/d hydrogen atoms are enhanced as expected, but also the signals of all the protons of the phenothiazine component including the N-CH_3 group, the benzylic CH_2 groups, and the CO_2CH_3 groups. This indicates that the donor and acceptor units of cyclophane **2** in dichloromethane are separated by only 3.5–4 Å for at least several hundred ms. Irradiation of the signals of the a/d hydrogen atoms also results in transannular nuclear Overhauser effects (NOEs). The NOEs in acetonitrile are analogous to those in dichloromethane but are weaker in dimethyl sulfoxide. NMR spectra measured in dichloromethane at low temperatures indicate that the donor and acceptor approach each other even closer: at $-90\,^\circ$C the a/d and b/c doublets are shifted further apart (from $\Delta\delta = 0.1$ to $\Delta\delta = 0.25$); moreover, the signals of the doublets of the inner bipyridinium hydrogen atoms at $\delta = 8.17$ and 8.07 are shifted upfield by $\Delta\delta = 0.34$ and $\Delta\delta = 0.22$, respectively, as a result of the transannular anisotropy of the neighboring aromatic ring.

In CD_2Cl_2 [17.17]cyclophane **4** also shows transannular NOEs, though weak, between the b/c hydrogen atoms and the signals of H(1), H(9), H(3), H(4), and H(6) of the phenothiazine.

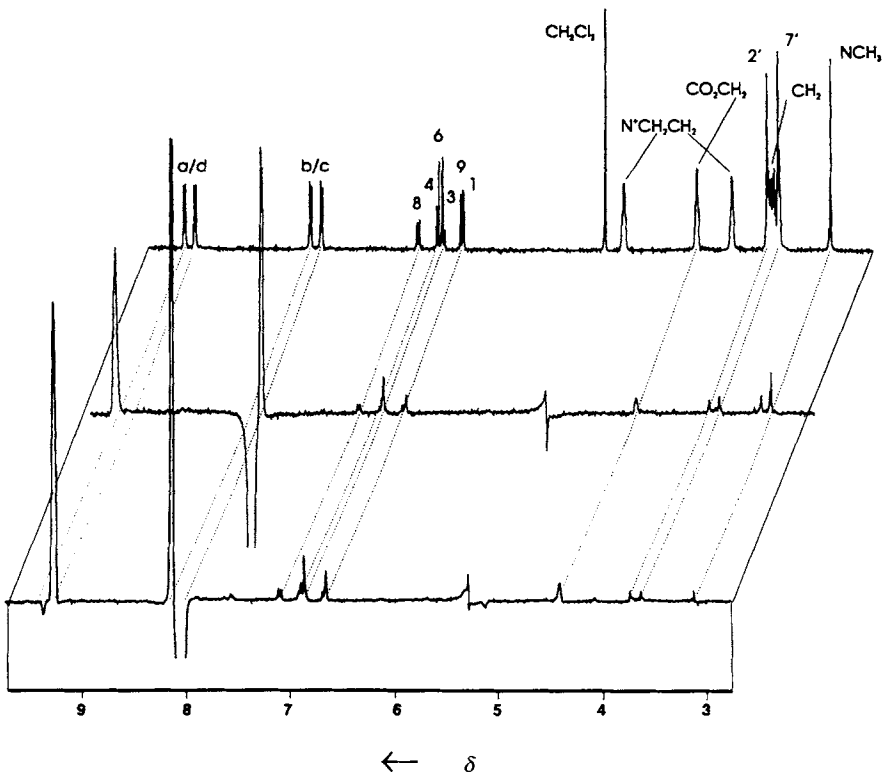

Fig. 2. ^{1}H NMR spectrum and ROE difference spectra of [11.11]cyclophane **2** in CD_2Cl_2, irradiation of signals b and c, 303 K, 360 MHz.

Table 1. Physical data of compounds **1**–**5**, 1,1′-didodecyl-4,4′-bipyridinium diiodide, and **24**.

1: ^{1}H NMR ([D$_6$]DMSO): δ = 3.11 (s, 3H, NCH_3), 3.55 (s, 2H, 7′-CH_2), 3.63 (s, 2H, 2′-CH_2), 3.73 (m, 4H, $N^+CH_2CH_2OCH_2$), 3.94 (m, 4H, $N^+CH_2CH_2$), 4.18 (m, 4H, CO_2CH_2), 4.75 (t, ^3J = 4.7 Hz, 2H, N^+CH_2), 4.84 (t, ^3J = 4.7 Hz, 2H, N^+CH_2), 6.70 ("d", 1H, ArH, pos. 1), 6.76 (d, ^3J = 8.2 Hz, 2H, ArH pos. 3 and pos. 9), 6.86 (d, ^4J = 2.0 Hz, 1H, ArH, pos. 6), 6.96 (d, ^3J = 7.6 Hz, 1H, ArH, pos. 4), 7.00 (dd, ^3J = 8.2 Hz, ^4J = 1.8 Hz, 1H, ArH, pos. 8), 8.49 (m, 4H, PyH), 9.02 (d, ^3J = 6.9 Hz, 2H, PyH), 9.08 (d, ^3J = 6.9 Hz, 2H, PyH); IR (KBr): $\tilde{\nu}$ = 1740 cm^{-1} [ν (C=O)]; MS (FAB): *m/z* 627 (100%) [$M^+ - 2I$]; correct elemental analysis for $C_{35}H_{37}I_2N_3O_6S$.

Exchange of the iodide ions in **2** for hexafluorophosphate provides violet crystals that are insoluble in dichloromethane. A solution of this salt in acetonitrile gives rise to two weak VIS absorptions at λ = 484 nm (ε = 95) and 564 nm (ε = 105), which are attributed to the CT effect between the phenothiazine and the bipyridinium components.

Heterolysis of Re_2O_7: Generation and Stabilization of the Cation $[ReO_3]^+$ **

By *Wolfgang A. Herrmann,* Peter W. Roesky, Fritz E. Kühn, Wolfgang Scherer,* and *Matthias Kleine*

Many alkyl, cyclopentadienyl, and aryl complexes of the type $[R\text{–}ReO_3]$ can be prepared from dirhenium heptaoxide and organotin or organozinc reagents.[1] Alkylation—as typical example $[CH_3ReO_3]$ of Equation (1a)—and arylation can formally be classified as heterolysis of Re_2O_7 into "rhenyl" and a "perrhenate" ion according to Equation (1b) (correct IUPAC nomenclature: trioxorhenate(VII) and tetraoxorhenate(VII) ions, respectively). We now show that a redox neutral cleavage (i.e., not accompanied by a change of oxidation number of the metal) of Re_2O_7 is indeed possible if the $[ReO_3]^+$ ion is generated and stabilized by amines.

$$Re_2O_7 + {}^1/_2\ Zn(CH_3)_2 \longrightarrow [CH_3ReO_3] + {}^1/_2\ Zn(ReO_4)_2 \quad (1a)$$

$$Re_2O_7 \longrightarrow [ReO_3]^+ + [ReO_4]^- \quad (1b)$$

Addition of 1,4,7-triazacyclononane (tcan) to a solution of dirhenium heptaoxide in THF causes immediate and quantitative precipitation of the metal complex **2a** [Eq. (2)] as a white solid, insensitive to air and water, which has salt-like properties and is a 1/1 electrolyte (Λ = 100 S cm^2 mol^{-1}; $c = 1 \times 10^{-3}$ mol L^{-1}). It is almost insoluble in organic solvents, but can be recrystallized from water. A crystallo-

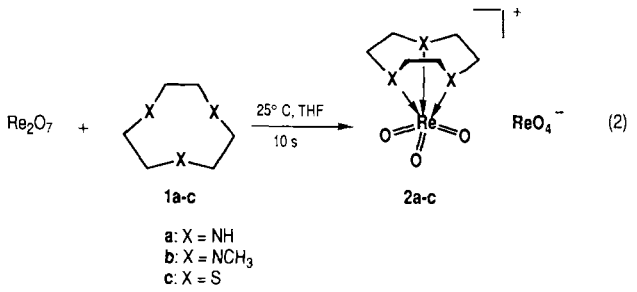
[**] Multiple Bonds between Main Group Elements and Transition Metals, Part 127. This work was supported by the Fonds der Chemischen Industrie (doctoral grant for P. W. R.) and the Hermann Schlosser Foundation (doctoral grant for F. E. K.). We thank Professor K. Wieghardt, University of Bochum, for the ligand **1a**. Part 126: K. Öfele, W. A. Herrmann, D. Michalios, M. Elison, E. Herdtweck, W. Scherer, J. Mink, *J. Organomet. Chem.*, **1993**, *459*, 177–184.



graphic study[2] analysis substantiated the ionic structure: two separate ions, the N,N,N-coordinated rhenyl ion and the perrhenate ion, are present (Fig. 1). The cation is isovalent with the crystallographically characterized half-sandwich complexes $[(\eta^5\text{-}C_5H_5)ReO_3]$ and $[(Hbpz_3)ReO_3]$ ($Hbpz_3$ = hydrotris(pyrazolyl)borate).[3] Complex **2a** forms a three-dimensional network of cations and anions that are linked together through linear $N-H\cdots O-ReO_3$ hydrogen bonds.

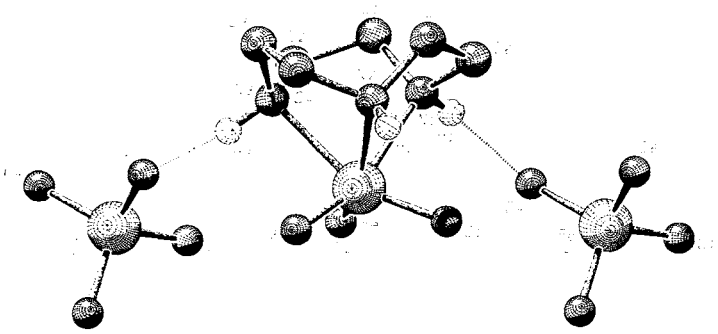


Fig. 1. Molecular structure of **2a** in the crystal (cross-section of the three-dimensional network structure; SCHAKAL representation). Shown are two typical linear hydrogen bonds between cations and anions. Selected distances [pm] and angles [°]: Re1-O1 172.4(3), Re1-O2 173.0(3), Re1-O3 171.9(3), Re2-O4 172.1(3), Re1-N1 223.1(3), Re1-N2 224.1(3), Re1-N3 225.4(1), H1-O4 214(4), H(3)-O(6) 190(4); O1-Re1-O2 106.0(1), O2-Re1-O3 106.4(1), N1-Re1-O1 86.0(1), N1-Re1-N2 74.1(1). – For comparison, selected bond distances [pm] and angles [°] of **2b**: Re1-O1 172.5(2), Re1-O2 172.1(2), Re1-O3 170.3(2), Re2-O4 173.1(2), Re1-N1 227.3(2), Re1-N2 228.9(3), Re1-N3 226.7(2); O1-Re1-O2 105.8(1), O2-Re1-O3 106.2(1), N1-Re1-O1 87.9(1), N1-Re1-N2 75.4(1).

An X-ray structure analysis was also performed on **2b**, the analogous complex containing the N-methylated ligand.[4] The most important bond lengths and angles are given in the legend of Figure 1 for comparison with those of **2a**. These complexes do not differ fundamentally in molecular structure, but **2b**, in contrast to **2a**, contains one water of crystallization per formula unit, which links the perrhenate ions into chains through hydrogen bonds.

Complex **2a** was prepared by Wieghardt et al. by nitric acid or H_2O_2 oxidation of $[(tacn)Re(CO)_3]Cl$.[5] The new route, however, enables the ligand to be varied: the derivatives containing *N*-methylated ligands (**2b**) or S-donor ligands (**2c**) can be synthesized directly by treatment of Re_2O_7 with the ligands **1b** and **1c**, respectively.[6]

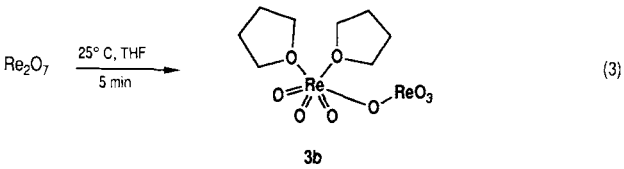
Also open-chain ligands like $[(CH_3)_2NCH_2CH_2]_2NCH_3$ form ionic compounds with Re_2O_7, which are, however, sensitive to moisture. The driving force for this heterolysis is the stabilization of the $[ReO_3]^+$ ion by the tridentate donor ligands, which help the metal attain its preferred octahedral coordination and valence saturation. Recombination of $[ReO_3]^+$ and $[ReO_4]^-$ is thus impossible. Potential mono- and bidentate ligands are not adequate for this purpose: they form only covalent adducts with the formula $[Re_2O_7\cdot L_2]$, which can be isolated as pure compounds. An example is the 2,2′-bipyridine (bpy) complex **3a**.[7]

$[Re_2O_7\cdot bpy]$ **3a**

The spectroscopic data of the cation of **2a** resembles those of the known complexes $[R\text{–}ReO_3]$ (R = aryl, alkyl): $\nu(ReO) = 935\ cm^{-1}$ (typical 920–960[3a]); $\delta(^{17}O) = 1019$ (D_2O). The perrhenate ion has its characteristic band at $909\ cm^{-1}$ (KBr) and an ^{17}O NMR signal at $\delta = 562$ (D_2O).

Thermogravimetric mass spectrometric (TG-MS) studies on **2a** and **2c** confirm the strong bonding between the ligand and the $[ReO_3]^+$ fragment.[8] Though a mass loss can be detected in the case of **3a** even at low temperatures,[7] this is attributable to the greater thermal lability of the ligands relative to bpy and not to a weaker bond to the Re atom. Consequently, for **2a** and **2c** a multistep decomposition by water and carbon dioxide expulsion (and in the case of **2c** ethene) is observed, which suggests a redox reaction between ligand and oxygen (from $[ReO_3]^+$). Only the intact ligand is eliminated from **3a** and other Re_2O_7 base adducts.[9]

The unsymmetrical cleavage of Re_2O_7 is predictable from the structure: whereas the compound displays a symmetrical Re-O-Re′ bridge in the gas phase,[10] the solid state structure reveals $[ReO_4]$ tetrahedra surrounded by chains of octahedrally coordinated rhenium atoms.[11] This polymeric structure is broken up by donor solvent molecules like water, pyridine, acetonitrile, or ether:[9, 10, 12] The structure of **3b** in solution consists of discrete Re_2O_7 molecules to which two solvent molecules coordinate unsymmetrically, that is, to one of the metal atoms according to Equation (3).[10] As a



result, in contrast to the structure in the gas phase,[10] the Re–O bonds of the Re-O-Re′ bridge are different lengths, which anticipates the decomposition into $[ReO_4]^-$ and $[ReO_3]^+$ ions [Eq. (3)]. The situation resembles that in chlorine(VI) oxide Cl_2O_6, which is present in the solid as $[ClO_2]^+[ClO_4]^-$.[13]

Our results show that dinuclear, covalent metal oxides are set up for a separation into ions by unsymmetric solvation, for instance in $[Re_2O_7\cdot L_2]$, which is then executed by suitable chelating ligands. This simple method of enhancing the reactivity of metal oxides by dissolving them in polar coordinating solvents seems to have far-reaching preparative consequences for their coordination chemistry and their organometallic chemistry.[1, 14]

Experimental Procedure

2a: Re_2O_7 (245 mg, 0.5 mmol) were dissolved in THF (10 mL), and tacn (70 mg, 0.5 mmol) was added. The complex **2a** precipitates immediately as a white substance that is analytically pure after washing with THF and drying in vacuum. Yield: 300 mg (98%); *IR (KBr)*: $\tilde{\nu}$ [cm^{-1}] = 3038(w), 2844(m), 935(vs, ν(ReO) of $[ReO_3]^+$), 912(vs, ν(ReO) of $[ReO_4]^-$). ^1H NMR (D_2O, 400 MHz, 20 °C): δ = 3.07 (s, 12H, CH_2); $^{13}C\{^1H\}$ NMR (D_2O, 100.53 MHz,

20 °C): $\delta = 42.04$ (CH_2); $^{17}O\{^1H\}$ NMR (D_2O, 54.21 MHz, 20 °C): $\delta = 562.9$ ($[ReO_4]^-$), 1019.2 ($[ReO_3]^+$). Correct elemental analysis.

Complexes **2b** and **c** were prepared analogously.

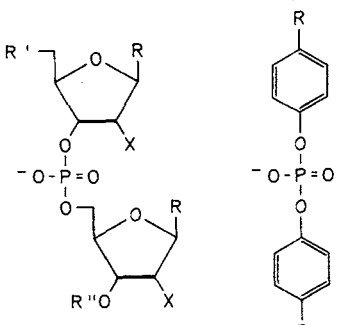
Catalysis of the Hydrolysis of Phosphoric Acid Diesters by Lanthanide Ions and the Influence of Ligands

By *Hans-Jörg Schneider,* Jörg Rammo,* and *Ronald Hettich*

Since Bamann discovered the catalytic effectiveness of lanthanide ions in the hydrolysis of glycerol phosphates,[1] these and transition metal ions have also been used as catalysts for the cleavage of ribose phosphates, which are structurally related through their vicinal hydroxy groups.[2–4] The hydrolysis of normal phosphoric acid esters or of DNA (**1**) requires much more drastic conditions than that of RNA (**2**) due to the absence of the 2′-OH group. Considerable acceleration of the reactions can be achieved with more highly charged transition metal ions.[5, 6] In particular, Chin et



1 (X = H) **3a** (R = H)
2 (X = OH) **3b** (R = NO_2)

al.[5b] have shown that with specific cobalt complexes even nonactivated esters such as dimethyl phosphate react up to 10^{10} times faster.[7] However, it appears that the—sometimes not very stable—metal complexes are used up during the reaction, that is they are not functioning as catalysts and Michaelis–Menten kinetics (as found with enzymes) were not observed. Recently Komiyama et al.[8a] showed for the

first time that the cleavage of plasmid DNA could also be accelerated by lanthanide ions. The conditions, however, are so drastic, in comparison to those of well-known radical DNA cleavage with redox metals,[8b] that the participation, at least in part, of a radical mechanism cannot be excluded.

We report here on the highly efficient catalysis of the saponification of the phosphoric acid diaryl ester **3** by lanthanide ions, characterized by saturation kinetics and "turnover", and on the main possibilities of controlling the hydrolysis with complex ligands. The most important factor in the potential use of synthetic reagents for the hydrolysis of phosphoric acid esters—be they insecticides, chemical weapons, or nucleic acids—is that the catalytic center is located in a kinetically stable complex. This should, for example, make it possible to immobilize catalysts, to raise their affinity for DNA (thus, for example, concentrations of drugs can be reduced to levels suitable for therapy), and to selectively cleave DNA strands (through the formation of a triple helix containing oligonucleotide complex conjugation [9]). This was realized—apart from a few exceptions[10]—largely with *oxidatively* active reagents,[11] of which the iron–EDTA oligonucleotides of Dervan et al.[12] are the best known. The very reactive oxygen-containing radicals that are formed have the disadvantage of not being very selective and of producing unnatural cleavage products; this can be avoided by the hydrolysis of phosphoric acid esters—as occurs in nature.

Initially, we tried to use strong nucleophiles such as thiolates, oximates, etc. (thiophenol, salicylaldoxim, iodosobenzene) with the aim of accelerating the hydrolysis of model phosphates such as **3b**, since their affinity for DNA can be raised almost without limit by combining such ligands with polyamines.[13a] After a preliminary test of this method with plasmid DNA had led to hardly any detectable effect,[13b] we measured, photometrically, the release of nitrophenolate from the model ester **3b** in the presence of different concentrations of europium(III) chloride at pH 7.0. At $[Eu^{3+}] = 5 \times 10^{-3}$ M, for example, $k_{obs} = 1.67 \times 10^{-4}\ s^{-1}$ was measured which corresponds to an acceleration of $k_{rel}/k_0 = 1.1 \times 10^8$.[7] Under the same conditions Yb^{3+} gave $k_{obs} = 3.7 \times 10^{-5}\ s^{-1}$; addition of Pb^{2+} salts produced cloudiness. All the reactions were (pseudo)-first order with up to 95% reaction with a linear correlation coefficient of $r > 0.997$; generally an excess of catalyst was used. The measured final extinction shows that hydrolysis under normal conditions ($[\mathbf{3b}] < [Eu^{3+}]$) leads to the removal of *both* phenoxy groups. This means that the corresponding monophenyl ester, as in noncatalyzed hydrolysis, reacts faster than the diester.[5a]

To ascertain that the catalyst retained its activity under "turnover conditions", measurements were made with a tenfold excess of substrate. These could again be evaluated with a first order kinetic equation. The observed rate of nitrophenolate release, $k_{obs} = 3.9 \times 10^{-6}\ s^{-1}$ (50 °C, $[Eu^{3+}] = 1 \times 10^{-4}$ M), was about half of that found with an excess of $[Eu^{3+}]$ ($k = 8.6 \times 10^{-6}\ s^{-1}$). Here the monoester was present at a much lower concentration than the starting material which released only *one* phenolate ion. In addition, when $[\mathbf{3}] > [Eu^{3+}]$, the concentration of active, free Eu^{3+} is reduced by binding to **3**. The saturation kinetics (Fig. 1) observed for the first time with Eu^{3+} yielded, by nonlinear curve-fitting for a 1:1 complex, a Michaelis–Menten constant of $K_M = 2.9 \times 10^{-3}$ M (the order of magnitude of this is in accord with the binding constants of lanthanide ions with phosphates[14]), and a catalytic constant of $k_{cat} = 2.6 \times 10^{-4}\ s^{-1}$. The rate constant for hydrolysis without a catalyst can be estimated from known data at 50 °C[5d] as $k = 3 \times 10^{-10}\ s^{-1}$.

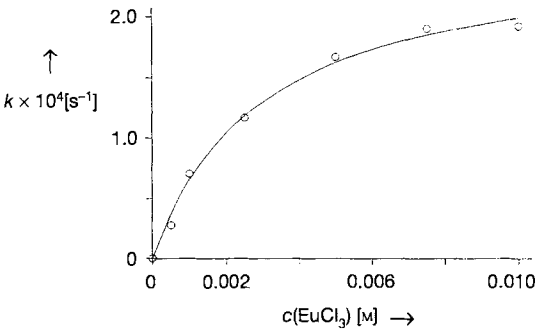

Fig. 1. Dependence of the kinetics of hydrolysis of bis(4-nitrophenyl)phosphate **3b** ($[\mathbf{3b}] = 3.76 \times 10^{-5}$ M) on catalyst concentration $[Eu^{3+}]$ (in 0.01 M EPPS buffer; 50.0 °C; pH 7.00); experimental points and a simulated Michaelis–Menten curve.

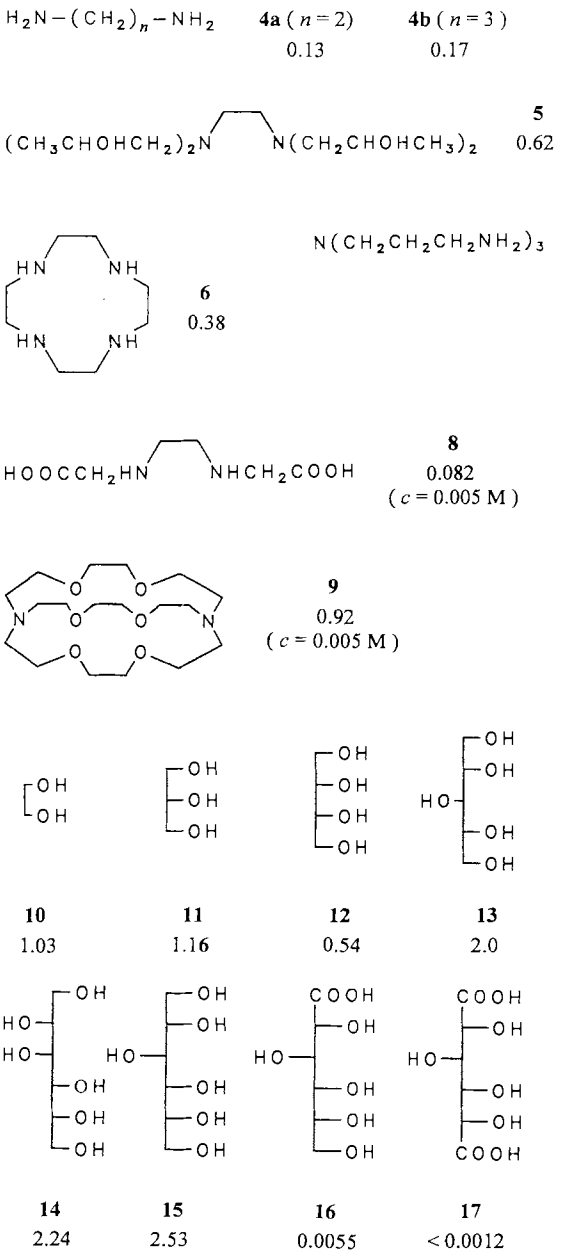
Although the rate of hydrolysis of nitrophenyl esters can be easily measured, the hydrolysis mechanism may be different from that of unactivated derivatives.[5, 10a] We have, therefore, investigated the effectiveness of lanthanide ions in the hydrolysis of the diphenylphosphate **3a**. This ester is so inert that the necessary constants for comparison of the hydrolysis at pH 7.0 are, as with dimethylphosphate,[5b] only obtainable by extrapolation from the correlations described by Kirby et al.[15] Assuming that the activation entropy for the hydrolysis in water is largely independent of the diester,[5b] an activation energy of about 30 kcal mol^{-1} is obtained. The calculated rate constant would then be $k_0 = 3.6 \times 10^{-12}\ s^{-1}$ (at 70 °C). The observed value with $[Eu^{3+}] = 4.3 \times 10^{-3}$ M is $k_{obs} = 3.95 \times 10^{-6}$ which, with $k_{obs}/k_0 \approx 10^6$ (at 70 °C), shows even a somewhat greater catalytic effect than with the nitrophenyl ester **3b** ($k_{obs}/k_0 = 0.56 \times 10^6$, 50 °C).

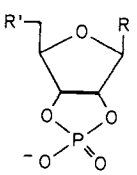
The effect of ligands on the catalytic effect of the Eu^{3+} ion was investigated with ligands **4**–**17** (Scheme 1) under the same conditions. From reactions with DNA it is known that with EDTA, for example, the metal effect may be completely suppressed.[4] With a series of nitrogen-containing ligands (**4**–**8**) we do indeed find a reduced rate of hydrolysis (see Scheme 1). It can be estimated from known complexing constants[14] how many "free", that is aqua-complexed, metal ions are still available at each concentration. Comparison with the values predicted from the saturation curve (Fig. 1) shows that even when they are complexed the metal ions are almost always still catalytically effective. In the presence of most ligands the activity drops only to 10–50% of that of the ligand-free solution, although with **8** and **9**, for example, only about one percent of "free" metal ion is present. The two hydroxycarboxylic acids **16** and **17** are exceptions; here, the residual activity is close to the detection limits. The Eu^{3+} complex with [2,2,2]cryptand (**9**) proved to be particularly promising. In spite of its high complexation constant, this was the only one that almost retained the activity of the free metal ion. Even the cryptands form complexes with trivalent lanthanide ions sufficiently fast under the measurement conditions,[16] whereas their dissociation, for example at 25 °C with $k_D = 10^{-3}\ s^{-1}$, is already relatively slow.[16] With their thermodynamic and kinetic stability, coupled with the retention of their activity, the most important prerequisites for the future use of such complexes are fulfilled.

In order to get closer to the typically high RNA rates of hydrolysis by varying the ligands in the complexes, a new concept was investigated. The generally accepted reason for the high reactivity of RNA is the formation of the cyclic ester *cyclo*-**2** through the participation of the neighboring 2′-OH



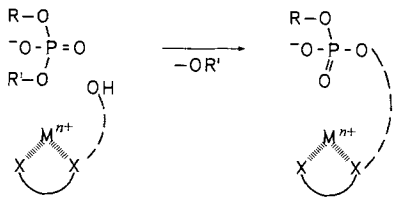
Scheme 1. Complex ligands L and their effect on the catalytic activity of Eu^{3+}; the values show the ratio of the rate constants with and without additional ligand ($[\mathbf{3b}] = 3.76 \times 10^{-5}$ M and $[\mathbf{L}] = 5 \times 10^{-2}$ M. With **8** and **9** $[\mathbf{L}] = 5 \times 10^{-3}$ M because of their low solubilities). The following compounds were also added but were unsuitable because of precipitation or clouding: spermine, *N*,*N*'-bis(3-aminopropyl)piperazine, 3,4-dihydroxyphenylalanine, m-hydroxybenzoic acid, 3,5-dihydroxybenzoic acid, pyrogallol.

group. In principle it should be possible to replace this group with a nucleophile attached to a metal complex instead of to the substrate (Scheme 2). The results of preliminary experiments with polyols, which bind—even though weakly[14a]—with the catalytically effective metal ions and, in addition, bear nucleophilic OH groups on their peripheries, support



cyclo-**2**

this hypothesis (see Scheme 1). The advantage of such polyols is that—as in RNA—they contain an additional vicinal OH group next to the already phosphorylated OH group, so that in a second (faster) step a cyclic phosphate analogous to *cyclo*-**2** can be formed. The observed effects enable an *additional* acceleration of catalysis by a factor of 2.5. More importantly this acceleration is clearly dependent on the structure of the polyols; a minimum distance is obviously required from the metal binding center to the OH group which serves as a nucleophile towards the phosphate. In view of the known small complexing constants of lanthanide ions with polyhydroxy compounds containing vicinal OH groups[14a] and the resulting minimum concentration of active complex in water the observed accelerations are considerable: The addition of, for example, 5×10^{-2} M **15** under realistically observable conditions (with $[Eu^{3+}] = 5 \times 10^{-3}$ M) leads to a total increase in the hydrolysis rate of 1.4×10^6.



Scheme 2. The mechanism of the hydrolysis of phosphoric acid diesters when the OH group in RNA-derived substrates is replaced by the OH group from a metal catalyst complex.

In summary, it has been shown that 1) phosphoric acid ester hydrolyses can be catalyzed with turnover and Michaelis–Menton kinetics analogous to those observed for enzymes by stable and readily available lanthanide complexes; even with only slightly activated leaving groups accelerations up to a factor of 10^6 are possible, 2) the catalytic activity is retained even in thermodynamically and kinetically very stable complexes so that it should be possible, through modification of the ligands, to further raise their effectiveness and selectivity with respect to biopolymers such as DNA, and 3) through the introduction of additional nucleophilic groups in the metal complexes, instead of the 2'-OH groups which are available on the ribophosphates in the substrate, a further raising of the catalytic activity is possible.[17]

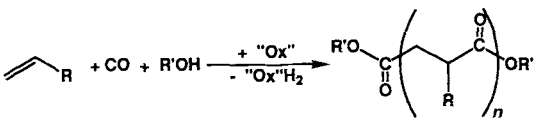
[16] E. L. Lee, O. A. Gansow, M. J. Weber, *J. Am. Chem. Soc.* **1980**, *102*, 2278; from the data given here it turns out that for Eu^{3+} + [2.2.2]cryptand (**9**) at 25 °C for the association under the conditions used by us a half-life of about 80 s was obtained. For this, as probably also for the even higher catalytic activity of the complex, it is important that some hydrated metal ions can still exist even inside the cryptands [14c,d].
[17] The reaction rates were measured photometrically at 400 nm (**3b**) and 275 nm (**3a**) (50 °C; pH 7.0; buffer: 0.01 M EPPS); other conditions are given in the legends to Figure 1 and Scheme 1. The nonlinear curve-fitting for (pseudo)-first order reactions, usually over two or three half-life times, had excellent correlation coefficients (> 0.997). The observed spread of the reaction rate constants obtained from the regression was ± 1%; the same spread was observed in duplicate runs.

Palladium-Catalyzed Enantioselective Bis-alkoxycarbonylation of Olefins**

By *Sylvia C. A. Nefkens, Martin Sperrle,* and *Giambattista Consiglio**

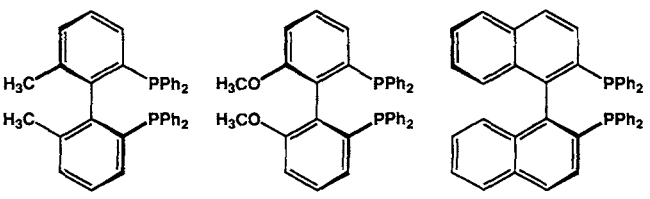
The bis-alkoxycarbonylation of olefins to give succinates as the products (Scheme 1, $n = 1$) is generally carried out with $PdCl_2$ in the presence of hydrogen acceptors.[1] Succinates have been prepared with high selectivities from various olefins by using $CuCl_2$ in the presence of sodium butyrate.[2] Other suitable catalyst systems for this reaction include $PdCl_2$ in combination with butyl nitrite,[3] $Pd(OAc)_2$ in the presence of benzoquinone and oxygen,[4] and $[Pd(acac)_2]$ (Hacac = 2,4-pentanedione) in the presence of di-*tert*-butyl peroxide.[5] Complexes of the type $[PdL_2X_2]$ with modified ligands have not been used for this reaction, despite their catalytic activity in many other carbonylation reactions.[6-9] When styrene is the substrate and either [(1,10-phenanthroline)$Pd(p\text{-}CH_3C_6H_4SO_3)_2$] or [(1,2-bipyridine)$Pd(CF_3COO)_2$] is employed as the catalyst precursor, poly(1-oxo-2-phenyltrimethylene) is formed. It was recognized that when the reaction is conducted in methanol some of the macromolecules formed contain two terminal methoxycarbonyl groups (Scheme 1).[6e] Oligomers (Scheme 1, $n = 1$, 2 up to 10) were obtained by increasing the amount of the oxidant.[10] When the catalyst precursor had diphosphane ligands, mainly saturated monoesters and α,β-unsaturated esters were observed; however, some succinate was formed as well.[11] The *syn* stereochemistry of the dicarbonylation reaction products[10] prompted us to attempt enantioselective bis-methoxycarbonylation to give optically active succinates.[12]



Scheme 1.

When the previously reported complex [Pd((*R,R*)-diop)$(O_2CCF_3)_2$][10] (diop = 3,4-bis[(diphenylphosphino)-methyl]-(2,2-dimethyl-1,3-dioxolane) was used as the catalyst precursor in the presence of $Sn(O_3SCF_3)_2$, (*R*)-dimethyl phenylsuccinate could in fact be isolated in 29% yield and with 30% *ee*. Similar results were obtained with an "in situ" system composed of $[Pd(acac)_2]$, (*R,R*)-diop, and two equivalents of trifluoroacetic or *para*-toluenesulfonic acid. With a similar "in situ" system, in which (*R*)-*N,N*-dimethyl-1-[(*S*)-1′,2-bis(diphenylphosphino)ferrocenyl]ethylamine served as the chiral ligand, comparable results (< 29% *ee*) were obtained. Analogously, dimethyl propylsuccinate was obtained with 17% *ee*[13] and 4% yield from the bis-methoxycarbonylation of 1-pentene with the diop-containing catalytic system.

The excellent stereochemical control achieved in the copolymerization of propene with carbon monoxide[6g, 14] (Scheme 1, $R = CH_3$) by using atropoisomeric diphosphanes prompted us to test this type of ligand (Scheme 2) for the enantioselective bis-methoxycarbonylation.



Scheme 2.

In a series of bis-methoxycarbonylations of styrene using the "in situ" system $[Pd(acac)_2]$/L–L/$p\text{-}CH_3C_6H_4SO_3H$ (1:1:2 mol ratio) the chiral diphosphane ligand (L–L) was varied. We found that the optical purity of the dimethyl phenylsuccinate obtained could be improved to 82–93% by employing the optically pure atropisomeric ligands **1**–**3** (Table 1). A maximum of 93% *ee* was obtained with 2,2′-dimethoxy-6,6′-bis(diphenylphosphino)biphenyl **2** (biphemp-OMe) as the ligand. The yield with respect to the

[a] For the reaction conditions see Experimental Procedure. [b] Methyl 2-phenylpropionate and methyl 3-phenylpropionate. [c] Methyl cinnamate. [d] Dimethyl phenylsuccinate. [e] Oligomeric products. [f] Enantiomeric excess determined by gas chromatography (see Experimental Procedure).

styrene consumed (chemoselectivity) of the reaction remained, however, modest (37–58%).

The enantioselectivity in the concomitant formation of methyl 2-phenylpropanoate was much lower (ca. 50% *ee* with **2**). With all ligands tested, however, the same enantiotopic face of styrene reacted prevailingly in both hydroalkoxycarbonylation and bis-methoxycarbonylation.

The chemoselectivity of the reaction towards dicarbonylation could be improved by using $[Pd(OSO_2CF_3)_2\{(S)\text{-biphemp-OMe}\} \cdot 2\,H_2O]$ as the catalyst precursor. Under reaction conditions similar to those reported in the experimental procedure (but with styrene/Pd 1000:1; and styrene/benzoquinone 1:1 in 20 mL CH_3OH[15]) dimethyl phenylsuccinate was obtained with 92% *ee* (69% conversion, 78% chemoselectivity). The chemoselectivity is even higher considering that some *p*-hydroxyphenyl methyl 2-phenylsuccinate is formed as a coproduct. By lowering the carbon monoxide pressure to 50 bar, similar selectivities (83%, 91% *ee*) are observed at 85% conversion. Under these conditions the main coproduct appears to be methyl cinnamate. The fact that of the two possible α,β-unsaturated esters only methyl cinnamate was formed, suggests that a β-(alkoxycarbonyl)-alkyl-palladium complex is a common intermediate in the formation of both the α,β-unsaturated ester and the diester.[11] Control experiments showed that the unsaturated esters are not intermediates in the formation of succinates.[8c]

The development of catalysts showing complete regioregularity coupled with high enantiofacial selection in the copolymerization of propene with carbon monoxide[6f–h] suggests possibilities for achieving high enantioselectivities in the synthesis of aliphatic succinic acid derivatives as well. Experiments in this direction are in progress.

Experimental Procedure

A 250 mL stainless steel autoclave equipped with a glass insert was charged under an atmosphere of N_2 with 0.14 mmol catalyst precursor, 18 mmol benzoquinone, and 36 mmol styrene in 15 mL methanol, then pressurized with 350 bar of CO, and heated to 50 °C. After 20 h the autoclave was cooled to room temperature and the residual gas released. Immediate quantitative gas chromatographic analysis was carried out on Hewlett Packard HP1 (50 m) and Macherey-Nagel OV1 (10 m) columns using acetophenone as the internal standard. After removal of the methanol from the reaction mixture under reduced pressure, approximately 50 mL toluene was added causing most of the hydroquinone to precipitate. The filtrate was evaporated and the residue fractionally distilled (Kugelrohr). Each fraction was purified by column chromatography over silica (70–230 mesh) eluting with hexane/ether (3:1). The products were characterized by NMR spectroscopy and GC-MS [10]. The enantiomeric excess was determined by gas chromatography with a cyclodextrin as the stationary phase [Macherey-Nagel Lipodex E (50 m column)].

[11] The formation of saturated monoesters does not require the presence of an oxidant. A catalytic cycle starting with a hydridopalladium or an alkoxycarbonylpalladium intermediate may be suggested for the formation of these products. The α,β-unsaturated ester and diester can only be formed starting with an alkoxycarbonylpalladium intermediate: D. Milstein, *Acc. Chem. Res.* **1988**, *21*, 428–434.

[15] The completely selective formation of succinic esters theoretically requires a 1:1 ratio of oxidant to olefin. To avoid having a large excess of unreacted benzoquinone at the end of the reaction, a 2:1 ratio of styrene/benzoquinone was used in the first experiments which yielded succinic esters with only moderate selectivities.

Phosphinic Acid-Based C_2-Symmetrical Inhibitors of HIV-Protease**

By *Anusch Peyman,* Karl-Heinz Budt, Jörg Spanig,* and *Dieter Ruppert*

One of the most interesting targets for AIDS chemotherapy is the virally encoded protease of the Human Immunodeficiency Virus (HIV).[1] The HIV-protease is an enzyme of the aspartylprotease family, and plays a key role in processing the HIV-polyproteins produced directly after translation.[1] If this processing step does not take place, only im-

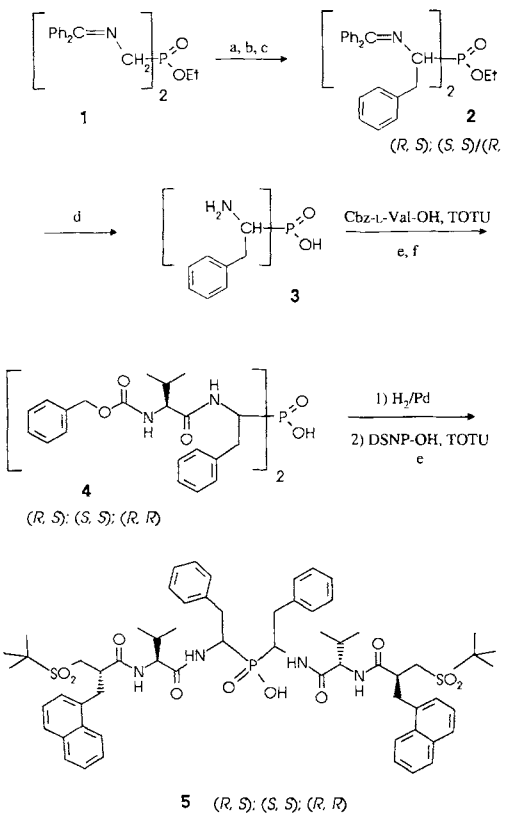
mature, uninfectious viral particles are produced.[2] The HIV-protease is a C_2-symmetrical, homodimeric protein.[3] This fact prompted several research groups simultaneously to synthesize inhibitors whose geometry was not derived from that of the natural substrate, but which instead was inspired by the symmetry of the enzyme.[4, 5] We recently reported the synthesis of bis(α-aminoalkyl)phosphinic acids,[6] which allow the placement of the phosphinic acid group into a C_2-symmetrical peptide environment, where it acts as a transition state analogue of peptide hydrolysis. This approach leads to effective inhibition of HIV-protease. Here we report on the effect the stereochemistry and substituents have on these inhibitors, and present a new synthetic approach to this class of compounds.

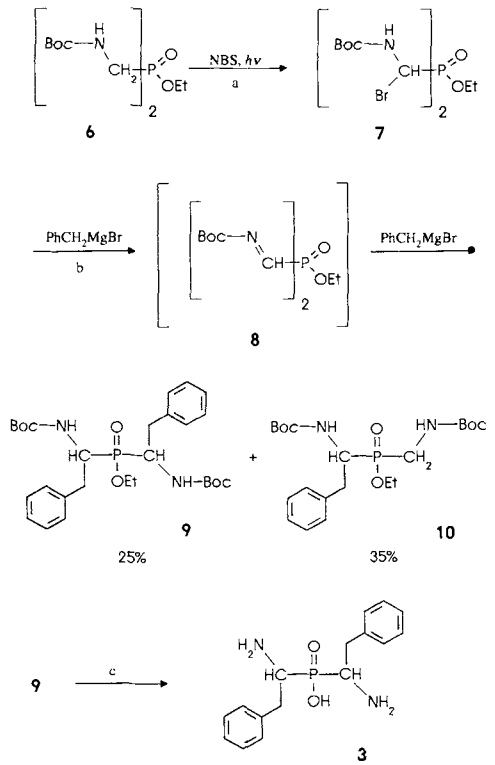
The synthesis of inhibitors **5** is shown in Scheme 1. The initial, decisive step in this synthesis was the alkylation of the bisimino compound **1** with benzyl bromide. The resulting



Scheme 1. Synthesis of C_2-symmetrical phosphinic acid inhibitors of HIV-protease by electrophilic substitution and separation of diastereomers: a) *n*BuLi, −78 °C. b) $PHCH_2Br$, 24 h, −78 °C, 95%. c) Chromatographic separation of (*R,S*) from (*R,R*)/(*S,S*): silica gel, ethyl acetate/*n*-heptane 4/6, R_f: (*R,S*) 0.8; (*R,R*)/(*S,S*) 0.7; yield 1:1. d) 30% HBr/AcOH, 95%. e) TOTU [7], DMF, 25 °C/2 h, 80%. f) HPLC separation of (*R,R*)/(*S,S*): C_{18}-Nucleosil 5U, CH_3CN, H_2O, NH_4OAc 4/6/0.05, pH 7.2, 1 mL min^{-1}, 40 °C, R_t(min): 11.2 (*R,R*), 19.5 (*S,S*). NBS = *N*-bromosuccinimide.

diastereomeric mixture of substitued bis(α-iminoalkyl)-phosphinic acids **2** may be separated by chromatography into an (*R,S*) and an (*R,R*)/(*S,S*) fraction, in a ratio of 1:3. After deprotection of the amino group by acid hydrolysis to give **3**, these fractions were condensed separately with *N*-benzyloxycarbonyl-L-valine (Cbz-L-Val-OH). Because of the limited solubility of **3** in organic solvents, TOTU[7] was utilized as a coupling reagent, and was found most effective in peptide condensations in aqueous organic solvents. The conversion of (*R,S*)-**2** to (*R,S*)-**4** afforded only one product, whereas conversion of the racemate (*R,R*)/(*S,S*)-**2** to (*R,R*)/(*S,S*)-**4** yielded two diastereomeric compounds. The latter could be separated by preparative high-performance liquid chromatography (HPLC).[8] After removal of the Cbz protecting group with H_2/Pd, all three fractions were coupled separately with DSNP-OH,[9] a particularly suitable N-terminal residue for inhibition of the HIV-protease.[5]

Since substituted bis(α-aminoalkyl)phosphinic acids are an interesting class of compounds with potential biological activity in a variety of areas,[10] we investigated alternative methods for their synthesis. Following studies by Steglich et al.[11] on α-aminophosphonic acids, we synthesized **3** by the method shown in Scheme 2, by nucleophilic substitution of the bis(α-acylamino-α-bromomethyl)phosphinic ester **7** with benzyl magnesium bromide. The unstable dibromo com-

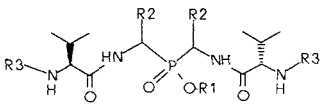


Scheme 2. Alternative synthesis of the bis(α-aminoalkyl)phosphinic acids **3** by nucleophilic substitution: a) CCl_4, 20 °C, 2 h, 96% crude yield. b) 4 equiv $PhCH_2MgBr$, −70 °C, 3 h. c) 30% HBr/AcOH, 95%.

pounds **7** were not isolated, but reacted further in situ. The first equivalent of the Grignard reagent presumably acts as a base, and the reaction proceeds via intermediate formation of the bis(α-acyliminomethyl)phosphinic ester **8**, to which the Grignard reagent then adds as a nucleophile. The yield of bis-alkylated **9** was rather low (ca. 20%, diastereomeric mixture). The major product was the monoalkylated compound **10**, in about 35% yield. However, with the two synthetic procedures presented here, both electrophilic and nucleophilic substitution are available for derivatization of the bis(α-aminomethyl)phosphinic acid, allowing access to a large palette of compounds.

The results of studies on the inhibition of the HIV-protease by compounds **4** and **5** and by several other derivatives with an unsubstituted central moiety are summarized in Table 1. The most obvious point here is that the free acid is essential for effective inhibition; the ester **12** proved to be less effective. Comparison of the unsubstituted compounds

Table 1. IC_{50} values for inhibition of the HIV-protease [13] by bis-(α-aminoalkyl)phosphinic acids and esters of type **A**.



Compd.	R^1	R^2 (conf.)	R^3	IC_{50} [nM]
4a	H	$PhCH_2$ (*R,S*)	Cbz	500
4b	H	$PhCH_2$ (*S,S*)	Cbz	180
4c	H	$PhCH_2$ (*R,R*)	Cbz	1.1
5a	H	$PhCH_2$ (*R,S*)	DSNP	1.4
5b	H	$PhCH_2$ (*S,S*)	DSNP	85
5c	H	$PhCH_2$ (*R,R*)	DSNP	0.5
11	H	H	DSNP	1.1
12	CH_3	H	DSNP	950
13	H	H	Cbz	10000
14	H	H	H-Phe	12
15	H	H	H	>10000

(R^2 = H) revealed a strong dependence on the terminal residue R^3. The DSNP group in **11** proved to be ten times more effective than the phenylalanyl group in **14**, whereas the latter was far superior to the Cbz group in **13**. In the absence of a terminal residue (compound **15**), no activity was observed. Interestingly, these differences were significantly reduced after the introduction of the central benzyl groups. Thus, compounds **5b** and **5c** with a terminal DSNP unit were only twice as effective as those with a terminal Cbz unit (**4b** and **4c**). Correspondingly, introduction of the central benzyl groups in the presence of the DSNP group (from **11** to **5c**) afforded only a slight improvement. This "saturation" possibly arose from the method used for the assay, in which the enzyme was titrated with very strong inhibitors. As expected, the inhibitory action was also strongly dependent on the configuration at the C atom bearing the benzyl groups; inhibition decreased in the DSNP series **5** in the order (*R,R*) > (*R,S*) > (*S,S*), and in the Cbz series **4** in the order (*R,R*) > (*S,S*) > (*R,S*). This change in the activity dependence could be interpreted as an indication of different modes of binding.

The combination of a central phosphinic acid unit with a symmetrical peptide arrangement proved to be most successful. Compound (*R,R*)-**5c** displays an IC_{50} value of 0.5 nM[12] and is hence an extremely potent inhibitor of the HIV-protease. The new procedures for synthesis of this class of compounds give us the opportunity to elucidate their structure–activity relationships in more detail, and thereby to discover further, highly active HIV-protease inhibitors.

[8] The configurations (*R,R*) and (*S,S*) have so far only been assigned with reference to the activity found with the HIV-protease. For related inhibitors bearing a bishydroxyethyl group instead of the phosphinic acid unit, activity decreases in the order (*S,S*) > (*R,R*) [5]. We have therefore assigned the more active compound **4c** the configuration (*R,R*) (the introduction of a phosphorus atom changes the priorities for the configuration assignment). A suitable derivatization and an X-ray structural analysis are still outstanding.

[12] IC_{50}: Inhibitor concentration causing a 50% reduction in enzyme activity.

[13] Inhibition of the HIV-protease was measured at pH 5.5 with an HPLC assay and the specific substrate SFNF'Opr'QI. Opr stands for 5-oxaproline, and replaces the proline in the natural substrate SFNFPQI (N terminus of the HIV-protease). The Opr-containing peptide is cleaved more rapidly, and a greatly reduced amount of enzyme is therefore required for the assay: S. Henke, G. Breipohl, W. König, K. Mölling, (Hoechst AG), EP-A 0373576, **1989**; *Chem. Abstr.* **1990**, *114*, P825535s.

The Pagodane Route to Dodecahedranes: An Improved Approach to the $C_{20}H_{20}$ Parent Framework; Partial and Total Functionalizations—Does C_{20}-Fullerene Exist?**

By *Fabian Wahl, Jürgen Wörth,* and *Horst Prinzbach**

The I_h-symmetrical pentagonal dodecahedrane (**1**) is an appealing hydrocarbon;[1] the increasing chemical modification of this molecule greatly enhances its appeal by opening a range of novel preparative and theoretical perspectives.[2] Monofunctionalizations of **1** (**A**) and directed 1,16-difunctionalizations (**B**) can be easily achieved following work of Paquette et al. and Olah et al.[3] Two to eight pairs of symmetrically positioned functionalities (**C**,[4] **D**[5]) are introduced through our pagodane → dodecahedrane route[6] by means of appropriately functionalized pagodane precursors. In this context the replacement of all the H atoms (**F**, e.g. the $C_{20}Br_{20}$ "bromine ball" **2** and the $C_{20}(OH)_{20}$ "vesicle" **3**)

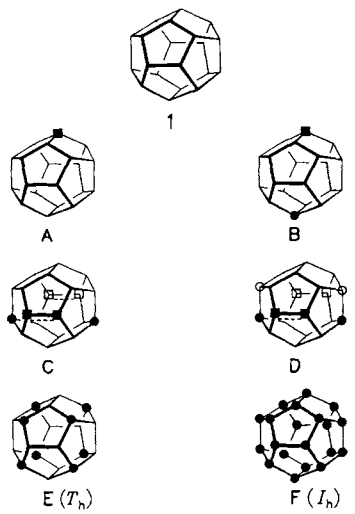
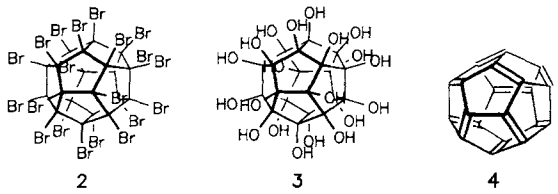
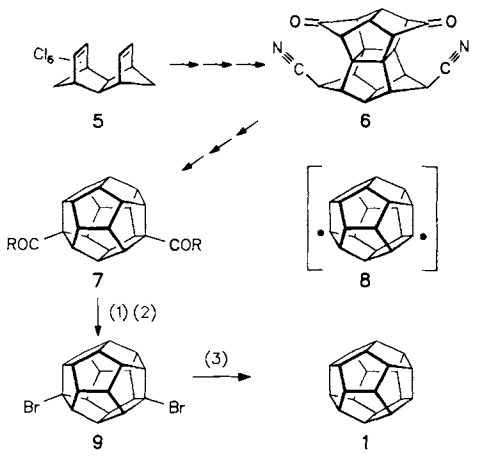
[**] This research was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG. We thank Dr. H.-D. Beckhaus (Freiburg) for help with the calculations, Doz. Dr. E. Campbell (Max-Born-Institut für Nichtlineare Optik und Kurzzeitspektroskopie (MBI), Berlin-Adlershof (FRG)) for the laser desorption time of flight (TOF) mass spectra, and Dr. W. Vetter (Ciba-Geigy, Basel) for the FAB/FD MS analyses (FAB = fast atom bombardment, FD = field desorption, MS = mass spectrometry).



and the total dehydrogenation to provide the extremely energy-rich 20 π electron polyene **4** (C_{20}-fullerene) are fascinating extensions. Compound **4**, in particular, is of current interest, as it is the smallest fullerene according to Euler's theorem and as recent calculations have identified it as the lowest energy structure in a series of C_{20} isomers.[7, 8] Still, **1** has not entered the fullerene literature as perhydro-**4**. In this communication we report on an improved route to **1** and on the first results in multiple (e.g. **E**) and total functionalization (**F**).[12]



Given the efficiency of the pagodane route it was tempting to base an improved approach to **1** on products of this route (Scheme 1). The reaction sequence that turned out to be highly expeditious started from dimethyl dodecahedrane-1,6-dicarboxylate (**7a**, R = OCH_3),[4] efficiently prepared from isodrin (**5**) via diketodinitrile **6**, and consisted of saponification, Barton degradation[13] to give 1,6-dibromide **9**, and reduction.[14] Apparently in both stages the intermediate dodecahedryl radicals (e.g. 1,6-diradical **8**)[15] are trapped efficiently, despite considerable frontal shielding. The yield of 90% based on **7a** met our expectations.



Scheme 1. (1) KOH, CH_3OH, H_2O; 8 h reflux, 99% **7b** (R = OH); (2) $(COCl)_2$, C_6H_6, 3 h reflux, **7c** (R = Cl); $BrCCl_3$, mercaptopyridine-1-oxide sodium salt, 4-dimethylaminopyridine (DMAP), 1 h reflux, 89% **9**; (3) tris(trimethylsilyl)silane, C_6H_6, low-pressure Hg lamp (254 nm), room temperature, 2 h, 99% **1**.

The dilemma in the multifunctionalization of **1** is expressed quantitatively (Polya theorem)[16] by the number of isomers (N_i) which increases rapidly even for the same X group (Table 1). Accordingly, only the preparation of

Table 1. Number of isomers (N_i) with the same substituent X and without vicinal X,X arrangements (A_i), and number of isomers of A_i (C_i) leading to **E**.

$C_{20}H_{20}$ → $C_{20}H_{20-n}X_n$

n =	1	2	3	4	5	6	7	8	9	10
N_i	1	5	15	58	149	371	693	1135	1466	1648
A_i	1	4	9	20	20	16	5	1	0	0
C_i	1	3	3	5	3	3	1	1	0	0

$C_{20}H_{19}X$, $C_{20}HX_{19}$, and $C_{20}X_{20}$ statistically makes sense. When vicinal X,X arrangements are excluded, the number of isomers N_i is reduced to A_i; for $n = 8$ this corresponds to a single, T_h-symmetrical isomer (**E**). However, **E** is directly accessible only from C_i subsets of A_i (statistical yield 0.4%).[17]

The strain energies (MM2 calculations)[18] listed in Table 2 are revealing with regard to the steric compression on the molecular surface, which is associated with increasing functionalization, and to the possibility of sterically steering multisubstitutions of **1**. This data implies that 1,2-dibromination and 1,2,3-tribromination cause an increase in strain approximately 3.4 and 11.7 kcal mol^{-1}, respectively, greater than that associated with 1,3-dibromination; in contrast perhydroxylation (→ **3**) leads to a decrease, perbromination (→ **2**) to a tremendous increase in strain (according to this **2** is more strained than **4**).

Table 2. Strain energies (MM2 calculations) E_{str} [kcal mol^{-1}] of some dodecahedrane derivatives. **1** = 68.9, **4** = 350.1 kcal mol^{-1}.

X					OH	69.0	69.1	69.0	69.1	64.5
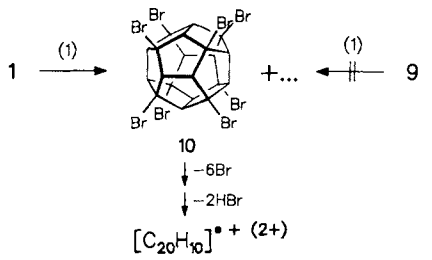
F	72.7	75.8	76.5	78.8	121.6
Cl	70.9	74.9	72.8	79.3	234.6
Br	73.3	80.9	77.5	89.2	383.5

Preliminary experiments on the steric control of the multisubstitution of **1** were directed towards the synthesis of the T_h-symmetrical octabromide **10** (**E**). When **1** was subjected to conditions for irreversible radical bromination (Scheme 2), which should not enforce vicinal dibromination, a red-brown, crystalline product was isolated, which was poorly soluble in $CHCl_3$ and consisted of a mixture of brominated derivatives $C_{20}H_{15}Br_5$ to $C_{20}H_{12}Br_8$ [IR (KBr): $\tilde{\nu}$ = 2948, 2920, 2848 (C–H), 1724, 1449, 1283, 864, 818,



Scheme 2. (1) **1** (10 mg, 3.85×10^{-5} mol) or **9** (10 mg, 2.39×10^{-5} mol) in 5 mL bromine/CCl_4 (2:1; 0.065 mol bromine), 4h irradiation with a 300W daylight lamp, reflux.

734, 655 cm^{-1}]. In the ^1H NMR spectrum (250 MHz, $CDCl_3$; series of multiplets between $\delta = 3.4$ and 5.0) a dominant singlet is observed at $\delta = 4.49$ which is in the anticipated range for T_h-symmetrical **10** (with ca. 5% the proportion is higher than expected statistically). In the electron ionization (EI) mass spectrum of the mixture (Fig. 1) the fragmentation cascade begins with the M^+ envelope of **10** (*m/z* 884–900 (1%)) and ends after a series of HBr/Br eliminations with the bromine-free $C_{20}H_{10}$ cluster (*m/z* 250 (60%)). The $C_{20}H_{10}$ cluster provides the base peak (*m/2e* 125 (100%)), which is regarded as an indication that multiply conjugated pentaenes (cf. **13**) are present.

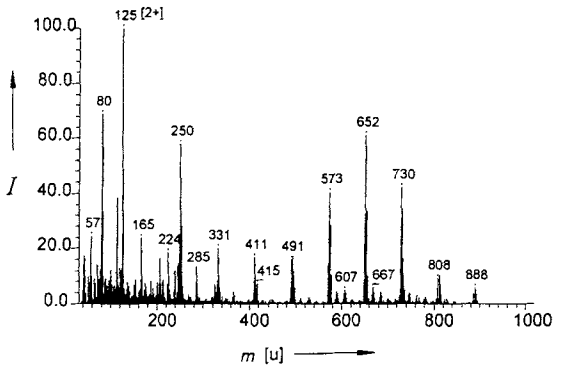


Fig. 1. EI mass spectrum (70 eV) of **10** and other products from the bromination of **1** according to Scheme 2. *I* = relative intensity, *m* = mass in atomic mass units u.

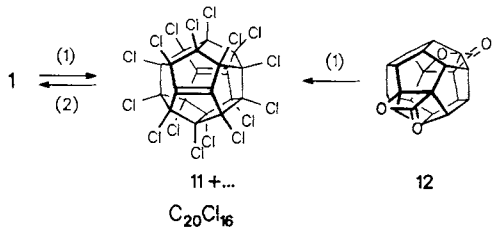
Control experiments on the irreversibility and the 1,3-selectivity of the substitutions were conducted with 1,6-dibromide **9**, as it is the only one of the four nonvicinal $C_{20}H_{18}Br_2$ isomers (A_1) that cannot lead directly to **10**. Analysis of the IR spectrum, EI mass spectrum, and ^1H NMR spectrum (series of multiplets between $\delta = 3.4$ and 5.0) of the reaction products indicates a mixture of penta- to heptabrominated dodecahedranes similar to the mixture obtained from **1** but definitely lacking octabromide **10**.

Analogous control was not evident in the initial attempts at the directed chlorination under "mild" ionic (reversible) conditions (Scheme 3). MS analyses of the readily soluble (in dimethylformamide (DMF) and $CHCl_3$) product mixtures confirm that up to 14 hydrogen atoms have been exchanged statistically for chlorine atoms [IR (KBr): $\tilde{\nu} = 2956$ (C–H),

Scheme 3. (1) **1** (10 mg, 3.85×10^{-5} mol), 20 mL CCl_4, $AlCl_3$ (100 mg, 0.75 mmol), dry chlorine gas, 5h–3d reflux.

1737, 1398, 1340, 1289, 1260, 1188, 1112, 876, 846, 801, 733, 707 cm^{-1}; ^1H NMR ($CDCl_3$, 400 MHz): $\delta = 4.20-4.72$ (series of m); ^{13}C NMR ($CDCl_3$, 100.6 MHz): $\delta = 99.1-97.2$ (20 signals for C-Cl), 90.7–82.6 (36 signals for α-C), 62.9–58.2 (17 signals for β-C))]. In the EI mass spectra (70 eV) of a number of samples, fragmentation of the framework is not evident besides the successive elimination of HCl/Cl, as was noticed for **10**; the signals at *m/z* 248 (60%) and *m/z* 246 (26%) could arise from dodecahexaenes ($C_{20}H_8$) and dodecaheptaenes ($C_{20}H_6$).

Reactions under "extreme" conditions (Scheme 4) intended to bring about total chlorination yielded a colorless, air-stable product, which crystallized from the hot reaction mixture(s) and was insoluble in all solvents tested (CH_2Cl_2, $CHCl_3$, CCl_4, tetrachloroethane, C_4Cl_6, C_6H_6, $C_6H_3Cl_3$, CH_3OH, C_5H_5N, CS_2, CF_3COOH, toluene, THF, isopropyl alcohol) even when heated. The vaporization curve (mass



Scheme 4. (1) **1** (10 mg, 3.85×10^{-5} mol) or **12** (10 mg, 2.91×10^{-5} mol) in 30 mL CCl_4 saturated with dry chlorine gas (ca. 0.11 mol); the reaction mixture was heated for 16h at ca. 130 °C in a glass ampule (60 mL) with a safety valve by irradiation with a 300W daylight lamp; (2) Pt/H_2; ethyl acetate/methanol, room temperature, 3d.

spectrum) indicates that the product is uniform (m.p. > 330 °C). No C–H bands are seen in the IR spectrum (KBr; $\tilde{\nu} = 1782$, 1636, 1341, 1161, 1027, 993, 970, 957, 940, 885, 800, 786, 665 cm^{-1}). The EI mass spectrum (70 eV; Fig. 2, Scheme 5) supports the composition $C_{20}Cl_{16}$ (e.g. **11**) and manifests the successive loss of all Cl substituents [path (a), noteworthy signals are *m/z* 594 (97%, $C_{20}Cl_{10}$ pentaenes (e.g. **13**)) and in particular *m/z* 240 (30%, C_{20} decaene **4** (?)] and two characteristic fragmentations of the framework [path (b), *m/z* 452 (36%, $C_{11}Cl_9$) and *m/z* 355 (88%, C_9Cl_7):

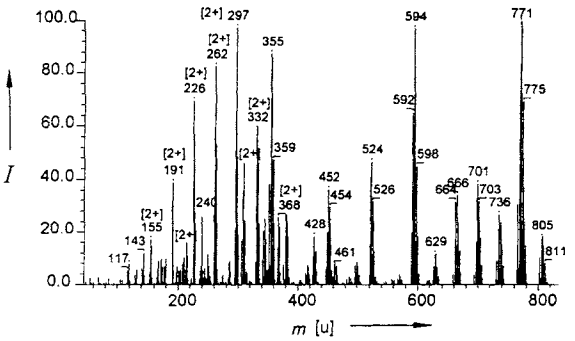


Fig. 2. EI mass spectrum (70 eV) of **11** and other products from the chlorination according to Scheme 4. *I* = relative intensity, *m* = mass in atomic mass units u.

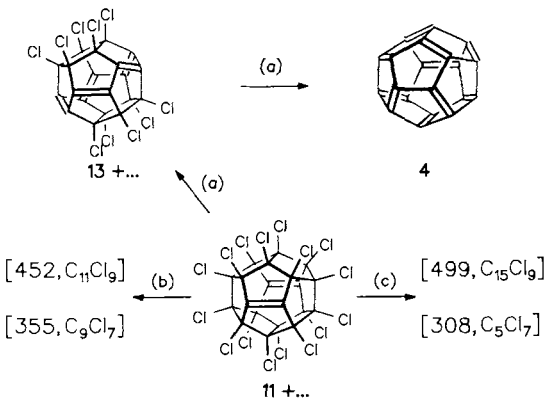
the cleavage $C_{20} \rightarrow C_{11} + C_9$ observed for the 1,16-dodecahedradiene and bislactone **12**; path (c), *m/z* 499 (6%, $C_{15}Cl_9$) and *m/z* 308 (20%, C_5Cl_7): the cleavage $C_{20} \rightarrow C_{15} + C_5$ observed for 1,7,16-dodecahedratriene[4, 10]. The



Scheme 5.

three fragmentation pathways are easier to trace in the mass spectrum recorded at 28 eV (Fig. 3), which does not have the signals of the doubly charged fragments. Under these conditions path (a) terminates at $C_{20}Cl_{10}$ with m/z 594 (15%). We can only speculate as to why the chlorination halts at $C_{20}Cl_{16}$ and which isomers are formed other than (most likely) 1,16-diene **11**. That $C_{20}Cl_{16}$ is remarkably stable to

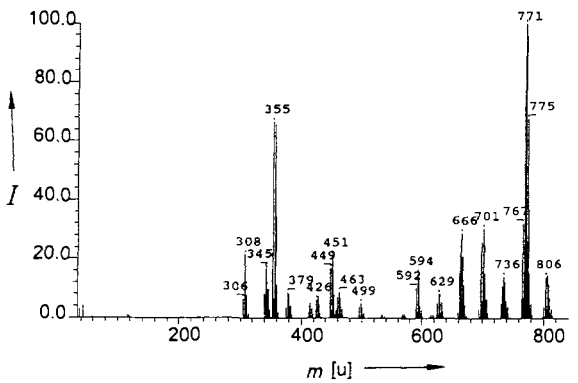


Fig. 3. EI mass spectrum (28 eV) of **11** and other products from the chlorination according to Scheme 4. I = relative intensity, m = mass in atomic mass units u.

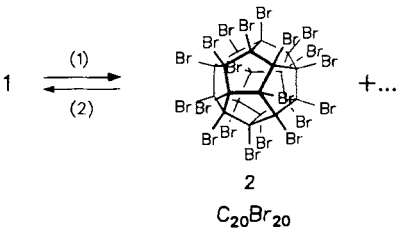
oxygen relative to the corresponding unsubstituted dodecahedradiene[4, 5] reflects the interplay of electronic and steric factors. Attempts at recording the $^1H/^{13}C$ NMR spectra and FAB/FD mass spectra of these perchlorinated dodecahedranes as well as of their chemical modifications have failed so far because of extremely poor solubility. It is unlikely that $C_{20}Cl_{16}$ is formed from $C_{20}Cl_{20}$ under measurement conditions. $C_{20}Cl_{16}$ can be reduced very cleanly by catalytic hydrogenation to provide **1**, proof that the dodecahedrane skeleton is unchanged in $C_{20}Cl_{16}$. According to mass spectrometry, the mother liquor from the chlorination reaction contains traces of derivatives that are more soluble because their symmetry is reduced by other substituents (e.g. $C_{20}Cl_{15}CCl_3$ from the reaction with CCl_3 radicals arising from CCl_4).[19] This observation could prove useful for the future preparation of more readily soluble polyhalogenated dodecahedranes.

In attempts to prepare the perchlorinated 1,16-diene **11** in a directed manner, bislactone **12**[20] was chlorinated under "extreme" conditions (Scheme 4; **12** was previously observed to give the 1,16-diene in gas-phase thermolyses). The solid isolated after a reaction time of 16 h is identical in every respect to the $C_{20}Cl_{16}$ cluster obtained from **1**.

The "extreme" bromination of **1** (Scheme 6) yields a deep brown, crystalline, high-melting (m.p. > 330 °C, decomp), and insoluble mixture of hydrogen-free bromides (IR (KBr): $\tilde{\nu}$ = 1627, 1598, 1479, 1365, 1191, 1160, 886, 775, 740, 694, 671 cm^{-1}), which most certainly contains the $C_{20}Br_{20}$ "bromine ball" **2**. This product is supported by signals in the



Scheme 6. (1) **1** (10 mg, 3.85×10^{-5} mol) in 10 mL bromine (0.20 mol) was heated for 8 h at ca. 130 °C in a glass ampule (60 mL) with a safety valve by irradiation with a 300 W daylight lamp; (2) Pt/H_2; ethyl acetate/methanol, room temperature, 3 d.

LD-TOF mass spectrum (Fig. 4), $M(C_{20}{}^{79}Br_{20}) = 1820$, $M(C_{20}{}^{81}Br_{20}) = 1860$. Here, too, more definitive characterization by ^{13}C NMR spectroscopy has not been possible yet. Dodecahedrane **1** can be recovered to a large extent (> 90%) from catalytic hydrogenation of the crude product of the bromination.

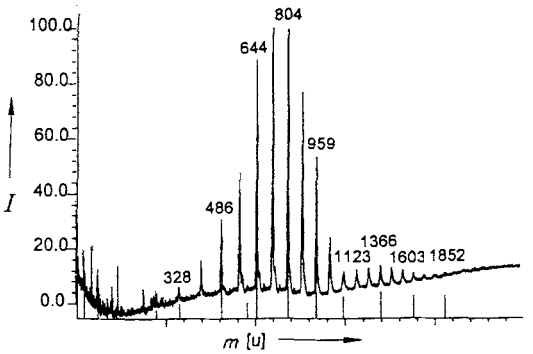


Fig. 4. LD-TOF mass spectrum of **2** and other products from the chlorination according to Scheme 6. I = relative intensity, m = mass in atomic mass units u.

The behavior of the poly- and perfunctionalized dodecahedranes, in particular the polyhalides,[21] in their mass spectra has interesting parallels and differences to that of the poly- and perfunctionalized (chlorinated,[22] brominated,[23] fluorinated[24]) C_{60}-fullerenes. The possibilities in the directed polyfunctionalization of **1** and its derivatives lend new dimensions to the chemistry of these cage molecules. In particular, routes to multiply unsaturated dodecahedranes, ultimately to C_{20}-fullerene (**4**), renders many attractive preparative and theoretical topics open to experimental study.

[8] Compound **4** is the final member in the series of dodecahedrapolyenes. Contrary to early calculations and expectations[9] the dodecahedrenes and nonconjugated dodecahedradienes[4,5,12] proved to have surprising thermal stability; owing to the steric shielding of the highly bent C=C bonds ($\varphi = 43-50°$), dimerization only occurs at high temperatures[10]. The existence of $C_{20}H_{14}$ trienes and $C_{20}H_{12}$ tetraenes was deduced previously from intense signals in the mass spectra of multifunctionalized dodecahedranes[4,5,10,12]. Multiple *cis*-HX elimination and release of multiply unsaturated dodecahedranes were recently achieved with Schwesinger bases[11].

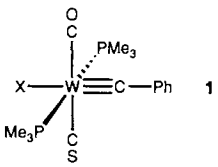
Formation of Alkynyltrithiocarbonato Ligands from Alkylidyne Ligands and Carbon Disulfide**

By *Andreas Mayr** and *Tsung-Yi Lee*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

Coupling reactions of alkylidyne ligands with carbonyl,[1] isocyanide,[2] and alkylidyne ligands[3] are well established.[4] A simple qualitative molecular orbital model for these reactions suggests that alkylidyne–thiocarbonyl coupling should also be feasible and even more facile than alkylidyne–carbonyl coupling.[4] However, no alkylidyne thiocarbonyl metal complexes are available to test this prediction. A proven method for the synthesis of thiocarbonyl ligands is the abstraction of sulfur from coordinated carbon disulfide by phosphanes.[5] Tris-trimethylphosphane-substituted tungsten alkylidyne complexes of type **2** [see Eq. (1)] appeared to be suitable precursors for alkylidyne thiocarbonyl tungsten complexes of type **1**. Dissociation of one phosphane ligand from **2** would provide an empty site for coordination of carbon disulfide and free phosphane for sulfur abstraction. The results described in this communication indicate that alkylidyne thiocarbonyl tungsten complexes can be obtained as intermediates by this strategy and that these undergo alkylidyne–thiocarbonyl coupling.



1

Alkylidyne complexes **2**[6] react slowly in THF with an excess of carbon disulfide to give the green complexes **3a–e** in moderate yields [Eq. (1)]. Trimethylphosphane sulfide is formed as a by-product.[7] The ^{13}C NMR spectra of complexes **3a–e** exhibit four signals in the low-field region at $\delta = 245-180$ (Table 1) and the expected number of signals for a phenyl group and two *trans* trimethylphosphane ligands. The ^{13}C NMR spectra thus contain one signal more than expected for complexes of type **1**. When **2b** is allowed to react with labeled $^{13}CS_2$, two ^{13}C NMR signals of complex **3b**, namely those at $\delta = 241$ and 218, are enhanced. Except for the signal at $\delta = 241$, the ^{13}C NMR data of complexes **3a–c** are similar to those of a class of tungsten

Table 1. Characteristic ^{13}C NMR (62.9 MHz, $CDCl_3$, 25 °C) and IR (THF) data of complexes **3a–e**.

3a: δ = 240.0 (CS_3), 224.4 (CO), 219.4 (PhC*C*S), 206.2 (Ph*C*CS); $\tilde{\nu}$ = 1959 cm^{-1} (s, CO).
3b: δ = 241.2 (CS_3), 223.9 (CO), 218.1 (PhC*C*S), 205.6 (Ph*C*CS); $\tilde{\nu}$ = 1960 cm^{-1} (s, CO).
3c: δ = 243.9 (CS_3), 223.1 (CO), 216.1 (PhC*C*S), 204.0 (Ph*C*CS); $\tilde{\nu}$ = 1957 cm^{-1} (s, CO).
3d: δ = 242.1 (CS_3), 231.8 (CO), 192.7 (PhC*C*S), 180.0 (Ph*C*CS); $\tilde{\nu}$ = 1924 cm^{-1} (s, CO).
3e: δ = 243.3 (CS_3), 231.1 (CO), 193.7 (PhC*C*S), 181.8 (Ph*C*CS); $\tilde{\nu}$ = 1927 cm^{-1} (s, CO).

alkynol, alkynolester, and alkynol silyl ether complexes $[WCl_2(EOCCPh)(CO)_2(PMe_3)_2]$ (E = H, RCO, R_3Si), which were obtained by photoinduced alkylidyne–carbonyl coupling of $[W(CPh)Cl(CO)_2(PMe_3)_2]$ in the presence of ECl (E = H, Cl, and R_3Si, respectively).[8] The presence of an alkyne unit in complexes **3** is also indicated by the upfield shift of the signals at δ = 218 and 205 for complexes **3a–c** to δ = 193 and 180 for **3d**, **e**, which have thiolate ligands. These signals lie in the range characteristic for four-electron donor alkyne ligands.[9] In **3d** and **3e** π donation by the alkyne unit is reduced by competition with the strong thiolato π donor ligands, thus causing the shift of the alkyne NMR signals to higher field.

The solid-state structure of **3b** was determined by X-ray crystallography and is shown in Figure 1.[10] The newly formed alkynyltrithiocarbonato ligand is coordinated to the tungsten atom through the acetylene group and one sulfur atom. The bond lengths and angles of **3b** exhibit no unusual features.

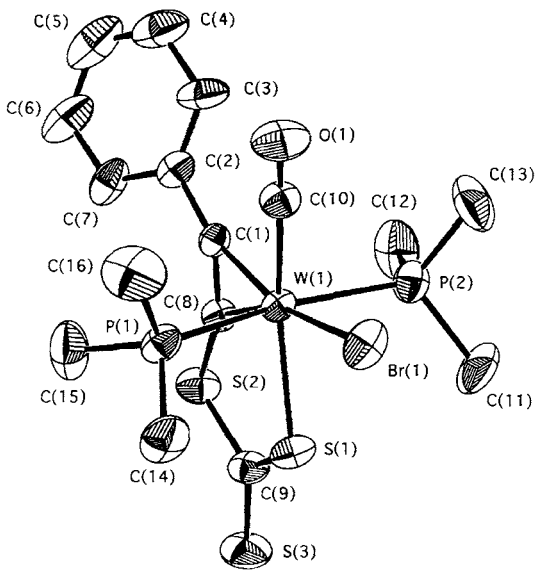

Fig. 1. Crystal structure of **3b**. Selected bond lengths [Å] and angles [°]: W1-C1 2.034(6), W1-C8 1.964(6), W1-C10 2.002(7), W1-Br1 2.6050(8), W1-P1 2.521(2), W1-P2 2.517(2), W1-S1 2.541(2), C1-C8 1.328(8), C8-S2 1.694(6), C9-S2 1.785(7), C9-S3 1.646(6), C9-S1 1.689(7); C2-C1-C8 136.9(6), C1-C8-S2 147.8(5), C8-S2-C9 98.7(3), S1-C9-S2 117.5(4), S2-C9-S3 115.3(4).

The mechanism of formation of complexes **3** is proposed to involve complexes **1** as the immediate coupling precursors.[11] An interesting question, which still remains open, is how the alkylidyne–thiocarbonyl coupling step is induced. Alkylidyne–carbonyl couplings are induced primarily by nucleophiles, whereas alkylidyne–isocyanide couplings are initiated exclusively by electrophiles.[4] Alkylidyne–thiocarbonyl couplings are expected to be susceptible to induction by both nucleophiles and electrophiles.[4] The nature of the products **3** suggests electrophilic attack of carbon disulfide at the thiocarbonyl ligand as a mechanistic possibility.[12] However, coupling could also be induced by nucleophilic attack of Me_3PS at the metal center to give an intermediate with a thioketenyl ligand. Further reaction of the thioketenyl ligand with carbon disulfide and displacement of Me_3PS from the metal center by the resulting trithiocarbonate group could also account for the formation of the products. Regardless of the actual coupling mechanism, if the alkylidyne thiocarbonyl complexes **1** are indeed intermediates in the reaction shown in Equation (1), then the results imply that alkylidyne–thiocarbonyl coupling is more facile than alkylidyne–carbonyl coupling, since the prerequisite structural components for both are present in complexes **1**.

Experimental Procedure

In a typical experiment a solution of **2b** (98 mg, 0.161 mmol) and CS_2 (50 µL, 0.831 mmol) in 30 mL THF was stirred at room temperature until most of the starting material had reacted (reaction was monitored by IR spectroscopy). During this time, the color of the solution changed from orange to brown-green. All volatile components were removed under vacuum. The product was purified by chromatography on silica gel at room temperature eluting with CH_2Cl_2/hexane (2:1). Recrystallization from CH_2Cl_2/hexane gave air-stable, green crystals. (Reaction times and yields, **3a**: 18 h, 14.7%; **3b**: 44 h, 41.9%; **3c**: 14 d, 38.0%; **3d**, 17 h, 32.7%; **3e**, 18 h, 16.9%.) Satisfactory C,H analyses were obtained for complexes **3a** and **3c–e**.

[10] Crystals of **2b** suitable for X-ray structure analysis were obtained by recrystallization from CH_2Cl_2/hexane. Crystal data for **2b**: $C_{16}H_{23}OP_2S_3W$, M_r = 653.24, $P2_1/n$ (no. 14), a = 8.955(4), b = 28.571(4), c = 9.183(1) Å, β = 99.20(2)°, V = 2319(2) Å^3, Z = 4, ϱ_{calcd} = 1.871 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 71.929 cm^{-1}, 3291 unique observed data, 0° < 2θ < 60.8°, 217 final variables, R = 0.033, R_w = 0.032. All intensity measurements at room temperature, $Mo_{K\alpha}$ radiation, graphite monochromator (λ = 0.71069 Å), θ-2θ scan mode. The structure was solved by direct methods and refined by full-matrix least squares. All calculations were performed using the TEXSAN programs. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-57807, the names of the authors, and the journal citation.
[11] An alternative mechanism could involve dissociation of PMe_3 and direct addition of CS_2 across the metal–carbon triple bond as the C–C bond-forming step. A precedent for this step is the cycloaddition of CO_2 to the aminomethylidyne complex $NEt_4[W(CNEt_2)(CO)_2(\mu\text{-}PPh_2)_2Mo(CO)_4]$: E. O. Fischer, A. C. Filippou, H. G. Alt, U. Thewalt, *Angew. Chem.* **1985**, *97*, 215; *Angew. Chem. Int. Ed. Engl.* **1985**, *24*, 203. We consider this possibility less likely. The cycloadduct $[X(CO)(PMe_3)_2W{=}C(Ph)\text{-}C(S)S]$ would be a 16-electron complex without significant stabilization of the metal center by π donation. Formation of the products from this type of intermediate would require the formulation of additional unprecedented steps.

Unprecedented Cage-Opening of P_4S_3 Initiated by an Organometallic Radical: Synthesis and Structure of $[Cp_4Cr_4(CO)_9(P_4S_3)]$**

By *Lai Yoong Goh,* Wei Chen,* and *Richard C. S. Wong*

We recently found that $[CpCr(CO)_3]$ radical-induced cleavage of P_4 and As_4 tetrahedra leads to the abstraction of $(\mu\text{-}\eta^2\text{-}E_2)$ and $(\eta^3\text{-}E_3)$ moieties (E = P, As) as ligands,[1, 2] and more interestingly, to a unique aggregation of P atoms to yield the novel $[\{CpCr(CO)_2\}_5P_{10}]$ complex.[3] We have now extended our study to cage compounds like P_4S_3, and we describe here the reaction of $[\{CpCr(CO)_3\}_2]$ with P_4S_3 which proceeds without fragmentation to form the title compound **1**, a new polyphosphido-sulfido complex.

$[Cp_4Cr_4(CO)_9(P_4S_3)]$ **1**

Previous examples of P_4X_3 (X = S, Se) as a ligand in transition metal complexes involve the coordination of intact P_4X_3 cages (through the apical P atom) with the metal center (Fig. 1), for example in *cis*-$[(P_4S_3)_2M(CO)_4]$ (M = Cr, Mo, W) and *cis*-$[(P_4S_3)_3M'(CO)_3]$ (M' = Cr, Mo),[4] $[Mo(CO)_5(P_4S_3)]$,[5] and $[(np_3)Ni(P_4X_3)]$ (X = S, Se; np_3 = $[N(CH_2CH_2PPh_2)_3]$).[6] In contrast, in the presence of the

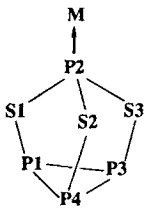

Fig. 1. Coordination of P_4S_3 to a metal complex fragment M.

chelating ligand triphos (triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane), the reaction of P_4X_3 (X = S, Se) with $Co(BF_4)_2 \cdot 6H_2O$[7, 8] and $[RhCl(cod)]_2$ (cod = cycloocta-1,5-diene),[9] resulted in fragmentation of the P_4X_3 cage, yielding the complexes $[(triphos)Co(P_2X)]BF_4$ and $[(triphos)Rh(P_3X_3)]$, respectively. In its reaction with $[\{Cp^*Mo(CO)_2\}_2]$ (*Mo*≡*Mo*) ($Cp^* = \eta^5\text{-}C_5Me_5$), the P_4S_3 cage likewise underwent fragmentation giving a mixture of $[Cp^*Mo(CO)_2P_3]$, $[Cp^*_2Mo_2(CO)_4P_2]$, $[Cp^*_2Mo_2P_2S_3]$, and $[Cp^*_2Mo_2P_4S]$.[10] In reactions with the square-planar d^8 metal complexes $[IrCl(CO)(PPh_3)_2]$ (Vaska's complex) or $[Pt(C_2H_4)(PPh_3)_2]$, cleavage of a single P–P bond in the basal P_3 triangle of the cage led to the $[\mu\text{-}P_4S_3]$-bridged binuclear $[\{Ir(\mu\text{-}P_4S_3)(PPh_3)Cl(CO)\}_2]$[11] and trinuclear $[\{Pt(\mu\text{-}P_4S_3)(PPh_3)\}_3]$[12] complexes, respectively.

$[\{CpCr(CO)_3\}_2]$ and P_4S_3 (1 molequiv) in toluene were allowed to react at ambient temperature for 13 days. The compounds **1** (66%), $[\{CpCr(CO)_2\}_2S]$ (8%; yields based on $[\{CpCr(Co)_3\}_2]$ employed), unreacted P_4S_3 (38%), and an as-yet-unidentified yellow crystalline complex were isolated from the reaction mixture following column chromatography on silica gel. Complex **1** was eluted with toluene/hexane (7:3) as a reddish brown fraction, and isolated as a dark brown crystalline solid which has been characterized by analytical and spectroscopic methods.[13] Dark brown platelets of **1** suitable for a single-crystal X-ray structural analysis[14] (Fig. 2) were obtained from a THF/Et_2O solution, after three weeks at −30 °C.

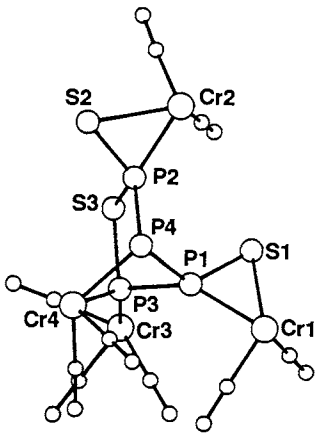

Fig. 2. Molecular structure of **1** (Cp rings omitted for clarity).

From Figure 2, it is apparent that the cleavage of the P2–S1, P4–S2, and P3–P4 bonds, with concomitant bond formation between P2 and P4, gives a five-membered P_4S ring with two external sulfur atoms as substituents, namely S1 at P1 and S2 at P2, as found in the structure of **1**. Together with Cr4, this five-membered ring forms a bicyclo[2.1.1] system, possessing common vertices at P3 and P4. In fact, the P_4S ring bridges four $[CpCr(CO)_n]$ ($n = 2$ or 3) fragments through its four P atoms; the S atom of the five-membered ring is not coordinated to a metal center. With the exception of Cr3, the other three Cr atoms are coordinated to two atoms of the P_4S_3 ligand. It should be noted that P3 is the only P atom that bridges two Cr atoms (Cr3 and Cr4), the Cr4–P3 distance is 0.084 Å shorter than that between P3 and Cr3. Cr1 and Cr2 have similar ligand environments, both possessing a pseudo η^2-PS ligand. An earlier example of η^2-PS coordination was established for the $Cr(CO)_5$ adduct of $[Cp^*_2Mo_2P_4S]$.[10] Each of the five-coordinate Cr atoms assumes a four-legged piano-stool geometry.

The P–P bond lengths (mean 2.201 Å) in **1** are significantly shorter than those in the P_4S_3 cage (mean 2.235 Å),[15] and are very close to the value for the single bond (2.21 Å) in P_4 vapor.[16] The P–S distances (mean 2.0067 Å) in **1** are also shorter than in the intact cage (mean 2.090 Å).[15] The Cr–P distances (mean 2.282 Å) in the CrPS rings for Cr1 and Cr2 are significantly shorter than the other three Cr–P bonds (mean 2.440 Å), which fall within the range 2.341–2.494 Å observed for other CpCr complexes with phosphorus ligands.[1, 3] The Cr–S distances (2.486 and 2.517 Å) in **1** are longer than those observed in $Cr(\mu\text{-}\eta^2\text{-}S_2)$ and $Cr(\mu\text{-}\eta^1, \eta^2\text{-}S_2)$ complexes (range 2.348–2.466 Å).[17]

In summary, this is the first example of multiple bond cleavage without fragmentation of the P_4S_3 cage by a transition metal complex. Slight cage rearrangement has been observed before in the insertion of a $Cr(CO)_5$ fragment into the isostructural nortricyclic homopolyatomic Zintl ion As_7^{3-}.[18] A very recent example of this reaction type is the insertion of three Ni(CO) fragments into Sb_7^{3-}.[19] The extensive cage opening cum structural rearrangement of the neutral P_4S_3 cage described here is unprecedented and may be attributed to the unusual reactivity of the radical-like

[13] Satisfactory elemental analysis. ^1H NMR (300 MHz, C_6D_6, 25 °C, residual C_6H_6): The spectrum indicates a 2:1 molar mixture of isomers A and B. Isomer A: δ(Cp) = 4.58(s), 4.61(s), 4.76(s), 4.77(d, J = 1.5 Hz) and isomer B: δ(Cp) = 4.61(s), 4.70(s), 4.79(d, J = 1.5 Hz) and 4.86(s). A variable-temperature ^1H NMR study in $C_6D_5CD_3$ shows that isomer A is the predominant species below −30 °C (δ(Cp) = 4.39, 4.53, 4.63 and 4.71), and that rapid exchange of the four Cp rings at 90 °C gives rise to a singlet at δ = 4.77. ^{13}C NMR (67.80 MHz, C_6D_6): δ(Cp) = 91.71, 92.07, 92.72, 93.15. IR(toluene): $\tilde{\nu}$[cm^{-1}] = 2028vs, 1983vs, 1969vs, 1950vs, 1942vs, 1899s, 1882sh s, 1874vs (CO).
[14] Crystal data for **1**: M_r = 1012.66, triclinic, space group $P\bar{1}$, a = 12.074(1), b = 12.880(3), c = 14.451(5) Å, α = 73.05(2), β = 73.21(1), γ = 78.67(1)°, V = 2042.5(9) Å^3, Z = 2, ϱ = 1.646 Mg m^{-3}, $F(000)$ = 1020, $\lambda(Mo_{K\alpha})$ = 0.71073 Å, μ = 13.65 cm^{-1}, T = 27 °C, crystal dimensions: 0.1 × 0.2 × 0.15 mm. Enraf-Nonius CAD4 diffractometer, ω-2θ scan mode. Of 6208 reflections measured, 3221 ($I > 3\sigma(I)$) were used in refinement. The crystal used for unit cell determination and data collection was coated with epoxy glue to prevent decomposition in air. Twenty-five strong reflections were used for accurate determination of the unit cell parameters. The measured intensities were processed for Lorentz-polarization effects and decay, and corrected for absorption [20]. The structure was solved by direct methods (MULTAN). All non-hydrogen atoms were subjected to anisotropic refinement. The hydrogen atoms were generated geometrically with a distance of 0.95 Å to the carbon atoms and were allowed to "ride" with B = 1.3. A THF solvent molecule was found at a general position in the unit cell and was disordered. The positional parameters for the THF ring were fixed, while their displacement parameters were refined as carbon atoms. Residual peaks in the final difference map account mainly for peaks around the THF molecule. Computations were performed by using the MolEN [21] package on a DEC MicroVAX-II computer. Analytic expressions of atomic scattering factors were employed and anomalous dispersion corrections were incorporated [22]. Final R = 0.048, (R_w = 0.057). Further details of the crystal structure investigation are available from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

A Simple Synthesis of $[(Cp^*Al)_4]$ and Its Conversion to the Heterocubanes $[(Cp^*AlSe)_4]$ and $[(Cp^*AlTe)_4]$ ($Cp^* = \eta^5$-$C_5(CH_3)_5$)**

By *Stephan Schulz, Herbert W. Roesky,* Hans Joachim Koch, George M. Sheldrick, Dietmar Stalke,* and *Annja Kuhn*

Dedicated to Professor Harry Emeléus on the occasion of his 90th birthday

Aluminum occurs preferably in the oxidation state III in its compounds. In addition, there are several compounds with aluminum in the oxidation state II[1–3] and only a few containing aluminum in the oxidation state I.[4–6] One of these is the $[(Cp^*Al)_4]$ tetrahedron (**1**) synthesized by Schnöckel et al. from AlCl and $[MgCp^*_2]$ ($Cp^* = \eta^5$-$C_5(CH_3)_5$) in 1991.[4] The synthesis of the starting material AlCl from HCl and Al at 1200 K is rather difficult.[7] We report here on a simple alternative synthetic route to **1** as well as the first reactions of this compound.

Freshly prepared $[Cp^*AlCl_2]$[8] is allowed to react with a small excess of potassium in toluene under reflux [Eq. (a)]. After filtration of all the insoluble material from the hot solution, **1** is obtained in form of yellow crystals in a yield of 20 %.

$$4[Cp^*AlCl_2] + 8\,K \longrightarrow \underset{\mathbf{1}}{[(Cp^*Al)_4]} + 8\,KCl \qquad (a)$$

Compound **1** is extremely thermally stable and decomposes at 205 °C turning to a brown solid.[9] Only one signal with 100% intensity for monomeric Cp*Al (M = 162 g mol^{-1}) occurs in the mass spectrum. We were not able to detect the molecular ion in the mass spectrum by field ionization (FI) methods. Compound **1** is only slightly air- and moisture-sensitive. Exposure of the crystalline material to air or even water for about 20 min leads to a white amorphous layer, presumably consisting of aluminum oxo and/or aluminum hydroxo compounds. This chemical inertness is a result of the steric shielding of the Al_4 tetrahedron by interlocked Cp* rings.[10] Because of the poor solubility of **1** NMR investigations in C_6D_6 were performed in the temperature range + 40 to + 78 °C. In the ^1H NMR spectrum a singlet appears for the methyl protons at δ = 1.89 and two signals occur in the ^{13}C NMR spectrum for the methyl-C and for the ring-C atoms at δ = 11.35 and 114.21, respectively. The ^{27}Al NMR spectrum shows, in contrast to the previously published results,[11] only one signal at $\delta = -78.3$,[12] whose position does not change on raising or lowering the temperature. We were not able to detect a second signal that should appear above 30 °C (at $\delta = -145$) corresponding to monomeric Cp*Al.[13, 14] In addition to finding a facile access to $[(Cp^*Al)_4]$ **1**, we were also interested in the reactivity of this compound. It should undergo redox reactions in which the aluminum proceeds from the oxidation state I to its preferred oxidation state III. Hitherto, apart from reactions with AlCl, no reactions of aluminum(I) compounds have been described. We report here for the first time about reactions of **1** with elements from group 16. These reactions lead to the

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, and the Fonds der Chemischen Industrie.

formation of the Al–Se and Al–Te heterocubanes, **2** and **3**, respectively. Moreover, **3** is the second organometallic

$[(Cp^*AlSe)_4]$ **2**

$[(Cp^*AlTe)_4]$ **3**

Al–Te compound characterized by X-ray crystallography.[23] Compounds of the type RAlE (E = Se, Te) are isolobal with those of the type RAlXR (X = N, P, As); the latter have been thoroughly investigated during the last few years, since they are potential precursors for industrially interesting AlX materials. In our opinion the compounds RAlE and AlE also have very promising material properties.

When a solution of **1** in toluene is treated with an excess of Se or Te [see Eq. (b)], yellow-green solutions are obtained

$$[(Cp^*Al)_4] + 4\,E \longrightarrow [(Cp^*AlE)_4] \qquad \text{(b)}$$
$$\mathbf{1} \qquad\qquad \mathbf{2},\ E = Se;\ \mathbf{3},\ E = Te$$

following the removal of the insoluble material by filtration. From these solutions **2** can be obtained in the form of colorless, octahedral crystals and **3** in the form of pale green shiny octahedral crystals by slow evaporation of the solvent.

Both compounds are extremely sensitive to air and moisture. Thus, they decompose with an accompanying change in color (red (**2**) or black (**3**)) and concomitant formation of H_2Se and H_2Te, respectively. Compound **2** decomposes at 244 °C and **3** does not melt until 350 °C.

Crystals of **2** are obtained from a THF solution of **2** by very slow evaporation of the solvent. Figure 1 shows the molecular structure of **2**. Suitable crystals for a single-crystal

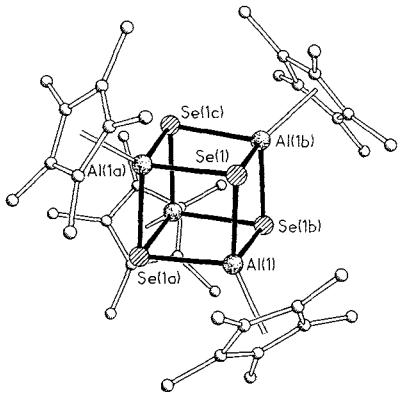

Fig. 1. Crystal structure of **2**. Selected bond lengths [pm] and angles [°]: Al(1)-Se(1) 249.70(10), Al(1)-Se(1a) 246.16(10), Al(1)-Se(1b) 247.13(10); Al(1b)-Se(1)-Al(1a) 85.38(4), Al(1b)-Se(1)-Al(1) 84.62(3), Al(1)-Se(1)-Al(1a) 85.57(4), Se(1b)-Al(1)-Se(1) 94.39(4), Se(1b)-Al(1)-Se(1a) 95.28(4), Se(1a)-Al(1)-Se(1) 94.16(4).

X-ray structural analysis of **3** can be obtained from toluene by slow evaporation of the solvent over a week. Figure 2 shows the molecular structure of **3**, which is isostructural to **2**. Both compounds are tetrameric; the parent skeleton comprises an Al–E heterocubane (E = Se, Te). The Al–Se bond lengths present in **2** vary from 246.2 to 249.7 pm. The Al–Se bond lengths thus lie in the range of those found in $[Ph_3PSe\cdot AlCl_3]$[15] and in $[CH_3Se\{Al(CH_3)_3\}_3]^-$.[16] The Al–Te bonds in **3** range from 268.8 to 275.0 pm and are thus slightly longer than those in Al_7Te_{10} (263.7–266.2 pm for the bonds from the three-coordinate Te atoms).[17] Since the atomic distances lie in a relatively narrow range and also the bond angles at Al and Se and Te, respectively, deviate very little from the ideal 90° angle (average Se-Al-Se: 94.61°, Te-Al-Te: 95.06°, Al-Se-Al: 85.19°, Al-Te-Al: 84.68°), **2** and **3** form almost ideal cubes. In both compounds, each Al atom is additionally coordinated to an η^5-Cp* ligand[18] (Al-Cp*(center) [pm]: 194.9 in **2** and 196.5 in **3**; 201.5 in $[(Cp^*Al)_4]$).

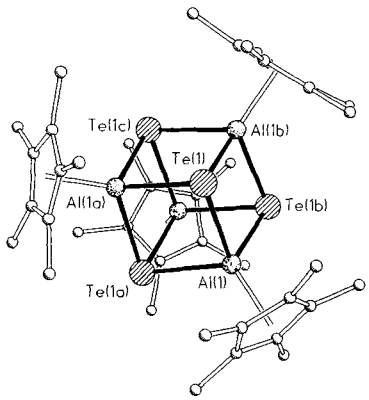

Fig. 2. Crystal structure of **3**. Selected bond lengths [pm] and angles [°]: Al(1)-Te(1) 275.00(9), Al(1)-Te(1a) 268.83(9), Al(1)-Te(1b) 269.17(9); Al(1b)-Te(1)-Al(1a) 84.86(2), Al(1b)-Te(1)-Al(1) 83.68(2), Al(1)-Te(1)-Al(1a) 85.51(2), Te(1b)-Al(1)-Te(1) 94.84(2), Te(1b)-Al(1)-Te(1a) 96.29(2), Te(1a)-Al(1)-Te(1) 94.06(2).

Noteworthy is the analogous construction of these Al heterocubanes to the $[RAlNR']_4$ compounds described by Veith[19] in a review on cage molecules. These compounds exhibit a cubic Al_4N_4 framework. The facile formation of this organometallic Al–Te compound under very mild reaction conditions in good yield is quite surprising. It illustates again the strong desire of aluminum in the oxidation state I (as occurs in **1**) to attain the more stable oxidation state III. The new facile synthesis of **1** accompanied by the high reactivity of **1** in solution should allow the access to other interesting Al compounds.

Experimental Procedure

All reactions were carried out under a nitrogen atmosphere and with dry solvents.

1: $AlCl_3$ (4.00 g, 30 mmol) was dissolved in hexane (60 mL), treated with $[Cp^*SiMe_3]$ (6.25 g, 30 mmol), and heated under reflux for 3 h. Subsequently the solvent and the Me_3SiCl formed were removed under vacuum. The white solid residue was then dissolved in toluene (60 mL) and treated with K (2.75 g, 70 mmol) and heated for 1.5 h. The insoluble material was then quickly filtered off from the hot solution; the temperature of the solution must not be allowed to drop below 80–90 °C. Compound **1** crystallized from the hot solution on cooling in the form of yellow crystals. Yield: 0.95 g (1.5 mmol)(20%). IR (nujol, CsI): $\tilde{\nu}$[cm^{-1}] = 1480, 1370, 1307, 1261, 1169, 1094, 1019, 800, 733, 595, 585, 352.

2: A mixture of **1** (0.32 g, 0.5 mmol) and Se (0.31 g, 4 mmol) in toluene (60 mL) was stirred for 4 d at room temperature. Subsequently all insoluble material was filtered off and the solvent was slowly removed under vacuum over a period of 2 d to afford **2**. Yield: 0.38 g (0.39 mmol) (78%). ^{1}H NMR (400 MHz, C_6D_6, 25 °C, TMS): δ = 1.99; ^{13}C NMR (100 MHz, C_6D_6, 25 °C, TMS): δ = 12.07, 115.68; ^{27}Al NMR (100 MHz, C_6D_6, 25 °C, $AlCl_3$): δ = −36.40. IR (nujol, CsI): $\tilde{\nu}$ [cm^{-1}] = 1261, 1095, 1064, 1021, 800, 727, 694, 661, 627, 591, 451, 425, 387. MS (EI): *m/z* 966 (M^+, 2%), 831 (M^+ −Cp*, 8), 162 (AlCp*, 100). Correct elemental analysis.

3: **1** (0.32 g, 0.5 mmol) and Te (0.50 g, 4 mmol) were stirred for 6 d in toluene (60 mL) at room temperature. After removal of the insoluble material by filtration, the solvent was slowly removed under vacuum. Compound **3** precipitated in the form of octahedral crystals. Yield 0.50 g (0.43 mmol) (86%). ^{1}H NMR (400 MHz, C_6D_6, 25 °C, TMS): δ = 1.96; ^{13}C NMR (100 MHz, C_6D_6, 25 °C, TMS): δ = 12.91, 116.44; ^{27}Al NMR (100 MHz, C_6D_6, 25 °C, $AlCl_3$): δ = −112.69 IR (nujol, CsI): $\tilde{\nu}$ [cm^{-1}] = 1262, 1168, 1019, 949, 799, 589, 446,

373, 350, 272. MS (EI): *m/z* 1025 (M^+−Cp*, 2%), 580 ($M/2^+$, 25), 135 (Cp*, 100). Correct elemental analysis.

[18] Crystal data of **2**: $C_{10}H_{15}AlSe$, M_r = 241.16, tetragonal, space group $I\bar{4}$, $a = b$ = 12.144(1), c = 14.373(2) Å, V = 2119.7(4) Å^3, Z = 8, ρ_{calcd} = 1.511 Mgm^{-3}, $F(000)$ = 976, λ = 0.71073 Å, $\mu(Mo_{K\alpha})$ = 0.397 mm^{-1}. The data were collected on a Stoe-Siemens-Huber diffractometer. Intensities of a rapidly cooled crystal with dimensions 0.6 × 0.5 × 0.4 mm in an oil drop [20] were collected at −120 °C by the $2\theta/\omega$ method in the range $8 \le 2\theta \le 50$°. Of the 1403 reflections collected, 1367 were unique and these were corrected for absorption by using a semiempirical procedure; highest minimum and maximum of the final difference Fourier synthesis: 0.32 and −0.28 eÅ^{-3}, respectively. $R1$ = 0.021, $wR2$ = 0.050 (all data). The absolute structure was determined to 0.00(14) by a refinement of the Flack parameter (H. D. Flack, *Acta Crystallogr. Sect. A* **1983**, *39*, 876). Crystal data of **3**: $C_{10}H_{15}AlTe$, M_r = 289.80, tetragonal, space group $I\bar{4}$, $a = b$ = 12.430(2), c = 14.546(3) Å, V = 2247.4(7) Å^3, Z = 8, ρ_{calcd} = 1.713 Mgm^{-3}, $F(000)$ = 1120, λ = 0.71073 Å, $\mu(Mo_{K\alpha})$ = 0.397 mm^{-1}. The data were collected on a Stoe-Siemens-Huber diffractometer. Intensities of a rapidly cooled crystal with the dimensions 0.5 × 0.4 × 0.4 mm in an oil drop [20] were collected at −120 °C by the $2\theta/\omega$ method in the range $8 \le 2\theta \le 55$°. Of the 2370 reflections collected, 2278 were unique and these were corrected for absorption by using a semiempirical procedure; highest minimum and maximum of the final difference Fourier synthesis: 0.39 and −0.44 eÅ^{-3}, respectively. $R1$ = 0.017, $wR2$ = 0.042 (all data). The absolute structure was determined to 0.03(2) by a refinement of the Flack parameter (H. D. Flack, *Acta Crystallogr. Sect. A* **1983**, *39*, 876). The values of $R1$ and $wR2$ were defined as $R1 = \Sigma||F_o| - |Fc||/[\Sigma|F_o|]$; $wR2 = \{[\Sigma w(F_o^2 - F_c^2)^2]/[\Sigma w(F_o^2)]\}^{1/2}$. The structures were solved by direct methods (SHELXS-90) [21] and refined by least-squares procedures (SHELXL-93) [22]. The hydrogen positions were refined according to a riding model in which the CH_3 groups were allowed to rotate about their local threefold axis. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallography Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), by quoting the full journal citation.

A Molecular Heterometal Amide with High Molecular Dynamics: Does the Lithium Atom Orbit?**

By *Michael Veith,* Michael Zimmer,* and *Stefan Müller-Becker*

Dedicated to Professor Ulrich Wannagat on the occasion of his 70th birthday

Whilst the motion of lithium atoms in solids, such as, for example, in solid Li_3N, has been thoroughly investigated and is generally accepted,[1] many indications, but little concrete evidence for such a motion in molecules exists, in spite of much effort (see e.g. ref. [2]). Here we report on our studies of the heterometal amide $[Me_2Si(NSiMe_3)_2]_2InLi$ (**1**), an example of a class of molecular complexes that has still not been investigated in detail.[3] Compound **1** can easily be prepared according to Equation (a).

$$2\,Me_2Si(NSiMe_3)_2Li_2 + InCl_3 \longrightarrow 3LiCl + \underset{\mathbf{1}}{[Me_2Si(NSiMe_3)_2]_2InLi} \quad (a)$$

According to the X-ray crystal structure analysis,[4] (Fig. 1) the trivalent indium and the monovalent lithium atom in **1** are bound close together in a tricycle of four-membered rings (In···Li = 2.748(9) Å). The ^{1}H, ^{13}C, ^{15}N, and ^{29}Si NMR spectra of **1** at room temperature in toluene (see Experimental Procedure) are not consistent with the molecular structure represented in Figure 1. Thus, only one resonance signal is found for both the dimethylsilylene and trimethylsilyl groups in the ^{13}C NMR spectrum, whereas a double set of signals would be expected because of the low C_2 symmetry of the molecule (the twofold axis passes through the two metal atoms).

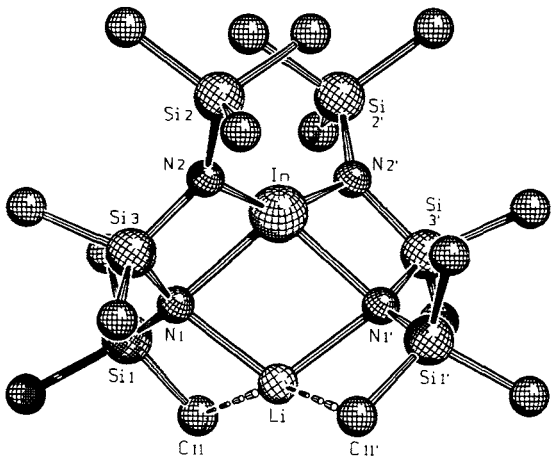

Fig. 1. Molecular structure of **1**. Some important distances [Å] and angles [°]: N1–In 2.223(3), N2–In 2.055(3), N1–Li 2.064(6), N1–Si1 1.720(3), N1–Si3 1.737(3), N2–Si2 1.714(3), N2–Si3 1.717(3), Li···C11 2.635(7); N1-In-N1' 95.2(1), N2-In-N2' 148.4(1), N1-In-N2 76.2(1), N1-In-N2' 127.3(1), N1-Li-N1' 105.4(3).

If a toluene solution of **1** is cooled, ^{1}H, ^{13}C, and ^{29}Si NMR spectra are obtained at lower temperature (as an ex-

ample ^{13}C NMR spectra are reproduced in Fig. 2) with twice (or one and a half times) the number of signals as expected from the crystal structure. An activation energy of 44.3 kJ mol^{-1} can be determined from analysis of the coalescence temperature and the signal splitting derived from heteronuclear NMR spectra.[5] The signal of the trimethylsilyl groups shifted to high field shows unusual behavior: With decreasing temperature a selective broadening is found, a phenomenon that can be explained by a rotation barrier about the Si–N bond, which is also found for trimethylsilyl groups of other molecules.[6] On examination of the solid-state molecular structure (Fig. 1), it becomes apparent that the reason for the rotational barrier of this one trimethylsilyl group is due to lithium methyl contacts (dotted lines); at the same time, this finding allows the assignment of the resonance signals.

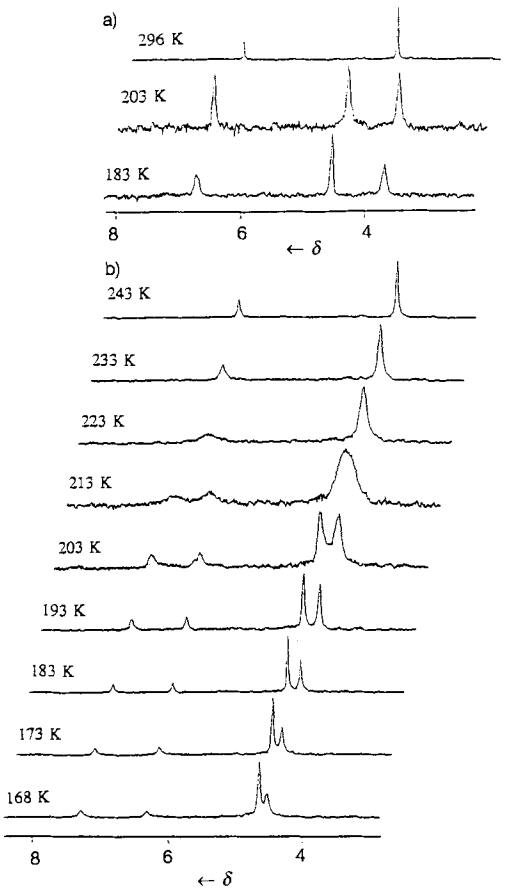

Fig. 2. ^{13}C NMR spectra (50.3 MHz) of **1** a) in hexane at three temperatures and b) in toluene between 243 and 168 K .

Temperature-dependent measurements of the spin-lattice relaxation T_1 of the ^{7}Li isotope give the expected curve shape on plotting the graph with a minimum at 203 K. Analysis of the Arrhenius plot gives a value of 13.8 kJ mol^{-1} for the high-temperature end; this value is typical for methyl and trimethylsilyl rotations about threefold axes.[7] It implies several coupled migrations in the molecule and suggests that the lithium atom is involved in these.

The series of temperature-dependent ^{13}C NMR spectra shown in Figure 2 were also repeated for significantly higher and lower concentrations of **1** in toluene (about five- and tenfold), without any observable changes occurring in the comparable spectra. We conclude from this that an intermolecular process is unlikely to be the reason for the observed spectra at room temperature. Clearly all findings are consistent with a higher "average" point symmetry of the molecule at room temperature. Instead of the $C_2(2)$ symmetry in the crystal lattice, in which the molecules are exclusively bound by van der Waals contacts, $D_{2d}(\bar{4}2m)$ symmetry must be ascribed to the whole molecular unit in solution. The increase in symmetry is clearly determined by dynamic phenomena in which lithium, as the lightest of the atoms (if one neglects the covalently bonded hydrogen atoms), plays a special role.

After exclusion of an intermolecular process only an intramolecular and a dissociative mechanism remain. We consider the formation of an ion pair of the type $Li^{+}[\{Me_2Si(NSiMe_3)_2\}_2In]^{-}$ in solution, which would involve an anion with D_{2d} symmetry, to be unlikely in toluene due to the large amount of energy required to break the Li–N bond and to the relatively low expected solvation energy. Furthermore, analogous ^{1}H and ^{13}C NMR spectra with few signals are obtained when **1** is dissolved in nonpolar hexane (Fig. 2a). Here too, a splitting of the Me_3Si signal is observed at lower temperatures. Thus, identical activation energies (44.3 kJ mol^{-1}) to those in toluene are determined. In contrast to the spectra in toluene (dipole moment: 0.36 D), in hexane the signal for the dimethylsilyl group does not split up to the freezing point of the solvent. The molecule must therefore retain a residual mobility in nonpolar solvents, which is suppressed in polar toluene, because the static molecule itself is strongly dipolar.

We believe that the observed spectra can best be explained by an *intramolecular* dynamic process. In this context, two processes can be discussed: One possibility is an essentially oscillating motion of the lithium atom in an orbit around the center of the molecule, which can be described as a indium-centered N_4-bisphenoid (Fig. 3). A conceivable alternative

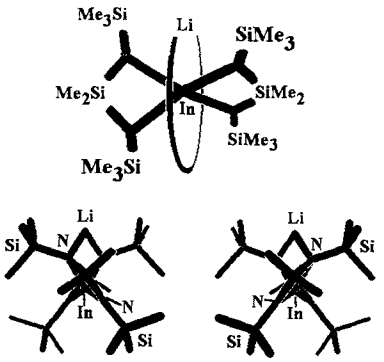

Fig. 3. Top: An intramolecular model for the "lithium migration". Bottom: The two structures of **1** found in the crystal (view orthogonal to the upper drawing). Their interconversion could explain the "residual mobility" of **1** in hexane.

would be that the $Me_2Si(NSiMe_3)_2$ ligands move disrotatory around a pseudo Si3-Si3′ axis (see Fig. 1); thus, the two metal atoms remain in their positions. Molecular dynamic model calculations[8] and the consideration of group vibrations show, however, that both processes are basically the same and that only a different reference point has been chosen. Moreover, this model explains the nature of the above-mentioned residual mobility in hexane below 220 K. In this

case the lithium atom is now only in contact with two nitrogen atoms at which inversions take place. In the extreme case this leads to the two molecules represented in the lower half of Figure 3. These are enantiomers and both crystallize together (in the crystal structure they are connected by inversion centers).

Solid-state NMR spectra were also obtained for **1**. The central line of the Magic Angle Spinning (MAS) ^{7}Li NMR spectrum (77.7 MHz) of **1** at room temperature consists of two components: a broad resonance signal showing the typical quadrupolar splitting obtained in MAS experiments for quadrupolar nuclei[9] (586 Hz), as well as a quasi-superimposed relatively sharp resonance with a half-width of about 120 Hz. If a second spectrum of the same sample is recorded at 116.5 MHz, the peak separation of the outer peaks is reduced, which is consistent with a quadrupolar effect. The sharp resonance signal at 296 K combines about 8% of the total intensity including the side bands and should be due to "readily mobile" lithium atoms.[10] Whether the signal is due to a partial "lithium dynamic" as a result of lattice vibrations in **1** or whether it is caused by a small amount of some impurity still needs to be clarified by further investigations.

Experimental Procedure

Indium chloride (0.7 g, 3.2 mmol) in diethyl ether (5 mL) was added to two molar equivalents of $Me_2Si(NSiMe_3)_2Li_2$ [11] in *n*-hexane (25 mL) and stirred for 6 h at room temperature. The suspension was filtered and the solution concentrated; during this process crystals of the ether adduct of **1** formed. The ether was eliminated from the compound in the subsequent sublimation (70–80 °C bath temperature/10^{-3} Torr) and 1.37 g (73%) of **1** were obtained as colorless crystals (m.p. 142 °C). Correct analyses and mass spectra. Chemical shifts of **1** in solution (200 MHz [D_8]toluene, 296 K, TMS): ^{1}H NMR: $\delta = 0.18$ (s, 36H, $SiMe_3$), 0.33 (s, 12H, $SiMe_2$); ^{13}C NMR ([D_8]toluene): $\delta = 4.2$ (s, 12C, $SiMe_3$), 6.6 (s, 4C, $SiMe_2$); ^{13}C NMR (hexane): $\delta = 3.9$ (s, $SiMe_3$), 6.4 (s, $SiMe_2$); ^{29}Si NMR: $\delta = -0.55$ (s, $SiMe_2$), -5.80 (s, $SiMe_3$); ^{15}N NMR (CH_3NO_2 ext.): $\delta = -308.5$ (s, $b_{1/2} = 10$ Hz); ^{7}Li NMR (ext. standard: LiCl/D_2O): $\delta = 3.0$ (s, $b_{1/2} = 5.7$ Hz). Chemical shifts of **1** in the solid state (200 MHz, 296 K, sec. standard: adamantane, TMS = 0), ^{13}C NMR: $\delta = 5.8$ ($b_{1/2} = 85$ Hz), ^{7}Li NMR (ext. standard: LiCl): $\delta = 1.0$ [12].

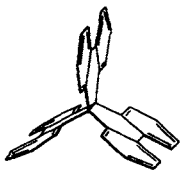
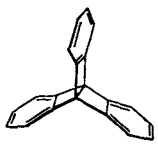
Palladium-Catalyzed Arylation of Tetrasubstituted Double Bonds: A Simple Synthesis of Annelated Propellanes**

By *Gerald Dyker,* Jutta Körning, Peter G. Jones,* and *Peter Bubenitschek*

As a result of their special topology propellanes have stimulated a multitude of syntheses and investigations into their chemical and physical properties.[1] The benzoannelated [4.4.4]propellane **1**[2] is of particular interest in this respect, as in this compound a hexaarylethane[3] structure is stabilized by triple clamping. However, the increased ring strain caused by reducing the size of the propellane rings can cause destabilization of the central single bond to reoccur. The highly strained dehydrotriptycene **2**—a [2.2.2]propellane—represents an extreme example and so far all attempts at its synthesis have been unsuccessful.[4] We report here on a rational entry to aryl-annelated [3.3.*n*]propellanes with $n = 2$, 3, and 4.



1



2

The hexacyclic hydrocarbon **7** is the key compound in the synthesis of the desired propellanes and can be prepared in one step from acenaphthylene and 1,8-diiodonaphthalene by a palladium-catalyzed annelation.[5] Formation of the [3.3.3]propellane **3**, which contains a threefold symmetry axis, was achieved in a single step by way of a second palladium-catalyzed annelation, this time with monoiodonaphthalene **5** (Scheme 1).[6] The use of 1,8-diiodonaphthalene in

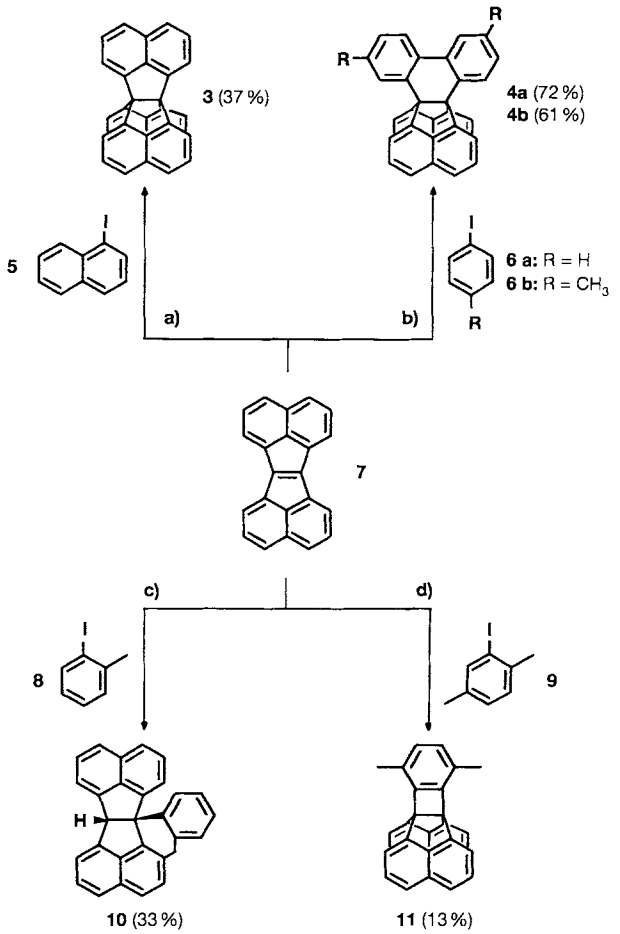
[**] Transition Metal-Catalyzed Annelation Reactions, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 5: *Angew. Chem.* **1994**, 106, No. 1; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, No. 1.



Scheme 1. Palladium-catalyzed annelation of **7**. Reaction conditions: 5 mol% $Pd(OAc)_2$, 30 equiv aryl iodide **5**, **6**, **8**, or **9**, K_2CO_3, nBu_4NBr, dimethylformamide, N_2, 100 °C, reaction times: a) 21 d, b) 14 d for **4a**, 7 d for **4b**, c) 7 d, d) 7 d.

place of **5** led exclusively to Ullmann products.[5b] As far as we are aware, examples of the intermolecular[7] palladium-catalyzed arylation of tetrasubstituted double bonds is unknown, since the reactivity of the olefins generally decreases with increasing degree of substitution.[8]

In order to investigate the range of application of such annelations on **7**, other aryl iodides were examined as coupling components. Iodobenzene **6a** and 4-iodotoluene **6b** led to good yields of the [4.3.3]propellanes **4a** and **4b**, respectively, as 1:2 products. The methyl substituents in **4b** allow the regiochemical course of the annelation process, which corresponds to similar reactions with norbornene, to be identified.[9] The X-ray crystal structure analysis[10] of **4a** revealed the twisting about the biphenyl unit and the pronounced elongation of the central single bond C8b-C14b with a bond length of 161.2(4) pm (Fig. 1).

The reaction of **7** with 2-iodotoluene **8** took a surprising course. The octacyclic hydrocarbon **10** was isolated as main product, apparently the result of activation of a C–H bond in the benzylic position. In the reaction with 2,5-dimethyliodobenzene **9**, the [3.3.2]propellane **11** was obtained as the only isolable product. In this case [4.3.3]propellanes as 1:2 products with methyl substituents in sterically demanding positions could not be demonstrated: it is possible that a methyl group sterically hinders formation of the octahedral Pd^{IV} intermediate, which has been postulated for such domino couplings.[11]

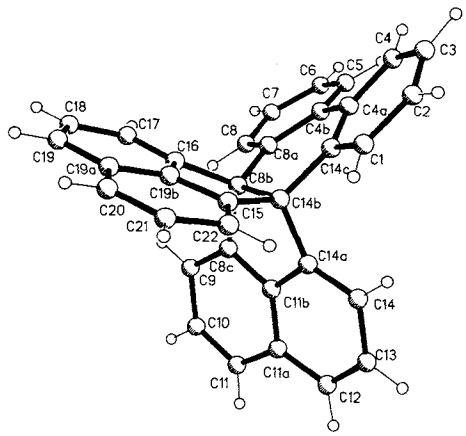


Fig. 1. Molecular structure of **4a** in the crystal (arbitrary radii) [10].

As tetrasubstituted olefin components dibenzo[*g*,*p*]-chrysene[12] and 9,9′-bifluorenylidene[13] have been shown to be too unreactive. In contrast, buckminsterfullerene C_{60} reacts with iodobenzene **6a** (5 equiv) under these reaction conditions; according to the mass spectrum[14] the resulting products were polyphenylfullerenes.[15]

The results described here prove that palladium-catalyzed arylations are also possible with tetrasubstituted olefins, providing that a strain activation is present. Thus, interesting propellanes can be rationally synthesized in annelation processes. The chemical reactivity and in particular the photochemical properties of the propellanes described here are the subject of investigations that are currently in progress.

Table 1. Selected physical and spectroscopic data [a] for the compounds **3**, **4a**, **4b**, **10**, and **11** [6]. ^1H NMR measurements: 400.1 MHz, $CDCl_3$, TMS; ^{13}C NMR measurements: 100.6 MHz, $CDCl_3$.

3: Colorless needles up to 400 °C unchanged; ^1H NMR: $\delta = 7.53$ (m, 1H), 7.60 ("d", "J" = 8.1 Hz, 1H), 8.03 ("d", "J" = 6.8 Hz, 1H); ^{13}C NMR: $\delta = 79.92$ (s), 119.14 (d), 124.20 (d), 128.50 (d), 132.46 (s), 137.20 (s), 146.65 (s); MS (70 eV): *m/z* (%): 403 (32), 402 (86, M^+), 401 (32), 400 (27), 277 (30), 276 (100), 252 (34), 57 (33); correct elemental analysis for $C_{32}H_{18}$ (402.49).

4a: Colorless solid, m.p. 338 °C; ^1H NMR: $\delta = 7.31$ (m_t, 2H; H-3,6), 7.43 (m_t, 2H; H-2,7), 7.46 (m_t, 4H; H-10, 13, 18, 21), 7.56 ("d", 4H; H-11,12,19,20), 7.65 ("d", 4H; H-9,14,17,22), 7.94 (m_d, 2H; H-4,5), 8.34 (m_d, 2H; H-1,8); ^{13}C NMR: $\delta = 67.59$ (s; C-8b,14b), 120.58 (d; C-9,14,17,22), 123.68 (d; C-11,12,19,20), 123.96 (d; C-4,5), 127.39 (d; C-3,9), 127.92 (d; C-10,13,18,21), 128.06 (d; C-2,7), 128.83 (d; C-1,8), 131.32 (s; C-4a,4b), 131.67 (s; C-8c,14a,15,16), 136.08 (s; C-8a,14c), 136.43 (s; C-8d,15a), 148.19 (s; C-11a,19a).

4b: Colorless solid, m.p. 341–342 °C; ^1H NMR: $\delta = 2.36$ (s, 3H; 6-CH_3), 2.47 (s, 3H; 2-CH_3), 7.12 (dd, J = 8.2, 1.7 Hz, 1H; H-3), 7.22 (dd, J = 8.0, 1.7 Hz, 1H; H-7), 7.43–7.48 (m, 4H; H-10,13,18,21), 7.53–7.56 (m, 4H; H-11,12,19,20), 7.62–7.65 (m, 4H; H-9,14,17,22), 7.73 (br. s, 1H; H-5), 7.84 (d, J = 8.2 Hz, 1H; H-4), 8.10 (br. s, 1H; H-1), 8.20 (d, J = 8.0 Hz, 1H; H-8); ^{13}C NMR: $\delta = 21.35$ (q; 6-CH_3), 21.65 (q; 2-CH_3), 67.48 (s; C-8b), 67.59 (s; C-14b), 120.44, 120.54 (d; C-9,14,17,22), 123.56, 123.60 (d; C-11,12,19,20), 123.88 (d; C-4), 124.26 (d; C-5), 127.87, 127.90 (d; C-10,13,18,21), 128.28 (d; C-3), 128.55 (d; C-7), 128.71 (d; C-8), 128.71 (s; C-4a), 129.28 (d; C-1), 131.21 (s; C-4b), 131.67 (s), 132.96 (s; C-8a), 136.05 (s; C-14c), 136.41 (s), 136.73 (s; C-6), 137.60 (s; C-2), 148.28 (s), 148.41 (s).

10: Colorless solid, m.p. 260–261 °C; ^1H NMR: $\delta = 4.16$ (d, J = 19.1 Hz, 1H), 4.90 (d, J = 19.1 Hz, 1H), 5.97 (s, 1H), 7.12 ("t", 1H), 7.17–7.21 (m, 2H), 7.27 (m_t, 1H), 7.39 (m_t, 1H), 7.48–7.68 (m, 9H), 7.89 ("d", 1H); ^{13}C NMR: $\delta = 36.05$ (t), 63.03 (d), 66.22 (s), 119.26 (d), 119.49 (d), 119.95 (d), 123.29 (d), 123.69 (d), 123.73 (d), 123.78 (d), 125.83 (d), 126.39 (d), 126.99 (d), 127.57 (d), 127.74 (d), 128.30 (d), 128.42 (d), 128.99 (s), 129.62 (d), 130.57 (s), 132.14 (s), 136.01(s), 136.27(s), 143.67 (s), 144.40 (s), 144.76 (s), 145.01 (s), 151.50 (s), a singlet is superimposed.

11: Colorless solid, m.p. 320 °C (decomp.); ^1H NMR: $\delta = 2.47$ (s, 6H), 6.81 (s, 2H), 7.54 (m, 4H), 7.66 ("d", 4H), 7.91 ("d", 4H); ^{13}C NMR: $\delta = 16.62$ (q), 75.48 (s), 120.23 (d), 124.50 (d), 128.07 (d), 129.56 (d), 130.68 (s), 133.13 (s), 140.09 (s), 142.27 (s), 145.31 (s).

Experimental Procedure

4a: A mixture of **7** (110.5 mg, 0.4 mmol), **6a** (2.45 g, 12.0 mmol), $Pd(OAc)_2$ (4.5 mg, 0.02 mmol), K_2CO_3 (440 mg, 3.2 mmol), and nBu_4NBr (258 mg, 0.8 mmol) in dimethylformamide (4 mL) was stirred under nitrogen for 14 d at 100 °C in a sealed reaction vessel. After the addition of water (100 mL), the mixture was extracted twice with dichloromethane (75 mL), the organic phase filtered through silica gel, and the solvent distilled off. More volatile by-products were removed by Kugelrohr distillation at 220 °C/0.1 Torr. Flash chromatography of the residue (silica gel, petroleum ether) gave 124 mg (72%) **4a**.

[14] Signals in the mass spectrum of the product from the Pd-catalyzed reaction of C_{60} with iodobenzene; relevant signals with more than 720 mass units are normalized with the signal $m/z = 720$ (100%); MS (70 eV): m/z (%) 797 (6), 798 (6), 874 (2.8), 875 (2.4), 952 (2.6), 1030 (1.3), 1106 (1.8), 1108 (1.6), 1184 (0.3), 1261 (0.10), 1262 (0.13), 1339 (0.05), 1340 (0.05). The mass differences of 78 (C_6H_6) and 154 (twice C_6H_5) units prove phenylation and not annelation, for which a mass difference of 152 is expected. An explanation for this observation could be a mobile palladium atom attached to the fullerene surface by a π-allyl complex.

Reverse Hydrozirconation Reaction: A Regio- and Diastereospecific Route to New Diphosphanes**

By *Maria Zablocka, Florence Boutonnet, Alain Igau, Françoise Dahan, Jean Pierre Majoral,** and *K. Michal Pietrusiewicz**

Organozirconium compounds resulting from hydrozirconation of alkenes and alkynes effect a wide variety of useful synthetic transformations.[1, 2] It is also well established that hydrozirconation of carbon–carbon multiple bonds always leads to *cis* addition products in which the zirconocene moiety is linked to the less hindered carbon atom. In this report we demonstrate for the first time that both α- and β-zirconated products can be prepared by direct hydrozirconation of dihydrophospholes in a completely regio- and diastereoselective fashion. Remarkably also, transmetalation reactions of the zirconated phospholanes with chlorophosphanes also occur diastereoselectively and afford the same diphosphane in both cases.

Hydrozirconation of dihydrophosphole **2** with $[Cp_2ZrHCl]$ (**1**) afforded quantitatively a stable α-substituted phospholane **3** (one diastereomer), which was characterized by NMR spectroscopy (Table 1), mass spectrometry, and elemental analysis. The ^1H NMR signals of the Cp protons of **3** appeared as two doublets at $\delta = 6.37$ and 6.45, each with a $^3J(C,P)$ coupling constant of 0.6 Hz, consistent with a Cp-Zr-P skeleton.[3] Similarly, two doublets ($^2J_{C,P} = 2.7$ and 2.8 Hz) were observed for the Cp carbons in the ^{13}C NMR spectrum and a large one-bond coupling constant ($^1J_{C,P} = 51.7$ Hz), typical for three-membered cyclic phosphanes,[4] for the α carbon that is part of the three-membered chelate ring. In marked contrast to other studies,[1] the formation of the less hindered β-zirconated product **5** was not observed in the reaction of **2**.[5] All these data suggest strongly that the observed reversal of regioselectivity is most likely

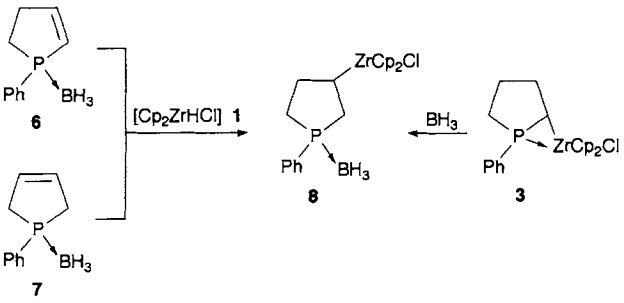
due to the coordination of zirconium to the phosphane site, which provides extra stabilization of the α-metalated phospholane.

Addition of **1** (1 equiv) to a solution of the isomeric dihydrophosphole **4** (1 equiv) in THF at room temperature also resulted in a regioselective reaction, but yielded exclusively the β-zirconated phospholane **5**, which was again stable enough to be isolated and fully characterized (Table 1). On the other hand, addition of **1** to a solution of **4** in THF maintained at +40 °C afforded the thermodynamically more stable product **3**. Migration of the metal along the carbon chain—which is reported to be facile for hydrozirconations proceeding "normally"[1b]—is also observed but the direction is reversed because of the effect of coordination at P.

During hydrozirconation of **2** neither the formation of **5** nor the conversion of **3** into **5** was observed. In addition, a ^{31}P NMR spectrum recorded on a solution of **5** in THF, kept at room temperature for three days, did not reveal any detectable signal of **3** and showed instead signals at $\delta = -10.3$ (90%, unchanged **5**) and at $\delta = -11.5$ (10%), attributable probably to the second possible diastereomer of **5**.

To confirm the key role of the phosphorus lone pair, hydrozirconation reactions on the corresponding dihydrophosphole borane adducts **6** and **7** (Scheme 2) were performed. In both cases exclusive formation of the β-zirconated phospholane **8** was observed. Interestingly, treatment of the α-substituted phospholane **3** with $BH_3 \cdot SMe_2$ at 0 °C also led to the formation of **8** (Scheme 2), apparently through cleavage of the phosphorus zirconium dative bond followed by complexation of the phosphorus lone pair with BH_3 and migration of the $ZrCp_2Cl$ moiety to the less hindered position. Compound **8** was obtained as one diastereomer as demonstrated by ^{13}C NMR (Table 1).



The synthetic utility of the organozirconium complex **3** will now be illustrated. Treatment of **3** with chlorophosphanes R_2PCl (**9**, R = Me; **10**, R = Ph) gave rise to the new diphosphanes **11** and **12** formed quantitatively in each case as a single diastereoisomer (Table 1). Similarly, addition of the salts $(iPr_2N)_2P^+CF_3SO_3^-$ (**13**) or $[(cyclohexyl)_2N]_2P^+CF_3SO_3^-$ (**14**) to **3** afforded other previously unknown α-diphosphanes **15** and **16** in high yield (>90%). As determined by an X-ray structure analysis of **12**[6] (Fig. 1), *cis*

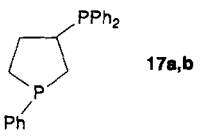
16: $^{31}P\{^1H\}$ NMR (C_6D_6): $\delta = -5.9$ (d, $^2J(P,P) = 33.7$ Hz; PPh), 56.8 (d, $^2J(P,P) = 33.7$ Hz; PN); $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = 25.60$, 26.23, 26.44, 27.45, 27.62, 27.75, 27.96 (s; CH_2-cy), 30.71 (d, $^2J(C,P) = 16.5$ Hz; ω-CH_2), 31.92 (d, $^2J(C,P) = 13.0$ Hz; β-CH_2), 41.0 (dd, $^1J(C,P) = 24.8$, $^1J(C,P) = 25.1$ Hz; α-CH), γ-CH_2 obscured, 54.10 (d, $^2J(C,P) = 63.6$ Hz; CH-cy), 58.15 (d, $^2J(C,P) = 63.7$ Hz; CH-cy), 134.85 (s; *p*-Ph), 135.36 (d, $^2J(C,P) = 18.4$ Hz; *o*-Ph), 135.41 (s; *m*-Ph), 141.19 (d, $^1J(C,P) = 27.9$ Hz; *ipso*-Ph)

[a] All NMR spectra were recorded at 25 °C on Bruker AC 80, AC 200, or WM 250: standards: ^{31}P, 85% H_3PO_4 external; ^1H and ^{13}C, $(CH_3)_4Si$ external. [b] Carbon atoms of the phospholane ring were assigned so that the substituted C atom adjacent to the P atom is the α carbon.

diphosphanes were formed in these reactions. This *cis* arrangement appears to be inconsistent with all the previous observations on stereochemistry of reactions involving alkyl- and alkenylzirconium complexes (protodezirconation, cleavage by halogens, transmetalations, etc.), which were reported to proceed with complete retention of configuration.[1b] The reasons for this apparent discrepancy are not clear at the moment. Noteworthy is the fact that the reactions of the β-zirconated **5** with chlorophosphanes **9** and **10** at -20 °C also afforded diphosphanes **11** and **12**, the same isomers as those obtained from **3**.

To summarize, the hydrozirconation and transmetalation reactions were both diastereospecific and gave α-diphosphanes otherwise difficult to obtain. In contrast the corresponding β-diphosphanes **17**, required for comparative purposes, could be readily prepared by conjugate addition of $Ph_2P(O)H$ to the oxide of **2** followed by isomer separation and stereoretentive reduction with $PhSiH_3$ (^{31}P NMR: **17a** $\delta = -4.0$ and 8.9, $^3J_{P,P} = 8.9$ Hz (*trans*); **17b** $\delta = -2.3$ and -10.0, $^3J_{P,P} \approx 0$ Hz (*cis*)).[7]



17a,b

Extension of this work to the synthesis of optically active diphosphanes[8] as well as the preparation of phosphanes containing main group elements is underway.

Experimental Procedure

All manipulations were performed in an inert atmosphere (argon).

Preparation of **3**: To a magnetically stirred solution of **2** [10] (0.146 g, 0.9 mmol) in THF (5 mL), cooled at -20 °C, was added a suspension of [Cp_2ZrHCl] (**1**, 0.232 g, 0.9 mmol) in THF (5 mL). The mixture was stirred for 15 minutes at -20 °C, then allowed to warm up slowly to room temperature, and stirred for a further 3 hours. During this time, the solution turned dark brown and became homogeneous. Evaporation of THF gave **3** quantitatively as a dark brown powder.

General procedure for transmetalations: To a magnetically stirred solution of **3** (0.9 mmol) in THF (10 mL) cooled at -20 °C was added **9** or **10** (0.9 mmol) [or a solution of **13** or **14** (0.9 mmol) in CH_2Cl_2 (3 mL)] by syringe. The mixture was kept at -20 °C for 30 min and then warmed up slowly to room temperature. The resulting colorless solution was evaporated to dryness, and the residue was extracted twice with pentane (20 mL). Diphosphanes **11**, **12**, **15**, and **16** were obtained as white powders (68–90% isolated yield).

Enzyme-Catalyzed Asymmetric Synthesis: Kinetic Resolution of Chiral Hydroperoxides by Enantioselective Reduction to Alcohols with Horseradish Peroxidase**

By *Waldemar Adam*,* *Ute Hoch*, *Chantu R. Saha-Möller*, and *Peter Schreier*

Dedicated to Professor Guiseppe Cilento on the occasion of his 70th birthday

The enzyme-catalyzed, enantioselective synthesis of organic substances has become increasingly important.[1] For example, heme-type enzymes such as peroxidases have been employed for the oxidation of numerous substrates with hydrogen peroxide and hydroperoxides.[2] Chloroperoxidase (CPO)[3] from *Caldariomyces fumago* effects the enantioselective oxidation of prochiral sulfides with H_2O_2 or *t*BuOOH to give sulfoxides in 13–99% *ee*.[3c] This peroxidase also mediates the regio- and stereoselective halogenation of glycals.[3c] Recently it was reported that CPO/H_2O_2 epoxidizes disubstituted alkenes efficiently and enantioselectively.[4]

For horseradish peroxidase (HRP), merely the asymmetric sulfoxidation of prochiral sulfides is known; however, the enantioselectivities (30–70% *ee*) are much lower.[5] While the CPO-catalyzed sulfoxidation with racemic 1-arylethyl hydroperoxides shows high affinity for the (*R*) enantiomer, such substrate selectivity has not been reported for HRP-catalyzed transformations. Moreover, besides the optically active (*R*) sulfoxides (13–99% *ee*), the corresponding (*R*) alcohols (17–80% *ee*) and the (*S*) hydroperoxides (24–91% *ee*) were isolated from the same CPO-catalyzed reaction.[3c] We report here on the kinetic resolution of chiral hydroperoxides by enantioselective HRP (Sigma, Type II, RZ 1.5–2.0) catalyzed reduction in the presence of guaiacol to provide alcohols (Scheme 1). With this enzyme-catalyzed route, we have succeeded in obtaining hydroperoxides and their alcohols simultaneously in high optical purity (>95% *ee*) (Table 1).

Scheme 1. HRP-catalyzed kinetic resolution of chiral hydroperoxides.

Table 1. Kinetic resolution of chiral hydroperoxides (±)-1 [a] by horseradish peroxidase in the presence of guaiacol [b].

Entry	(±)-1	[mmol]	(±)-1:HRP	t [min] [c]	ee [%] (S)-1	ee [%] (R)-2
1	1a	0.03	12000:1	5	>99	>99
2	1a	1.50	60000:1	120	>99	>99
3	1b	0.03	12000:1	5	97	>99
4	1b	1.50	60000:1	120	95	98
5	1c	0.03	21000:1	10	>99	>99
6	1c	1.50	12000:1	120	91	95

[a] The hydroperoxides were prepared according to literature procedures: (±)-1a [7a], (±)-1b,c [7b]. [b] Guaiacol was employed in equimolar amounts with respect to (±)-1. [c] The reaction was halted after complete consumption of guaiacol.

To assess optimal substrate concentrations for the enzymatic transformations of the racemic hydroperoxides, the kinetic parameters were determined (Table 2). At constant guaiacol concentration the K_M and V_{max} values were measured for each hydroperoxide. The data shows (Table 2) that these enzyme parameters depend notably on the R^1 and R^2 substituents of **1**. Consequently, (±)-**1** (0.03 mmol) in 5 mL 0.1 M phosphate buffer (pH 6) and (±)-**1b,c** (0.03 mmol) in 1 mL buffer solution were employed. Fortunately, the hydroperoxides (±)-**1a–c** do not react at room temperature with guaiacol in the absence of HRP, so that the enzyme-catalyzed kinetic resolution could be conducted at about 20 °C. Since it is known that the stoichiometric ratio of oxidant to substrate for the peroxidase-catalyzed oxidation of phenols is 1:2,[1a] a guaiacol:hydroperoxide ratio of 1:1 was chosen, in order to limit the hydroperoxide consumption to at most 50%. The results in Table 1 demonstrate that guaiacol was completely consumed under simultaneous formation of nearly enantiomerically pure hydroperoxides (*S*)-**1a–c** and the corresponding alcohols (*R*)-**2a–c**.

Table 2. Kinetic parameters [a] for the horseradish peroxidase catalyzed oxidation of guaiacol with hydroperoxides (±)-1.

Substrate	K_M [mM]	V_{max} [b] [mmol mg^{-1} min^{-1}]	V_{max}/K_M [L mg^{-1} min^{-1}] × 10^{-3}
guaiacol	0.2 ± 0.06	19.0 ± 0.1	95
(±)-1a	0.6 ± 0.04	18.0 ± 0.1	30
(±)-1b	37.2 ± 2.5	18.0 ± 0.6	0.48
(±)-1c	63.0 ± 2.3	8.3 ± 0.4	0.13

[a] The kinetic parameters for guaiacol were determined with 1.25 mM hydroperoxide (±)-1a; for the hydroperoxides (±)-1a–c a guaiacol concentration of 500 mM was used. [b] The initial rates were monitored by following the appearance of the guaiacol oxidation product (ε = 2.66 × 104 M^{-1}cm^{-1}) [9] at 470 nm in 0.1 M phosphate buffer (pH 6). V_{max} and K_M were calculated with the Duggleby program on an IBM computer.

The absolute configuration of (*S*)-**1a** and (*R*)-**2a** was determined by comparison of the HPLC data with those of the authentic substances.[3c, 6] The absolute configurations of (*S*)-**1b,c** and (*R*)-**2b,c** were assigned analogously. The enantiomeric excesses of the hydroperoxides (*S*)-**1** and alcohols (*R*)-**2** were determined from the ratio of areas corresponding to the two enantiomers in the HPLC (Chiracel OD column) chromatogram. A representative chromatogram is given in Figure 1 for hydroperoxide **1b** and alcohol **2b**. As can be seen for the present examples, the HRP enzyme selectively recognizes the (+)-(*R*)-hydroperoxides. Consequently, the kinetic resolution affords the optically pure (−)-(*S*)-hydroperoxides and (+)-(*R*)-alcohols. A control experiment confirmed that when sufficient guaiacol was employed to reduce all of the racemic hydroperoxide (i.e. guaiacol:hydroperoxide 2:1), the optically pure (>95% *ee*) alcohol and hydroperoxide were still obtained. This selectivity of the HRP for the oxidant, which resulted in the exclusive reduction of the (+)-(*R*) enantiomer, is unprecedented.[11] For the synthetic exploitation of this novel HRP-catalyzed, enantioselective reduction of racemic hydroperoxides to the corresponding alcohols, the enzymatic reaction was conducted on a semipreparative scale. The results in Table 1 (entries 2,4, and 6) demonstrate convincingly that the HRP-catalyzed kinetic resolution serves for the preparation of enantiomerically pure hydroperoxides and their alcohols on a 1.5 mmol scale. After conventional workup and purification by column chromatography, the optically pure hydroperoxides (80–98%, relative to 50% conversion) and the corresponding alcohols (72–88%, relative to 50% conversion) were isolated in good yields.

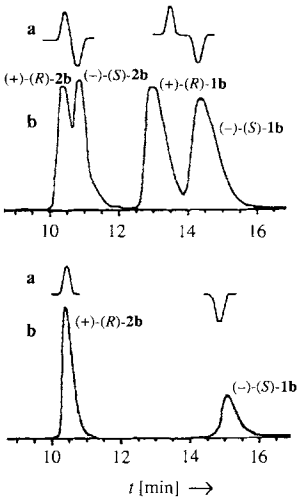

Fig. 1. HPLC chromatograms from the HRP-catalyzed reaction of (±)-**1b** with guaiacol. Top: authentic racemic samples of alcohol (±)-**2b** and hydroperoxide (±)-**1b**. Bottom: reaction products after resolution of (±)-**1b**. The polarimetric detection with the ChiraLyser (a) is placed above the UV signals (b) at 220 nm. Column: Daicel-Chiralcel OD, 250 × 4 mm; eluent: *n*-hexane/isopropyl alcohol (90:10); flow rate: 0.6 mL min^{-1}

In summary, horseradish peroxidase is highly selective for (*R*) hydroperoxides, which allows kinetic resolution of racemic hydroperoxides by means of enantioselective reduction to furnish the corresponding alcohols. This enzyme-catalyzed reduction can be performed on preparative scale and provides optically pure alcohols and hydroperoxides conveniently. In contrast, the preparation of enantiomerically pure hydroperoxides by nonenzymatic means is quite cumbersome.[8]

Experimental Procedure

In the preparative-scale reaction, 1.50 mmol hydroperoxide (±)-**1** and 1.50 mmol guaiacol were dissolved in 10 mL 0.1 M phosphate buffer (pH 6) and subsequently 0.25–1.25 × 10^{-4} mmol HRP was added. The reaction mixture was allowed to stand at 20 °C for 2 h and then extracted with CH_2Cl_2 (3 × 20 mL). The combined organic phases were dried over Na_2SO_4 and the solvent removed on the rotary evaporator (ca. 20 °C/17 Torr). Hydroperoxide (*S*)-**1** and alcohol (*R*)-**2** were separated by column chromatography (silica gel, 0.032–0.62 mmol eluting with petroleum ether/diethyl ether (4:1).

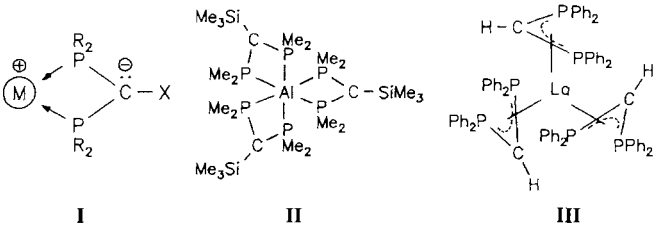
Highly Coordinated Lanthanoid–Phosphane Complexes**

By *Hans H. Karsch,* Gunter Ferazin, Oliver Steigelmann, Huub Kooijman,* and *Wolfgang Hiller*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

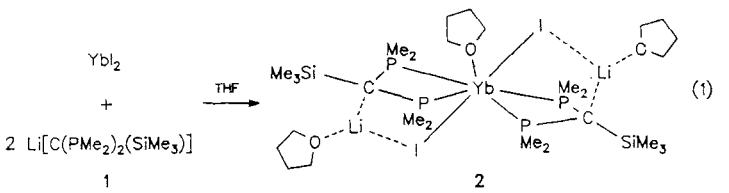
Phosphane ligands are almost indispensible in transition metal chemistry. Complexes with high numbers of coordinated phosphanes are known and are very important in many catalytic processes. Although lanthanoid complexes also have notable catalytic properties, there are only few structurally characterized examples of compounds in which the metal center is coordinated by a number of phosphane ligands. Only with heteroatom–phosphane chelating ligands, for example $[N(SiMe_2CH_2PR_2)_2]^-$, can up to four lanthanoid–phosphorus bonds be formed.[1] The electrophilicity of lanthanoid centers generally resembles that of "hard" main group metal centers such as Al^{3+}.[2] With diphosphinomethanides as chelating ligands, metal centers can attain high phosphane coordination numbers by forming covalent and ionic bonds (**I**), as in the case of Al^{3+} (**II**).[3]

In fact the corresponding lanthanum diphosphinomethanide complex **III** could also be synthesized;[4] however, the coordination modes in **II** (σ) and **III** (π) are completely different. This can be attributed at least in part to the exocyclic carbanion substituent (Me_3Si in **II**, H in **III**), which in **II** markedly reduces the nucleophilic nature of the carbanion. We have now succeeded in synthesizing highly coordi-



I **II** **III**

nated lanthanoid–phosphane complexes in which the ligands are bound as in **II**. The methanide **1** acts as a source of anionic diphosphinomethanide ligands. For the syntheses of these complexes metal halides are not appropriate starting materials, since only mixtures containing substantial amounts of lithium halide are formed. Evidently addition and only partial substitution occurs, as is established by the isolation and structural characterization of **2** (violet crystals from pentane) [Eq. (1)].



1 **2** (1)

In **2** (Fig. 1) a $YbI_2 \cdot THF$ moiety has been inserted into the framework of **1** · THF, which exists as the dimer $[(THF)Li\{C(PMe_2)_2(SiMe_3)\}]_2$,[5] whereby all Li–P bonds are broken and replaced by four Yb–P bonds. This results in a seven-coordinate Yb^{2+} ion and the formation of Li–I bonds.[6]

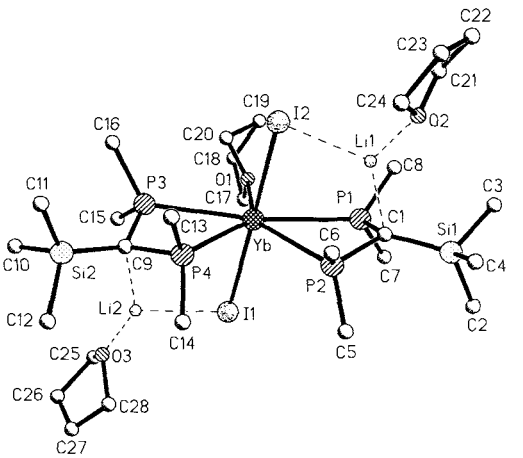


Fig. 1. Crystal structure of **2**. Important distances [Å] and angles [°]: Yb-I1 3.131(5), Yb-I2 3.114(3), Yb-P1 3.08(1), Yb-P2 2.99(2), Yb-P3 3.03(2), Yb-P4 2.96(1), Yb-O1 2.44(4), Li1-I2 2.67(7), Li1-C1 2.22(8), Li1-O1 1.93(8), Li2-I2 2.87(10), Li2-C9 2.20(10), Li2-O3 1.72(10); I1-Yb-I2 176.5(2), P1-C1-P2 103(2), Yb-P2-C1 98(1), P1-Yb-P2 55.7(3), Yb-P1-C1 96(1), P3-C9-P4 101(2), P3-Yb-C4 54.9(4), Yb-P4-C9 98(1), Yb-P3-C9 100(2).

In order to achieve complete substitution, lanthanoid complexes containing a better leaving group are needed.

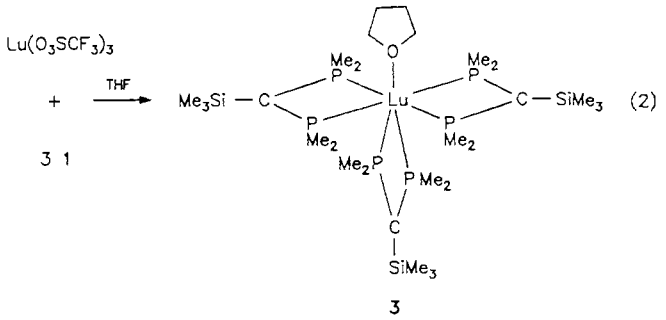
[**] This work was funded by the Fonds der Chemischen Industrie.

Lanthanoid triflates[7] have now been shown to be successful reagents. Complex **3** was obtained according to Equation (2) as yellow crystals (pentane).[8]



(2)

3

In **3** (Fig. 2) the lanthanoid center is also seven-coordinate: one THF and three planar diphosphinomethanide ligands surround the lutetium ion in a distorted pentagonal-bipyramidal arrangement. Thus the ion is coordinated by six phosphane donor units. The four-membered chelate rings are also planar. The THF ligand can be removed in vacuo; however, the resulting yellow solid could not be recrystallized.

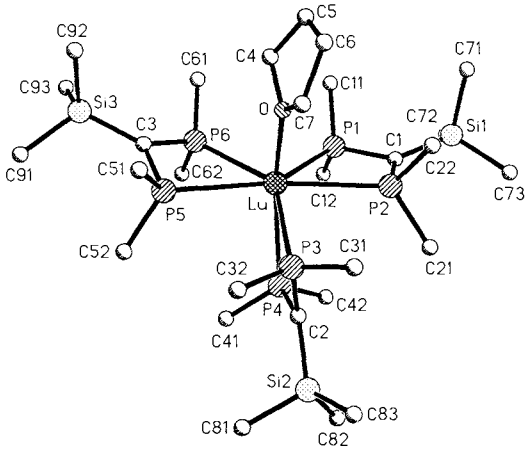


Fig. 2. Crystal structure of **3**. Important distances [Å] and angles [°]: Lu-P 2.814(2)-2.922(2), Lu-O 2.271(5); P1-C1-P2 106.1(3), C1-P1-Lu 99.4(2), C1-P2-Lu 96.8(2), P1-Lu-P2 57.7(1), P3-C2-P4 107.5(3), C2-P4-Lu 96.3(2), P3-Lu-P4 59.8(1), Lu-P3-C2 95.0(2), P5-C3-P6 104.3(3), C3-P6-Lu 97.3(2), P5-Lu-P6 57.7(1), Lu-P5-C3 95.9(2).

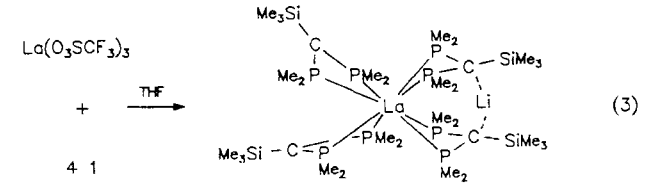
Lutetium, the smallest lanthanoid, is obviously coordinatively saturated in **3**. Even in the complexes with the only slightly larger erbium,[9] as well as with yttrium[9] or lanthanum, the coordination changes dramatically. The lanthanum complex **4**, which was formed as orange crystals according to Equation (3),[10] is a representative example.



(3)

4

Not less than four diphosphinomethanide chelating ligands (regardless of the stoichiometry) are arranged around the lanthanum ion such that the eight P atoms form one almost square-planar and one tetrahedral P_4 ligand arrangement (Fig. 3). The resulting distorted dodecahedral coordination is sterically favorable. The centers of the four chelating ligands are at the corners of a tetrahedron, such that the two sets of four phosphorus atoms form together with the lanthanum center two mutually orthogonal planes. The resulting complex has "ate" character; in other words, an excess anionic charge must be compensated for. This is achieved intramolecularly by the inclusion of a lithium ion between the carbanionic atoms of two diphosphinomethanide ligands which results in a significant folding of the four-membered chelate rings. The lithium ion shows additional contacts to two P atoms and also to a PCH_3 and $SiCH_3$ group (Li···H···C), so that on the one hand it is coordinatively saturated and on the other hand so well protected, especially by the $SiCH_3$ group, that it neither coordinates additional THF nor is it released from its "basket" by, for example, crown ethers. Consider going from the largest to the smallest metal: if the lighter homologue scandium is

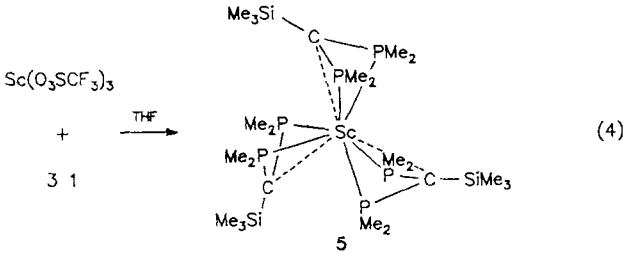
used ($r(Sc^{3+})$: 0.75 Å) instead of lanthanum ($r(La^{3+})$: 1.03 Å), the coordination number changes again. Compound **5** is obtained as yellow needles[11] according to Equation (4).



(4)

Unlike the arrangement in **3**, but similar to that in **III** the scandium center in **5** is not coordinated by a solvent molecule, and, just as in **III** the M-P-C-P four-membered rings are not planar. The CP_2 and ScP_2 planes form an angle of 121°, which is intermediate between that in **II** and **3** (180°) and in **III** (80°) (Fig. 4). As a result of the trigonal symmetry in **5** the

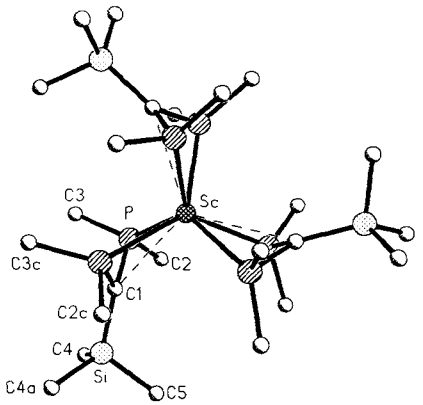


Fig. 4. Crystal structure of **5**. Important distances [Å] and angles [°]: Sc-P 2.617(1), Sc-C1 2.908(2); Sc-P-C1 80.8(2), P-C1-P 105.4(3), P-Sc-P 94.13(3), P-C1-Si 126.5(1).

P atoms are arranged in a trigonal-prismatic fashion. The planar carbanionic C atoms approach the scandium center without forming a bond (Sc···C: 2.908 Å). The coordination mode of the diphosphinomethanide ligands in **5**, intermediate between a σ-chelating (as in **3**) and a π coordination mode (as in **III**), appears almost like a snapshot of the mutual conversion of either type of coordination into the other. This accounts for the facile change in hapticity and for rearrangement reactions as, for example in silicon[12] and zirconium[13] disphosphinomethanide compounds; here we have observed this structurally for the first time. The folding of the four-membered chelates in the scandium complex can be attributed to the additional Sc···C d-orbital interactions. The reduced nucleophilicity of the Me_3Si-protected carbanion compared to that in **III** and the steric hindrance at the small Sc^{3+} ion prevents a closer approach of the carbanions to the coordination center. The four-, six-, and especially eight-coordinate phosphane–lanthanoid complexes presented here demonstrate that the disinclination of lanthanoids to coordinate phosphanes can be reversed and even transposed into a marked affinity by an appropriate choice of ligands, namely phosphinomethanides.

Experimental Procedure

All reactions were carried out under purified and dried nitrogen using conventional vacuum techniques. The glassware was dried by heating, evacuated several times, and flushed with inert gas. NMR spectra in [D_8]toluene; standards: ^1H, ^{13}C: TMS; ^{31}P: H_3PO_4.

2: To 50 mL YbI_2 (36.7 mM in THF, 1.84 mmol) was added **1** (0.84 g, 3.92 mmol) at −78 °C. The mixture was allowed to warm to room temperature, and after 12 h stirring the solvent was removed in vacuo. The remaining solid was extracted twice with 40 mL pentane. On evaporation of the pentane in vacuo violet crystals formed (1.31 g, yield 97.2%). Correct C,H,I analysis.

$^{31}P\{^1H\}$ NMR (109 MHz): δ −24.27 (s), −24.20 (d, $^1J(^{31}P, ^{171}Yb)$ = 497.3 Hz); ^1H NMR (270 MHz): δ = 1.38 (s, 24H; PMe_2), 0.32 (s, 18H; $SiMe_3$), 3.28 (s, br, 12H; THF); $^{13}C\{^1H\}$ NMR (67.8 MHz): δ = 20.21 ("t", N (separation of the outermost signals) = 21.3 Hz, PMe_2), 7.54 (s, $SiMe_3$), 25.19 (s, THF), 68.23 (s, THF).

3: $Lu(O_3SCF_3)_3$ (0.65 g, 1.05 mmol) and **1** (0.75 g, 3.50 mmol) were added together, and 40 mL THF was condensed into the mixture at −78 °C. The solution was allowed to warm to room temperature and stirred for 12 h. After removal of the solvent the residue was dried in vacuo and extracted three times with pentane. During evaporation of the solvent from the combined filtrates in vacuo **3** precipitated as a yellow, crystalline solid (0.49 g, yield: 60.3%). Correct C,H analysis.

$^{31}P\{^1H\}$ NMR (109.4 MHz, 25 °C): δ = −26.60 (br), (−110 °C): two AB patterns (2:1): δP_{A1} = −25.41, δP_{B1} = −31.72, $J_{(AB)1}$ = 245.2 Hz, δP_{A2} = −27.78, δP_{B2} = −30.13, $J_{(AB)2}$ = 240.0 Hz; ^1H NMR (270 MHz): δ = 1.35 (s, br, 36H; PMe_2), 0.37 (s, 27H; $SiMe_3$), 3.62 (s, br, 4H; THF), 1.45 (s, br, 4H; THF); $^{13}C\{^1H\}$ NMR (67.8 MHz): δ = 22.29 ("t", N = 25.3 Hz, PMe_3), 6.43 (s, $SiMe_3$), 68.48 (s, THF), 25.66 (s, THF).

4: To a mixture of $La(O_3SCF_3)_3$ (0.78 g, 1.33 mmol) and **1** (0.96 g, 4.48 mmol) at −78 °C was added 40 mL THF by condensation. After warming to room temperature the mixture was stirred for 3 d. The solvent was evaporated and the residue dried in vacuo and extracted with pentane (3 × 30 mL). When the solvent from the combined pentane extracts was removed under vacuum, the product precipitated as an orange, crystalline solid. (0.71 g, yield: 65.0%). Correct C,H analysis.

$^{31}P\{^1H\}$ NMR (109.4 MHz, 25 °C): δ = −29.0 (s, br), −30.8 (s, br), (−100 °C): δ = −22 to −48 (m); ^1H NMR (270 MHz): δ = 1.31 (s, br, 48H; PMe_2), 0.32 (s, 36H; $SiMe_3$); $^{13}C\{^1H\}$ NMR (67.8 MHz): δ = 22.95 ("t", N = 25.9 Hz, PMe_2), 7.10 (s, $SiMe_3$).

5: To a mixture of $Sc(O_3SCF_3)_3$ (0.85 g, 1.73 mmol) and **1** (1.17 g, 5.46 mmol) at −78 °C was added 40 mL THF by condensation. The resulting solution was allowed to warm to room temperature and stirred for 3 h before the solvent was evaporated. The residue was dried in vacuo and extracted with pentane (3 × 30 mL). During evaporation of the pentane from the combined extracts orange needles precipitated (0.91 g, yield: 79.3%). Correct C,H analysis.

$^{31}P\{^1H\}$ NMR (109.4 MHz, 25 °C): δ = −11 to −23 (br), (−100 °C): δ = −12.82 (s), (+70 °C): δ = −17 to −23 (br); ^1H NMR (270 MHz): δ = 1.25 (s, br, 36H; PMe_2), 0.33 (s, 27H; $SiMe_3$); $^{13}C\{^1H\}$ NMR (67.8 MHz): δ = 20.36 ("t", N = 30.2 Hz, PMe_2), 6.11 (s, $SiMe_3$).

The Mechanism of Anaerobic, Radical-Induced DNA Strand Scission**

By *Bernd Giese*,* *Xenia Beyrich-Graf*, *Jutta Burger*, *Christoph Kesselheim*, *Martin Senn*, and *Thomas Schäfer*

Radicals generated either radiolytically or chemically may cleave the DNA strand by H abstraction. An important intermediate in this process is the 4′-deoxyribonucleotide radical **1**[1] (Scheme 1). This reactive intermediate can lead to strand breakage either by direct fragmentation or by reaction with O_2. In order to account for the cleavage products that are observed under anaerobic conditions, Schulte-Frohlinde et al. have proposed that the radical cation **2** is an intermediate, and have demonstrated analogous heterolytic β-bond cleavage in simple radicals.[2, 3]

By selective generation of 4′-nucleotide radicals, we have now been able to prove that nucleotide radical cations are produced and have studied their reactivity. Alkene **3a** and selenide **4b** were both utilized as precursors of the 4′-nucleotide radical **5**. As we recently showed, radical addition of PhSH to alkene **3a** leads via the 4′-nucleotide radical **5a** to the cyclic enol ether **7a**.[4]

If the radical cation **6a** is indeed an intermediate, then breakage of the C–O bond ought to be strongly accelerated by increasing either the polarity of the solvent or the acidity of the phosphoric dialkylester which is released as an anion.[5] We measured the ratio of the rate constants for H abstraction (k_H) and for C–O bond cleavage (k_E) under pseudo-first-order conditions, using thiophenol as the source of the radical X$^\cdot$ and as H donor.[6] Since k_H ought to be largely independent of both the nature of the solvent[7] and the type of substituent R on the phosphate group, the change in the ratio k_E/k_H is a measure of the change of the rate of C–O bond cleavage.

The data in Table 1 show that the rate of cleavage of the C–O bond (**5a** → **7a**) increases by a factor of about 100 on changing from toluene to ethanol/water (4:1) as solvent.

Table 1. Influence of the solvent and the alkyl substituent R of the leaving group $(RO)_2PO_2^-$ on the competition constant k_E/k_H of radical **5a** at 30 °C.

Solvent		K_a of $(RO)_2PO_2H$ [a]	k_E/k_H

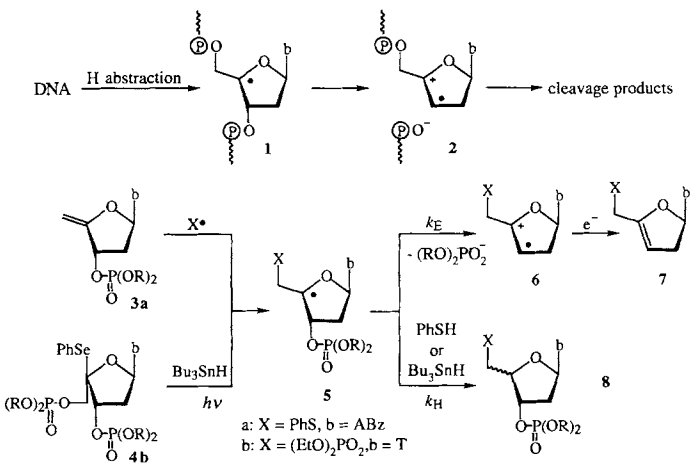
	Et	7.08×10^{-4}	7.7
	*n*Pr	5.13×10^{-4}	6.5
	*i*Pr	2.19×10^{-4}	1.7
$C_6H_5CH_3$	Me		0.17
	Et		0.077
	*n*Pr		0.056
	*i*Pr		0.021

[a] Values in $EtOH/H_2O$ (4:1) at 25 °C.

When the selectivity $\lg k_E/k_H$ was plotted against the acidity $\lg K_a$ of the phosphoric dialkylester in the two solvents, a linear correlation was observed with a gradient β of about 1.3 (Fig. 1). The solvent effect, which is unusually large for neutral radicals, and the high value for the slope of the Brönsted relationship are clear indications of heterolytic C–O bond cleavage in the reaction **5a** → **6a**.

Interestingly, radical cation **6a** is not trapped nucleophilically in the presence of thiophenol, because electron transfer



Scheme 1. ABz = 6-*N*-benzoyladenin-9-yl.

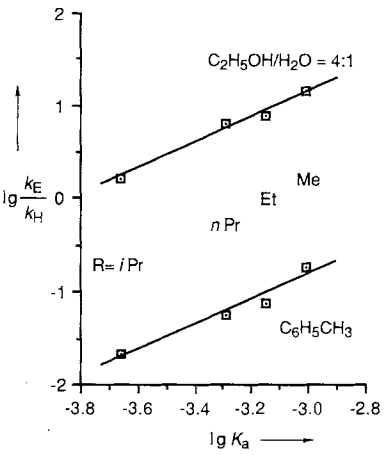


Fig. 1. Dependence of the C–O bond breakage in radical **5a** ($\lg k_E/k_H$) on the acidity ($\lg K_a$) of the phosphoric dialkylester $(RO)_2PO_2H$.

from thiophenol is faster than attack by the nucleophilic solvent.[4] Different reactivity is seen when radical **5b** is generated from the selenide **4b**.[8] Photolysis of a methanolic solution of **4b** in the presence of various amounts of Bu_3SnH yields the methanol trapping products **12**–**15**, in yields of 85–91 %[9] (Scheme 2).

	8b	12	13	14	15
1.2 equiv Bu_3SnH:	<2%	28%	34%	~2%	27%
7.5 equiv Bu_3SnH:	9.5%	22%	55%	~1%	7.5%

Scheme 2.

Compounds **12** and **13** are produced by the trapping of radical cation **6b**. In contrast, **14** and **15** are trapping products from radical cation **10**, which arises from radical **9** after cleavage of a second C–O bond. As expected, the yield of **14** and **15** drops with increasing concentrations of Bu_3SnH. When a 7.5-fold excess of Bu_3SnH is employed (pseudo-first-order conditions), then the competition constants may be determined from the product yields. The product ratio **(13 + 14 + 15)/12**, reveals that attack of methanol on the secondary C atom of radical cation **6b** is about 2.5 times faster than attack on the tertiary C atom. The primary C atom in radical cation **10** is attacked even more selectively. Ionic methanol attack on **6b** occurs stereoselectively *trans* to the thymine unit. In contrast, radical H abstraction is unselective, because the thymine and methoxy groups are *trans* to each other. From the product ratios **(12–15)/8b** = 9.0 and **(14–15)/13** = 0.15 (7.5 equivalents of Bu_3SnH), one can conclude that the bond between the secondary C atom and the O atom in radical **5b** is broken about 60 times faster than the bond between the primary C atom and the O atom in radical **9**. This large difference in reactivity also points to heterolytic C–O bond cleavage.

In contrast to methanol, which is a good cation trap, allyl alcohol ought to be able to trap both cations and radicals. Indeed, reaction of selenide **4b** in allyl alcohol yields the bicyclic products **16** and **17** (Scheme 3). They arise from radical cation **6b**, which reacts nucleophilically with a regioselectivity of about 2.5:1 to yield the radicals **19** and **20**.

In the presence of a large excess of Bu_3SnH, radical **20** is partially converted to the reduction product **18** by intermolecular reaction. However, the majority of the radicals **19** and **20** cyclize to give the bicyclic products **16** and **17**, respectively.[10] The formation of **16** and **17** as the major products is unambiguous evidence for the presence of radical cations.

In the case of radical-induced DNA cleavage under anaerobic conditions in H_2O, Schulte-Frohlinde et al. observed analogous open-chain hydrolysis products of **12**–**15**.[2] Our studies with mononucleotide radicals in alcohols made it

possible to trap the postulated intermediates and to prove that the reaction mechanism of DNA strand cleavage proceeds via 4′-deoxyribonucleotide radicals.

[5] T. A. Mastryukova, T. A. Melent'eva, A. E. Shipov, M. I. Kabachnik, *Zh. Obshch. Khim.* **1959**, *29*, 2178. The K_a value for $(i\text{PrO})_2PO_2H$ was measured potentiometrically with a glass electrode in $EtOH/H_2O$ (4:1).

[6] For competition experiments, a solution of 0.05 mmol of the starting material **3a** and 0.5–1.7 mmol PhSH was diluted up to 0.5 mL with the relevant solvent under Ar, degassed by freezing and evacuating twice, and irradiated for 1–2 h at 30 °C (Heraeus TQ, 150 W). After the reaction mixture was concentrated and the residue dissolved in $CDCl_3$, NMR spectroscopy was used to analyze the products **7a** and **8a** (β-D-*erythro*:α-L-*threo* = 3:1, the R group had only a minor effect on the stereoselectivity). **7a** and β-D-*erythro*-**8a** were also independently synthesized.

[7] D. V. Avila, C. E. Brown, K. U. Ingold, J. Lusztyk, *J. Am. Chem. Soc.* **1993**, *115*, 466.

[8] Selenide **4b** was synthesized from the 5′-aldehyde of deoxythymidine (see C. O. Yang, H. Y. Wu, E. B. Fraser-Smith, K. A. M. Walker, *Tetrahedron Lett.* **1992**, *33*, 37) by selenation at C-4′ ($PhSeCl/NEt_3$) followed by reduction (diisobutylaluminum hydride, DIBAH) and phosphorylation ($(EtO)_2POCl$).

[9] For the trapping experiments, 0.3 mmol of selenide **4b** and 1.2–7.5 equivalents of Bu_3SnH were dissolved in 5 mL MeOH and irradiated for 3–5 h at 20 °C (Osram HQI-T250W/D). After the reaction mixture was concentrated and the residue dissolved in CH_3CN, the tin-containing by-products were removed with pentane. The products **8b** (1:1 mixture), **12**, **13** (1:1 mixture), and **15** (1:1 mixture) were isolated by flash chromatography, and the structures elucidated by NMR spectroscopy (^1H, ^{13}C, ^{31}P, NOE) and by independent synthesis (**8b**, **15**). Compound **14** could only be analyzed in the mixture in solution.

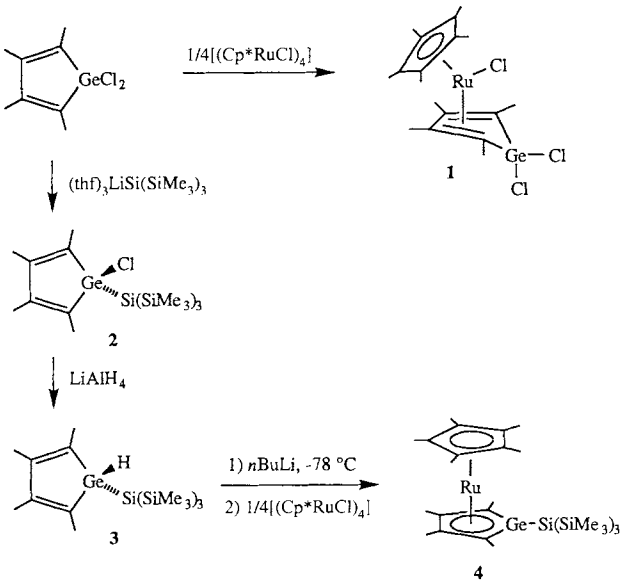
[10] The trapping experiments followed the procedure in ref. [9]. Allyl alcohol was used as the alcohol, and 1.2–3.0 equivalents of Bu_3SnH were employed. Flash chromatography afforded **16** (2:1 mixture), **17** (only one isomer was isolated, other possible isomers of **17** were below the detection limit of 2%), and **18** (4.5:1 mixture). When the reaction was carried out with 1.2 equivalents of Bu_3SnD, the methyl group of **16** and **17** was monodeuteriated (deuteriation level 75% and 90%, determined by mass spectroscopy and NMR spectroscopy, respectively).

A Stable η^5-Germacyclopentadienyl Complex: $[(\eta^5\text{-}C_5Me_5)Ru\{\eta^5\text{-}C_4Me_4GeSi(SiMe_3)_3\}]$**

By *William P. Freeman, T. Don Tilley,* Arnold L. Rheingold,* and *Robert L. Ostrander**

The chemistry of compounds containing multiple bonds to the heavier group 14 elements (Si, Ge, Sn, and Pb) has advanced significantly over the past few years.[1] It is therefore of interest to consider extensions to delocalized π systems containing these bonds, which could exhibit new chemical and electronic properties. Much attention has previously focused on low-temperature observation of unstable silabenzene (SiC_5H_6) and its derivatives, which appear to have some aromatic character.[2] Chemical and theoretical studies indicate that stable sila- and germacyclopentadienide anions, which have been generated in solution, possess some degree of resonance stabilization.[3] However, numerous attempts to prepare η^5-sila- and η^5-germacyclopentadienyl transition metal complexes, usually from the corresponding η^4-silole or η^4-germole derivatives, have proven unsuccessful.[3] Jutzi et al. have synthesized the $[(C_4Ph_4GeMe)Fe(CO)_3]^+$ cation, which was characterized on the basis of ^{13}C NMR shift data as an η^4-diene complex with the positive charge localized on the germanium atom.[4] Here we report the first isolation and complete characterization of an η^5-germacyclopentadienyl transition metal complex.

The η^4-germole complex **1** was obtained simply by addition of the free germole to $[\{Cp^*Ru(\mu\text{-}Cl)\}_4]$[5] ($Cp^* = \eta^5\text{-}C_5Me_5$). The structure of **1** (Fig. 1)[6] contains a folded germole ring, in which the germanium atom is displaced out of the least-squares plane of the C_4 diene by 0.97 Å. The ruthenium atom is 1.76 Å from this plane, and 1.89 Å from the least-squares plane of the Cp* ring carbon atoms. Although it appears that there is little bonding between Ru and Ge (the interatomic distance is 2.985(2) Å), a significant lengthening of the Ge–Cl2 bond (2.246(2) Å) relative to the Ge–Cl3 bond (2.151(3) Å) suggests that a Ru → Ge dative interaction operates primarily through donation of electron density from the Ru atom to the Ge–Cl2 σ^* orbital.



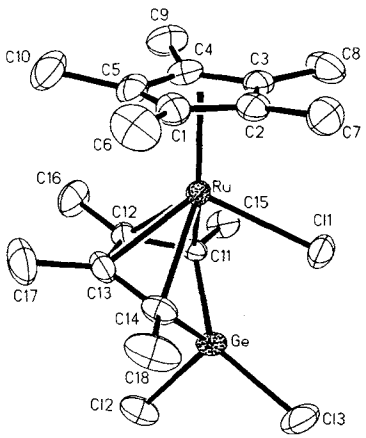


Fig. 1. Molecular structure of **1** drawn with 35% probability ellipsoids. Selected interatomic distances [Å] and angles [°]: Ru-Ge 2.985(2), Ru-Cl1 2.424(3), Ru-C1 2.278(7), Ru-C2 2.242(7), Ru-C3 2.233(7), Ru-C4 2.242(7), Ru-C5 2.235(9), Ru-C11 2.197(6), Ru-C12 2.199(6), Ru-C13 2.194(7), Ru-C14 2.218(6), Ge-Cl2 2.246(2), Ge-Cl3 2.151(3), Ge-C11 1.936(6), Ge-C14 1.925(7), C11-C12 1.421(9), C12-C13 1.458(9), C13-C14 1.412(11); C11-Ge-C14 86.2(3), C11-Ge-Cl2 102.9(2), C11-Ge-Cl3 134.7(2), C14-Ge-Cl2 108.3(2), C14-Ge-Cl3 127.1(2), Cl2-Ge-Cl3 94.8(1).

Addition of *n*BuLi to a THF solution of **3** at −78 °C generates the (germacyclopentadienyl)lithium $Li[C_4Me_4GeSi(SiMe_3)_3]$, as indicated by formation of a yellow solution (the related $Li[C_4Me_4GePh]$ species is also yellow in THF[7]). The reaction of the $Li[C_4Me_4GeSi(SiMe_3)_3]$ solution with $[\{Cp^*Ru(\mu\text{-}Cl)\}_4]$ produces the amber, η^5-germacyclopentadienyl complex **4** which was purified by crystallization from pentane. Compound **4** is thermally stable, but benzene solutions of the compound are air- and moisture-sensitive. The $^{13}C\{^1H\}$ NMR spectrum of **4** contains two resonances for the germacyclopentadienyl ring carbon atoms with similar chemical shifts, at $\delta = 80.23$ and 87.82. This would seem to reflect "aromatic" character in the coordinated C_4Ge ring, since the Cp* ring carbon atoms in the same molecule resonate at $\delta = 85.38$. In addition, the chemical shifts for ring carbon atoms in η^4-germole complexes usually differ more considerably. For example, the corresponding chemical shift values for the ring carbon atoms of **1** appear at $\delta = 80.50$ and 95.77.

X-ray quality crystals of **4** were obtained by cooling a concentrated hexamethyldisiloxane solution to −40 °C. The molecular structure of **4** (Fig. 2)[8] consists of two planar five-membered rings bound in a "sandwich" fashion to the ruthenium atom. The least-squares planes for the two five-membered rings form an angle of 8.6°, and the ruthenium atom is symmetrically positioned between these two planes (1.81 Å from the C_4Ge plane and 1.82 Å from the Cp* plane). The germanium atom deviates by only 0.02 Å from the C_4Ge ring's least-squares plane, and summation of the angles about the Ge atom (358.1°) further reflects sp^2 hybridization. Also consistent with greater s character at the germanium center are the Ge–C distances in **4** (average

1.90 Å), which are slightly shorter (by 0.03–0.04 Å) than the corresponding distances in **1**. Similarly, the Ru–C bond lengths involving the η^5-germacyclopentadienyl ligand (average 2.21 Å) are very similar to the Ru–C(Cp*) distances (average 2.17 Å). As expected the bulky $Si(SiMe_3)_3$ group is bent out of the C_4Ge plane, by 12.9°. For comparison, the methyl groups in **1** and **4** bend out of their ring planes by −2 to +10°. Finally the Ru–Ge distance (2.493(1) Å) is clearly bonding given that the four known structures with Ru–Ge single bonds have Ru–Ge distances that average to 2.46 Å.[9]

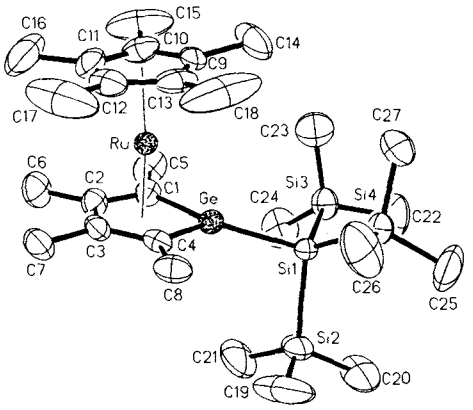

Fig. 2. Molecular structure of **4** drawn with 35% probability ellipsoids. Selected interatomic distances [Å] and angles [°]: Ru-Ge 2.493(1), Ru-C1 2.245(8), Ru-C2 2.172(8), Ru-C3 2.174(8), Ru-C4 2.252(7), Ru-C9 2.187(11), Ru-C10 2.169(9), Ru-C11 2.172(8), Ru-C12 2.166(11), Ru-C13 2.172(10), Ge-Si1 2.357(2), Ge-C1 1.900(6), Ge-C4 1.899(7), C1-C2 1.425(11), C2-C3 1.415(11), C3-C4 1.424(9); C1-Ge-C4 89.1(3), C1-Ge-Si1 136.4(2), C4-Ge-Si1 132.6(2), Ge-Si1-Si2 103.1(1),Ge-Si1-Si3 106.7(1), Ge-Si1-Si4 113.8(1).

Interestingly, it appears that the η^5-$C_4Me_4GeSi(SiMe_3)_3$ and Cp* ligands in **4** are bonded similarly to the Ru center. An irreversible oxidation wave was observed for **4** at $E_{1/2}$ = 0.25 V (vs SCE) by cyclic voltametry (dichloromethane, 0.1 M $[N(nBu)_4]ClO_4$ as the supporting electrolyte). For comparison, decamethylruthenocene displays a reversible oxidation wave at 0.42 V (vs SCE) under comparable conditions.[10] The electrochemical data therefore suggests that the η^5-$C_4Me_4GeSi(SiMe_3)_3$ ligand is more electron-donating than η^5-C_5Me_5. We are currently characterizing additional chemical and electronic properties for the η^5-germacyclopentadienyl ligand in **4**.

Experimental Procedure

Manipulations were performed under anaerobic and anhydrous conditions. NMR spectra were recorded for [D_6]benzene solutions (unless indicated otherwise) on a GE QE-300 instrument at 300 (^{1}H) and 75.5 (^{13}C) MHz.

1: Benzene (20 mL) solutions of the germole $C_4Me_4GeCl_2$ [11] (0.708 g, 2.81 mmol) and $[(Cp^*RuCl)_4]$ (0.765 g, 2.81 mmol) were combined at 5 °C. After stirring the reaction mixture for 1 h at room temperature, the volatiles were removed and the product was extracted into diethyl ether (8 × 50 mL) to give an orange solution. Concentration and cooling (−40 °C) of this solution gave **1** as orange crystals in 70% yield. Correct elemental analysis for $C_{18}H_{27}Cl_3GeRu$. ^{1}H NMR: δ = 1.10 (s, 15H, Cp*), 1.51, 1.59 (s, 6H, CMe). $^{13}C\{^1H\}$ NMR: δ = 8.92 (C_5Me_5), 11.26, 13.62 (*C*Me), 80.50, 95.77 (*C*Me), 96.78 (C_5Me_5).

2: To $C_4Me_4GeCl_2$ (0.998 g, 3.97 mmol) in benzene (75 mL) was added $(thf)_3LiSi(SiMe_3)_3$ [12] (1.68 g, 3.97 mmol) in benzene (10 mL) at 5 °C. After stirring the reaction mixture for 1 h at room temperature, the volatiles were removed and the product was extracted into pentane (3 × 50 mL), and crystallized from a concentrated solution at −78 °C. Yield 70%. Correct elemental analysis for $C_{17}H_{39}ClGeSi_4$. ^{1}H NMR: δ = 0.32 (s, 27H, $SiMe_3$), 1.59, 2.07 (s, 6H, CMe). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 2.42 ($SiMe_3$), 14.53, 15.47 (*C*Me), 133.63, 146.02 (*C*Me).

3: A solution of **2** (0.30 g, 0.63 mmol) in THF (20 mL) was added to $LiAlH_4$ (0.024 g, 0.630 mmol) in THF (50 mL) at 0 °C. The resulting solution was stirred at 0 °C for 5 min, and then at room temperature for 1.5 h. The product was extracted into pentane (2 × 20 mL) and crystallized from a concentrated solution at −78 °C. Yield 80%. Correct elemental analysis for $C_{17}H_{40}GeSi_4$. ^{1}H NMR: δ = 0.29 (s, 27H, $SiMe_3$), 1.77, 2.13 (s, 6H, CMe), 4.96 (s, 1H, GeH). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 2.46 ($SiMe_3$), 14.80, 17.36 (*C*Me), 132.89, 146.45 (*C*Me).

4: To a cold (−78 °C) solution of **3** (0.980 g, 2.28 mmol) in THF (25 mL) was added *n*BuLi (1.43 mL, 1.6 M in hexane). To the resulting yellow solution was then added $[(Cp^*RuCl)_4]$ (0.62 g, 2.28 mmol) in THF (25 mL), also cooled to −78 °C. Stirring was continued for 15 min at −78 °C, and then for 90 min at room temperature. After removal of the volatiles by vacuum transfer, the oily residue was extracted into pentane (2 × 50 mL). Concentration and cooling (−78 °C) of the solution gave amber crystals in 50% yield. Correct elemental analysis for $C_{27}H_{54}GeRuSi_4$. ^{1}H NMR: δ = 0.36 (s, 27H, $SiMe_3$), 1.78 (s, 6H, CMe), 1.80 (s, 21H, Cp* + CMe). $^{13}C\{^1H\}$ NMR: δ = 2.54 ($SiMe_3$), 11.61 (C_5Me_5), 13.05, 17.87 (*C*Me), 80.23, 87.82 (*C*Me), 85.38 (C_5Me_5).

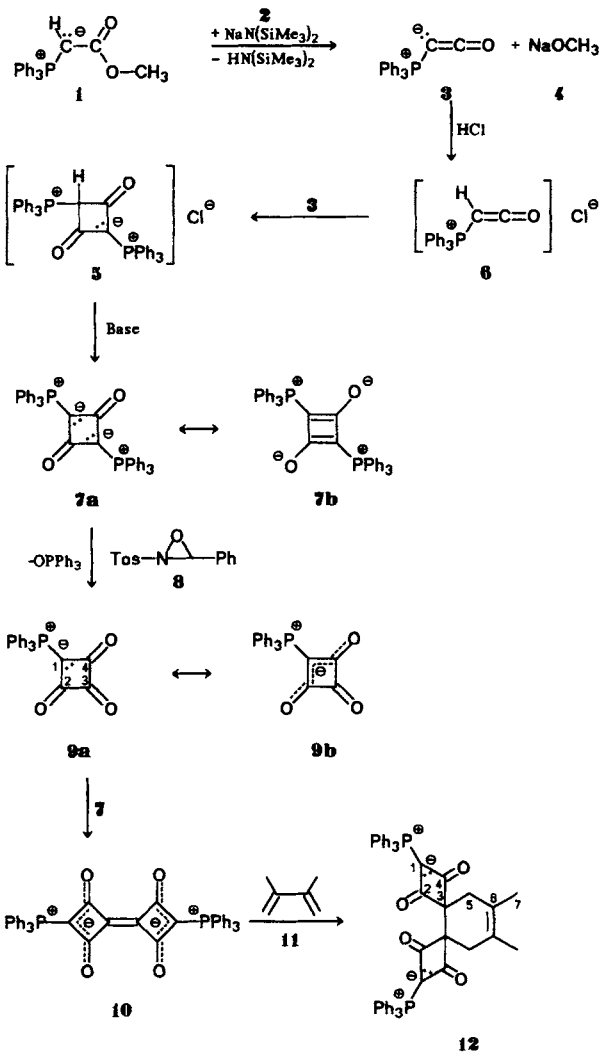
Structures and Reactions of the Oxidation Products of Dimeric Ketenylidene(triphenyl)phosphorane**

By *Hans Jürgen Bestmann,* Thomas G. Fürst,* and *Annette Schier*

Ketenylidene(triphenyl)phosphorane (**3**), readily accessible[1] from methoxycarbonyl(triphenyl)phosphorane (**1**) and sodium bis(trimethylsilyl) amide (**2**), is a monomeric crystalline compound, the structure of which has long been known.[2] When **3** is treated with HCl, the ketenylphosphonium salt **6** is formed initially; it immediately undergoes cycloaddition with another molecule of **3** to give the salt **5**. When **5** is exposed to base, **7**, a dimer of **3** forms,[3] which can be depicted by the mesomeric resonance structures **7a** ↔ **7b**, where **7b** is a push-pull-substituted cyclobutadiene.



Oxidation of **7** provides trione **9** (Table 1).[3, 4] *N*-*p*-tolylsulfonyl(phenyl)oxaziridine (**8**) has been proven recently to be a particularly well-suited oxidizing agent.[5] When a solution of two equivalents of **8** is added to one equivalent of **7** suspended in ether, cyclobutanetrione **9** is collected in 75% yield. The X-ray structure analysis of **9** is the first obtained for a neutral cyclobutanetrione.[6, 7]

Table 1. Selected spectroscopic and physical data for **9**, **10**, and **12**.

9: Yellow crystals; m.p. 273–275 °C (decomp); IR (KBr): $\tilde{\nu}$ = 1770, 1755, 1650, 1630 cm^{-1}; ^{13}C NMR (100.4 MHz, $CDCl_3$, 26 °C): δ = 214.61 (d, $^3J(C,P)$ = 56.4 Hz; C3), 194.62 (d, $^2J(C,P)$ = 12.2 Hz; C2 and C4), 141.85 (d, $^1J(C,P)$ = 83.9 Hz; C1); ^{31}P NMR (161.7 MHz, $CDCl_3$, 25 °C, H_3PO_4 ext.): δ = +8.34.

10: Faintly yellow crystals which do not have a sharp melting point but char between 300 and 360 °C; IR (KBr): $\tilde{\nu}$ = 1650, 1640 cm^{-1}; ^{31}P NMR (161.7 MHz, $CDCl_3$, 25 °C, H_3PO_4 ext.): δ = +1.20.

12: Colorless crystals; m.p. 288 °C (decomp); ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 2.61 (s; CH_2), 1.64 (s; CH_3); ^{13}C NMR (100.4 MHz, $CDCl_3$, 25 °C): δ = 193.17 (d, $^2J(C,P)$ = 3.0 Hz; C2 and C4), 123.04 (s; C6), 76.32 (s; C3), 73.24 (d, $^1J(C,P)$ = 39.7 Hz; C1), 18.70 (s; C7); ^{31}P NMR (40.48 MHz, $CDCl_3$, 25 °C, H_3PO_4 ext.): δ = −5.02.

All C atoms of the four-membered ring of **9** lie in one plane. The bonds between two carbonyl groups in the distorted rectangle are longer (C2–C3 = 152.5(3) pm, C3–C4 = 153.8(3) pm), C1–C2 and C1–C4 substantially shorter (143.7(3) pm and 145.1(3), respectively). The distance

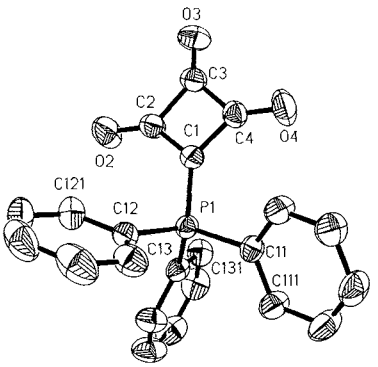


Fig. 1. Crystal structure of **9** with selected bond lengths [pm] and angles [°]: C1-C2 143.7(3), C2-C3 152.5(3), C3-C4 153.8(3), C4-C1 145.1(3), C1-P1 175.3(2), C2-O2 121.6(3), C3-O3 119.4(2), C4-O4 120.6(3); C2-C1-P1 129.0(1), C4-C1-P1 136.2(1), C4-C1-C2 94.6(1), C3-C2-C1 89.4(1), O2-C2-C1 137.9(2), O2-C2-C3 132.7(2), C4-C3-C2 87.7(1), O3-C3-C2 134.8(2), O3-C3-C4 137.4(2), C3-C4-C1 88.3(1), O4-C4-C1 138.3(2), O4-C4-C3 133.4(2).

C3–O3 (119.4(2) pm) is shorter than C4–O4 (120.6(3) pm) and C2–O2 (121.6(3) pm). These data indicate the predominance of resonance structure **9b**. The interior angle is largest at C1, 94.6(1)°, to which the P atom is bound, while the remaining three fall short of 90°. The dihedral angles (P1-C1-C2-O2: 2.67°, P1-C1-C4-O4: 2.74°, O2-C2-C3-O3: 1.14°, and O3-C3-C4-O4: 0.84°) indicate that the four substituents project out of the plane of the ring and are all on the same face (*Z* arrangement), despite the sp^2 character of the C atoms in the four-membered ring.

In the ^{13}C NMR spectrum of **9** the signal of C3 (δ = 214.61) appears as expected downfield from the signals of the CO groups adjacent to the ylide function (δ = 194.62). Remarkably the C1 signal (δ = 141.85) is found at considerably lower field than those of all other ylidic C atoms of cyclic acyl ylides such as **12** (see also analogous compounds in the following communication). The ^{31}P NMR signal appears at δ = +8.34, substantially below that of other acyl ylides hav-

[**] We thank J. Riede for recording the crystallographic data.

ing a four-membered ring structure (see **10** and **12**, as well as refs. [8, 9]).

The central CO group of **9** is very reactive.[4] We could therefore oxidize **7** with just one equivalent of **8**. As soon as **9** forms, it reacts with unoxidized **7** to give **10** (95–98% yield, Table 1).[10] Logically **10** is also obtained by reaction of **9** with **7**. Formally a derivative of ethylenetetracarboxylic acid, **10** is a bicyclic, double bis(acyl)ylide and can described by several mesomeric resonance structures.

According to an X-ray structure analysis of **10** (Fig. 2),[11] the C atoms in either of the four-membered rings lie in the same plane and are related to one another through an inversion center. Their planes, however, are shifted parallel by

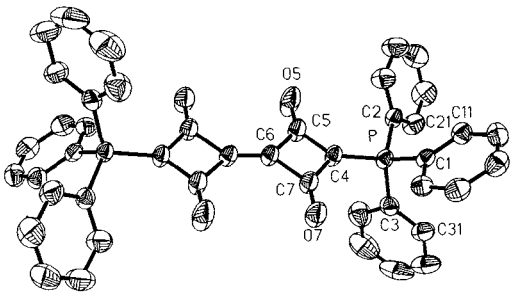

Fig. 2. Crystal structure of **10** with selected bond lengths [pm] and angles [°]: C4-C5 144.6(2), C4-C7 145.4(2), C5-C6 151.0(2), C6-C7 151.3(2), C6-C6a 132.8(3), C7-O7 121.6(2), C5-O5 120.9(2), C4-P 173.9(2); P-C4-C5 135.5(1), P-C4-C7 132.4(1), C5-C4-C7 91.9(1), C4-C5-C6 90.7(1), C4-C5-O5 136.4(2), C6-C5-O5 132.9(2), C5-C6-C7 87.1(1), C4-C7-C6 90.3(1), C4-C7-O7 136.0(2), C6-C7-O7 133.8(2).

3.2 pm. Atoms C6 and C6a are separated by 132.8(3) pm (normal length of a double bond).[12] The C–C distances and interior angles in the four-membered ring are comparable to those of **9**. The distances from the P-substituted C atoms to the adjacent O-substituted atoms are almost identical, which indicates a complete delocalization of the ylidic electron pair. The bonds C5–C6 and C7–C6 have the same length within standard error limits. Here again, the substituents of the four-membered ring project from the plane of the ring in an all-*Z* arrangement (dihedral angles: P-C4-C7-O7 4.8°, P-C4-C5-O5 4.4°, O5-C5-C6-C6a 1.3°, O7-C7-C6-C6a 2.0°).

Compound **10** is suitable as a dienophile in Diels–Alder reactions. When **10** is heated with 2,3-dimethylbutadiene (**11**) in nitrobenzene for 24 h, the bis-spirocyclic compound **12** forms in 58% yield (Table 1), the two adjacent cyclobutanedione rings of which have the characteristics of a bis(acyl) ylide. We are currently studying the photochemistry and the complex-forming behavior of the cyclobutanediones and -triones.

Trimeric Ketenylidene(triphenyl)phosphorane: A Hybrid between an Arene and an Ylide**

By *Hans Jürgen Bestmann,* Thomas G. Fürst,* and *Annette Schier*

Studies on the dimer of ketenylidene(triphenyl)phosphorane **1**[1, 2] have led to the question whether a cyclic trimer **6** can also be prepared. Such a compound would be of interest, because it could be a tris-ylide, **6a**, a cyclohexatriene with alternating double bonds, **6b**, or a push–pull arene, **6c**. Or could all three forms be mesomeric resonance structures of **6**?

We prepared **6** in the following way: the salt **3**, accessible from **1** and HCl (**2**), was refluxed with **1** (eightfold excess) in dichloromethane for 16 h. Faintly yellow crystals of the desired trimer **1** were collected in 30% yield. We assume that **1** reacts with **3** to initially give **4**, which is converted to **5** by 1,6-cyclization. Excess ylide **1** deprotonates **5** to form **6**.

According to an X-ray structure analysis[13] (Figs. 1 and 2), **6** crystallizes with one equivalent of dichloromethane in the triclinic space group $P(-1)$, lacking any crystallographical symmetry. The average C–C bond length in the central six-membered ring (C1 through C6) is 144.1 pm; the C–C distances increase from C1–C2 to C6–C1 by a total of 2.5 pm. Alternation of bond lengths, as expected from the mesomeric formula **6b**, is not observed. The lengths of the C–O bonds

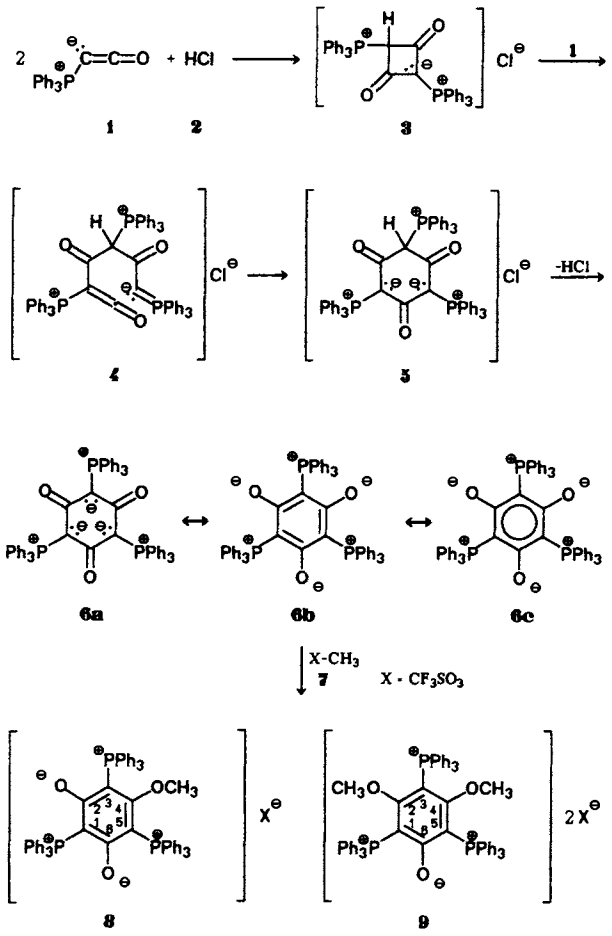
[**] We thank J. Riede for recording the crystallographic data.



decrease from C2–O through C4–O to C6–O by 2.1 pm, whereas the C–P bonds vary only minimally.

The central six-membered ring is not planar but has a twisted boat conformation when the O and P atoms are included. C2 and C5 deviate from the plane established by C1, C3, C4, and C6, C5 much more than C2. The fold angles amount to 21.3° and 2.5°, respectively.[4] The dihedral angles shown in Figure 2 reflect the deviations from planarity. The two torsion angles involving C5 have the greatest absolute values, −20.2° and +21.6°. The sum of the six interior angles comes to 716.6°. The interior angles at C4, C5, and C6 show the most significant deviations from 120°, that is, again those angles involving C5.

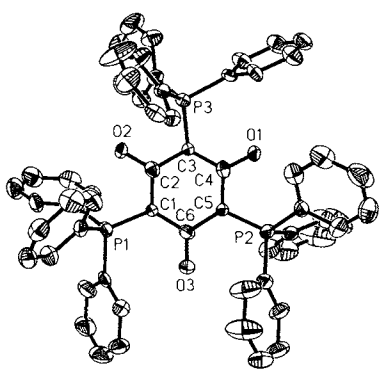


Fig. 1. Crystal structure of **6** with selected bond lengths [pm] and angles [°]: C1-C2 143.1(1), C2-C3 143.6(1), C3-C4 143.8(1), C4-C5 143.8(1), C5-C6 144.7(1), C6-C1 145.6(1), C2-O2 127.7(1), C4-O1 126.6(1), C6-O3 125.6(1), C1-P1 173.8(1), C3-P3 173.9(1), C5-P2 173.2(1); C2-C1-C6 121.8(1), P1-C1-C2 112.5(1), P1-C1-C6 125.7(1), C3-C2-C1 119.5(1), O2-C2-C1 120.5(1), O2-C2-C3 120.0(1), C2-C3-C4 121.2(1), P3-C3-C2 111.8(1), P3-C3-C4 126.1(1), C3-C4-C5 115.9(1), O1-C4-C3 124.0(1), O1-C4-C5 120.0(1), C4-C5-C6 123.5(1), P2-C5-C4 114.7(1), P2-C5-C6 121.5(1), C1-C6-C5 114.7(1), O3-C6-C1 122.9(1), O3-C6-C5 122.3(1).

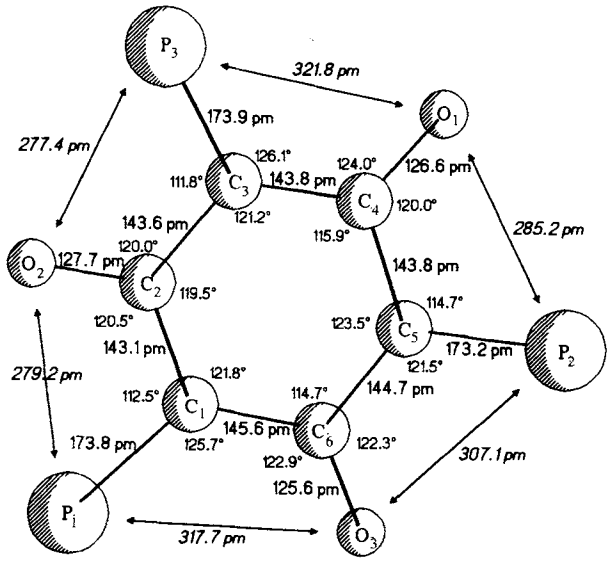

Fig. 2. Bond lengths and angles of trimer **6** (P-O distances in italics). Dihedral angles of the central six-membered ring [°]: C1-C2-C3-C4 −2.3, C2-C3-C4-C5 +9.5, C3-C4-C5-C6 +21.6, C4-C5-C6-C1 −20.2, C5-C6-C1-C2 +7.0, C6-C1-C2-C3 +3.6.

The mean bond length within the six-membered ring (144.1 pm) is distinctly greater than that in typical arenes (138.4 pm).[5] It definitely falls into the range of bond lengths found in tris-donor–tris-acceptor-substituted push–pull arenes.[6] The structure of **6** can be compared to those of the potassium salts of trinitrophloroglucinol, which closely resemble **6**. Here the mean bond lengths are 141.5 and 142.4 pm for the mono-K salt, 143.8 pm for the di-K salt, and 145.2 pm for the tri-K salt. In all of these compounds the benzene ring is likewise nonplanar.[7] The mean C–O distance in **6** (126.6 pm) is comparable to the corresponding distance in the potassium trinitrophloroglucinolates (mono 129.5, di 126.7, tri 124.5 pm). Based on its structure parameters, the trimeric ketenylidene(triphenyl)phosphorane **6** can be considered an electronically perturbed and sterically distorted push–pull arene.

The ^{13}C NMR spectrum of **6** (in CD_2Cl_2) shows two signals with greatly different chemical shifts for alternating C atoms in the central six-membered ring (Table 1). The positions of the two signals indicate a strong delocalization of the ylidic lone pairs of electrons, which is known for cyclic acyl ylides.[2] The high-frequency ν(CO) bands in the IR spectrum indicate the same.

Methylation of **6** with one to three equivalents of methyl trifluoromethylsulfonate (**7**) resulted in mono- and di-O-methylations affording **8** and **9**. Trimethylation was not possible even with a great excess of **7**. The ^{13}C NMR signals of the C atoms in **8** and **9** bearing O-methyl groups are shifted upfield by $\Delta\delta = 5-6$ relative to the related C atoms in **6**, whereas the ^{13}C resonances due to C–O groups are shifted somewhat less. The signals of the ylidic C atoms are shifted in the opposite direction and more strongly so, which is indicative of the expected decreased charge density at these atoms (Table 1).

We were especially interested in the extent of ylidic character in **6**. Although **6** undergoes Wittig reaction with aromatic

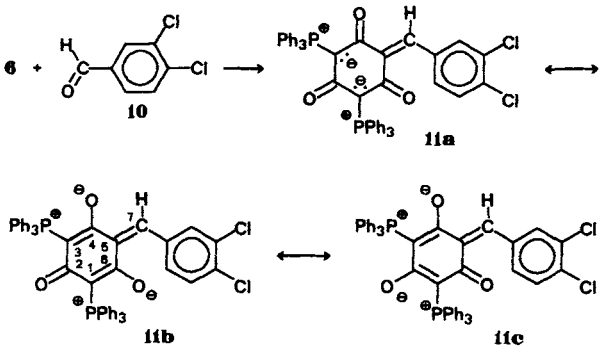
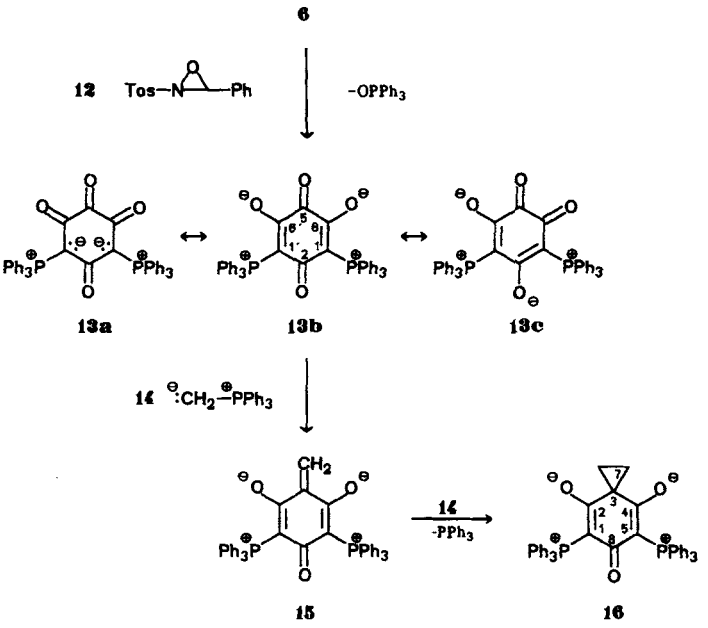
19: Colorless crystals; m.p. 301–302 °C (decomp); IR(KBr): $\tilde{\nu} = 1660$, 1595, 1570 cm^{-1}; ^{13}C NMR (100.4 MHz, $CDCl_3$, 25 °C): $\delta = 196.08$ (t, $^2J(C,P) = 9.1$ Hz; C5), 187.39 (dd, $^3J(C,P) = 19.9$ Hz, $^2J(C,P) = 6.1$ Hz; C2, C3), 67.32 (dd, $^1J(C,P) = 112.2$ Hz, $^3J(C,P) = 3.8$ Hz; C1, C4); ^{31}P NMR (40.48 MHz, $CDCl_3$, 25 °C, H_3PO_4 ext.): $\delta = 8.77$.

aldehydes (several days in boiling toluene), multiple carbonyl olefinations proved to be impracticable. The reaction of **6** with 3,4-dichlorobenzaldehyde (**10**), for instance, furnished compound **11** (91% yield), which can be represented by the resonance structures **11b** or **11c** (i.e. as a *p*- or an *o*-quinone methide).



N-*p*-tolylsulfonyl(phenyl)oxaziridine **12** oxidized **6** to give **13** (92% yield),[8] which can be considered either a *p*- or an *o*-quinone **13b**↔**13c**. Figure 3 shows the result of an X-ray structure analysis.[9]



The orange-red compound **13**, also crystallizing with one equivalent of CH_2Cl_2, displays C_s symmetry and distinctly *p*-quinoid character (**13b**). The C1–C6 bond (140.3(4) pm) is significantly shorter than C1–C2 and C5–C6 though longer than the corresponding bonds in substituted benzoquinones (134.9 pm).[5] C1–C2 (144.4(3) pm) is comparable to the corresponding bond in **6**, whereas C5–C6 (155.6(3) pm) is longer than the pertinent bonds in *p*-quinone (147.8 pm). Such long C_{sp^2}–C_{sp^2} bonds are also found in the salts of oxalic acid (mono-salt 154.9, di-salt 156.4 pm).[5]

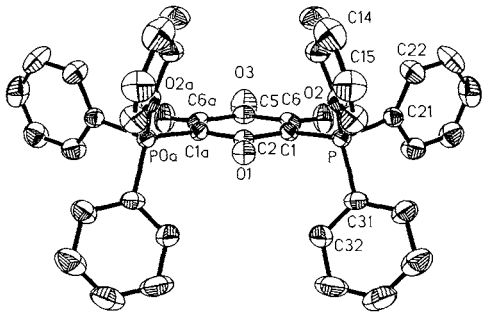


Fig. 3. Crystal structure of **13** with selected bond lengths [pm] and angles [°]: C1-C2 144.4(3), C1-C6 140.3(4), C5-C6 155.6(3), C2-O1 125.2(4), C5-O3 119.1(5), C6-O2 123.6(3), P-C1 175.1(3); P-C1-C6 123.0(2), P-C1-C2 114.2(2), C2-C1-C6 122.8(3), C1-C2-C1a 121.6(4), C1-C2-O1 119.2(3), C6-C5-C6a 120.3(4), C6-C5-O3 119.8(2), O2-C6-C1 129.0(3), O2-C6-C5 114.8(3), C1-C6-C5 116.1(3).

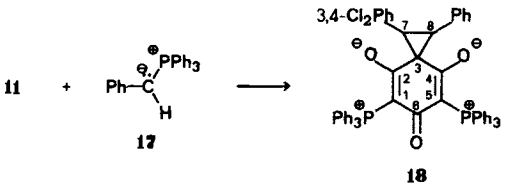
The central six-membered ring in **13** is approximately planar. The sum of the interior angles is 719.7°. The fold angles of the planes C1, C2, C1a and C6, C5, C6a with the reference plane C1, C6, C1a, C6a amount to a mere 3.6° and 2.2°, respectively.

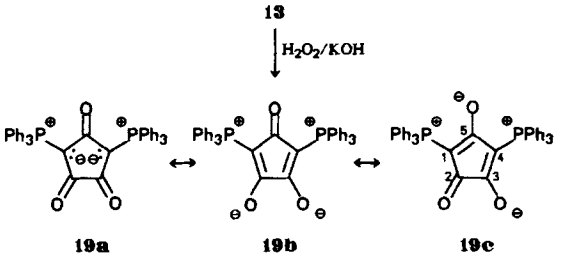
The ^{13}C NMR data of **13** (Table 1) show a high-field shift of the signals of the carbonyl groups from C2 through C5 to C6/C6a, as expected. The signals of C1/C1a are shifted downfield (as in **11**) relative to those of **6**. The X-ray structure analysis and the ^{13}C NMR spectrum indicate the dominance of the mesomeric resonance form **13b**.

As expected, the carbonyl group at C5 in **13** is very reactive. It undergoes a Wittig reaction with methylene(tri-

phenyl)phosphorane **14** to give, rather than **15**, product **16** (92% yield) upon loss of triphenylphosphane. The presumed initial product **15**, a quinone methide with a very electron-poor double bond, reacts with another molecule of **14** to provide **16** in a precendented conversion.[10] As a logical consequence we found that **11** and ylide **17** react to give **18** (83% yield) as one diastereomer. Based on the ^{1}H NMR coupling constants of the protons at the three-membered ring (^3J(H,H) = 8.85 Hz), we have assigned it the *trans* configuration.



When **13** is oxidized with H_2O_2 + KOH, the bis(ylidic) cyclopentanetrione **19** (92% yield) forms, which can be described by the mesomeric forms **19a**–**19c**. According to an



X-ray structure analysis and the ^{13}C NMR signals, **19b** seems to prevail.[11] The bonds C1–C2 (141.6(5) pm) and C3–C4 (143.0(5) pm) are shortest yet still longer than C1–C6 (140.3(4) pm) in **13**. The distances C1–C5 and C5–C4, (145.4(5) and 144.4(5) pm respectively) are comparable with those of C5–C6 (144.7(1) pm) and C6–C1 (145.6(1) pm) in **6**. Once more the distance C2–C3 (156.5(5) pm) between the vicinal carbonyl groups is strikingly different and even longer than that in **13** (155.6(3) pm).

The "cyclic acyl ylides" described here decompose upon melting. We are currently studying their thermolyses in detail. Decomposition of trimer **6** should be of particular interest to us, because release of three equivalents of triphenylphosphane oxide could lead to a C_6 compound or its subsequent reaction products.

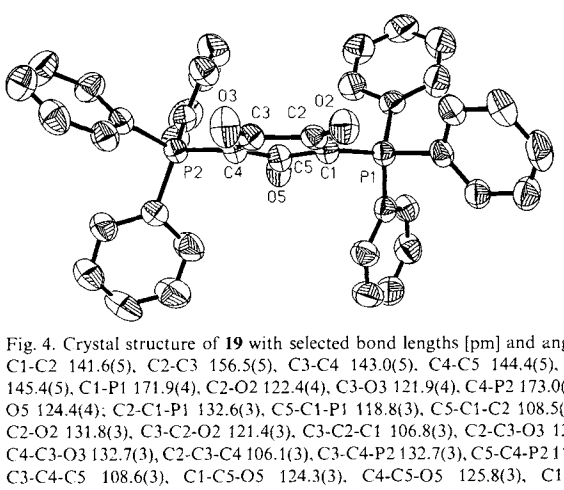


Fig. 4. Crystal structure of **19** with selected bond lengths [pm] and angles [°]: C1-C2 141.6(5), C2-C3 156.5(5), C3-C4 143.0(5), C4-C5 144.4(5), C1-C5 145.4(5), C1-P1 171.9(4), C2-O2 122.4(4), C3-O3 121.9(4), C4-P2 173.0(4), C5-O5 124.4(4); C2-C1-P1 132.6(3), C5-C1-P1 118.8(3), C5-C1-C2 108.5(3), C1-C2-O2 131.8(3), C3-C2-O2 121.4(3), C3-C2-C1 106.8(3), C2-C3-O3 121.2(3), C4-C3-O3 132.7(3), C2-C3-C4 106.1(3), C3-C4-P2 132.7(3), C5-C4-P2 118.5(3), C3-C4-C5 108.6(3), C1-C5-O5 124.3(3), C4-C5-O5 125.8(3), C1-C5-C4 109.9(3).

$[(I_6Te_2)Nb(Te_2)_2Nb(Te_2I_6)]$, a Metal Complex with Halochalcogenate Ligands**

By *Astrid Leist* and *Wolfgang Tremel**

Polycations of the main group elements have been known for almost thirty years.[1] In some cases, they have been isolated as their AsF_6^-, SbF_6^-, $Sb_2F_{11}^-$,[2] $AlCl_4^-$, or $Al_2Cl_7^-$ salts from superacid media or melts.[3] Moreover, recent investigations have shown that the halides of electron-poor transition metals, such as WCl_6 or $ZrCl_4$, are suitable oxidizing agents for the preparation of polycations of tellurium.[4, 5] Whereas a wealth of information is known about discrete polycations of the main group elements, and also the corresponding Zintl polyanions,[6] very little is known about polycations that are bound to transition metal complex fragments. Thus, the complexes $[M(CO)_4(\eta^3\text{-}Te_3)][SbF_6]$ (M = Mo, W)[7, 8] and $[(Te_4)Nb_3O(Te_2)_2I_7]$[9] are the only three compounds known in which polycations of tellurium are bound to metals. With only a few exceptions (e.g. $[Pb_9Cr(CO)_3]^{4-}$,[10] $[Sn_6\{Cr(CO)_5\}_6]^{2-}$,[11] or $[Sb_7Mo(CO)_3]^{3-}$[12]), the binding of transition metal complex fragments to Zintl polyanions is likewise a rarity. It was already apparent from the synthesis of $[(Te_4)Nb_3O(Te_2)_2I_7]$[9] that the formation of transition metal complexes with unusual ligands is possible from high-temperature reactions. We report here on a further example of this; the title compound, $Nb_2Te_8I_{12}$, has two $Te_2I_6^{2-}$ ligands coordinated to a $Nb_2Te_4^{2+}$ center.

The title compound $Nb_2Te_8I_{12}$[13] is formed by the reaction of the elements at 620 °C. The crystal structure[14] consists of discrete $Nb_2Te_8I_{12}$ molecules (Fig. 1) each of which has idealized D_{2h} and crystallographic C_i symmetry. In each molecule, the Nb atoms of the $Nb_2(Te_2)_2$ central unit are bridged by two Te_2 groups. The Te–Te distance within the Te_2 groups is 2.682(1) Å. This value is in accord with the 2.74 Å[15] reported for twice the covalent radius of tellurium and is similar to the corresponding values from compounds with typical Te–Te single bonds like diphenylditelluride Ph_2Te_2 (2.712 Å)[16] and $[Ta(Te_2)_2I_4][PtI_6]I_2$ (2.781 Å).[17] The range of Nb–Te distances (2.814(2)–2.934(1) Å) within the Nb_2Te_4 center are in agreement with the values found in $Nb_2Te_2I_6$,[18] $NbTe_4I$,[19] and Nb_2Te_6I.[20]

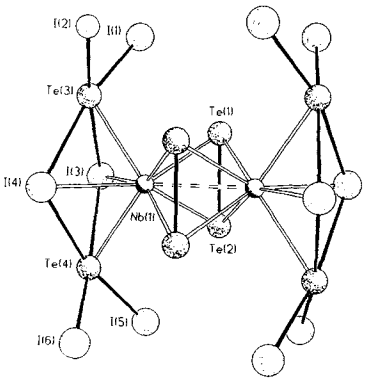

Fig. 1. The molecular structure of $Nb_2Te_8I_{12}$ in the crystal. Selected interatomic distances [Å]: Nb(1)-Te(1) 2.817(2), Nb(1)-Te(2) 2.814(1), Nb(1)-Te(3) 2.920(2), Nb(1)-Te(4) 2.934(1), Nb(1)-I(3) 2.960(1), Nb(1)-I(4) 2.951(2), Nb-Te(1A) 2.814(1), Nb(1)-Te(2A) 2.811(1), Te(1)-Te(2) 2.682(1), Te(1)···Te(2A) 3.871(1), Te(3)-I(1) 2.760(2), Te(3)-I(2) 2.789(1), Te(3)-I(3) 3.167(1), Te(3)-I(4) 3.210(1), Te(4)-I(3) 3.211(2), Te(4)-I(4) 3.217(1), Te(4)-I(5) 2.769(1), Te(4)-I(6) 2.755(2)), I(1)···Te(1) 3.705(1), I(2)···Te(2A) 3.738(1), I(5)···Te(2) 3.646(1), I(6)···Te(1A) 3.803(1). Shortest intermolecular distances: I(2)···I(2B), 3.674(1); I(2)···I(5C), 3.718(1).

The Nb–Nb distance of 3.083(2) Å is about 0.1 Å longer than the corresponding metal–metal distances in related compounds such as Nb_2Te_6I (d_{Nb-Nb}: 2.834(2) Å),[20] $Nb_2Te_2I_6$ (d_{Nb-Nb}: 2.932(2) Å),[13] and $Nb_2Cl_4S_2 \cdot 4tht$ (tht = tetrahydrothiophene, d_{Nb-Nb}: 2.888(2) Å),[21] in which formal Nb–Nb single bonds are present. An obvious question is, therefore, whether the Nb–Nb distance of 3.083(2) Å corresponds to a formal Nb–Nb single bond. Extended Hückel calculations[22] for $Nb_2Te_8I_{12}$ have shown that the HOMO–LUMO energy gap is only mildly influenced by variations in the Nb–Nb distances over the region between 2.9 Å and 3.1 Å. In contrast, larger changes in the metal–metal distances lead to either strong Van der Waals repulsions of the ligands or bond breaking within the Te_2 groups of the Nb_2Te_4 center.[23] The sum of the restraints imposed by the ligand–ligand, ligand–metal, and metal–metal bonds in this group of compounds permits changes in the molecular geometry to occur only within narrow limits if the structure type is to be retained. Hence, the structure of the title compound should also contain a dimetal center with a formal Nb–Nb single bond.

The tetragonal antiprismatic surroundings of the Nb atoms are completed with the two slightly tilted Te_2I_6 groups, each bound to a metal through the central Te and bridging I atoms. The distances between the Nb and Te atoms of the Te_2I_6 group (2.920(2) and 2.934(2) Å) as well as the Nb–I distances (2.951(2)–2.960(2) Å) are enlarged compared to the sums of their respective covalent radii. It is possible then to formally describe the bonding as $[((Nb^{4+})_2(Te_2^{2-})_2)((Te^{2+})_2(I^-)_6)_2]$. The dinuclear $Te_2I_6^{2-}$ groups are thus isoelectronic with I_2Cl_6 and isostructural to Au_2Cl_6.

The bond lengths and angles of the Te_2I_6 groups coordinated to the metal center in $Nb_2Te_8I_{12}$ are significantly different from those in the free $Te_2I_6^{2-}$ anion[25] ($Te_2I_6^{2-}$: $\bar{d}_{Te-I}$ (terminal) 2.827 Å; $Nb_2Te_8I_{12}$: $\bar{d}_{Te-I}$ (terminal) 2.768 Å; $Te_2I_6^{2-}$: $\bar{d}_{Te-I}$ (bridging) = 3.138 Å; $Nb_2Te_8I_{12}$: $\bar{d}_{Te-I}$ (bridging) = 3.201 Å). The next notable facet is that the asymmetry found in the four-membered Te_2I_2 ring of the free $Te_2I_6^{2-}$ anion[25] is virtually absent in the complexed species. Further differences are apparent, in particular, in the Te–I bond lengths of the central Te_2I_2 four-membered ring as well as the terminal Te–I bond lengths. Whereas the Te–I distances ($d_{Te(3)-I(3)}$: 3.167(1) Å) to the bridging I atoms are up to about 0.1 Å longer, the terminal Te–I distances ($d_{Te(3)-I(1)}$: 2.760(1) Å, $d_{Te(3)-I(2)}$: 2.789(1) Å) are about 0.04 Å shorter. That the shorter terminal Te–I bonds lie transverse to the longer bridging bonds can be understood as an effect of the hypervalency in the Te_2I_6 unit. The changes which occur as a result of the coordination of the $Te_2I_6^{2-}$ group to the $Nb_2Te_4^{4+}$ center therefore lead to a significant lengthening in the bridging Te–I bonds. Thus, the bonding situation changes in the transition from a free to a complex-bound ligand $[((Nb^{4+})_2(Te_2^{2-})_2)((I^-)_4(TeI_2)_4)]$ (i.e. now with the donor ligands I^- and TeI_2).

Figure 2 shows a [100] projection of the unit cell. As a result of their nearly spherical shape, the $Nb_2Te_8I_{12}$ molecules are ordered as close-packed layers in the crystal lattice. Although $Nb_2Te_8I_{12}$ exists as discrete molecules, it does not remain intact when dissolved in organic solvents like chloroform or acetonitrile. The stable decomposition product was shown to be TeI_4.

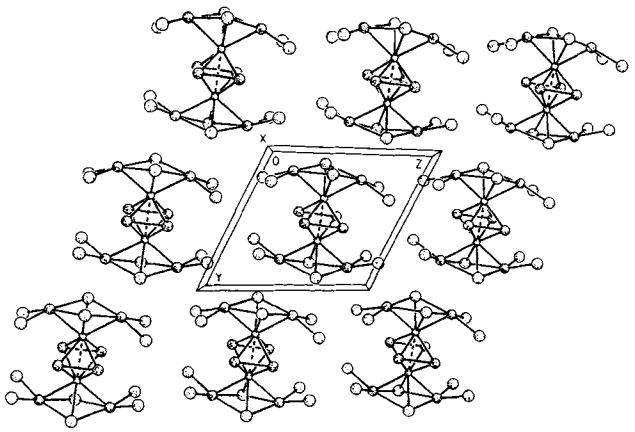

Fig. 2. [100] projection of the unit cell of $Nb_2Te_8I_{12}$.

It is not only remarkable, but also surprising, that halotellurate(II) ions, which have so far only been known to exist in free form, can be obtained in complexed form from high-temperature reactions. In compounds of tellurium and selenium with halogens, the chalcogens usually have an oxidation state IV; the most well-known examples of this class of compounds are the tetrameric molecular halides X_4Y_{16} (X = Se, Te; Y = Cl, Br, I)[26] and their solution decomposition products $[X_3Y_{13}]^-$,[27] $[X_2Y_{10}]^{2-}$,[28] and $[X_2Y_9]^-$.[29] The halides of Se^{II} and Te^{II} are much less stable; chalcogen(II) halides are not known in the solid state, but do exist in solution and in the gas phase.[30] Chalcogen(II) halides can be stabilized in solution through the formation of adducts with electron donors. The synthesis of halogeno anions like $[Se_2Cl_6]^{2-}$[31] and $[Se_5Br_{12}]^{2-}$ as well as a few mixed-valent species (such as $[Se_3Br_{10}]^{2-}$) has only recently been possible.[32] These compounds are generally prepared from organic solvents by the disproportionation of the tetrahalide with subsequent addition of halide. Whereas the chemistry of the free halogeno anions has been well described, there is to date no information on their complexation properties.[33] Since unstable or short-lived compounds appearing in the solvolysis equilibium might possibly be trapped and characterized through complex formation, the investigation of transition metal complexes having halochalcogenate ligands is of special interest.

[13] Niobium powder, finely powdered tellurium, and iodine in a molar ratio of 1:4:6.1 were placed in a dried quartz ampule. The ampule was flame-sealed under vacuum and heated to 620 °C. After about one week, blue-black, platelike crystals of $Nb_2Te_8I_{12}$ formed which were easily separated from the adhering powdery material. The composition of the latter product is still unknown.

Tetrahedral Coordination of Palladium in $Ta_2Pd_3Te_5$: A Compound with a "Stuffed" Ta_2NiSe_5 Structure**

By *Wolfgang Tremel**

Chalcogenides of the early transition metals are very attractive solid-state materials both in terms of their chemical and physical properties. From the chemical point of view, layered structure compounds of the type MQ_2 (M = Ti, Nb, Ta; Q = S, Se) should be mentioned first in relation to investigations on their charge storage reactions and for use in photovoltaic cells.[1, 2] The Chevrel phases, such as AMo_6Q_8 (A = Pb, Sn, Ba, Au, Cu, Li, etc.; Q = S, Se, Te), with their

associated metal clusters have become, in the meantime, textbook material.[3] The superconducting properties of many of the Chevrel phases[4] and the charge density waves in compounds of the type MQ_2 or MQ_3 (M = Nb, Ta; Q = S, Se)[5] are especially interesting from a material science point of view.

Sulfides and selenides have been extremely well investigated, whereas tellurides have remained rather neglected since it was assumed that their structures and properties would be analogous to those of the group's lighter homologues. As recent investigations have shown, however, this assumption is not justified. The compounds $CsTe_4$,[6] $[NbTe_{10}]^{3-}$,[7] Al_7Te_{10},[8] Ta_4SiTe_4,[9] M_3ATe_6 (M = Nb, Ta; A = Si, Ge),[10a-c] $Ta_{13}Ga_3Te_{24}$,[10d] and $TaNi_2Te_2$[11] are only a few particularly prominent examples which illustrate the nonconformitive behavior of the tellurides. None of these compounds has a stoichiometric counterpart among the sulfides and selenides, and each exhibits unusual chemical properties and structural features. Thus, Te–Te distances are found in the structures of $CsTe_4$[6] and $NbTe_{10}^{3-}$[7] which correspond to fractional Te–Te bond orders. Aluminum occurs in the oxidation state II in Al_7Te_{10}.[8] The silicon atoms in the structure of Ta_4SiTe_4[9] are surrounded by a square antiprismatic arrangement of eight metal atoms. The main group elements in the structures of M_3ATe_6 (M = Nb, Ta; A = Si, Ge)[10a-c] and $Ta_{13}Ga_3Te_{24}$[10d] are coordinated in a square-planar fashion to four tellurium atoms. An obvious question is therefore: Can unusual coordination geometries of transition metals also be stabilized in chalcogenides, particularly in tellurides, of niobium and tantalum? Our investigations have led to the synthesis of the title compound $Ta_2Pd_3Te_5$, in which the palladium is not coordinated in a square-planar fashion, but *tetrahedrally* to the chalcogenides.

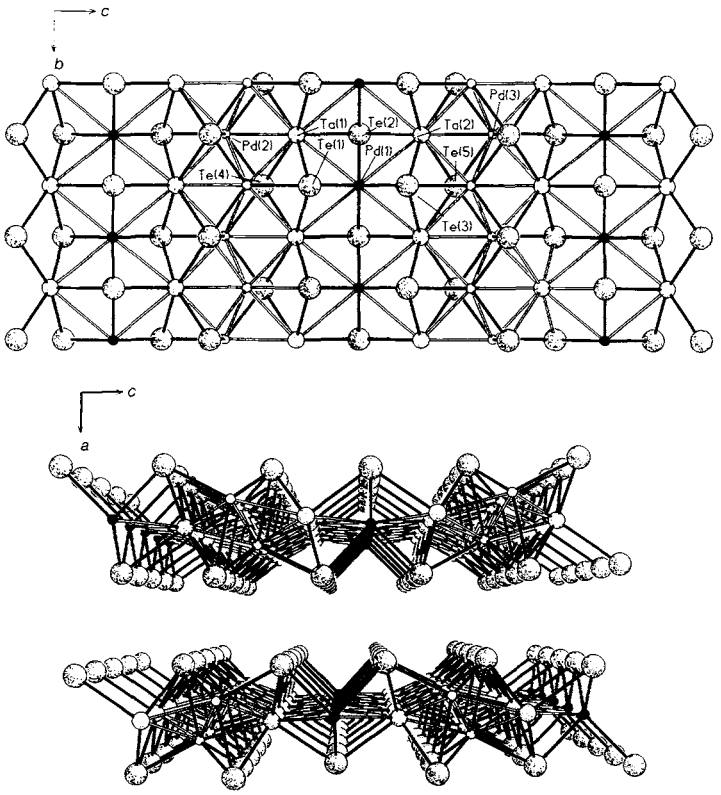

Fig. 1. Top: Structure of $Ta_2Pd_3Te_5$ (ball-and-stick representation): parallel projection of a layer along [100]. Bottom: parallel projection of the structure along [010]. Large, heavily dotted circles: Te; medium, lightly dotted circles: Ta; small, filled black circles: Pd(1); small, open circles: Pd(2) and Pd(3). Selected interatomic distances [Å]: Ta-Te 2.820(2)–2.854(2), Pd(1)-Te 2.623(2)–2.665(2), Pd(2)-Te 2.653(2), 2.716(2) (2 ×), 3.059(2), Pd(3)-Te 2.639(2), 2.716(2) (2 ×), 3.059(2), Ta-Pd(1) 2.990(2) (2 ×) and 2.990(2) (2 ×), Ta-Pd(2)2.845(2) and 2.888(2) (2 ×), Ta-Pd(3)2.853(2) (2 ×) and 2.813(2), Pd(2)-Pd(3)2.701(2) (2 ×).

Each $Ta_2Pd_3Te_5$ layer is composed of three atomic layers: tellurium atoms form the top and bottom layers (not close packed), and the middle layer contains tantalum and palladium atoms. The Pd atoms are each surrounded by a distorted tetrahedron of Te atoms. The Ta atoms are coordinated to five Te neighbors in an approximate square pyramid at distances between 2.7 and 2.8 Å, with an additional sixth Te atom at a nonbonding Ta–Te distance of 4.137 Å. Although the description of the coordination around Ta as a distorted octahedron is not chemically justified, it simplifies the discussion and emphasizes the structural relationship between Ta_2NiQ_5 (Q = S, Se)[14] and $Ta_2Pd_3Te_5$. An idealized polyhedral representation of one such layer from the $Ta_2Pd_3Te_5$ structure is shown in Figure 2. Accordingly, each $Ta_2Pd_3Te_5$ layer can be described as being based on double chains of edge-sharing Ta_2Te_6 octahedra which are condensed over their apical Te atoms to give Ta_2Te_5 layers. The unit cell contains two double chains per layer, which are displaced from one another by $a/2$.

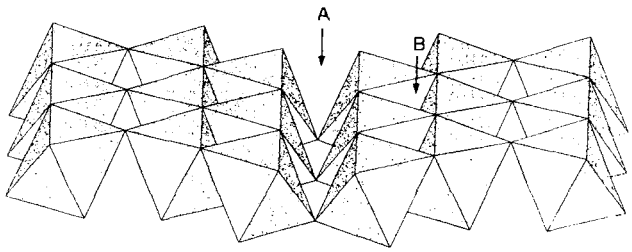

Fig. 2. Polyhedral representation of a $Ta_2Pd_3Te_5$ layer.

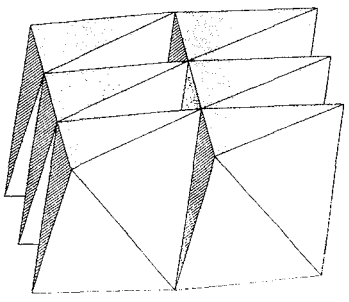


Scheme 1. Polyhedral representation of the double chains of edge-sharing Ta_2Te_6 octahedra.

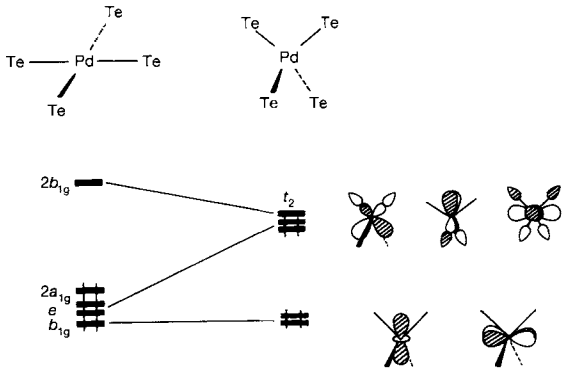
The environment of the palladium atoms in this structure is rather unusual. Whereas the metal atoms in practically all known four-coordinate palladium and platinum complexes are square-planar coordinated as a result of the strong ligand-field splitting, the palladium atoms in the title compound show tetrahedral Te coordination. Each of the layers illustrated in Figures 1 and 2 contain two types of tetrahedral voids which are capable of accepting "interstitial" Pd

atoms. The tetrahedral voids A (Fig. 2) are situated between the double chains and are built from the corner- and edge-shared Te atoms of four octahedra. The tetrahedral voids B lie within the double chains; thus, their formation involves the edge-shared Te atoms from three octahedra. The ratio of A to B sites is 1:2. The complete occupation of only the A sites leads to the Ta_2NiQ_5 structure (Q = S, Se),[14] whereas filling both the A and B sites gives the $Ta_2Pd_3Te_5$ structure. The Pd(1) atoms occupy the A, and Pd(2) and Pd(3) occupy the B sites. Consequently, the $Ta_2Pd_3Te_5$ structure can be viewed as a "stuffed" Ta_2NiQ_5 structure. A structure type in which only the B holes are occupied is not known.

The most important differences between the parent and the derivative structures can be summarized: 1) While the Ta atoms in the Ta_2NiQ_5 structure are surrounded by an octahedron of Q atoms, they have only five Te neighbors in the $Ta_2Pd_3Te_5$ structure (the sixth Ta–Te distance, as mentioned earlier, is 4.137(2) Å and should therefore be considered as nonbonding). 2) Conversely, the Ta atoms in the $Ta_2Pd_3Te_5$ structure have five Pd neighbors, whereas in the Ta_2NiQ_5 structure only two Ni neighbors are found. The decrease in the number of Te neighbors is formally compensated for by an increase in the number of adjacent metal atoms.

At present, the Pd coordination cannot be fully explained. Whereas nickel is tetrahedrally coordinated to the chalcogenide ligands in, for example, the Ni analogue $Ta_2Ni_3Te_5$,[15] Ta_2NiQ_5,[14,16] and numerous other complexes,[17] examples exhibiting the coordination geometry found here for Pd are limited to only a few unstable phosphane complexes like $[Pd(PF_3)_4]$[18] and clusters of the type $[Pd_9E_6(PPh_3)_8]$ (E = As, Sb).[19] Moreover, there are no known tetrahedrally coordinated palladium or platinum chalcogenides and halides. Even in related solid-state compounds like $TlPd_2Te_3$[20] or $Ta_4Pd_3Te_{16}$[21] palladium is bound in either square-planar or an octahedral fashion.

As illustrated in Scheme 2, square-planar Pd coordination is energetically preferred, based on ligand field arguments.



Scheme 2. Molecular orbitals of a $PdTe_4$ unit with a square-planar (left) and a tetrahedrally (right) coordinated central atom.

The occurrence of tetrahedral coordination in the present case must therefore be a result of other factors. Scheme 2 shows that each tetrahedral $PdTe_4$ unit does in fact have several metal-centered orbitals which are oriented in such a way as to allow overlap with the 5d orbitals of neighboring tantalum atoms through the shared faces of adjoining $TaTe_6$ octahedra as well as with the 4d orbitals of neighboring Pd atoms over their common tetrahedra edges. The resulting metal–metal interactions are strong.

The calculated[22] density of states (DOS) for $Ta_2Pd_3Te_5$ is illustrated in Figure 3 together with the partial densities for tantalum, palladium, and tellurium (Figs. 3a–c). The mean Ta–Ta, Ta–Pd, and Pd–Pd overlap populations are reproduced as a function of energy in Figure 4. The Fermi level is indicated in both figures by a horizontal line. For comparison, the position of the 4d levels of an isolated palladium atom has also been illustrated in Figure 3b to show that the stabilization of the Pd states is clearly a result of the metal–metal interactions. The formation of metal–metal bonds is also a reason for the tetrahedral coordination of the palladium atoms in the previously mentioned $[Pd_9E_6(PPh_3)_8]$ clusters.[23] Since the Fermi level is found in the region of a finite density of states, $Ta_2Pd_3Te_5$ is expected to have metallic properties. Investigations by photoemission spectroscopy have provided evidence for the metallic character in the corresponding Ni compound $Ta_2Ni_3Te_5$.[24]

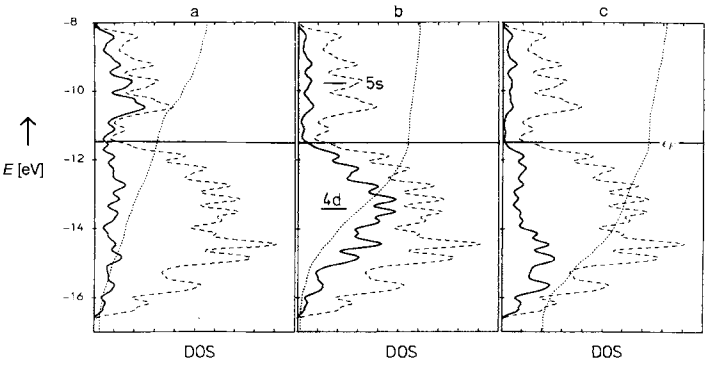


Fig. 3. Density of States (DOS) in $Ta_2Pd_3Te_5$. Dashed lines: total density; solid lines: a) Ta partial density, b) Pd partial density, c) Te partial density; dotted lines: integration curves for the respective partial densities. The Fermi level is marked by a horizontal line.

The COOP (Crystal Orbital Overlap Population) diagrams in Figure 4 further illustrate the significance of the metal–metal interactions to the stability of the structure.

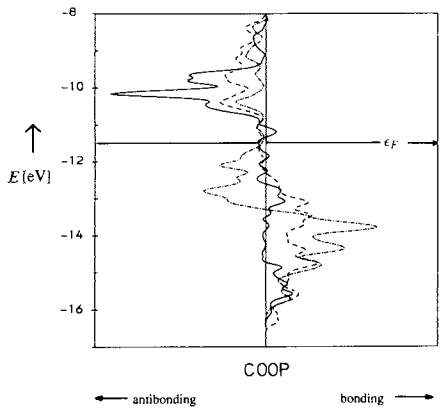

Fig. 4. COOP diagram for $Ta_2Pd_3Te_5$. Solid line: Ta–Ta, dashed line: Pd–Ta (averaged), dot-dashed line: Pd–Pd.

The strong bonding interactions between tantalum and palladium are to be noted first.[25] Interactions between electron-poor and electron-rich transition metals are an important factor for the electronic stability of the structure. It is furthermore remarkable that a large portion of the Pd–Pd antibonding states is occupied. The Pd–Pd interactions should therefore be only weakly bonding, despite the short Pd–Pd distances. In accord with this formulation is the ob-

servation of only a small calculated Pd–Pd overlap population.[25] A structural indication for the existence of Pd–Pd bonding interactions is the fact that the Pd(2) and Pd(3) atoms are not centered in the tetrahedral B sites of the Ta_2NiS_5 parent structure, but instead are displaced from the centers of these tetrahedral voids towards the two respective neighboring Pd atoms. The Ta–Ta interactions are weak, as expected from their large Ta–Ta distances (d_{Ta-Ta}: 3.713 Å).

The reasons for the preferential formation of the "filled-in" Ta_2NiQ_5 structure type with the tellurides are not yet clear. Geometric conditions cannot be the only cause since the respective radius relationships with the sulfides would also allow an occupation of the tetrahedral sites within the layers. A possible argument for the occurrence of the lattice distortions associated with the incorporation of the interstitial atoms as well as for the strong tendency for formation of the "filled-in" structure with the tellurides is the high polarizability of Te^{2-} anions. Thus, lattice distortions should preferentially occur with "soft" lattices.

[12] $Ta_2Pd_3Te_5$: Pure phase samples of thin needle-shaped, metallic lustrous crystals (ca. 0.1 mm long) were prepared by reaction of stoichiometric amounts of the respective elements with the addition of iodine as transport agent (quartz ampule, 1–3 mg cm^{-3}, V = 7–10 cm^3, transport from 850 → 800 °C). In a typical synthesis of $Ta_2Pd_3Te_5$, a quartz ampule (ca. 12 mm diameter) was heated under vacuum, then charged with tantalum powder (0.181 g, 1 mmol), palladium powder (0.160 g, 1.5 mmol), tellurium powder (0.319 g, 2.5 mmol), and an appropriate amount of iodine (ca. 2 mg cm^{-3} ampule volume), and finally flame-sealed. The ampule was then slowly heated to 500 °C in a two-zone furnace, after which time the temperatures in the respective heating zones were raised to 800 and 850 °C. The polarity of the temperature gradient was reversed after one week. Long, flat, metallic lustrous needles were formed on the cooler side of the ampule after an additional two weeks. Energy-dispersive X-ray microanalysis (EDAX): Ta/Pd/Te = 2.13/2.88/4.92.

[23]): Ta–Te (4.137 Å) = –0.017; Pd–Te (2.716 Å) = 0.137; Pd–Te (3.000 Å) = 0.067; Pd–Te (3.059 Å) = 0.063. Additional values for Ta–Ta, Ta–Pd, and Pd–Pd overlap populations: Ta–Ta = 0.051; Ta–Pd(1) = 0.095; Ta–Pd(2,3) = 0.136; Pd(2,3)–Pd(2,3) = 0.072.

Monoclinic and Triclinic Tetraisopropyl-*p*-phenylenediamine: To what Extent do n_N/π Interactions Determine Structures?**

By *Hans Bock,* Ilka Göbel, Christian Näther, Zdenek Havlas, Angelo Gavezzotti,* and *Giuseppe Filippini*

Dedicated to Professor Robert Corriu

The structure of polymorphic modifications of the same compound provide multifaceted information on weak interactions in and between organic molecules.[1] In the following, we report on the serendipitously discovered monoclinic and triclinic crystals of tetraisopropyl-*p*-phenylenediamine,[2] which contain different conformers with and without n_N/π interactions between the nitrogen electron pairs n_N and the benzene π system (Fig. 1. center: dihedral angles $\omega(C_2N-C_6)$ = 28 or 74°).[3, 4]

The molecular structures (Fig. 1 top and center) demonstrate that in the conformer giving monoclinic crystals the axes of the lone pairs on the nitrogen centers deviate from those of the π system perpendicular to the six-membered ring plane by only 28° and thus allow a tenfold stronger n_N/π delocalization [$\cos^2$ (28°) = 0.78] relative to the triclinic one

[**] Structure of charge-perturbed and sterically overcrowded molecules as well as interactions in crystals. Part 30. This research project has been supported by the Deutsche Forschungsgemeinschaft, the state of Hesse, and the Fonds der Chemischen Industrie.—Part 29.: Ref. [4].

with dihedral angles of 74° [$\cos^2(74°) = 0.08$]. The lattice-enforced effects of the diisopropylamino donor substituents cause significant structural changes: the NC_3 pyramids are flattened by 12° to 353°, the NC_{ring} bonds are shortened by 4 pm to 141 pm, and the *ipso* angles at the substituted centers are reduced by 3° to 115°.[5, 6]

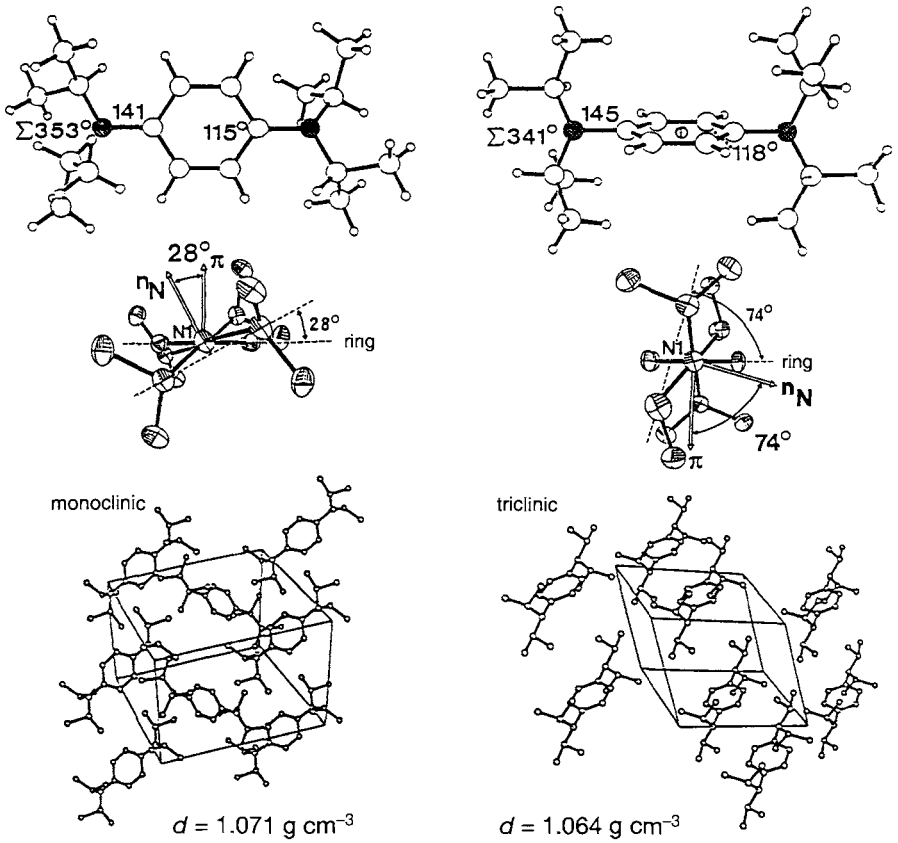

Fig. 1. Top and center: molecular structures of the tetraisopropyl-*p*-phenylenediamine conformers exhibiting skeletal symmetry C_1 and C_i in side and axial view (50% thermal ellipsoids) [3]. Significant differences between the monoclinic and triclinic conformers (bond lengths in pm and angles in °): dihedral angles $\omega(C_2N-C_6)$ 28/74, distances d_{CN} 141/145, angles α_{ipso}(ring) 115/118, and angle sums $\Sigma(\sphericalangle CNC)$ 353/341. Bottom: lattice packing in the polymorphic monoclinic ($P2_1/c$, unit cell with $Z = 4$ in x direction) [3a] and triclinic modifications ($P\bar{1}$, unit cell with $Z = 1$ in x direction and arrangement of the molecule around a crystallographic inversion center) [3b].

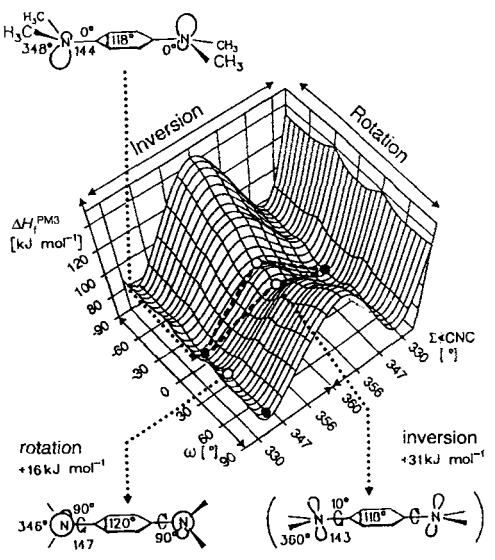
The molecular dynamics has been approached first for the spatially not yet overcrowded tetramethyl derivative by PM3 enthalpy hypersurface calculations (Scheme 1). For an assumed uncoupled rotation and inversion, rotation with a barrier of only 16 kJ mol^{-1} should be favored and, therefore, activated at room temperature (o: transition states). The enthalpy surface for the tetramethyl derivative (Scheme 1) reproduces all structural trends observed for the tetraisopropyl-*p*-phenylendiamine conformers (Fig. 1 top and center): the n_N/π delocalization, which sets in with the decrease of the dihedral angle $\omega = 90° \rightarrow 0°$, flattens the NC_3 pyramids, shortens the NC_{ring} bonds, and reduces the *ipso* ring angles.

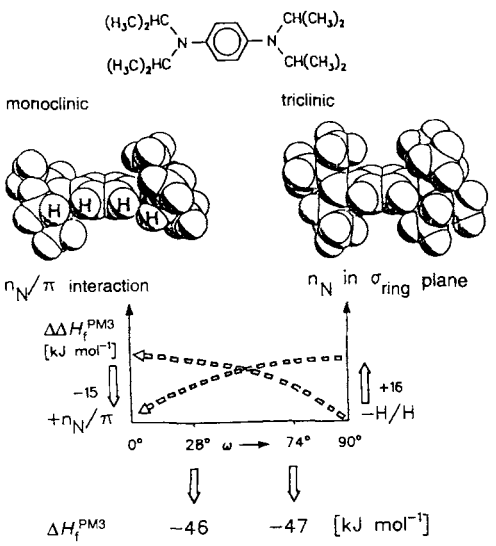


Scheme 1.

According to analogous PM3 calculations, in tetraisopropyl-*p*-phenylendiamine a complete rotation of the bulky $[(H_3C)_2HC]_2N$ substituents around the NC_{ring} bonds is no longer possible because of steric hindrance from the *ortho* ring hydrogens (van der Waals radius $r_H^{vdW} \approx 120$ pm[6]) without deformation of the isopropyl groups, which can be calculated on geometry optimization. An analysis of the wave functions for the resulting conformer set[7] shows that the maximum possible stabilization by n_N/π delocalization of about -15 kJ mol^{-1} at a dihedral angle of $\omega = 0°$ is compensated on increased twisting of ω to 90° by a fourfold H/H repulsion of a total of up to 16 kJ mol^{-1} (Scheme 2). This is in accord with the almost identical enthalpies of formation for the rather different monoclinic and triclinic crystalline conformers of tetraisopropyl-*p*-phenylenediamine, $\Delta H_f^{PM3} = -46$ and -47 kJ mol^{-1} (Scheme 2), calculated based on the experimental molecular structure data (Fig. 1).

The repulsive H/H interactions are in accord with the crystal structure data for both polymorphs (Fig. 1 top and center): In the monoclinic modification, the shortest intramolecular H···H distances amount to only 200 and 221 pm (rest > 323 pm) in contrast to 254 and 296 pm (rest > 359 pm) in the triclinic one. The almost identical en-

thalpies of formation, ΔH_f^{PM3} are in addition an essential precondition for the crystallization of polymorphic modifications, the lattice energies of which usually differ only by $< 20\ kJ\ mol^{-1}$.[1a, b, f]



Scheme 2.

The lattice energies of nondisordered polymorphic modifications, according to an often successfully tested empirical rule,[8] can be correlated with their crystallographically determined densities. Therefore, the monoclinic crystals grown by sublimation with $\varrho = 1.071\ g\,cm^{-3}$[3a] should possess a more negative lattice energy that the triclinic ones crystallized from petroleum ether solution $\varrho = 1.064\ g\,cm^{-3}$.[3b] In the monoclinic crystal, the n_N/π interacting conformers are packed crosswise with shortest intermolecular H···H distances of 242 pm (Fig. 1 bottom left), whereas in the triclinic crystal the n_N/σ-planarized ones are stacked perpendicularly to the aligned molecular long axes with shortest intermolecular H···H distances of 240 pm (Fig. 1 bottom right). Because their difference in densities of only 0.7% borders on the precision of measurement, in addition total lattice energies have been calculated by the atom/atom potential approximation[9a] from a parameter set[9b] that recently has been optimized for a large data base of organic molecular crystals, by using either the crystallographically determined torsion angles of all methyl groups or by imposing a constant value of 60°.[10] The two resulting lattice (sublimation) energies for each of the modifications of tetraisopropyl-*p*-phenylenediamine are -115.5 or $-114.7\ kJ\,mol^{-1}$ (monoclinic) and -108.8 or $-109.4\ kJ\,mol^{-1}$ (triclinic) and indicate that, as inferred from the rather small density difference, the monoclinic modification should always be the thermodynamically more stable one, irrespective of the selected methyl group torsion angles.

The monoclinic crystals have been grown by slow vacuum sublimation of the triclinic melt over a period of about one week,[3a] whereas the triclinic ones crystallize "in a flash" (within a few minutes) from the saturated petroleum ether solution. The band pattern at low ionization energies in the photoelectron spectrum[2] and its agreement with the superposed PM 3 eigenvalue sequences for the different tetraisopropyl-*p*-phenylenediamine conformers exhibiting comparable PM 3 enthalpies of formation (Scheme 2) suggests a rotamer mixture in the gas phase as well as in solution at room temperature. Possibly, therefore, the thermodynamically based Oswald's step rule[11] should be supplemented—if surface effects could be excluded in the growth of the monoclinic crystals by vacuum sublimation—with a kinetic component: The monoclinic modification, which is more stable according to both its density and the lattice energy calculation, must have been formed by slow crystallization from the gaseous rotamer mixture and the somewhat less favored triclinic one possibly by a kinetically controlled rapid growth from solution. This speculative assumption further illustrates the subtle energy balance that enables the isolation of two rather dissimilar conformers of tetraisopropyl-*p*-phenylenediamine by crystallization in different local total energy minima.

[2] I. Göbel, Ph.D. thesis, University of Frankfurt, **1993**; contains all details of the investigations: Tetraisopropyl-*p*-phenylenediamine was prepared by heating of *p*-phenylenediamine with a threefold excess of 2,2-dimethoxypropane in acetone/acetic acid in presence of Pt_x/Al_2O_3 under a pressure of 100 bar H_2 in an autoclave (A. Gaydash, J. T. Arrigo, US-A 3 234 281, **1966**; *Chem. Abstr.* **1966**, *64*, 11 125 h). Fractional distillation at 10^{-2} mbar yielded about 20% yield of a yellow oil from which at 277 K a clorless solid with m.p. 308 K crystallized (correct elemental analysis; ^1H NMR ($DCCl_3$, TMS) δ: 1.09–1.20 (d, 24H), 3.4–3.9 (m, 4H); *m/e* = 276 (M^+), 261 ($M^+ - CH_3$), 246 ($M^+ - 2CH_3$), 233 ($M^+ - CH(CH_3)_2$), 218 ($M^+ - CH_3 - CH(CH_3)_2$, 203 ($M^+ - 2CH_3 - CH(CH_3)_2$). Crystal growth: 200 mg was dissolved in 5 mL petroleum ether at 20 °C, the solvent evaporated at 20 °C and 10^{-2} mbar until crystallization began, and the oily solution kept in a refrigerator at 277 K. Under petroleum ether the triclinic modification crystallized. After evaporation almost to dryness, the monoclinic modification recrystallized at the glass wall, but it can be better synthesized by sublimation of a melt of the triclinic modification at 10^{-2} mbar to a cooler glass wall. All crystalline products were characterized by an X-ray determination of the unit cell; the polymorphic modifications were unexpectedly discovered on selection of crystals with an optimum reflection profile from different crystallizations. Differential scanning calorimetry investigations of the polymorphic modifications by slow warming (1 K/min) of a melt at 110 K to 320 K did not indicate any solid phase transitions. Investigations with photoelectron spectroscopy in the gas phase [4] showed two broad ionization bands between 6 and 9.4 eV; the peak of the first one begins at 6.6 eV, increases slowly to the maximum at 7.83 eV and dros steeply to 8.1 eV; that of the second one increases steeply from 8.2 eV to a double maximum at 8.64 and 8.92 eV and then drops slowly to about 9.6 eV. Band analysis based on MNDO eigenvalue correlation suggests the assignmet $(n_N\text{-}\pi_s) < \pi_{as} < (\pi_s\text{-}n_N)$ and can be rationalized by assuming different propotions of the doubly twisted (dihedral angle $\omega(C_2N\text{–}C_6) \approx 80°$, $\Delta IE_{1,2} \approx 0.8$ eV), the singly twisted ($\omega_1 \approx 80°$, $\omega_2 \approx 10°$, $\Delta IE_{1,2} \approx 2$ eV), and the planarized ($\omega \approx 10°$, $\Delta IE_{1,2} \approx 2{,}9$ eV) conformers in a mixture.

Structure

solution by direct method and difference Fourier technique (SHELXTL-Plus); $R = 0.0474$, $R_w = 0.0435$ for 310 parameters, $w = 1/(\sigma^2(F) + 0.0003F^2)$; GOF: 4.616, shift/error < 0.001; extinction correction, residual electron density: +0.23/−0.21 $e_o/Å^3$. All C and N atoms are anisotropically refined, all H atoms are unconditionally refined with isotropic temperature factors. b) Triclinic modification: $a = 698.2(2)$, $b = 746.3(2)$, $c = 970.5(4)$ pm, $\alpha = 70.77(2)$, $\beta = 87.25(2)$, $\gamma = 65.35(2)°$, $V = 431.58 \times 10^6$ pm^3 (150 K), $Z = 1$, $\varrho_{calcd} = 1.064$ g cm^{-3}, $\mu = 0.06$ mm^{-1}, triclinic, space group $P\bar{1}$ (no. 2), Siemens-AED four-circle diffractometer, $Mo_{K\alpha}$ radiation, 2550 measured reflections within $3° < 2\theta < 55°$, of which 1983 are independet and 1950 with $I > 0.5\,\sigma(I)$, $R_{int} = 0.0143$. Structure solution with direct methods and difference Fourier technique (SHELXTL-Plus); $R = 0.0432$, $R_w = 0.0451$ for 156 parameters, $w = 1/(\sigma^2(F) + 0.00002F^2)$; GOF: 4.93, shift/error < 0.001; extinction corrections; residual electron density: +0.27/−0.21 $e_o/Å^3$. All C and N atoms anisotropically, all H atoms unconditionally refined with isotropic temperature factors. The molecule is centered at a crystallographic inversion center. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57768, the names of the authors and the journal citation.

[4] Additional investigations on conformers of *p*-phenylenediamine derivatives that like the benzylidenanilines [1a, 3] exhibit two energetically favored rotational degrees of freedom around both of the $N-C_{ring}$ bonds concern inter alia *N,N'*-bis(trimethylsily)- and tetrakis(trimethylsily)phenylenediamines (H. Bock, J. Meuret, C. Näther, *Tetrahedron Lett.* **1993**, *34*, in press.). The tetrasubstituted molecule can be reduced in ether solution to its blue radical anion(!)—in addition to the usual oxidation to Wurster's Blue radical cation (F. Gerson, U. Krynitz, H. Bock, *Angew. Chem.* **1969**, *81*, 786, *Angew. Chem. Int. Ed. Engl.* **1969**, *8*, 767). This surprising discovery can be rationalized from the different band patterns at low ionization energies of PE spectra and their assignment by Koopman's correlation with eigenvalues from geometry-optimized AM1 calculations, by assuming that the disubstituted derivative must possess an approximately planar skeleton $SiN-C_6H_4-NSi$, whereas the tetrasubstituted one should exhibit dihedral angles $\omega(Si_2N-C_6) \approx 90°$. Single crystal structures confirm the gas phase measurements: contrary to the situation in the largely planar *N,N'*-substituted derivative, the steric overcrowding by four bulky $(H_3C)_3Si$ substituents causes the H/H repulsion from the *ortho*-ring hydrogens to exceed the stabilizing n_N/π interactions, which results in a dihedral angle $\omega(Si_2N-C_6) = 83°$.

[7] The PM 3 potential energy surface calculations (J. J. P. Stewart, *J. Comput. Chem.*, **1989**, *10*, 209, 221) have been performed based on the experimental structural data [3] and partly geometry optimized (tetramethyl derivative) using the program version MOPAC 6.0/QCPE no. 455 with an IBM RISC 6000/320. Additional data (cf. Scheme 1): Inversion transition state $\Delta H_f^{PM3} = 104$ kJ mol^{-1}, $d_{CN} = 147$, $d_{CC} = 138$, 140 pm, $\sphericalangle CCC = 121°$; conformer ($\omega = 0°$) $\Delta H_f^{PM3} = 73$ kJ mol^{-1}, $d_{CN} = 148$, $d_{CC} = 139$, 140 pm, $\sphericalangle CCC = 121°$; conformer ($w = 90°$) $\Delta H_f^{PM3} = 87$ kJ mol^{-1}, $d_{CN} = 149$, $d_{CC} = 139$, 140 pm, $\sphericalangle CCC = 120°$. Estimate of the H···H repulsion between isopropyl groups and H_{ortho} (cf. Scheme 2): $\Delta\Delta H_f^{PM3}$ (kJ mol^{-1})/$d_{H\cdots H}$ (pm): 0/277, 1/250, 2.5/222, 6/195, 9.5/170, 22/149, 36/135.

[8] Cf., for example, I. Bar, J. Bernstein, *J. Phys. Chem.* **1984**, *88*, 243 and references therein.

[9] a) Summary/Survey: A. J. Pertsin, A. I. Kitaigorodsky, *The Atom-Atom Potential Method*, Springer, Berlin, **1987**; b) G. Filippini, A. Gavezzotti, *Acta Crystallogr. Sect. B* **1993**, *49*, 868 (optimized parameter set for approximate atom/atom-potential calculations of lattice (sublimation) energies).

[10] The H positions were readjusted by setting all CH bond lengths to 108 pm and, partly, by inserting torsional angles of 60° for all methyl groups. The potential is defined as an intermolecular one, and no corrections for the intramolecular energy differences have been made. Additional lattice vibration calculations yielded reasonable lattice vibration frequencies.

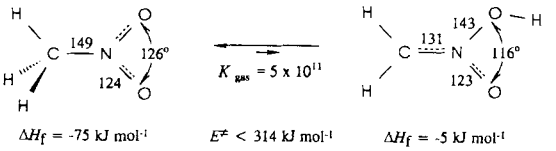
aci-Nitrodiphenylmethane: A Hydrogen-Bonded Dimer**

By *Hans Bock**, *Rüdiger Dienelt*, *Holger Schödel*, *Zdenek Havlas*, *Eberhardt Herdtweck*, and *Wolfgang A. Herrmann*

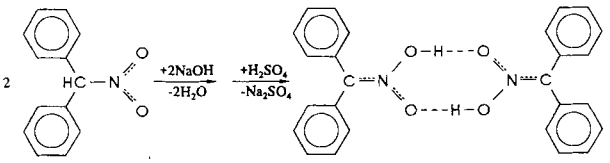
Dedicated to Professor Helmut Schwarz on the occasion of his 50th birthday

A recent report[2] offered a summary on the nitro ⇄ *aci*-nitro tautomerism for prototype nitromethane as well as predictions from highly correlated calculations, which largely reproduce the known experimental data sketched in Scheme 1.



Scheme 1.

The thermally forbidden[1, 3] H transfer has a prohibitively high barrier $E^{\neq}$, and a gas-phase equilibrium constant of 5×10^{11}, which can be estimated from the difference in the enthalpies of formation $\Delta\Delta H_f$ of 70 kJ mol^{-1}, overwhelmingly favors the nitro tautomer.[2] The tautomerization should predominantly shorten the CN bond length and close the ONO angle. However, consideration of potential aggregation through hydrogen bonding, which was previously neglected, as well as a CSD search that revealed that the compounds containing *C*-phenyl and *C,C*-diphenyl-*O*-(*t*-butyl)dimethylsilyl groups are the only structurally characterized covalent *aci*-nitromethane derivatives prompted further investigations.[3] We now report on the successful crystal growth[4] of the title compound, prepared from nitrodiphenylmethane (Scheme 2) and characterized by structure determination at both 163 and 238 K[5] (Fig. 1).



Scheme 2.

The *aci*-nitrodiphenylmethane dimers are packed perfectly in the crystal lattice (Fig. 1 top). Obviously, this is favored by the chair conformation of the H-bonded eight-membered

[**] Interactions in Molecular Crystals, Part 33. This research project has been supported by the Deutsche Forschungsgemeinschaft, the State of Hesse, the Fonds der Chemischen Industrie, and the A. Messer Foundation. Part 32: Ref. [1].

ring $N(OHO)_2N$, exhibiting fold angles of 40° through the oxygen centers of the planar nitro groups. Accordingly, the phenyl rings in their Y-shaped arrangement stacked with parallel axes are packed so close that the distance between their centroids is about 500 pm. At this distance substantial, attractive $>CH\cdots\pi$ interactions are evident, for instance, in the folding of phenyl group containing proteins[6a] or in the "herringbone"-motif of crystallization of unsaturated six-membered ring hydrocarbons.[6b]

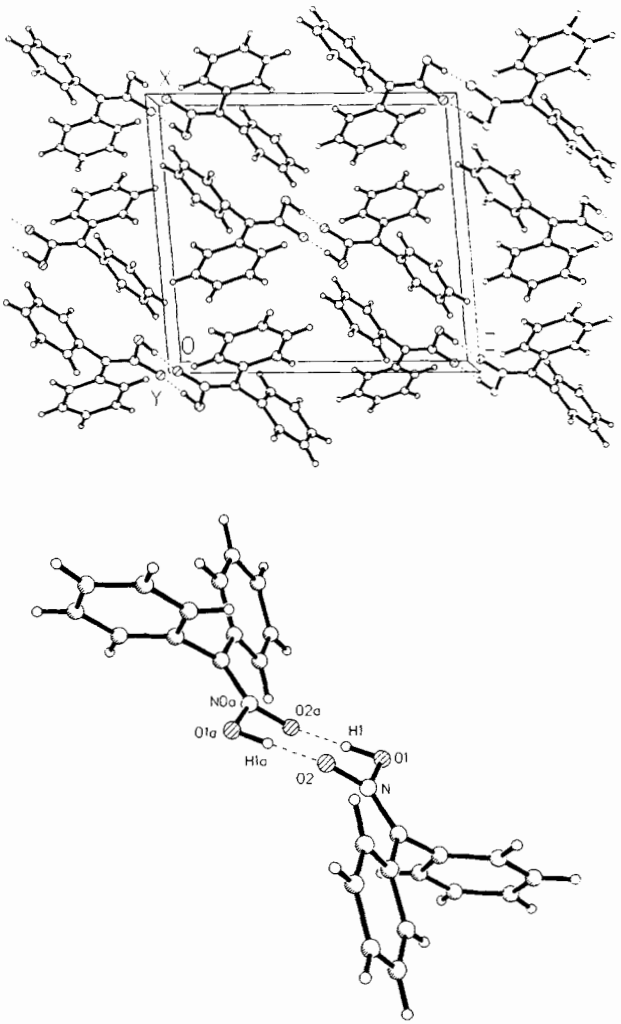

Fig. 1. Single crystal structure of the *aci*-nitrodiphenylmethane dimer at 163 K. Top: unit cell (monoclinic, $Z = 4$, $\varrho_{calc} = 1.324\ g\,cm^{-3}$) viewed along the y direction. Bottom: side view of the chair conformation of the H-bonded pair. Essential distances (pm) and angles (°): C···N 130, N···O 138, O–H 97, O(H)···O 261, C···N···O 127, C···N–O 118, O···N–O 115, O(H)O 172, φ(CC–CN) 24° and 67°, $\tilde{\omega}$ ($C_2C=NO_2$) 4°.

The hydrogen bonds are relatively short (261 pm between the O centers),[7] unsymmetrical (uncorrected distances O–H 97 pm and O···H 164 pm) and slightly bent (172°) (Fig. 1). The NO distances, ···N···O···(H) and ···N–O(H) of 130 and 138 pm are different as expected and comparable to those in the *C,C*-diphenyl-*O*-trialkylsilyl derivative (127 and 140 pm) and in part considerably stretched relative to nitroalkanes (*aci*-nitromethane:[2] N···O 123 pm). Moreover, the ONO angles are reduced by 10° as predicted in Scheme 1. The largest change (more than 20 pm) is observed for the bond shortening C–N → C···N (Scheme 1 and [3]), which accompanies the planarization of the tetrahedral methane C center.

Additional ab initio calculations (cf. Scheme 1) with a uniform 6-31G** basis set[8] have been performed on the *aci*-nitromethane tautomers (Fig. 2). Geometry optimization yields a total energy minimum structure[8] for the dimer with a doubly folded eight-membered ring $N(OHO)_2N$, which agrees satisfactorily with the experimental structure determined for the diphenyl derivative (Fig. 1 bottom). A rather small enthalpy difference of only 0.4 kJ mol^{-1} is calculated for the folding of the H-bonded ring at the O···O axes by 30°, which deviates from the usual planar arrangements in carbonic acid dimers $C(OHO)_2C$.[7] The chair conformation $N(OHO)_2N$, therefore, should be predominantly determined by the CH···π interactions between the phenyl rings in the monoclinic lattice[6] (Fig. 1 top). The H-bonded pair $N(OHO)_2N$ can be rationalized by a symmetrical double minimum potential[8] with a barrier of only 12 kJ mol^{-1} (Fig. 2). The cooperative effect on its formation, $2\,OH\cdots O \rightarrow (OH\cdots O)_2$, should amount to a considerable 40% according to the PM3 enthalpy difference of $\Delta\Delta H_f = 2(-11) - (-36) = 14$ kJ mol^{-1}, and therefore play an essential role in the stabilization of the *aci*-dimer relative to nitromethane by a total of $2 \times 71 - 73 = 69$ kJ mol^{-1} (Fig. 2).

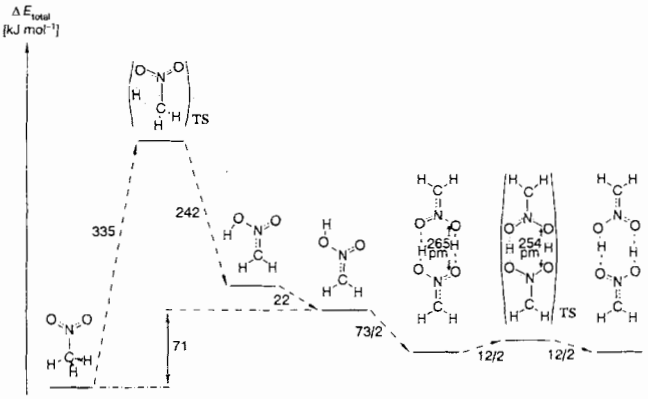

Fig. 2. Ab initio energy profile for the tautomerization of nitromethane to *anti*- and *syn-aci*-nitromethane and its H-bonded dimer.

The extremely high tautomerization barrier of the ab initio energy profile (Fig. 2) also demonstrates, why *aci*-nitro compounds can be obtained, in general, only by acidification of their salts (Scheme 2). The *aci*-nitrodiphenylmethane dimer prepared this way is also a remarkable example both for the stabilization of a thermodynamically unfavorable tautomer by H-bonded pairs,[9] as well as for molecular self-organization by their cooperative effect.[1]

Experimental Procedure[4]

Sodium methyldiphenylnitronate: 65% HNO_3 (20 mL), H_2O (80 mL), and diphenylmethane (20 mL, 0.12 mol) were mixed in a 250 mL flask and heated for 15 h at 108 °C under reflux. After cooling, the reaction solution was extracted with diethyl ether (3 × 50 mL). The combined ether phase was washed three times with H_2O (20 mL portions), cooled to 0 °C after separating from the aqueous layer, and poured slowly into a stirred solution of 33% NaOH (50 mL) cooled at 0 °C. During the strongly exothermic reaction a white amorphous precipitate formed, was filtered off, washed three times with *n*-hexane, and dried at 10^{-2} mbar; yield 20.04 g (53.6 mmol, 78%); ^1H NMR (D_2O): $\delta = 7.3-7.5$ (m,H).

aci-Nitrodiphenylmethane: Sodium methyldiphenylnitronate (0.5 g, 2.1 mmol) was dissolved in H_2O (25 mL), cooled with ice, and acidified while stirring with

5% H_2SO_4 to pH 2. The white solid with a pink luster, which precipitated immediately was filtered off at 10 mbar, washed three times with 25 mL portions of ice water, three times with 25 mL portions of *n*-hexane, and dried for 3 h at 5×10^{-3} mbar. Yield: 0.25 g (1.2 mmol, 57%). M.p. 93 °C (decomp.). ^{1}H NMR [$(D_5C_2)_2O$]: $\delta = 7.2-7.6$ (m, 10H), 4.35 (s, OHO). IR(film): $\nu = 3400\ cm^{-1}$ (hydrogen bonds), $3000\ cm^{-1}$ (C–H), $1650\ cm^{-1}$ (C=N), 1550, $1450\ cm^{-1}$ (C=C), $1300\ cm^{-1}$ (C=N). Single crystal growth: *aci*-Nitrodiphenylmethane, precipitated by acidification of the nitronate, was dissolved in diethyl ether (20 mL) and dried at 273 K by stirring for 2 h with Na_2SO_4. After filtration, the ether solution was concentrated at 273 K by slow evaporation until colorless plates crystallized, which have to be stored at 0 °C under argon and aprotic ($c_{H_2O} < 1$ ppm) *n*-hexane because of their temperature- and moisture-sensitivity.

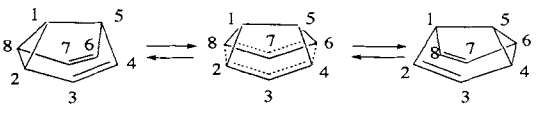
Elimination of the Barrier to Cope Rearrangement in Semibullvalene by Li^+ Complexation**

By *Haijun Jiao* and *Paul von Ragué Schleyer**

Substituents that reduce or eliminate the already quite small barrier to valence isomerization (Cope rearrangement) in semibullvalene have been sought in many theoretical[1] and experimental[2] studies. Based on extended Hückel calculations, Hoffmann et al.[1a] predicted that the barrier can be lowered by π-donor substituents at C1,5 and π-acceptors at C2,4,6,8. Similar conclusions were reached both by Dewar et al.[1b,c] and by Dannenberg et al.,[1d] who employed semiempirical methods (MINDO/2, AM1, and MNDO-CI). The transition state for the rearrangement might even be stabilized by substituents to such an extent that the "bishomoaromatic" symmetric structure **1b** would become more stable than the classical structure **1a**!



The isomerization barriers of many substituted semibullvalenes have now been measured using dynamic ^{13}C NMR spectroscopy,[2] particularly by Quast et al. The lowest measured barrier is approximately 4.5 kcal mol^{-1} for 1,5-dimethylsemibullvalene, but the barrier actually increases with some substituents, for example, to roughly 10 kcal mol^{-1} for 3,7-dicyano-2,6-dimethoxy-1,5-dimethylsemibullvalene. We now describe a new strategy which might eliminate the barrier to the Cope rearrangement in semibullvalene. According to ab initio calculations, complexation of a Li^+ ion stabilizes **1b** more effectively than **1a**. The evidence from our computations establishes that the transition state **1b** does have bishomoaromatic character.

Geometries were fully optimized first at the RHF/6-31G* level using the Gaussian 92 program package.[3] The stationary points were characterized as minima or saddle points by calculation of the vibrational frequencies. The geometries

C4-C6	0.046	0.368	0.093	0.370

[a] RMP2(full)/6-31G* geometries were used.

Possible mechanisms of the prototypical degenerate Cope rearrangement in 1,5-hexadiene have been investigated experimentally[2, 8] and theoretically.[1, 9–11] Because of the constrictions of the polycyclic structure, the Cope rearrangement in semibullvalene must take place via a boatlike transition state. This is facilitated by the proximity of C4 and C6.

The RMP2(full)/6-31G* optimized structural parameters for C_s semibullvalene **1a** are shown in Figure 1. The optimized bond lengths agree with those obtained by electron diffraction (values given in parentheses in Fig. 1, top[12]). The elongation of the C2–C8 bond (to ca. 1.60 Å) is noteworthy. The Wiberg bond orders for **1a** (Table 3) indicate a largely localized structure, except for the C2–C8 bond.

Transition structure **1b** (C_{2v}, Fig. 1 bottom) has one imaginary frequency (− 606 cm^{-1}). The calculated activation enthalpies, 5.2 kcal mol^{-1} at RMP2(full)/6-31G* and 4.1 kcal mol^{-1} with the RHF/6-31G* zero-point energy correction, agree well with the measured value of 4.8 ± 0.2 kcal mol^{-1}.[2] The separation of 2.036 Å and bond order of 0.368 for C2–C8 and C4–C6 in **1b** show that this transition structure may indeed be designated as homoconjugated.[1] The bond orders of 1.453 and bond lengths of 1.391 Å for the delocalized, allyl-like bonds in **1b** are close to those in the allyl radical, anion, and cation as well as in benzene and many homoaromatic systems.[13]

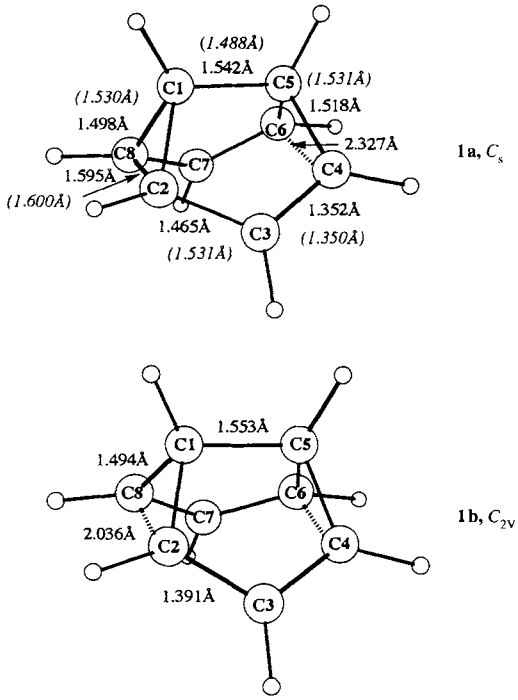

Fig. 1. The RMP2(full)/6-31G* optimized structures for the ground state of semibullvalene **1a** and the rearrangement transition state **1b**.

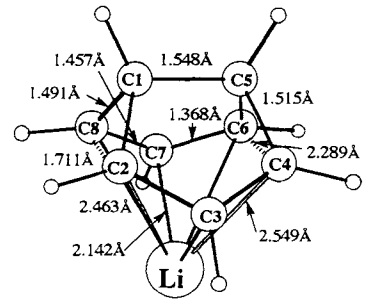
The effects of Li^+ complexation of **1a** and **1b** are remarkable! Although the C_s-symmetric structure **2a** (MP2(full)/6-31G*) (Fig. 2 top) is a minimum, the C_{2v} structure **2b** (Fig. 2 bottom) is only 0.1 kcal mol^{-1} less stable at this level! The C2–C8 bond length in **2a** increases to 1.711 Å (from 1.595 Å in **1a**); the corresponding bond orders, 0.790 in **2a** and 0.875 in **1a**, reflect this difference. The changes due to Li^+ complexation in the lengths of the other C–C bonds involved in the rearrangement of **1a** are smaller, but also point to the more delocalized character of the electron system of **2a**. C3,7 and C2,8 are more negatively charged and C4,6 more positive in **2a** than in **1a**. Li^+ complexation polarizes **2a** and results in a partially delocalized structure.

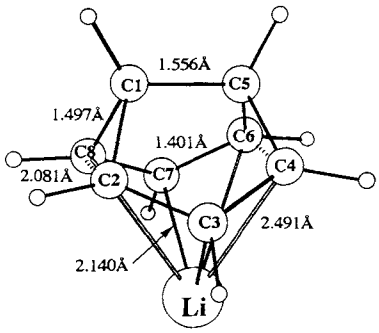
The C–C bond orders in the Li^+ complexed transition structure **2b** are nearly the same as in **1b**. The Li^+ ion has a charge of 0.959 in **2a** and 0.947 in **2b**. The binding of Li^+ is largely electrostatic and involves polarization of the π-electron systems. The Li^+ complexation energies for **2a** and **2b**, −47.6 and −52.7 kcal mol^{-1}, respectively, are even somewhat larger than that for benzene (− 44.8 kcal mol^{-1}, RMP2(full)/6-31G*). (This is due to the shorter Li–C3,7

distances in **2a** and **2b** than the corresponding distance in the Li^+–benzene complex (2.371 Å)).

Note that Li^+ complexes the transition state **1b** to a greater extent than semibullvalene **1a**. This essentially eliminates the activation barrier even before correction for the zero-point energies. When this ZPE correction is applied, the computed energy for **2b** at 0 K is 0.7 kcal mol^{-1} lower than for **2a**![14] The bishomoaromatic **2b** is indicated to be more stable than **2a** (Table 1). This result, which has long been sought by the introduction of substituents, is achieved by Li^+ complexation (at least at the level of theory employed here).



2a, C_s



2b, C_{2v}

Fig. 2. The RMP2(full)/6-31G* optimized structures for the Li^+ complexes **2a** and **2b**.

The presence of a Li^+ ion in **2a** and **2b** affords a means of assessing the "aromaticity" of these species. Normally, lithium NMR chemical shifts have a small range (δ = ca. ± 2 relative to the standard) $\delta(Li^+)$ used as a reference in calculations). The most conspicuous experimental exceptions have been noted for lithium cyclopentadienide and its derivatives, as well as Li^+ π-complexed aromatic compounds.[15] The large shieldings observed are attributed to ring current effects (although this conclusion may be premature). IGLO chemical shift computations provide a convenient means of assessing the influence of various complexed π systems on Li NMR chemical shifts. It does appear from the data gathered in Table 4 that $\delta(Li^+)$ can be employed as an aromaticity probe.

The homoaromaticity of **2b** and the partial homoaromaticity in **2a** are indicated by the upfield chemical shifts, $\delta(Li^+) = -10.8$ and -5.7, respectively [$\sigma(Li^+) = 95.4$, $\sigma(Li^+[\mathbf{2b}] = 106.2$ and $\sigma(Li^+[\mathbf{2a}]) = 101.1$, IGLO/DZ//RMP2(full)/6-31G*]. For comparison, the computed Li NMR shifts are $\delta = -7.4$ for the C_{6v} Li^+–benzene complex, -6.9 for cyclopentadienyllithium, and -10.8 for the biscyclopentadienyllithium anion.[15] In contrast, the influence on $\delta(Li^+)$ by complexation with ethene, ethyne, and even allyl anion is much less, and the antiaromatic cyclobutadiene produces a downfield shift (Table 4).

Table 4. Absolute lithium shielding constants (σ) and chemical shifts (δ, relative to $Li^+ \equiv 0.0$) calculated by the IGLO method (IGLO/DZ//RMP2(full)/6-31G*) [a].

Complex	Point group	σ	δ
Li^+	K_h	95.4	0.0
Li^+–C_4H_4 (cyclobutadiene)	C_{2v}	92.3	+3.1
Li^+–$C_3H_5^-$ (allyl anion)	C_s	95.5	−0.1
Li^+–C_4H_6 (*cis*-1,3-butadiene)	C_s	96.9	−1.5
Li^+–HC≡CH	C_{2v}	97.2	−1.8
Li^+–H_2C=CH_2	C_{2v}	97.3	−1.9
2a	C_s	101.1	−5.7
Li^+–$C_5H_5^-$ (Cp^-)	C_{5v}	102.3	−6.9 [b]
Li^+ C_6H_6 (benzene)	C_{6v}	102.8	−7.4
2b	C_{2v}	106.2	−10.8
$LiCp_2^-$	D_{5d}	106.2	−10.8 [b]

[a] For additional data see ref. [5c]. [b] See ref. [15].

The very low activation enthalpy of 4.1 kcal mol^{-1} [RMP2(full)/6-31G* + ZPE(RHF/6-31G*)] for the degenerate Cope rearrangement of semibullvalene can be eliminated by Li^+ complexation. The C_{2v} delocalized bishomoaromatic structure **2b** is computed to be slightly more stable than the unsymmetrical form **2a**, but even the latter shows pronounced delocalization. The Li^+ ion stabilizes the more polarizable C_{2v} transition state to a greater extent than the C_s. We find such electrostatic acceleration of electrocyclic process to be general, and will report further examples subsequently. The aromaticity of **2b** is reflected by its geometry and population analysis, as well as the upfield chemical shift of Li^+ due to ring current effects. The partial delocalization of **2a** also is apparent from the same criteria.

A Detailed Theoretical Analysis of the 1,7-Sigmatropic Hydrogen Shift: The Möbius Character of the Eight-Electron Transition Structure**

By *Haijun Jiao* and *Paul von Ragué Schleyer**

While the [1,5] sigmatropic hydrogen shift in a polyene is, according to the Woodward–Hoffmann rules, a thermally favored suprafacial isomerization involving six electrons, the eight-electron [1,7] hydrogen shift is an antarafacial sigmatropic rearrangement with a Möbius topology.[1] The first observed [1,7] H shift was the rearrangement of calciferol to precalciferol.[2] Theoretical studies of the [1,7] H shift[1b,3] have been less detailed than those for the [1,5] H shift.[1b,4,5] The first ab initio calculation of the [1,7] H shift was carried out by B. Hess et al.[3] with the 3-21G basis set. The transision state was found to have C_2 symmetry, but the computed activation energy of 44 kcal mol^{-1} was much higher than the experimentally observed values (ca. 15–20 kcal mol^{-1}).[6]

A direct kinetic investigation of the [1,7] H shift in the parent 1,3,5-heptatriene **1** was reported only recently by Y. N. Bubnov et al.[7] As the process is too slow to be measured by NMR line shape analysis, the rates of site exchange in a deuterium-labeled compound were determined by ^{2}H NMR spectroscopy over a temperature range of 75–116 °C. The rate constant was described by the Arrhenius equation: $k_H = 1.6 \times 10^8 \exp[-(20.8 \pm 0.7)\,\text{kcal mol}^{-1}/RT]\,\text{s}^{-1}$. The Russian group noted that both the activation energy and the frequency factor were lower than those measured for [1,5] H shifts ($E_a = 24.3 \pm 0.5$ kcal mol^{-1} and $A = 1.3 \times 10^{12}$ s^{-1} for cyclopentadiene; $E_a = 35.6 \pm 0.5$ kcal mol^{-1} and $A = 2.8 \times 10^{11}$ for 1,3-pentadiene).[8]

We now provide a detailed theoretical analysis of the [1,7] H shift prototype in 1,3,5-heptatriene **1**. Ground and transition state geometries of 1,3,5-heptatriene, **1** and **2**, respectively (Fig. 1), were fully optimized first at the RHF/6-31G* and then at the correlated RMP2(full)/6-31G* levels employing the Gaussian 92 program package.[9] RHF/6-31G*

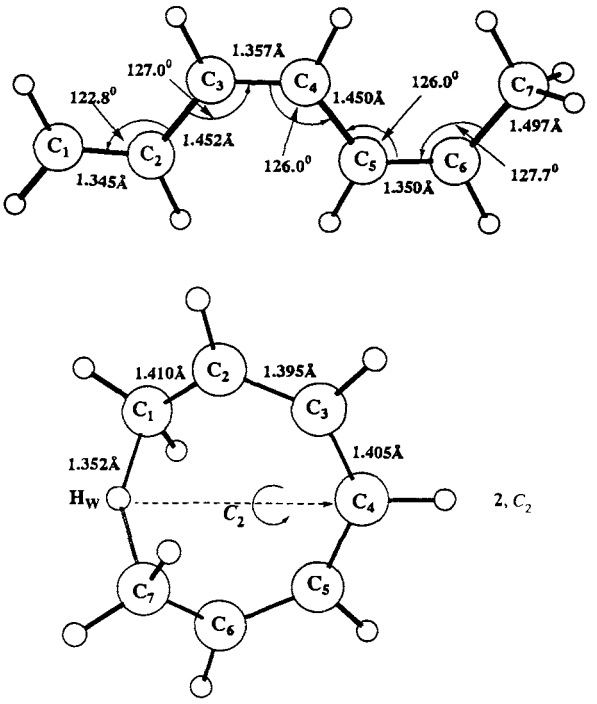

Fig. 1. The RMP2(full)/6-31G* optimized ground state structure of (*Z*,*Z*)-1,3,5-heptatriene (**1**, top) and the 1,7 H shift transition structure **2** (bottom).

frequency calculations established the nature of each stationary point and provided the thermochemical data, for example, the thermal energies E_{Th} (including zero-point energy, vibrational, transitional, and rotational energies) and entropies. The final activation enthalpy ($\Delta H^{\neq}$) and the activation energy ($E_a = \Delta H^{\neq} + RT$)[10] were computed at the RMP2(full)/6-31G* level by addition of ΔE_{Th} (RHF/6-31G*) scaled by 0.89 at 400 K[11] (Table 1).

Table 1. Experimental [7] and calculated [a] activation parameters for the [1,7] H shift in (*Z*,*Z*)-1,3-5-heptatriene (**1**) at 400 K, and for the [1,5] H shift in cyclopentadiene (CPD) and 1,3-pentadiene (PD) (measured values in parentheses).

	E_a [kcal mol^{-1}] [b]	A [c]	$\Delta S^{\neq}$ [d]
1,7 shift in **1**	19.7 (20.8 ± 0.7)	97.7×10^8 (1.6×10^8)	−13.4 (−21.6)
1,5 shift in CPD [e]	25.2 (24.3 ± 0.5)	7.9×10^{12} (1.3×10^{12})	−0.2 (−3.3)
1,5 shift in PD [e]	35.4 (36.3 ± 10^{11})	1.6×10^{11} (2.8×10^{11})	−8.4 (−7.1)

[a] Total energies [a.u.] for the ground state (**1**), −271.76233; the transition state (**2**), −271.72672, and for the isomer with two *trans* double bonds, −271.76775 RMP2(full)/6-31G*). These values were adjusted by the RHF/6-31G* zero-point energies, scaled by 0.89 (88.4 and 86.5 kcal mol^{-1} for **1** and **2**, respectively), and by thermal energies at 400 K [10]. [b] $E_a = \Delta H^{\neq} + RT$. [c] Frequency factor [s^{-1}]. [d] The computed absolute entropies [cal mol^{-1} K^{-1}] are 97.3 for **1** and 83.9 for **2** at 400 K. [e] See ref. [5] (at the same level of theory) and ref. [8].

The optimized (RMP2(full)/6-31G*) transition structure **2** (one imaginary frequency, −2200 cm^{-1}) is helical (C_2 symmetry, Fig. 1 bottom).[3] The C_2 axis is defined by the migrating hydrogen atom, H_w, and the C4 carbon atom. The C1–C7 distance is 2.600 Å, and the W_w–C1 and H_w–C7 bond lengths are 1.352 Å. In accord with Woodward–Hoffmann rules for such an allowed process, the transition structure

[**] This work was supported by the Fonds der Deutschen Industrie, the Deutsche Forschungsgemeinschaft, and the Convex Computer Corporation. We also thank Prof. Dr. W. Kutzelnigg, and Dr. U. Fleischer, Bochum (FRG), and Dr. A. Dorigo, Erlangen, for suggestions and helpful discussions. H. J. thanks the Shanxi Normal University (People's Republic of China) for a scholarship.

can be termed aromatic, since the C–C bond lengths (ca. 1.40 Å) are nearly equal and comparable to that in benzene (1.395 Å, also at RMP2(full)/6-31G*). Thus, the geometric criterion of aromaticity[12] is fulfilled.

The magnetic criterion of aromaticity[12] is based on ring current effects, in other words, on the downfield shifts of the outer protons produced by a diamagnetic ring current in a planar $(4n + 2)$ π electron annulene. While *eight* delocalized electrons are involved in **2**, this transition structure has a Möbius, rather than a Hückel topology.[12] What is to be expected in such an unusual case?

Although NMR chemical shifts of transition states cannot be measured, they can be computed easily by the IGLO[14] (Individual Gauge for Localized Orbitals) method. The vinylic hydrogens H1–6 in the ground state structure **1** have IGLO shifts δ (^{1}H) in the range $\delta = 5.0$–6.4 (Table 2). But in the transition structure **2** the calculated δ(^{1}H) values for H2–6 are shifted by $\Delta\delta \approx 1$ to $\delta = 6.3$–6.9 which is very close to the calculated value in benzene (δ (^{1}H) = 7.0; 7.1 is the experimental value in the gas phase). The migrating H_w atom is computed to have a shift of $\delta = 1.9$. The shifts of the two protons at C1 and C7 are revealing. The equatorial protons H1 and H7 are computed to have a chemical shift of $\delta = 5.6$, while the axial protons H1 and H7 have a strong upfield shift of $\delta = -4.6$. The axial protons in **2** (H1 and H7) point toward the center of the carbon skeleton (Fig. 1) and experience a strong ring current (Table 2).

Pauling[15a] noted in 1936 that aromatic compounds exhibit enhanced magnetic susceptibility. This criterion of aromaticity,[15b–e] attributed to the presence of a diamagnetic ring current, applies well to transition structure **2**. The calculated isotropic susceptibility is -71.7 ppm cgs for **1** and -95.1 ppm cgs for **2**. Most of the difference (23.4 ppm cgs) results from the change in the diamagnetic contribution (17.1 ppm cgs). The paramagnetic (1.3 ppm cgs) and nonlocal contributions (3.8 ppm cgs) change little. The calculated diamagnetic exaltation of 17.1 ppm cgs also points to the considerable aromaticity in **2**. For benzene a value of 13.7 ppm cgs is derived from experimental data[15b] and 15.4 ppm cgs from IGLO calculations.[15e] In agreement with this interpretation, the change in the calculated out-of-plane component of χ from **1** to **2** (-65.9 ppm cgs) is much larger than the change in the in-plane component (-2.2 ppm cgs).

The differences in the ^{1}H chemical shifts are not caused by differences in the charges on the hydrogen atoms. According to natural population analysis (NPA),[13] the charges of *all* hydrogen in the transition structure **2** are nearly the same (0.22–0.24) and differ very little form those in the ground state structure **1**. The migrating H_w atom (+0.24) in **2** has almost the same charge as that of the corresponding hydrogen in **1** (+0.22). In comparison, the charge on H_w is +0.36 in the transition structure and +0.23 in the ground state structure.[5] Thus, H_w is more proton-like in the [1,5] H shift transition structure but resembles a "normal" hydrogen atom in the [1,7] H shift transition structure in (*Z*,*Z*)-1,3-5-heptatriene.

Since transition structure for the [1,7] H shift is helix-shaped and chiral, the corresponding ground state structure also might be helical. For this reason we chose a starting geometry for 1,3,5-heptatriene that resembled **2**, but the optimization led to the planar C_s (*Z*,*Z*) isomer **1**. This configuration agrees with that deduced from the ^{1}H NMR spectrum.[7] While (*Z*,*Z*)-1,3,5-heptatriene (**1**) is a minimum on the potential energy surface, the most stable 1,3,5-heptatriene isomer has two *trans* double bonds and is 3.4 kcal mol^{-1} (RMP2(full)/6-31G*) more stable than **1**. But this planar (*E*,*E*) isomer would not lead directly to the transition structure **2**.

The calculated activation energy (E_a) [RMP2(full)/6-31G* energy + 0.89 × E_{Th} (RHF/6-31G*) + RT (400 K)] is 19.7 kcal mol^{-1} (Table 1) and agrees well with the measured value of 20.8 ± 0.7 kcal mol^{-1}.[7] Thus, the barrier for the [1,7] H shift is lower than that for the [1,5] H shifts in cyclopentadiene (25.2 kcal mol^{-1})[5] and in 1,3-pentadiene (35.4 kcal mol^{-1}),[1b,4] although the ground state structure **1** is not helix-shaped and the migrating hydrogen atom H_w at C7 is very far from C1. The barrier for the [1,7] H shift is lower on account of the greater flexibility of 1,3,5-heptatriene, which permits the transition state to have better orbital overlap and to be reached with less distortion energy that in the [1,5] H shift systems.[1b] The experimental frequency factor of **1** (1.6×10^8 s^{-1}) is much lower than those for the [1,5] H shifts in cyclopentadiene (1.3×10^{12} s^{-1}) and 1,3-pentadiene (2.8×10^{11} s^{-1}), which can be explained by the loss of more degrees of freedom during cyclization of larger acyclic systems. For example, the entropy loss on cyclization of 1-pentene to give cyclopentane ($\Delta S = -12.7$ cal mol^{-1} K^{-1}) is smaller than that for cyclization of 1-heptene to give cyclopheptane ($\Delta S = -19.4$ cal mol^{-1} K^{-1}).[16] The calculated frequency factor for the [1,7] H shift (97.7×10^8 s^{-1}) is 61-fold greater than that measured, whereas the calculated frequency factors for the [1,5] H shifts in cyclopentadiene (7.9×10^{12} s^{-1}) and in 1,3-pentadiene (1.6×10^{11} s^{-1}) are very close to the measured values (Table 1). Considering the uncertainties inherent in rate measurements and in the determination of activation parameters, our computed values are in reasonable agreement. It should also be noted that our theoretical level, dictated by the size of the system, is not particularly high.

Our computed results for the [1,7] H shift confirm the predictions of Woodward and Hoffmann and are in agreement with the experimental results. The allowed antarafacial [1,7] H shift has an exceptionally large energy of concert (ca. 60.0 kcal mol^{-1}) relative to the alternative, stepwise, diradical mechanism.[17] The eight-electron Möbius transition

Table 2. IGLO calculated ^{1}H NMR chemical shifts for the ground state structure of (*Z*,*Z*)-1,3,5-heptatriene (**1**) and for the [1,7] H shift transition structure **2** (IGLO/BII//RMP2(full)/6-31G*; IGLO/DZ values given in parentheses) [14].

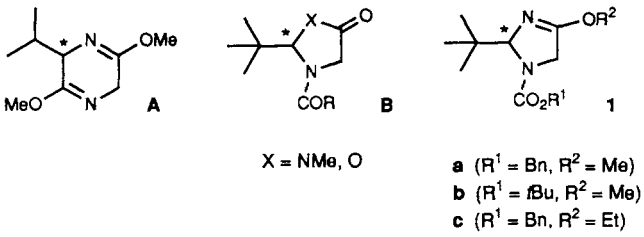
(*R*)- and (*S*)-4-Alkoxy-2-*tert*-butyl-2,5-dihydroimidazole-1-carboxylates—New Chiral Glycine Derivatives for Amino Acid Synthesis**

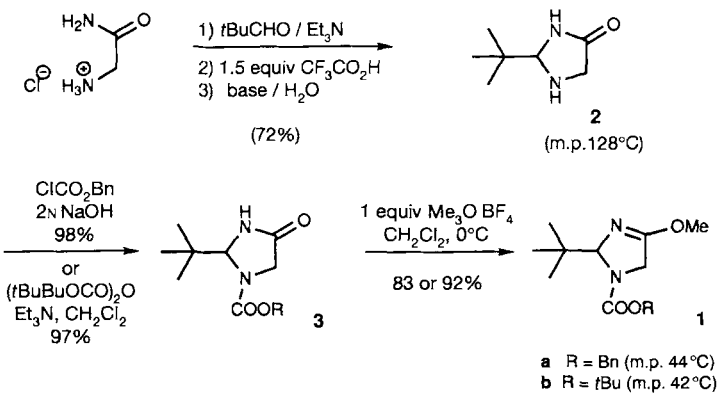
By *Stefan Blank* and *Dieter Seebach**

For the synthesis of nonproteinogenic α-amino acids there are several chiral glycine derivatives available having electrophilic, radical, or nucleophilic reactivity. Nearly all of them contain a chiral building block, an auxiliary incorporated in the synthesis that must be removed and recycled, discarded, or destroyed after use.[1] Schöllkopf's "bis-lactim ether" **A**, which is obtained from valine, is an example of these chiral glycine derivatives.[1,2] A different approach is chosen in the synthesis of the heterocyclic glycine derivatives **B**:[1,3] the enantiomers are separated by formation of diastereoisomeric salts or on chiral columns, and the undesired enantiomer is recycled.[4] A disadvantage in this case is the harsh conditions necessary for the hydrolysis, in particular of imidazolidinones (from **B**, X = NMe), to provide the free amino acids.[3,4]



The (*R*)- and (*S*)-alkoxydihydroimidazolecarboxylates **1** we are now introducing combine all the advantages of previously employed reagents regarding accessibility of starting material, stability, reactivity, and selectivity of the Li derivative, as well as ease of hydrolysis. All preliminary experiments were performed on racemic materials.

The synthesis of the dihydroimidazoles is outlined in Scheme 1. Imidazolidinone **2** is prepared from commercial glycine amide hydrochloride following standard procedures.[4] The protective group is introduced, and the amide group is O-alkylated with Me_3OBF_4.



Scheme 1. Synthesis of benzyl and *tert*-butyl 2-*tert*-butyl-2,5-dihydro-4-methoxyimidazole-1-carboxylates (**1a**, **1b**).

The reactions carried out so far with Boc-protected dihydroimidazole **1b** are summarized in Scheme 2 and Table 1. Treatment of **1b** with lithium diisopropylamide (LDA) in THF at −78 °C provides enaminate **C** of the cyclic imidate, which reacts with alkyl halides in good yields (Table 1) and with such high selectivity (> 99:1) that a second diastereoisomer is not evident in the 300 MHz ^{1}H NMR spectrum of the crude product. The *trans* configuration of the products was proved by NOE (nuclear Overhauser effect) measurements and X-ray analysis (for **4f**). The reactions of lithium derivative **C** with isopropyl iodide (92%, **4d**) and *p*-nitrobenzyl bromide (30%, **4f**) are remarkable demonstrations of its high nucleophilicity. Second alkylations also proceed smoothly (→ **5**, **6**), as shown by the reaction of ethylated compound **4b** with isopropyl iodide (62% yield).[6] Finally Li-dihydroimidazole **C** adds to benzaldehyde (→ **7a**) and acetaldehyde (→ **7b**) giving mainly one out of four pos-

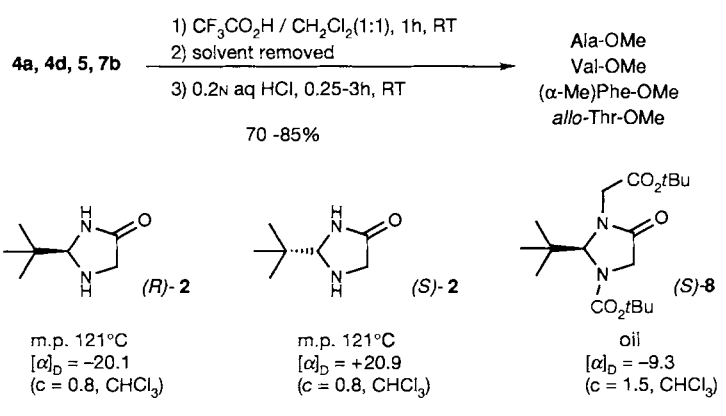
4d	$(CH_3)_2CHI$	92	**6** [b]	$(CH_3)_2CHI$	62

[a] Prepared from **4e**. [b] Prepared from **4b**.

As expected, hydrolysis of the dihydroimidazoles to give α-amino acid methyl esters is very easy (Scheme 3) and provides pure products directly, as evidenced by NMR spectroscopy. The mild hydrolysis conditions employed should allow for the synthesis of many sensitive amino acid derivatives previously not accessible to us,[3,4] for example those containing double bonds, three-membered rings, and other acid-labile groups in the side chain, as well as racemization-prone aryl glycines.



Scheme 3. Transformation of dihydroimidazoles **4a,d**, **5**, and **7b** to provide α-amino acid methyl esters.

For the preparation of enantiomerically pure alkoxydihydroimidazoles **1a** and **1b**, the enantiomers of the stable imidazolidinone **2** were separated by crystallization of their diastereoisomeric salts. Camphorsulfonic acid (CSA), available in both enantiomeric forms,[7a] turns out so far to be best suited for this.[7b] A preliminary experiment using enantiomerically enriched (*S*)-**1b**[7c] (87% *ee*) gave the L-valine methyl ester after isopropylation and hydrolysis with 81% *ee*. Further investigations with enantiomerically pure material are currently in progress.

Since the imidazolidinones **2** and **3** are readily available, we now have a route to the glycyl glycine building block **8** in enantiomerically pure form.[8a] Previous work has demonstrated the utility of racemic **8**.[8b]

Self-Assembly Through Hydrogen Bonding: Preparation of a Supramolecular Aggregate Composed of Ten Molecules**

By *John P. Mathias, Eric E. Simanek, Christopher T. Seto*, and *George M. Whitesides**

Learning how to control the association of many molecules into single, highly-structured supramolecular aggregates is a current objective in molecular self-assembly.[1-5] In this communication we report the self-assembly of a supramolecular aggregate based on a compound containing

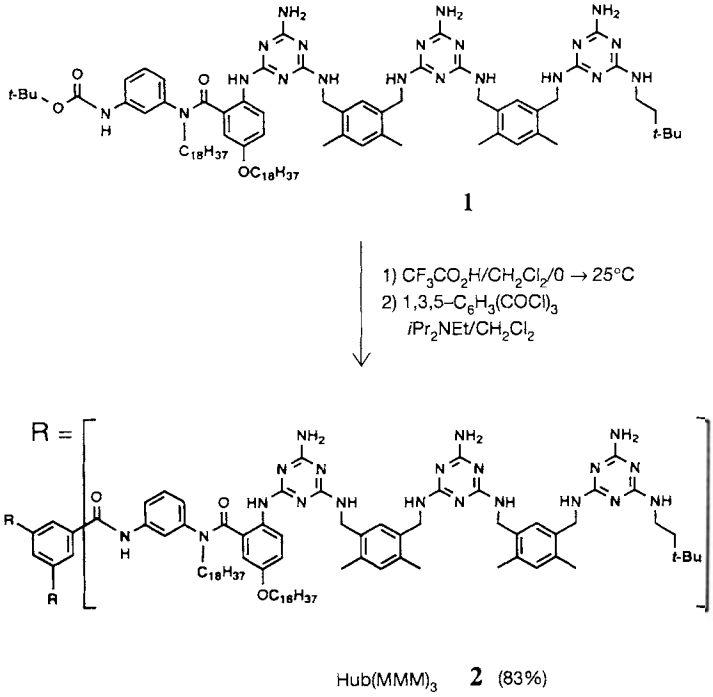
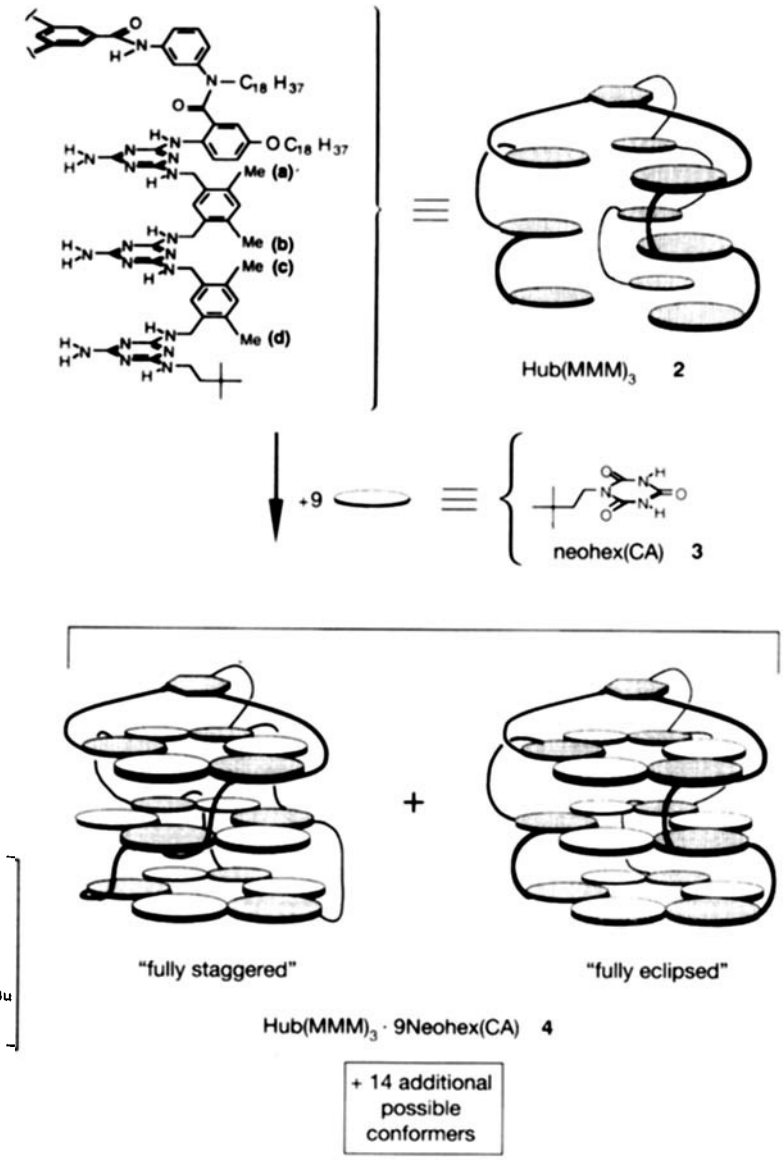
nine melamine rings (M) that we have called Hub(MMM)$_3$ (**2**). This molecule associates with nine equivalents of neohexylisocyanurate (neohex(CA) **3**) to form a hydrogen-bonded supramolecular aggregate of composition Hub-(MMM)$_3$ · 9neohex(CA) (**4**). This aggregate is composed of ten molecules in three parallel $CA_3 \cdot M_3$ "rosettes",[6] and is stabilized by 54 hydrogen bonds.

The nonamelamine derivative **2** was synthesized by using the procedure shown in Scheme 1. This synthesis extends a strategy we have described previously.[2, 7] The *m*-xylyl spacers between adjacent melamine rings in each arm of **2** match those we have used in aggregates based on two parallel $CA_3 \cdot M_3$ rosettes.[3, 8]



Scheme 1. Synthesis of Hub(MMM)$_3$ (**2**).



Scheme 2. Self-assembly of Hub(MMM)$_3$ · 9neohex(CA) (**4**). The conformational isomers shown are just two of at least 16 possibilities.

A homogeneous solution of Hub(MMM)$_3$ · 9neohex(CA) (**4**) was prepared by mixing one equivalent of **2** and nine equivalents of **3** in chloroform (Scheme 2). We have ennumerated at least 16 different geometrical conformers as being possibilities for **4**.[9] We believe that the aggregate exists initially as a mixture of the many available conformers on mixing the two different components. The conversion of this mixture to a single supramolecular aggregate of composition **4** occurs over about 48 h at room temperature (or 1 min at reflux) in chloroform, as judged by ^{1}H NMR spectroscopy.

The supramolecular aggregate **4** was characterized by ^{1}H NMR spectroscopy (COSY, NOE, and NOESY experiments), gel permeation chromatography (GPC), and vapor pressure osmometry (VPO). The ^{1}H NMR spectrum of **4** (Fig. 1a) shows a sharp set of resonances that can be assigned to a single conformer of the supramolecular aggregate. These sharp resonances contrast with the broad, poorly-defined resonances observed in the spectrum obtained from uncomplexed **2** in $CDCl_3$ (Fig. 1c); the broadening of the resonances in this spectrum may reflect hindered rotation about amide bonds in **2** and/or self-association of **2**. Even in a strong hydrogen-bonding solvent such as dimethylsulfoxide (DMSO), however, there is little detail in the ^{1}H NMR spectrum of **2**. The spectrum in Figure 1b shows the aggregate immediately after mixing the components **2** and **3**. The progression from a mixture of conformers of **4** (Fig. 1b) to a single conformer (Fig. 1a) is clear in these ^{1}H NMR spectra. The observation of discrete resonances for the different conformers confirms that exchange between them is slow on the NMR time scale. The six resonances with equal intensities (●, in Fig. 1a) between $\delta = 14$ and 16 correspond to three sets of the two unsymmetrical hydrogen-bonded isocyanurate protons seen in each $CA_3 \cdot M_3$ rosette in **4**. The observation of four discrete singlets (▽, Fig. 1a) between $\delta = 1.8$ and 2.1 for the four methyl substituents [(a)–(d), Scheme 2] provides further support for the proposed structure of **4**. Cooling the sample has no effect on the signals observed in the ^{1}H NMR spectrum. This feature strengthens the inference that the resonances observed at 298 K in Figure 1a belong to a single conformer and not to a rapidly-equilibrating mixture of conformations.[10] Nuclear Overhauser effects between the imide protons on the isocyanurate molecules (**3**) and those of the melamine rings in **2** confirm the geometry of the hydrogen-bonded regions, and are

consistent with the structure that we propose for **4**. We do not see NOE interactions between protons in adjacent $CA_3 \cdot M_3$ rosettes. This feature means that we cannot deduce, unambiguously, which of the possible conformational isomers is the thermodynamically preferred (observed) one.

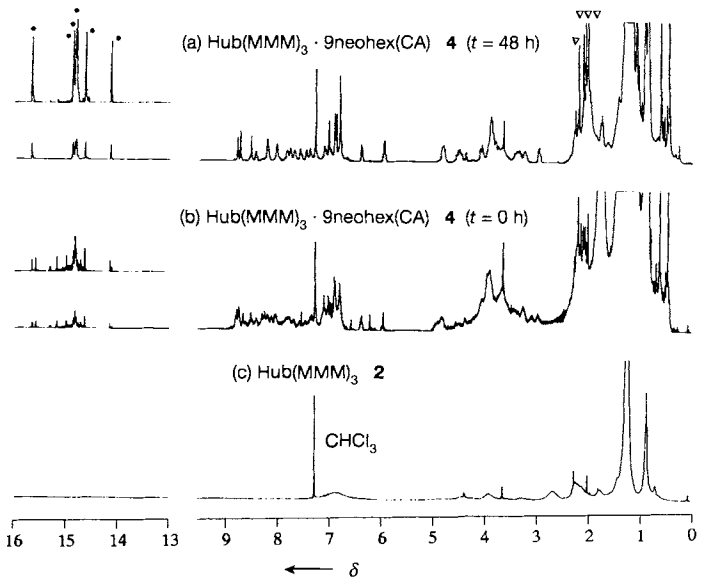


Fig. 1. ^{1}H NMR spectra (500 MHz, $CDCl_3$) of **4** (a) after equilibration and (b) on initial mixing of the components. The spectrum of uncomplexed **2** is shown in (c).

Retention times and shapes of the peaks for **4** (hatched) in $CHCl_3$ and CH_2Cl_2 as the eluent are consistent with observations from other self-assembled aggregates (Fig. 2). In each trace, *p*-xylene (shaded peak) was used as an internal standard. The trace in CH_2Cl_2 shows a single peak for the aggregate. The trace in $CHCl_3$ shows a much broader peak for the aggregate with a larger degree of "tailing" toward longer retention time. In each case, the peaks for the aggregate have sharp leading edges. This feature indicates that the solutions do not contain stable self-assembled or associated supramolecular aggregates that are *larger* than **4**. The tailing in these traces is a consequence of dissociation of the aggregate that occurs during the analysis by GPC, and more tailing is seen in $CHCl_3$ than in CH_2Cl_2. This difference indicates that the stability of **4** is lower in $CHCl_3$, the stronger hydrogen-bonding solvent, than it is in CH_2Cl_2.[11] Although dissociation occurs during analysis of **4**, the GPC results establish that the dissociation is slow and indicate, therefore, that **4** is surprisingly stable.

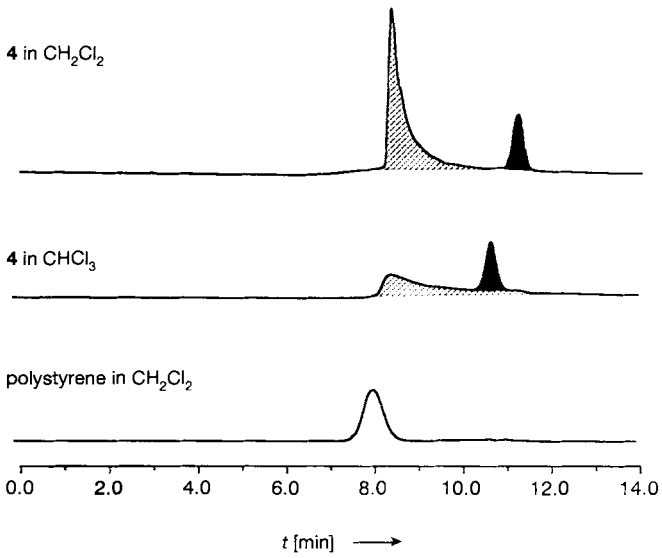

Fig. 2. Top and middle: Gel permeation chromatograms of **4** (hatched peaks). The shaded peaks are *p*-xylene, which is used as an internal standard. Bottom: Gel permeation chromatogram of polystyrene (PS) (F.W. 5050).

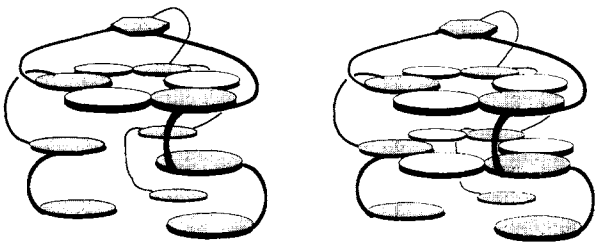
The molecular weight *m* for **4** has been obtained by VPO in chloroform, using four different molecular weight standards.[12] Each standard gives an observed *m* that is within 15% of the calculated value of **4** (6.435 kDa). Observed molecular weights of **4** are 5.6 kDa (standard: *N,N'*-bis-*tert*-butoxycarbonyl-gramicidin S), 6.4 kDa (sucrose octaacetate), 6.5 kDa (polystyrene), 7.5 kDa (perbenzoyl-β-cyclodextrin).

Addition of only three equivalents of **3** to one equivalent of **2** leads to formation of only fully assembled **4**; excess **2** remains uncomplexed. We do not observe any intermediates (such as Hub(MMM)$_3$ · 3neohex(CA)—the single layer aggregate **5**—or Hub(MMM)$_3$ · 6neohex(CA)—the double layer aggregate **6**) on the pathway between **2** and **4**. This observation indicates that the self-assembly of **4** displays positive cooperativity.



5 **6**

The self-assembly of *ten* molecules into a single *supramolecular aggregate* (**4**) that is stabilized by *fifty four* hydrogen bonds demonstrates further the potential of molecular self-assembly as a stategy for the preparation of well-defined chemical nanostructures. In particular, these results illustrate that parallel hydrogen-bonded $CA_3 \cdot M_3$ rosettes are a structural motif that is well-suited to the preparation of large, structurally complex supramolecular aggregates.

Experimental Procedure

Hub(MMM)$_3$ (**2**): Trifluoroacetic acid (2.5 mL) was added dropwise to a solution of **1** (451 mg, 0.29 mmol) in CH_2Cl_2 (10 mL) at 0 °C. The reaction mixture was warmed to 25 °C and stirred for 2 h. This solution was diluted with toluene (20 mL) and concentrated in vacuo. The residue was partitioned between EtOAc (50 mL) and aqueous Na_2CO_3 (5% solution, 25 mL). The organic extract was washed with aqueous Na_2CO_3 (5% solution, 25 mL), brine (2 × 25 mL), dried over $MgSO_4$, filtered, and concentrated in vacuo to give 402 mg (0.276 mmol, 95%) of the deprotected amine as a white foam [high-resolution FAB-MS: *m/z* calcd for $C_{84}H_{133}N_{20}O_2$: ($[M + H]^+$) 1454.0920, found: 1454.0959]. This amine (399 mg, 0.274 mmol) was dissolved in CH_2Cl_2 (10 mL) and di-isopropylethylamine (DIPEA) (0.19 mL) and the solution was cooled to 0 °C. 1,3,5-Benzene tricarbonyl chloride (24.2 mg, 0.0913 mmol) was added and the solution was allowed to warm to 25 °C. After 90 mins, the reaction mixture was diluted with CH_2Cl_2 (25 mL) and washed with aqueous Na_2CO_3 (5% solution, 20 mL), brine (2 × 35 mL), dried over $MgSO_4$, filtered, and concentrated in vacuo. The residue was purified by column chromatography (eluted with a solution of 7.5% NH_4OH/MeOH in CH_2Cl_2 [7.5:92.5 v:v]) to give 342 mg (0.0757 mmol, 83%, two steps) of the product (**2**) as a white solid; correct elemental analysis.

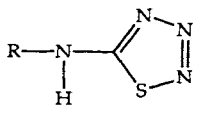
[9] In principle, there are least four conformations in which the linker arm can join the uppermost melamine ring in **4** to the central benzene "hub" [2]. Additionally, adjacent melamine rings in each arm of the Hub(MMM)$_3$ unit can lie in eclipsed or staggered conformations, resulting in a total of at least 16 discrete conformers.
[10] Supramolecular aggregates based on a single $CA_3 \cdot M_3$ rosette often exist as mixtures of different geometrical isomers. The exchange between these structures can be slowed to reveal the separate isomers by ^{1}H NMR at temperatures below ambient; M. Wazeer, J. P. Mathias, E. E. Simanek, G. M. Whitesides, unpublished results.
[11] The traces from **4** in the GPC are significantly broader than those of previously reported double-layer aggregates, such as that between the hexamelamine derivative Hub(MM)$_3$ and six equivalent of neohexylisocyanurate, Hub(MM)$_3$ · 6*neo*hex(CA). The reduction in stability for **4** suggested by this observation places this aggregate close to the lower limit of stability that can be observed successfully by GPC.
[12] Chloroform was Aldrich HPLC grade. No attempt was made to monitor its moisture content during analysis by VPO.

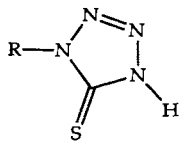
The First Structure of a Lithiated Cyanamide; Synthesis of (PhNCNLi · HMPA)$_n$ by Extrusion of N_2 and S from 5-Phenylamino-1,2,3,4-thiatriazole with Li Reagents and HMPA**

By *David R. Armstrong, F. Adele Banbury, Ian Cragg-Hine, Matthew G. Davidson, Francis S. Mair, Ehmke Pohl, Paul R. Raithby*, and *Ronald Snaith**

We described recently the product resulting from the reaction of solid $Ba(OH)_2$ with aminothiatriazole (**AH**; R = naphthyl) and HMPA [O=P(NMe$_2$)$_3$] dissolved in toluene.[1] Instead of the expected aqua complex, (**A**)$_2$Ba · 2H$_2$O · *x* HMPA,[2] a rearrangement occurs to give the thioxotetrazole derivative, (**B**)$_2$Ba · 3HMPA, in 60% yield. This rearrangement has been known for a long time[3] as has the fact that compounds of the type **AH** react with excess aqueous NaOH along two different paths: the first path involves the degradation of the heterocycle **AH** to give RNCS and azide; the RNCS is subsequently hydrolyzed to the corresponding amine. The second path involves the isomerization of the thiatriazole **AH** to the thioxotetrazolyl anion (**B**$^-$). Path 1 is favored when an excess of OH^- ions and H_2O is used. In contrast, our recent study[1] showed that in the presence of HMPA ligands, the use of stoichiometric amounts of solid $Ba(OH)_2$ and **AH** prevent the hydrolysis step in path 1, and indeed, constructively favor path 2: the rearrangement increases the distance of the R group (naphthyl) from the $(N\cdots C\cdots S)^-$ unit which chelates the large $Ba(HMPA)_3^{2+}$ fragment.



AH



BH

Here we report a third, and rather more spectacular, pathway for the deprotonation of aminothiatriazoles **AH**: extrusion of N_2 and S at ambient temperature lead to metal complexes of the anion of R–N(H)–C≡N. Thus, in this way complex **1**, whose solid-state structure—the first of a lithiated cyanamide—was determined, was formed from **AH** (R = phenyl). Deprotonations of 5-(phenylamino)-1,2,3,4-thiatriazole (**AH**; R = Ph) were performed with a range of lithium bases. In general, equimolar amounts of **AH** and HMPA are dissolved in toluene at −78 °C, and then one equivalent of the chosen base (LiOH, MeOLi, $LiNH_2$, *i*Pr$_2$NLi as solids; *n*BuLi as a solution in hexane; see the Experimental Procedure for specific details) is added. Warming the mixture to room temperature causes dissolution of any solid, usually accompanied by visible gas evolution. Refrigeration of the resulting solution gives crystals of **1** (20–60% yield) except when the base used for the reaction is solid LiOH. In this case crystals of (**B**)Li · H_2O · HMPA are isolated initially; that is those containing the rearranged, rather than the extruded, anion. However, subsequent treatment of these crystals with additional LiOH/HMPA, or with *n*BuLi/HMPA, affords **1**. Interestingly, the reaction of **BH** with *n*BuLi/HMPA affords (**B**)Li · HMPA rather than **1**. The most immediate evidence for an extrusion product [$(RNCN)_x \cdot M^{x+} \cdot y$ ligand] is the appearance of a strong $\nu(N\cdots C\equiv N)^-$ stretch in the IR spectrum; for **1**, this band appears at 2147 cm^{-1}. The products of the reactions of **AH** (R = naphthyl) with HMPA and all the above-mentioned lithium bases show a similar absorption. However, treatment of HMPA and **AH** (R = Ph) in toluene with the highly reactive system Ba/Ba(NH$_2$)$_2$ (obtained by evaporating a solution of metallic Ba in liquid NH_3) affords a product having no such band. In this case the rearrangement product (**B**)$_2$Ba · 3HMPA (R = Ph) is formed. This product is akin to that [R = naphthyl in **B**] obtained from a similar reaction in which rather unreactive solid $Ba(OH)_2$ is used.[1] Thus it seems that formation of extrusion products is dependent on the metal atom attached to the base (switch from Ba to Li) rather than on the R group (switch from R = naphthyl to R = Ph in **AH**), or on a change in the general reactivity of the metalating reagent used.

C-H., M.G.D.), Queens' College, Cambridge and Associated Octel (Research Fellowship, F.S.M.), and St. John's College, Cambridge (Research Fellowship, M.G.D.). We thank Professor G. M. Sheldrick (University of Göttingen) for providing access to crystallographic facilities.

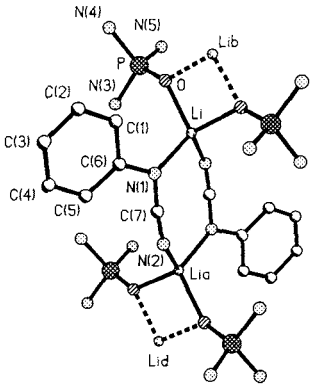

Fig. 1. The molecular structure of **1**, showing the central $(LiNCN)_2$ ring and adjacent $(LiO)_2$ rings.

The solid-state structure of **1** has been resolved by X-ray crystallography.[4] The most important structural feature (Fig. 1) is a $(LiNCN)_2$ ring [distances: Li–N1 2.061(4) Å; Lia–N2 1.984(4) Å]. The distances along the near-linear N1-C7-N2 portion of the anion are N1–C7 1.303(3) and C7–N2 1.157(3) Å, suggesting that the anion is best considered as $[Ph\text{-}N\cdots C\equiv\!\!=N]^-$. The eight-membered ring itself is slightly chair-shaped [internal angles: 106.4(2) at Li, 111.3(2) at N1, 175.7(2) at C7, and 142.8(2)° at N2; Li and Lia are 0.311 Å above and below the mean plane defined by N1-C7-N2].

Each Li is also coordinated to two HMPA molecules [Li–O 1.958(4) Å, Lib–O 1.973(4) Å] which in turn bridge to a Li atom in a neighboring $(LiNCN)_2$ ring. This leads to the formation of polymeric strands (Fig. 2) consisting of alternating and orthogonal eight-membered $(LiNCN)_2$ and four-membered $(LiO)_2$ rings.

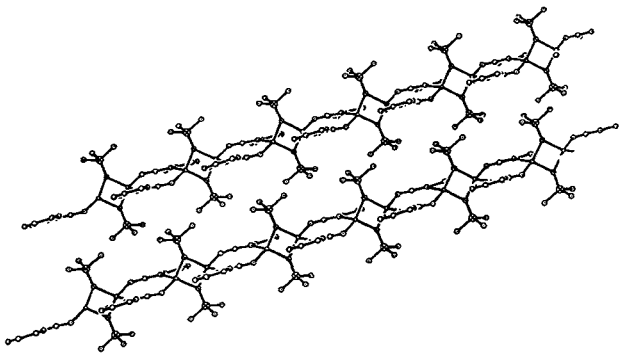

Fig. 2. Two polymeric strands of **1** showing alternating and orthogonal eight- and four-membered rings.

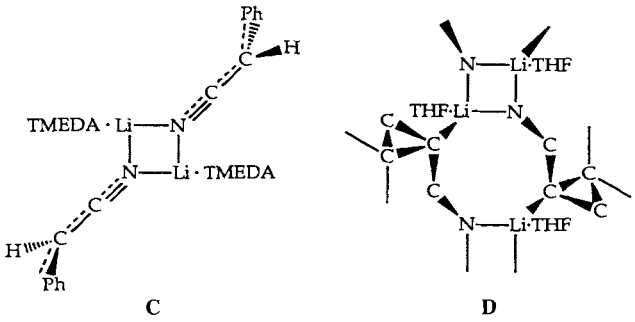
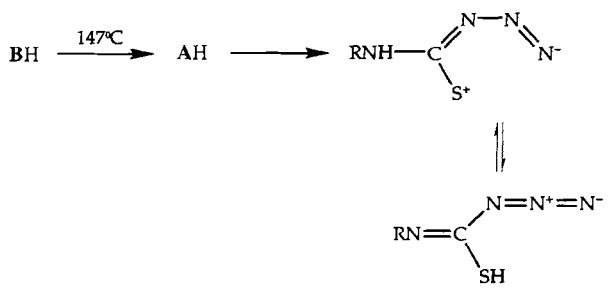
The structure of **1** is the first for a lithium cyanamide and as such it is unique, although certain of its features have analogies. For example, eight-membered rings of type $(LiXYZ)_2$ are well known in dimeric systems such as the lithium thiobenzoate $[PhC(=O)SLi \cdot TMEDA]_2$ with a $(LiOCS)_2$ ring[5] and the lithiosulfones $[PhSO_2CH(R)Li \cdot TMEDA]_2$ (R = H,[6] R = Ph[7, 8]) with $(LiOSO)_2$ rings. However, in comparison with the near-linear NCN^- unit in **1**, in all these structures an acute angle is found at atom Y. More akin to cyanamides, lithiated nitriles might be expected to contain eight-membered $(LiCCN)_2$ rings. MNDO calculations predict such a feature for uncomplexed $(LiCH_2CN)_2$.[9] However, on complexation a ketenimine structure $(H_2C\cdots C\equiv\!\!=NLi \cdot OH_2)_2$ with a four-membered $(NLi)_2$ ring is favored; such was indeed found for the first structurally characterized lithionitrile $[PhC(H)\cdots C\equiv\!\!=NLi \cdot TMEDA]_2$ (**C**).[8, 10] An example of the eight-membered $(LiCCN)_2$ unit is found in the structure of the 1-cyano-2,2-dimethylcyclopropyllithium complex (**D**).[8, 11] Here, the anionic α-C atom of the cyclopropyl unit is coordinated to the Li center so that an eight-membered $(LiCCN)_2$ ring results. The N atoms of each such ring bridge to the lithium atoms of neighboring eight-membered rings, resulting in alternating eight- and four-membered rings sharing a common LiN edge. In contrast, in **1**, the alternating rings share merely a common Li atom.



C **D**

It has not yet been possible to explain the rather dramatic extrusion reactions that occur when thiatriazoles **AH** are treated with HMPA and lithium bases. An earlier report[3] noted that a mercaptotetrazole **BH** (R = Ph) degraded violently at its melting point (147 °C), evolving N_2 and forming sulfur and unidentified organic product(s). It was suggested that isomerization to the thiatriazole **AH** occurs first, followed by bond cleavage and an "explosive internal oxidition–reduction" between the thiol and azido groups (Scheme 1).



Scheme 1.

Our results here imply that the unidentified organic product of the earlier study was PhNHC≡N. However, a striking difference between the two studies is that all the reactions we describe occur at or below room temperature. Furthermore, it is clear that the metal cation and the added ligand play crucial roles. The different reactions of **AH** and HMPA with lithium (extrusion) and with barium (rearrangement) reagents have been noted; however, **AH**, $LiNH_2$, and the ligand PMDETA $[(Me_2NCH_2CH_2)_2NMe]$ react to give a rearrangement product containing $\mathbf{B}^-$. In addition, some of the reactions of **AH** and HMPA with lithium bases (e.g., with $LiNH_2$, *n*BuLi) proceed through numerous color changes, but others (e.g., with MeOLi, iPr_2NLi) do not. Further experiments are planned in the hope of elucidating the mechanisms of these unusual reactions.

Experimental Procedure

Typical syntheses of **1**: 1) With *n*BuLi. Solid **AH** (R = Ph; 0.89 g, 5 mmol) was dissolved under nitrogen in a mixture of HMPA (0.89 g, 5 mmol) and toluene (10 mL). The solution was cooled to −78 °C in an acetone/dry ice bath, and

*n*BuLi solution (5 mmol; in hexane) added. On warming to room temperature the original yellow solution changed color from green to reddish-brown, and gas evolution was observed. After the mixture had been stirred at room temperature for 30 min the resulting clear yellow solution was refrigerated overnight. This afforded very pale yellow crystals of **1** [first batch yield, 0.76 g, 50%; m.p. 132–135 C; correct analysis for $C_{13}H_{23}LiN_5OP$; ^1H NMR (CD_3CN, 250 MHz, 25 C): $\delta = 7.03$ (m_c, 2H), 6.78 (m, 2H), 6.53 (m, 1H), 2.58 (d, 18H, HMPA)]. – 2) With $LiNH_2$. To a chilled solution of **AH** and HMPA in toluene [as in 1)] was added solid $LiNH_2$ (0.12 g, 5 mmol). On warming to room temperature with stirring the yellow solution became first green and then blue, with gradual dissolution of the white solid. Stirring the blue solution at room temperature for a further 45 min gave, after a green color, a yellow solution. Storage at 25 C over 2 days afforded yellow crystals of **1** (first batch yield, 0.30 g, 20%).

Synthesis and Reactivity of α,α-Dichloroglycyl Peptides**

By *Stefan Jaroch, Thomas Schwarz, Wolfgang Steglich,** and *Peter Zistler*

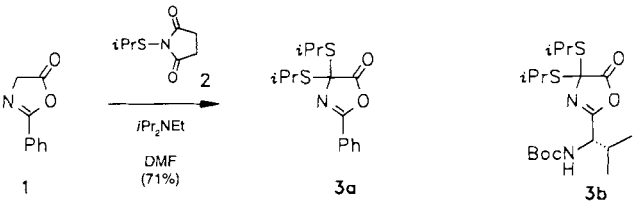
Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

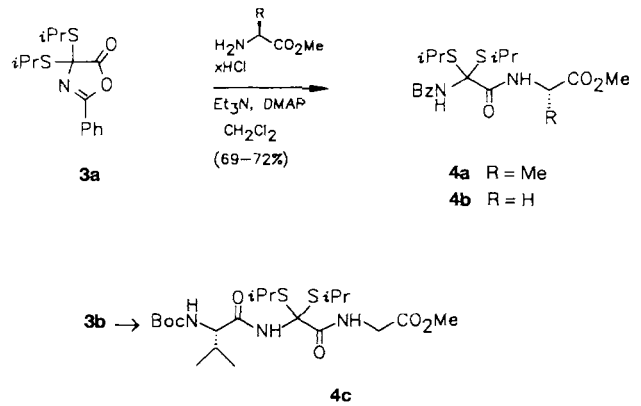
We recently introduced a new method for the synthesis of α-chloroglycyl peptides which makes it possible to prepare interesting peptide modifications.[1, 2] We now describe for the first time an approach to peptide derivatives that contain the α,α-dichloroglycine residue.

[*] Prof. Dr. W. Steglich, Dr. S. Jaroch, Dipl.-Chem. T. Schwarz, Dipl.-Chem. P. Zistler
Institut für Organische Chemie der Universität
Karlstrasse 23, D-80333 München (FRG)
Telefax: Int. code + (89)5902-604

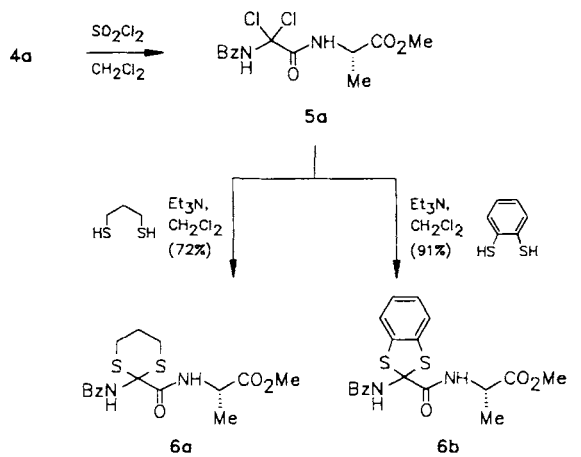
[**] S. J. would like to thank the Fonds der Chemischen Industrie for a predoctoral fellowship.

The synthesis of these peptide derivatives begins with 2-phenyl-5(4*H*)-oxazolone (**1**),[3] which reacts readily with *N*-sulfenylsuccinimides such as **2**[4] to give 4,4-di(isopropylthio)oxazolones **3**.[5] If this reaction is conducted with the azlactone of Boc-Val-Gly-OH,[6] the doubly sulfurated peptide azlactone **3b**[5] is obtained in 37% yield. The oxazolones **3** can be stored at approximately −20 °C for several days without decomposition. We found that the five-membered ring of 4,4-disubstituted oxazolones **3** opens to give *N*-acyl peptides **4** containing an α,α-di(isopropylthio)glycine residue (see Table 1) when amino acid esters are added in the presence of catalytic quantities of 4-dimethylaminopyridine (DMAP). Reaction of a peptide azlactone such as **3b** provides peptide derivatives of type **4c**, in which the α,α-di(isopropylthio)glycine residue is not located terminally but within the peptide chain. These compounds are generally obtained as stable solids that can be purified by chromatography or recrystallization.





In analogy to the mono(alkylthio)glycine derivatives,[1, 2] when **4** is treated with sulfuryl chloride the alkylthio residues are readily exchanged for chlorine substituents. In this way



the reactive α,α-dichloroglycyl peptides **5** are obtained, which in turn react with nucleophiles in a double elimination–addition reaction to give the peptide derivatives **6**. Reaction of the dichloro compound **5a**, for example, with propane-1,3-dithiol produces the dithiane derivative **6a**, whereas benzodithiolane **6b** is formed with 1,2-dithiophenol (Table 1). As a result of conformational restrictions, the melting points of these dipeptides are approximately 50 °C higher than the melting point of the open-chain compound **4a**.

Table 1. Selected physical and spectroscopic properties of compounds **4** and **6**.

4a: M.p. 107–108 °C; $[\alpha]_D^{25} = -26.1$ ($c = 1.53$ in $CHCl_3$); ^1H NMR ($CDCl_3$, 80 MHz): $\delta = 1.25$ (d, $J = 7$ Hz, 12H), 1.55 (d, $J = 7$ Hz, 3H), 2.80–3.30 (m, 2H), 3.78 (s, 3H), 4.60 (quint, $J = 7$ Hz, 1H), 7.30–7.55 (m, 3H), 7.60–8.00 (m, 3H), 8.35 (br. S, 1H); FAB-MS: $m/z = 413$ [MH^+].

4b: M.p. 130–132 °C; ^1H NMR ($CDCl_3$, 400 MHz): $\delta = 1.23$ (d, $J = 6.9$ Hz, 12H), 3.09 (sept. $J = 6.9$ Hz, 2H), 3.80 (s, 3H), 4.18 (d, $J = 5.6$ Hz, 2H), 7.44–7.56 (m, 3H), 7.78 (m, 1H), 7.86–7.91 (m, 2H), 8.35 (br. s, 1H); FAB-MS: $m/z = 399$ [MH^+].

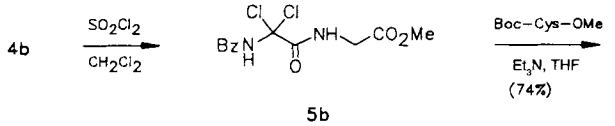
4c: M.p. 113–114 °C; $[\alpha]_D^{25} = -40.3$ ($c = 1.1$ in MeOH); ^1H NMR ($CDCl_3$, 400 MHz): $\delta = 0.94$ (d, $J = 7$ Hz, 3H), 1.01 (d, $J = 7$ Hz, 3H), 1.18 (d, $J = 7$ Hz, 3H), 1.19 (d, $J = 7$ Hz, 3H), 1.22 (d, $J = 7$ Hz, 3H), 1.24 (d, $J = 7$ Hz, 3H), 1.44 (s, 9H), 2.24 (m, 1H), 3.04 (sept, $J = 7$ Hz, 1H), 3.10 (sept, $J = 7$ Hz, 1H), 3.79 (s, 3H), 4.00 (dd, $J = 8$, 6 Hz, 1H), 4.11 (dd, $J = 18$, 6 Hz, 1H), 4.14 (dd, $J = 18$, 6 Hz, 1H), 5.03 (d, $J = 8$ Hz, 1H), 7.66 (t, $J = 6$ Hz, 1H), 7.92 (s, 1H); FAB-MS: $m/z = 494$ [MH^+].

6a: M.p. 156–157 °C; $[\alpha]_D^{25} = +26.0$ ($c = 0.53$ in $CHCl_3$); ^1H NMR ($CDCl_3$, 400 MHz): $\delta = 1.55$ (d, $J = 7$ Hz, 3H), 2.10–2.22 (m, 2H), 2.88–3.03 (m, 2H), 3.24–3.42 (m, 2H), 3.78 (s, 3H), 4.64 (quint, $J = 7$ Hz, 1H), 7.40–7.55 (m, 3H), 7.57 (br. s, 1H), 7.80–7.85 (m, 2H), 7.89 (br. d, $J = 7$ Hz, 1H); FAB-MS: $m/z = 369$ [MH^+].

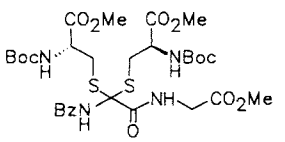
6b: M.p. 162–163 °C; $[\alpha]_D^{25} = +40.4$ ($c = 1.24$ in $CHCl_3$); ^1H NMR ($CDCl_3$, 80 MHz): $\delta = 1.50$ (d, $J = 7$ Hz, 3H), 3.75 (s, 3H), 4.55 (quint, $J = 7$ Hz, 1H), 7.00–7.90 (m, 10H), 8.00 (br. s, 1H); FAB-MS: $m/z = 403$ [MH^+].

6c: M.p. 56–58 °C; $[\alpha]_D^{25} = -13.9$ ($c = 1.0$ in $CHCl_3$); ^1H NMR ($CDCl_3$, 400 MHz): $\delta = 1.36$ (s, 9H), 1.41 (s, 9H), 2.95–3.30 (m, 4H), 3.64 (s, 3H), 3.73 (s, 3H), 3.80 (s, 3H), 4.17 (t, $J = 6$ Hz, 2H), 4.53 (m, 2H), 5.44 (br. d, $J = 8$ Hz, 1H), 5.68 (br. d, $J = 8$ Hz, 1H), 7.44–7.55 (m, 3H), 7.73 (t, $J = 6$ Hz, 1H), 7.85–7.96 (m, 2H), 8.50 (br. s, 1H); FAB-MS: $m/z = 717$ [MH^+].

Reaction of *N*-benzoyl-α,α-dichloroglycyl glycine methyl ester **5b** with *N*-Boc-L-cysteine methyl ester leads to the interesting pseudotetrapeptide **6c**. This synthesis demonstrates that it is possible to connect three peptide chains by means of cysteine residues.

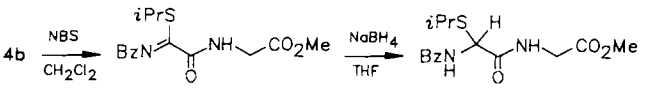


5b



6c

Treatment of di(isopropylthio)glycyl peptide **4b** with *N*-bromosuccinimide (NBS) results in cleavage of an isopropylthio residue to give the *N*-acylthioimino ether **7**. The reaction of **7** with sodium borohydride leads to the α-(isopropylthio)glycyl glycine methyl ester **8**. We are currently trying this same approach with chiral hydride donors to develop a route to homochiral α-(alkylthio)glycine derivatives.



7 **8**

Experimental Procedure

3a: Oxazolone **1** (2.32 g, 14.4 mmol) and **2** (5.00 g, 28.9 mmol) were added under Ar to dry dimethylformamide (DMF) in a flame-dried Schlenk flask. Diisopropylethylamine (5.06 mL, 29 mmol) added slowly through a septum, and the mixture was allowed to stir for 15 h at room temperature. The reaction was quenched with water and extracted twice with diethyl ether. The combined organic extracts were washed with 20% citric acid solution and saturated $NaHCO_3$ solution and were then dried over $MgSO_4$. The solvent was evaporated in vacuo and the residue purified by flash chromatography (SiO_2, petroleum ether/ethyl acetate) to give 3.20 g of product (71% yield).

4a: Oxazolone **3a** (1.15 g, 3.7 mmol), Ala-OMe × HCl (0.56 g, 4 mmol), and DMAP (10 mg) were dissolved under Ar in 10 mL of dry methylene chloride. Triethylamine (0.6 mL, 4.3 mmol) was slowly added while stirring. After 48 h the reaction was diluted with diethyl ether and washed twice with each of three aqueous solutions: 20% citric acid, saturated $NaHCO_3$ and saturated NaCl. After the collected extracts were dried over $MgSO_4$, the solvent was removed in vacuo and the residue recrystallized from ethyl acetate/petroleum ether to give 1.05 g (69%) of product.

[(CO)$_5$Cr=Tl=Cr(CO)$_5$]$^-$, the First Complex Containing Linear Twofold-Coordinated Thallium**

By *Berthold Schiemenz* and *Gottfried Huttner**

Dedicated to Professor Hans Bock on the occasion of his 65 birthday

The compounds [Cp′(CO)$_2$Mn=Ge=Mn(CO)$_2$Cp′][1] (Cp′ = C_5H_4Me) and [Cp(CO)$_2$Mn=Pb=Mn(CO)$_2$Cp][2] are of particular interest as cumulene analogues[3] containing linear-coordinated germanium and lead, respectively.[4] In these complexes all four electrons of the bridging atoms Ge^0 and Pb^0, respectively, participate in the bonding to the 16-electron complex fragments L_nM [Cp′(CO)$_2$Mn and Cp(CO)$_2$Mn, respectively]. The remaining coordination sites on the bridging building blocks are saturated by back bonding from donor orbitals of the metal complex fragments. The

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247) and the Fonds der Chemischen Industrie.

short Ge=Mn and Pb=Mn bonds and the linear coordination of the main group elements in these compounds are in agreement with this description, which should also be applicable to other four-electron building blocks. For As^{I}[5] and Sb^{I},[6] this expectation has been confirmed by structure analyses. Access to isoelectronic complexes containing Tl^{-I}[7] as a four-electron building block from group 13 has now been achieved.

$TlCl_3$ reacts with three equivalents of $K_2[Cr(CO)_5]$[8] to give the anionic trimetallacumulene complex **1**. After the addition of [2,2,2]cryptand,[9] [K^+-[2,2,2]cryptand]·**1**·0.6 THF was obtained as a crystalline salt.

$$3\ K_2[Cr(CO)_5] \xrightarrow[\text{[2,2,2] cryptand}]{TlCl_3\ /\ THF} \underset{\mathbf{1}}{\left[(CO)_5Cr{=}Tl{=}{=}Cr(CO)_5\right]^-}$$

The X-ray structure analysis of **1** (Fig. 1)[10] shows that the Tl center in **1** bridges two $Cr(CO)_5$ units in a linear fashion.[11]

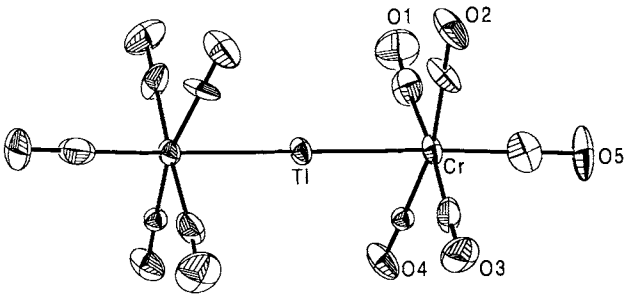

Fig. 1. Crystal structure of the anion $[(CO)_5Cr{=}Tl{=}Cr(CO)_5]^-$ (**1**). The relevant geometric data for the crystallographically independent halves of the two C_2 symmetric anions **1** in the crystal of [K^+-[2,2,2]cryptand]·**1**·0.6 THF are given, separated by a slash: Cr–Tl 264.9(3)/262.9(4) pm; Cr–Tl–Cr' 180.0(2)/177.0(1).

Two crystallographically independent anions **1** occur in the crystal of [K^+-[2,2,2]cryptand]·**1**·0.6 THF; each has crystallographically imposed C_2 symmetry. Since the equatorial carbonyl groups of the $Cr(CO)_5$ groups are almost superimposable, the effective symmetry of **1** is almost D_{4h}.

The Tl centers are each bound only to the Cr atoms; all contacts between the Tl centers and the oxygen atoms of the carbonyl groups of the neighboring complex ions in the crystal are longer than 310 pm.[11] The Tl–Cr distance in **1** (264 pm, Fig. 1) is thus very much shorter than that in **2** (287 pm),[12] which can be considered as a measure for a Tl–Cr single bond. This observation supports the classification of **1** as a member of the isoelectronic series of "cumulene" complexes $[L_nM{=}E{=}ML_n]^m$ (E = Ge, Pb: $m = 0$;[1,2] E = As, Sb: $m = 1$ +[5,6]). A similarly short Tl–Cr distance to that in **1** is only found in **3** (269 pm),[13] which belongs to the isoelectronic series of "inidene" complexes[14] $[L_nM{\cdots}E(R){\cdots}ML_n]^{m-1}$.[15] As expected, in cases when the structure of the "cumulene" complexes $[L_nM{=}E{=}ML_n]^m$ and those of the "inidene" complexes $[L_nM{\cdots}E(R){\cdots}ML_n]^{m-1}$ (E = Ge,[1,16] Pb,[2,17] As,[4,18] Sb,[5,19]) derived from them is known, slightly shorter M–E bonds (7–11 pm) are found for the "cumulene" complexes than for the corresponding "inidene" compounds. Correspondingly, the Tl–Cr distance in "cumulene" complex **1** is about 4 pm shorter than the Tl–Cr distance in the related "inidene" complex **3**.[13] The "cumulene" complex **4**, isoelectronic to **1**, is stabilized by dimerization to give **5** which contains a three-coordinate Tl

$$\underset{\mathbf{2}}{[Tl\{Cr(CO)_3Cp\}_3]} \qquad \underset{\mathbf{3}}{[(CO)_5Cr{\cdots}Tl(Cl){\cdots}Cr(CO)_5]^{2-}}$$

$$\underset{\mathbf{4}}{[(CO)_4Fe{=}Tl{=}Fe(CO)_4]^-} \qquad \underset{\mathbf{5}}{[\{(CO)_4Fe{-}Tl{-}Fe(CO)_4\}_2]^{2-}}$$

center.[20] The "cumulene" complex **1** can only be isolated because the bulky and rigid $Cr(CO)_5$ groups effectively shield the linear-coordinated thallium.

Experimental Procedure

All operations were carried out with freshly dried, and distilled solvents under argon. IR spectra: Bruker IFS 66, NMR spectra: Bruker AC 200.

To a suspension of KC_8 (568 mg, 4.2 mmol) in THF (15 mL) at −70 °C was added $Cr(CO)_6$ (440 mg, 2 mmol) in one batch. The dirty green suspension of the resulting $K_2[Cr(CO)_5]$ [8] was treated with $TlCl_3$ (218 mg, 0.7 mmol) at −70 °C. The mixture was allowed to warm to 20 °C with stirring over 5h; during this time the suspension turned orange. It was then treated with [2,2,2]cryptand (263 mg, 0.7 mmol) and stirred for an additional 5 min. The solvent was then decanted and filtered through 2 cm Celite/THF. The black residue (graphite) was washed twice, each time with THF (10 mL), and the solvent was distilled from the combined orange filtrates under vacuum at 20 °C. The residue was washed twice with deoxygenated H_2O (5 mL). After the washings were decanted off, an orange residue remained which was dried under vacuum for 3 h at 20 °C and then dissolved again in THF (5 mL). The resulting solution was divided equally into three test tubes (∅ = 1 cm), which were then placed in a Schlenk tube (250 mL). The Schlenk tube was filled with diethyl ether (50 mL) and left to stand for 3 h at 20 °C. During this time about 0.5 mL diethyl ether diffused into the THF solutions in the three test tubes. The diethyl ether was removed from the Schlenk tube and the solution in each of the test tubes was layered with 2 mL petroleum ether 40/60. The compound [K^+-[2,2,2]cryptand·1·0.6 THF] crystallized out at 20 °C over three days in the form of orange needles. $M = 1004.07\ g\,mol^{-1}$, $C_{28}H_{36}Cr_2KN_2O_{16}Tl{\cdot}0.6C_4H_8O$, yield: 700 mg (40% based on Tl), correct C, H, N analysis, IR (THF): $\tilde{\nu}$ = 2030 vw, 1982 w, 1939 vs, 1906 s, 1878 m cm^{-1} (CO). The number of bands and the similarity of the band shapes with the absorption pattern observed for the "inidene" complex **3** [13] indicates that in THF solution the Tl center of **1** is additionally coordinated by the solvent. ^1H NMR (200 MHz, [D_6]acetone, 193 K): δ = 3.77 (m, 12H), 3.64 (m, 24H), 3.62 (m, THF), 2.61 (t, THF).

The Bis(cyclopentadienyl)thallate(I) Anion Isoelectronic with Stannocene**

By *David R. Armstrong, Regine Herbst-Irmer, Annja Kuhn, David Moncrieff, Michael A. Paver, Christopher A. Russell, Dietmar Stalke,* Alexander Steiner,* and *Dominic S. Wright**

We have recently shown that a range of tri(cyclopentadienyl)stannate and -plumbate complexes consisting of discrete, "ion-separated" ion pairs and bridged, "contacted" ion pairs can be prepared by nucleophilic addition reactions of [Cp_2Mg] and [CpNa] to [Cp_2E] (Cp = C_5H_5; E = Sn, Pb).[1-3] In all these derivatives the heavy p block metals behave as acceptors rather than donating their electron pairs. In the Pb complexes[3] [$(\eta^5\text{-Cp})_2Pb(\mu\text{-}\eta^5\text{-Cp})Na\cdot PMDETA$] [PMDETA = $(Me_2NCH_2CH_2)_2NMe$] and [$\{(\eta^3\text{-Cp})Pb^-\}_2\cdot Mg(THF)_6^{2+}$], the $[Cp_3Pb]^-$ ions can be seen as extruded fragments of the polymeric zig-zag chain structure of orthorhombic $[Cp_2Pb]_x$.[4] With this in mind, we have turned our attention to cyclopentadienyl complexes with elements of Group 13 (E=Ga, In, Tl). The solid-state structures of [CpIn] and [CpTl] are both known and display polymeric zig-zag chains, $[(\mu\text{-}\eta^5\text{-Cp})E]_x$, in which the metal centers again behave as acceptors to the bridging Cp ligands.[5] We wondered whether complexes containing $[Cp_2E]^-$ units could be prepared by addition of Cp^- to Group 13 metallocenes.

We report the syntheses and structures of the ion-separated complex **1** and of the contacted complex **2**.[6] Both com-

$[(\eta^5\text{-Cp})_2Tl(\eta^5\text{-Cp})Mg\cdot PMDETA]$ **1**
$[(\eta^5\text{-Cp})Tl(\mu\text{-}\eta^5\text{-Cp})Li\cdot PMDETA]$ **2**

plexes contain bent $[(\eta^5\text{-Cp})_2Tl]^-$ ions which are isoelectronic and isostructural with the 14-electron complex stannocene.

Complex **1** is prepared by stirring a mixture of [CpTl] and [Cp_2Mg] (1:1 mol ratio) in THF. Addition of PMDETA (1 mol equiv) produces a colorless precipitate of **1** which is recrystallized from THF. Similar reaction of [CpTl] and [CpLi] (1:2 mol ratio) in THF, followed by addition of PMDETA (1 mol equiv), produces **2** (see Experimental Procedure).

An X-ray crystallographic study on complex **1**[6] shows a structure with discrete ion pairs (Fig. 1). The unit cell con-

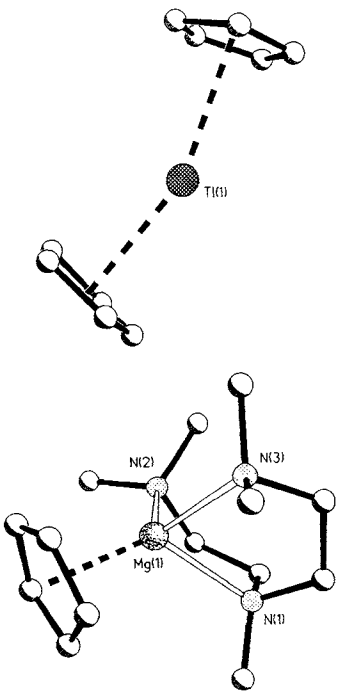

Fig. 1. Molecular structure of **1**. Hydrogen atoms have been omitted for clarity. sists of two independent $[(\eta^5\text{-Cp})_2\text{Tl}]^-$ ions and two independent $[(\eta^5\text{-Cp})\text{Mg}\cdot\text{PMDETA}^+]$ ions. The structure of **2** contains two independent contacted ion pairs in the solid state (Fig. 2), in which one Cp ligand bound to Tl is additionally involved with a Lewis base solvated Li^+ ion (av $Li-Cp(b)_{centroid}$ 2.25 Å) as a (μ–Cp) bridge.[6] All the independent $[(\eta^5\text{-Cp})_2\text{Tl}]^-$ units of **1** and **2** are bent, with a mean Cp-Tl-Cp angle (from the centroids of the Cp ligands) of 156.7° in **1** and 153.3° in **2**. These angles can be compared to the average centroid Cp-E-Cp angle of 146° for the two independent bent molecules of $[Cp_2Sn]$ in the solid state[10] and approximately 135° for $[Cp_2Pb]$ in the gas phase,[11] with which the 14-electron thallate ions in **1** and **2** are isostructural and isoelectronic. The Cp-Tl-Cp angle in polymeric $[(\eta^5\text{-Cp})\text{Tl}]_\infty$ is significantly more acute (ca. 137°) than those observed in the $[(\eta^5\text{-Cp})_2\text{Tl}]^-$ ions of both complexes.[5]

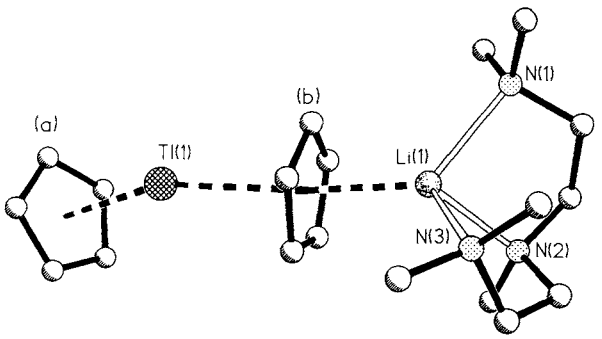

Fig. 2. Molecular structure of **2**. Hydrogen atoms have been omitted for clarity. Selected distances [Å]: Molecule 1: Tl(1)-C(11) 3.02(1), Tl(1)-C(12) 3.07(1), Tl(1)-C(13) 3.20(1), Tl(1)-C(14) 3.19(1), Tl(1)-C(15) 3.10(1), Tl(1)-C(16) 2.81(1), Tl(1)-C(17) 2.86(1), Tl(1)-C(18) 2.89(1), Tl(1)-C(19) 2.89(1), Tl(1)-C(12) 2.82(1), Li(1)-C(11) 2.69(2), Li(1)-C(12) 2.53(2), Li(1)-C(13) 2.34(2), Li(1)-C(14) 2.42(2), Li(1)-C(15) 2.62(2). Molecule 2: Tl(2)-C(21) 3.00(1), Tl(2)-C(22) 3.04(1), Tl(2)-C(23) 3.13(1), Tl(2)-C(24) 3.10(1), Tl(2)-C(25) 3.03(1), Tl(2)-C(26) 2.82(1), Tl(2)-C(27) 2.86(1), Tl(2)-C(28) 2.91(1), Tl(2)-C(29) 2.90(1), Tl(2)-C(30) 2.86(1), Li(2)-C(21) 2.68(2), Li(2)-C(22) 2.61(2), Li(2)-C(23) 2.45(2), Li(2)-C(24) 2.46(2), Li(2)-C(25) 2.59(2). Averages over all molecules in the unit cell: Tl-Cp(a) (centroid) 2.61, Tl-Cp(b) (centroid) 2.85, Li-Cp(b) (centroid) 2.25, Li-N 2.23, Cp(a) (centroid)-Tl-Cp(b) (centroid) 153.3, Cp(a) (centroid)-Li-Cp(b) (centroid) 175.7.

While the Tl center of the discrete $[(\eta^5\text{-Cp})_2\text{Tl}]^-$ ion in **1** is attached almost equivalently to the two η^5-Cp ligands (av $Tl-Cp_{centroid}$ 2.72 Å), in **2** the terminal η^5-Cp contact (av $Tl-Cp(a)_{centroid}$ 2.60 Å) is significantly shorter than that made with the Li^+-bridging μ-Cp ligand (av $Tl-Cp(b)_{centroid}$ 2.85 Å). In **2**, the Li^+ ion competes with Tl for the electron density on the bridging Cp ligand. The Cp ligand is "dragged" away from the Tl center, and there is a compensatory enhancement in the interaction between the terminal η^5–Cp ligand and Tl; the $Tl-Cp(a)_{centroid}$ distance approaches that found in the gas-phase structure of monomeric $[(\eta^5\text{-Cp})\text{Tl}]$ (ca. 2.41 Å).[12] Similarly to the bridging μ–η^5-Cp ligand found in $[(\eta^5\text{-Cp})_2\text{E}(\mu\text{–}\eta^5\text{-Cp})\text{Na}\cdot\text{PMDETA}]$ (E = Sn, Pb), the μ-Cp bridge of **2** is bent (av $Tl-Cp(b)_{centroid}$-Li 175.2°, cf. ca. 172° in $[(\eta^5\text{-Cp})_2\text{E}(\mu\text{-}\eta^5\text{-Cp})\text{Na}\cdot\text{PMDETA}]$).[1–3]

Complexes **1** and **2** are only the second examples of monomeric Cp thallium(I) species characterized in the solid state; the only other known monomeric complex is $[TlC_5(CH_2Ph)_5]$.[13] Almost all structurally characterized Cp-based derivatives of thallium so far have had polymeric structures akin to that of $[(\eta^5\text{-Cp})\text{Tl}]_\infty$.[5] Additionally, **1** and **2** are the only structurally characterized unsubstituted Cp derivatives apart from $[(\eta^5\text{-Cp})\text{Tl}]_\infty$. The closest structural analogue to **1** and **2** is the dimeric ring complex $[\{\text{TlAu}(C_5H_4PPh_2)_2\}_2]$, in which essentially linear $[C_5H_4PPh_2\text{–Au–}C_5H_4PPh_2]$ units are linked together through η^5-Cp contacts to Tl^I ($Cp_{centroid}$-Tl-$Cp_{centroid}$ ca. 135°).[14] In view of our results this complex can be reinterpreted as an ion-contacted gold thallate complex rather than the implied Tl-contacted gold diphosphide, although there is some ambiguity as to the charge distribution in the ligand.

To our knowledge, $[(\eta^5\text{-Cp})\text{Mg}\cdot\text{PMDETA}]^+$ of **1** is the first example of a mononuclear cationic fragment derived from $[Cp_2Mg]$.[15] It is interesting to note that, although its bonding is largely ionic, the cation is formally isoelectronic with the 12-electron compound $[Cp_2Mg]$.

Ab initio MO calculations were performed on various isomers of the discrete $[Cp_2Tl]^-$ ion in **1** at the Hartree–Fock level and with electron correlation.[16, 17] Initially minimum basis set (MBS) calculations were performed on different Cp ring conformations, to assess the relative stabilities of the "linear" and "bent" models. The most stable bent C_s conformer (**I**), the same as that observed for the $[Cp_2Tl]^-$ ion in **1** in the solid state, and the most stable linear D_{5d} conformer (**II**) were then optimized using the ECP-DZ basis set. Their geometries and that of [CpTl] (**III**) are shown in Figure 3. The

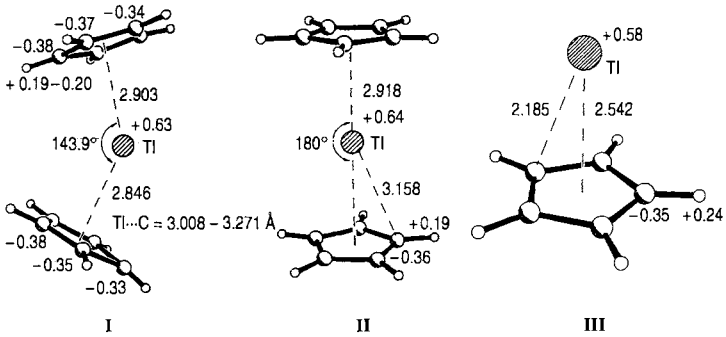

Fig. 3. Optimized geometries (DZ basis set) of the $[Cp_2Tl]^-$ ion—the bent structure with C_s symmetry (**I**) and the linear structure with D_{5d} symmetry (**II**)—and that of monomeric [CpTl] (**III**).

energy for the association of Cp^- and [CpTl] is reasonably favorable (– 6.38 kcal mol^{-1} to give the most stable bent structure **I**).[17] Although the Cp–Tl contacts are significantly elongated in **I** and **II** compared to the Cp–Tl distance in **III**, there is little difference either in the charge carried by the Cp ring atoms or in the charge on the Tl center. Bending of the linear structure **II** producing **I** slightly enhances the Cp–Tl interactions but has only a marginal effect on the charge distribution within the molecule. However, whereas in **II** the Cp ligands are symmetrically attached to Tl ($Cp_{centroid}$–Tl 2.918 Å), in **I** one of the Cp ligands is closer to the metal than the other is ($Cp_{centroid}$–Tl) 2.846 and 2.903 Å).

The optimized geometries (DZ basis set) of the linear and bent isomers of $[Cp_2Tl]^-$ were employed in a series of calculations with electron correlation. The results (MP2, MP3, MP4) confirm that the bent geometry is only slightly more stable than its linear counterpart; at the MP4 level the difference in energy is 0.82 kcal mol^{-1}.[17] This finding is contrary

to that calculated for the 14-electron complex $[Cp_2Ge]$ and to the general concensus concerning $[Cp_2Sn]$,[18–20] which proposes that bent structures are preferred on electronic grounds since bending presumably stabilizes the lone pair in the antibonding a_{1g}^* molecular orbital as a consequence of the admixing of this orbital with the metal p_x atomic orbital. Overall, the calculations on $[Cp_2Tl]^-$ indicate that the geometry of the thallocene anion is highly flexible. Orbital admixing appears to be ineffective here and a largely spherical lone pair orbital is present. This feature is illustrated in Figure 4 where, in addition, it can be seen that there is a constriction in the electron density between Tl and the more weakly attached Cp ligand.

Fig. 4. One of the isosurfaces of electron density for the bent structure of $[Cp_2Tl]^-$ having C_s symmetry (geometry optimization with the DZ basis set).

Experimental Procedure

1: [CpTl] (0.538 g, 2.0 mmol) was stirred with $[Cp_2Mg]$ (0.308 g, 2 mmol) in 10 mL THF. The reactants dissolved giving a golden brown solution. On addition of PMDETA (0.42 mL, 2 mmol) a pink solid precipitated, which dissolved on heating the reaction mixture to reflux. The reaction mixture was filtered and cooled slowly (12 h at 20 °C) to give air-sensitive, light-pink crystals of **1**. Yield 0.360 g (30%) over two batches; decomp 120 °C to black solid; IR (Nujol) $\tilde{\nu}$=3059 cm^{-1} (Cp-H); ^1H NMR (+25 °C, 400 MHz, $[D_8]$ THF): δ=5.66 (s, 15 H; CpH), 2.41 (s, 3H; CH_3N), 2.34 (s, 12H; $(CH_3)_2N$), 2.11 (s, 8 H; $(CH_2)_2$); ^{13}C NMR (+25 °C, 100.6 MHz, $[D_8]$ THF): δ=107.0 (C_5H_5), 55.0–59.0 (CH_3N and $(CH_3)_2N$), 46.0–49.0 ($(CH_2)_2$; correct C, H, N analysis.

2: [CpTl] (0.538 g, 2.0 mmol) was stirred with [CpLi] (0.288 g, 4 mmol) in 10 mL THF. The solid dissolved giving a yellow solution which was filtered before PMDETA (0.42 mL, 2 mmol) was added. Cooling of the resulting solution (2 d at −35 °C) gave air-sensitive, colorless crystals of **2**. The crystals melt and/or redissolve below 0 °C, and all attempts to isolate them were unsuccessful. **2** could only be characterized by low-temperature X-ray crystallography [7].

[6] Crystal data for **1**: $C_{24}H_{38}N_3MgTl$, M = 597.3, monoclinic, space group $P2_1/c$, a = 15.129(3), b = 15.483(4), c = 21.090(4) Å, $\alpha = \gamma = 90°$, β = 90.02(3), V = 4.940 nm^{-3}, Z = 8, ρ_{calcd} = 1.606 $Mg\,m^{-3}$, λ = 0.71073 Å, T = −120 °C, $\mu(Mo_{K\alpha})$ = 6.578 mm^{-1}. Data were collected on a Siemens-Stoe AED diffractometer using an oil-coated, rapidly cooled crystal of dimensions 0.2 × 0.2 × 0.2 mm in an oil drop [7] by the $2\theta/\omega$ method ($8° \le 2\theta \le 45°$). Of a total of 13787 collected reflections, 6434 were independent. The data were corrected for absorption by a semiempirical method based on Ψ scans. The structure was solved by Patterson methods (SHELXS-90)[8] and refined by full-matrix least-squares on F^2 [9] to final values of $R1$ ($F > 4\sigma(F)$) = 0.083 and $wR2$ = 0.193 (all data) [$R1 = \sum|F_o - F_c|/\sum F_o$ and $wR2 = (\sum w(F_o^2 - F_c^2)^2/\sum w(F_o^2)^2)^{0.5}$]; largest peak and hole in the final difference Fourier map were 4.152 and −2.218eÅ^{-3}. The structure was successfully refined as a twin, in which the monoclinic angle, very close to 90°, shows orthorhombic symmetry to be emulated. The twinning factor B refines to 0.488 (C. S. Pratt, B. A. Coyle, J. A. Ibers, *J. Chem. Soc. A.* **1971**, 2146–2152). Crystal data for **2**: $C_{19}H_{33}LiN_3Tl$, M = 514.79, monoclinic, space group $P2_1/c$, a = 13.390(3), b = 25.604(6), c = 13.390(3) Å, $\alpha = \gamma = 90°$, β = 112.39(3)°, V = 4245(2)Å^{-3}, Z = 8, ρ_{calcd} = 1.611 $Mg\,m^{-3}$, λ = 0.71073 Å, T = −120 °C, $\mu(Mo_{K\alpha})$ = 7.615 mm^{-1}. Data were collected on a Siemens-Stoe AED diffractometer using an oil-coated, rapidly-cooled crystal of dimensions 0.2 × 0.1 × 0.1 mm in an oil drop [7] by the $2\theta/\omega$ method ($8° \le 2\theta \le 45°$). Of a total of 17661 collected reflections, 5644 were independent. The data were corrected for absorption by a semiempirical method based on Ψ scans. The structure was solved by Patterson methods (SHELXS-90)[8] and refined by full-matrix least-squares on F^2 [9] to final values of $R1$ ($F > 4\sigma(F)$) = 0.043 and $wR2$ = 0.112 (all data) [$R1 = \sum|F_o - F_c|/\sum F_o$ and $wR2 = (\sum w(F_o^2 - F_c^2)^2/\sum w(F_o^2)^2)^{0.5}$]; largest peak and hole in the final difference Fourier map were 2.117 and −1.887 eÅ. The structure was successfully refined as a twin. Since a and c are the same length orthorhombic symmetry is shown to be emulated. The twinning factor B refines to 0.474(1) (C. S. Pratt, B. A. Coyle, J. A. Ibers, *J. Chem. Soc. A.* **1971**, 2146–2152). Conformational Analysis of Model Complexes for Methyl-Coenzyme-M Reductase from Methanogenic Bacteria: A Comparison of Crystal and Solution Structures**

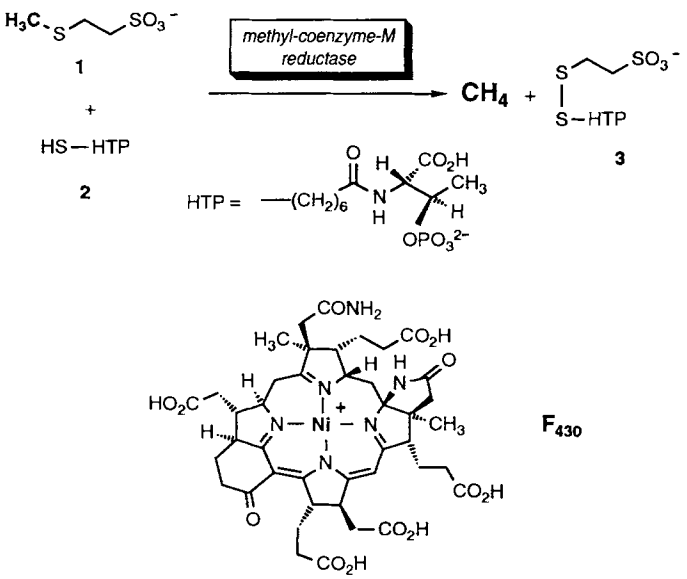
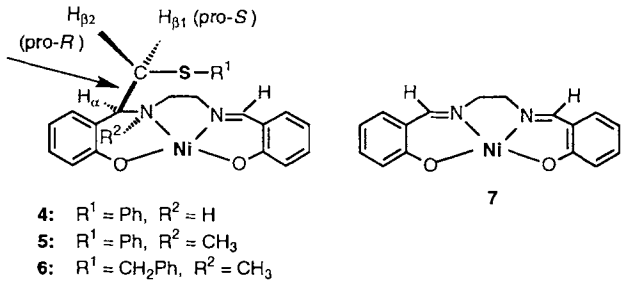
By *Albrecht Berkessel,* Michael Bolte, Christian Griesinger,* Gottfried Huttner, Thomas Neumann, Berthold Schiemenz, Harald Schwalbe,* and *Thomas Schwenkreis*

In the last step of the archaebacterial methanogenesis, the methylthioether methyl-coenzyme-M **1** reacts with the thiol *N*-7-mercaptoheptanoyl-*O*-phospho-*L*-threonine ("HS-HTP", **2**) to yield methane and the mixed disulfide **3**.[1] This unusual reaction is brought about by the enzyme methyl-coenzyme-M reductase, which contains the nickel tetrahydrocorphinoid "factor 430" (F_{430}) as cofactor.[2] In general, metalloenzyme-mediated catalysis depends on the specific interaction between substrate(s) and metal ion(s). Also in the case of methyl-coenzyme-M reductase it is assumed that the nickel ion of F_{430} participates in the catalytic process.[3]



Transition metal complexes of multidentate ligands have been used successfully as models for the study of metal–substrate interactions in metalloenzymes.[4] For methyl-coenzyme-M reductase, nickel chelates such as *rac*-**4** have been used to simulate the interaction of the organosulfur substrates **1** and **2** with cofactor F_{430}: the comparison of the redox properties of model complexes made it possible to develop a mechanistic hypothesis for the catalytic cycle of methyl-coenzyme-M reductase.[5] The Ni^{II} complexes *rac*-**4**–**6** are derivatives of Ni^{II}-salen, in the sense that one C–N double bond has been modified into a C–N single bond.[7, 10] The corresponding carbon atom now bears a thioether-containing side chain; the nitrogen atom is bound to a hydrogen atom in *rac*-**4** and to a methyl group in *rac*-**5**, **6**. The flexibility of the side chain enables the coordination of its heteroatom to the metal ion. Through rotation around the C–C single bond marked by an arrow, however, other local conformations are possible, in which the sulfur atom is turned away from the metal ion. Figure 1 shows the Newman projections of the three staggered conformations about this C–C single bond.



4: $R^1 = Ph$, $R^2 = H$
5: $R^1 = Ph$, $R^2 = CH_3$
6: $R^1 = CH_2Ph$, $R^2 = CH_3$

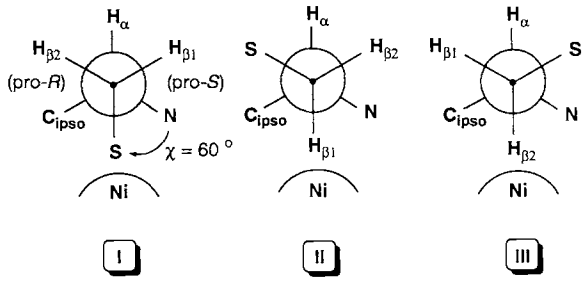


Fig. 1. Newman projections for the staggered conformations of the side chains of the nickel chelates *rac*-**4**–**6**; antiperiplanar arrangement of H_α and S, H_α-$H_{\beta 1}$, and H_α-$H_{\beta 2}$.

In order to find out whether model complexes of the type *rac*-**4**–**6** can be used to demonstrate an attractive interaction between the sulfur atom in the side chain (representing the sulfur-containing substrates of methyl-coenyzme-M reductase) and the nickel ion (representing the nickel ion in F_{430}), it appeared promising to determine the preferred conformation of the thioether side chain in *rac*-**4**–**6**. Herein we report the conformational analysis of the nickel complexes *rac*-**4**–**6** in solution by NMR spectroscopy and compare the preferred conformations thus found with the side chain conformations in the crystals of the respective compounds.

The thioether side chain in the crystal structure of the Ni^{II} complex *rac*-**4** has the local conformation I; the sulfur atom is coordinated to the nickel ion, the dihedral angles H_α-C-C-$H_{\beta 1}$ and H_α-C-C-$H_{\beta 2}$ are $-59.2°$ and $59.7°$, respectively (Fig. 1, conformation I and Fig. 2a). A centrosymmetric dimer is formed from one molecule each of **4** and *ent*-**4**. This dimer is stabilized by two NH···O hydrogen bonds. In this arrangement the sixth coordination site of the nickel ion of one molecule is filled by the phenolate oxygen atom of the other molecule in the dimer, resulting in a distorted octahedral coordination geometry at Ni. The distances from the nickel ions in *rac*-**4**, **5**, and **6** to the N, O, and S atoms of the ligands are listed in Table 1.

Table 1. Distances [Å] between the nickel ion and the heteroatoms in the ligands in complexes *rac*-**4**[7], *rac*-**5**[9], and **6**[11,12] (from crystal structures).

Complex	Ni-S	Ni-O1	Ni-O2	Ni-O1*	Ni-N1	Ni-N2
rac-**4**	2.575(5)	2.026(4)	1.981(4)	2.109(4)	2.060(5)	1.989(5)
rac-**5**	4.826(3)	1.834(3)	1.864(3)	–	1.846(3)	1.922(4)
6	4.751(3)	1.841(3)	1.847(5)	–	1.843(7)	1.926(4)

Table 2. Vicinal coupling constants[a] and distances determined by NOE experiments[a] on the nickel chelates *rac*-**4**–**6**.

No.	Vicinal coupling constants, distance	Nickel chelate *rac*-**4**	*rac*-**5**	*rac*-**6**
1	$^3J(H_x,H_{\beta 1})$ [Hz]	2.9	2.5	3.4
2	$\delta(H_{\beta 1})$	4.45	5.24	4.29
3	$^3J(H_x,H_{\beta 2})$ [Hz]	9.5	8.0	7.9
4	$\delta(H_{\beta 2})$	4.54	4.82	4.52
5	NOE(H_x-$H_{\beta 1}$) [b] [pm]	278	269	278
6	NOE(H_x-$H_{\beta 2}$) [b] [pm]	250	250	250
7	NOE($H_{\beta 1}$-$H_{ethylene}$) [b, c] [pm]	237	213	213
8	NOE($H_{\beta 2}$-$H_{ethylene}$) [b, c] [pm]	344	272	286

[a] For experimental details see ref.[13]. [b] Calibrations based on NOE cross peak intensities of the two geminal protons $H_{\beta 1}$, $H_{\beta 2}$; $d(H_{\beta 1}\cdots H_{\beta 2}) = 178$ pm (standard bond lengths and angles; error ± 10 pm). [c] pro-*S*-H of the methylene group adjacent to the amine nitrogen atom, labeled H_e ("$H_{ethylene}$") in Figures 2a–c.

The crystal structure of the nickel complex *rac*-**5** shows it to be monomeric, and the sulfur atom of the thioether side chain is *not* bound to the Ni^{II} ion (Fig. 2b).[7,9] Instead, the side chain exhibits conformation II (Fig. 1). Hence, the Ni^{II} ion in *rac*-**5** is four-coordinate with a square-planar coordination geometry. The exchange of the phenylthio moiety in the side chain with a benzylthio group led to the Ni^{II} complex *rac*-**6**, which formed high-quality crystals readily. Its crystal structure[7,11,12] shows that **6** is monomeric in the crystalline state and is present in conformation II (Fig. 1).

The three Ni^{II} chelates *rac*-**4**–**6** are diamagnetic in solution (^{1}H NMR); for *rac*-**4** in $CDCl_3$, however, slightly broadened signals were observed for $H_{x,\beta 1,\beta 2}$. The addition of [D_6]dimethylsulfoxide ([D_6]DMSO) led to "normal" line widths. In spite of the completely different side chain conformations found in the crystal structures, *rac*-**4**–**6** exhibit similar vicinal coupling constants $^3J_{Hx-H\beta 1}$, $^3J_{Hx-H\beta 2}$ (Table 2). These NMR data can be interpreted with three models: 1) *one* staggered conformation (I *or* II *or* III in Fig. 1), 2) *one* nonstaggered conformation ($\varkappa \neq 60, 180, -60°$), and 3) a Pachler equilibrium[14] of the three staggered conformations I–III (Fig. 1). Model 1: The "large–small" coupling pattern observed for all three complexes cannot be explained by the exclusive presence of the staggered conformation I, which was found in the crystal structure of *rac*-**4** (Fig. 2a). The approximately equal dihedral angles H_x-C-C-$H_{\beta 1}$ and H_x-C-C-$H_{\beta 2}$ ($\varkappa \approx \pm 60°$) should lead to roughly equal coupling constants $^3J_{Hx-H\beta 1}$ and $^3J_{Hx-H\beta 2}$. The presence of *exclusively* conformations II and III is contradicted by the value of $^3J_{Hx-H\beta 2}$ (Table 2, line 3), which is too small for a purely *trans* coupling. Model 2: The attempt to interpret the experimental data with a nonstaggered conformation leads to high standard deviations and incompatible results from the ^3J and NOE analyses. Model 3: Table 3 lists the results of the Pachler analysis[14] for the complexes *rac*-**4**–**6**. For all three complexes an approximately 1:1 distribution of a *trans–gauche* (II or III, Fig. 1) and the *gauche–gauche* conforma-

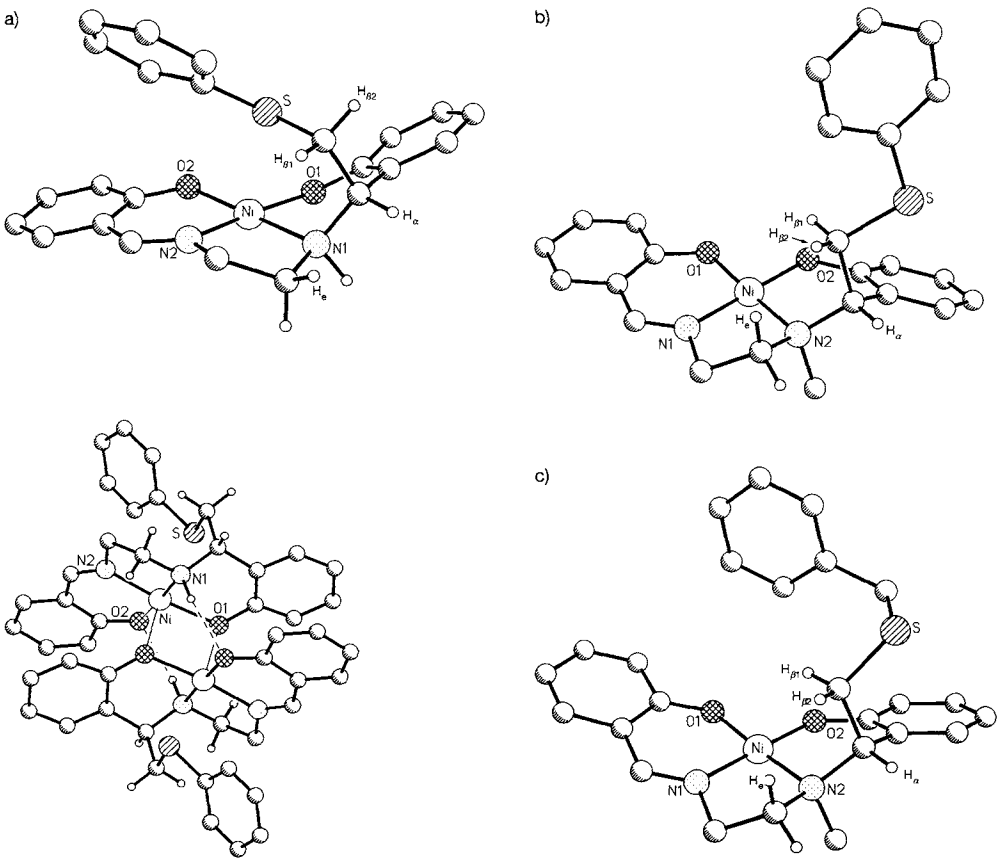

Fig. 2. a) Crystal structure of *rac*-**4**. Top: only **4** is shown; bottom: centrosymmetric dimer of **4** and *ent*-**4**. The hydrogen bonds between N1 and O2* as well as between N1* and O2 are depicted by dashed lines, the intermolecular Ni–O coordination is indicated by thin lines. b) Crystal structure of *rac*-**5** (only one enantiomer is shown). c) Crystal structure of **6**.

Table 3. Model 3: Calculated conformer populations (I, II, III) for the complexes *rac*-**4**–**6** (in %).

Conformation	*rac*-**4**		*rac*-**5**		*rac*-**6**	
	J [a]	NOE [b]	*J* [a]	NOE [b]	*J* [a]	NOE [b]
I	63	60	50	56	49	60
II	6(31) [c]	2(38) [c]	2(48) [c]	1(43) [c]	10(41) [c]	2(38) [c]
III	31(6) [c]	38(2) [c]	48(2) [c]	43(1) [c]	41(10) [c]	38(2) [c]

[a] The Karplus equation was parameterized according to McLaughlin et al. [15c], $^3J(H\alpha,H\beta)(\theta) = 12.1\cos^2\theta - 1.6\cos\theta$. [b] The conformer distribution was calculated assuming an r^{-6} averaging of the NOE. [c] Based on the homonuclear $^3J(H\alpha,H\beta)$ coupling data and the NOEs between these nuclei, it is impossible to distinguish between equilibria of II and I, and III and I.

tion (I, Fig. 1) is found. The determination of the preferred *trans–gauche* conformation and the assignment of the diastereotopic protons $H_{\beta1}$ and $H_{\beta2}$ was possible by measuring the NOE between the pro-*S* methylene proton adjacent to N2 in *rac*-**6** (labeled H_e, "$H_{ethylene}$" in Fig. 2a–c) and $H_{\beta1}$ and $H_{\beta2}$, respectively. If one assumes the conformation for the ethylene group that was found in the crystal structure,[16] the local conformations I, II, and III of the thioether side chain lead to the distances between $H_{\beta1}$, $H_{\beta2}$, and $H_{ethylene}$ that are summarized in Figure 3. By using the Pachler equi-

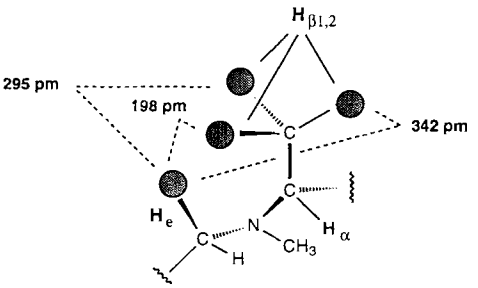

Fig. 3. Distances from the H_e atom ("$H_{ethylene}$", pro-*S*-H) to the three possible positions of $H_{\beta1}$ and $H_{\beta2}$.

librium, (derived from analysis of the coupling constants) for complex *rac*-**6** (conformation I, 49%; II, 10%; III, 41%) (Table 3), the protons $H_{\beta1}$ and $H_{\beta2}$ are calculated to be on average 227 and 269 pm from $H_{ethylene}$. This is in agreement with the experimentally found data (Table 2, lines 7,8). The stereochemical assignment of $H_{\beta1}$ and $H_{\beta2}$ follows from this equilibrium to be pro-*S* and pro-*R*, respectively. The reverse population of conformers II and III (I, 49%; II, 41%; III, 10%) leads to roughly equal average distances between $H_{\beta1,2}$ and $H_{ethylene}$ (225 and 221 pm), which is in contrast to the NOE-derived distances of 213 and 286 pm (Table 2, lines 7,8) and is therefore ruled out. In all three complexes (*rac*-**4**–**6**) one observes average distances between $H_{\beta1,2}$ and $H_{ethylene}$ that are different in magnitude. Hence, it appears justified to assume an approximately 1:1 equilibrium of the conformers I and III for all three complexes in solution. The equilibria found for the three complexes are in agreement with the nearly equal average coupling constants $^3J_{N-H\beta1}$ and $^3J_{N-H\beta2}$ for *rac*-**5** of 1.4 and 1.8 Hz, respectively. These couplings were determined according to the method of Keeler and Neuhaus[18] from a 2D heteronuclear multiple bond correlation (HMBC) NMR spectrum of the complex which was ^{15}N labeled at N2 (Fig. 4).

In summary, the following conclusions appear justified: 1) There is no dominant, attractive Ni–S interaction in the monomeric, neutral Ni^{II}-dihydrosalen complexes *rac*-**4**–**6** in

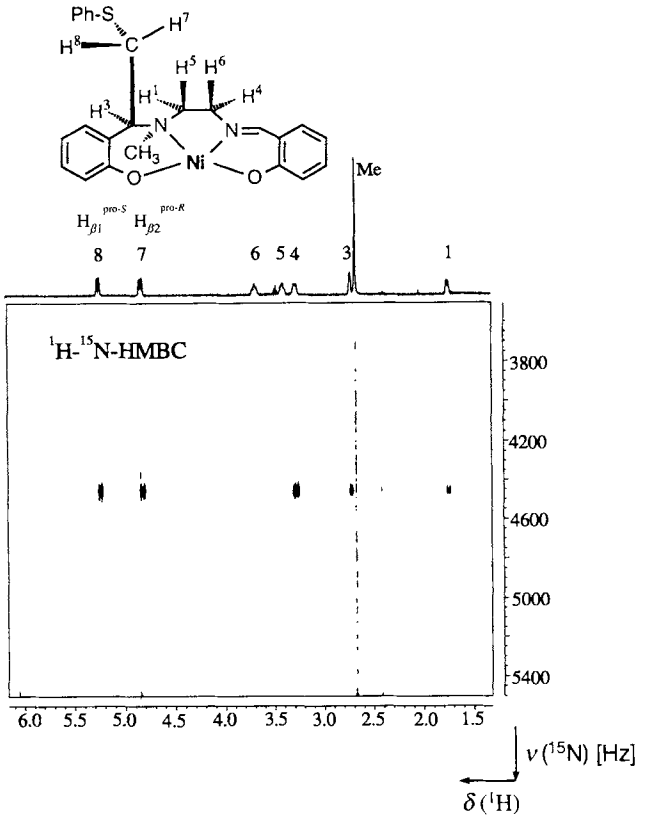

Fig. 4. ^1H-^{15}N HMBC NMR spectrum of the complex *rac*-**5**.

solution. Presumably the conformer equilibrium is regulated in all three cases to about the same extent by nonbonding, intramolecular interactions. 2) The formation of two NH···O hydrogen bonds favors the dimerization of complex *rac*-**4** in the crystal[19] and leads to a higher coordination number for the nickel ion, initially by the axial coordination of a phenolate oxygen atom. The coordination of the thioether sulfur atom then completes the pseudooctahedral ligand sphere.

The study of the complexes *rac*-**4**–**6** by NMR spectroscopy and X-ray crystal structure analysis shows once again[20] that the conformation that is "frozen out" in the crystal is not necessarily the preferred conformation in solution and that the support or hindrance (in the crystal or by the solvent) of hydrogen-bond- induced self-association can result in dramatic changes in the conformer distribution. For the substrate–cofactor interaction in methyl-coenzyme-M reductase, this leads to the interesting possibility that the strength of the binding could be regulated by the absence or presence of a sixth ligand on the nickel ion of F_{430}.

[16] In the case of *rac*-**4**, the crystal structure indicated the "inverted" conformation for the ethylene bridge with a pseudoequatorial $H_{ethylene}$ (pro-*S*-H) (Fig. 2a). The assumption of this conformation for the ethylene bridge leads unambiguously to the same results with quantitatively slightly differing distance data.

Cation Inclusion within the Mixed-Valence Polyanion Cluster $[(Mo^{VI}O_3)_4Mo^{V}_{12}O_{28}(OH)_{12}]^{8-}$: Syntheses and Structures of $(NH_4)_7[NaMo_{16}(OH)_{12}O_{40}]\cdot 4H_2O$ and $(Me_2NH_2)_6[H_2Mo_{16}(OH)_{12}O_{40}]$**

By *M. Ishaque Khan, Achim Müller,* Stephan Dillinger, Hartmut Bögge, Qin Chen,* and *Jon Zubieta**

The understanding of the driving force for the formation of high-nuclearity clusters is still a challenge. This is especially valid for polyoxometalates having a tremendous variety of quasi-spherical structures with highly symmetrical core assemblies of MO_x units.[1] Though the famous α-Keggin anion $[Mo_{12}O_{40}P]^{3-}$,[2] which has an extremely high formation tendency, was isolated nearly 200 years ago and numerous compounds based on this isomer have been reported, the ε isomer (formally obtained by rotation of all four Mo_3O_{13} groups by 60°) seems to be rather unstable. *No pure Mo/O or W/O compound with ε-Keggin structure has yet been isolated.* The reason seems to be that the density of packing of the oxygen atoms decreases gradually from the α to the ε isomer,[3] whereby 12-membered ring systems result. This class of compounds is also of interest with regard to the new area of inorganic host–guest chemistry.[4–7] The polyvanadates, for instance, adopt basket, bowl, belt, barrel, and spherical structures which can encapsulate neutral, anionic, and cationic species, and even cation–anion aggregates.[8–16] Likewise, cyclic arsenic(III) polytungstates and phosphorus (V) polytungstates have been shown to encapsulate a variety of cations.[17, 18] In contrast, oxomolybdate cages or clusters accommodating guest species remain relatively rare, with the notable exception of the recently described cluster species $[Na(H_2O)_3Mo_{42}H_{15}O_{109}\{(OCH_2)_3CCH_2OH\}_7]^{7-}$.[19] We report here on the synthesis of a mixed-valence Mo^V/Mo^{VI} polyanion cluster which exhibits a central ε-Keggin unit and a cavity capable of accommodating protons or metal cations, as demonstrated by clusters **1** and **2**.

$(Me_2NH_2)_6[H_2Mo_{16}(OH)_{12}O_{40}]$ **1**

$(NH_4)_7[NaMo_{16}(OH)_{12}O_{40}]\cdot 4H_2O$ **2**

Both **1** and **2** were isolated in 20% yield from aqueous solutions containing molybdate and both organic and inorganic templates. The red needles of **1** and red-orange cubes of **2** are water soluble, and the latter rapidly become opaque when removed from the mother liquor. X-ray structural analyses[20] of **1** and **2** reveal the presence of discrete, ordered $[Mo_{16}(OH)_{12}O_{40}]^{8-}$ anions (Fig. 1) that have a central cavity encapsulating protons or a Na^+ ion. Both anions contain four Mo^{VI} centers, twelve Mo^V centers, forty oxo groups, and twelve hydroxy groups in full tetrahedral T_d symmetry.

The twelve Mo^V centers in **1** and **2** form six binuclear units with an Mo–Mo distance of 2.62(1) Å (single bond). The

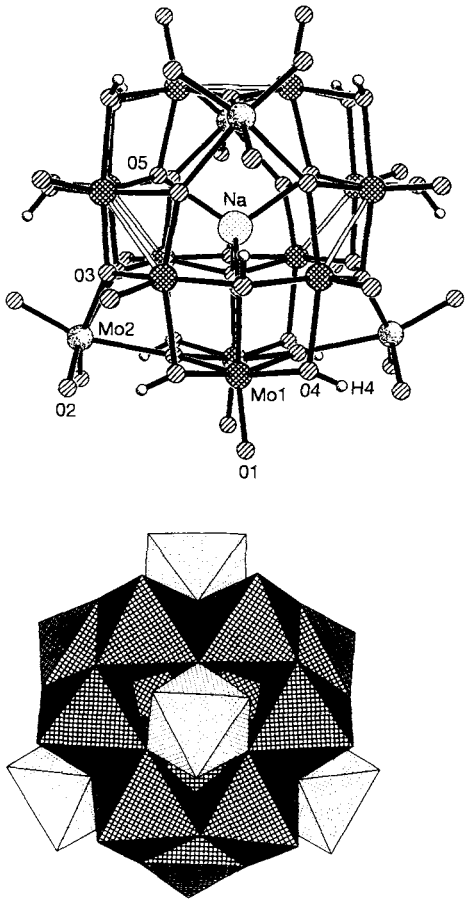

Fig. 1. Top: The structure of the cluster anion of **2**, $[Na(Mo^{VI}O_3)_4Mo^{V}_{12}(OH)_{12}O_{28}]^{7-}$, which possesses a $(H_{12}Mo_{16}O_{52})$ core essentially identical to that of **1**. Bottom: A polyhedral representation of the sturcture of the anion of **2** along the crystallographic threefold axis showing the location of the trioxomolybdenum(VI) units on the hexagonal faces of the $(Mo_{12}O_{40})$ core (see text).

four facial ($Mo^{VI}O_3$) "anti-Lipscomb" units[21] cap four faces of a Mo/O framework based upon the Mo^{V}_{12} truncated tetrahedron, whereby the four Mo^{VI} sites form an expanded Mo_4 tetrahedron. The high degree of reduction of the central core ($Mo_{12}O_{40}$) significantly increases the basicity of the oxygen atoms on the surface, which allows aggregation of the electrophilic (MoO_3) units.

The 52 oxygen atoms of the cluster anion are of five distinct types. The twelve O1 oxygen atoms are each terminally bonded to a Mo^{V} atom of the ($Mo_{12}O_{40}$) core at a distance of 1.69(2) Å. The twelve O2 oxygen atoms are associated with the four facial trioxomolybdenum ($Mo^{VI}O_3$) capping units as strongly bonded terminal oxo groups with an Mo2–O2 separation of 1.74(3) Å. Each of the twelve O3 oxygen atoms binds in an μ_3 fashion to Mo^{V} centers of the binuclear units and an Mo2 site; the bridging to the Mo1 sites is unsymmetrical with Mo1–O3 distances of 1.89(3) Å and 2.08(3) Å, while the Mo2–O3 distance is 2.22(3) Å. The Mo1–O4 bond lengths of 2.14(4) and 2.09(3) Å and valence sum calculations[24] identify the twelve O4 bridging functions as μ_2-hydroxy groups. Although the protons could not be unambiguously located from the X-ray analysis,[25] they most likely form intramolecular hydrogen bonds with the O2 centers, as shown in Figure 1, with O2···O4 and O2···H4 distances of 2.82 Å and 1.89 Å, respectively. The four O5 oxygen atoms define the perimeter of the cavity formed by the molybdenum–oxygen cage. Each O5 atom coordinates in an μ_4 fashion to three Mo^{V} sites and to the encapsulated and tetrahedrally coordinated Na^+ ion in the case of **2**. The Mo1–O5 and Na–O5 distances are 2.10(1) Å and 2.18(3) Å, respectively. The relatively short Na–O distances are consistent with those previously reported in hexanuclear molybdophosphate and molybdophenylphosphonate units in cluster anions such as $[(H_3O)_2NaMo_6P_4O_{24}(OH)_7]^{2-}$[26] and $[Na\{Mo_6O_{15}(O_3PC_6H_5)_4\}_2]^{15-}$.[27, 28] While the low coordination number for Na^+ is unusual, it is not without precedent,[29] and a similar tetrahedral environment has been described for the encapsulated ion of $[Na(i\text{PrSn})_{12}O_4(OH)_{24}]^{5+}$.[30] These results suggest that the geometric requirements of the metal–oxygen cage dictate the size of the cavity. The four oxygen atoms that define the cavity perimeter for **1** exhibit valence sums of 1.19 to 1.35, which suggests that these sites are partially protonated. In view of the total charge of the $[Mo_{16}(OH)_{12}O_{40}]^{8-}$ host and the cation accomodated in the cluster core of **2**, two protons appear to occupy the cavity of **1**, in analogy to the situation in $[H_2W_{12}O_{40}]^{6-}$.[31]

The central ($Mo_{12}O_{40}$) core of the polyanion clusters of **1** and **2** has a type of metal–oxygen framework which has been previously observed only for the cluster species $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$,[32] $[Al_{13}O_4(OH)_{25}(H_2O)_{11}]^{6+}$,[33] $[H_3Mn_3V_{12}O_{40}]^{5-}$[34] and the recently described $[(C_5Me_5Rh)_8(Mo^{V}_{12}O_{36})(Mo^{VI}O_4)]^{2+}$.[35] It is instructive to compare the structure of the central ($Mo_{13}O_{40}$) core of this last cationic cluster to the ($H_2Mo_{12}O_{40}$) and ($NaMo_{12}O_{40}$) cores of **1** and **2**, respectively. All adopt the ε-Keggin structure[36] in which the octahedral Mo^{V} centers form binuclear units with short localized Mo–Mo bonds, a characteristic feature of Mo^{V} compounds encountered both for isolated binuclear species and for reduced polyanions.[37–40] In a very formal consideration the cavity of $[(C_5Me_5Rh)_8(Mo^{V}_{12}O_{36})(Mo^{VI}O_4)]^{2+}$ is occupied by a tetrahedrally coordinated Mo^{VI} center with short Mo–O distances of 1.75(1) Å as expected. In **2** the relevant Na–O distances are 2.18(3) Å. The cavity diameters in both **1** and **2** are defined by O5···O5 distances of 3.3 Å.[40a] The remarkable flexibility of the host ε-$\{Mo^{V}_{12}O_{40}\}$ cage is demonstrated by the existence of clusters encapsulating cationic guests with such diverse coordination requirements as protons and Na^+ ions.

It is noteworthy that encapsulation of a Na^+ ion has also been observed for a supramolecular species of tin, $[Na(i\text{PrSn})_{12}O_4(OH)_{24}]^{5+}$, in which the tin–oxygen frame-

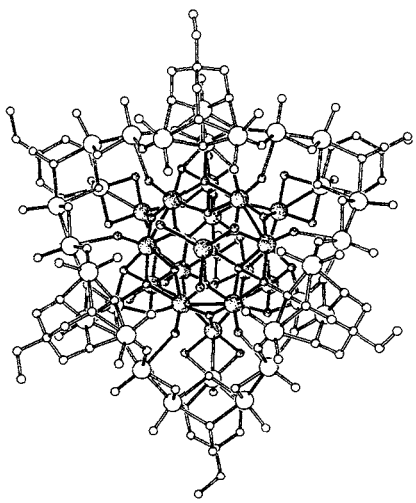

Fig. 2. A view of the structure of $[Mo_{43}H_{15}O_{112}\{(OCH_2)_3CCH_3\}_7]^{8-}$; the ($Mo_{16}O_{52}$) core is highlighted.

work adopts the γ-Keggin core.[30] The structures of this latter cluster cation and of the cluster anions of **1** and **2** most likely reflect the construction of the host framework about the guest in condensation reactions in solution, employing the template effect.[6] It is also significant that **2** is isolated from the same reaction mixtures as the cluster anions $[Na(H_2O)_3Mo_{42}H_{15}O_{109}\{(OCH_2)_3CCH_2OH\}_7]^{7-}$[19] and $[Mo_{43}H_{15}O_{112}\{(OCH_2)_3CCH_3\}_7]^{8-}$.[41] Thus, the structure of $[Mo_{43}H_{15}O_{112}\{(OCH_2)_3CCH_3\}_7]^{8-}$ (Fig. 2) is derived formally from the $(Mo_{16}O_{52})$ core by adding a $[(CH_2)_3CCH_3]^{3+}$ unit to one face of the $(Mo_{16}O_{52})$ cage, condensing three of the (MoO_3) units of the core with three $[Mo_5O_{14}\{(OCH_2)_3CCH_3\}]$ units, and connecting the central core and these latter units through three $[Mo_4O_7\{(OCH_2)_3CCH_3\}]$ moieties.[42] This observation suggests that the $(Mo_{16}O_{52})$ core of **1** and **2** itself could mediate the template-directed synthesis of more complex clusters from simple soluble precursors.

Experimental Procedure

1: $(NH_4)_6[Mo_7O_{24}]\cdot 4H_2O$ (3.18 g, 2.57 mmol) and phenylphosphonic acid (0.6 g, 3.80 mmol) were dissolved in 100 mL of H_2O at 85 °C. Upon addition of hydrazinium dichloride (0.3 g, 2.86 g), the color of the solution turned rapidly from yellow to green to dark blue. After stirring for 15 min at 85 °C, the resultant red solution was treated with a solution of dimethylammonium chloride (1.65 g, 20.23 mmol) in *N*,*N*-dimethylformamide/H_2O (50 mL/10 mL). The volume of the reaction mixture was reduced to 70 mL by heating at 75 °C. After standing at 20 °C for 12 h, red crystals of **1** were collected and air dried. Correct C, H, N, Mo analysis for $C_{12}H_{62}N_6O_{52}Mo_{16}$; IR (KBr): $\tilde{\nu}$ = 963(s), 841(sh), 779(sh), 738(vs), 533(s) cm^{-1}. UV/VIS (solid-state reflectance spectrum with cellulose as reference): λ = 320, 380 nm. Magnetic susceptibility at room temperature: μ_{eff}=1.1 μ_B (0.32 μ_B per Mo^V center).

2: The reaction of MoO_3, $Na_2MoO_4\cdot 2H_2O$, $C(CH_2OH)_4$, $(Et_4N)Cl$, Me_3NH, and H_2O in the mol ratio 6:6:10:10:10:300 at 160 °C for 3 d gave a mixture of red-brown crystals of $(Me_3NH)_2(Et_4N)Na_4[Na(H_2O)_3H_{15}Mo_{42}O_{109}\{(OCH_2)_3CCH_2OH\}_7]\cdot 15H_2O$ and a red-brown solution. After the solid was collected, the filtrate was allowed to stand at room temperature for 10 d, whereupon orange-red cubes of **2** were isolated in 20% yield.

Attempts to prepare **2** in the absence of organic cations and the pentaerythritol template resulted in improved yields of **2** but in microcrystalline precipitates unsuitable for X-ray analysis. In a representative synthesis a mixture of $Na_2MoO_4\cdot 2H_2O$, MoO_3, molybdenum metal (− 325 mesh), NH_4Cl, and water in the mol ratio 6:6:4:20:300 was heated at 160 °C for 3 d to give **2** in 65% yield. Correct H,N,Na, Mo analysis for $N_7H_{48}NaO_{56}Mo_{16}$; Thermogravimetric analysis of **2** exhibited a 3% weight loss at 110–120 °C consistent with the loss of four water molecules of crystallization (2.77% theoretical loss). IR (KBr): $\tilde{\nu}$ = 1407(s), 984(m), 946(vs), 842(m), 786(sh), 732(vs), 535(s), 488(m) cm^{-1}. UV/VIS (solid-state reflectance spectrum), λ = 325, 380 nm. Magnetic susceptibility at room temperature: μ_{eff} = 1.2 μ_B (0.35 μ_B per Mo^V center).

The similar magnetic properties of **1** and **2** suggest that the moments are a consequence of incomplete spin–spin coupling of the metal–metal bonded binuclear units rather than of impurities. Variable-temperature studies are currently in progress; the $M(H)$ isotherms indicate that the contributions of impurities are negligible.

[20] Crystal data for monoclinic space group $C2/c$, a = 23.851(14), b = 15.167(8), c = 20.496(13) Å, β = 113.59(4); V = 6795(7) $Å^3$, Z = **4**, $\mu(Mo_{K\alpha})$ = 28.76 cm^{-1}; structure solution and refinement based on 3830 independent reflections with $F_o \geq 4.0\sigma(F_o)$; the refinement converged at R = 0.083. Crystal data for **2**: cubic space group $F\bar{4}32$, a = 26.978(3) Å, V = 19539(10) $Å^3$, Z = 8 = 1.768 $g\,cm^{-3}$, $\mu(Mo_{K\alpha})$ = 20.5 cm^{-1}; structure solution and refinement was based on 660 independent reflections with $I_o \geq 3\sigma(I_o)$ to give a final discrepancy factor of 0.076. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57755, the names of the authors, and the journal citation.
[21] The *fac* $[MO_3]$ unit is predicted to be unstable in polyanion frameworks as a consequence of the strong *trans* influence of the M–O(terminal) groups. This results in weakly bonded *fac* $[MO_3]$ groups and consequent dissociation: Lipscomb, W. N. *Inorg. Chem.* **1965**, *4*, 132. However, the *fac* $[MoO_3]$ unit has been observed in the derivatized polyoxomolybdate species $[Mo_3O_7\{(OCH_2)_3CCH_3\}_2]^{2-}$ [22] and $K_{10}[H_6As_8^{III}Mo_8^{V}Mo_{16}^{VI}O_{88}]\cdot 12H_2O$ [23].

[25] The final Fourier difference map exhibits an electron density maximum of about 0.7 $eÅ^{-3}$ at a distance of 0.80 Å from O4 and close to the calculated position of H4. However, the positional coordinates could not be refined, and the calculated hydrogen atom position has been used in the discussion.

[40] a) The small edge lengths of the central O_4 tetrahedron correspond to the small size of the cavity, which allows the incorporation of Na^+. The corresponding distances are, of course, significantly smaller in the case of a central MO_4 entity with covalent M—O bonds, and therefore it makes no sense to define a cavity from a physical point of view. Ab initio calculations
- A Detailed Theoretical Analysis of the 1,7-Sigmatropic Hydrogen Shift: The Möbius Character of the Eight-Electron Transition Structure (C) 1763
- $[Al\textit{t}Bu]_6^-$: EPR Spectroscopic Evidence and Ab Initio Calculations (C) 1428
- An Ab Initio MO Study on Stabilizing Interactions in Dinuclear Zr/Al Complexes with a Planar Tetracoordinate Carbon Center (C) 754
- Aza- versus Phospha-Substitution in Cyclobutadiene: A Theoretical Evaluation of Bonding Properties (C) 617
- Contrasting Structures of Pyramidal Carbocations and Their Silicon Analogues (C) 865
- Elimination of the Barrier to Cope Rearrangement in Semibullvalene by Li^+ Complexation (C) 1760
- Gaseous Mercury(IV) Fluoride, HgF_4: An Ab Initio Study (C) 861
- $[Ni(P\textit{t}Bu)_6]$ and $[Ni(SiH_2)_6]$ Are Isolobal, Related to $[In\{Mn(CO)_4\}_5]^{2-}$, and Have 16-Electron Counts (C) 1616
- On the BO Bond Length in Oxadiboriranes (C) 1154
- The Classical 2-Norbornyl Cation Rigorously Defined Ab Initio (C) 1606
- The Nature of the 7-Norbornyl Cation and its Rearrangement into the 2-Norbornyl Cation (C) 1604
- The Search for an Isolable Silyl Cation Must Continue (C) 1471

Acetals
- A Diastereoselective Synthesis of β-(*N*-Acylamino)aldehydes by Rearrangement of *O*-Vinyl-*N*,*O*-Acetals (C) 83

ACRL Toxin III B
- Linear Total Synthesis of (−)-ACRL Toxin III B (C) 1452

Activation of oxygen
- The Coupled Activation of Molecular Oxygen and C–H and C–C Bonds in Gas-Phase Reactions of $[M(C_2H_4)]^+$ (M = Sc–Zn) with O_2 (C) 1420

Adamantanes
- Carbenes in Constrained Systems I: 1,3 C–H Insertion Reaction of Adamantylidene within the β-Cyclodextrin Cavity (C) 1344
- Dilithiation of Two Diphenyl Ethers Each Containing Two $NHCH_2CH_2Y$ (Y = OMe, NMe_2) Side Arms in *ortho* Positions: Assembly of "Adamantanoid" $Li_4O_2N_4$ Cores (C) 1182
- The First Neutral Adamantanoid Iron(III)–chelate Complex: Spontaneous Formation, Structure, and Electrochemistry (C) 1179

Adsorption
- Adsorption of Molecules at Metal Electrodes (B) 1107

AIDS
- Diastereo- and Enantioselective Synthesis of C_2-Symmetrical HIV-1 Protease Inhibitors (C) 423
- Phosphinic Acid-Based C_2-Symmetrical Inhibitors of HIV-Protease (C) 1720
- Selective Cleavage of a 35-mer Single-Stranded DNA Containing the Initiation Codon of the TAT Gene of HIV-1 by a Tailored Cationic Manganese Porphyrin (C) 557
- The Absolute Configuration of Michellamine B, a "Dimeric", Anti-HIV-Active Naphthylisoquinoline Alkaloid (C) 1190

Alcohols
- Enantioselective Catalytic Addition of Functionalized Dialkylzinc Compounds to β-Stannylated Aldehydes: A Convenient Preparation of Chiral β- and γ-Functionalized Secondary Alcohols (C) 582

Aldol reactions
- Computer-Assisted Design of Chiral Boron Enolates: A Novel, Highly Enantioselective Aldol Reaction for Thioacetates and Thiopropionates (C) 1618
- Enantioselective Aldol Reactions with a Phosphoenolpyruvate Equivalent: Asymmetric Synthesis of 4-Hydroxy-2-oxocarboxylic Acid Esters (C) 421

Alkali metal compounds
- A Molecular Heterometal Amide with High Molecular Dynamics: Does the Lithium Atom Orbit? (C) 1731
- [*tert*-Butylcyanide · Lithium Bis(trimethylsilyl)amide]$_2$, a Model of the Intermediate RCN · MR′ Complex Formed in Reactions of Cyanides RCN with Organometallic Compounds R′M (C) 1171
- 1-Chloro-2,2-bis(4-chlorophenyl)-1-lithioethene · TMEDA · 2THF: Structure of a Li-Cl Carbenoid (C) 1032
- Crystal Structure of [(α-Cyanoisopropylsodium · Tetramethylenediamine)$_4$]: How Coordination Expansion from Li to Na Centers can Increase the Aggregation State of an α-Nitrile "Carbanion" (C) 1366
- Cs_3AuO, the First Ternary Oxide with Anionic Gold (C) 1049
- Dilithiation of Two Diphenyl Ethers Each Containing Two $NHCH_2CH_2Y$ (Y = OMe, NMe_2) Side Arms in *ortho* Positions: Assembly of "Adamantanoid" $Li_4O_2N_4$ Cores (C) 1182
- Effects of Ion Pair Separation on Inversion and Rotation of Sulfur-, Selenium-, and Silicon-Stabilized Organolithium Reagents (C) 1469
- Elimination of the Barrier to Cope Rearrangement in Semibullvalene by Li^+ Complexation (C) 1760
- First Structure of a Mixed Organosodium/Lithium Alkoxide Compound: Model for a Superbase (C) 1066
- High-Pressure Synthesis of LiSi: Three-Dimensional Network of Three-Bonded Si^- Ions (C) 1442
- Lithium Di-*tert*-butylmethylsilylhydrazide, a Hexamer with Li^+ Ions Bound Side-on and End-on (C) 1625
- β-Na_3Hg: A Solid with a Quasi-Fluid Sodium Substructure between 36 and 60 °C (C) 1494
- Novel Alkynylcopper(I) Complexes and Lithium Alkynyl Cuprates (C) 1077
- One-Flask Synthesis of Propargylic Alcohols from Organolithium Reagents, *N*,*N*-Disubstituted Amides, and Acetylenes (C) 608
- Reduction of Geminal Dihalocyclopropanes with Lithium 4,4′-Di-*tert*-butylbiphenyl; Cyclopropyl Derivatives of Dilithiomethane and 1,2-Dilithioethane; Inferences Regarding the Intermediate Carbenoids (C) 574
- Rotation about the C–Se Bond as the Rate-Determining Step in the Racemization of α-Selenium-Substituted Alkyllithium Compounds (C) 1467
- Structures of Classical Reagents in Chemical Synthesis: $(n\text{BuLi})_6$, $(t\text{BuLi})_4$, and the Metastable $(t\text{BuLi} \cdot Et_2O)_2$ (C) 580
- Structures of Organo Alkali Metal Complexes and Related Compounds (R) 1501
- Successful X-Ray Structure Analysis of an Alkylidene Carbenoid—A Milestone in Carbenoid Research (H) 1023
- The Dimeric Tris(lithioarsino)germane tBuGe[As(Si*i*Pr$_3$)Li]$_3$: A Self-Assembled, Solvent-Free Lithium–Main Group Element Aggregate with a $Ge_2As_6Li_6$ Rhombododecahedral Framework (C) 1439
- The First Structure of a Lithiated Cyanamide; Synthesis of (PhNCNLi · HMPA)$_n$ by Extrusion of N_2 and S from 5-Phenylamino-1,2,3,4-thiatriazole with Li Reagents and HMPA (C) 1769
- The First Trigonal-Bipyramidal Cluster with an Interstitial C_2 Unit: $[Rb\{Pr_5(C_2)\}Cl_{10}]$ (C) 1318
- (Trimethylstannyl)methyllithium as a Source of a Methylene Bridge Connecting Two Acyl Groups: A Potential Route to D-Mycaroside (C) 105

Alkaline earth metal compounds
- *ansa*-Metallocenes of Calcium and Strontium: One-Pot Synthesis of Organometallic Complexes of the Heavier Alkaline Earth Metals (C) 1079
- The First Unsolvated Chelate and Cubane-Type Barium Complexes: Effective Compounds for the Sol–Gel Process (C) 596

Alkaloids
- The Absolute Configuration of Michellamine B, a "Dimeric", Anti-HIV-Active Naphthylisoquinoline Alkaloid (C) 1190

Alkanes
- Amination of Methane and Ethane by Mercury Photosensitization in the Presence of Ammonia (C) 1491

Alkenes
- Bi[1,3-bis(dicyanomethylene)indan-2-ylidene]—An Ethylene Derivative with Extremely Pronounced Twisting of the C=C Bond (C) 1352
- Non-Twisted Tetrakis(organosilyl)-ethene (C) 1473

Alkoxycarbonylation
- Palladium-Catalyzed Enantioselective Bis-alkoxycarbonylation of Olefins (C) 1719

Alkyne complexes
- Transformation of the First Zirconocene Alkyne Complex without an Additional Phosphane Ligand into a Dinuclear σ-Alkenyl Complex by Hydrogen Transfer from η^5-C_5H_5 to the Alkyne Ligand (C) 1193

Alkynes
- Metal-Initiated Coupling of C_2 Units to Enynes and Butatrienes: Two Different Routes for the Dimerization of 1-Alkynes (C) 1315

- Protonation of Phenyl(trimethylsilyl)-acetylene: A Surprisingly Weak Stabilization of a Carbocation by a β-Trimethylsilyl Group (C) 721
- Rapid Carboalumination of Alkynes in the Presence of Water (C) 1068
- The First Complex with a Tetraethynylcyclobutadiene Ligand (C) 1653

Aluminum compounds
- A Simple Synthesis of $[(Cp^*Al)_4]$ and Its Conversion to the Heterocubanes $[(Cp^*AlSe)_4]$ and $[(Cp^*AlTe)_4]$ ($Cp^* = \eta^5$-$C_5(CH_3)_5$) (C) 1729
- $[AlrBu]_6^-$: EPR Spectroscopic Evidence and Ab Initio Calculations (C) 1428
- An Al–Al One-Electron π Bond (C) 388
- Decamethylaluminocenium, a π-Stabilized R_2Al^+ Cation (C) 1655
- Dimeric and Trimeric Aminoalanes with Inverse Bridging Functions (C) 886
- Organoelement Compounds with Al–Al, Ga–Ga, and In–In Bonds (R) 1386
- Synthesis and Structure of a Sixteen-Membered $(AlNCO)_4$ Ring (C) 1483
- Transition-Metal-Substituted Volatile Alanes, Gallanes, and Indanes: Synthesis and Structure (C) 746

Amides
- Structure and Reactivity of a Highly Twisted Amide (C) 1083

Amination
- Amination of Methane and Ethane by Mercury Photosensitization in the Presence of Ammonia (C) 1491

Amines
- Monoclinic and Triclinic Tetraisopropyl-*p*-phenylenediamine: To what Extent do n_N/π Interactions Determine Structures? (C) 1755
- Tris(chlorodimethylstannyl)amine, a Molecule with a Planar Sn_3N Skeleton Stabilized by Intramolecular Sn-Cl-Sn Bridges (C) 1608

Amino acids
- (*R*)- and (*S*)-4-Alkoxy-2-*tert*-butyl-2,5-dihydroimidazole-1-carboxylates—New Chiral Glycine Derivatives for Amino Acid Synthesis (C) 1765
- Asymmetric Synthesis of α-Amino Acids and N-Protected α-Amino Aldehydes by Addition of Chiral Vinyl Anions to Sulfonylimines (C) 578
- Enantioselective Synthesis of α-Amino Acetals and α-Amino Acids by Nucleophilic 1,2-Addition to Diethoxyacetaldehyde SAMP Hydrazone (C) 418
- New Chiral Porphyrins—Syntheses and Molecular Recognition of Amino Acid Esters (C) 723
- Selective Pd^0-Mediated C–C Bond Constructions on the Imidazole Ring of L-Histidine: A Practical Approach to the Synthesis of Diphthamide and Related Histidine Analogues (C) 1326
- Synthesis of 4-Oxo-L-proline and *cis*-4-Hydroxy-L-proline Derivatives from L-Aspartic Acid (C) 285

Aminoacyl-tRNA synthetases
- Aminoacyl-tRNA Synthetases: The Division into Two Classes was Predicted by the Chemistry of Substrates and Enzymes (R) 190

Amphiphiles
- Can Single-Chain Perfluoroalkylated Amphiphiles Alone Form Vesicles and Other Organized Supramolecular Systems? (C) 741

Analytical methods
- Accurate Molecular Structures. Their Determination and Importance (B) 1668
- Adsorption of Molecules at Metal Electrodes (B) 1107
- Capillary Electrophoresis: Methods and Scope (R) 629
- Capillary Electrophoresis. Principles, Practice and Applications (B) 1372
- Optical Spectroscopy of Single Impurity Molecules in Solids (R) 457
- Rapid Reactions in Solution (B) 624
- Spectrochemical Analysis by Atomic Absorption and Emission (B) 627
- Spectroscopy of Polymers (B) 1109

Annulenes
- A Novel 1,6-Methano[10]annulene Derivative with Bisnorcaradiene Structure—Syntheses with Transition Metal Complexes (C) 1324
- Porphyrin-Like [22]Annulenoquinones (C) 1333
- Stable [12]- and [18]Annulenes Derived from Tetraethynylethene (C) 406

Anthracyclines
- Synthesis of 4-Deoxyaklanonic acid and its Microbial Conversion into Anthracyclinones (C) 1151

Antibiotics
- Posttranslational Backbone Modifications in the Ribosomal Biosynthesis of the Glycine-Rich Antibiotic Microcin B17 (C) 1336
- The Use of Radical Cyclization in the Preparation of Substituted Methyl Carbapenem Antibiotic Precursors (C) 867

Antibodies
- New Developments in the Chemistry of Catalytic Antibodies (H) 1291
- Tautomer-Specific Anti-(N-3-Substituted)-Adenine Antibodies: New Tools in Molecular Dosimetry and Epidemiology (C) 1640

Antimony compounds
- Electrochemical Synthesis of New Sb–Te Zintl Anions by Cathodic Dissolution of Sb_2Te_3 Electrodes: Structures of $[Sb_4Te_4]^{4-}$ and $[Sb_9Te_6]^{3-}$ (C) 1646

Antisense systems
- A Sulfide-Linked Oligonucleotide Analogue with Selective Hybridization Properties (C) 729

Antitumor agents
- The Battle of calicheamicin γ_1^1 (R) 1377
- The Role of Chemistry in the Development of Baron Neutron Capture Therapy of Cancer (R) 950
- Total Synthesis of (−)-Pyrimidoblamic Acid and Deglycobleomycin A_2 (C) 273

Arachidonic acid
- Biologically Active Linear Metabolites of Arachidonic Acid—The First Endogenous Ligand of the Cannabinoid Receptor (H) 1027

Arene complexes
- A Nickel–Anthracene Complex Having η^3 and η^4 Coordination in One Crystal (C) 1475
- A Novel Complex with Boat-Shaped, Synfacially Bound η^3:η^3-Benzene Bridges and the First μ_3-η^2:η^2:η^2-Arenetrirhodium Complex (C) 1697
- η^6-(1,2-Dioxocyclobutabenzene)-tricarbonylchromium(0): Starting Material for Double Anionic Oxy-Cope Rearrangements under Very Mild Conditions (C) 267
- The First Complex with a Tetraethynylcyclobutadiene Ligand (C) 1653
- (η^1-tpMn, η^5-tpCr) → (η^1-tpCr, η^5-tpMn) Thiophene (tp) Conversion due to Bimetallic Activation: A Novel Metal-Exchange Reaction (C) 710
- Two Modifications of a Cyclopentadienylthallium(I) Complex Linking the Chemistry of the Cp and Arene Complexes of Main Group Elements (C) 90

Arenes
- Arene–Arene Interactions: Electrostatic or Charge Transfer? (H) 1584
- Liquid-Crystalline Perylene Derivatives as "Discotic Pigments" (C) 1660
- Trimeric Ketenylidene(triphenyl)-phosphorane: A Hybrid between an Arene and an Ylide (C) 1747

Aromaticity
- Porphyrin-Like [22]Annulenoquinones (C) 1333
- Porphyrins with Aromatic 26π-Electron Systems (C) 1148
- Structural Evidence of the Aromaticity of Borepins: A Comparison of 1-Chloroborepin and Tricarbonyl(1-chloroborepin)molybdenum (C) 1065

Arsaalkenes
- Novel Arsaalkenes from an Arsasilene Derivative and Isocyanides (C) 283

Arsenic compounds
- New As–S Cage Structures with Organometallic Components Formed by Complex-Induced Realgar Fragmentation (C) 1627
- Synthesis and Structure of the Arsaalkyne Tetramer $(AsCtBu)_4$ and its $Fe(CO)_4$ Derivative (C) 103
- The First Heteroallyl Metal Complexes of Arsenic with the Coordination Number 2 (C) 1628

Asymmetric syntheses
- (*R*)- and (*S*)-4-Alkoxy-2-*tert*-butyl-2,5-dihydroimidazole-1-carboxylates—New Chiral Glycine Derivatives for Amino Acid Synthesis (C) 1765
- A Catalytic Enantioselective Michael Addition of a Simple Malonate to Prochiral α,β-Unsaturated Ketones and Aldehydes (C) 1176
- A Diastereoselective Synthesis of β-(*N*-Acylamino)aldehydes by Rearrangement of *O*-Vinyl-*N*,*O*-Acetals (C) 83
- Absolute Asymmetric Synthesis by Irradiation of Chiral Crystals (H) 694
- Asymmetric Synthesis and Highly Diastereoselective *ortho*-Lithiation of Ferrocenyl Sulfoxides. Application to the Synthesis of Ferrocenyl Derivatives with Planar Chirality (C) 568
- Asymmetric Synthesis of α-Amino Acids and N-Protected α-Amino Aldehydes by Addition of Chiral Vinyl Anions to Sulfonylimines (C) 578
- Carbohydrates as Chiral Auxiliaries in Stereoselective Synthesis (R) 336
- Chiral 2-Amino-1,3-butadienes: New Reagents for Asymmetric Cycloadditions (H) 1582
- Chiral Phosphinoaryldihydrooxazoles as Ligands in Asymmetric Catalysis: Pd-Catalyzed Allylic Substitution (C) 566
- Computer-Assisted Design of Chiral Boron Enolates: A Novel, Highly Enantioselective Aldol Reaction for Thioacetates and Thiopropionates (C) 1618
- Diastereo- and Enantioselective Synthesis of 2-Substituted 3-Trialkylstannylcyclohexanones by Michael Addition of Trialkylstannyllithium to Cyclohexenone SAMP Hydrazone (C) 598
- Diastereo- and Enantioselective Synthesis of C_2-Symmetrical HIV-1 Protease Inhibitors (C) 423
- Enantioselective Addition of Aromatic Thiols to a Ketene (C) 1044
- Enantioselective Aldol Reactions with a Phosphoenolpyruvate Equivalent: Asymmetric Synthesis of 4-Hydroxy-2-oxocarboxylic Acid Esters (C) 421
- Enantioselective Catalytic Addition of Functionalized Dialkylzinc Compounds to β-Stannylated Aldehydes: A Conve-

nient Preparation of Chiral β- and γ-Functionalized Secondary Alcohols (C) 582
- Enantioselective Synthesis. Natural Products from Chiral Terpenes (B) 1216
- Enantioselective Synthesis of α-Amino Acetals and α-Amino Acids by Nucleophilic 1,2-Addition to Diethoxyacetaldehyde SAMP Hydrazone (C) 418
- Enantioselective Transition Metal-Catalyzed Hydrogenation for the Asymmetric Synthesis of Amines (H) 232
- Enzyme-Catalyzed Asymmetric Synthesis: Kinetic Resolution of Chiral Hydroperoxides by Enantioselective Reduction to Alcohols with Horseradish Peroxidase (C) 1737
- Highly Enantioselective Protonation of Thiol Ester Enolates (C) 1042
- Linear Total Synthesis of (−)-ACRL Toxin III B (C) 1452
- Palladium-Catalyzed, Enantioselective Allylic Substitutions (H) 547
- Palladium-Catalyzed Enantioselective Bis-alkoxycarbonylation of Olefins (C) 1719
- Stereodivergent Enantioselective Synthesis by Exploiting Unusually Large Kinetic H/D Isotope Effects on Deprotonation (C) 394
- Stereoselective Synthesis of C-Glycosides with a Glycosyl Dianion (C) 1091
- Temperature Effects in Asymmetric Dihydroxylation: Evidence for a Stepwise Mechanism (C) 1329
- The First Example of an Increase in the Enantioselectivity of a Chemical Reaction in the Presence of a Chiral Lewis Acid under High Pressure (C) 1485
- Titanated Methoxyallene as Novel Homoaldol Equivalent for Diasteroselective Additions to Chiral Amino Aldehydes (C) 1449
- Titanium-Catalyzed Epoxy-Hydroxylation of Allylic Alcohols: A Convenient Diastereoselective Synthesis of Epoxy Diols (C) 733
- Vitamin D_3 Synthetic Studies: Enantiospecific Synthesis of the CD Ring Fragment (C) 1444

Atomic absorption spectroscopy
- Spectrochemical Analysis by Atomic Absorption and Emission (B) 627

Atomic force microscopy
- Gas/Solid Reactions of Aliphatic Amines with Thiohydantoins: Atomic Force Microscopy and New Mechanisms (C) 1587

Atropo-diastereomers
- The Absolute Configuration of Michellamine B, a "Dimeric", Anti-HIV-Active Naphthylisoquinoline Alkaloid (C) 1190

Atropo-enantiomers
- Separation of the Enantiomers of 2,2′-Dihydroxy-1,1′-binaphthyl and 10,10′-Dihydroxy-9,9′-biphenanthryl by Complexation with *N*-Alkylcinchonidinium Halides (C) 1147

Atropo-enantioselectivity
- A New Atropisomeric Molecular Structure for Efficient Enantiodifferentiation (C) 606

Autobiographies

Catenanes
- Isomeric Self-Assembling [2]Catenanes (C) 1297
- Multiring Catenanes with a Macrobicyclic Core (C) 1434
- Photoswitchable Catenanes (C) 1295
- The Self-Assembly of Catenated Cyclodextrins (C) 854

Cations
- Octaethyltetraoxaporphyrin Dication—Counterpart of Octaethylporphyrin in the Tetraoxaporphyrin Series (C) 1597
- Superelectrophiles (R) 767

Cellular regulation
- Protein Phosphorylation and Cellular Regulation I (Nobel Lecture) (R) 1122
- Protein Phosphorylation and Cellular Regulation II (Nobel Lecture) (R) 1130

Cerium compounds
- $CeCl_3$-Mediated Addition of Grignard Reagents to 1,3-Diketones (C) 1061

C-H activation
- C–H Bond Addition to a V=NR Bond: Hydrocarbon Activation by a Sterically Crowded Vanadium System (C) 903
- C–H-Activation by Reaction of (Butadiene)zirconocenes and -hafnocenes with 9-BBN (C) 1213
- Transition Metal Complexation of σ Bonds (R) 789

Chalcogen compounds
- $[Tc_6X_8]$ Clusters in ternary Technetium Chalcogenides (C) 576

Chelate ligands
- Axial Ligation of Diazacyclooctanenickel and -Zinc Complexes (C) 116
- Dilithiation of Two Diphenyl Ethers Each Containing Two $NHCH_2CH_2Y$ (Y = OMe, NMe_2) Side Arms in *ortho* Positions: Assembly of "Adamantanoid" $Li_4O_2N_4$ Cores (C) 1182
- Highly Coordinated Lanthanoid–Phosphane Complexes (C) 1739
- Monomeric Tris(η^2-pyrazolato)lanthanoid Complexes with the Bulky 3,5-Di(*tert*-butyl)pyrazolato Ligand (C) 874
- The Coordination Chemistry of Multidentate Isocyanide Ligands (R) 650
- The First Neutral Adamantanoid Iron(III)–chelate Complex: Spontaneous Formation, Structure, and Electrochemistry (C) 1179

Chemical equilibria
- Chemical Equilibria in Solution. Dependence of Rate and Equilibrium Constants on Temperature and Pressure (B) 308

Chemical sensors
- Organic Clathrate-Forming Compounds as Highly Selective Sensor Coatings for the Gravimetric Detection of Solvent Vapors (C) 110

Chiral auxiliaries
- (*R*)- and (*S*)-4-Alkoxy-2-*tert*-butyl-2,5-dihydroimidazole-1-carboxylates—New Chiral Glycine Derivatives for Amino Acid Synthesis (C) 1765
- A New Atropisomeric Molecular Structure for Efficient Enantiodifferentiation (C) 606
- Carbohydrates as Chiral Auxiliaries in Stereoselective Synthesis (R) 336
- Chiral Phosphinoaryldihydrooxazoles as Ligands in Asymmetric Catalysis: Pd-Catalyzed Allylic Substitution (C) 566

Chirality
- Asymmetric Synthesis and Highly Diastereoselective *ortho*-Lithiation of Ferrocenyl Sulfoxides. Application to the Synthesis of Ferrocenyl Derivatives with Planar Chirality (C) 568

Chlorofluorocarbons
- Complexation of Methane and Chlorofluorocarbons by Cryptophane-A in Organic Solution (C) 1169

Chloroglycyl peptides
- Synthesis and Reactivity of α,α-Dichloroglycyl Peptides (C) 1771

Chromatography
- Chromatographic Separation of the Four Possible Structural Isomers of a Tetrasubstituted Phthalocyanine: Tetrakis(2-ethylhexyloxy)phthalocyaninatonickel(II) (C) 1422
- HPLC of Proteins, Peptides and Polynucleotides. Contemporary Topics and Applications (B) 305
- Ion-Spray Mass Spectrometry and High-Performance Liquid Chromatography—Mass Spectrometry of Synthetic Peptide Libraries (C) 894
- Preparative Enantiomer Separation of the Anesthetic Enflurane by Gas Inclusion Chromatography (C) 1662

Chromium compounds
- Carbonyl–Metal Complexes of Diphosphadiboretane (mesB–P*t*Bu)$_2$ and of Triphosphatriborinanes (mesB–P*t*Bu)$_3$ (C) 1446
- $[(CO)_5Cr=Tl=Cr(CO)_5]^-$, the First Complex Containing Linear Twofold-Coordinated Thallium (C) 1772
- $[Cr(CO)_5PCl_3]$—A P_1 Building Block for the Formation of Complexes with *cyclo*-P_x Ligands (x = 3, 5) (C) 593
- η^6-(1,2-Dioxocyclobutabenzene)-tricarbonylchromium(0): Starting Material for Double Anionic Oxy-Cope Rearrangements under Very Mild Conditions (C) 267
- Synthesis and Reactivity of Hexafluoro-1,2-diisocyanocyclobutanechromium Complexes (C) 1456
- Synthesis of the First Stable 2-Chromaoxetane and its Homologues via α-Phosphonio(methylidene) Complexes of Hexavalent Chromium, Molybdenum, and Tungsten (C) 731
- (η^1-tpMn, η^5-tpCr) → (η^1-tpCr, η^5-tpMn) Thiophene (tp) Conversion due to Bimetallic Activation: A Novel Metal-Exchange Reaction (C) 710
- Unprecedented Cage-Opening of P_4S_3 Initiated by an Organometallic Radical: Synthesis and Structure of $[Cp_4Cr_4(CO)_9(P_4S_3)]$ (C) 1728

Circular dichroism
- CD Exciton Chirality Method: New Chromophores for Primary Amino Groups (C) 888

Clathrates
- Organic Clathrate-Forming Compounds as Highly Selective Sensor Coatings for the Gravimetric Detection of Solvent Vapors (C) 110

Clusters
- A Hexanuclear Organogallium Fluoride Oxide (C) 1701
- A New Copper Selenide Cluster with PPh_3 Ligands: $[Cu_{146}Se_{73}(PPh_3)_{30}]$ (C) 1303
- A New Type of Hexanuclear Iron(III) Hydroxo(oxo) Cluster (C) 570
- Cage Extension to Clusters with Co_2/Co_3MoAs_6 Polyhedron Frameworks (C) 914
- Cation Inclusion within the Mixed-Valence Polyanion Cluster $[(Mo^{VI}O_3)_4Mo^V_{12}O_{28}(OH)_{12}]^{8-}$: Syntheses and Structures of $(NH_4)_7[NaMo_{16}(OH)_{12}O_{40}]\cdot 4H_2O$ and $(Me_2NH_2)_6[H_2Mo_{16}(OH)_{12}O_{40}]$ (C) 1780
- Compounds Containing Silicon, Germanium, and Tin Polyhedra: The First Octahedral Tin Cluster (H) 545
- Control of the Linkage of Inorganic Fragments of V–O Compounds: From Cluster Shells as Carcerands via Cluster Aggregates to Solid-State Structures (C) 909
- $[Cp^*TaS_3\{Rh(cod)\}_2]$ and $[Cp^*TaS_3\{RuH(PPh_3)_2\}_2]$: A New Class of Heterometallic TaM_2 Clusters (C) 763
- Extending the Metal Cluster–Metal Surface Analogy (H) 228
- Mercury, a Structural Building Block and Source of Localized Reactivity in Extended Metal–Metal Bonded Systems (R) 24
- New Cu–Te Clusters (C) 238
- New Phosphido-Bridging Copper Clusters (C) 242
- Structure and Electrochemical Behavior of the Paramagnetic Anion $[Ir_{14}(CO)_{27}]^-$, Possessing a Trigonal Bipyramidal Arrangement of Metal Atoms (C) 1347
- $[Tc_6X_8]$ Clusters in ternary Technetium Chalcogenides (C) 576
- Tetranuclear Cuboidal and Hexanuclear Prismatic Iron–Sulfur–Nitrosyl Clusters (C) 564
- The Application of Au_{55} Clusters as Quantum Dots (C) 250
- The First Trigonal-Bipyramidal Cluster with an Interstitial C_2 Unit: $[Rb\{Pr_5(C_2)\}Cl_{10}]$ (C) 1318

CO dehydrogenases
- Functional Modeling of CO Dehydrogenase: Catalytic Reduction of Methylviologen by CO/H_2O with an N,O,S-Ligated Nickel Catalyst (C) 92

Cobalt compounds
- Cage Extension to Clusters with Co_2/Co_3MoAs_6 Polyhedron Frameworks (C) 914
- Controlling Valence Tautomerism of Cobalt Complexes Containing the Benzosemiquinone Anion as Ligand (C) 880
- Formation and Complex Stabilization of a New Chainlike Phosphazene Anion by Co^{II}-Assisted Oxidative Scrambling of $[N(PPh_2)_2]^-$ (C) 700
- Molecular Recognition within a Rigid Host: Structural Changes Induced in μ-Carboxylato Dimetal(II) Complexes by Replacing Steric Repulsions with Hydrogen Bonds (C) 1321
- Regiospecific Alkylation of 6-Chloropurine and 2,6-Dichloropurine at N7 by Transient Protection of N3/N9 by Methylcobaloxime (C) 1696
- The First Structurally Characterized Heterodinuclear Double-Helicate Complex (C) 1465

Coenzyme A
- Propionyl-Aza(dethia)coenzyme A as Pseudosubstrate of the Biotin-Containing Transcarboxylase (C) 278

Colloids
- Colloidal Semiconductor Q-Particles: Chemistry in the Transition Region Between Solid State and Molecules (R) 41
- Electrochemistry in Colloids and Dispersions (B) 1373

Complexes with arsenic ligands
- Cage Extension to Clusters with Co_2/Co_3MoAs_6 Polyhedron Frameworks (C) 914
Complexes with carbon ligands
- A New Form of Coordinated Carbon: A C_3 Chain That Is Anchored by a Transition Metal on Each End and Spanned by a Third (C) 891
- The First Trigonal-Bipyramidal Cluster with an Interstitial C_2 Unit: $[Rb\{Pr_5(C_2)\}Cl_{10}]$ (C) 1318
Complexes with chalcogen ligands
- Formation of Monomeric Terminal Chalcogenides by Template-Induced Disilylchalcogenide Elimination; the Crystal Structures of $[ETa\{(Me_3SiNCH_2CH_2)_3N\}]$ (E = Se,Te) (C) 1450
Complexes with halogen ligands
- The Behavior of Cp^*MoBr/Br_2 Redox Systems: The Unusual Structure of $[(Cp^*_2Mo_2Br_4)_2(Cp^*MoBr_4)_3]$, a Compound Containing Mo^{III}, Mo^{IV}, and Mo^V (C) 1486
Complexes with hydrido ligands
- Structure and Reactivity of $[HFe(CO)_3(\eta^3\text{-}C_3H_5)]$ (C) 1073
Complexes with nitrogen ligands
- Cavities for Binding Two Metal Atoms: A Novel Pentanuclear Copper(I) Complex with an Anionic, Pentadentate Aryl Ligand with Two *ortho*-Chelating Diamine Substituents (C) 72
- C–H Bond Addition to a V=NR Bond: Hydrocarbon Activation by a Sterically Crowded Vanadium System (C) 903
- Hexakis(benzotriazolato)tetrakis(2,4-pentanedionato)pentacopper(II): A Model for Corrosion Inhibition (C) 1036
- How "Innocent" Are Pentane-2,4-dione-bis(*S*-alkylisothiosemicarbazonate) Ligands in Biomimetic Fe^{II} and Fe^{IV} Complexes? (C) 1635
- Monomeric Tris(η^2-pyrazolato)lanthanoid Complexes with the Bulky 3,5-Di(*tert*-butyl)pyrazolato Ligand (C) 874
- Multicomponent Self-Assembly: Spontaneous Formation of a Cylindrical Complex from Five Ligands and Six Metal Ions (C) 69
- Nucleophilic Substitution of Bis(cyclopentadienyl)tin(II); Synthesis, Structure, and Solution Dynamics of *trans*-$[(\eta^3\text{-}Cp)Sn\{\mu_2\text{-}N=C(NMe_2)_2\}]_2$ (C) 428
- Rigid Rodlike Metal Complexes of Nanometric Dimension: Synthesis, Luminescence Properties, and Long-Range Energy Transfer (C) 1643
- Self-Assembly of a New Class of Tetranuclear Copper(I) and Silver(I) Complexes (C) 877
- Self-Assembly, Structure, and Spontaneous Resolution of a Trinuclear Triple Helix from an Oligobipyridine Ligand and Ni^{II} Ions (C) 703
- Structure of a One-Dimensional Infinite Double-Helical Copper(I) Complex (C) 1463
- Synthesis and Structure of the First Homoleptic Imidotechnetium Complex: $[Tc_2(NAr)_6]$ (Ar = 2,6-diisopropylphenyl) (C) 94
- The First Heteroallyl Metal Complexes of Arsenic with the Coordination Number 2 (C) 1628
- The First Structurally Characterized Heterodinuclear Double-Helicate Complex (C) 1465
- The First Unsolvated Chelate and Cubane-Type Barium Complexes: Effective Compounds for the Sol–Gel Process (C) 596
Complexes with oxygen ligands
- A New Type of Hexanuclear Iron(III) Hydroxo(oxo) Cluster (C) 570
- A Two-Dimensional Ice with the Topography of Edge-Sharing Hexagons Intercalated between $CdNi(CN)_4$ Layers (C) 884
- Alternating Ferro- and Antiferromagnetic Interactions in a Chainlike Cu^{II} Coordination Polymer (C) 1046
- Catalysis of the Hydrolysis of Phosphoric Acid Diesters by Lanthanide Ions and the Influence of Ligands (C) 1716
- Hydrolysis to a Complex with a Central, Octahedral $(\mu_6\text{-}O)In_6$ Unit (C) 1426
- Metal-Mediated Oxyfunctionalization of Organic Substrates by Organometallic Intermediates—More Recent Developments and Perspectives (H) 1144
- Molecular Recognition of Hexaaqua Transition Metal(II) Ions (C) 714
- Structural Variations Observed in the $[Bi(O_2CCF_3)_4Ph]^{2-}$ Anion: Selective Cation–Anion Interactions through Hydrogen Bonds (C) 589
Complexes with phosphorus ligands
- A Highly Electrophilic Unsaturated Ditungsten Dication (C) 1156
- Catalytic Hydrogenation with Rhodium Complexes Containing dipamp-pyrphos Hybrid Ligands (C) 1052
- $[Cr(CO)_5PCl_3]$—A P_1 Building Block for the Formation of Complexes with *cyclo*-P_x Ligands (x = 3, 5) (C) 593
- Formation and Complex Stabilization of a New Chainlike Phosphazene Anion by Co^{II}-Assisted Oxidative Scrambling of $[N(PPh_2)_2]^-$ (C) 700
- Highly Coordinated Lanthanoid–Phosphane Complexes (C) 1739
- New Phosphido-Bridging Copper Clusters (C) 242
- Palladium-Catalyzed Enantioselective Bis-alkoxycarbonylation of Olefins (C) 1719
- Phosphinidenetantalum(V) Complexes of the Type $[(N_3N)Ta{=}PR]$ as Phospha-Wittig Reagents (R = Ph, Cy, *t*Bu; $N_3N = (Me_3SiNCH_2CH_2)_3N$) (C) 756
- Photochemical 1,2 Shift of the Phosphane Ligands in the Silanediyl Complex $[(2\text{-}Ph_2PCH_2C_6H_4)_2Si{=}Cr(CO)_5]$ (C) 1313
- $[(\widehat{PP})_2RhH]$ and $[(\widehat{PP})_2Rh][O_2CH]$ Complexes as Models for the Catalytically Active Intermediates in the Rh-Catalyzed Hydrogenation of CO_2 to HCOOH (C) 739
- Tantalum(V) Phosphinidene Complexes as Phospha-Wittig Reagents (H) 850
- Unprecedented Cage-Opening of P_4S_3 Initiated by an Organometallic Radical: Synthesis and Structure of $[Cp_4Cr_4(CO)_9(P_4S_3)]$ (C) 1728
Complexes with sulfur ligands
- Competing $M{=}C_{carbonyl}$ and $M{=}C_{carbene}$ Bonds: Cycloaddition to the Metal–$C_{carbonyl}$ Bond in η^2-Thiocarbene Complexes (C) 1152
- $[Cp^*TaS_3\{Rh(cod)\}_2]$ and $[Cp^*TaS_3\{RuH(PPh_3)_2\}_2]$: A New Class of Heterometallic TaM_2 Clusters (C) 763
- Formation of Alkynyltrithiocarbonato Ligands from Alkylidyne Ligands and Carbon Disulfide (C) 1726
- $[Mo_2(S)_2(\mu\text{-}S)(syn\text{-}Me_8[16]aneS_4)_2]^{2+}$, a Novel Sulfidomolybdenum Complex Containing a Linear S=Mo–S–Mo=S Linkage (C) 1621
- New Half-Sandwich Polysulfidorhenium Complexes (C) 85
- Novel V^{III} Complexes with a Central $[V_3(\mu_3\text{-}S)(\mu\text{-}S_2)_3]^+$ or $[V_2(\mu\text{-}O)(\mu\text{-}SPh)_2]^{2+}$ Unit (C) 594
- Reduced $[Fe_8S_6]$ Clusters: Binding Links between FeS and Active Centers of Iron-Sulfur Proteins (C) 863
Complexes with tellurium ligands
