

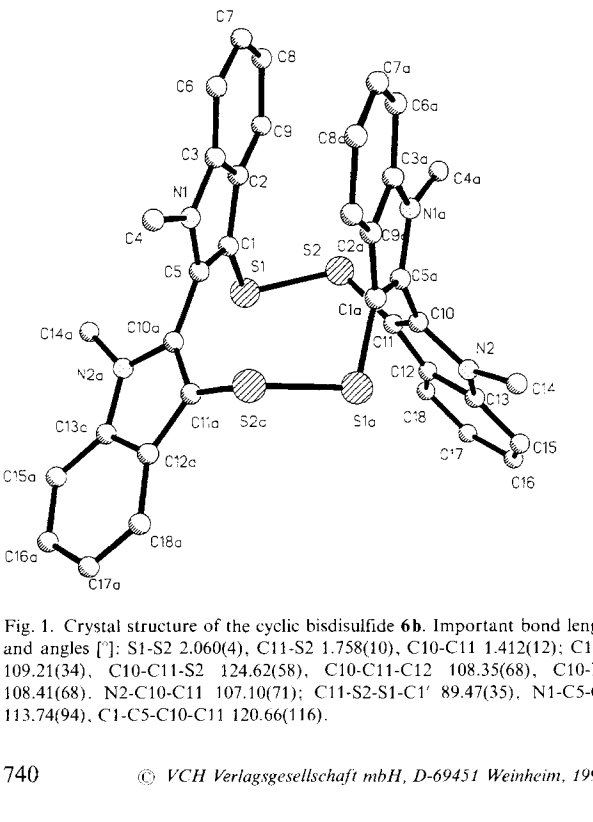

Fig. 1. Crystal structure of the cyclic bisdisulfide **6b**. Important bond lengths [Å] and angles [°]: S1-S2 2.060(4), C11-S2 1.758(10), C10-C11 1.412(12); C11-S2-S1 109.21(34), C10-C11-S2 124.62(58), C10-C11-C12 108.35(68), C10-N2-C13 108.41(68), N2-C10-C11 107.10(71); C11-S2-S1-C1′ 89.47(35), N1-C5-C10-N2 113.74(94), C1-C5-C10-C11 120.66(116).

Table 1. Physical and spectroscopic data for selected compounds [a].

5d: Deep red needles; m.p. 215 °C (ref. [1b]: 213–215 °C). UV (MeCN): λ_{max} (lgε) = 227 (4.582), 244 (4.347, sh), 274 (4.045), 331 (4.240), 465 nm (4.413); ^{1}H NMR ($CDCl_3$): δ = 7.30–7.50 (m, 4H, arene H), 7.75–7.86 (m, 4H, arene H) (multiplets in a 1:1 ratio, ABCD spectrum); ^{13}C NMR ($CDCl_3$): δ = 120.9 (C-3), 122.8 (C-7), 123.4 (C-4), 125.5, 125.8 (C-5/C-6 exchangeable signals), 134.1 (C-2), 137.0 (C-3a), 138.5 (C-7a); MS (70 eV): *m/z* (%): 328 (100) [M^+], 296 (50) [M^+ − S], 164 (14) [$M/2^+$].

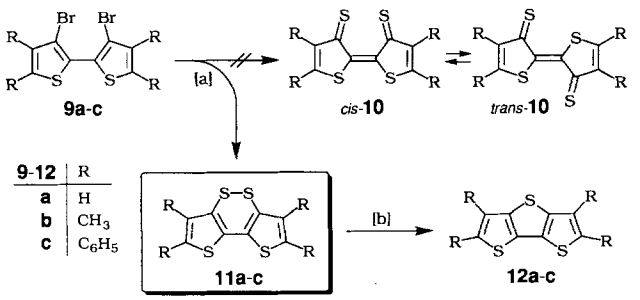
6a: Yellow powder, insoluble; m.p. >360 °C (decomp). MS (70 eV): *m/z* (%): 588 (5) [M^+], 556 (9) [M^+ − S], 294 (100) [$M/2^+$], 261 (29) [$M/2^+$ − SH].

6b: Yellow plates; m.p. 319–320 °C (decomp). UV ($CHCl_3$): λ_{max} (lgε) = 235.5 (4.54), 300 nm (4.27); ^{1}H NMR ([D_{18}]HMPT, 500 MHz): δ = 3.45 (s, 12H, $4CH_3$), 7.09–7.30 (m, 12H, arene H), 7.74–7.81 (m, 4H, arene H); ^{13}C NMR ([D_{18}]HMPT, 500 MHz): δ [b] = 133.9, 132.0, 132.1 (C-2), 112.0, 106.9, 110.4 (C-3), 123.6, 123.4, 123.2/121.5, 120.6, 120.5/119.4, 118.9, 118.4 (C-4, C-5, C-6), 111.4, 111.2, 109.5 (C-7), 139.3, 137.9, 138.5 (C-7a), 128.5, 126.5, 127.9 (C-3a), 31.8, 31.5, 31.2 (CH_3); MS (70 eV) [c]: *m/z* (%): 644 (6) [M^+], 612 (23) [M^+ − S], 580 (19) [M^+ − 2S], 548 (45) [M^+ − 3S], 322 (100) [$M/2^+$].

6c: Brick-red needles; m.p. 244 °C (decomp). UV (CH_2Cl_2): λ_{max} (lgε) = 243 (4.14), 334 (4.13), 473 nm (3.26); ^{1}H NMR ([D_{18}]HMPT, 500 MHz): δ = 6.73–6.74 (m, 4H, C-4-H), 7.29–7.30 (m, 4H, C-6-H), 7.57–7.60 (m, 4H, C-5-H), 7.88–7.90 (m, 4H, C-7-H); ^{13}C NMR ([D_{18}]HMPT, 500 MHz): δ [b] = 148.8, 145.6 (C-2), 115.6, 109.7 (C-3), 120.2, 120.9 (C-4), 125.0, 125.3/128.3, 127.6 (C-5, C-6), 112.7, 111.2 (C-7), 154.1, 155.1 (C-7a), 128.6, 125.2 (C-3a); MS (70 eV) [c]: *m/z* (%): 592 (8) [M^+], 296 (100) [$M/2^+$], 264 (9) [$M/2^+$ − S].

8: Pale yellow prisms; m.p. 303–304.5 °C (decomp). UV ($CHCl_3$): λ_{max} (lgε) = 235 (4.31), 295 nm (4.18); MS (70 eV): *m/z* (%): 386 (17) [M^+], 322 (99) [M^+ − 2S], 290 (100) [M^+ − 3S], 274 (61) [M^+ − 3S − CH_4].

11a: Brick-red needles; m.p. 66 °C. UV (MeCN): λ_{max} (lgε) = 260 (3.54, sh), 307 (3.98), 425 nm (3.22); ^{1}H NMR ($CDCl_3$): δ = 6.83, 6.85, (d, 2H, arene H; J = 4.0 Hz), 7.21, 7.23 (d, 2H, arene H; J = 4.0 Hz); ^{13}C NMR ($CDCl_3$): δ = 123.8, 125.1, 126.7, 134.3 (4C, arene C); MS (70 eV): *m/z* (%): 228 (100) [M^+], 196 (20) [M^+ − S], 164 (4) [M^+ − 2S], 151 (16) [M^+ − C_6H_5].



11b: Red blocks; m.p. 202–203 °C. UV (MeCN): λ_{max} (lgε) = 238 (4.22, sh), 296 (4.21), 335 (4.18), 441 nm (3.52); ^{1}H NMR ($CDCl_3$): δ = 1.79 (s, 6H, $2CH_3$), 1.74 (s, 6H, $2CH_3$); ^{13}C NMR ($CDCl_3$): δ = 12.8, 13.5 ($2CH_3$), 125.3, 130.5, 131.4, 131.8 (arene C); MS (70 eV): *m/z* (%): 284 (100) [M^+], 269 (16) [M^+ − CH_3], 252 (40) [M^+ − S], 251 (61) [M^+ − SH].

11c: Orange-red needles; m.p. 304–306 °C. UV ($CHCl_3$): λ_{max} (lgε) = 290 (4.29), 401 nm (4.08); ^{1}H NMR ($CDCl_3$): δ = 7.08–7.37 (m, 20H, arene H); ^{13}C NMR ($CDCl_3$): δ = 127.4, 127.6, 127.9, 128.3, 128.4, 128.9, 130.1, 130.7 (8C, phenyl), 133.2, 134.5, 136.8, 138.7 (4C, thiophene rings); MS (70 eV): *m/z* (%): 532 (100) [M^+], 500 (50) [M^+ − S], 466 (13) [M^+ − 2SH].

[a] Correct elemental analyses were obtained for all compounds. [b] Three sets of signals for **6b** (relative intensities A ≈ B > C) and two sets of signals for **6c** (relative intensities: A > B), reversible increase of C (**6b**) or B (**6c**) at increased temperature (80 °C); assignments based on the attached proton test (APT) in the ^{13}C NMR spectrum. [c] Cf. ref. [11b].

c) When X = NH, oxidation led to an amorphous and extremely insoluble mixture of products which melted above 360 °C over a wide range and was separated into its components only with difficulty. The same result was obtained from the stepwise reaction of **1a** with iodine and thiourea followed by alkaline hydrolysis and oxidation analogous to the procedure in reference [12]. The mass spectrum up to *m/z* 600 contains a peak consistent with **6a** (*m/z* 588) together with a base peak corresponding to **4a**/**5a** (*m/z* 294). Reduction of the product with $NaBH_4$ regenerated the starting material **3a**. The presence of oligomeric cyclic disulfides including **6a** can be inferred (associated by intermolecular NH hydrogen bonds according to the IR spectrum: strong NH bands at 2700 ± 50 and 3340 cm^{-1}).

Similarly in the 2,2′-dithienyl series no thioxoindigoid compounds of type *cis*- or *trans*-**10** were obtained (Scheme 3): the reaction of 3,3′-dibromo-2,2′-dithienyls **9a–c**[13] with *n*BuLi and elemental sulfur and subsequent oxidation of the 3,3′-dithiolate salts thus formed led to the valence isomeric dithieno-2,2′-dithiines **11a–c**. The cyclic disulfide structure appeared both in solution (no indication in the ^{13}C NMR spectrum of a C=S group as in **10**) and the solid state. The X-ray structure analysis showed a C-S-S-C dihedral angle of 50.85° for **11a** and 52.55°

Scheme 3. [a] 1. 2 equiv nBuLi/Et_2O, 2.5 h, −70 °C; 2. S_8, 3 h −10 °C; 3. 10% NaOH/H_2O; 4. $K_3[Fe(CN)_6]$; 19% **11a**, 64% **11b**, 61% **11c**. [b] Cu powder (mixed), 45 min 200 °C, extraction with hot $CHCl_3$; 47% **12a** (m.p. 64–66 °C, ref. [19]: 66.5–67 °C); 50% **12b** (m.p. 206–207 °C); 69% **12c** (m.p. 298 °C).

for **11b** (see Fig. 2).[10] Although colored like the 3,6-disubstituted 1,2-dithiines,[3a,e] compounds **11** do not spontaneously extrude sulfur under mild conditions (in daylight in solution at room temperature). Only with copper bronze at high temperatures (melt) could the sulfur be removed with the formation of dithieno[3,2-*b*;2′,3′-*d*]thiophenes **12a–c**.[14]

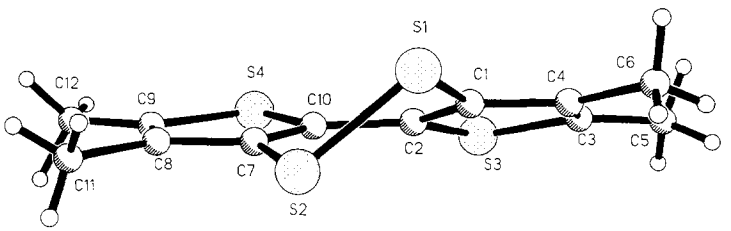


Fig. 2. Crystal structure of the thieno-annelated 1,2-dithiine **11b**. Important bond lengths [Å] and angles [°]: S1-S2 2.059(1), S2-C7 1.763(2), S1-C1 1.761(2), C7-C10 1.365(3), C1-C2 1.376(3), C2-C10 1.450(3); S1-C1-C2 120.99(13), C1-C2-C10 125.06(16), C1-C2-S3 109.98(14), C2-S3-C3 92.65, C4-C3-S3 111.54(14); C1-S1-S2-C7 52.55(10), C1-C2-C10-C7 21.45(26).

Attempts to convert the cyclic disulfides **5**, **6**, and **11** to **4** and **10**, respectively, by heating them above their melting points or in high boiling solvents (e.g. decalin) have so far not succeeded. From our results it can be concluded that thioindigoid compounds **B** (≡ **4a–d**, **10**) cannot be prepared by the "classical" route (oxidation of thioanalogues of leuco compounds) and that their ability to exist at all, either in the solid state or in solution at room temperature, is questionable.[15] It remains to be seen whether compounds of type **B** can be generated and spectroscopically characterized in low-temperature matrices.

The predominance of the cyclic disulfides **5**, **6**, and **11** as opposed the open-ring thioxo valence isomers finds parallels in some other S-heterocycles such as 1,2-dithietes,[16] 1,2-dithiolium-3-olates,[17] 1,2-dithiolo[3,4-*d*]-1,2-dithioles,[18] 1,2-dithiapentalenes,[19] and 1,7,8-trithiapentalenes.[20]

The Reactivity of Phosphacymantrenes towards Palladium(II) and Palladium(0) Compounds: Synthesis, Structure, and Chemistry of Pd_2Mn_2 and Pd_3Mn_4 Arrays**

Lionel Brunet, François Mercier, Louis Ricard, and François Mathey*

The presence of nonbonding e_{2g} electrons on the iron atom of ferrocene implies the possibility of dative bonds between iron and electron-deficient transition metal centers. Indeed, such compounds have been found for gold(I)[1], mercury(II)[2], palladium(II),[3-5] and platinum(II).[4] In order to prevent both the dissociation of such complexes and redox processes yielding ferricinium salts, cyclopentadienyl ligands with chelating substituents are generally used to hold the electron-accepting metal center close to the iron center. In 1986 Roberts, Silver, and Wells[6] demonstrated that 1,1'-diphosphaferrocenes also form such complexes with copper(I) and silver(I), but these complexes were not structurally characterized. Their results reflect the similarity of the electronic structures of ferrocene and diphosphaferrocene[7] and the greater resistance of diphosphaferrocene toward oxidation.[8]

Theoretically, the manganese center in phosphacymantrenes should also be able to participate in their coordination chemistry, since their HOMOs have predominantly 3d(Mn) character.[9] A priori, either a two-electron donation by manganese or an insertion into the P–Mn bond might be observed. These two possibilities have indeed found to occur with palladium as the electron-accepting metal center.

With palladium(II), the most satisfactory results were obtained with 3,4-dimethyl-2-phenylphosphacymantrene (**1**).[10] The reaction of **1** with $[PdCl_2(PhCN)_2]$ in dichloromethane at room temperature was monitored by ^{31}P NMR spectroscopy. Initially, the resonance of **1** at $\delta = -35$ disappears, and two new signals appear at $\delta = 12.9$ and 24.6. These most likely arise from two classical isomeric or diastereomeric $[Pd(\mathbf{1})_2Cl_2]$ complexes. After some time these complexes disappear, and a new complex **2** is formed with a signal at $\delta(^{31}P) = 116.5$.

The X-ray crystal structure analysis of **2** indicates the presence of a Mn-Pd-Pd-Mn chain and a completely planar $Mn_2Pd_2Cl_2P_2$ core (Fig. 1). At 2.8373(3) Å the Pd–Pd separation is shorter than the Pd–Pd bonds in some Pd_3 clusters with phosphido bridges.[12] Similarly, the Pd–Mn separation (2.7812(6) Å) falls in the range of genuine Pd–Mn bonds.[13] The Pd–P bond lengths are in the normal range,[12] although significantly different (2.286(1) and 2.2268(9) Å). The most fascinating observation concerns the P–Mn separation, which at 2.3712(9) Å clearly indicates that there is still a bond between phosphorus and manganese. For 2,5-diphenylphosphacymantrene (**4**) we have recorded a P–Mn distance of 2.392(1) Å,[14] and a value of 2.376(3) Å was reported for $[W(\mathbf{4})(CO)_5]$.[15] Since manganese is still η^5-bonded to the phospholyl ring, and since both IR and X-ray analysis exclude bridging carbonyl ligands, the Pd–Mn bond necessarily corresponds to the donation of two electrons by manganese to palladium. The carbonyl ligands are a sensitive probe for this transfer of electrons away from manganese. The CO stretching frequencies (Table 1) increase from 2017.2 and 1937.7 in **1** to 2018.2 and 1964.8 cm^{-1} in **2**. The $\delta(^{13}CO)$ signal shifts from 224 in **1** to 220 in **2**. The Mn–CO separations are 1.791–1.794(4) in **4** and 1.804–1.825(4) Å in **2**; the corresponding CO bond lengths are 1.149–1.155(5) in **4** and 1.132–1.149(5) Å in **2**. All these data suggest that the carbonyl ligands are significantly less polarized in **2** than in **1**, which indicates a lower electronic density on manganese. From another standpoint, in **2** phosphorus shares its two nonbonding electrons with the two palladium atoms.

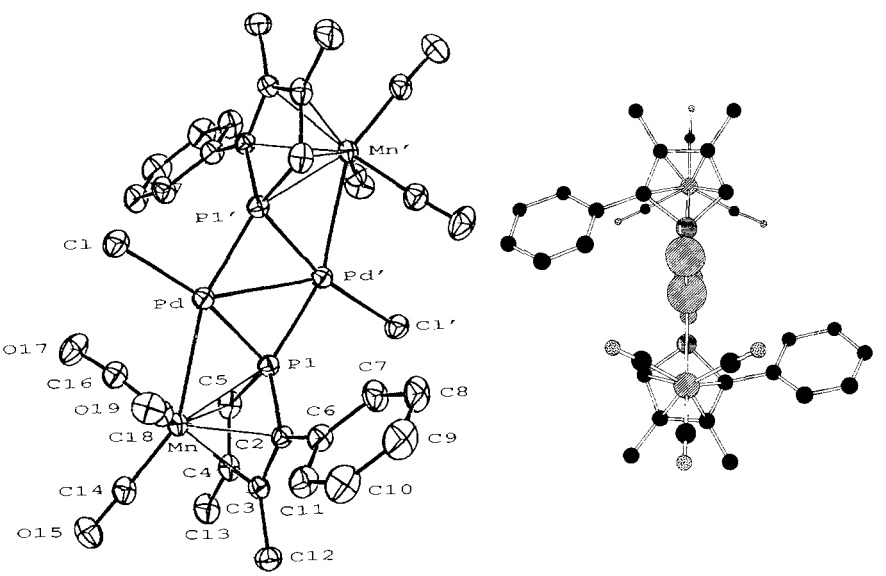

Fig. 1. Left: Crystal structure of **2** [11] (ellipsoids at the 50% probability level, hydrogen atoms omitted for clarity). Important bond lengths [Å] and angles [°]: Pd-Pd' 2.8373(3), Pd-Mn 2.7812(6), Pd-Cl 2.338(1), Pd-P1 2.286(1), Pd-P1' 2.2268(9), Mn-P1 2.3712(9), Mn-C2 2.227(3), Mn-C3 2.208(3), Mn-C4 2.180(4), Mn-C5 2.186(4), P1-C2 1.773(3), P1-C5 1.756(3), C2-C3 1.411(5), C3-C4 1.450(5), C4-C5 1.409(6); Pd'-Pd-Mn 104.87(1), Pd'-Pd-Cl 142.77(2), Pd'-Pd-P1 50.12(2), Pd'-Pd-P1' 51.97(2), Mn-Pd-P1 54.76(2), Mn-Pd-P1' 156.83(3), Cl-Pd-P1 167.09(3), Cl-Pd-P1' 90.81(3), P1-Pd-P1' 102.09(3), Pd-P1-Pd' 77.91(3), C2-P1-C5 92.1(2). Right: A Chem-Draw view of one molecule of **2** showing its perfect symmetry and the planarity of the $Mn_2Pd_2Cl_2P_2$ core.

This kind of bonding has some precedent for two-coordinate phosphorus centers.[16] Finally, the ^1H and ^{13}C NMR spectra of crude **2** (Table 1) indicate the presence of a second isomer in which the two phenyl groups are probably on the same side of the $Mn_2Pd_2Cl_2P_2$ plane.

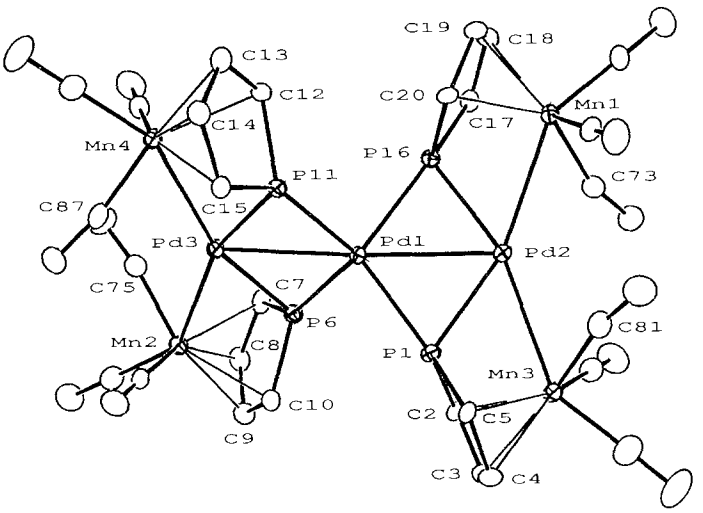
[a] 200.13 MHz ^{1}H, 50.32 MHz ^{13}C, 81.01 MHz ^{31}P NMR spectra.

A similar reaction with PdI_2 gave complex **3**, which according to spectroscopic data (Table 1) has a $[Pd_2(\mathbf{1})_2I_2]$ formulation similar to that of **2**. As expected, **3** is formed as a mixture of two isomers.

With palladium(0) the most satisfactory results were obtained with 2,5-diphenylphosphacymantrene (**4**).[17] The reaction with $[Pd(dba)_2]$ (dba = dibenzylideneacetone) essentially gives one product, **5**, with a 3:4 stoichiometry. A clue to the best formula-

4 **5** (77% / Pd)

tion of **5** comes from the comparison of its structure (Fig. 2) with those of free **4**[14] and $[W(\mathbf{4})(CO)_5]$.[15] Whereas the overall structure of **4** does not change drastically (in particular, the P–C



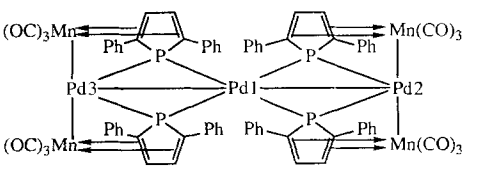


Fig. 2. Crystal structure of **5** [18] (ellipsoids at the 50% probability level, hydrogen atoms and phenyl groups omitted for clarity). Important distances [Å] and angles [°]: Pd1-Pd2 2.8004(5), Pd1-Pd3 2.7877(5), Pd1-P1 2.355(1), Pd1-P6 2.352(1), Pd1-P11 2.384(1), Pd1-P16 2.362(1), Pd2-Mn1 2.7939(8), Pd2-Mn3 2.8142(9), Pd2-P1 2.359(1), Pd2-P16 2.343(1), Pd3-Mn2 2.7332(9), Pd3-Mn4 2.8297(8), Pd3-P6 2.374(1), Pd3-P11 2.322(1), Mn1···P16 2.474(1), Mn2···P6 2.470(2), Mn3···P1 2.473(1), Mn4···P11 2.489(1), P1-C2 1.791(5), P1-C5 1.799(5), P6-C7 1.803(5), P6-C10 1.795(5), P11-C12 1.795(5), P11-C15 1.800(5), P16-C17 1.807(5), P16-C20 1.800(5); Pd2-Pd1-Pd3 176.67(2), P1-Pd1-P16 106.78(5), P6-Pd1-P11 106.85(4), P1-Pd2-P16 107.27(5), P6-Pd3-P11 108.21(5); interplane angle P6-Pd1-P16/P6-Pd1-P11: 60.15 ± 0.05.

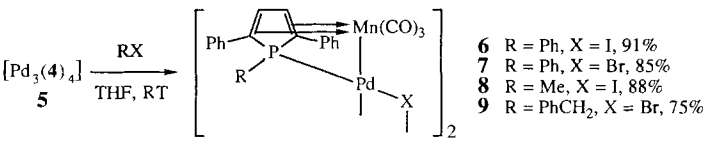
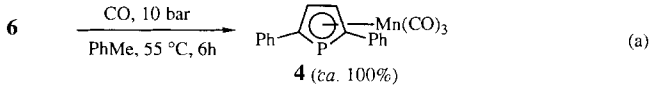
and C–C separations within the ring remain almost the same), the P–Mn separations are significantly larger in **5** than in either **4** or $[W(\mathbf{4})(CO)_5]$; **5**: 2.470(2)–2.489(1) Å; **4**: 2.392(1) Å; $[W(\mathbf{4})(CO)_5]$: 2.376(3) Å. Simultaneously, the folding of the phospholyl ring about the C_α–C_γ axis and away from manganese is more pronounced in **5**: 2.54 ± 2.88, 5.68 ± 1.86, 5.75 ± 1.59, and 5.96 ± 1.52°; **4**: 0.87 ± 0.32°. These observations suggest that the phospholyl ring acts as two distinct subunits: an η^4-diene and a μ-phosphido ligand with no P–Mn bonding. Such situations have already been described.[19, 20] On the other hand, a significant interaction exists between the external palladium atoms Pd2, Pd3 and the vicinal manganese atoms: the Pd–Mn separations (2.733(1)–2.829(1) Å) are in the range of genuine Pd–Mn bonds.[13] Similarly, the Pd–Pd separations of 2.8004(5) and 2.7877(5) Å are less than those reported for some phosphido-bridged Pd–Pd bonds in trinuclear clusters.[12] Besides, the distorted tetrahedral coordination of Pd1 and the diamagnetism of **5** exclude a 16-electron configuration for Pd1. Taking all these observations into account, we propose the formulation for **5** depicted in Scheme 1.



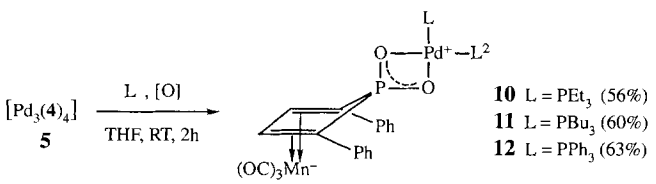
Scheme 1. Proposed formulation for **5**.

Basically, this formulation indicates that an insertion of Pd^0 into the P–Mn bond of **4** has taken place with disruption of the delocalization in the phospholyl ring. That the electronic situation within the phospholyl rings of **5** is dramatically different from that in **2** is clear from the ^{31}P NMR data: δ^{31}P = 12.2 (**5**),



116.5 (**2**). The reduction in the electron transfer from manganese to palladium in **5** is also suggested by the IR and ^{13}C NMR data: IR: $\tilde{\nu}$(CO; CH_2Cl_2, *E* band): 1949.3 (**5**), 1964.8 cm^{-1} (**2**); ^{13}C NMR: δ(CO; $CDCl_3$): 224 (**5**), 220 (**2**). The manganese atoms appear to be more electron-rich in **5** than in **2**, as suggested by the higher polarization of the carbonyl ligands and in agreement with the presence of dative Mn → Pd bonds in **2** and apolar Mn–Pd bonds in **5**. Thus the phosphacymantrene ligand in **5** acts as a (3 + 1)-electron donor and in **2** as a (2 + 2)-electron donor.

The disruption of the P–Mn bond and of the electronic delocalization of the phospholyl rings upon formation of **5** also has a dramatic effect on the chemistry of ligand **4**. Whereas phosphorus is electrophilic in **4**,[21] it is nucleophilic in **5**, and easy arylation and alkylation at phosphorus can be performed (Scheme 2).



Scheme 2. Electrophilic substitution at the phosphorus center of **5**. RT = room temperature.

The formulation of the products is based on the X-ray crystal structure analysis of **6** (Fig. 3). These arylation/alkylations probably proceed by the oxidative addition of R–X to the 16-electron Pd2 and Pd3 centers followed by the collapse of the Pd1-Pd2-Pd3 unit and the migration of R from Pd to P. A curious finding was that the treatment of **6** with an excess of a two-electron ligand (CO or PBu_3) regenerates **4**, through cleavage of the P–Ph bond and rearomatization of the ring [Eq. (a)]. This observation cast some light on the mechanism of the synthesis of phosphacymantrenes by reaction of $[Mn_2(CO)_{10}]$ with phospholes.[21]

(a)

Another interesting aspect of the chemistry of **5** concerns its reaction with phosphanes (Scheme 3). All the products (**10**–**12**) display very similar ABX ^{31}P NMR spectra. The formulation of these species is based on an X-ray crystal structure analysis of **11** (Fig. 4). The Pd–Mn separation of 5.209 Å implies the absence of any bond between these atoms and hence a zwitterionic formulation. The shift of the CO stretching frequencies to lower energies further suggests the presence of partial negative charge on the manganese atom. The folding of the phosphole ring about the C_α–$C_{\alpha'}$ axis is now 27.85 ± 0.64°, which is in the normal range for such systems.[23]

Scheme 3. Reactions of **5** with phosphanes.

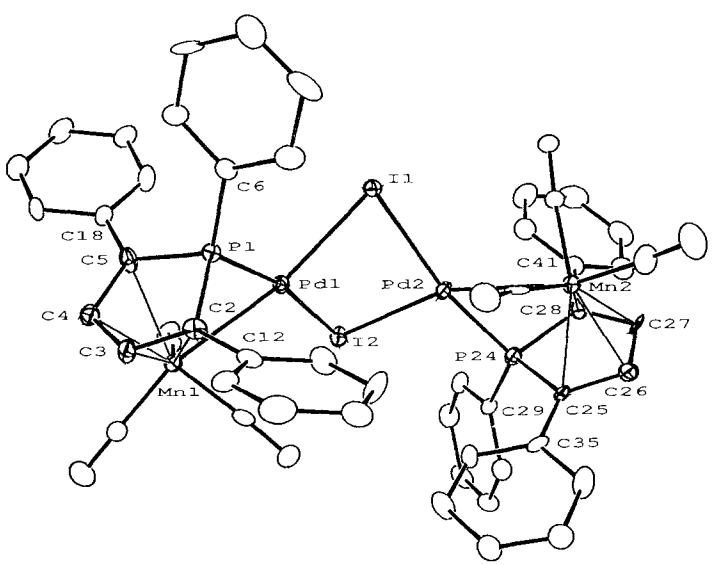


Fig. 3. Crystal structure of **6** [22a] (ellipsoids at the 50% probability level). The first palladium η^2-phosphinate has been described very recently.[24] The analogous complexes **10**–**12** are probably formed via an intermediate $[Pd(\mathbf{4})(L)_2]$ complex in which the palladium atom is inserted into the P–Mn bond of **4**. Then, coordination of oxygen as an η^2 species,[25] could take place followed by intramolecular oxidation of phosphorus. It must be noted here that the direct reaction of $[Pd(PPh_3)_4]$ with **4** also gives **12**.

We have described two new coordination modes of phosphacymantrenes: complexation at manganese and insertion into the P–Mn bond. High-valent Pd^{2+} prefers the first mode, whilst low-valent Pd^0 favors the second. In the second case, umpolung of the phosphorus center from electrophilic to nucleophilic is observed, and alkylation, arylation, and oxidation at phosphorus is then possible. This series of results probably can be transposed to other η^5-phospholyl complexes, thus extending significantly the coordination chemistry of this class of compounds.

Experimental Procedure

2: To phosphacymantrene **1** (1 g, 3.1×10^{-3} mol) in CH_2Cl_2 (30 mL) was added $[PdCl_2(PhCN)_2]$ (1 g, 2.6×10^{-3} mol) in CH_2Cl_2 (30 mL) dropwise. After stirring at room temperature under dry nitrogen for 24 h, the solvent was evaporated and the residue washed several times with diethyl ether. Yield of **2**: 0.8 g (67%).

3: To PdI_2 (0.2 g, 5.5×10^{-4} mol) in acetone (10 mL) was added **1** (0.27 g, 8.3×10^{-4} mol). After stirring at room temperature for 5 h under nitrogen, the solution was filtrated and evaporated. The residue was washed with hexane to remove excess **1**. Complex **3** is less stable than complex **2**.

5: To the palladium(0) complex $[Pd(dba)_2]$ (1 g, 1.8×10^{-3} mol) in CH_2Cl_2 (30 mL) was added phosphacymantrene **4** (1.1 g, 3×10^{-3} mol) in CH_2Cl_2 (20 mL). After stirring at room temperature under dry nitrogen for 2 h, the solvent was evaporated and the residue treated with diethyl ether (20 mL). The pale red precipitate of **5** was recovered (0.84 g, 77%/Pd); m.p. 192 °C (decomp).

6: To **5** (1 g, 5.5×10^{-4} mol) in freshly distilled and degassed THF (30 mL) was added iodobenzene (0.35 g, 1.7×10^{-3} mol). The mixture was stirred at room temperature under dry nitrogen for 2 h. The solution was concentrated to one-third of its volume. Then, 20 mL of distilled and degassed hexane was added and the precipitate filtered. Yield of **6**: 1.1 g (91.7%), m.p. 200 °C (decomp).

7: Same procedure as for **6**, reaction time 24 h. From 1 g of **5** and 0.31 g of PhBr was obtained 0.9 g of **7** (85%); m.p. ≈190 °C (decomp).

8: Same procedure as for **6**, reaction time 48 h. From 0.2 g of **5** and 0.1 g of MeI was obtained 0.18 g of **8** (88%); m.p. ≈200 °C (decomp).

9: Same procedure as for **6**, reaction time 24 h. From 0.1 g of **5** and 0.05 g of $PhCH_2Br$ was obtained 0.09 g of **9** (75%); m.p. ≈180 °C (decomp).

10: To **5** (0.1 g, 5.5×10^{-5} mol) in freshly distilled and degassed THF (10 mL) was added triethylphosphane (5×10^{-2} g, 4×10^{-4} mol). The mixture was stirred at room temperature in a Schlenk tube under nitrogen for 2 h. After evaporation, The residue was treated with diethyl ether (10 mL). The precipitate was recovered.

11: Same procedure as for **10**. From 0.2 g of **5** and 0.13 g of PBu_3 was obtained 0.185 g of **11** (60%); m.p. ≈215 °C (decomp).

12: Same procedure as for **10**. From 0.5 g of **5** and 0.87 g of PPh_3 was obtained 0.53 g of **12** (63%); m.p. ≈196 °C (decomp).

[11] Crystals of $\mathbf{2} \cdot 2CH_2Cl_2$, $C_{32}H_{28}Cl_2Mn_2O_6P_2Pd_2 \cdot 2CH_2Cl_2$, were grown from a dichloromethane solution of the compound. Data were collected at -150 ± 0.5 °C. The compound crystallizes in space group $P2_1/c$, $a = 10.927(1)$, $b = 14.404(1)$, $c = 13.152(1)$ Å, $\beta = 109.96(1)°$; $V = 1945.61(58)$ Å^3; $Z = 2$; $\rho_{calc} = 1.936$ g cm^{-3}; $\mu = 20.5$ cm^{-1}; $F(000) = 1116$. A total of 5668 unique reflections were recorded in the range $2° \le 2\theta \le 60.0°$, of which 4121 were used for solution and refinement. The structure was solved by Patterson methods (localization of the Pd, P, and Cl atoms). The hydrogen atoms were included as riding atoms in the final stages of least-squares refinement. A non-Poisson weighting scheme was applied with a p factor of 0.08; $R = 0.033$, $Rw = 0.054$, GOF = 1.12 [26].

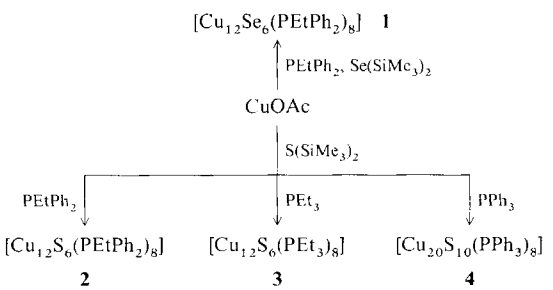
New Sulfur- and Selenium-Bridged Copper Clusters; Ab Initio Calculations on $[Cu_{2n}Se_n(PH_3)_m]$ Clusters **

Stefanie Dehnen, Ansgar Schäfer, Dieter Fenske,* and Reinhart Ahlrichs



Copper(I) chloride reacts with tertiary phosphanes and $Se(SiMe_3)_2$ with the elimination of $SiMe_3Cl$ to give selenium-bridged copper cluster complexes.[1] Hitherto only metal-rich copper clusters have been observed and characterized as reaction products for these reactions. Examples of these include:[1]

$[Cu_{30}Se_{15}(PiPr_3)_{12}]$ $[Cu_{70}Se_{35}(PEt_3)_{22}]$ $[Cu_{146}Se_{73}(PPh_3)_{30}]$

In contrast, it has not been possible to isolate intermediates of these reactions, as has been achieved in the synthesis of tellurium-bridged copper clusters.[2]

In 1991 I. G. Dance et al. reported the existence of smaller copper chalcogenide cluster ions, such as $[Cu_{11}E_6]^-$, $[Cu_{12}E_7]^-$, and $[Cu_{19}E_{10}]^-$, which were produced after laser ablation of the elements or of the binary chalcogenides, and subsequently could be detected by mass spectrometry.[3] This encouraged us to search for synthetic methods for ligand-protected copper clusters of this type.

In order to synthesize these intermediates as well as the sulfur-bridged species still missing in the series of chalcogenide-bridged copper clusters, copper(I) acetate was treated with PR_2R' (R, R' = Ph, Et) and $E(SiMe_3)_2$ (E = S, Se) in diethyl ether or THF. In this way compounds **1**–**4** were isolated and characterized by X-ray crystal structure analyses (see Figs. 3 and 4).[4, 5]

Compounds **2**, **3**, and **4** are the first sulfur-bridged copper clusters which could be prepared in this way and characterized. Compounds **1** and **4** precipitate in the form of red crystals from dark brown solutions; **2** forms red and **3** forms violet crystals, which were each isolated from colorless reaction solutions. The IR spectra of the compounds are not very informative, since they only contain characteristic vibrations for the phosphane ligands.

After the synthesis of **1**, ab initio calculations for $[Cu_{12}Se_6]$ were carried out parallel to and independent of the crystal structure analysis of **1**. The structural features and energetics of such molecules had been investigated previously as part of a systematic study of small $[Cu_2Se]_n$ clusters with and without phosphane ligands.[6] The calculations were carried out with the TURBOMOLE[7] program at the MP2 approximation,[8] which had proved successful for the above study, whereas the SCF method had proved to be insufficient.

Several important structure principles shall be outlined by using clusters **5**–**8** (Fig. 1) as examples; each of these form local minima on the energy hypersurface. More accurate calculations were also carried out for **5** at the coupled cluster level (CCSD(T)), from which errors in the Cu–Cu (±5 pm) and Cu–Se (±3 pm) bond lengths of the MP2 structures can be estimated.

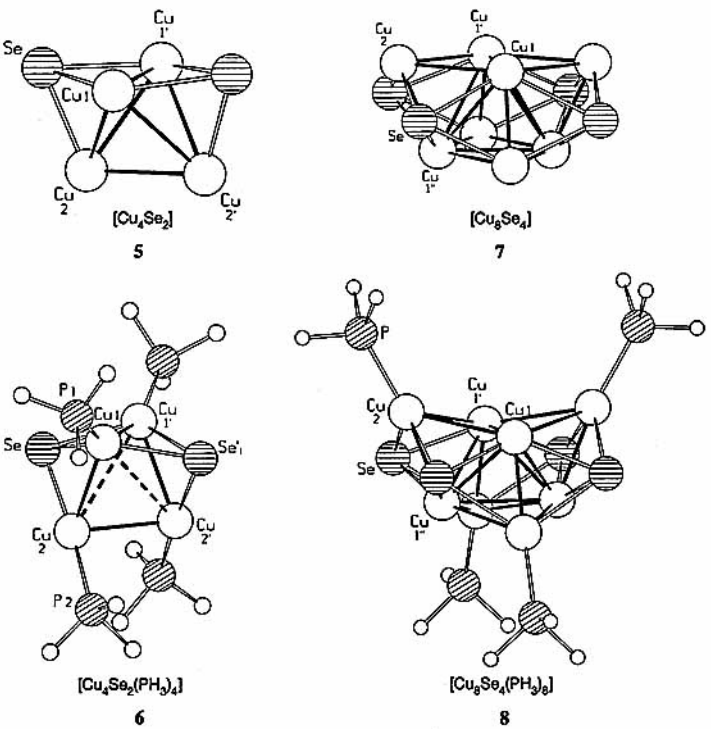


Fig. 1. Structures of **5**–**8** resulting from MP2 calculations. Selected bond lengths [pm] (error ±5 pm) and angles [°]: **5**: Cu1–Cu1′ 221.6, Cu1–Cu2 260.2, Cu2–Cu2′ 261.2, Cu1–Se 237, Cu2–Se 222.8. - **6**: Cu1–Cu1′ 244.4, Cu1–Cu2 251, Cu1–Cu2′ 323.9, Cu2–Cu2′ 260.4, Cu1–Se′ 237.7, Cu1–Se 244.3, Cu2–Se 222.7, Cu1–P1 218.3, Cu2–P2 216; Se-Cu2-P2 172. - **7**: Cu1–Cu1′ 262.6, Cu1–Cu1″ 275.4, Cu1–Cu2 260.1, Cu1″–Cu2 223.8, Cu1–Se 245.2, Cu2–Se 233.1. - **8**: Cu1–Cu1′ 280.4, Cu1–Cu1″ 260.5, Cu1–Cu2 271.2, Cu1″–Cu2 234.7, Cu1–Se 232.2, Cu2–Se 246.5, Cu2–P 219.

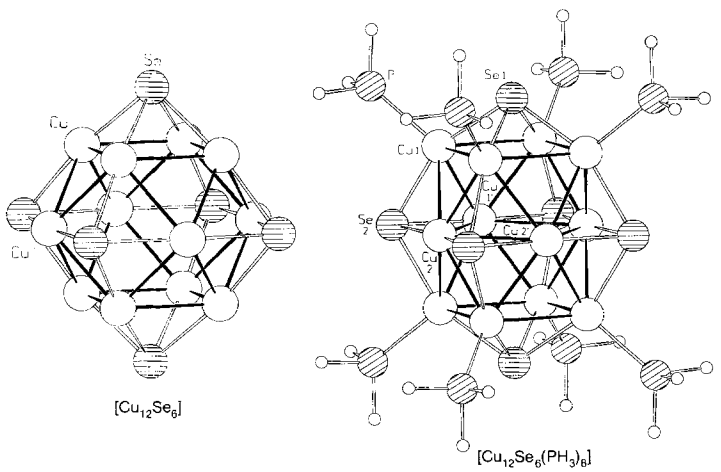

For at least three, but mostly four Cu–Se contacts per selenium atom, the structure with the maximum number of short Cu–Cu contacts (< 260 pm) is always preferred. Generally, this leads to structures with relatively high symmetry. Accordingly, a distorted Cu_4 tetrahedron exists in **5** in which two Cu_3 faces are capped by μ_3-selenido ligands. In contrast, in **7** a highly distorted cube of copper atoms is observed, whose two selenium-free faces are deformed to rhombuses that are rotated by 90° relative to each other. The Cu–Cu interaction exhibits marginal covalent contributions and is best considered as a dispersion interaction of the d^{10} systems.[9]

The PH_3 ligands in **6** and **8** coordinate to exposed sites on the cluster framework and favor—as far as possible—a linear Se-Cu-P arrangement (the Se-Cu2-P2 angle in **6** is 172°); this tendency is typical for the coinage metals in the oxidation state +I.[10] For increased loading with Se ligands, trigonal-planar coordination at the Cu centers is preferred (in **8** P projects 21.5°

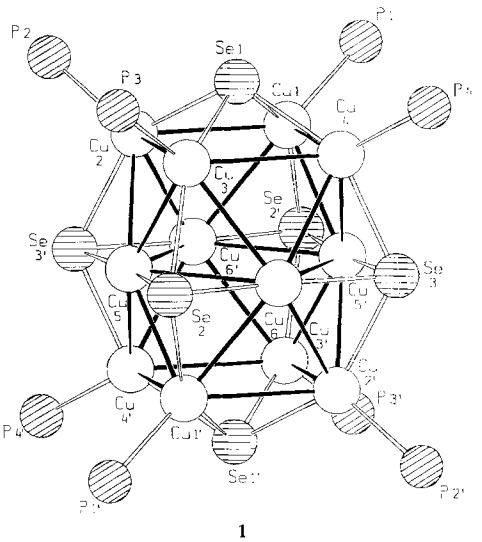
above the Se–Cu2–Se plane). The rules found for smaller molecules, regarding the choice of the most stable arrangement of copper and selenium atoms, support the structure of **9** (Fig. 2). Other considered structures always gave higher energy. Compound **9** has O_h symmetry and can be described as a Cu_{12} cubooctahedron with Se-capped square faces or as a Se_6 octahedron whose edges are linked by Cu atoms.

9 **10**

Fig. 2. Structures of **9** and **10**, resulting from MP2 calculations. Selected bond lengths [pm] (error ±5 pm): **9**: Cu–Cu′ 252, Cu–Se 233.3; **10**: Cu1–Cu1′ 275.2, Cu1–Cu2 256.5, Cu2–Cu2′ 283.4, Cu1–Se1 234.5, Cu1–Se2 242.1, Cu2–Se2 227.6, Cu1–P 232.6.

For the calculation of the structure of the ligand-clad cluster framework of **9**, PH_3 was used as a model ligand and the highest possible symmetry, D_{4h}, was assumed for the resulting molecule **10**. This considerably reduced the effort required for the calculation. The structure of **10** (Fig. 2) determined in this way is in agreement with (within the limits of the methods) the molecular structure of **1** (cf. Fig. 3)[4] determined by crystal structure analysis. The calculated Cu–Se distances in **10** lie in the range of measured values of **1** or slightly above (< 2 pm). The calculated Cu–P bond is at least 3 pm longer than that found in **1**, which can be attributed to the fact that substituted phosphanes are stronger donors than PH_3. Slightly larger deviations occur for several Cu–Cu distances; the greatest difference (11 pm) between the calculated and measured values is found for Cu1–Cu2 (see Fig. 3). Here, however, very soft modes are observed—in the small clusters they typically lie at 100 cm^{-1}; as a result packing effects might play a role in the crystal.



The PH_3 ligands lead to a distortion of the Cu_{12} framework in **9**, in such a way that two face-shared Cu_8 antiprisms are formed in **10**. The copper atoms bearing phosphane ligands (Cu1–Cu4 in **1**) in **10** and **1** are positioned further away from the center of the cluster than in **9** and adopt trigonal-planar coordination. In contrast, the four remaining copper atoms (Cu5, Cu6 and inverted positions in **1**) are shifted further towards the center of the cluster, retaining almost linear Se-Cu-Se arrangements (the angle is about 167° in **10**); as a result the coordination of additional ligands to these atoms is prevented.

The stabilization energy E_n of the naked clusters **5**, **7**, and **9** is calculated to be −160, −302, and −427 kJ mol^{-1}, respectively.[*] The bond energy of the naked clusters increases with growing cluster size; thus, these clusters are not thermodynamically stable systems.

$$E_n = \frac{1}{n} E[Cu_{2n}Se_n] - E[Cu_2Se]$$

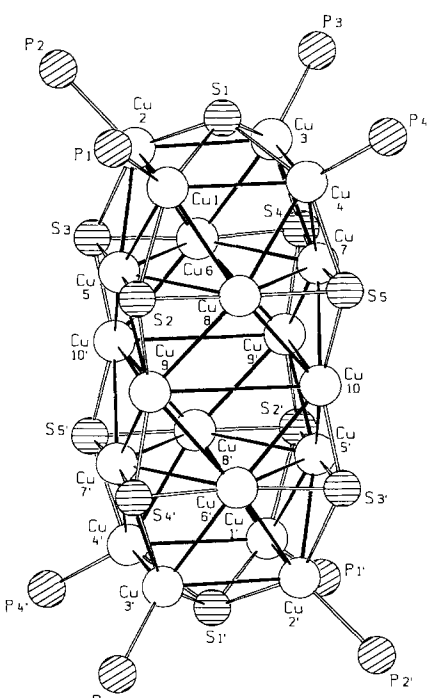
From the calculated total energies (MP2) of **6**, **8**, and **10**, the following bond energies of the Cu–P bonds result: 103, 98, and 50 kJ mol^{-1}. The Cu–P bond becomes weaker as the size of the cluster increases, since the copper atoms are then loaded with selenium neighbors, and thus, the ideal (linear) Se-Cu-P arrangements are no longer formed. This also explains why the PR_3 ligands preferably bind to the exposed copper atoms. The low bond energy of the Cu–P bond (50 kJ mol^{-1}) in **10** clarifies why **1** must be prepared with cooling.

The structural buildup of **1**, **2**, and **3** is the same. The molecular structures of these compounds in the crystal is exemplified in Figure 3, which shows the structure of **1**. Compounds **1**, **2**, and

1

Fig. 3. Structure of $[Cu_{12}Se_6(PEtPh_2)_8]$ **1** in the crystal (without ethyl and phenyl groups, Cu–Cu distances up to 318 pm are drawn). Selected bond lengths [pm] and angles [°] (error ±0.9 pm and ±0.3°, respectively): Cu(1,2,3,4)–Cu 257.2–292.8, Cu5–Cu(6,6′) 296.2 and 286.9, Se1–Cu 232.9–233.9, Se2–Cu 220–245, Se3–Cu 216.5–239.3, P–Cu 226.2–229.1; Se1-Cu-Se 143.4–147.4, Cu1-Se2′-Cu3′ 123.2, Cu2-Se3′-Cu4′ 127.9, Se1-Cu-P 115.7–120.9, Cu1-Cu5′-Cu3′ 113.2.

3 have an inversion center. The copper part of the framework consists of two face-shared, slightly distorted square antiprisms. This rare structural fragment exists, however, in a highly deformed form, for example, in $[Rh_{12}C_2(CO)_{24}]^{2-}$, $[Rh_{12}C_2(CO)_{23}]^{3-}$, and $[Rh_{12}C_2(CO)_{23}]^{4-}$.[5] The distances of the copper atoms from the inversion center range from 205.4–300 pm in **1**, 206.4–295.9 pm in **2**, and 203.8–310 pm in **3**. The atoms of the middle Cu_4 faces (Cu5, Cu5′, Cu6, Cu6′) are each closer to the center than those of the basal faces (Cu1–Cu4). Thus, the copper part of the framework cannot be described as a distorted cubooctahedron; cubooctrahedral cluster compounds or structural fragments always have almost identical distances between the apecies of the polyhedron and the center. One example of this is the framework of copper atoms in $[Cu_{12}(PPh)_6(PPh_3)_6]$.[2]



[*] The calculated total energies (MP2) of the naked clusters **5**, **7**, and **9** using the basis set given in [6] are −220.962573, −442.141384, and −663.497772 au, respectively; 1 au (atomic unit) = 2625.5 kJ mol^{-1}. For the ligand-clad clusters **6**, **8**, and **10** values of −253.693704, −474.865664, and −728.799384 au are obtained.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0707-0747 $ 10.00+.25/0

The eight phosphane ligands in **1**, **2**, and **3** coordinate to the eight copper atoms of the two basal faces. The sulfur and selenium atoms always act as μ_4-bridging ligands. Together they form a slightly distorted octahedron. The copper atoms of the outer faces (Cu1–Cu4) are each bound to two chalcogen atoms and one phosphorus atom (E-Cu-E = 142–147°, E-Cu-P = 112–122°, and 95–105°). The copper atoms of the middle face are each coordinated by two chalcogen atoms, leading to an almost linear E-Cu-E arrangement (172–176°). In the equatorial face of the chalcogen octahedron an eight-membered Cu_4E_4 metallacycle (Cu5, Cu6, E2, E3 and inverted positions) is found. Cu_4R_4 metallacycles without additional coordination are known for R = CH_2SiMe_3 or R = *O-tert*-butyl.[11] The ability of chalcogen atoms to adopt higher coordination enables the formation of the three-dimensional structures for the cluster complexes presented here.

In addition to differences in bond lengths, compounds **1**, **2**, and **3** show different degrees of tetragonal distortion. In this way the molecules (without taking the organic groups into consideration) do not achieve D_{4h} symmetry, but only D_{2h} symmetry. The Cu–Cu distances in all of the compounds are too large (255–354 pm) to be considered as bonding interactions. The Cu–Cu and the Cu–E distances found in **1**–**3** are of the same order of magnitude as those in binary chalcogenides. This was also established for other copper–selenide clusters.[1]

The molecular structure of the cluster complex **4** (Fig. 4) can now be derived in a simple way from the structures of **1**, **2**, and **3**: in **4**, two Cu_{12} fragments were formally linked through one of the Cu_4 faces previously described as basal faces. The sulfur atoms which are arranged above these faces in **1**, **2**, and **3** and the eight phosphane molecules bound to the corresponding copper atoms are no longer present after this formal cluster condensation. Instead the new, almost square Cu_4 face is extended; thus, the framework of copper atoms in **4** forms an arrangement of four square antiprisms linked through three Cu_4 faces. An inversion center is also present in **4**.

4

Fig. 4. Structure of $[Cu_{20}S_{10}(PPh_3)_8]$ **4** in the crystal (without phenyl groups, Cu–Cu distances up to 354 pm are drawn). Selected bond lengths [pm] and angles [°] (error ±0.9 pm and ±0.4°, respectively): Cu(1,2,3,4)–Cu 264.1–290, Cu(9,10)–Cu 267.7–354.4, S1–Cu 224.5–226.1, S2–Cu 214.2–235.8, S3–Cu 215.7–235.1, S4–Cu 215.7–234.8, S5–Cu 214.9–235.2, P–Cu 227.3–229.6; S1-Cu-S 140.2–152, Cu1-S2-Cu9 140.1, Cu2-S3-Cu10' 138.9, Cu3-S4-Cu9' 140.6, Cu4-S5-Cu10 140, S1-Cu-P 117.2–120.2, Cu1-Cu5-Cu9 103.5, Cu1-Cu8-Cu9 105, Cu2-Cu5-Cu10' 104.8, Cu2-Cu6-Cu10' 103.2, Cu3-Cu6-Cu9' 105.4, Cu3-Cu7-Cu9' 102.3, Cu4-Cu7-Cu10 105.1, Cu4-Cu8-Cu10 102.9.

There are numerous examples of the condensation of cluster fragments to larger units. Face-shared octahedra exist, for example, in the species $[Cs_{11}O_3]$ and $[Rb_9O_3]$,[12,13] described by A. Simon; examples for the formation of strands of octahedra by face-sharing include the Chevrel phases $[Mo_{12}Se_{14}]^{2-}$, $[Mo_{18}Se_{20}]^{4-}$, $[Mo_{24}Se_{26}]^{6-}$, and $[Mo_{30}Se_{32}]^{8-}$.[12,14,15] Cluster complexes which exhibit this building principle are also known for cobalt and nickel: $[Co_9Se_{11}(PPh_3)_6]$, $[Ni_{15}Se_{15}(PPh_3)_6]$, and $[Ni_{12}Se_{12}(PEt_3)_6]$.[16] Ecliptic stacking of trigonal prisms through triangular faces has been described for $[Pt_{15}(CO)_{30}]^{3-}$.[5]

The linkage of more than three tetragonal antiprisms is, however, new in cluster chemistry. Besides icosahedral (e.g. $[Ni_{10}As_2(CO)_{18}(CH_3)_2]^{2-}$) and anticubooctahedral structures (e.g. $[PtRh_{12}(CO)_{24}]^{4-}$) as well as polyhedra consisting of three face-shared octahedra (e.g. $[Ir_{12}(CO)_{26}]^{2-}$) also many, far less symmetrical arrangements (e.g. $[Co_3Ni_9C(CO)_{20}]^{3-}$ and $[Os_{11}CuC(CO)_{27}(CH_3CN)]^{-}$)[5] of twelve metal atoms in cluster compounds have been observed. For the few known metal clusters with 20 metal atoms so far no uniform structural principle has been formulated.

If it is assumed that in **1**–**4** the chalcogenido ligands exist as Se^{2-} or S^{2-}, the copper fragments of the compounds carry the formal charges Cu_{12}^{12+} and Cu_{20}^{20+}. Consequently, the copper atom in the cluster complexes can be assigned the formal oxidation state +1 (d^{10} configuration). This supports the assumption that metal–metal bonding can be ruled out in these systems, and that at most weak interactions exist between the copper atoms. There are, however, several cases in which d^{10}–d^{10} interactions contribute to metal bonding.[11,17]

Compounds **1**–**4** are possibly intermediates in the synthesis of larger cluster compounds. This is indicated first by the dark brown color of the reaction mixtures from which the red crystals of **1** and **4** were isolated, and second the compounds are more readily decomposed than known large cluster complexes. There is still a lack of concrete evidence for the formation of larger cluster complexes in the colorless reaction mixtures from which **2** and **3** were isolated.

Experimental Procedure

1: $PEtPh_2$ (1.61 mL, 6 mmol) was added to a suspension of CuAc (0.37 g, 3 mmol) in diethyl ether (25 mL), which resulted in the dissolution of the CuAc. The reaction mixture was cooled to −65 °C and treated with (0.37 mL, 1.5 mmol) $Se(SiMe_3)_2$. The solution was allowed to warm to room temperature over 4 d, during which time it had turned dark brown and red needles of **1** had crystallized out (yield 5%).

2: $PEtPh_2$ (1.61 mL, 6 mmol) was added to a suspension of CuAc (0.37 g, 3 mmol) in diethyl ether (25 mL), which resulted in the dissolution of the CuAc. $S(SiMe_3)_2$ (0.31 mL, 1.5 mmol) was added to the solution at −78 °C, and the reaction mixture was subsequently allowed to warm to −20 °C over 4 d. Cherry red rhombuses of **2** crystallized from the colorless solution (yield 100%).

3: PEt_3 (1.18 mL, 8 mmol) was added to a suspension of CuAc (0.25 g, 2 mmol) in diethyl ether (40 mL), which resulted in the dissolution of the CuAc. $S(SiMe_3)_2$ (0.21 mL, 1 mmol) was added to the solution at −78 °C, and the reaction mixture was subsequently allowed to warm to −20 °C over 4 d. In this way violet square crystals of **3** were obtained in 82% yield.

4: PPh_3 (1.31 g, 5 mmol) was added to a suspension of CuAc (0.12 g, 1 mmol) in THF (20 mL), which resulted in the dissolution of the CuAc. Subsequently, $S(SiMe_3)_2$ (0.10 mL, 0.5 mmol) was added, which caused the reaction mixture to turn dark brown. The mixture was cooled to −40 °C, and after 7 d a powdery precipitate was filtered off. Red octahedra of **4** crystallized out after a further 6 d at −20 °C.

Borophosphates—A Neglected Class of Compounds: Crystal Structures of $M^{II}[BPO_5]$ (M^{II} = Ca, Sr) and $Ba_3[BP_3O_{12}]$**

Rüdiger Kniep,* Güller Gözel, Brigitte Eisenmann, Caroline Röhr, Matthias Asbrand, and Meral Kizilyalli

Given all the current activity in the field of microporous solids, it is remarkable that intermediate phases of the $M^I_2O/M^{II}O$-B_2O_3-P_2O_5(-H_2O) systems (M^I = alkali metal, M^{II} = alkaline earth metal) have been "forgotten". Bauer[1, 2] (1965/1966) reported the synthesis and X-ray diffraction patterns of the isostructural (hexagonal) phases $M^{II}[BPO_5]$ (M^{II} = Ca, Sr, Ba). Ramamoorthy and Rockett[3] (1974) confirmed the existence of $Ca[BPO_5]$ from phase equilibria studies on the system CaO-B_2O_3-P_2O_5 at 900 °C. Liebertz and Stähr[4] (1982) reported on the compound $Mg_3[BPO_7]$ (dimorphous; isostructural with α-/β-$Zn_3[BPO_7]$). Rulmond and Tarte[5] (1988) studied the borophosphates $M^{II}[BPO_5]$ synthesized by Bauer[1, 2] and assumed that they crystallized in the stillwellite type[6] ($Ce[BSiO_5]$). The neutral borophosphate BPO_4[7–9] is of particular interest because of its isostructural relationship to the polymorphic modifications of SiO_2.[10]

$Ca[BPO_5]$ and $Sr[BPO_5]$ were obtained as single-phase microcrystalline powders, as outlined in Equations (a) and (b) respectively, in platinum crucibles at 900 °C, following the procedures described by Bauer.[1]

$$CaHPO_4 \cdot 2H_2O + H_3BO_3 \longrightarrow Ca[BPO_5] + 4H_2O \quad (a)$$

$$SrCO_3 + H_3BO_3 + (NH_4)_2HPO_4 \longrightarrow Sr[BPO_5] + 3H_2O + 2NH_3 + CO_2 \quad (b)$$

Well-ground mixtures were used in the mole equivalents given in Equations (a) and (b). $Ca[BPO_5]$ was synthesized by heating the reaction mixture at a rate of 2 K min^{-1} to 900 °C and then cooling to room temperature at the same rate. For the synthesis of $Sr[BPO_5]$ the reaction mixture was heated at 2 K min^{-1} to 600 °C, cooled to room temperature, and ground up again; the reaction was completed by heating at 900 °C for 24 h. According to DTA experiments the borophosphates melt incongruently at 1025 °C ($Ca[BPO_5]$) and 1092 °C ($Sr[BPO_5]$).

Single-phase samples of the compound $Ba[BPO_5]$ could not be synthesized under the same conditions. Experiments employing an excess of $(NH_4)_2HPO_4$ as a flux medium or a solvent provided single crystals of the new compound $Ba_3[BP_3O_{12}]$: mixtures of $BaCO_3$, H_3BO_3, and $(NH_4)_2HPO_4$ in the mole ratio 2:1:3 were heated to 1300 °C over 4 h in a platinum crucible and were kept at this temperature for 8 h. After a further 24 h at 1000 °C the mixtures were cooled to room temperature over 4 h. A glassy matrix was formed in which were embedded elongated orthorhombic prisms of $Ba_3[BP_3O_{12}]$; $Ba_2[P_2O_7]$ was detected as an additional crystalline side product by X-ray powder diffraction studies. The crystal structures of the isostructural phases $Ca[BPO_5]$ and $Sr[BPO_5]$ were refined with X-ray powder data[10] (see also Fig. 1); the crystal structure of $Ba_3[BP_3O_{12}]$ was determined by single-crystal methods.[11]

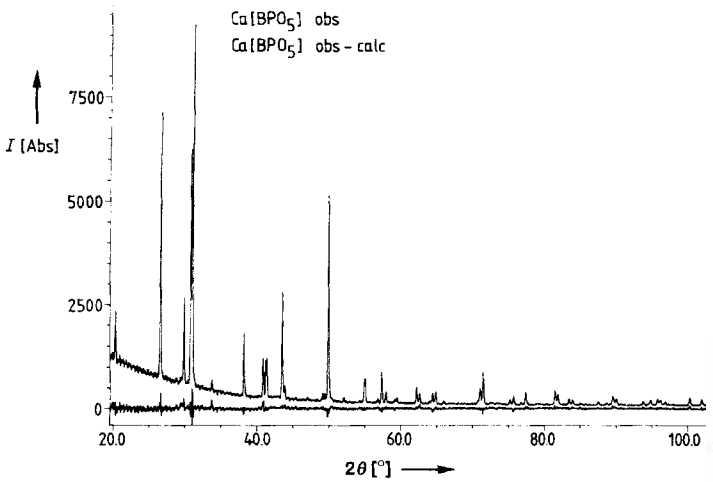

Fig. 1. Top: X-ray powder diffraction pattern of $Ca[BPO_5]$ ($Cu_{K\alpha}$ radiation). Bottom: difference diagram (measured − calculated).

The crystalline phases $Ca[BPO_5]$ ($Sr[BPO_5]$) and $Ba_3[BP_3O_{12}]$ contain $^1_\infty$anionic units of BO_4 and PO_4 tetrahedra joined by common vertices (Figs. 2 and 3). The $M^{II}[BPO_5]$ compounds, which crystallize in the stillwellite type,[6] contain central "dreier" single chains of BO_4 tetrahedra running parallel to [001], which are linked to terminal PO_4 tetrahedra to form loop-branched chains.[13] The polymeric assembly of tetrahedral anions in crystalline $Ba_3[BP_3O_{12}]$ consists of central "vierer" single chains (BO_4 and PO_4 in alternation) which run parallel to [001]; the two free vertices of each BO_4 tetrahedron are connected with terminal PO_4 tetrahedra, resulting in "zweifach" open branched "vierer" single chains.[13] Tetrahedral connections of this kind were hitherto unknown. $Ba_3[BP_3O_{12}]$ contains wide channels in which the barium ions are located.

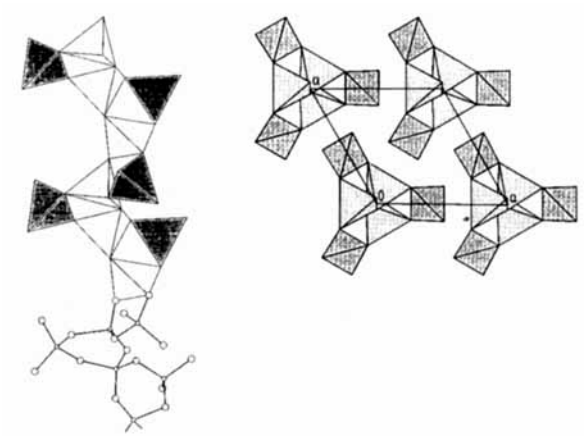

Fig. 2. Section of the crystal structure of $Ca[BPO_5]$ ($Sr[BPO_5]$). Left: loop-branched chains of tetrahedra $^1_\infty[BPO_5^{2-}]$ running parallel to [001]: light tetrahedra: BO_4; dark tetrahedra: PO_4. Right: packing of the chains of tetrahedra $^1_\infty[BPO_5^{2-}]$; view along [001].

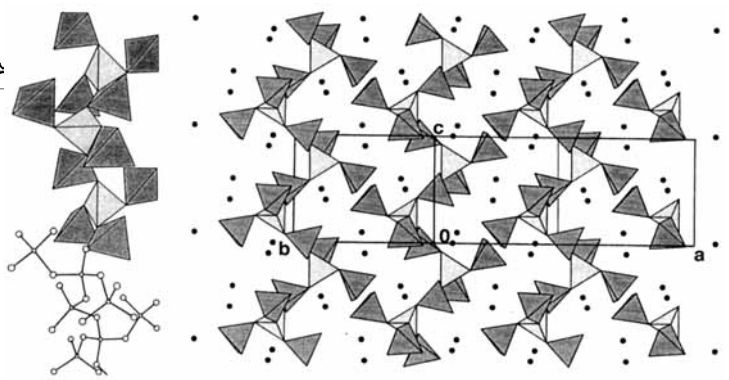

Fig. 3. Section of the crystal structure of $Ba_3[BP_3O_{12}]$. Left: "zweifach" open branched chains of tetrahedra $^1_\infty[BP_3O_{12}^{6-}]$; light tetrahedra: BO_4; dark tetrahedra: PO_4. Right: arrangement of chains of tetrahedra in the crystal structure; Ba^{2+} ions (black circles) within wide channels.

The bond lengths and angles in the polymeric tetrahedral anions of these borophosphates are quite similar to those in known polyphosphates and borates with a tetrahedrally coordinated central atom (see Table 1).

Given the results presented here and considering the known linking modes of tetrahedral groups, the formation of borophosphates with layered or framework structures or structures containing cavities may also be envisaged. The variety of possible structural linking patterns is certainly increased, since boron displays the trigonal-planar arrangement as well as the tetrahedral coordination by oxygen. In this context the "microporous" zincoborate $Zn_4O(BO_3)_2$[17] should be mentioned; here ZnO_4 tetrahedra and trigonal-planar BO_3 groups from a three-dimensional network with large cavities running through it. The technological importance of the incorporation of boron into microporous structures composed of tetrahedra (e.g. alu-

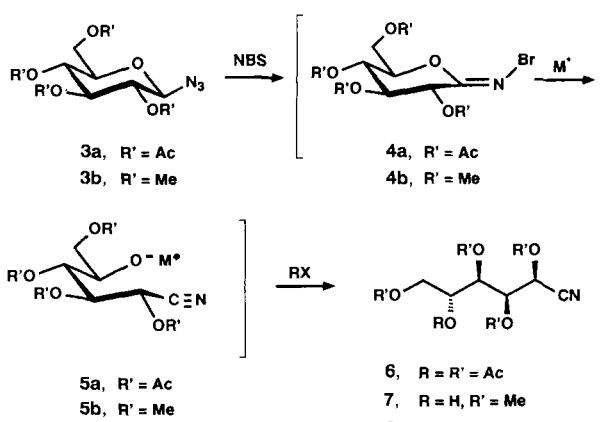
[19] Note added in proof: A recent, more extensive literature search revealed the structure determinations of the minerals lüneburgite ($Mg_3(H_2O)_6[B_2(OH)_6(PO_4)_2]$) and seamanite ($Mn_3(OH)_2[B(OH)_4][PO_4]$). Lüneburgite contains dimeric tetrahedral units $[BPO_7]^{6-}$ (P. K. S. Gupta, G. H. Swikart, R. Dimitrijević, M. B. Hossain, *Amer. Mineral.* **1991**, *76*, 1400–1407)), whereas the crystal structure of seamanite contains isolated BO_4 and PO_4 tetrahedra (P. B. Moore, S. Ghose, *Amer. Mineral.* **1971**, *56*, 1527–1538.).

Conversion of Glycosyl Azides via *N*-Bromoglycosylimines to Aldononitriles

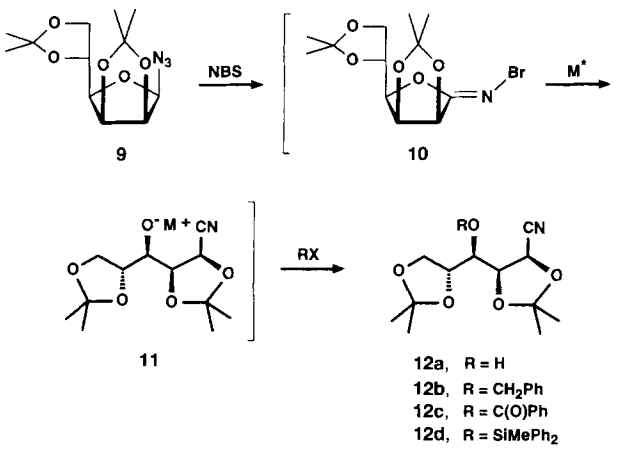
Alois Fürstner* and Jean-Pierre Praly*



N-bromosuccinimide (NBS) reacts with β-glycosyl azides to afford *N*-bromoglycosylimines **1** in good yield,[1] the chemistry of which is completely unexplored. Their similarity with (*Z*)-hydroxyiminoglyconolactones **2**, which have been used, for example, for the synthesis of spiro sugars, carbohydrate derived oxazoles, glycosylidene carbenes, and ring-expanded structures,[2] makes it worthwhile to explore the reactivity of **1** in more detail. Any synthetic application, however, must take their hydrolytic lability and low thermal stability into account. We report here on a metal-triggered reaction which converts these sensitive compounds to substituted aldononitriles.

The extraordinary reactivity of metal-graphite reagents makes them suitable for inducing many transformations under neutral conditions in aprotic media at low reaction temperatures; therefore, they can be applied nicely to hydrolytically labile substrates.[3] Furthermore, they are compatible with a variety of functional groups and can thus also be applied to complex natural products.[4] Deoxyhalo sugars, for example, on treatment with either C_8K or Zn/Ag-graphite are prone to reductive eliminations, resulting in the smooth ring opening of the carbohydrate precursors.[5] *N*-bromoglycosylimines may also undergo such dealkoxyhalogenations, if clean *N*-metalation can be achieved (Scheme 1).

Scheme 1. Successive reaction of glycosyl azides with NBS and metal-graphite (M*) (schematic representation). The structural analogy between *N*-bromoglycosylimines **1** and (*Z*)-hydroxyiminoglyconolactones **2** is evident.



The reaction of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl azide **3a**[6] with NBS and azobisisobutyronitrile (AIBN) in CCl_4 according to the literature procedure[11] and the subsequent treatment of the crude bromoimine derivative **4a** with an excess of Zn/Ag-graphite in THF, however, did not lead to a clean transformation. Since the NMR study of the crude product indicated the presence of several aldononitrile derivatives, the mixture was acetylated (Ac_2O/pyridine), affording penta-*O*-acetylgluconolactone **6**[7] in 71% isolated yield (Scheme 2). Since partial migration of the acetyl groups in the intermediate ring-opened zinc alcoholate **5a** (M = ZnBr) apparently accounted for the observed mixture, we chose azides stable to basic conditions, such as **3b** and **9** (Scheme 3),[8] as substrates. In fact, after

Scheme 2. Reactions according to Scheme 1 in the glucose series; M* = Zn/Ag-graphite or $2C_8K$ (see Table 1).

conversion to the corresponding bromoimines, both nicely gave the respective nitriles in good yield upon reaction with either Zn/Ag-graphite or C_8K (Table 1). The use of C_8K provided the additional advantage that the intermediate potassium alcoholates **5b** and **11** (M = K) may be trapped in situ with electrophiles, thus affording differently protected aldononitriles in one high-yielding step (Table 1). The synthetic potential of these highly functionalized sugar derivatives previously prepared by multistep approaches has been outlined recently.[10]

Table 1. Preparation of aldononitriles from glycosyl azides.

Substrate	M*-Graphite	RX	Product (Yield)
3a	Zn/Ag	Ac_2O [a]	**6** (71%)
3b	C_8K	CS_2/MeI	**7** (10%), **8** (62%)
9	Zn/Ag	– [b]	**12a** (87%)
9	C_8K	– [b]	**12a** (90%)
9	C_8K	$C_6H_5CH_2Br$	**12b** (76%)
9	C_8K	C_6H_5COCl	**12c** (80%)
9	C_8K	$Ph_2MeSiCl$	**12d** (86%)

[a] Acetylation using Ac_2O (5 equiv) in pyridine. [b] Moisture of solvents used for workup as proton source.

Attempts to cyclize xanthate **8**, obtained by quenching the potassium alcoholate **5b** (M = K) with CS_2 followed by alkylation with methyl iodide, under radical conditions failed.[11]

In summary, we describe the first transformations of sensitive *N*-bromoglycosylimines. Upon treatment with metal-graphite reagents these carbohydrate derivatives can be reductively ring-opened to aldononitriles, with an additional option for in situ derivatization if C_8K is used as the reducing agent. The reaction sequence constitutes not only a high-yielding approach to enantiomerically pure open-chain building blocks from sugars, but also proves for the first time that dealkoxyhalogenations can occur along (hetero) double-bond systems.

Experimental Procedure

12c: To a solution of 2,3:5,6-di-*O*-isopropylidene-β-D-mannofuranosyl azide **9** (300 mg, 1.05 mmol) [8] in CCl_4 (40 mL) was added NBS (393 mg, 2.21 mmol) and AIBN (10 mg). The mixture was stirred at room temperature until TLC showed complete conversion of the substrate and the appearance of a faint brown color in the reaction medium indicated the end of the conversion (2–3 h). The insoluble residues were filtered off, rinsed with CCl_4 (10 mL), the solvent removed in vacuo at < 20 °C (bath temperature), and the residue coevaporated twice with THF (3 mL each) to ensure complete removal of the CCl_4 from the syrup. The crude **10** thus obtained was dissolved in THF (3 mL) and added to a suspension of C_8K (426 mg, 3.15 mmol) [5, 9] in THF (20 mL) under argon. TLC showed rapid conversion (< 5 min) to a more polar compound. After addition of benzoyl chloride (300 mg, 2.13 mmol) in THF (1 mL), the reaction mixture was stirred for 1 h at room temperature, filtered, the solvent evaporated, and the residue purified by flash chromatography affording **12c** as colorless crystals (304 mg, 80%).

Table 2. Physical and analytical data of **3b**, **6**–**8**, and **12a**–**d**.

3b: Syrup; $[\alpha]_D^{20} = -22$ ($c = 2$ in $CHCl_3$); IR: $\tilde{\nu} = 2110\ cm^{-1}$ (N_3); ^1H NMR (200 MHz, C_6D_6): $\delta = 2.91$ (t, $J(2,3) = 8.5$, 1H, H-2), 3.06 (t, $J(3,4) = 8.8$, 1H, H-3), 3.06 (m, $J(5,6) = 1.5$, $J(5,6') = 3.8$, 1H, H-5), 3.14 (s, 3H, OMe), 3.22 (t, $J(4,5) = 9.5$, 1H, H-4), 3.38, 3.40 (s, each 3H, OMe), 3.41 (m, 2H, H-6,6'), 3.50 (s, 3H, OMe), 4.12 (d, $J(1,2) = 8.4$, 1H, H-1); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 59.17$, 60.25, 60.37, 60.75, 71.27, 77.49, 79.29, 83.90, 87.30, 90.13.

Determination of the Relative Configuration by Distance Geometry Calculations with Proton–Proton Distances from NOESY Spectra**

Michael Reggelin,* Matthias Köck, Kilian Conde-Frieboes, and Dale Mierke

Investigations of the structures of reactive organometallic compounds such as lithiated or titanated 2-alkenylsulfoximides[1] are quite difficult. Studies of these species under the conditions required for their reaction, in other words at low temperatures and in solution, are particularly problematic. Here NMR spectroscopy is the method of choice, since in principle the reaction dynamics (e.g. conformational flexibility, configurational behavior) of the metalated intermediates can be examined, which may aid in the interpretation of the stereochemical outcome of the reaction.[1] Often when no other method is available, only the relationship between the configuration of the metalated intermediates and the stereochemistry of the products of a stereoselective organometallic reaction can provide information on the stereochemistry of these intermediates. Thus, the development of a method independent of postulated models of transition states (e.g. Zimmerman–Traxler model) would be very valuable.

The obvious question is how NMR data (H–H distances, coupling constants) can be used to determine the relative configurations of molecules that may be flexible. To answer this question we conducted "NOE-restrained" molecular dynamics calculations with heavily weighted experimental distances.[2] The problem of the parametrization of the force field prevents the general application of this approach. Since suitable parameters are not available for many interesting systems such as polar organometallic compounds, alternative procedures had to be developed. The best approach appeared to be the application of as many actual measurable quantities, in other words H–H distances, as possible.

In principle conformations can be determined from distance data by distance geometry (DG) calculations,[3, 4] a procedure used for the NMR spectroscopic structure determination of biopolymers.[3] The absolute configuration of a stereogenic center is determined by the sign of the "chiral volume" (V_C)[5] taken up by the atoms bound to this chiral center. Typically a constant value is maintained for the chiral volume in the calculations to ensure the stereochemical integrity of the stereogenic center under consideration. If this chiral restraint is removed, the sense of chirality can be inverted and a new conformational space is opened up, within which a conformation can be found that optimally fits the distances obtained from the NOESY data. This method was applied for the assignment of diastereotopic protons in proteins,[6] and we have demonstrated its suitability for the determination of the configuration of a model compound.[7] Since the stereogenic centers of interest were in a section of the molecule that could be determined quite well from NOEs (bridgehead positions), we wondered if this method was generally applicable. To find out more about the potential of DG calculations for the determination of relative configurations we chose the much more flexible bisoxazolidine **1**.[8]

1

In addition to the known stereogenic centers in the norpseudoephedrin section of the molecule, **1** has six additional centers with unknown configurations. Two-dimensional NMR spectroscopy was used for the assignment of all of the protons in **1**.[9] The analysis began with the differentiation of the two quasisymmetric halves of the molecule. The OH-bearing carbon atom (C-11) was easy to identify, because it does not give rise to a cross peak in the proton-detected H–C correlation spectrum (HMQC[10]). This atom has a heteronuclear long-range correlation ($^3J_{C,H}$) with the proton at C-16 (HMBC[11]), which was used to identify the halves of the molecule. The ^{1}H signals within each half were assigned based on DQF-COSY and TOCSY experiments.[12] The arene protons were assigned with a selective HMBC experiment (excitation with a 270° Gaussian pulse[13]). Seven 400 MHz NOESY spectra were recorded for the determi-

nation of the H–H distances (mixing times: $\tau_{mix} = 100, 200, 300, 400, 500, 800, 1200$ ms). The cross peak between the geminal protons on C-10 was used as a calibration peak ($r = 178$ pm), and the distances corresponding to the volume integrals of the other cross peaks were calculated. Only results that were independent of the mixing time (generally up to $\tau_{mix} = 500$ ms, initial rate approximation) were used for the determination of the distances.

The DG calculations were conducted with a modified version[7, 15] of the DISGEO program.[3, 14] Ninety-nine structures were calculated by "random metrization", optimized[15, 16] with "distance bounds driven dynamics" (DDD)[17, 18] in four-dimensional space, and finally reduced to three-dimensional space with the "embed" algorithm. These structures were again refined with DDD.[19] The planarity of amide functions and aromatic rings, as well as the configurations of carbon atoms of known chirality, were secured with a penalty function.[20] The chiral volumes of the six centers of unknown absolute configuration were removed from the list of chiral restraints.

The 99 structures generated could be divided into three structure families according to their "pseudoenergies"[20] from the DDD calculations. The family with the lowest pseudoenergies (between 47 and 52) consists of 70 structures, the next has 11 structures (pseudoenergies between 67 and 95), and the last family comprises 18 structures with very high pseudoenergies (between 121 and 261). All the structures in the first two families except one (in the second family) have the same absolute configurations at the six unknown stereogenic centers as in the crystal structure.[21] Even in the third, energetically unfavorable family two structures (of 18) have the correct configurations. In the superpositioned structures from the first family shown in Figure 1a the conformations of the two inner five-membered rings of oxazolidine **1** are close to those in the structure determined by X-ray analysis. The intramolecular hydrogen bond between the acidic hydrogen atom and the carbonyl oxygen atoms is also accurately reproduced (Fig. 1c, d).

The distinct structural fluctuations in the arene region, which affect the precision of the description of the oxazolidine rings, are a consequence of the *o*- and *m*-protons. For this reason no individual distances from these protons are available. The average chiral volumes for the first family and for all calculated structures as well as the minimum and maximum volumes are listed in Table 1.

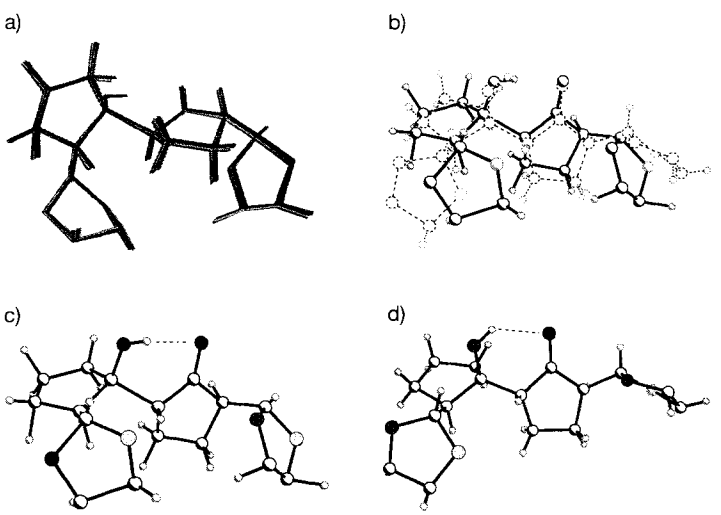

Fig. 1. a) Superposition of 43 randomly chosen structures from the first structure family obtained from DG calculations. b) Superposition of the crystal structure of **1** (dotted lined) and the DG structure (without the arene units). c) The intramolecular hydrogen bond is reproduced in the DG structure. d) The corresponding section of the crystal structure with the hydrogen bond drawn in. (Nitrogen: light gray circles, oxygen: dark gray circles).

Table 1. Calculated chiral volumes V_C of the six unknown stereogenic centers in **1**.

Atom no.	[b]		[c]		[d]	
	V_C	σ	V_C	σ	V_C^{min}	V_C^{max}
1	5.499	0.083	4.895	0.257	−6.417	7.162
6	7.752	0.020	6.924	0.244	−9.146	8.291
8	8.651	0.009	7.848	0.240	−9.156	7.108
11	5.074	0.010	4.291	0.351	−8.150	7.156
12	−4.944	0.009	−4.647	0.136	−3.313	5.843
16	5.129	0.008	4.926	0.108	−1.296	6.684

[a] Here positive values correspond to an (*R*)-configurated chiral center. σ = standard deviation. [b] Average chiral volume from the 70 structures of the first family. [c] Average chiral volume from all 99 structures. [d] Minimum and maximum volumes for all 99 structures.

Even after averaging over *all* structures, including those with large deviations from the required distances, the correct absolute configurations are obtained for the previously unknown chiral centers. This may be traced back to the fact that in general even in the "high-energy family" only one stereogenic center is determined incorrectly.

[5] A, B, C, and D are the ligands on the stereogenic center X in order of decreasing priority. The chiral volume (V_C) spanned by these four points is one-sixth of the oriented volume of the vectors extending from one point to the other three: $V_C = 1/6\ \vec{AD} \cdot [\vec{BD} \otimes \vec{CD}]$. If the vectors $\vec{AD}$, $\vec{BD}$, $\vec{CD}$ form a right-handed coordinate system, the volume is positive ((*S*) configuration), if they form a left-handed system, the volume is negative ((*R*) configuration).

In Situ NMR Investigations of Photocatalyzed Hydrogenations with Parahydrogen in the Presence of Metal Carbonyl Compounds of Group 6**

Angelika Thomas, Mathias Haake, Friedrich-Wilhelm Grevels, and Joachim Bargon*

Hydrogenations with parahydrogen (p-H_2) lead to nuclear spin polarization effects in ^{1}H NMR spectra.[1, 2] The extreme sensitivity of this method enables organometallic-catalyzed hydrogenations to be investigated. The amplification of the signal by up to 10^5 fold, the PASADENA effect (*P*arahydrogen *A*nd *S*ynthesis *A*llows *D*ramatically *E*nhanced *N*uclear *A*lignment), results from the breakdown of the H_2 symmetry during the hydrogenation;[1] the in situ NMR method based on this is called parahydrogen induced polarization (PHIP)[2–5] and is suitable for the detection of short-lived reaction intermediates.

A detailed analysis of the nuclear spin polarization pattern of the reaction products (or intermediates) identifies directly the positions of the transferred H_2 protons and thus indirectly allows conclusions about the nature of the intermediary binding of the H_2 molecule to the organometallic complex.[3b] Labeling experiments with D_2 are therefore unnecessary.

The systems studied previously were concerned with thermally induced hydrogenations in the presence of metal complexes of Groups 8–10, which activate the H_2 molecule by an oxidative addition.[2–7] In this communication, the hydrogenation of norbornadiene (NBD) is used as example to show that also in the photolytic activation of metal carbonyls of Group 6, the nuclear spin polarization of p-H_2 is transferred to the reaction products. The metal carbonyl compounds were used in the form of $[M(CO)_4(\eta^4\text{-NBD})]$ complexes (M = Cr, Mo). From an earlier study it is known that NBD is hydrogenated in the presence of the Mo complex mainly to give norbornene (NBN), whereas in the presence of the Cr complex the hydrogenation leads to nortricyclene (NTC) and NBN in the ratio of 3:1 (see Fig. 1).[8] The activation here results from photolytic cleavage of a CO ligand from the $[M(CO)_4(\eta^4\text{-NBD})]$ complex.[9] An H_2 molecule can be coordinated to the resulting free coordination site of the $[M(CO)_3(\eta^4\text{-NBD})]$ fragment, leading to the formation of the nonclassical hydrogen complex $[M(CO)_3(\eta^4\text{-NBD})(\eta^2\text{-}H_2)]$.[10] The other steps of the catalytic cycle, in which the $M(CO)_3$ group is the repeating unit, are shown in Scheme 1.

Scheme 1. Activation and catalytic cycle for the hydrogenation of NBD in the presence of carbonyl complexes of group 6.

The polarization signals of the 1,2-hydrogenation product NBN and also those of the homo-1,4-hydrogenation product NTC were detected (Fig. 1). The PHIP signals of NBN are identical with those which occur during thermally activated hydrogenations with the cationic rhodium catalyst $[Rh(NBD)(PPh_3)_2]PF_6$,[3b] although the H_2 molecule is activated in different ways. The analysis of the polarization pattern as an eight-spin system with a computer program (PHIP 9, J. Kandels, dissertation, Universität Bonn, FRG, 1992) developed for the PHIP NMR method confirms the formation of *cis-endo* hydrogenated NBN (Fig. 2). The necessary NMR parameters were taken from the literature (Scheme 2).[12]

A prerequisite for the computer-assisted evaluation of the experimental PHIP spectra is the assumption of a spontaneous hydrogenation.[3c] Spontaneous hydrogenation means that the breakdown of the symmetry of the H_2 molecule occurs on product formation. Thus, the H_2 molecule then cannot be bound hydridically to the catalyst for a longer period of time, which for $[RhCl(PPh_3)_3]$ is several milliseconds, since this would have resulted in the loss of the phase correlation because of the different chemical shifts of the two protons by different precession frequencies. Also in the case of a classical dihydrido complex, only an extremely short residence time of p-H_2 at the catalyst can prevent a loss of the phase correlation, otherwise both hydrogen atoms stemming from H_2 must be in chemically equivalent positions. Since the latter should apply for a η^2-H_2 complex, in this case the phase correlation of the nuclear spin is retained. A product molecule with an AA'BB' nuclear spin system or one with a partial spin system, as formed by the *endo*/*exo* protons of NBN, is a particularly sensitive probe for exploring the chemical environment in which the H_2 atoms occur in the course of the hydrogenation.[3c] A loss of the phase correlation of the H_2 atoms prior to their transfer to the substrate (NBD) would lead to considerable changes of the polarization pattern (Fig. 2c). The best agreement between experiment and simulation occurs under the assumption of spontaneous hydrogenation (see Fig. 2), that is, the bond of the H_2 molecule in the intermediate catalyst

complex remains unbroken; thus, an oxidative addition of H_2 to the catalyst does not take place.[3c]

The quantitative analysis of polarization spectra permits statements about the nature and the reaction path of isomeric reaction products. Thus, the hydrogenation with $[Mo(CO)_4(\eta^4\text{-NBD})]$ only leads to polarization signals of the NBN formed by *cis-endo* hydrogenation (see Fig. 1a). In contrast, for the hydrogenation

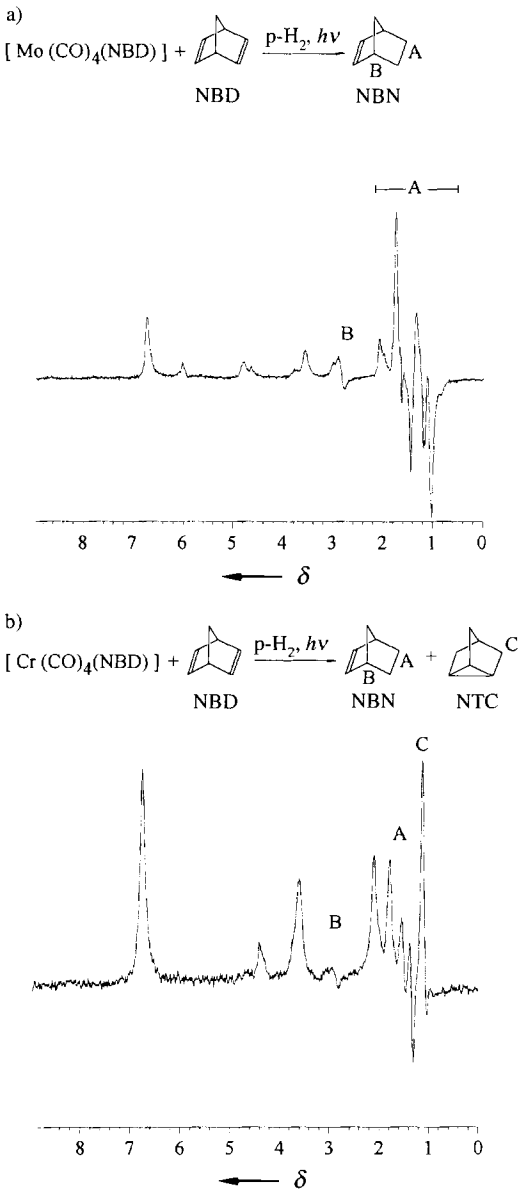

Fig. 1. Experimental PHIP spectra of the photocatalytic hydrogenation of norbornadiene in the presence of a) $[Mo(CO)_4(\eta^4\text{-NBD})]$ (165 accumulations, pulse delay 10 s, $\pi/4$ pulse) and b) $[Cr(CO)_4(\eta^4\text{-NBD})]$ (50 accumulations, pulse delay 10 s $\pi/4$ pulse). The spectra show in addition to the thermal signals of the reactants the polarization signals of protons of the nortricyclene (C: CH_2) and of the norbornene (A: *endo/exo* protons, B: bridgehead protons).

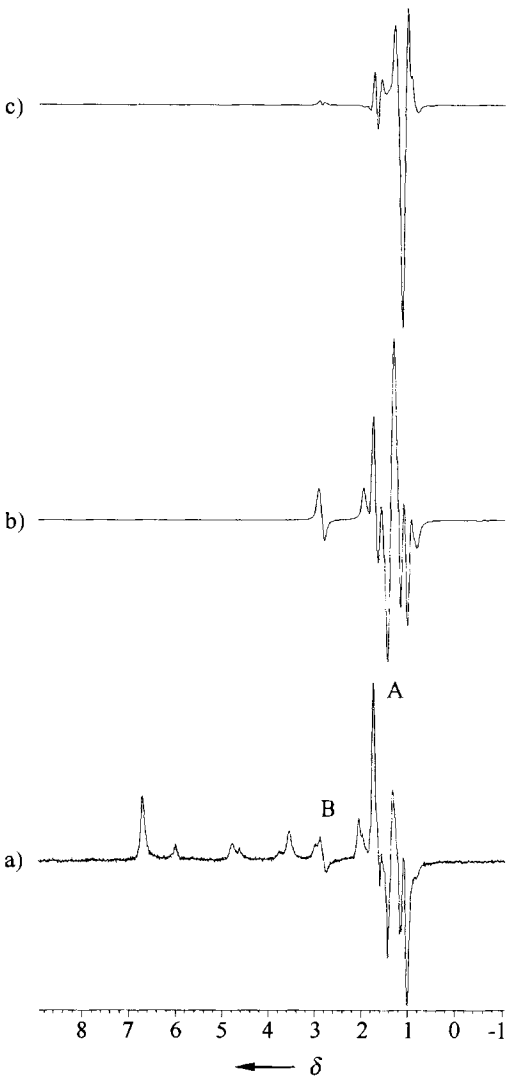
with $[Cr(CO)_4(\eta^4\text{-NBD})]$, in addition to a low polarization of the 1,2-hydrogenation product NBN mainly a polarization of the methylene protons of the homo-1,4-hydrogenation product NTC is detected. The formation of NBN can be detected above all as a result of the polarization of the bridgehead protons (group B in Fig. 1b), which show a coupling with the *endo/exo* proton system.



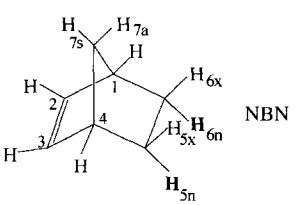


Fig. 2. Photocatalytic hydrogenation of norbornadiene in the presence of $[Mo(CO)_4(\eta^4\text{-NBD})]$. Experimental PHIP spectrum with polarization in the *endo/exo* protons (A) and the bridgehead protons (B) of NBN (a). Simulated PHIP spectra of the norbornene formed by *cis-endo* hydrogenation (b) under the assumption of spontaneous hydrogenation with additional W_2 relaxation of the geminal protons 5x, 5n and 6x, 6n as well as W_0 relaxation of the protons 1, 6x and 4, 5x (numbering see Scheme 2) ($W_0 = 0.16$, $W_2 = 0.15$), c) under the assumption of no spontaneous hydrogenation with a S/T_0 mixture of 1/1 [3c] during the hydrogenation and with the analogous assumption for the relaxation as for (b).

For both catalyst systems polarization signals occur only after an irradiation period of about 20 s. The hydrogenation with $[Mo(CO)_4(\eta^4\text{-NBD})]$ under continuous irradiation can be followed over 2.5 h by means of the polarization signals of the product (NBN). If the photoactivation is interrupted, the polar-

Scheme 2. Hydrogenation product norbornene: n = *endo*, x = *exo*, s = *syn*, a = *anti*.

ization signals for the two catalytic systems decrease over a period of 60 s; however, they can be reactivated by renewed irradiation.

The in situ PHIP NMR method allows a dynamic determination of the hydrogenation activity of catalysts. Recombination of the photoactivated catalyst with its original CO ligand or complex binding of olefinic substrates, that is, the formation of $[M(CO)_3(\eta^4\text{-NBD})(\eta^2\text{-L})]$ (L = NBN or NBD) lowers the catalytic activity.[11] Additional PHIP measurements at various CO pressures and NBD concentrations are required for the differentiation of these deactivation steps.

Experimental Procedure

The experiments were performed in a 80 MHz FT-^{1}H NMR spectrometer. For this, a pressure sample head with continuous flow system was used, which ensured the exclusion of O_2. This was important, since the catalysts employed are considerably air sensitive after photoactivation. The closed system enables continuous irradiation during the hydrogenation process as well as quantitative statements. The experimental set up and the p-H_2 enrichment have been described previously [5,8]. The reactions were carried out at room temperature and under atmospheric pressure with a solution of norbornadiene (2.0×10^{-3} M) and catalyst (8.0×10^{-4} M) in [D_{12}]cyclohexane. In control experiments with p-H_2 and pressure up to 10 bar without UV irradiation, it was shown that the catalyst systems proved to be inert. The samples were irradiated through a Pyrex window in the pressure probe head with unfiltered light from a 500 W-Hg lamp (Osram XBO 162).

The Oxovanadium–Organophosphonate System: Complex Cluster Structures $[(VO)_6(t\text{BuPO}_3)_8\text{Cl}]$, $[(VO)_4\{\text{PhP(O)}_2\text{OP(O)}_2\text{Ph}\}_4\text{Cl}]^-$, and $[V_{18}O_{25}(H_2O)_2(\text{PhPO}_3)_{20}\text{Cl}_4]^{4-}$ with Encapsulated Chloride Anions Prepared from Simple Precursors**

José Salta, Qin Chen, Yuan-Da Chang, and Jon Zubieta*

Current interest in the oxovanadium–organophosphonate system $V/O/RPO_3^{2-}$ is based on the practical applications of such materials as sorbents[1,2] and their diverse structural types. Recent developments in the chemistry of the $V/O/RPO_3^{2-}$ system have revealed the dinuclear complexes **1** and **2**, fully oxidized clusters **3** and **4**, mixed-valence clusters **5**–**7**, and layered compounds **8** and **9**.

$[(VO)_2Cl_2(RPO_3H)_2Y_2]^{n-}$[3] **1**

$[(VO_2)_2(RPO_3)_2]^{2-}$[3] **2**

$[V_5O_7(OCH_3)_2(PhPO_3)_5]^{1-}$[4] **3**

$VO(PhPO_3)] \cdot H_2O$[1] **8**

$[(VO)_2\{CH_2(PO_3)_2\}_2] \cdot 4H_2O$[9] **9**

These studies indicate that the composition and structure of the products isolated are critically dependent on solvent, temperature, and the presence or absence of templates. While the large mixed-valence clusters were obtained from hydrothermal reactions,[10,11] the penta- and heptanuclear complexes were prepared in organic solvents by conventional methods;[4,5] the dinuclear species was isolated under strictly controlled conditions in the presence of a bulky organic cation.[3] In solvothermal reactions with organic solvents intermediate temperatures and pressures are accessible, which should allow the isolation of metastable phases not accessible by conventional or hydrothermal techniques.[11] Furthermore, while controlled linkage of simple molecular units to form oligomers or solid phases remains elusive, the condensation of vanadium coordination polyhedra with organophosphonate tetrahedra to form aggregates can be directed to some extent by anionic templates. Directed condensations of this type were noted for the "naked" or predominantly inorganic clusters with a $[V_xO_yE]^{n-}$ core (E = encapsulated anionic unit) described by Müller et al.[12] and for oxovanadium phosphate phases.[13] We report here on the syntheses and structures of a series of clusters (**10**–**13**) of the $V/O/RPO_3^{2-}$ system,

in which the outer framework, which is constructed from the corner-sharing of vanadium-centered square pyramids and/or octahedra and organophosphonate tetrahedra, encloses chloride ions.

The solvothermal reaction of tBuPO$_3$H$_2$ with [Ph$_4$P][VO$_2$Cl$_2$][14] in acetonitrile yields lustrous dark green crystals of the mixed-valence cluster [(V^{V}O)$_5$(V^{IV}O)(tBuPO$_3$)$_8$Cl] (**10**).[15] X-ray crystallographic analysis of **10**[16] revealed that its structure (Fig. 1) consists of a spherical V/P/O shell of corner-sharing vanadium-centered square pyramids and organophosphonate tetrahedra encapsulating a chloride anion, which seems to serve as a template for cluster formation.[17] Although the structure of

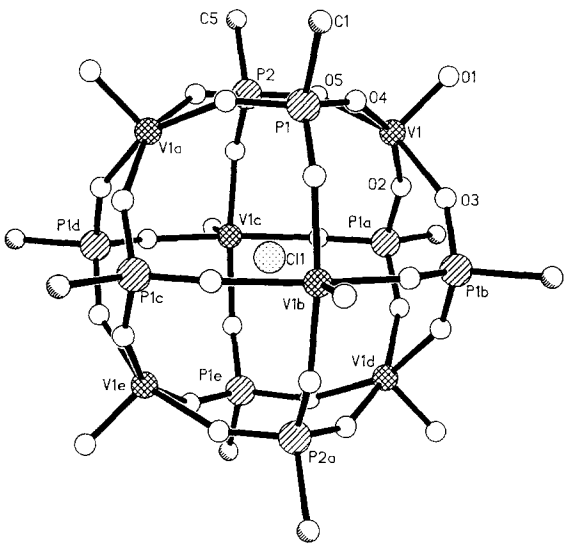

Fig. 1. A view of the structure of **10**. Selected bond lengths [Å] and angles [°]: V1-O1 1.563(7), V1-O2 1.850(3), V1-O3 1.863(8), V1-O4 1.860(5), V1-O5 1.848(9), P-O (average) 1.494(10); O(apical)-V1-O(plane) (average) 101.2(6). The central chloride ion lies on a crystallographic threefold inversion axis; P2 lies on a crystallographic threefold axis. Consequently, all atomic positions are related by to the unique set labeled V1 through C5 and shown in the upper right quadrant of the spherical shell.

10 is somewhat reminiscent of those of [V$_7$O$_{12}$(PhPO$_3$)$_6$Cl]$^{2-}$[5] and [V$_{15}$O$_{36}$Cl]$^{6-}$,[18] its topological details are distinct. The structure of [V$_{15}$O$_{36}$Cl]$^{6-}$ is constructed exclusively from {VO$_5$} square pyramids in a highly symmetrical arrangement of approximate D_{3h} symmetry; the faces of the sphere consist of two {V$_3$O$_3$}, three {V$_4$O$_4$}, and eighteen {V$_2$O$_2$} rings. The structure of [V$_7$O$_{12}$(PhPO$_3$)$_6$]$^-$ is much less symmetrical, exhibiting C_2 symmetry and faces constructed from {V$_2$PO$_3$}, {V$_2$P$_2$O$_4$}, {V$_3$PO$_4$}, and {V$_3$P$_2$O$_5$} rings. The structure of **10** exhibits idealized D_{4h} symmetry, and the shell is constructed exclusively from twelve {V$_2$P$_2$O$_4$} faces. In contrast to the structure of [V$_7$O$_{12}$(PhPO$_3$)$_6$]$^-$, **10** does not possess {V-O-V} bridges, and the vanadium centers are isolated from each other. The structural relationship of **10** to the dinuclear complexes of the type [(VO)$_2$Cl$_4$(tBuPO$_3$H)$_2$]$^{2-}$[3] is also apparent. Formally, the shell of **10** is constructed from the condensation of three such units with concomitant loss of HCl and incorporation of two additional tBuPO$_3^{2-}$ groups. The structure of **10** is also related to that of the layered phase VO(PhPO$_3$) · H$_2$O, since cleavage of three V – O(phosphonate) bonds in **10** and flattening of the cage produces a motif seen in the layered phase. These compounds display an unusually broad range of compositions: [V$_7$O$_{12}$(PhPO$_3$)$_6$Cl]$^{2-}$ exhibits a V:P ratio of 7:6, in **10** this ratio is 3:4, and ratios of 9:10, 1:1, 3:2, 7:4, and 2:1 have now been reported for V/O/RPO$_3^{2-}$ clusters.

Relatively minor changes in the starting materials in the solvothermal synthesis often lead to dramatically different products. Thus, the reaction of PhPO$_3$H$_2$ with [Ph$_4$P][VO$_2$Cl$_2$] under identical conditions to those employed for the synthesis of **10** results in the isolation of green crystals of the V^{IV} species **11**. The structure of **11**[19] consists of discrete Ph$_4$P$^+$ cations and [(VO)$_4${PhP(O)$_2$OP(O)$_2$Ph}$_4$Cl]$^-$ anions (Fig. 2). In this instance, the shell is constructed from vanadium-centered square pyramids and the fused tetrahedra of the pyrophosphonate ligands [PhP(O)$_2$OP(O$_2$)Ph]$^{2-}$, which are formed in a metal-mediated, thermally induced condensation process.[20] As in the structure of **10**, the structure of **11** exhibits isolated vanadium-centered square pyramids with no {V-O-V} interactions. Each vanadium center is bonded to the oxygen donors of three neighboring pyrophosphonate ligands; two ligands are each bonded through one O atom and the third through two O atoms to form a {V-O-P-O-P-O-} ring. The V/P/O shell of **11** acts as a cage for a Cl$^-$ ion. The V···Cl distances in **11** are 3.07 Å compared to 3.39 Å for **10**.

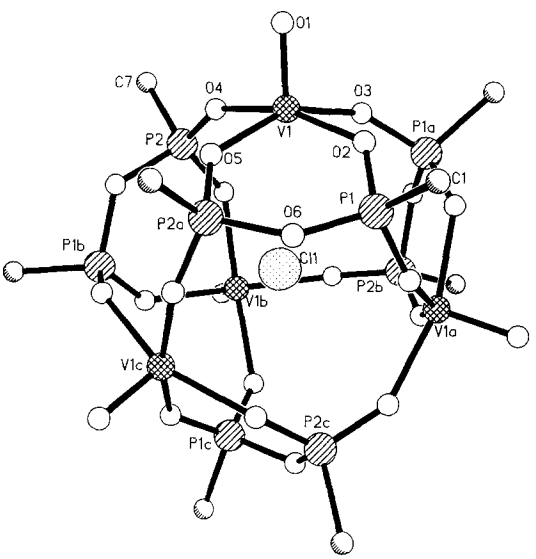

Fig. 2. A view of the anion of **11**. Selected bond lengths [Å] and angles [°]: V1-O1 1.571(10), V1-O2 1.981(8), V1-O3 2.003(9), V1-O4 1.977(9), V1-O5 1.986(8), P1-O6 1.607(9), P2-O6 1.603(9), P-O(other) (average) 1.499(12); O(apical)-V1-O(plane) (average) 100.7(8). The central chloride ion lies on a crystallographic fourfold inversion axis. The V/O/P shell of **11** is thus generated by symmetry from the unique quadrant.

The reaction of [Ph$_4$P][VO$_2$Cl$_2$] with PhPO$_3$H$_2$ in methanol yields [Ph$_4$P][V$_5$O$_7$(OCH$_3$)$_2$(PhPO$_3$)$_5$] (**12**),[21] which contains the same anion as described previously for [nBu$_4$N][V$_5$O$_7$-(OCH$_3$)$_2$(PhPO$_3$)$_5$].[4] However, when **12** is heated in acetonitrile at reflux, deep red crystals of the octadecanuclear species **13** are isolated. The structure of **13**[22] consists of discrete Ph$_4$P$^+$ cations and {V$_{18}$O$_{25}$(H$_2$O)$_2$(PhPO$_3$)$_{20}$}^{0} groups which encapsulate four chloride anions (Fig. 3 top). The structure of the anion of **13** may be described as a cyclic arrangement of four {V$_4$O$_6$(PhPO$_3$)$_5$}$^{2-}$ clusters linked through four P-O-V interactions and fused through eight V – O(phosphonate) bonds to a central {V$_2$O(H$_2$O)$_2$}$^{8+}$ moiety. The four chloride ions occupy the resulting four cavities.

The structural relationship of the anion of **13** to [V$_5$O$_7$(PhPO$_3$)$_5$]$^-$, shown in the lower part of Figure 3, is apparent. Removal of the pendant {VO(OCH$_3$)} group of **12** frees three phosphonate oxygen atoms to condense to additional vanadium atoms. One phosphonate oxygen atom displaces a

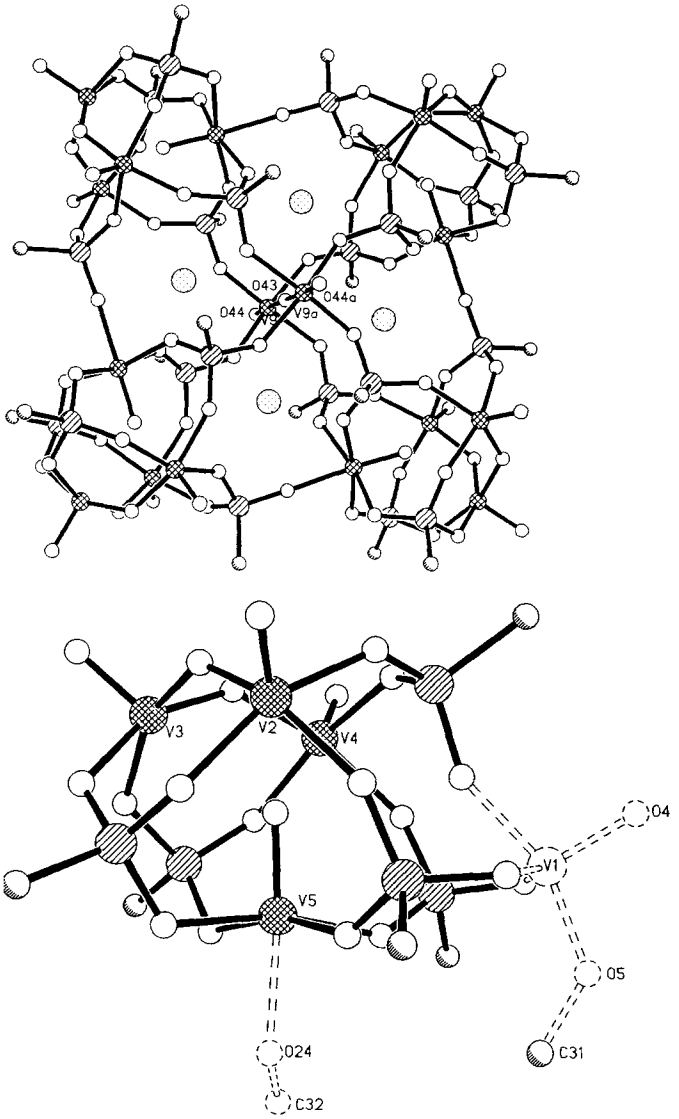

Fig. 3. Top: A view of the anion of **13**. Selected bond length ranges [Å]: Square-pyramidal V sites, V1-V6: V-O(terminal): 1.56–1.58; V-O(bridging): 1.71–1.81; V-O(phosphonate): 1.90–2.00; octahedral sites in the $\{V_4O_6(PhPO_3)_5\}^{2-}$ units, V7 and V8: V-O(terminal): 1.62; V-O(phosphonate, *trans* to oxo): 2.09; V-O(phosphonate, other): 1.99–2.03; central octahedral site, V9: V-O(oxo): 1.60; V-O(phosphonate): 1.96–2.02; V-O44 (aqua): 2.012. Bottom: A view of the anion of **13**, showing the $\{VO(OCH_3)_3\}^{2+}$ unit and the methoxy group which are displaced in the aggregation process to form the "supercluster."

methoxy group from the site *trans* to the interior-directed V=O unit of a $\{VO(OCH_3)(PhPO_3)_4\}$ center of a second $\{V_4O_6(OCH_3)(PhPO_3)_5\}$ unit; the remaining two P—O groups are utilized in bonding to the central $\{V_2O(H_2O)_2\}^{8+}$ moiety. Two of these $[\{V_4O_6(PhPO_3)_5\}_2]^{4-}$ units are then organized about the central $\{V_2O(H_2O)_2\}^{8+}$ fragment to form the cluster shell. It is noteworthy that the unusual $\{V=O\}$ units, which are directed toward the interior of the subunit cavities and which were first described for $[V_5O_7(OCH_3)_2(PhPO_3)_5]^-$, are retained in the structure of the supercluster. The anion in **13** may be considered a "cluster of clusters" and demonstrates that small oligomers may be linked by appropriate ligand types to form clusters of nanometer dimensions by more or less rational synthetic routes.

While the clusters of this study appear to organize about chloride anions, the roles of different anions as templates for the formation of various $V/O/RPO_3^{2-}$ materials remain largely unexplored. The topological and electronic diversity of the $V/O/RPO_3^{2-}$ system may rival or even exceed that of the "naked" V/O cluster system.[12, 23] The introduction of organophosphonate tetrahedra as a new type of polyhedra for cluster construction expands the structural possibilities, as does the ability of RPO_3^{2-} groups to bridge cluster subunits to form superclusters and undergo condensation reactions to form polyphosphonate species. These interesting features of the $V/O/RPO_3^{2-}$ system are even more forcefully demonstrated in the $V/O/RAsO_3^{2-}$ system and will be discussed in the immediately following report.[24]

Experimental Procedure

10: A suspension of $[Ph_4P][VO_2Cl_2]$ (0.65 g, 1.25 mmol) and $tBuPO_3H_2$ (0.341 g, 2.47 mmol) in acetonitrile (6 mL), was transferred to a thick-walled glass tube. After evacuation, the tube was sealed and placed in an oven for 36 h at 100 °C. After cooling to room temperature, dark green crystals of **10** were collected by filtration. Yield: 0.0808 (25% based on V). Correct C,H,P analysis. IR (KBr): $\tilde{\nu}$[cm^{-1}]: 2969(m), 2870(w), 1480(m), 1461(w), 1395(w), 1365(w), 1206(m), 1159(s), 1037(s), 1005(s), 935(m), 832(m), 666(m), 600(m), 467(s). Manganometric titration confirmed the presence of one V^{IV} atom per cluster.

11: A suspension of $[Ph_4P][VO_2Cl_2]$ (0.605 g, 1.23 mmol) and $PhPO_3H_2$ (0.395 g, 2.80 mmol) in acetonitrile (6 mL) was transferred to a thick-walled glass tube. After evacuation and sealing, the tube was heated for 36 h at 100 °C. After cooling to room temperature, green needles of **11** were collected. Yield: 34% (0.191 g). Correct C,H,P analysis. IR (KBr): $\tilde{\nu}$[cm^{-1}]: 3078(m), 1594(m), 1486(m), 1439(s), 1248(s), 1183(s), 1148(s), 1105(s), 1070(m), 1028(m), 998(s), 954(s), 764(m), 746(m), 721(m), 695(s), 618(w), 594(s), 561(w), 521(s), 460(m). Manganometric titration confirmed that all vanadium atoms are V^{IV}.

12: $[Ph_4P][VO_2Cl_2]$ (0.712 g, 1.45 mmol) and $PhPO_3H_2$ (0.205 g, 1.45 mmol) were refluxed in methanol for 6 h. After filtration and evaporation to dryness, the red powder was dissolved in CH_3CN (5 mL) and this solution carefully layered with diethyl ether. After standing at room temperature for two weeks, red crystals of **12** were isolated in 45% yield. X-ray quality crystals were grown by slow diffusion of methanol into a CH_2Cl_2 solution of **12** to give red blocks of $[Ph_4P][V_5O_7(OCH_3)_2(PhPO_3)_5] \cdot MeOH \cdot 0.5CH_2Cl_2$ (**12a**). Correct C,H,P analysis. IR (KBr): $\tilde{\nu}$[cm^{-1}]: 3058(w), 1484(w), 1438(m), 1262(w), 1138(vs), 1108(s), 1037(sh), 1007(vs), 990(vs), 753(m), 723(m), 691(m), 587(sh), 572(m), 527(m).

13: Method 1: Compound **12** (0.512 g, 0.32 mmol) was dissolved in acetonitrile (5 mL) and placed in a thick-walled glass tube. After evacuation and sealing, the tube was heated for 36 h at 100 °C. After cooling to room temperature, red needles of **13** were collected in 53% yield. (0.296 g).

Method 2: Under a nitrogen atmosphere, a solution of $[Ph_4P][VO_2Cl_2]$ (1.90 g, 3.9 mmol) in methanol (20 mL) was added to a solution of $PhPO_3H_2$ (1.20 g, 7.7 mmol) in methanol (25 mL). Upon addition of Et_3N (0.80 g, 7.7 mmol) with stirring, the red-orange color of the solution darkened to an intense red. After 48 h of stirring at room temperature, a dark red solid was collected, washed with diethyl ether, and dried. Recrystallization from CH_3CN/CH_3OH at 0 °C gave red translucent needles of **13** in 58% yield (0.794 g). Correct C,H,P analysis. IR (KBr): $\tilde{\nu}$[cm^{-1}]: 3058(w), 1484(m), 1438(s), 1314(w), 1178(vs), 1132(vs), 1040(vs), 1020(vs), 990(vs), 833(m), 753(m), 722(m), 689(m), 553(m), 526(s), 492(m).

All other conditions and information as in reference [16].
[20] The organophosphonate forms only in the presence of vanadium. Although no organic condensation products were isolated in the absence of vanadium, condensation products were observed under solvothermal conditions in the presence of catalytic amounts of V^V.
[21] X-ray structure analysis of **12a**: monoclinic space group $P2_1/n$ with $a = 21.360(4)$, $b = 13.134(3)$, $c = 26.583(5)$ Å, $\beta = 112.20(3)^\circ$, $V = 6905(3)$ Å^3, $Z = 4$, $\varrho_{calc} = 1.564$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 9.07$ cm^{-1}; $R = 0.0764$ for 4395 reflections with $2\theta < 45^\circ$ and $I_o \geq 3\sigma(I_o)$. All other conditions and information as in reference [16].
[22] X-ray structure analysis of **13**: orthorhombic space group *Pbca* with $a = 38.750(6)$, $b = 17.048(2)$, $c = 39.526(6)$ Å, $V = 26111(1)$ Å^3, $Z = 4$, $\varrho_{calc} = 1.519$ g cm^{-3}, $\mu = 8.80$ cm^{-1}; $R = 0.072$ for 5187 reflections with $2\theta < 45^\circ$ and $I_o \geq 3\sigma(I_o)$. The positions of V9 and O44 in the central $\{V_2O(H_2O)_2\}$ unit are disordered along the crystallographic y axis. This is a consequence of the unequal V–O distances in the $\{V{=}O43\cdots V\}$ unit which, because of the center of symmetry coincident with the location of O43, results in two locations for V9 and O44, each with 0.5 occupancy. The V9–O44 distance and valence sum calculations for V9 and O44 identify O44 as an aqua ligand. This assignment is consistent with the diamagnetism of **13** and the charge requirements of the cluster which identify all V atoms as V^V.

The Oxovanadium–Organoarsonate System: $[2CH_3OH \subset V_{12}O_{14}(OH)_4(PhAsO_3)_{10}]^{4-}$ and $[2H_2O \subset V_{12}O_{12}(OH)_2(H_2O)_2(PhAsO_3)_{10}(PhAsO_3H)_4]^{2-}$, Clusters with Nanometer Dimensions and Cavities for Neutral Molecules**

M. Ishaque Khan and Jon Zubieta*

The complex cage and cluster structures adopted by polyoxovanadates have been extensively studied,[1–3] but recent developments have shown that these compounds exhibit structures beyond such classical structural types as the Keggin core[4] and the closely related $[V_{18}O_{42}]^{12-}$ cage;[5] a variety of novel structural types[6–10] have been found including frameworks with readily accessible cavities.[11–15] Clusters such as $[CH_3CN \subset V_{12}O_{32}]^{4-}$,[11] $[Me_4N^+ \subset H_6V_{16}O_{24}(MePO_3)_8]^{7-}$,[14] $[2NH_4^+, 2Cl^- \subset V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$,[15] and $[4Cl \subset V_{18}O_{25}(H_2O)_2(PhPO_3)_{20}]^{4-}$[10] are examples of new classes of polyoxoanions serving as hosts for neutral and charged species with vastly different cavity requirements. Although the fusing of vanadium-centered square pyramids and octahedra in "naked core" polyoxovanadium clusters $[V_xO_y]^{n-}$ provides a series of possible complex host shells, the introduction of bridging ligating moieties such as the tetrahedral organophosphonate group may dramatically expand the structural possibilities.[9–10] Frameworks constructed from square-pyramidal, octahedral, tetrahedral units are well documented in the solid-state phases of the V/O/P system,[16] and recent investigations demonstrate that a variety of cluster cores organize about anionic templates in the V/O/organophosphonate system.[14, 15] In contrast, the chemistry of the oxovanadium–organoarsonate system V/O/$RAsO_3^{2-}$ remains largely unexplored and is represented only by the mixed-valence cluster $[V_6O_{10}(PhAsO_3)_4(PhAsO_3H)_2]^{2-}$ and the decanuclear V^V species $[V_{10}O_{24}(NH_2C_6H_4AsO_3)_3]^{4-}$.[17] Whereas the hexanuclear cluster forms exclusively in organic solvents under conventional conditions, other compounds in the V/O/$RAsO_3^{2-}$ system may be accessible by solvothermal synthesis.[18] The potential of this approach is demonstrated in the organization of clusters **1**–**3** of nanometer dimensions which serve as "hosts"[15] for neutral template molecules.

$[H_7O_3]_2[n\mathrm{Bu}_4\mathrm{N}]_2[2CH_3OH \subset V_{12}O_{14}(OH)_4(PhAsO_3)_{10}] \cdot H_2O$ **1**

$[PhCH_2NEt_3]_2[PhCH_2NMe_3]_4[2CH_3CN \subset V_{14}O_{22}(OH)_4(PhPO_3)_8] \cdot 2CH_3CN \cdot 2CH_3OH \cdot 2H_2O$ **2**

$[Et_4N]_2[2H_2O \subset V_{12}O_{12}(OH)_2(H_2O)_2(PhAsO_3)_{10}(PhAsO_3H)_4] \cdot 6H_2O$ **3**

The solvothermal reaction of $[n\mathrm{Bu}_4\mathrm{N}]_3[H_3V_{10}O_{28}]$ with phenylarsonic acid in methanol/water yields translucent light green crystals of **1**. The IR spectrum of **1** exhibits a strong bands at 1093 cm^{-1} and 998 cm^{-1}, associated with the $\{PhAsO_3\}^{2-}$ group and the $\nu(V^{IV}{=}O)$ stretching vibration, respectively.

The anion of **1**[19] (Fig. 1 top) lies on a crystallographic inversion center and possesses approximate D_{2h} symmetry. The structure is constructed from edge- and corner-sharing vanadium-centered square pyramids, organoarsonate tetrahedra, and arsonate square pyramids, and may be described as two $\{V_4^{IV}O_5(PhAsO_3)\}$ units bridged by two dinuclear $[V_2^{IV}O_2(OH)_2(PhAsO_3)_4]^{6-}$ moieties. The cavity formed encloses two methanol molecules. While the structure of **1** is clearly related to that of $[V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$,[15] there are a number of significant differences. In the organophosphonate cluster the vanadium centers in the bridging dinuclear $[V_2O_2(OH)_2(H_2O)(PhPO_3)_4]^{6-}$ units have octahedral coordination because of a bridging aqua ligand; since **1** lacks this bridging water molecule, the vanadium centers of the corresponding dinuclear units have square-pyramidal coordination. Consequently, the interior of the cluster shell may be less polar in **1** than in the organophosphonate analogue, a situation which favors enclosure of neutral organic molecules; in contrast inorganic cation/anion pairs are encapsulated in the hydrophilic cavity of $[V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$. It is also noteworthy that the $\{V_5O_9\}^{3+}$ fragments in $[V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$ and common to the structures of $[V_5O_9(\text{thiophene-2-carboxylate})]^{2-}$[13] and $[H_4V_{18}O_{42}Cl]^{2-}$[2] are replaced in **1** by $\{V_4O_5(PhAsO_3)\}^{4+}$ fragments. Thus, in a topological sense, the $\{VO\}^{3+}$ unit is equivalent to $\{RAs\}^{4+}$. In fact, valence bond arguments indicate that the lengths of As^V–O and V^V–O single bonds should be nearly identical,[20] which confirms the geometric equivalence of these groups. Since the P^V–O bond is 0.15 Å

shorter than the As^V–O, organophosphonate analogues of **1** containing the hypothetical $\{V_4O_5(PhPO_3)\}^{4+}$ unit will be inaccessible.

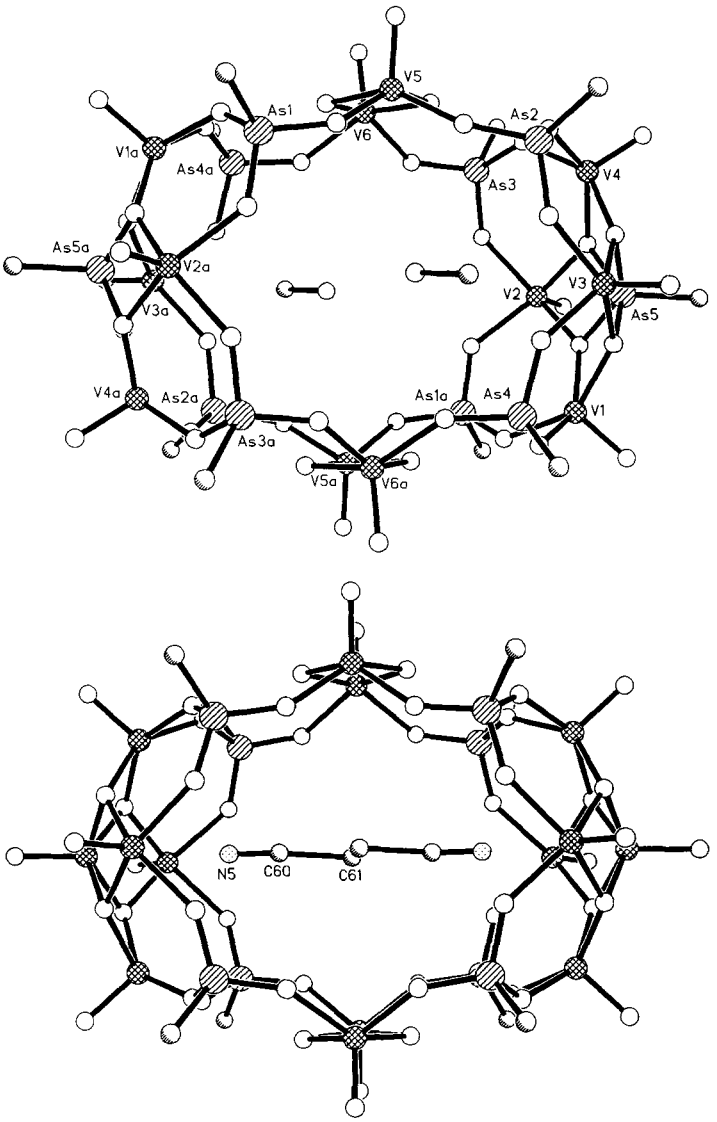

Fig. 1. Top: A view of the structure of anion in **1**. Selected bond lengths [Å]: V-O(terminal), 1.55–1.65(2); V-O(arsonate, μ^2), 1.92–1.99(2); V-O(arsonate, μ^3) 1.95–2.03(2); As1-O, 1.80–1.82(2); As(other)-O, 1.65–1.68(2); V5-O(H), 1.96(2) and 1.98(2); V6-O(H), 1.96(2) and 1.97(2). Bottom: A view of the anion in **2**. Selected bond lengths [Å]: V-O(terminal), 1.56–1.60(1); V-O(bridging), 1.88–1.99(1); V-O(phosphonate), 1.95–1.99(1); P-O, 1.51–1.53(1); V-O(H), 1.96–1.97(1).

The isolation of **1** did, however, suggest that the analogous $[V_{14}O_{22}(OH)_4(PhPO_3)_8]^{6-}$ shell should be formed about neutral organic templates in the absence of inorganic cations and in nonaqueous reaction media. Indeed, **2** was prepared from the solvothermal reaction of $[nBu_4N]_3[H_3V_{10}O_{28}]$, phenylphosphonic acid, $PhCH_2NMe_3Cl$ and $PhCH_2NEt_3Cl$ in CH_3CN/MeOH at 120 °C. The IR spectrum of **2** exhibits four characteristic bands for the PO_3 group of the $(PhPO_3)^{2-}$ ligands in the 1000–1200 cm^{-1} region and a feature at 996 cm^{-1} associated with the $\nu(V^{IV}{=}O)$ stretch.

The structure of the anion shell of **2** (Fig. 1 bottom) is identical to that of $[2NH_4^+, 2Cl^- \subset V_{14}O_{22}(OH)_4(H_2O)_2(PhPO_3)_8]^{6-}$ [15] except that the bridging aqua ligands in the dinuclear moieties are lacking. In **2** the shell has organized about two CH_3CN molecules, which are aligned within the cavity so as to nestle the nitrogen in the polar cavity of the $\{V_5O_9\}$ basket and direct the methyl group toward the relatively open and nonpolar central region of the framework. The acetonitrile molecules interact only weakly with the vanadium centers of the $\{V_5O_9\}$ unit (average V···N distance 3.21 Å), which is reminiscent of the $[CH_3CN \subset V_{12}O_{32}]^{4-}$ inclusion complex.[11]

The synthesis of **2** establishes that the $[V_{14}O_{22}(OH)_4(PhPO_3)_8]^{6-}$ shell may organize about different templates. While the template effect is well known for cluster shells of this type, the mechanism is not well understood. Both charge-compensation and space-filling effects play a role,[22] and the relative importance of these influences may reflect the synthetic conditions. It is noteworthy that the same shell may enclose species as diverse as neutral organic molecules and inorganic cations and anions.

Small variations in the conditions of solvothermal synthesis often result in novel products, as was found in the preparation of **3**. The reaction of $[nBu_4N]_3[H_3V_{10}O_{28}]$, $PhAsO_3H_2$, and CH_3OH/H_2O under identical conditions to those employed for the synthesis of **1** yields shiny green crystals of **3**. Incorporation of the $PhAsO_3^{2-}$ ligand into the framework is confirmed by the presence of a strong band at 1093 cm^{-1} in the IR spectrum, and the very strong absorption at 987 cm^{-1} is consistent with the $\nu(V^{IV}{=}O)$ stretch.

The structure of the anion of **3**[23] (Fig. 2) is constructed from vanadium-centered square pyramids and octahedra, and organoarsonate tetrahedra and square pyramids. The dominant structural motifs are two $\{V_5^{IV}O_6(PhAsO_3)_3\}^{2+}$ units bridged by two $\{V^{IV}(OH)(H_2O)(PhAsO_3)_2(PhAsO_3H)_2\}^{3-}$ groups. The shell encloses two water molecules, which are confined to the rather restricted free volume of the interior and strongly hydrogen-bonded to the hydroxo groups of the central bridging units.

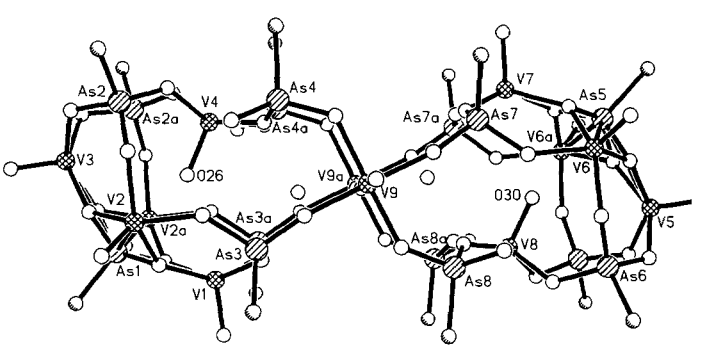

Fig. 2. The structure of the anion in **3**. Selected bond lengths [Å]: V-O(terminal), 1.55–1.67(3); V-O(arsonate, μ^2), 1.92–2.01(3); V-O(arsonate, μ^3), 1.92–2.10(3); As-O(μ^3), 1.73–1.81(3); As-O(H), 1.72–1.75(3); As-O(other), 1.60–1.70(3); V9-O(H), 1.74(3); V9-O(aqua), 2.24(5).

These hydroxo groups, as well as the oxo groups of one vanadium center in each $\{V_5O_6(PhAsO_3)_3\}^{2+}$ unit, are directed toward the interior of the cavity and thus reduce the volume accessible to guest molecules. The core of the $\{V_5O_6(PhAsO_3)_3\}^{2+}$ unit consists of four vanadium-centered square pyramids which

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0707-0761 $ 10.00+.25/0

share edges with a central $\{PhAsO_4\}$ square pyramid. This is yet another structural motif first observed in **1**. Two $\{PhAsO_3\}^{2-}$ tetrahedra each bridge three vanadium centers of this core and provide linkage to the fifth vanadium center. Reminiscent of the structures of $[V_5O_7(PhPO_3)_5]^-$[7] and $[V_{18}O_{25}(H_2O)_2(PhPO_3)_{20}Cl_4]^{4-}$,[10] the oxo group of this vanadium center is directed into the interior of the shallow bowl formed by the $\{V_4O_5(PhAsO_3)\}$ fragment and interacts weakly with the four vanadium atoms in this fragment. An oxo group with such an orientation was first described only recently, but it appears to be a common structural motif in the chemistry of the V/O/organophosphonate and V/O/organoarsonate systems. The central $\{V(OH)(H_2O)\}$ fragments are each linked to these $\{V_5O_6(PhAsO_3)_3\}^{2+}$ units by two $(PhAsO_3)^{2-}$ and two $(PhAsO_3H)^-$ groups. The protonated oxygen atoms are identified by the relatively long As–O distances and the pendant position.

The structural variety of the "naked" polyoxovanadium clusters $\{V_xO_y\}^{n-}$ is well documented. However, the compositional diversity of the $V/O/RPO_3^{2-}$ and $V/O/RAsO_3^{2-}$ systems may well exceed that of the naked clusters. The connectivity possibilities for the construction of cluster frameworks are expanded by the incorporation of $\{REO_3\}$ tetrahedra (E = P or As) and $\{RAsO_4\}$ square pyramids. Furthermore, thermally induced condensations of the $\{REO_3\}$ groups can provide polyphosphonate and polyarsonate units[24] which also enhance the structural possibilities. Solvothermal reactions may provide access to metastable species not available through conventional or hydrothermal techniques.

Certain target molecules are suggested by the analogy of the $V/O/RPO_3^{2-}$ and $V/O/RAsO_3^{2-}$ systems. These include organoarsonte analogues of $[V_2O_2Cl_2(PRO_3H)_2(H_2O)_2]$ and $[V_2O_2Cl_4(RPO_3H)_2]^{2-}$,[9] $[(VO)_6(RPO_3)_8Cl]$,[10] and $[V_7O_{12}(PhPO_3)_8Cl]^{-2}$.[25] Similarly, since $[V_5O_7(OCH_3)_2(PhPO_3)_5]^-$ and $[V_{18}O_{25}(H_2O)_2(PhPO_3)_{20}Cl_4]^{4-}$ are chemically and structurally related,[10] we expect that by analogy to the $\{V_5O_6(PhAsO_3)_3\}^{2+}$ unit of **3** a species of the type $[V_6O_7(RAsO_3)_7]^{n-}$ should exist. Likewise, aggregation of multiple units of $[V_6O_7(RAsO_3)_7]^{n-}$ would provide "clusters of clusters" in a fashion akin to that observed for the $V/O/RPO_3^{2-}$ system. Such rational design of superclusters and even solid phases from simple inorganic building blocks remains the elusive but ultimate objective of these investigations.[9]

Experimental Section

Compounds **1**, **2**, and **3** were characterized by C,H,N analyses, manganometric titration of the V^{IV} content, thermogravimetric determination of water content, IR spectroscopy, single-crystal X-ray crystallography, and the determination of bond valence sums.

1: A mixture consisting of $[nBu_4N]_3[H_3V_{10}O_{28}]$ (0.30 g, 0.18 mmol), $PhAsO_3H_2$ (0.40 g, 1.98 mmol) and CH_3OH/H_2O (2 mL, 99:1) was placed in a thick-walled pyrex tube (27 cm long, 8 mm inner diameter). The contents of the tube were frozen in liquid nitrogen, and the tube was sealed under vacuum. After the mixture was allowed to warm to room temperature, the tube was heated at 100 °C for 17 h. The resultant dark brown-black solution was then heated for 3 d at 120 °C. Upon cooling to room temperature, light green needles of **1** were filtered from the green mother liquor. The crystals of **1** were separated manually from an amorphous gray material and stored in the mother liquor. Yield: 20% based on vanadium. The crystals are slightly soluble in CH_3CN. Exposure to air or to other solvents such as alcohols, acetone, or water causes the crystals to become opaque. IR (KBr): ν[cm^{-1}]: 1482(m), 1438(s), 1093(s), 998(vs), 895(sh), 840(vs), 740(m), 690(s), 639(vs), 503(s).

2: A mixture of $[nBu_4N]_3[H_3V_{10}O_{28}]$ (0.33 g, 0.19 mmol), $PhPO_3H_2$ (0.158 g), $PhCH_2NMe_3Cl$ (0.370 g), $PhCH_2NEt_3Cl$ (0.454 g, 2.00 mmol), CH_3CN (4 mL), and CH_3OH (1 mL) was placed in a Teflon-lined Parr acid digestion vessel and heated at 120 °C for 87 h. After cooling to room temperature, dark green blocklike crystals of **2** were collected in 60% yield. IR (KBr): ν[cm^{-1}]: 1121(s, broad), 1097(vs), 1068(m), 1032(m), 1015(s), 996(vs), 751(m), 720(m), 698(s), 645(m), 619(m), 609(s), 559(s), 523(s).

3: A mixture of $[nBu_4N]_3[H_3V_{10}O_{28}]$ (0.30 g), $PhAsO_3H_2$ (0.20 g), Et_4NCl (0.30 g) and CH_3OH/H_2O (4 mL, 99:1) was treated according to the procedure described for **1**. Light green needles of **3** were manually separated from an amorphous black powder and stored in the light green mother liquor. Yield: 30% based on vanadium. Exposure to air or other organic solvents results in opacity of the solid. IR (KBr): ν[cm^{-1}]: 1483(m), 1438(s), 1093(s), 1012(s), 987(vs), 895(sh), 840(vs), 812(sh), 740(s), 690(s), 637(vs), 507(s).

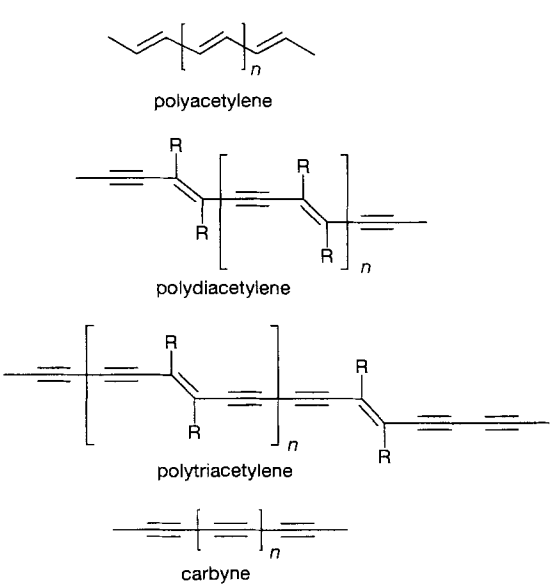
Stable Soluble Conjugated Carbon Rods with a Persilylethynylated Polytriacetylene Backbone**

John Anthony, Corinne Boudon, François Diederich,* Jean-Paul Gisselbrecht, Volker Gramlich, Maurice Gross, Markus Hobi, and Paul Seiler

Rigid acetylenic frameworks are being used with increasing frequency for the fabrication of molecular nanostructures.[1] Here we report the preparation of the conjugated, nanometer-sized molecular rods[2] **2**–**6** through end-capping polymerization of *trans*-bis(triisopropylsilyl)-protected tetraethynylethene **1** (Scheme 1).[3, 4]

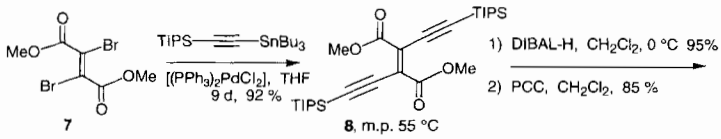


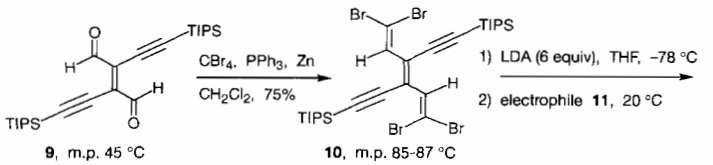
Scheme 1. Preparation and length of the soluble carbon rods **2**–**6**. TIPS = triisopropylsilyl, TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine.

Oligomers **2**–**6** are polytriacetylenes and are thus intermediate between polyacetylene[5] and polydiacetylene,[6] and carbyne (Scheme 2).[7] Derivatives of **2**–**6** could exhibit interesting nonlinear optical properties[8] and function as molecular wires.[9]

trans-Bis(triisopropylsilyl)-protected tetraethynylethenes are readily prepared in multigram quantities by the general synthetic route shown in Scheme 3. Both the diester **14** and the free diethynyl derivative **1** were characterized by X-ray crystallography (Figs. 1 and 2).[10] In the crystal, the carboxyl groups of **14** are twisted out of the plane of the tetraethynylethene backbone because of steric hindrance between the ester residue and the neighboring TIPS group. The angle between the least-squares planes passing through C(2), C(1), O(1), O(2), and the tetraethynylethene fragment is 42(1)°. The stability of crystalline **1** is quite remarkable, since bisdeprotected *trans*-enediynes typically polymerize rapidly upon concentration of solutions.[11] An analysis of the crystal packing shows that the stability of **1** is related to the "insulating effect" of the TIPS groups, which we had previously found to stabilize crystals of a persilylethynylated tetradehydro[12]annulene.[12] The molecules of **1** align in a herringbone fashion with the reactive free ethynyl groups pointing directly towards the silyl groups of neighboring molecules.

End-capping reactions are used in polymer chemistry to control polymer length.[13] When phenylacetylene was added to the oxidative polymerization of **1** (Scheme 1), a mixture of oligomers was obtained, from which compounds **2**–**6** were isolated by chromatography (SiO_2, hexanes). If a large excess of phenylacetylene (6 equiv) was added at the beginning of the reaction, **2** was the only compound isolated. If phenylacetylene (2 equiv) was added after 6 to 8 h, oligomers **2**–**4** were isolated in fair yields. For the preparation of the larger derivatives **5** and **6** the oxidative coupling had to be allowed to run for at least 24 h before the end-capping reagent was added.





Scheme 2. Progression of polymeric backbones from polyacetylene to carbyne.

Scheme 3. Synthesis of *trans*-bis(triisopropylsilyl)-protected tetraethynylethene derivatives. **10** was metalated and then treated with the following electrophiles H^+, I_2, acetaldehyde, isobutyl chloroformate, fluorenone. DIBAL-H = diisobutylaluminum hydride, PCC = pyridinium chlorochromate, LDA = lithium diisopropylamide.

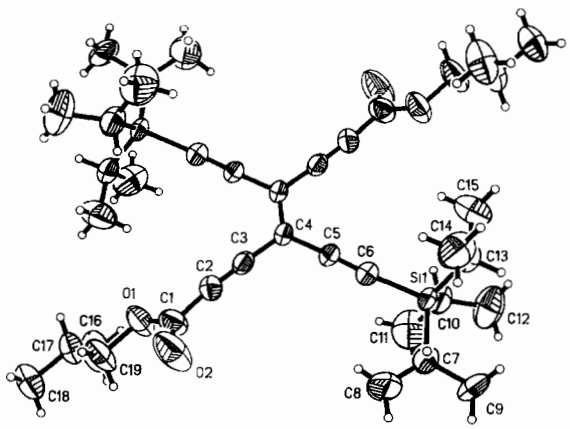

Fig. 1. Crystal structure of **14**. Selected bond lengths [Å] and angles [°]: C(2)-C(3) 1.173(8), C(3)-C(4) 1.436(7), C(4)-C(5) 1.426(6), C(5)-C(6) 1.204(6), C(4)-C(4A) 1.353(11); C(1)-C(2)-C(3) 175.9(6), C(2)-C(3)-C(4) 176.7(5), C(3)-C(4)-C(4A) 121.4(4), C(3)-C(4)-C(5) 116.5(5), C(4A)-C(4)-C(5) 122.0(5), C(4)-C(5)-C(6) 178.2(6), C(5)-C(6)-Si(1) 174.8(4).

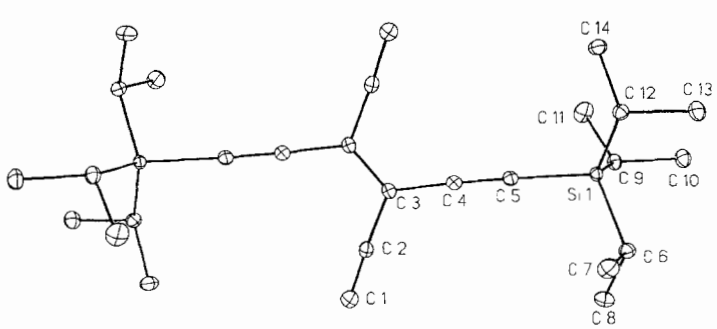

Fig. 2. Crystal structure of **1**. Selected bond lengths [Å] and angles [°]: C(1)-C(2) 1.194(4), C(2)-C(3) 1.431(4), C(3)-C(3A) 1.368(5), C(3)-C(4) 1.437(3), C(4)-C(5) 1.207(3), C(5)-Si(1) 1.850(2); C(1)-C(2)-C(3) 177.3(3), C(2)-C(3)-C(3A) 121.9(3), C(2)-C(3)-C(4) 116.8(2), C(3A)-C(3)-C(4) 121.3(3), C(3)-C(4)-C(5) 177.1(3), C(4)-C(5)-Si(1) 175.4(2).

Oligomers **2**–**6** are amazingly stable, high-melting materials (Table 1) that remain unchanged for months at room temperature when exposed to air and light. The TIPS groups both stabilize the extended conjugated chromophores and render them soluble in common solvents. The shorter derivatives **2**–**4** dissolve in hexane, while all five molecular rods are soluble in chloroform,

which allowed their full analytical characterization (Table 1). Mass spectra of **2**–**6** with the molecular ions as parent ions were obtained by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) with detection in the negative ion mode. Upon recrystallization from hexane, the shorter rods **2** and **3** formed crystals suitable for X-ray analysis (Figs. 3 and 4). The conjugated carbon frames of both molecules, including the phenyl rings, are nearly perfectly planar with a maximum deviation from the least-squares plane passing through the entire carbon chromophore of 0.22 Å in **2** and only 0.03 Å in **3**.[3] Distances between the *para*-phenyl C atoms at the termini of the rods are 19.37 Å (in **2**) and 26.84 Å (in **3**), which is in agreement with the calculated values in Scheme 1.[14]

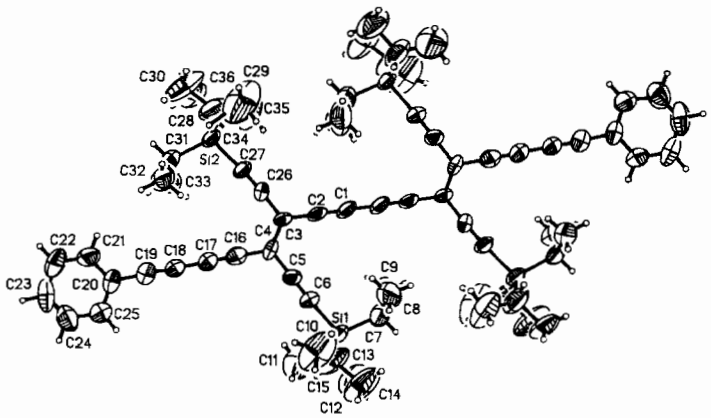

Fig. 4. Crystal structure of **3**. Selected bond lengths [Å] and angles [°]: C(1)-C(1A) 1.368(3), C(2)-C(3) 1.432(2), C(3)-C(4) 1.352(2), C(4)-C(5) 1.452(2), C(5)-C(6) 1.175(2), C(6)-Si(1) 1.852(2), C(4)-C(16) 1.424(2), C(16)-C(17) 1.192(2), C(17)-C(18) 1.371(2), C(18)-C(19) 1.197(2), C(19)-C(20) 1.429(2), C(3)-C(26) 1.441(2), C(26)-C(27) 1.187(2), C(27)-Si(2) 1.844(2); C(1)-C(2)-C(3) 176.4(2), C(2)-C(3)-C(4) 119.5(2), C(3)-C(4)-C(5) 121.8(1), C(4)-C(5)-C(6) 179.6(1), C(5)-C(6)-Si(1) 175.9(8), C(3)-C(4)-C(16) 121.9(2), C(4)-C(16)-C(17) 179.6 (2), C(16)-C(17)-C(18) 178.1(2), C(17)-C(18)-C(19) 178.0(2), C(18)-C(19)-C(20) 178.4(2), C(2)-C(3)-C(26) 118.1(1), C(3)-C(26)-C(27) 176.0(1), C(26)-C(27)-Si(2) 175.8(1), C(4)-C(3)-C(26) 122.4(1).

In the electronic absorption spectra of **2**–**6** (Fig. 5) the wavelength of the end absorption increases with the length of the oligomeric chain. It is well known that the band gap E_g of a polymer can be determined from plots of the longest wavelength UV/VIS absorption for a series of related oligomers versus the length of the oligomers.[15] When the end absorptions of **2**–**6** were plotted against the inverse of the oligomeric length, a straight line was obtained ($r^2 = 0.996$) with an intercept at 540 nm (2.3 eV), which corresponds to the longest wavelength absorption cutoff for an infinite polymer in solution, in other words, its solution band gap. This band gap is comparable to that of many polydiacetylenes ($E_g \approx 2.1$ eV).

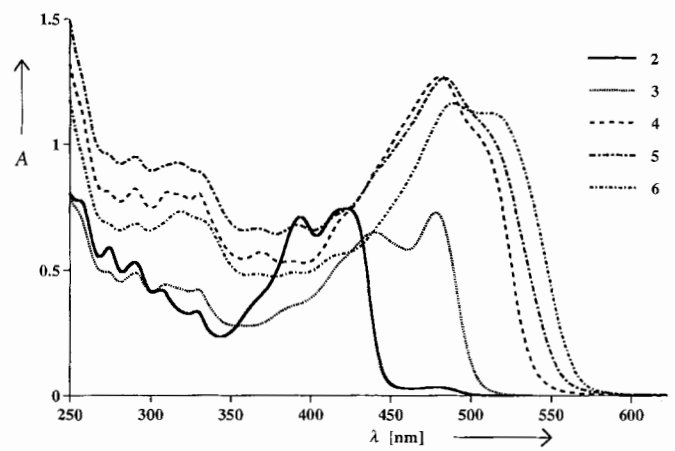

Fig. 5. Electronic absorption spectra of **2**–**6** in $CHCl_3$, $c = 2.3 \times 10^{-5}$ M, $T = 293$ K.

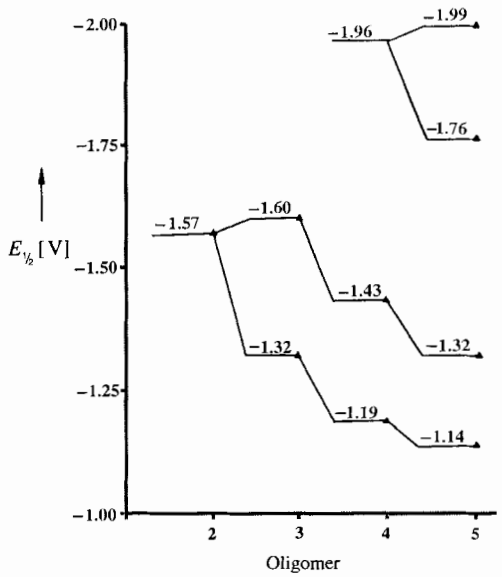
Of particular interest were the redox properties of the conjugated rods, which were examined by polarography and cyclic voltammetry in THF with $Bu_4N^+PF_6^-$ (0.1 M) as the supporting electrolyte.[16] While none of the oligomers **2**–**5** could be oxidized below +1.0 V (vs ferrocene), which helps explain their stability in air, they were all readily reduced with the number of reversible one-electron reduction steps corresponding to the number of tetraethynylethene moieties in each rod.[17] For longer oligomers the first reduction occurred at increasingly less negative potentials (Fig. 6). A plot of reduction potential vs 1/(oligomer length) gave nearly identical first and second reduction potentials of −1.01 V and −1.05 V, respectively, for an infinite polymer.[18]



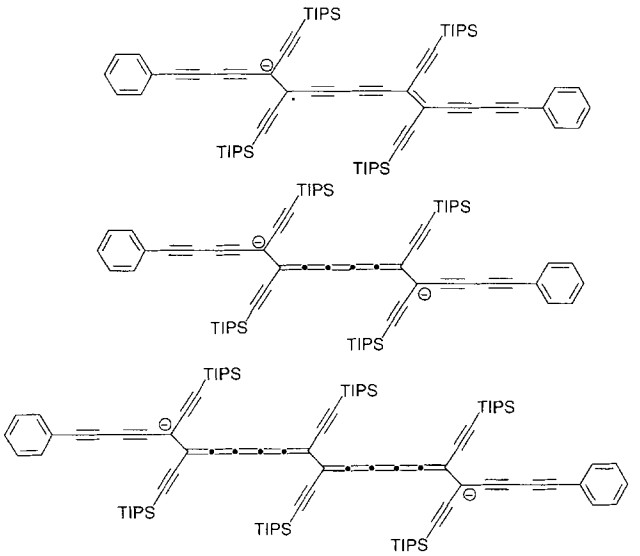


Fig. 6. Reduction potentials $E_{1/2}$ (V, vs ferrocene) for **2**–**5** in THF with $Bu_4N^+PF_6^-$ (0.1 M) as the electrolyte.

A closer inspection of the reduction potentials shows an interesting trend (Fig. 6). The monomeric compound **2** undergoes one reversible one-electron reduction at −1.57 V. The first reduction potential of dimeric **3** is significantly less negative (−1.32 V) and the second reduction step occurs at a potential (−1.60 V) similar to that for the reduction of **2**. The trimeric compound **4** undergoes a facile first (−1.19 V) and second (−1.43 V) reduction, but the third reduction occurs at significantly higher energy (−1.96 V). Tetramer **5** undergoes its fourth one-electron reduction (−1.99 V) at nearly the same potential as the third one-electron reduction in **4** (−1.96 V). This "pairwise" reduction behavior is best explained by especially stable dianions and tetraanions. In the first one-electron reduction, a radical anion forms which is delocalized over the entire backbone (Scheme 4). We propose that in the dianion the anionic centers are separated by a [5]cumulene unit. In such a structure the anionic centers are held far apart, minimizing repulsive electrostatic interactions. Furthermore, the negative charges are delocalized over what are essentially dialkynylmethyl moieties, which have been shown previously to form quite stable anions.[19] In the trimer **the negative**

Scheme 4. Proposed structures of the radical anion of **3** (top) and the dianions of **3** (middle) and **4** (bottom).

charges of a dianion are localized on the dialkynylmethyl moieties on opposite ends of the molecule (Scheme 4). A third electron would have to add to the central dicumulenic unit, which explains the difficulty in forming the trianion.

Because of their remarkable stability, oligomers such as **2**–**6** could become useful in the field of molecular electronics. Other substituents may also be attached to the end of the rods by changing the end-capping reagent. The properties of these nanometer-scale materials could be easily altered by exchanging the silyl groups for other substituents. This study of new oligomeric rods has allowed us to predict interesting properties of the corresponding polymers, on which we will report in due course.

[16] In the electrochemical investigations of **2**–**5** polarography and cyclic voltammetry gave concurring results. In THF with 0.1 M $Bu_4N^+PF_6^-$ as the supporting electrolyte the accessible potential range on mercury was +0.15 to −3.4 V vs ferrocene. In a standard three-electrode cell, the working electrode was a dropping mercury electrode, the counter electrode a mercury pool, and the pseudo-reference electrode a silver wire dipped in a solution of supporting electrolyte. Under these conditions, ferrocene, used as an internal standard, is oxidized at 0.87 V vs Ag. Similar results were also obtained in THF with a platinum working electrode (available potential range +1.0 to −2.2 V vs ferrocene). A detailed account on the electrochemical properties of **2**–**5**, including spectroelectrochemical studies, will be given elsewhere.

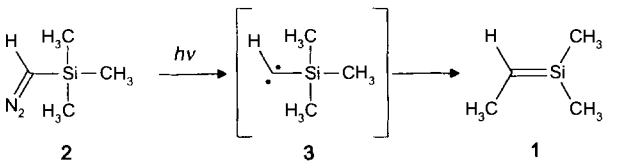
1,1-Dimethyl-1*H*-silirene**



Martin Trommer, Wolfram Sander,* and Claudia Marquard

Silyldiazo compounds are frequently used as precursors for the synthesis of silaethenes (silenes). For instance, 1,1,2-trimethylsilene (**1**), the first silene characterized spectroscopically, was obtained by irradiation of trimethylsilyldiazomethane (**2**) in an argon matrix.[1] Carbene **3**, formulated as an intermediate in this reaction, is produced only in a very low stationary concentration and could be detected by ESR but not by IR spec-

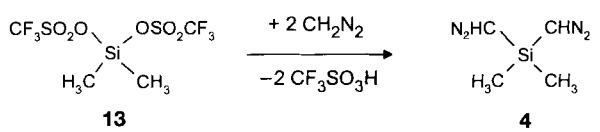
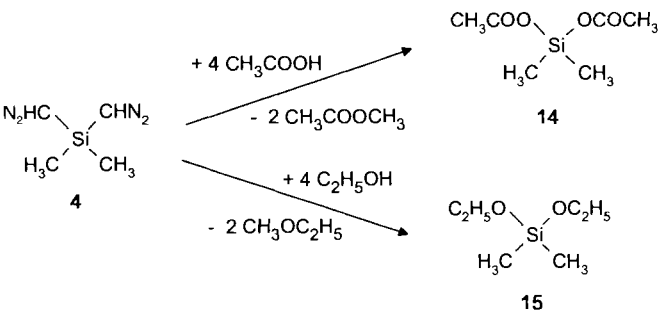
troscopy.[1b] In an analogous way, a series of other silenes was produced in solution and these were characterized indirectly by trapping experiments.[2, 3]



2 3 1

We report here on the photochemistry of 2-sila-1,3-bis(diazo)propane (**4**). The elimination of nitrogen from **4** should lead to biscarbene **5** or its rearrangement products **6**–**12** (Scheme 1).

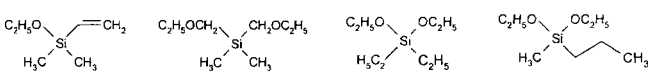
Scheme 1. Possible rearrangement products of biscarbene **5**; only closed-shell molecules were considered. The HF energies (kcal mol^{-1}) calculated by ab initio methods (RHF/6-31G(d,p)) relative to **6** are given in parentheses.



The bisdiazo compound **4** was synthesized by treating dimethylsilanediylbis(trifluoromethanesulfonate) (**13**) with diazomethane[4] in diethyl ether at $-60\,^{\circ}C$ and was purified by preparative gas chromatography (yellow oil). Compound **4** is stable at room

13 4

temperature for short periods and can be stored for several months at $-78\,^{\circ}C$ without decomposition. As expected, two singlets are observed in the ^1H NMR spectrum of **4** at $\delta = 0.29$ and 2.72 (ratio 1:3), and two signals are found in the ^{13}C NMR spectrum at $\delta = -2.14$ and 19.8. The mass spectrum shows a peak for the molecular ion at $m/z = 140$ as well as the expected fragmentation pattern. The most intense absorptions in the IR spectrum (2082 and 2073 cm^{-1}) were assigned to the N=N stretching vibration of the diazo groups. Solutions of **4** lose color rapidly on irradiation or by addition of acids, with the evolution of gas.



The major products of the reaction of **4** with acetic acid are dimethylsilanediyldiacetate (**14**) and methyl acetate. Compound **4** reacts with ethanol slowly at room temperature to give diethoxydimethylsilane (**15**). Thus, **4** behaves like other silyldiazo compounds towards protic compounds.[5]

4 14 15

If the diazo compound **4** is irradiated ($\lambda \geq 305$ nm) in ethanol or EPA glasses[6] at 77 K, four products are observed after warming to room temperature (yields >95% determined by gas chromatography), none of which contain nitrogen (GC-MS). At the same time a large amount of gas (probably N_2) is evolved. These products were characterized as ethenylethoxydimethylsilane (**16**), bis(ethoxymethyl)dimethylsilane (**17**), diethoxydiethylsilane (**18**), and diethoxymethylpropylsilane (**19**) (Table 1). In order to elucidate the mechanism for the formation of these products, the photolyses were also carried out in C_2H_5OD and C_2D_5OD.

Vinylsilane **16** is formed in ethanol or EPA glasses (irradiation at 77 K) in 46% yield and is the trapping product of 1,1-dimethyl-1*H*-silirene (**7**). Photolysis of **4** at 273 K leads to a considerable reduction in the yield of **16** (Table 1). After irradiation in

16 17 18 19

Table 1. Yields of the trapping products determined by gas chromatography for irradiation ($\lambda \geq 305$ nm) of **4** in ethanol at various temperatures.

Compound	Product [a]	Yield [%] 77 K	170 K	273 K
7	**16**	46	45	30
5	**17**	14	5	3
9, 10, 12	**18**	23	25	28
8	**19**	13	15	19

[a] The yields were determined by gas chromatography. The total yield of **16**–**19** was 96% at 77 K, and decreases to 90% at 170 K, and further to 80% at 273 K. The by-products that occur at higher temperatures have so far not been identified unequivocally.

C_2H_5OD, a deuterium atom is found in the vinyl group. The addition of alcohols under cleavage of a Si–C bond and the formation of vinylsilanes is characteristic for 1*H*-silirenes.[7, 8] Dimethylsilane **17** is the formal reaction product of biscarbene **5** with ethanol (the release of N_2 from **4** can, however, also occur stepwise); with C_2H_5OD as trapping reagent, as expected, one deuterium atom is found in each of the methylene groups adja-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0707-0767 $ 10.00+.25/0

cent to the Si atom. The yield of **17** is highly temperature-dependent and decreases from 14% at 77 K to 3% at 273 K (Table 1).

The formation of **18** is indicative of a precursor which contains two C_2 units. This precursor could be 1-silaspiropentane (**9**), 2-sila-2-ethylidenecyclopropane (**10**), or 3-sila-2,3-pentadiene (**12**) (Table 1). With C_2H_5OD and C_2D_5OD, the expected deuterated isotopomers of **18** are formed, each with one deuterium atom in the ethyl groups adjacent to the Si atom (C_2H_5OD) and with additional perdeuterated ethoxy groups (C_2D_5OD), respectively.

The propyl group in **19** can only stem from a precusor which already contains a C_3 unit. The best candidate for this is 1-methylsilacyclobutene (**8**), which can be formed from biscarbene **5** by a [1,2] methyl shift followed by an insertion of the remaining carbene center in a terminal C–H bond of the ethylidene group.

Evidently, carbene **5** can follow several reaction pathways. In order to elucidate which is the primary photolysis product of the bisdiazo compound **4**, we have studied the photochemistry in an argon matrix at 10 K and have followed the course of the reaction by IR and UV/VIS spectroscopy. Irradiation of **4** for several hours with $\lambda \geq 305$ nm results in the disappearance of all of the IR bands assigned to the diazo compound, and a single photoproduct is formed, which is assigned the structure of silirene **7** by comparison of the experimental and ab initio-calculated (RHF/6-31G(d,p))[9] IR spectra (Fig. 1, Table 2). Other structures, such as silirene **11**, silaallene **12**, silacyclopropane **10**, or silaspiropentane **9** could be ruled out after comparison of the experimental IR spectrum with the spectra calculated for these compounds.

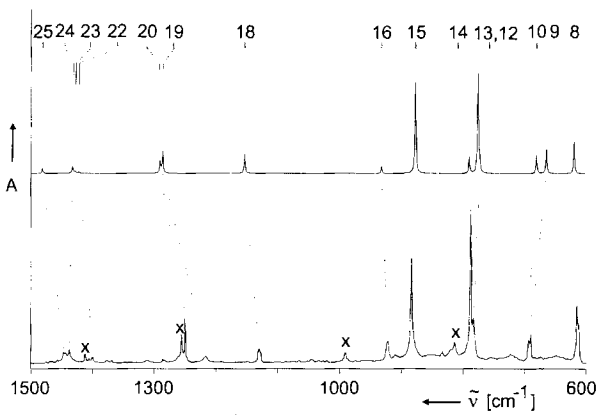


Fig. 1. IR spectrum of 1,1-dimethyl-1*H*-silirene (**7**), matrix-isolated in argon at 10 K (bottom) and ab-initio-calculated at the RHF/6-31(d,p) level (top). Tentative assignment based on the band position and band intensity. The calculated spectrum was scaled by a factor of 0.9 to allow the direct comparison with the experimental spectrum, and a Lorentz band shape was simulated with a half-value width of 2 cm^{-1}. The bands labeled with X were assigned to the solvent.

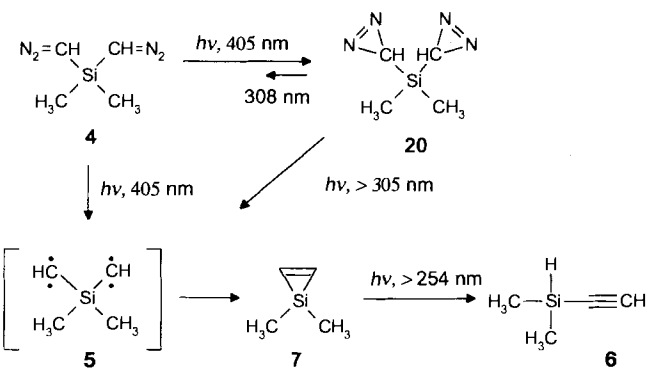

Irradiation of compound **4** with blue light (λ = 405 nm) initially leads only to the formation of a small amount of **7**; however, instead, an additional photoproduct, **20**, is obtained, which on short wavelength irradiation (λ > 305 nm) also results in **7**. The IR and UV spectrum of **20** reveal that this compound is a diazirine. Whether **20** is the bisdiazirine shown or a monodiazirine cannot be determined unambiguously from the IR and UV/VIS spectra. The formation of **20** is partially reversible, and on irradiation at 308 nm (XeCl excimer laser) in addition to **7** also small quantities of **4** are reformed. This is in agreement with the photochemistry of other silyl-substituted diazomethanes, for which a photostationary equilibrium between diazomethanes and diazirines is frequently observed.[1, 10] On irradiation

[a] Number of calculated vibration (ab initio). The assignment of the experimental to the calculated vibrations is based on the comparison of band positions and relative intensities and is—particularly in the range of the C–H stretching vibrations—only tentative. [b] Relative intensities based on the most intense band (100%). [c] Calculated frequencies are scaled by 0.9. [d] Assignment of vibrations from the calculated spectrum (cf. Fig. 1).

with short-wavelength UV light ($\lambda \geq$ 254 nm), silirene **7** finally rearranges into dimethyl(ethynyl)silane (**6**), which was characterized by comparison with an authentic matrix-isolated sample. The formation of **6** provides further evidence that for the photolysis in an argon matrix—in contrast to the photolysis in an ethanol glass—no migration of the methyl groups to the carbene center occurs. Silane **6** is also the main product of the flash vacuum pyrolysis (500 °C, 10^{-4} mbar) of **4**.

The synthesis of **7** described here is a new, high-yield route to 1*H*-silirenes. Compound **7** is the first silirene without substituents at the double bond, which could be proven unambiguously. We are currently investigating whether this synthesis can also be applied to other silirenes—in particular, to the as yet unknown parent compound.

Experimental Procedure

All operations were carried out under the exclusion of moisture and under inert gas in glass apparatus with silylated surfaces (through treatment of the glass surfaces with hexamethyldisilazane). The photolyses were performed with a 500 W-Hg high-pressure lamp (Oriel) in combination with cut-off and interference filters. For a description of the matrix apparatus see ref. [11]. The ethynylsilane **6** and the ethanol adducts **16**, **18**, and **19** were characterized by comparison with authentic samples, and **17** by mass spectrometry of the three isotopomers obtained with C_2H_5OH, C_2H_5OD, and C_2D_5OD.

4: A solution of **13** (4.0 g, 1 equiv) [12, 13] in dry pentane (50 mL) was added slowly dropwise to a solution of diazomethane (1.0 g, 2.15 equiv) in Et_2O (80 mL) and ethyldicyclohexylamine (5.0 g, 2.1 equiv) at $-50\,^{\circ}C$ and stirred vigorously for 1 h. The ammonium salt precipitated during the reaction was separated from the yellow solution by rapid filtration with a frit. The solution was subsequently concentrated under vacuum to about 6 mL at $-45\,^{\circ}C$. The yellow concentrate was separated from a nonvolatile residue by one recondensation under vacuum (0.5 mbar) and subsequently separated by gas chromatography (Shimadzu GC-8a, column: 3m SE 30, 80 °C, det./inj.: 140 °C). **4** was obtained as a yellow liquid, which was stable for several weeks in $CDCl_3$ at $-10\,^{\circ}C$. The yield determined by gas chromatography was 14%. ^1H NMR (400 MHz, $CDCl_3$): $\delta = 0.29$ (s, 6H, CH_3), 2.72 (s, 2H, CH); ^{13}C NMR (100 MHz, $CDCl_3$); $\delta = -2.14$, 19.8; IR (Ar, 10 K): $\tilde{\nu}$ (%) = 2082.5 (100, N=N), 2073.3 (99, N=N), 1267.5 (36), 1263.6 (34), 1262.3 (28), 840.8 (23), 837.4 (9), 832.1 (35), 828.8 (15), 822.5 (6), 810.9 (7), 794.1 (14), 727.0 (4), 518.2 (4), 514.1 (13), 480.9 (3); UV/VIS (EPA glass, 77 K): $\lambda_{max} = 398$ nm; EI-MS: *m/z* (%): 140 (4) $[M^+]$, 125 (8) $[M^+ - CH_3]$, 112 (2) $[M^+ - N_2]$, 99 (5) $[M^+ - CHN_2]$, 84 (24) $[M^+ - 2N_2]$, 58 (60) $[SiC_2H_6^+]$, 43 (100) $[SiCH_3^+]$.

A mixture of **20** and **7** was obtained by irradiation ($\lambda \geq 360$ nm) of **4** in argon at 10 K; irradiation at $\lambda \geq 305$ nm afforded **7** quantitatively. Irradiation at 254 nm led finally to the formation of **6**.

20: IR (Ar, 10 K): 3013.3 (14), 3003.3 (16), 1642.6 (22), 1638.9 (22), 1636 (22), 1297.7 (19), 1261.6 (38), 968.3 (57), 962.3 (54), 960.4 (78), 957.4 (51), 954.1 (35), 949.2 (38), 945.2 (30), 845.2 (65), 842.3 (54), 828.3 (73), 825 (51), 797.8 (57), 795.3 (100), 718.3 (19), 705.3 (16); UV/VIS (Ar, 10 K): $\lambda_{max} = 320$ nm.

6: IR (Ar, 10 K): 3318.4 (11), 3316.1 (10), 3312.6 (9), 2159.5 (11), 2142.5 (32), 2052.9 (17), 2050.7 (10), 2048.9 (11), 1336.3 (7), 1257.9 (7), 1253.9 (31), 899.4 (55), 889.4 (69), 886.1 (100), 843.2 (50), 775.1 (35), 773.1 (38), 745.2 (12), 739.6 (26), 684 (14), 678.5 (21), 675.8 (43), 584.2 (14).

Aurophilicity at Sulfur Centers: Synthesis and Structure of the Tetragold(I) Species $[(Ph_3PAu)_4S](CF_3SO_3)_2 \cdot 2CH_2Cl_2$**

Fernando Canales, M. Concepción Gimeno, Peter G. Jones, and Antonio Laguna*

The structural chemistry of gold(I) complexes shows many examples of inter- and intramolecular contacts of about 3 Å between the formally closed-shell (d^{10}) metal centers. This phenomenon is based on relativistic effects that cause a contraction of the 6s orbital of the heavy elements; these effects reach a maximum for gold.[1–3]

In the last few years Schmidbaur et al. have shown that (phosphane)gold(I) cations can coordinate to main group elements, often giving structures with high coordination numbers in which the main group elements do not always show classical bonding configurations. Thus, in addition to complexes with more conventional stoichiometry,[4a] interesting hypercoordinated species such as $[(LAu)_5C]^+$, $[(LAu)_6C]^{2+}$, $[(LAu)_5N]^{2+}$, $[(LAu)_5P]^{2+}$,[4a] and $[(LAu)_6P]^{3+}$[4b] have been described.

In the sixth main group, compounds of the type $[(LAu)_3X]^+$ (X = O, S, Se) have been reported,[5–8] but further coordination around the central atom has not yet been achieved. Here we report the synthesis and structural characterization of the tetranuclear cationic species tetrakis(triphenylphosphanegold)sulfonium, which can be isolated as its bis-triflate salt **1**. The most common quadruply bridging forms for the sulfido ligand are the tetrahedron[9] or square pyramid.[10, 11] In the former the sulfido ligand serves as an eight-electron donor, while in the latter it is believed to serve as a six-electron donor, and therefore a lone pair of electrons has to be located in the apical position.

$[(Ph_3PAu)_4S](CF_3SO_3)_2$ **1**

The reaction of $[(Ph_3PAu)_2S]$[8] with two equivalents of $[AuPPh_3(CF_3SO_3)]$ in dichloromethane affords a solution from which the colorless air- and moisture-stable complex **1** can be isolated in 73% yield. Solutions of **1** in acetone show conductivities typical of 1:2 electrolytes.[12] The $^{31}P\{^1H\}$ NMR spectrum shows one unique resonance at $\delta = 32.5$ for the four phosphorus atoms, shielded in comparison to the starting material.

Crystals of **1** suitable for X-ray structure analysis[13] were obtained from dichloromethane/hexane. The structure of the cation of **1** is shown in Figure 1; it possesses a tetragonal pyramidal framework, with the sulfur atom occupying the apical position. The SAu_4 core of **1** thus has to be regarded as electron-deficient, since only three bonding molecular orbitals under approximate local C_{4v} symmetry are occupied. The Au-S-Au angles in **1** (73.5(2) to 75.6(2)°) are smaller than those in $[(Ph_3PAu)_3S]^+$ (82.9(3)–95.0(3)°).[6, 7] This leads to short metal–metal distances between adjacent Au atoms (2.883(2)–2.938(2) Å) and longer ones (ca. 3.4 Å) between opposite Au atoms in the base of the pyramid. The Au atoms are arranged in a butterfly form

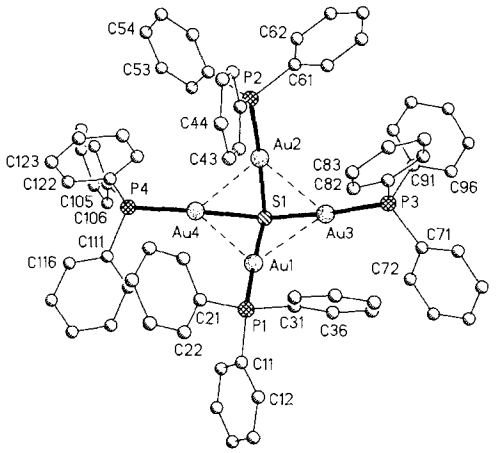

Fig. 1. The structure of the cation of **1** in the crystal. The radii are arbitrary, and the H atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Au1-P1 2.270(6), Au2-P2 2.266(6), Au3-P3 2.273(5), Au4-P4 2.272(6), Au1-S1 2.362(5), Au2-S1 2.388(5), Au3-S1 2.429(5), Au4-S1 2.417(5), Au1-Au4 2.911(2), Au2-Au3 2.883(2), Au1-Au3 2.938(2), Au2-Au4 2.907(2); P1-Au1-S1 175.8(2), P2-Au2-S1 176.2(2), P3-Au3-S1 171.2(2), P4-Au4-S1 175.1(2), Au2-S1-Au4 74.5(2), Au2-S1-Au3 73.5(2), Au1-S1-Au4 75.0(2), Au1-S1-Au3 75.6(2).

with a hinge angle of 30°. The deviations of the Au atoms from the best Au_4 plane are ± 0.3 Å, where the S atom lies 1.3 Å out of the same plane. There are two distinctive pairs of Au-Au-Au angles in the framework: about 75° at Au3 and Au4 and about 100° at Au1 and Au2. It is probable that the Au···Au interactions at the base of the S-capped pyramid contribute strongly to the stability of **1**, as was suggested for the similar As-centered complex $[(Ph_3PAu)_4As]^+$.[14]

The Au–P bond lengths in **1** fall into the expected range for two-coordinate gold(I) and are very similar to those in $[(Ph_3PAu)_3S]^+$, although the Au–S distances, which vary from 2.362(5) to 2.429(5) Å, are, as expected, longer than in the latter complex.

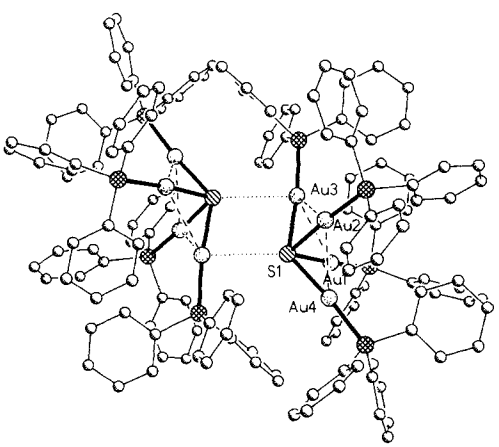

Fig. 2. The weak association of two cations of **1** in the crystal. The $CF_3SO_3^-$ ions and the CH_2Cl_2 molecules have been omitted.

In the crystal the cations of **1** are paired across symmetry centers (Fig. 2); the intermolecular S···Au3′ and Au3···Au3′ contacts are 3.202 and 4.256 Å, respectively. A similar arrangement was observed in $[(Ph_3PAu)_4As]^+$.[14]

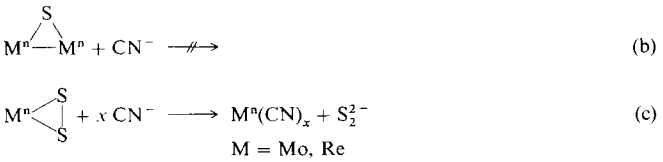
A Building Principle of Amorphous Chalcogenides of Transition Metals: The "Extrusion" of the Electron-Rich Cluster $[Re_4S_2(SO_2)_4(CN)_{10}]^{8-}$ from a-Re_2S_7**

Achim Müller,* Erich Krickemeyer, Hartmut Bögge, Henryk Ratajczak, and Anja Armatage



Amorphous sulfides of Groups 5–7 are of fundamental interest due to,among other things, their significance as catalysts,[1] their material properties,[1] their occurrence as minerals, for example jordisite (MoS_2), as well as their application in classical separation processes. Since their structures have been up to now controversially debated, we looked at the question whether one could obtain chemically, for instance, through cyanolysis—at least in some special cases—supplemental structural information. Furthermore, we were interested in the question whether a uniform structural principle exists. In this context, a decisive factor is the well-known stability of the M(μ_2-S)M and (μ_3-S)M_3 cluster fragments as well as clusters composed thereof (M = Mo, W, Re) against nucleophilic attack by CN^- [2] corresponding to the schematic reaction equations (a)–(c) (Scheme 1).

(c)

M = Mo, Re

Scheme 1. Reactions of cluster fragments with cyanide ions. *n* is the oxidation number.

We have obtained the diamagnetic compounds **1a**, **1b** (brown), and **2** (green) through the reaction of either **3**[3] or amorphous Re_2S_7[4] with aqueous CN^- solution at 85 °C (Fig. 1) and characterized them by electronic and IR spectroscopy as well as single-crystal X-ray structure analysis.[5] In the reaction of **3** to **1a**, the central $\{Re_4^{IV}S_4\}^{8+}$ cluster (cf. structure of the cluster anion of **1a** in Fig. 1) remains intact as expected—that is, according to our working hypothesis and the reaction type (b) and (c)—whereas in the reaction with a-Re_2S_7 **2** is formed in addition to **1b** which has the same anion as **1a**.[6] This compound contains a noteworthy, novel, electron-rich, mixed-valent, tetranuclear cluster anion (see the reaction scheme in Fig. 1).

The structure of the rhombic anion in **2** (Fig. 2) with approximate C_{2h} symmetry can be (formally) obtained by condensing two trinuclear $\{Re_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3(CN)_9\}$ clusters that are isostructural with $[Mo_3S_4(CN)_9]^{5-}$.[2c] The anion of **2** is obviously formed from the "intermediate product" $[Re_4(\mu_3\text{-}S)_2(\mu_2\text{-}S)_4(CN)_{10}]^{8-}$ through the oxidation of the four $(\mu_2\text{-}S)^{2-}$ ligands, which show a higher electron density than the $(\mu_3\text{-}S)^{2-}$ ligands.

$K_4[Re_4^{IV}S_4(CN)_{12}] \cdot 4\,H_2O$ **1a**

$K_4[Re_4^{IV}S_4(CN)_{12}] \cdot 6\,H_2O$ **1b**

$K_8[Re_2^{III}Re_2^{IV}S_2(SO_2)_4(CN)_{10}] \cdot 5\,H_2O$ **2**

$(NH_4)_4[Re_4^{IV}S_4(S_3)_6] \cdot 2\,H_2O$ **3**

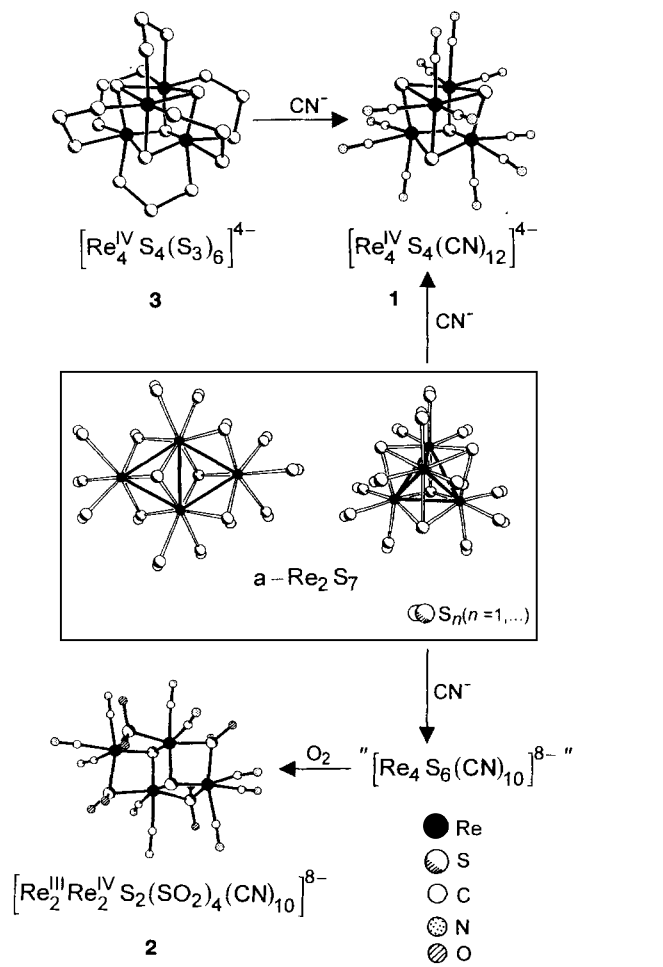

Fig. 1. An illustrative reaction scheme for the cyanolysis of **3** and a-Re_2S_7 (**1**, **2**, and **3** shown without Re–Re bonds, cations, and water molecules) and the structure of $[Re_4S_4(CN)_{12}]^{4-}$ in the crystals of **1a**; range of bond lengths [pm] (values for **1b** in parentheses): Re–Re 274.5(1)–275.6(1) (273.9(1)–275.3(1)), Re–S 234.3(2)–235.1(2) (233.9(4)–234.9(3)), Re–C 210.8(10)–211.5(10) (209.0(16)–212.4(17)), C–N 113.7(15)–115.4(13) (112.7(12)–117.4(13)); range of bond angles [°]: S-Re-S 105.2(1)–106.0(1), C-Re-S 84.2(3)–86.1(3) and 159.7(3)–162.2(3), C-Re-C 79.7(4)–81.1(4), Re-S-Re 71.5(1)–71.9(1), Re-C-N 176.4(9)–178.4(9).[5] For the structure of the anion in **2** see Fig. 2.

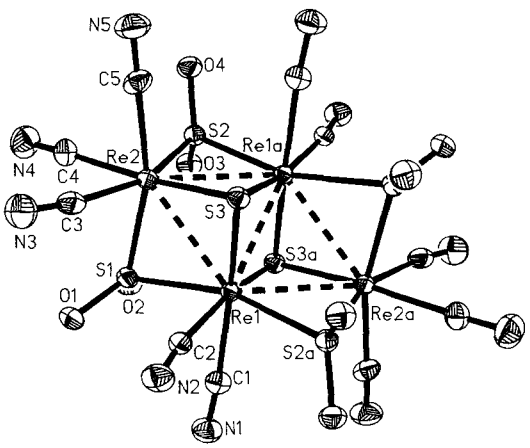

Fig. 2. Structure of the anion $[Re_4S_2(SO_2)_4(CN)_{10}]^{8-}$ in the crystals of **2**. Selected distances [pm] and angles [°]: Re1-Re1a 274.0(1), Re1-Re2 283.7(1), Re1-S1 238.7(2), Re1-S3 236.6(2), Re2-S1 231.7(2), Re2-S3 236.8(2), Re1-C1 209.1(8), S1-O1 149.3(5), C1-N1 116.9(11); S1-Re1-S3 103.4(1), S1-Re1-S2a 162.9(1), S3-Re1-S2a 86.4(1), S1-Re2-S3 105.5(1), S1-Re1-C1 79.8(2), S1-Re1-C2 89.3(2), S3-Re1-C1 165.2(2), C1-Re1-C2 81.7(3), O1-S1-O2 108.2(3), Re1-S1-O2 117.9(2), Re1-S1-Re2 74.2(1), Re1-C1-N1 175.3(6).

Metal clusters with planar M_4 rhombuses are rare (see, for example, the notable compound $CsNb_4Hal_{11}$[7] which shows bridged Nb_4Hal_{16} rhombuses). The electronic structure of clusters of this type is especially interesting, because on one hand—particularly for the previously unknown electron-rich systems—the planarity of the four-membered ring of metal atoms allows for very strong metal–metal interaction, and on the other hand, in the case of strong transannular interactions, nonequivalent metal centers must be present. The mixed valent cluster of **2** is electron-rich and is indeed the first of this type (electron configuration $\{Re_4\}^{14}$), since the formation of the five Re–Re bonds—like that in the case of the Nb_4 cluster mentioned above—requires only ten electrons in the appropriate d levels. The short transannular Re–Re distance is indicative of considerable double-bond character. EH-SCCC MO calculations on the $\{Re_4S_2(SO_2)_4\}^{2+}$ fragment found in **2** confirm this, but also reveal an increase in the (negative) charge of the two central Re atoms (formally Re^{III} according to Fig. 3) relative to the others, along with a pronounced delocalization of the HOMOs over the Re centers. The distance to the LUMO, the "transannular π^* orbital" is only about 1.3 eV. The assignment of the band with the longest wave-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0707-0771 $ 10.00+.25/0

length in the VIS spectrum follows accordingly. This band is missing, as expected, in the spectra for **1a** and **1b**, in which the metal clusters do not contain π orbitals. This explains why **2** has a different color. The above-mentioned charge distribution corresponds to a formulation as SO_2^{2-}, which follows from all data, for example, from the position of the ν(SO) frequency and the results of earlier investigations.[2e] The high electron density, related to the electron richness of the ring system, on the sulfur centers of the "intermediate product $[Re_4(\mu_3\text{-}S)_2(\mu_2\text{-}S)_4(CN)_{10}]^{8-}$" explains the easy oxidizability of the μ_2-S centers.[8]

The Re_4S_6 fragment in **2** interestingly corresponds to a section of the ReS_2 or $ReSe_2$ lattice,[9] in which comparable rhombohedral Re_4 cluster units are present and linked through (additional) Re–Re bonds, which are, however, longer than the bonds in the Re_4 units (cf. Fig. 3).[9] ReS_2 and $ReSe_2$ crystallize like, for example, MoS_2 (in which the metal centers, however, have trigonal-prismatic coordination geometry), in an XMX layered lattice with a van der Waals gap between the X layers. The greater number of valence electrons ($5d^3$) in the rhenium chalcogenides results in strong metal–metal bonding, which is further strengthened because the 5d–5d overlap is larger than the 4d–4d overlap.

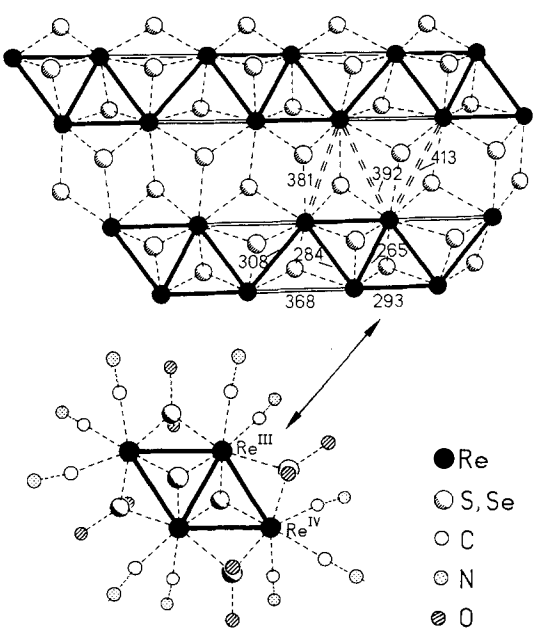

Fig. 3. A descriptive illustration of the relationship between **2** (bottom) and the structure of ReS_2 ($ReSe_2$) (top) [9], which in close approximation possesses a zigzag type of linking between the Re_4 rhombuses (bond lengths in pm). The assignment Re^{IV}/Re^{III} reflects the predominant character of the metal center.

Re_nS_m clusters—like those in **1b** ($\{Re^{IV}\}_4$) and **2** ($\{Re_2^{III}Re_2^{IV}\}$)—can be "extruded" through cyanolysis out of amorphous Re–S phases like Re_2S_7 while apparently retaining their topology, so long as the clusters are not connected through additional Re–Re bonds like in crystalline ReS_2, which does not react in an analogous manner with CN^-. The cluster anion of **1** is formed from a-Re_2S_7 only when the reduction according to Equation (a) (which leads to the formation of **2**) does not occur simultaneously. Obviously, 12-electron Re_4 clusters exist in Re_2S_7,[10] which are linked irregularly through S_x^{2-} ligands. This has a certain amount of similarity to the linking principle found for the structure of $CsNb_4Hal_{11}$.[7] An analogous cluster $[Mo_3^{IV}S_4(CN)_9]^{5-}$, which (besides $[Mo_4^{III}S_4(CN)_{12}]^{8-}$) is generated from the Mo_3^{IV} cluster through a reduction of type (a)) can be extruded by cyanolysis[2b,e] from the phases a-MoS_3 and a-MoS_2 in which Mo_3 clusters[11] are not linked by MoS_xMo bonds with metal–metal interactions.

Our investigations indicate that cyanolysis supplements other physical methods for the characterization of amorphous metal sulfide phases of early transition elements and relevant catalysts, as well as metalloenzymes with metal sulfide bonds in the active center. a-Re_2S_7—but also other analogous amorphous sulfides of electron-poor transition metals—can obviously be considered (formally) a "quasi-solid" solution of clusters linked irregularly through S_x^{2-} ligands. The reason for this is the well-known pronounced tendency to form clusters with metal centers in intermediate oxidation states.[12] Such clusters also form in solution under comparable conditions. Trinuclear clusters are formed preferentially for Mo/W (d^2), tetranuclear for Tc/Re (d^3).[12] This corresponds to the "precise electron count", an approximate rule that is valid for clusters of the transition elements of Groups 5–7.[12]

The structure principle introduced here also explains why the sulfides discussed above and the corresponding selenides, do not crystallize upon annealing. The S_n^{2-} units transform upon decomposition into S^{2-} and S_{n-1}^0 to form—it is even possible to observe—elemental sulfur. The fact that amorphous phases like MoS_3, WS_3, Tc_2S_7 and Re_2S_7 and the corresponding selenides have compositions which formally correspond to the highest possible valence of the metal has often led to misconceptions in the past.[13] The presence of reduced metal centers in such amorphous metal sulfides became obvious for the first time through the generation of discrete polythiometalates (from mononuclear species), which is, notably, achieved under similar conditions as the formation of the amorphous sulfides.[14] In both cases an intramolecular redox process involving S^{2-} oxidation and M^{n+} reduction takes place, a process which is often associated with the generation of metal–metal bonds.[14] The presence of metal–metal bonds in the sulfides is concluded from the unequivocal evidence obtained from pair distribution functions, as determined from the Debye reflections of the amorphous materials (see, for example, [4b]).

In general, discrete metal clusters can exist in virtually pure form, for example, in the gas phase or in a noble gas matrix, in classical chemical form (that is, ligand stabilized) in solution or in the corresponding crystalline arrangement, but also as described here, in a quasi-solid solution. Condensed clusters in solid state structures are not included in this context.

Experimental Procedure

1b, **2**: A solution of KCN (16.0 g, 245.7 mmol) in H_2O (80 mL) was mixed with Re_2S_7 [4] (2.0 g, 3.35 mmol) and kept for 24 h at 85 °C on a hot plate (without stirring) in a 100 mL Erlenmeyer flask (wide neck, covered with a watch glass). (Re_2S_7 was not dried over P_4O_{10}, but instead, after washing, dried under a stream of inert gas). Subsequently, the mixture was concentrated by evaporation to a volume of 75 mL in a open vessel at the same temperature. After cooling to 20 °C brown crystals of **1b** precipitated, which were filtered off after 1–1.5 weeks and dried in air on filter paper. Yield **1b**: 0.40 g (16.5 % based on the amount of Re_2S_7 used). Dark green crystals of **2** (apart from some KCN) slowly precipitate out of the mother liquor kept on a hot plate without stirring at 85 °C (evaporation from a 100 mL Erlenmeyer flask covered with a watch glass). These were filtered from the hot solution and recrystallized in water. Yield **2**: 0.35 g (12.1 % based on the amount of Re_2S_7 used).

Main IR absorption bands (solid state/KBr pellet/[cm^{-1}]) for **2**: ca. 2130(sh), 2120(s), 2100(m)(ν(CN)), 1147(m), 1110(m), 1015(s), 1000(s)(ν(SO)). Bands in electronic absorption spectra (solid state/reflectance/[nm]) for **1**: 550, ca. 465(sh), 420, 375, ca. 320, and for **2**: ca. 700(sh), 615, 465, ca. 350(br).

Lanthanide(III) Tetraamide Macrocyclic Complexes as Synthetic Ribonucleases: Structure and Catalytic Properties of $[La(tcmc)(CF_3SO_3)(EtOH)](CF_3SO_3)_2$**

Shahid Amin, Janet R. Morrow,* Charles H. Lake, and Melvyn Rowen Churchill

Trivalent lanthanide ions (Ln^{3+}) efficiently promote RNA cleavage by phosphate ester transesterification.[1] Our interest lies in the design of ligands that strongly bind lanthanide ions without inhibiting their catalytic properties.[2] Such catalysts tethered to nucleic acid recognition agents may find application as RNA sequence-specific cleaving agents for antisense oligonucleotide strategies.[3] Our efforts have focused on the synthesis of robust cationic Ln^{3+} complexes that may be effective catalysts in vivo.[2a] Recently we have synthesized Ln^{3+} complexes of macrocyclic ligands that are structurally similar to dota (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetate), but, instead of acetate groups, contain neutral amide or hydroxyethyl groups.[2b,c] Here we report on Ln^{3+} tetraamide macrocyclic complexes that are remarkably inert to dissociation in water (**1**, Ln = La, Eu, Dy). Only $[La(tcmc)]^{3+}$ efficiently promotes RNA cleavage. Its X-ray crystal structure features a ten-coordinate La^{3+} cation.

1

The tcmc ligand and $[Ln(tcmc)](CF_3SO_3)_3$ complexes were prepared in good yield and characterized as detailed in the Experimental Procedure. Potentiometric titrations of 1.0 mM solutions of the La^{3+} and Eu^{3+} complexes indicate there are no ionizable protons in the pH region between 4.0 and 9.0. For $[Ln(tcmc)](CF_3SO_3)_3$ (Ln = La, Eu), plots of molar conductivity versus the square root of concentration give slopes of 3200 and 1600 cm^2 L$^{1/2}$ mol$^{-3/2}$ ohm^{-1} with intercepts of 350 and 308 cm^2 mol^{-1} ohm^{-1}, respectively, consistent with 3:1 electrolytes.[4] $[La(tcmc)]^{3+}$ has ^{1}H and ^{13}C NMR properties that support strong coordination of the amide groups and demonstrate the rigidity of the tcmc macrocycle. At $-10\,^\circ$C, the ethylenic units of the cyclen ring are rigid on the NMR time scale and are present in the highly symmetric [3333] square conformation. There is a dynamic process, similar to that for $[La(dota)]^-$,[5] that involves a change in conformation of the ethylenic units in concert with movement of the pendant groups. The ^{13}C NMR

tcmc = 1,4,7,10-tetrakis(carbamoylmethyl)-1,4,7,10-tetraazacyclododecane. Cyclen is the trivial name for the unsubstituted macrocyclic ligand.

resonances for the ethylenic carbons ($\delta = 50.1$ and 54.3 at $-20\,^{\circ}C$) broaden ($0\,^{\circ}C$) and coalesce. An activation energy of $56.1 \pm 0.5\ kJ\,mol^{-1}$ is calculated at coalescence ($22\,^{\circ}C$). $[La(dota)]^-$ and $[La(thed)]^{3+}$ (thed = 1,4,7,10-tetrakis(2-hydroxyethyl)-1,4,7,10-tetraazacyclododecane) have activation energies of 60.7 and 52.0 $kJ\,mol^{-1}$ for similar dynamic processes;[2b, 5] the order $[La(dota)]^- > [La(tcmc)]^{3+} > [La(thed)]^{3+}$ may reflect stronger coordination of acetate and amide groups than hydroxyethyl groups, which is in accord with formation constants for similar macrocycles.[6-8] In [D$_6$]DMSO an activation barrier of $82.6 \pm 0.3\ kJ\,mol^{-1}$ for rotation about the C–N bond was calculated from the slow-exchange line-broadening approximation ($115\,^{\circ}C$). The large activation energy for this rotation in $[La(tcmc)]^{3+}$ compared to that of the free tcec ligand (tcec = 1,4,7,10-tetrakis(2-carbamoylethyl)-1,4,7,10-tetraazacyclododecane, $70.5 \pm 0.5\ kJ\,mol^{-1}$)[2c] is attributed to polarization of the C=O bond and an increase in C–N double-bond character due to coordination.

Lanthanide complexes must be robust if they are to be useful as catalysts. The kinetic inertness of a complex to dissociation may correlate better than thermodynamic stability with the ability of a complex to remain intact in vivo.[9] Although poly(aminocarboxylate) ligands containing one or two amide groups and three acetate groups bind strongly to Ln^{3+},[8, 10] our initial studies with ligands containing four amide groups (tcec) failed to produce complexes that remained intact in water.[2c] In contrast, tcmc complexes do not dissociate in water at $37\,^{\circ}C$, pH 6.0, as determined by studies with excess Cu^{2+} as a trapping agent. First-order rate constants are 1.2×10^{-6} and $4.4 \times 10^{-7}\ s^{-1}$ ($t_{1/2}$ = 6.7 and 18 days) for $[La(tcmc)]^{3+}$ and $[Dy(tcmc)]^{3+}$, respectively. For $[La(tcmc)]^{3+}$ the rate of dissociation is independent of Cu^{2+} concentration, consistent with a process that is not assisted by Cu^{2+}. $[Eu(tcmc)]^{3+}$ did not dissociate over a period of 6 weeks (<1%). A rate constant of $1.6 \times 10^{-7}\ s^{-1}$ ($t_{1/2}$ = 50 days) at pH 2.0 and $60\,^{\circ}C$ indicates that $[Eu(tcmc)]^{3+}$ is as inert as the agent $[Gd(dota)]^-$ used in magnetic resonance imaging experiments.[6]

$[La(tcmc)]^{3+}$ promotes rapid cleavage of RNA oligomers. The pseudo-first-order rate constant ($0.57\ h^{-1}$) for cleavage of oligomers of adenylic acid (A_{12}–A_{18}) by 0.200 mM $[La(tcmc)]^{3+}$ at $37\,^{\circ}C$ and pH 7.6 is similar to that for the highly efficient Eu^{3+} Schiff-base catalyst.[2a, 11] $[La(tcmc)]^{3+}$ (1.00 mM) also promotes rapid transesterification of the RNA model substrate, the phosphate diester **2**, at pH 7.4 and $37\,^{\circ}C$ ($k = 5.8 \times 10^{-2}\ h^{-1}$). That

$[P(O)_2(4\text{-}NO_2C_6H_4O)(OCH_2CH(CH_3)OH)]^-$ **2**

0.02 mM ethylenediaminetetraacetate (EDTA) has no effect on RNA cleavage rates, nor 0.5 mM EDTA on the rate of transesterification of **2** indicates that catalysis is not due to trace free La^{3+}.[12] Under similar conditions, $[Eu(tcmc)]^{3+}$ or $[Dy(tcmc)]^{3+}$ neither promote RNA cleavage in the presence of 0.02 mM EDTA over 8 h nor the transesterification of **2** over 1 h. These differences in catalytic activity are unusual. Past studies have shown that there is little difference in the extent of RNA cleavage with various Ln^{3+} salts; generally the later Ln^{3+} ions are better promoters because of their greater Lewis acidity.[1a, b] One explanation for the different catalytic activity lies in the fact that octadentate ligands such as tcmc nearly encapsulate Ln^{3+} ions. The larger La^{3+} ion may attain a higher coordination number and thus has more coordination sites remaining for binding substrate and for catalysis. Structural data support this argument. Gd^{3+} and Eu^{3+} complexes of similar macrocycles are all nine-coordinate with an octadentate macrocycle and a water molecule. These include Eu^{3+} and Gd^{3+} complexes of dota, dota-like macrocycles containing an amide pendant group, and thp (thp = 1,4,7,10-tetrakis(2-hydroxypropyl)-1,4,7,10-tetraazacyclododecane).[2d, 8, 13, 14] Recent X-ray diffraction studies indicate that the Eu^{3+} complex ion of $[Eu(tcmc)(H_2O)](CF_3SO_3)_3 \cdot 2CH_3OH$ is nine-coordinate.[15]

The single-crystal X-ray structure of $[La(tcmc)(EtOH)(CF_3SO_3)](CF_3SO_3)_2$ features a ten-coordinate La^{3+} ion. The crystallographic asymmetric unit consists of one $[La(tcmc)(EtOH)(SO_3CF_3)]^{2+}$ ion and two triflate counterions.[16] The ten-coordinate La^{3+} ion is bound to four nitrogen atoms and four oxygen atoms from the tcmc ligand, an oxygen atom of the coordinated ethanol molecule and an oxygen atom of a coordinated trifluoromethylsulfonate ion (Fig. 1). The coordinated

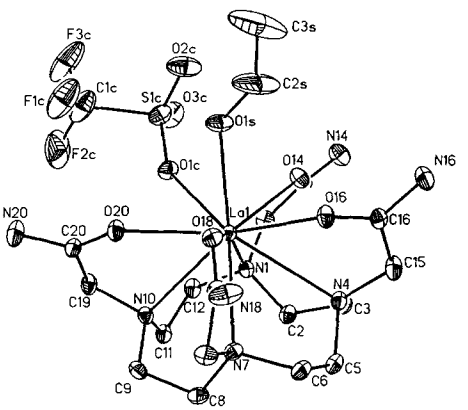

Fig. 1. Structure of the $[La(tcmc)(EtOH)(SO_3CF_3)]^{2+}$ ion. Selected distances [Å] and angles [°]: La1-O14 2.492(3), La1-O16 2.496(3), La1-O18 2.582(2), La1-O1c 2.600(3), La1-O1s 2.524(4), La1-O20 2.551(3), La1-N4 2.950(4), La1-N1 2.858(3), La1-N7 2.757(4), La1-N10 2.853(4); N1-La1-N7 97.2(1), N4-La1-N10 98.5(1), N7-La1-N10 65.8, O14-La1-O16 73.6(1), O20-La1-O1s 78.3(1), N1-La1-O14 61.5(1).

atoms are arranged about the La^{3+} ion in an unusual 1,5,4 geometry. The six oxygen atoms form a pentagonal pyramid with that from ethanol providing the cap (rms deviation of the other oxygens from the pentagonal plane is 0.133 Å). The pentagonal pyramid is stacked base upon apex on top of a square pyramid with the four nitrogen atoms forming the base and the La^{3+} ion occupying the vertex (rms deviation of the nitrogen atoms from a plane is 0.017 Å). The regularity of the pentagonal plane can be shown by examining the angles formed with the centroid of the pentagonal plane: O14-centroid-O16 = 74.2, O16-centroid-O18 = 68.8, O18-centroid-O20 = 70.2, O20-centroid-O1c = 74.0, and O1c-centroid-O14 = 74.0°. (For a regular pentagon the angles are all 72°.) The centroid of the pentagonal plane is 1.151 Å from the lanthanum(III) ion. The square arrangement of nitrogen atoms is oriented relative to the pentagonal arrangement of oxygen atoms such that N7 is eclipsed with O18. The centroid of the four nitrogen atoms lies 1.875 Å from the lanthanum(III) ion, and the dihedral angle formed by the intersection of the plane of nitrogen atoms and the plane of oxygen atoms is only 3.5°.

Studies of phosphate ester and nucleic acid binding to $[Ln(tcmc)]^{3+}$ are underway to elucidate differences in catalytic properties and to further our efforts in catalyst design.

Experimental Procedure

Cyclen (0.500 g, 2.91 mmol), bromoacetamide (1.810 g, 13.12 mmol), and triethylamine (2 mL, 14.38 mmol) were heated at reflux in anhydrous ethanol for 4 h. The

tcmc ligand precipitated out during the course of the reaction and was recrystallized from boiling ethanol/water; yield 61%. Synthesis of a similar ligand has been reported [19]. $Ln(SO_3CF_3)_3$ (0.63 mmol) in 75 mL of anhydrous ethanol was treated with tcmc (0.250 g, 0.63 mmol) in 225 mL of ethanol. The mixture was heated at reflux under nitrogen for 3.5 h following the dissolution of tcmc. The solution was concentrated in vacuo, and hexane was added until cloudiness was observed. For Eu^{3+} and La^{3+} complexes, crystals formed within about 12 h. The Dy^{3+} complex was isolated as a powder. Yields were greater than 55%. Satisfactory microanalytical data were obtained for all compounds. ^1H NMR (CD_3CN): [La(tcmc)]-$(CF_3SO_3)_3$ (−10 °C): δ = 2.42 (NCH_2 (equatorial), d, J(C,H) = 14.8 Hz), 2.56 (NCH_2 (equatorial), d, J(C,H) = 13.6 Hz), 2.85 (NCH_2 (axial), pseudo t), 3.35 (NCH_2 and $CH_2C(O)NH_2$, m), 3.84 ($CH_2C(O)NH_2$, d, J(C,H) = 16.4 Hz), 7.27 (NH_2, s), 7.81 (NH_2, s); (75 °C): 2.69 (NCH_2, br.), 3.03 (NCH_2, br.), 3.65 ($CH_2C(O)NH_2$, s), 7.08 (NH_2, s), 7.68 (NH_2, s). ^{13}C NMR (CD_3CN): [La(tcmc)]-$(CF_3SO_3)_3$ (−20 °C): δ = 50.1, 54.3 (NCH_2, ring), 58.9 (NCH_2, amide), 178.8 ($C(O)NH_2$); [Eu(tcmc)]$(CF_3SO_3)_3$ (19 °C): δ = 76.3, 91.5, 110 (NCH_2 ring and amide), 198.3 ($C(O)NH_2$). Kinetic measurements of RNA cleavage were made as described previously [2a, 20].

[11] In buffered solutions (10 mM (4-(2-hydroxyethyl)piperazino)ethanesulfonic acid (Hepes)) at 37 °C, first-order rate constants for cleavage of A_{12} to A_{18} oligomers at pH 7.6 and for transesterification of **2** at pH 7.4 in the absence of catalyst are 2.3×10^{-3} h^{-1} and 5.4×10^{-4} h^{-1}, respectively. Because the pseudo-first-order rate constant for the catalyzed reaction is dependent on the concentration of lanthanum complex, calculation of rate enhancements awaits the determination of true first-order rate constants for catalysis, which may be obtained through saturation kinetic studies or by the determination of binding constants.

[12] $[Ln(edta)]^-$ complexes are inactive in RNA cleavage (ref. [2a]).

[16] Colorless crystals ($0.4 \times 0.27 \times 0.2$ mm) were mounted on an upgraded Siemens $P2_1/P3$ diffractometer. Data were collected through the use of the coupled $2\theta/\omega$ scan technique. A total of 5469 reflections were collected ($Mo_{K\alpha}$, λ = 0.71073, 2θ = 5–45°) and were merged into a unique set of 5061 reflections (R_{int} = 0.0126). All data were corrected for Lorentz and polarization effects. An empirical absorption correction was also applied to the data set. The crystal belongs to the triclinic system, space group $P\bar{1}$, a = 10.019(1), b = 12.754(2), c = 16.116(3) Å, α = 96.614(14), β = 92.035(13), γ = 108.960(12)°, V = 1928.8(6) Å^3 and Z = 2. All crystallographic calculations were carried out with the Siemens SHELXTL PLUS program package [17]. The analytical scattering factors for neutral atoms were corrected for both the $\Delta f'$ and $i\Delta f''$ components of anomalous dispersion [18]. The structure was solved by means of a Patterson map. Refinement of parameters was achieved through the minimization of the function $\sum w(|F_o|-|F_c|)^2$. The extreme features on the final difference-Fourier map were a peak of height 0.53 eÅ^{-3} and a negative feature of −0.84 eÅ^{-3}. Refinement converged with R = 0.0260 and R_w = 0.0283 for 542 parameters refined against those 4169 reflections with $|F_o| > 6\sigma|F_o|$ and R = 0.0358 for all 5061 data. Further details are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK).

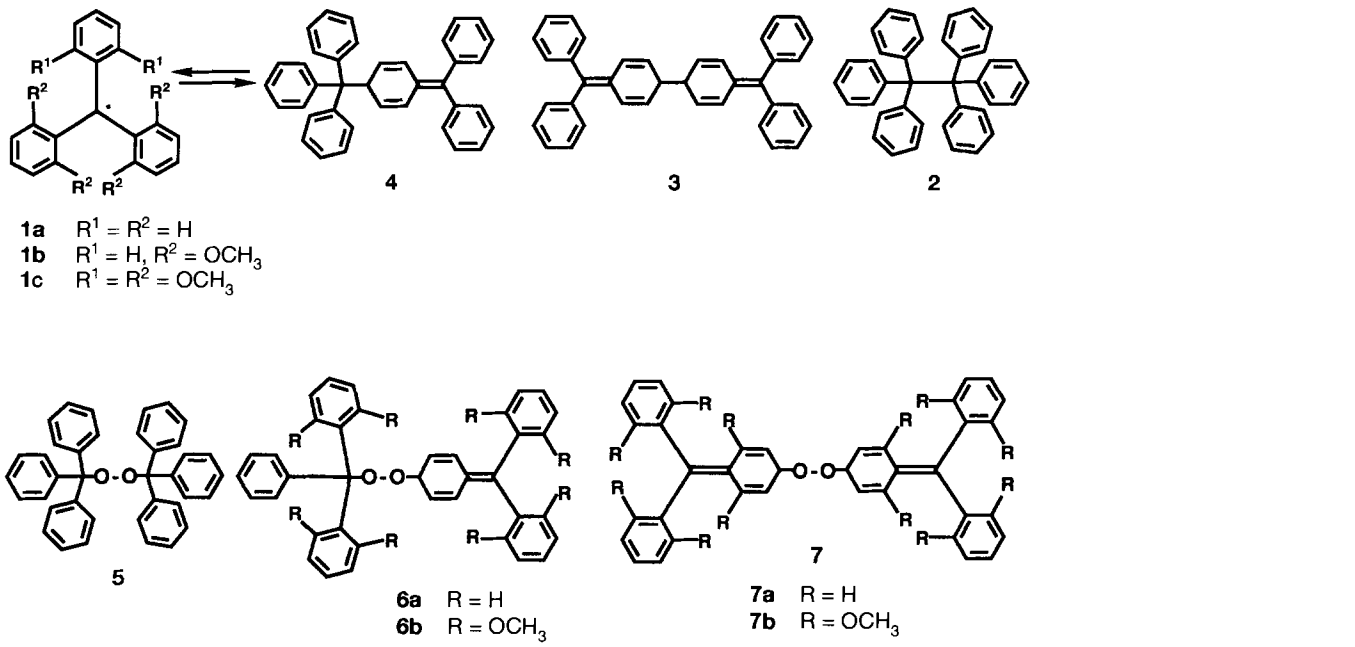
Jacobson and Heintschel Peroxides**

Sei-Hum Jang, Prakash Gopalan, James E. Jackson,* and Bart Kahr*



In 1908, Schmidlin[1] titrated solutions of Gomberg's[2] triphenylmethyl radical (**1a**) with oxygen and demonstrated that the revolutionary, hypovalent carbon species was in equilibrium with an unreactive one. Molecular weight determinations in anaerobic solutions[3] indicated a dimer for which several structures had been proposed: Markownikoff (1902) insisted upon hexaphenylethane (**2**),[4] Heintschel (1903) proposed a "tail-to-tail" or *para*–*para* coupling (**3**),[5] and Jacobson (1905) favored a "head-to-tail" or methyl–*para* coupling (**4**).[6] After a decade, Gomberg settled on **2**, which became entrenched as the consensus choice.[7] However, NMR studies in 1968 confirmed Jacobson's proposal (**4**), much to the surprise of the many scientists who had assumed that **2** was the correct structure.[8] In his 1974 review, McBride uncovered neglected chemical evidence that should have supported Jacobson, and argued that democracy is not always the best way to make scientific judgements.[9]

Another dimer—bis(triphenylmethyl)peroxide (**5**)[10]—was the product in Schmidlin's titration. In fact, the ready formation of this peroxide on exposure of solutions of triphenylmethyl to air forced Gomberg to conclude that he had prepared a novel, reactive species in 1900.[2] It since has been assumed that only methyl–methyl coupled peroxides, like **5**, are produced from triarylmethyls and oxygen. Herein, we describe the preparation and characterization of Jacobson and Heintschel peroxides in which triarylmethyl radicals add oxygen between methyl–*para* (**6**) and *para*–*para* positions (**7**), respectively. Presumably, analogous peroxides long have been present in many triarylmethyl radical oxidations.

We recently proposed a scheme for assembling molecular magnetic materials based on complexation of the stable free radical, tris(2,6-dimethoxyphenyl)methyl (**1c**), with metal cations.[11] As part of this work we determined the crystal structure of **1c**.[12] It displays an anomalous conformation far from the symmetrical D_3 ground state expected from ESR spectroscopy[13, 14] (Fig. 1) and molecular orbital calculations (see next paragraph). Two aryl rings are twisted out of the plane of

Scheme 1. Triarylmethyl dimers and peroxides.

coordination of the central carbon atom by 61°, while the third ring is twisted by only 12°. This conformation is similar to the transition state structure for the two-ring flip enantiomerization mechanism in Ar_3Z propellers.[15]

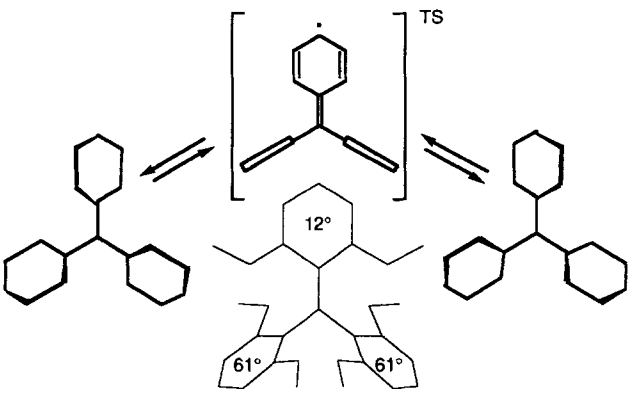

Fig. 1. Schematic illustration of the two-ring flip enantiomerization showing the near equivalence of the transition state (TS) with the conformation of **1c** in the crystal (bottom).

We surmised that a tetra-*ortho*-substituted radical such as **1b** might have a ground state geometry that resembled the crystallographic conformation of **1c**. ENDOR studies of **1b** by Ishizu et al.[16] qualitatively support these expectations, yielding twist angles of 65° for the substituted rings and 30° for the unsubstituted rings. Calculations of the molecular structure of **1b** with the AM1 Hamiltonian[17] were consistent with the ENDOR geometry. The structure was found to have C_2 symmetry with twists of 10° for the unsubstituted ring and 61° for the substituted rings. By contrast, the calculated ring twists for the hexamethoxy radical (**1c**) were 46°.[18]

In **1b**, the twist angles of two rings are increased, relative to those of the unsubstituted triphenylmethyl, by the out-of-plane deforming *ortho* substituents; the unique ring can now turn to an orientation nearly in the plane of coordination of the methyl carbon. In this way, **1b** maximizes its spin density at the *para* position of one ring while sterically hindering the methyl center.[19] The reactivity of such a radical should be concentrated at this *para* position.

Solutions of **1b** were allowed to stand in air for three days after which yellow-brown crystals were collected. Single-crystal X-ray analysis revealed a Jacobson peroxide **6b** (Fig. 2) in which oxygens link the central methyl position of one and the *para* position of the other triarylmethyl subunit.[20] In contrast to **5**, which was centrosymmetric in the crystal with a peroxide dihedral angle of 180°, C17-O10-O9-C20 was measured as 127.6(4)° in **6b**. The latter is much closer to the standard value of approximately 110° for the skew conformation in dialkyl peroxides.[21] Other geometric parameters such as the O–O bond length and C-O-O valence angles compare favorably with **5** (see legend to Fig. 2).

Martin et al. noted that solutions of **1c** react slowly with oxygen in the air to give an orange-brown precipitate.[13] Our attempts to recrystallize this material gave single crystals too small for X-ray analysis. As with **6b**, acid treatment of the oxidation product of **1c** gives the corresponding triarylmethyl

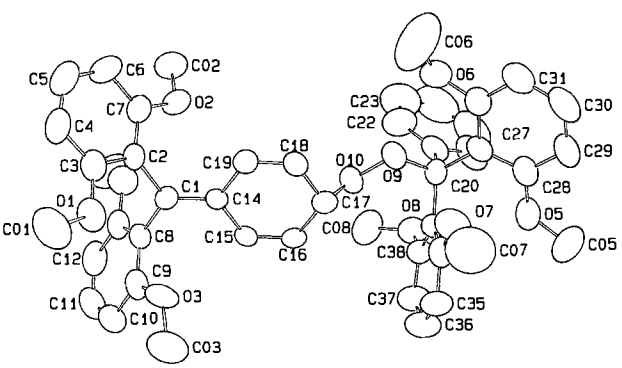

Fig. 2. ORTEP representation (50% probability ellipsoids) of the crystal structure of **6b**. Selected bond lengths [Å] and angles [°] are followed by the corresponding parameters for bis(triphenylmethyl)peroxide in square brackets. cation. Elemental analysis and FAB mass spectrometry established the composition as $C_{50}H_{54}O_{14}$, consistent with a peroxide. The structure of **7b** was determined by ^{1}H NMR spectroscopy. *Para* attachment is indicated by the presence of the methine and olefinic protons giving the pattern characteristic of an AA'BB'C spin system. This spectrum, in contrast to that of **6b**, results from a symmetric or Heintschel peroxide; the radical **1c** undoubtedly forms a compound in which the dioxygen bridge joins *para* positions.

Like the Jacobson dimer of triarylmethyl radicals, Jacobson and Heintschel peroxides, the common oxidation products in a variety of triarylmethyl radical studies, have escaped the attention of chemists for generations. These structures raise a concern: Why are not all bis(triarylmethyl)peroxides methyl–*para*-coupled in a Jacobson configuration? It previously has been shown that large radicals such as the *tert*-butoxy radical prefer to attach to *para* positions of triarylmethyls.[22] Such behavior has not been observed for oxygen. But since the first formed peroxy radical (a large radical by most standards) must attach to the second triarylmethyl radical we always might expect attack at the less hindered *para* site. Experiments are in progress to determine the first position bound in the formation of **6b**.

Experimental Procedure

Bis(2,6-dimethoxyphenyl)phenylmethanol (**1b**-OH): A solution of 1,3-dimethoxyphenyllithium was prepared by addition of 2.5 M *n*BuLi (34.8 mL, 86.9 mmol) in *n*-hexane to a solution of 1,3-dimethoxybenzene (10 g, 72.4 mmol) in anhydrous diethyl ether at −78 °C. The mixture was stirred at room temperature under argon for 48 h. Methylbenzoate (3.13 g, 23.0 mmol) in benzene (20 mL) was added, and the reaction solution was heated at reflux for 3 days under argon. The reaction mixture was poured into 200 mL of water, and the organic layer was dried and concentrated to yield the methanol as an oil. The oil was crystallized in CH_2Cl_2 and hexane. Mp 104 °C, 46% yield. ^{1}H NMR ($CDCl_3$, 299.95 MHz): δ = 3.38 (s, 12H), 6.43 (s, 1H), 6.54 (d, J = 8 Hz, 4H), 7.11 (t, J = 8 Hz, 2H), 7.13 (m, 1H), 7.21 (m, 2H), 7.46 (m, 2H); ^{13}C{^{1}H}NMR ($CDCl_3$, 75.46 MHz): δ = 56.5, 79.5, 106.74, 125.37, 126.31, 126.50, 126.63, 127.28, 149.5, 158.5.

1b$^+ \cdot$ **BF**$_4^-$: A solution of **1b**-OH (500 mg, 1.31 mmol) in 150 mL diethyl ether was treated with 0.1 mL of 48% HBF_4. The resulting crystalline blue precipitate was filtered and dried to give the BF_4^- salt of bis(2,6-dimethoxyphenyl)phenylmethyl cation quantitatively. Mp 142–143 °C. ^{1}H NMR ($CDCl_3$, 299.95 MHz): δ = 3.54 (s, 12H), 6.63 (d, J = 8 Hz, 4H), 7.44 (m, 4H); 7.61 (m, 1H), 7.79 (t, J = 8 Hz, 2H); ^{13}C{^{1}H} NMR ($CDCl_3$, 75.46 MHz): δ = 56.83, 105.36, 125.00, 129.09, 134.59, 137.02, 145.90, 163.79, 191.58.

1b: Compound **1b**$^+ \cdot$ **BF**$_4^-$ (200 g) was reduced by a 5 M $CrCl_2$ solution (20 mL, prepared with $CrCl_3 \cdot 6H_2O$ and Zn/Hg in 10% HCl solution), extracted with CH_2Cl_2, washed with water, and dried with $MgSO_4$. The solution was chromatographed over silica gel to give the radical (35%, based on SQUID measurement (SQUID = Superconducting Quantum Interference Device), μ_{eff} = 0.61 μ_B); m.p. 155–157 °C.

6b: Solutions of **1b** were allowed to stand in air for 3 days. Red-orange crystals of the peroxide precipitated during this time. Mp 121 °C; ^{1}H NMR ($CDCl_3$, 299.95 MHz): δ = 3.40 (s, 12H), 3.58(d, J = 2 Hz, 12H), 4.82 (m, 1H), 5.54 (m, 2H), 6.12 (m, 2H), 6.44 (m, 8H), 6.55 (m, 2H), 7.03 (t, J = 6 Hz, 4H), 7.05 (m, 1H0, 7.11 (t, J = 6 Hz, 2H), 7.68(d, J = 6 Hz, 2H); ^{13}C{^{1}H} NMR ($CDCl_3$, 75.46 MHz): δ = 55.94, 56.33, 103.94, 104.13, 106.47, 117.50, 124.71, 125.63, 125.85, 126.15, 127.07, 127.88, 127.99, 130.05, 147.20, 154.50, 158.43, 158.50; IR (KBr): $\tilde{\nu}$ = 2992, 2936, 2832, 1586, 1472, 1430, 1288, 1252, 1110, 1030, 928, 780, 726 cm^{-1}.

7b: Tris(2,6-dimethoxyphenyl)methyl (**1c**) was prepared as described previously [11]. A pale orange solid (**7c**) precipitated from ether solutions that stood in air for 3 days. The solid was washed with diethyl ether and recrystallized from THF. Mp > 300 °C; correct C,H elemental analyses. ^{1}H NMR ($CDCl_3$, 299.95 MHz): δ = 3.13 (s, 12H), 3.52 (d, J = 2 Hz, 24H), 5.02 (d, J = 8 Hz, 4H), 5.34 (t, J = 8 Hz, 2H), 6.39 (d, J = 8 Hz, 8H), 6.99 (d, J = 8 Hz, 4H); satisfactory C,H analysis; IR (KBr): $\tilde{\nu}$ = 2928, 2828, 1654, 1611, 1584, 1470, 1431, 1382, 1298, 1249, 1219, 1108, 912, 742 cm^{-1}.

[18] This value is in excellent agreement with the twist angle originally predicted by ESR data [14].
[19] It would have an electronic structure that would mimic the transition state in the two-ring flip enantiomerization (see Fig. 1).
[20] Crystals of **6b** suitable for single crystal X-ray analysis were obtained as described in the Experimental Procedure. $C_{46}H_{46}O_{10}$, M = 758.87 g · mol^{-1}, monoclinic, a = 9.398(1) Å, b = 27.900(2), c = 15.259(2) Å, β = 96.87(1), V = 3972(1) Å^3, space group $P2_1/n$, Z = 4, $\mu(Cu_{K\alpha})$ = 6.88 cm^{-1}, ϱ_{calcd} = 1.269 g cm^{-3}, 3031 unique, observed ($I > 3.0\sigma(I)$) reflections with $2\theta < 116°$, R = 0.062, R_w = 0.080. The intensities were measured on an Enraf-Nonius CAD4 diffractometer with ω-2θ scans. The structure was solved by direct methods (SHELX-86: G. M. Sheldrick, Institut for Anorganische Chemie der Universitat Gottingen, F.R.G. 1986) and non-H atoms were refined anisotropically using the programs in MolEN (C. K. Fair, MolEN Structure Determination system, Delft Instruments, Delft, The Netherlands (1990). Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB21EZ (UK) on quoting the full journal citation.

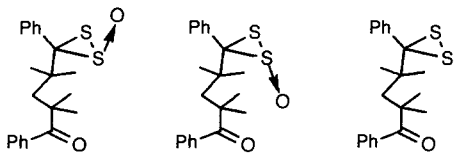
The First Isolable Dithiirane by Oxidation of a Dithietane



Akihiko Ishii, Toru Akazawa, Teruo Maruta, Juzo Nakayama,* Masamatsu Hoshino, and Motoo Shiro

The smallest cyclic disulfides, the dithiiranes, are of interest as isomers of thiocarbonyl *S*-sulfides (thiosulfines) and dithioesters.[1, 2] In dithiiranes the dihedral angle of 0° leads to significant repulsive lone pair–lone pair interactions in addition to large angle strains,[3] and therefore, although several dithiiranes have been recognized as elusive intermediates, no isolable ex-

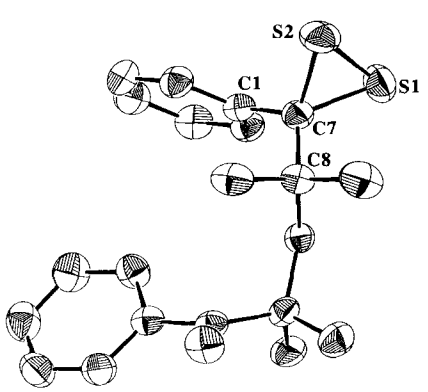
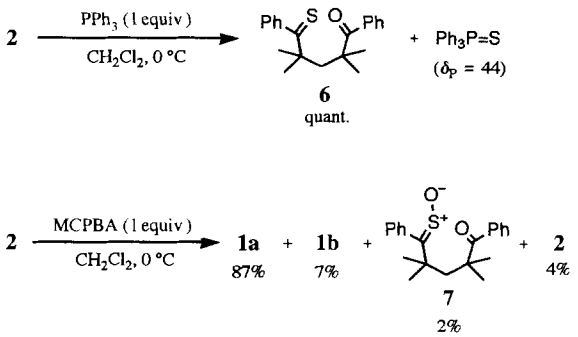
amples (including their oxidized derivatives)—with the exception of **1**[4]—were reported in spite of much effort.[1] In contrast, the oxygen analogues, the dioxiranes are known and used as oxidizing reagents, though they are not very stable molecules for similar reasons.[5] We report here on the synthesis of the first isolable, *unoxidized* dithiirane **2** by oxidation of the bicyclic 1,3-dithietane **3**[6] with potassium peroxomonosulfate (OXONE, Aldrich, $2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$)[7, 8] and its chemical properties, for example the thermal isomerization to the corresponding thiocarbonyl *S*-sulfide.

Treatment of the bicyclic 1,3-dithietane **3** with OXONE (pH 5–6) and a catalytic amount of $[MeN(C_8H_{17})_3]Cl$ led to **2** in 20% yield (Scheme 1).[9] The dithiirane **2** is an orange crys-

Scheme 1. Synthesis of the dithiirane **2**.

talline compound that is stable at room temperature in air but decomposes to give the thioketone **6**[10] (see Scheme 2) and elemental sulfur when heated at 68–75 °C in a capillary tube. The structure of **2** was determined by spectroscopy and X-ray single-crystal structure analysis (Fig. 1).[11] In the UV/VIS spectrum, the longest absorption maximum was observed at 452 nm. This absorption corresponds to the first electronic transition ($n_\pi \rightarrow$ (S-S, S-C)σ^*, 422 nm) of the parent dithiirane calculated by Snyder and Carlsen with the CNDO/S-CI method.[3a] The X-ray structure analysis shows that no unusual bond lengths and angles are observed in the dithiirane ring of **2**. The S–S bond length (2.073 Å) corresponds to the mean value (2.070 Å)[12] of S–S bond lengths found in disulfides in which the dihedral angles between two C–S bonds are constrained to 0–20° and the two C–S bond lengths (1.821 and 1.814 Å) are very similar to that of the parent thiirane (1.815 Å).[13]





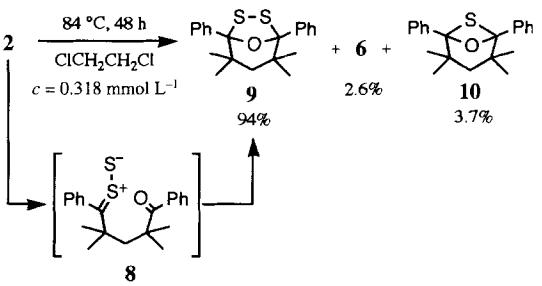


Fig. 1. ORTEP view of dithiirane **2**. Selected bond lenghts [Å] and angles [°]: S1-S2 2.073(2), S1-C7 1.821(2), S2-C7 1.814(3), C1-C7 1.515(3), C7-C8 1.566(3); S2-S1-C7 55.07(8), S1-S2-C7 55.37(8), S1-C7-S2 69.55(9), S1-C7-C1 113.1(2), S1-C7-C8 117.0(2), S2-C7-C1 113.2(2), S2-C7-C8 118.0(2), C1-C7-C8 117.2(2).

Dithiirane **2** is rather inert to acids such as *para*-toluenesulfonic acid, but very sensitive to nucleophiles such as amines and phosphanes. Thus, **2** decomposed quickly by treatment with triethylamine or triphenylphosphane to give the thioketone **6** quantitatively. Oxidation of **2** with an equimolar amount of *m*-CPBA (*meta*-chloroperoxybenzoic acid) gave the corresponding sulfoxides **1a** and **1b** in addition to small amounts of the sulfine **7**[4] and the starting material (Scheme 2).

Scheme 2. Reactions of the dithiirane **2**.

We next examined the thermal isomerization of **2** to the corresponding thiocarbonyl *S*-sulfide or dithioester. Thus, a dilute solution of **2** in 1,2-dichloroethane (0.318 mmol L^{-1}) was heated at 84 °C for 48 h. The ^1H NMR spectroscopic analysis of the residue after removal of the solvent revealed that the bicyclic 1,3,4-oxadithiolane **9**[10] was formed in high yield along with **6** and the 1,3-oxathietane **10**. The most straightforward explanation for the formation of **9** involves the isomerization of **2** to the thiocarbonyl *S*-sulfide **8** followed by an intramolecular 1,3-dipolar cycloaddition between the thiocarbonyl *S*-sulfide and carbonyl moieties. Interestingly, the yield of **9** markedly de-

creased to 27% with increased yields of **6** (51%) and **10** (22%), when the thermolysis of **2** was carried out in refluxing benzene (0.290 mmol L^{-1}). This influence of the solvent polarity can be attributed to the polar character of the thiocarbonyl *S*-sulfide functional group. An attempt to trap **8** by intermolecular cycloaddition with dimethyl acetylenedicarboxylate was unsuccessful.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0707-0778 $ 10.00+.25/0

Thiocarbonyl *S*-sulfides have been considered thermodynamically less stable than the corresponding dithiiranes.[3b] The driving force of the thermal isomerization of **2** to **9** is probably attributed to the rapid intramolecular ring closure, leading to thermodynamically far more stable **9**, even when the equilibrium concentration of **8** is very low. Incidentally, no isomerization of **2** to the corresponding dithioester was detected.

Experimental Procedure

2: A solution of **3** (681 mg, 2 mmol) in CH_2Cl_2 (500 mL), an aqueous solution (180 mL) of OXONE (18.4 g, 30 mmol) whose pH was adjusted to 5–6 by adding 1 M KOH, and a catalytic amount of $[MeN(C_8H_{17})_3]Cl$ were stirred vigorously at 0 °C for 6 d. During the reaction, 1 M KOH (2–3 mL) was added once or twice a day to maintain the pH of the aqueous layer between 5–6. The orange organic layer was separated, washed with cold water, dried over anhydrous $MgSO_4$, and evaporated under reduced pressure at 0 °C. The residue was dissolved in CH_2Cl_2 (2–3 mL) and the solution diluted with hexane. The resulting mixture was allowed to stand in a refrigerator and the first white crystalline crop, which consisted of by-products, was removed by filtration and the filtrate was cooled again in the refrigerator for 2 d. The orange crystals separated were collected by filtration and purified by medium-pressure liquid chromatography (silica gel, CH_2Cl_2) to give 146 mg of **2**. By-products of this oxidation consisted of the dithiirane oxide **1a**, the sulfoxide **4**, and the dicarbonyl compound **5**, whose yields were not determined.

Tetra-*p*-tolylporphyrin with an Inverted Pyrrole Ring: A Novel Isomer of Porphyrin**

Piotr J. Chmielewski, Lechosław Latos-Grażyński,* Krystyna Rachlewicz, and Tadeusz Głowiak

In our search of core-modified tetraarylporphyrin and metallotetraarylporphyrin analogs we have discovered a novel isomer of 5,10,15,20-tetra-*p*-tolyl-porphyrin ($TTPH_2$), namely 2-aza-21-carba-5,10,15,20-tetra-*p*-tolylporphyrin ($CTTPH_2$) (**1**, Scheme 1).[***] The interest in this new macrocycle centers on its remarkable ability – as a tetradentate ligand to form carbon–metal bond. Spectral properties of **1** highlight to its potential applications as the photosensitizer in photodynamic therapy.

Scheme 1.

Since its discovery by Rothemund,[1] 5,10,15,20-tetraphenylporphyrin and its substituted analogs have become the most ubiquitous models of the coordination centers of hemoproteins in biomimetic chemistry and in investigations on metalloporphyrin catalyzed oxidation. Conventional syntheses of tetra-

[**] This work was supported by the State Committee for Scientific Research KBN (Grant 207329101).

[***] Note added in proof: After acceptance of this paper, the synthesis and the X-ray structure analysis of 2-aza-21-carbatetraphenylporphyrin were reported by H. Furuta, T. Asano, and T. Ogawa (*J. Am. Chem. Soc.* **1994**, *116*, 767). Our conclusions concerning the dissociation scheme (the protonation of the peripheral nitrogen in the first step) and the condensation mechanism of $CTTPH_2$ contradict suggestions of Furuta et al. – Editorial comment: Both papers will be comprehensively discussed in a Highlight on "New Porphyrin Isomers" (J. L. Sessler, *Angew. Chem.* **1994**, *106*, in press; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, in press).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0707-0779 $ 10.00+.25/0

meso-substituted prophyrins involve one- or two-step condensation of pyrrole and suitable aldehydes,[2–5] a stepwise route[6] to control substitutions of β-positions,[6] or a modification[7] of the coordination core.

The isomer **1** of $TTPH_2$ can be formally constructed by an interchange of a β-methine moiety and pyrrolic nitrogen within the pyrrole ring while preservation of the general pattern of the porphyrin skeleton. Mechanistically, the synthesis of the isomeric porphyrin requires one β-condensation instead of the typical all α-condensation at the pyrrole nuclei.

The reaction of *p*-tolylaldehyde with excess pyrrole in dichloromethane, catalyzed by BF_3 Et_2O, yields the usual tetra-*p*-tolylporphyrin and its novel isomer **1** (Table 1). An electronic spectrum of **1** (Fig. 1) is porphyrin-like with the characteristic band at 730 nm. Its ^{1}H NMR spectrum exhibits three AB patterns of regular pyrrole protons (Fig. 2A). The inverted pyrrole ring contributes one proton signal. Two protons located on inner pyrrole nitrogens gave a broad singlet at 25 °C, but presented two well-separated singlets at −50 °C. The definitive confirmation of the structure is provided by the enormous upfield shift of the unique 21-CH proton ($\delta = -5.083$, $CDCl_3$, −50 °C) of the inverted pyrrole ring, spin-spin-coupled to 3-H, and showing strong nuclear Overhauser effects (NOE) to 22-NH and 24-NH. The NH protons ($\delta = -2.588$, -2.672) can be easily exchanged by deuterium of D_2O to leave only the 21-CH resonance in the upfield region. Heating of **1** in $CDCl_3$/CH_3COOD mixture (95:5 volume ratio, 0.5 h, 60 °C) finally introduced deuterium in the 21-position. The molecule **1** preserves the aromaticity, because all outer pyrrole and *p*-tolyl resonances are strongly downfield shifted due to the ring current effect, which is also demonstrated by the remarkable shift difference ($\Delta\delta \approx 14$) between outer and inner pyrrolic resonances. The full assignments have been obtained by 2D ^{1}H NMR COSY and NOESY experiments.

Table 1. Selected physical data of **1**, $(1\text{-H})^+$, $(1\text{-H}_2)^{2+}$, and **2**.

1: ^{1}H NMR (300 MHz, $CDCl_3$, −50 °C): δ = 8.990 (7-H), 8.614 (8-H) (J(AB) = 5.0 Hz), 8.925 (18-H), 8.582 (17-H), (J(AB) = 5.0 Hz), 8.578, 8.556 (12, 13-H) (J(AB) = 4.8 Hz), 8.694 (s, 3-H), -2.558(24-NH), -2.672 (22-NH), -5.083 (21-CH); UV/VIS (CH_2Cl_2): λ_{max} [nm] ($\varepsilon \cdot 10^{-3}$) = 383(sh), 440 (Soret) (96.8), 506 (4.7), 543 (7.5), 585 (10.9), 672 (2.8), 730 (9.7); MS (EI): m/z (%) = 670 (100), HR-MS: m/z = 670.309557 (found for M^+) 670.30965 (calcd for $C_{48}H_{38}N_4$); correct elemental analysis for $CTTPH_2 \cdot MeOH$

$(1\text{-H})^+$: ^{1}H NMR (300 MHz, $CDCl_3$, −50 °C, 2 equiv, CF_3COOH): δ = 8.995, 8.497 (J(AB) = 4.8 Hz), spin-spin-coupled to NH at -1.155, 8.852, 8.468 (J(AB) = 5.2 Hz) spin-spin-coupled to NH at -1.237, 8.376 (unresolved, 12,13-H), 8.391 (s, 3H), 16.670 (s, 2-NH), -3.854 (21-CH). 3-H, 2-NH, and 21-CH are spin-spin coupled.

$(1\text{-H}_2)^{2+}$: ^{1}H NMR (300 MHz, $CDCl_3$, −50 °C, 30 equiv CF_3COOH): δ = 8.580 (d, J(AB) = 4.0 Hz, pyrrole), 8.470 (d, J(AB) = 4.3 Hz, pyrrole). The unresolved multiplet in the δ = 8.3–7.4 range is attributable to pyrrole and tolyl resonances, 11.669 (2-NH), 2.034, 1.877, 1.612 (22,23,24-NH), -1.611 (21-CH)

2: ^{1}H NMR (300 MHz, $CDCl_3$, 20 °C): δ = 8.029, 7.750 (J(AB) = 5.0 Hz, 7,8-H), 7.996, 7.798 (J(AB) = 5.0 Hz, 17,18-H), 7.877, 7.874 (J(AB) = 5 Hz, 12,13-H), 10.034 (2-NH), 8.485 (3-H) (J(AX) = 3.4 Hz); UV/VIS ($CHCl_3$): λ_{max} [nm] ($\varepsilon \cdot 10^{-3}$) = 359 (48.5), 426 (Soret) (88), 460 (sh), 515 (10.7), 557 (10.3), 595 (11.4), 660 (sh), 718 (6.9), 789 (7.1); MS (EI): m/z(%) = 726 (M^+, 100)

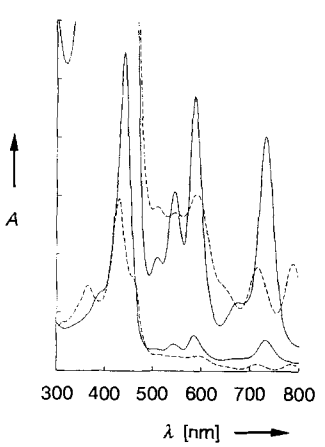

Fig. 1. The electronic spectra of **1** (solid line) and **2** (dashed line) in dichloromethane.

Two discrete stages of the protonation of **1** in chloroform have been demonstrated (−50 °C). The addition of the first proton to the outer nitrogen has been confirmed by the downfield shift of the 2-NH resonance (δ = 16.670) of $(1\text{-H})^+$ (Scheme 1 and Fig. 2B). The second titration step $(1\text{-H}_2)^{2+}$ completely protonates the inner nitrogens (δ = 2.034, 1.877, 1.611).

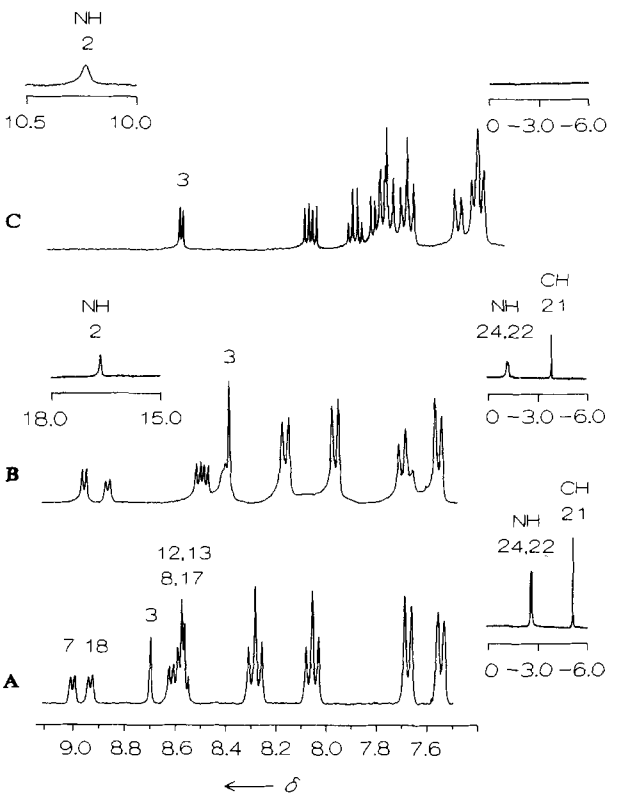

Fig. 2. The ^{1}H NMR spectra (300 MHz) (selected downfield and upfield regions presented) of **1** in $CDCl_3$ at −50 °C (A) $(1\text{-H})^+$ in $CDCl_3$ containing 2 equiv CF_3COOH(B), and **2** in CD_2CL_2 at 20 °C (C). Resonance assignments follow the systematic numbering of porphyrin positions.

The insertion of nickel (II) ions into **1** under mild conditions results in the formation of $[Ni^{II}(CTTP)]$ (**2**). The electronic spectrum of **2** contains features expected for metalloporphyrins (see Fig. 1). The ^{1}H NMR spectrum of the diamagnetic species **2** (Fig. 2C), resembles that of $(1\text{-H}_2)^{2+}$. The 2-NH proton (δ = 10.208, CD_2Cl_2, 20 °C) is spin-spin-coupled to 3-H (δ = 8.553) and exchangeable for deuterium of D_2O. The most notable feature of the nickel (II) complex **2** is coordination through the unprotonated β-carbon in the equatorial plane deduced from the disappearance of the 21-H resonance in the ^{1}H NMR spectrum of **2**. This observation implies unusual labilization of the inner C–H bond.

The structure of **2** was determined by X-ray crystallography (Fig. 3).[8] The average distances of Ni···N and Ni···C of 1.955(3) and 1.963(3) Å are comparable to the Ni···N distances in the nearly planar $[Ni^{II}(OEP)]$ derivative (1.958(2) Å, OEP = octaethylporphyrin dianion),[9] and are in the range of Ni^{II}–C bond lengths (1.87–1.97 Å).[10]

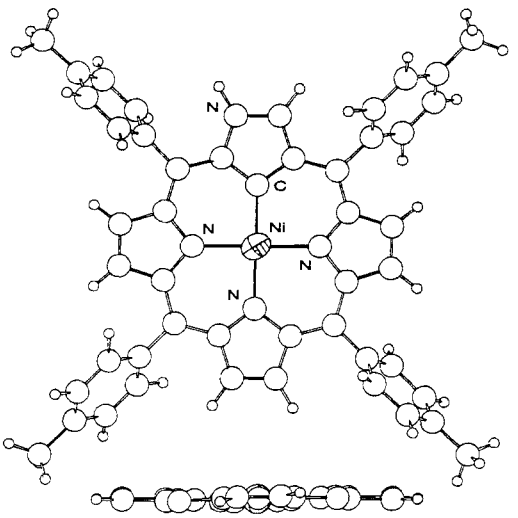

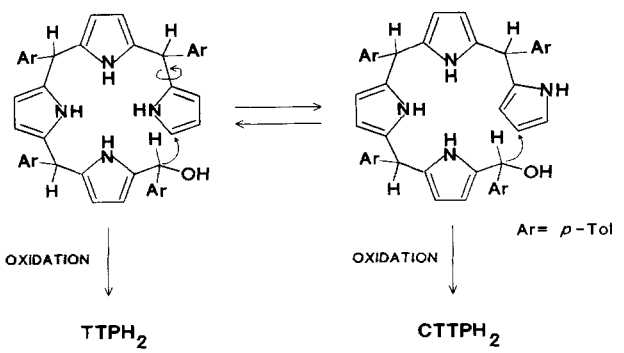

Fig. 3. Crystal structure of **2** (top). A projection emphasizing the planar nature of **2** (bottom). Phenyl groups are omitted from the side view for clarity. Only one of eight possible forms is shown.

To summarize, the typical pyrrole–arylaldehyde condensation provides a convenient access to the new family of core-modified porphyrins exemplified here by a tetra-*p*-tolylporphyrin containing one inverted pyrrole ring. This „carbaporphyrin" is structurally different from the other isomer, porphycene.[11]

For the mechanism of carbaporphyrin formation we suggest that two helical conformations of tetrapyrromethane differing only by a single 180 °C rotation of the terminal pyrrole ring around the *α-meso* carbon bond contribute in the porphyrinogen ring closure.[5, 12–14]. They provide two optimal orientations for the macrocyclic ring closure at the pyrrole α- or β-positions, both susceptible to electrophilic attack[5, 12–14] to afford regular or inverted porphyrinogen, and on oxidation of it, $TTPH_2$ or inverted $CTTPH_2$, respectively.

Experimental procedure

The condensation of *p*-tolylaldehyde (40 mmol) and pyrrole (70 mmol) in dichloromethane (1L) catalyzed by $BF_3 \cdot Et_2O$ (8 mmol), conducted over 1 h under nitrogen at room temperature, followed by oxidation with *p*-chloranil (8 g) carried out under reflux for 1 h, produced a mixture of $TTPH_2$ and **1** (4:1 molar ratio). The solution was evaporated to dryness, and the solid material subjected to chromatography on basic Al_2O_3 to remove tar products. The crude porphyrin products were eluted with dichloromethane. Small amount of basic Al_2O_3 was added to the solution, followed by removal of solvent by rotary evaporation. The solid material was deposited on the top of a column packed with basic Al_2O_3 and eluted with tetrachloromethane. The first eluted band contained $TTPH_2$. The second brown band of **1** was eluted with tetrachloromethane/dichloromethane (4/1 v/v). The fraction containing **1** was evaporated to dryness, and the product recrystallized from benzene/methanol to give **1** in 4% yield (0.27 g). Only a trace amount (less than 1% of the overall macrocycle crop) of **1** can be detected by ^1H NMR in the tail of the $TTPH_2$ chromatographic band if a 1:1 pyrrole/*p*-tolyladehyde molar ratio is used, as typical in the $TTPH_2$ synthesis described by Lindsey et al.[5].

Insertion of nickel(II): A mixture of **1** (0.12 mM) in $CHCl_3$ was heated at reflux with an ethanolic solution of $NiCl_2 \cdot 6H_2O$ (1.2 mM) for 0.5 h. After evaporation of the solution, the residue was subjected to chromatography on silica with dichloromethane as an eluent. The first green band was collected, and the solvent removed. The product Ni^{II} (CTTP) (**2**, 40% yield) was recrystallized from pyridine.

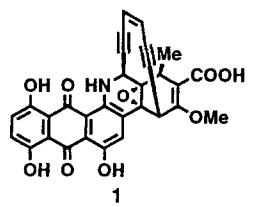
Synthesis of the Anthraquinone Framework of Dynemicin A**

K. C. Nicolaou,* Jonathan L. Gross, Michael A. Kerr, Robert H. Lemus, Kiyoshi Ikeda, Kouichi Ohe



Dynemicin A (**1**), a naturally occurring enediyne anticancer antibiotic, is characterized by a unique molecular architecture and an interesting biological profile.[1] Dynemicin's antibiotic and antitumor activities stem from its ability to generate, upon in vivo activation, benzenoid diradicals that damage DNA.[1–3] Numerous efforts directed towards the total synthesis of **1** and

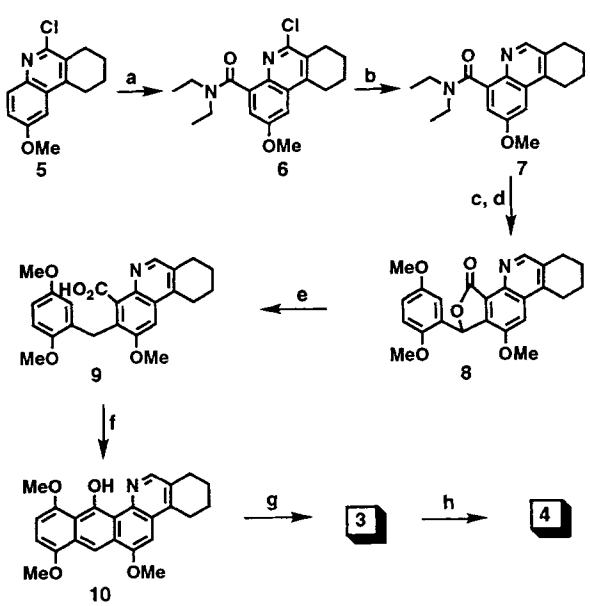
towards various model systems and biological mimics have been reported.[2, 4] Particularly impressive are Schreiber's recent advances in the field, which include the construction of the angular anthraquinone **2**[5] and of methylated forms of the natural product.[6] In this communication we report our synthesis of dynemicin A polycyclic frameworks, compounds **3** and **4**, by chemistry that should serve as a prelude to a projected total synthesis of the naturally occurring compound.

1



2

3: X = H_2; **4**: X = O

The synthesis of the target compounds **3** and **4** began with the tricyclic intermediate **5**[7] (Scheme 1). Thus regioselective metalation of compound **5** with *sec*-BuLi in the presence of *N*,*N*,*N*′,*N*′-tetramethyl-1,2-ethanediamine (TMEDA) followed by quenching with diethylcarbamoyl chloride gave diethyl amide **6** in 84% yield. The chloro substituent was then reductively removed from **6** by hydrogenolysis of the carbon–chlorine bond with Pd/C and hydrogen to yield quinoline derivative **7** in 92% yield. A second metalation[8] of quinoline **7** at the available position adjacent to the amide side chain, and facilitated by it, followed by addition of 2,5-dimethoxybenzaldehyde and subsequent exposure to *p*-toluenesulfonic acid (TsOH) at 110 °C furnished the γ-lactone **8** in 65% overall yield. In preparation for the construction of the final ring of the desired anthraquinone skeleton, the γ-lactone was reductively opened by treatment of compound **8** with Zn dust in 10% aqueous NaOH solution at reflux, which resulted in the smooth formation of carboxylic acid **9** by cleavage of the benzylic C–O bond (98% yield). Finally, ring closure of the carboxylic acid group in **9** onto the dimethoxy aromatic ring under the influence of trifluoroacetic anhydride, followed by treatment with base, furnished the pentacyclic system **10** in 93% yield. The oxidation of **10** with Jones reagent at 0 °C led to the anthraquinone system **3** (58% yield). Compound **3** could be oxidized further to the keto derivative **4** by prolonged treatment with CrO_3 in acetic acid (50% yield).

Scheme 1. Synthesis of the pentacyclic anthraquinone compounds **3** and **4**. Reagents and conditions: a) 1.2 equiv TMEDA, 1.15 equiv *s*BuLi, THF, −78 °C, 1 h, then 1.15 equiv diethylcarbamoyl chloride, 25 °C, 16 h, 84%; b) H_2, 10% Pd on charcoal, 1.0 equiv KOH, EtOH, 25 °C, 24 h, 92%; c) 1.2 equiv TMEDA, 1.15 equiv *s*BuLi, −78 °C, 1 h, then 1.15 equiv 2,5-dimethoxybenzaldehyde, 25 °C, 16 h; d) 0.1 equiv TsOH, toluene, 110 °C, 6 h, 65%; e) 5.0 equiv Zn dust, excess of NaOH, H_2O, 100 °C, 8 h, 98%; f) 3.0 equiv trifluoroacetic anhydride, CH_2Cl_2, 0 °C, 2 h, 93%; g) excess of Jones reagent, acetone, 0 °C, 2 h, 58%; h) excess of CrO_3, acetic acid, 25 °C, 24 h, 50%.

The reported chemistry represents a facile entry into anthraquinone systems and culminates in the rapid assembly of pentacyclic frameworks relevant to the total synthesis of the enediyne anthraquinone antibiotic dynemicin A (**1**). Thus, combining this strategy with that already reported for the enediyne segment of **1** should open a viable route to advanced dynemicin A systems and to the natural product itself. Furthermore, the synthesized molecules **3** and **4** are quite interesting in their own right as potential intercalating agents to double stranded DNA and as useful biological tools.[9, 10]

An Easy Route to Homo- and Heteroleptic Biscycloplatinated Complexes without Recourse to Organolithium Compounds**

Alexander D. Ryabov* and Rudi van Eldik

Cycloplatination reactions are characterized by a diversity of mechanisms for C–H bond cleavage[1] on one hand, and low yields of platinacycles formed[2] on the other. Moreover, certain types of complexes, such as *cis*-[Pt(C ~ N)$_2$], have not yet been prepared by metalation of C–H bonds. These homoleptic species were obtained by lithiation of organic ligands followed by interaction with the appropriate platinum(II) derivatives.[3] The synthesis of heteroleptic species of the type *cis*-[Pt(C ~ N)(C* ~ N)] is even more laborious.[4] Such homo- and heteroleptic complexes exhibit remarkable stereochemistry,[5] photochemistry, and chemical reactivity,[3] but the synthetic difficulties limit their wide use.

We report here on facile cycloplatinations through C–H bond cleavage leading to both homo- and heteroleptic complexes, as well as on novel exchange of cycloplatinated ligands, similar to that observed in palladium(II) complexes.[6] The platination of C–H bonds is expected to be easier when promoted by abstraction of the chloro ligands by $AgNO_3$.[7] We have found that it is even more advantageous to use $AgBF_4$ instead of $AgNO_3$. The role of the silver salts is obvious: they create coordinative unsaturation at platinum(II) and thus increase the electrophilicity of the metal center. Naturally, higher efficiency is anticipated with a poorly coordinating anion, BF_4^-, as Ag^+ counterion. The principal results are shown in Scheme 1. A solution of the chloro-bridged diplatinum complex $[Pt(C_6H_4CH_2NMe_2)Cl]_2$[8] in CH_2Cl_2 or C_6H_6 was treated with $AgBF_4$ dissolved in acetone. Addition of azobenzene, after filtering off AgCl, triggered a reaction which occurred readily at 25–50 °C. The main products are *cis* complexes **1a** and **2a**. When using 4,4′-azotoluene, the corresponding complexes **1b** and **2b** were isolated. The $^3J_{Pt,H}$ coupling constants clearly show that *cis* species are formed under these conditions.[9a] Such complexes usually have *cis* geometry,[3] but *trans* compounds are also known.[9] Complexes **1** and, in particular, **2** display properties typical of biscycloplatinated compounds.[3] Their UV/VIS spectra contain many bands, and in addition, **2a** shows fluorescence in CH_2Cl_2 at room temperature with a maximum at 359 nm when excited with light with wavelength λ = 254 nm.

Scheme 1. A new route to homo- and heteroleptic monomeric biscycloplatinum complexes.

The data in Figure 1 suggest that complex **1a** is formed first and is then converted into **2a**, a novel example for the exchange of cyclometalated ligands in platinum(II) complexes. It illustrates an easy way to the heteroleptic biscycloplatinated compounds, since the primary product **1a**, if treated with a ligand other than azobenzene, could afford the heteroleptic complex after dissoci-

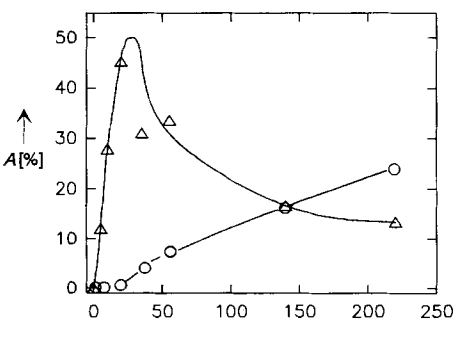

Fig. 1. The course of the formation of **1a** (Δ) and **2a** (O) from [Pt(C$_6$H$_4$CH$_2$NMe$_2$)(Solv)$_2$]BF$_4$ and azobenzene in C_6H_6/acetone (1:1 v/v) at 50 °C monitored by UV/VIS spectroscopy; [Pt(II)] = [azobenzene] = 1.09×10^{-2} M.

[**] We are grateful to Prof. Paul S. Pregosin for his persistent advice to test the use of silver salts in these systems and to R. Wimmer for experiments with proton scavengers. A stipend (1991–1993) from the Alexander von Humboldt Foundation for ADR is gratefully acknowledged.

ation of *N*,*N*-dimethylbenzylamine. We attempted to carry out this transformation by treating **1a** with 4,4′-azotoluene under exactly the same conditions: in CH_2Cl_2/acetone or C_6H_6/acetone mixtures at 50 °C. Surprisingly, there was no exchange. Assuming that there was a catalytic process, we tried unsuccessfully to induce the reaction by addition of $AgBF_4$, $[Pt(C_6H_4CH_2NMe_2)Cl]_2$, or both to the reaction mixture. What was then responsible for the exchange? The analogy with the palladium(II) reactions helped to solve the problem.[6] The first cycloplatination to form **1** from the solvento complex (Scheme 1) must generate a strong acid, HBF_4, which in turn is able to cleave the more basic dimethylaminomethylbenzenido ligand of **1**, as does acetic acid as cosolvent in related palladium(II) complexes.[10] Since the acid anion is noncoordinating, the product $[Pt(C_6H_4N{=}NPh)(Solv)_2]BF_4$ is able to cyclometalate the next azobenzene molecule to form **2**.

If this rationalization is correct, the following two processes must occur: Firstly, strong acids with noncoordinating anions should induce the conversion of **1** into **2** and, secondly, heteroleptic compounds could be generated under the same conditions as in Scheme 1 from the cycloplatinated azobenzene dimer $[Pt(C_6H_4N{=}NPh)Cl]_2$.[11] We were, in fact, able to carry out both these reactions. The exchange, achieved by addition of stoichiometric amounts of F_3CSO_3H to the mixture of **1a** and 4,4′-azotoluene, and direct cycloplatination of the same ligand by the solvento complex derived from $[Pt(C_6H_4N{=}NPh)Cl]_2$ gave the identical heteroleptic complex **3**.

One of the referees of this paper raised the question whether it is possible to preclude the formation of **2** by addition of a "proton sponge" to the reaction mixture. Therefore, 1,8-bis(dimethylamino)naphthalene or 2,6-di-*tert*-butylpyridine was added to the solvento species to bind the acid liberated in subsequent reaction with azobenzene. However, these nitrogen ligands themselves react instantaneously with $[Pt(C_6H_4CH_2NMe_2)(Solv)_2]BF_4$ affording dark brownish complexes. No attempt was made to characterize these species.

The formation of homoleptic complexes **2** from the *N*,*N*-dimethylaminomethylbenzenide complex (Scheme 1) is a unique example of "suicidal" cyclometalation, since the activation of C–H bonds by electrophilic substitution generates a strong acid which then "kills" the more basic ligand of the primary product **1**. Azobenzenes are less basic than tertiary amines, and this makes complexes **2** and **3** more resistant to small concentrations of strong acids. The exchange reaction resembles processes that are well-known in palladium(II) chemistry.[6] The principal difference is that the exchange reactions of the platinum complexes involve monomeric biscycloplatinum complexes of the type [Pt(C ~ N)(C* ~ N)]. In the palladium(II) case, however, exclusively monometalated dimeric complexes of the type [Pd(C ~ N)X]$_2$, in which only organic ligand is bound to the metal center, participate. Related monometalated platinum(II) dimers are insufficiently labile to undergo the proton-induced exchange and react with azobenzenes in a different way.[12] The Pt–C bond of one platinacycle is needed to increase the lability of the other cycloplatinated leaving ligand toward proton attack. We have recently shown that the kinetic labilization brought about by orthoplatination (that is, labilization by the Pt–C bond *trans* to the leaving ligand) increases the reactivity by four orders of magnitude, with the result that the anation rate of platinum(II) complexes reaches that of analogous [Pd(dien)] complexes.[13] In the present case, the Pt–C bond of azobenzene labilizes the *trans*, Pt–N bond of the leaving dimethylaminomethylbenzenido ligand. The corresponding Pt–C bond becomes less stabilized by chelation and is easily cleaved by the acid.

Experimental Procedure

The typical procedure was as follows: the solution of $[Pt(C_6H_4CH_2NMe_2)Cl]_2$ (0.080 mmol) in CH_2Cl_2 (1.5 mL) was mixed with $AgBF_4$ (0.164 mmol) dissolved in acetone (1 mL); AgCl was removed, and azobenzene (0.170 mmol) was added. The mixture was kept for 18 min at 30 °C, then cooled in ice, and the products were separated by preparative TLC (SiO_2, C_6H_6). If the goal is the isolation of **1**, as in this example, TLC operations must be carried out fast. Azobenzene is eluted first, then **2a** (brown band) followed by **1a** (orange). The products were washed off with $CHCl_3$ and recrystallized from $EtOH/H_2O$ after removal of the solvent. A brownish red material that was difficult to elute from SiO_2 was always present. Its ^1H NMR spectrum showed a mixture of compounds which was not investigated further. Yields: **1a** 53%, **2a** 7%. Satisfactory C,H,Pt analyses were obtained;

1a: ^1H NMR ($CDCl_3$): $\delta = 2.41$ (s, $^3J(Pt,H) = 16.1$ Hz, NCH_3), 3.85 (s, $^3J(Pt,H) = 20.4$ Hz, NCH_2), 7.06 (t, H4 ("dimethylbenzylamine", dmba)), 7.12 (d, H3 (dmba)), 7.20 (t, H5 (dmba)), 7.21 (td, H4 ("azobenzene", azb)), 7.34 (td, H5 (azb)), 7.45 (t, H4′(azb)), 7.51 (d, H2′,6′(azb)), 7.56 (t, H3′,5′ (azb)), 8.00 (d, $^3J(Pt,H) = 53.0$ Hz, H6(azb)), 8.02 (d, $^3J(Pt, H) = 53.5$ Hz, H6 (dmba)), 8.02 (dd, H3 (azb)); IR (KBr): $\tilde{\nu} = 699$, 769 (monosubstituted azb ring), 721 (1,2-disubstituted azb ring), 742 cm^{-1} (1,2-disubstituted dmba ring)[12]; UV/VIS (CH_2Cl_2): λ_{max} (ε[$M^{-1}cm^{-1}$]) = 474 (5300), 394 (4250), 334 (8500) nm. – **2a**: ^1H NMR: $\delta = 7.01$ (t, H3′,5′), 7.11 (t, H4′), 7.31 (t, H4), 7.49 (d, H2′,6′), 7.50 (t, H5), 8.13 (d, H3), 8.21 (d, $^3J(Pt,H) = 47.3$ Hz, H6); IR: $\tilde{\nu} = 691$, 762 (monosubstituted ring), 718 cm^{-1} (1,2-disubstituted ring); UV/VIS λ_{max} (ε) = 600sh, 513 (6900), 377 (16000), 337 (15100), 317 (14700), 284 (19400), 251 (19700) nm. – **1b**: ^1H NMR: $\delta = 2.41$ (s, CCH_3), 2.43 (s, NCH_3), 2.45 (s, CCH_3), 3.85 (s, $^3J(Pt,H) = 20.05$ Hz, NCH_2), 6.99 (d, H4 ("azotoluene", azt)), 7.06 (t, H4 (dmba)), 7.12 (d, H3 (dmba)), 7.22 (t, H5 (dmba)), 7.32 (d, H3′,5′ (azt)), 7.40 (d, H2′,6′(azt)), 7.78 (s, $^3J(Pt,H) = 54.4$ Hz, H6 (azt)), 7.87 (d, H3 (azt)), 8.01 (d, $^3J(Pt,H) = 45.39$ Hz, H6(dmba)); IR: $\tilde{\nu} = 741$ (1,2-disubstituted dmba ring), 804, 820, 844 cm^{-1}(azt); UV/VIS: λ_{max} (ε) = 454 (5100), 342 (9700), 281 (12000) nm. – **2b**: ^1H NMR: $\delta = 2.26$ (s, CCH_3), 2.52 (s, CCH_3), 6.78(d, H3′,5′), 7.10 (d, H4), 7.32 (d, H2′,6′), 7.97 (d, H3), 7.97 (s, $^3J(Pt,H) = 48.6$ Hz, H6); IR: $\tilde{\nu} = 805$, 820 cm^{-1}; UV/VIS: λ_{max} (ε) = 597 (2350), 510 (7800), 393 (21000), 359 (18600), 325 (22900), 289 (23200), 259 (22200) nm. – **3**: ^1H NMR: $\delta = 2.24$ (s, CCH_3), 2.52 (s, CCH_3), 6.76 (d, H3′,5′ (azt)), 7.00 (t, H3′,5′ (azb)), 7.10 (d, H4 (azt)), 7.11 (t, H4′ (azb)), 7.31 (t, H5 (azb)), 7.34 (d, H2′,6′ (azt)), 7.46 (d, H2′,6′ (azb)), 7.51 (td, H4 (azb)), 7.98 (s; $^3J(Pt,H) = 49.1$ Hz, H6 (azt)), 7.98 (d, H3 (azt)), 8.14 (dd, H3 (azb)), 8.20 (d, $^3J(Pt,H) = 46.6$ Hz, H6 (azb)); IR: $\tilde{\nu} = 692$, 766 (monosubstituted azb ring), 718 (1,2-disubstituted azb ring), 823 cm^{-1} (azt); UV/VIS: λ_{max} (ε) = 590sh, 512 (3600), 387 (8700), 359 (8500), 322 (9000), 286 (10500), 257 (10100) nm.

The data shown in Figure 1 were obtained from samples (0.10 mL) withdrawn intermittantly from the reaction mixture and purified on Merck silica gel 5 × 10 cm aluminium sheets for TLC (eluted with benzene). The brown and orange bands of **2a** and **1a**, respectively, were cut out, the products washed off with $CHCl_3$, and their concentrations determined by UV/VIS spectroscopy.

Synthesis and Crystal Structure of the First Tetraaminophosphonium Salt $P(NH_2)_4I$**

Wolfgang Schnick,* Stefan Horstmann, and Alfred Schmidpeter

Dedicated to Professor Otto J. Scherer on the occasion of his 60th birthday

The characteristic building blocks in phosphorus(v) nitrides are PN_4 tetrahedra. Linkage of these structural elements through common corners allows access to a large number of condensation degrees. This is reminiscent of the varied structural chemistry of the silicates and phosphates.[1] One of the extremes in the series of differently condensed phosphorus nitrides is the ionic compound Li_7PN_4, which comprises "isolated" PN_4^{7-} ions.[2] Due to its extremely high formal charge, no indications for the existence of this anion in solution have yet been found; therefore, Li_7PN_4 is accessible only by solid-state reaction of the corresponding binary nitrides. Thus, the certainly high synthetic potential of isolated PN_4 groups in solution for the formation of well-defined P–N solid compounds has remained unexplored.

The salt Li_7PN_4 is derived from the hypothetical acid H_7PN_4, which is suspected to be an unstable monophosphazene intermediate during ammonolysis of PCl_5.[3] However, due to its high basicity and tendency to undergo condensation reactions it has not yet proven possible to isolate imidophosphoric acid triamide, H_7PN_4. With $P(NH_2)_4I$ (**C**) we report the first successful synthesis and structural proof of a tetraaminophosphonium salt, which can be regarded as a hydroiodide of H_7PN_4. The synthesis followed the modification of a procedure[4] that starts from phosphorothionic triamide (**A**).[5] Methylation of the sulphur atom in **A** with methyl iodide and careful subsequent ammonolysis of **B** readily yields the desired product **C**. As the last

A **B** **C**

reaction step is a heterogeneous solid–liquid reaction, **C** is obtained as a sparingly-soluble, fine-crystalline powder. The crystal growth of tetraaminophosphonium iodide was severely hampered by the fact that **C** is insoluble in most solvents and that, due to its reactivity, it easily undergoes hydrolysis and condensation reactions. In the past methanol had been suggested as a solvent for **C**. However, according to our investigations prolonged exposure of **C** to methanol leads to the formation of tetramethylammonium iodide [Eq. (a)]. Sufficiently large single crystals of **C** were obtained by crystallization from dry acetonitrile employing a temperature gradient between 70 °C and room temperature. Obviously, tetraaminophosphonium iodide is sufficiently soluble at the higher temperature.

$$4P(NH_2)_4I + 4CH_3OH \longrightarrow (CH_3)_4NI + 4OP(NH_2)_3 + 3NH_4I \qquad (a)$$

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. W. Milius, Universität Bayreuth, for help with and discussion of the X-ray structure analysis.

Unprecedented in chemistry, the acid–base pair $H_8PN_4^+$/PN_4^{7-} enables structural comparison over a range of eight successive dissociation steps: According to the results of the X-ray structure analysis,[6] $P(NH_2)_4^+$ and I^- ions form a CsCl-analogous arrangement in the solid. The P–N bond length (160.7(2) pm) (Fig. 1) represents the shortest P–NH_2 bond distance reported to date. The valence sum for the phosphorus center (5.56), calculated from the four P–N bonds according to O'Keeffe et al.,[7] is indicative of significant polar bonding or multiple bonds between the phosphorus and nitrogen atoms. The electrostatic repulsion between the nitrogen atoms in PN_4^{7-} (P–N: 171 pm[2]) is obviously compensated by the interaction between the nitrogen atoms and the terminal protons of the tetraaminophosphonium ion. This results in a marked shortening of the P–N bonds by approximately 10 pm. In accord with these short P–N bond lengths the H-N-H and H-N-P bond angles (114(3)° and 120(2)°, respectively) in the tetraaminophosphonium ion indicate a significant P–N double-bond character. Even though there are no N–H···N hydrogen bonds present between the cations, the NH_2 groups are fixed with regard to rotation around the P–N bonds. Accordingly, it was possible to locate the positions of the hydrogen atoms unambiguously[8] during X-ray structure analysis by difference-Fourier synthesis.

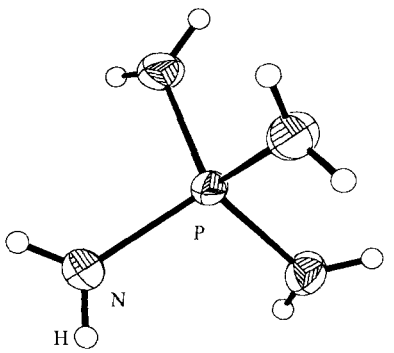

Fig. 1. Structure of the tetraaminophosphonium cation in $P(NH_2)_4I$. Distances [pm] and angles [°]: P–N 160.7(2), N–H 74.9(26), N-P-N 124.2(2) and 102.7(1), H-N-H 114(3), P-N-H 120(2).

Experimental Procedure

$SP(NH_2)_3$ (4.53 g, 0.04 mol) was treated with CH_3I (8.17 g, 0.06 mol) in dry acetonitrile (25 mL) for 6 days at room temperature. The resulting solid **B** (yield: 76%) was separated and washed with diethyl ether. ^{31}P NMR (36.9 MHz, $CDCl_3$, 25 °C): $\delta = 48.1$ (*s*). **B** (4.82 g, 0.02 mol) was suspended in 100 mL of dichloromethane and treated at room temperature (duration: 3 h) with a vigorous stream of NH_3 (KOH drying column). The resulting solid **C** was separated off and washed with diethyl ether (yield: 96%). For purification and crystal growth, 1.0 g of **C** in 25 mL acetonitrile was transferred to a Schlenk tube, and a temperature gradient (bottom: 70 °C, top: 25 °C) was applied to the supernatant. Coarse-crystalline, colorless **C** deposited at the cooler end. According to X-ray powder diffraction studies and ^{31}P NMR MAS measurements the product was obtained as a single phase. IR(KBr): $\tilde{\nu}$ [cm^{-1}] = 3378 (NH), 3280 (NH), 3097 (NH), 1078 (PN), 946 (PN). $T = 180$ °C (10^{-3} mbar, decomposition). All reactions were carried out in dry solvents under an inert argon atmosphere.

$C_{60}H_4$: Kinetics and Thermodynamics of Multiple Addition to C_{60}**

Craig C. Henderson, Celeste McMichael Rohlfing, Roger A. Assink, and Paul A. Cahill*

The regiochemistry of addition of X_2 to fullerenes has now been thoroughly investigated through both theory and experiment.[1–3] In C_{60} and C_{70}, and presumably in the higher fullerenes, both the kinetic and thermodynamic products are derived from "localized" addition, that is, 1,2 addition across 6-6 bonds or 1,4 addition across six-membered rings. In C_{70}, addition to the 6-6 bonds closest to the poles of the molecule leads to the most stable products by both calculation and experiment. However, products resulting from 1,4 addition to the six-membered ring spanning the equatorial region of C_{70} are predicted to lie only slightly higher in energy. Questions of the regiochemistry of both the kinetic and thermodynamic products of multiple additions to C_{60} and C_{70} have not yet been resolved and are highly relevant to the chemical modification of fullerenes for applications ranging from pharmaceuticals to materials science. We report here the synthesis, isolation, characterization, and equilibration of several isomers of $C_{60}H_4$ which, in combination with ab initio Hartree–Fock computations, have yielded insight into the regiochemistry of multiple additions to C_{60}. Remarkably, the major kinetic product of hydroboration *and* the thermodynamically most stable isomer of $C_{60}H_4$ is 1,2,3,4-$C_{60}H_4$ (**1**) (Fig. 1), in which the four hydrogens atoms have added to adjacent 6-6 bonds.[4, 5]

Hydroboration of C_{60} and C_{70} has led to the isolation of one isomer of $C_{60}H_2$[1] and two isomers of $C_{70}H_2$,[2] all of which have been shown to be products resulting from 1,2 addition to 6-6 bonds. These products are the thermodynamically most favored isomers at all levels of calculation. For $C_{60}H_4$, Matsuzawa et al.[6] have reported semiempirical calculations that suggest that only 3.5 kcal mol^{-1} separate the heats of formation of the highest and lowest energy isomers in which addition is limited to 6-6 bonds (Fig. 1a). Four of these eight isomers are predicted to lie within 0.6 kcal mol^{-1} of the lowest energy isomer **4** ("orthogonal" addition of the H_2 pairs, see Fig. 1a). However, these values are suspect because recent results indicate that semiempirical calculations are unreliable for closely spaced fullerene isomer energies.[7, 8] We therefore undertook an ab initio study of the previously identified isomers in concert with our experimental work.

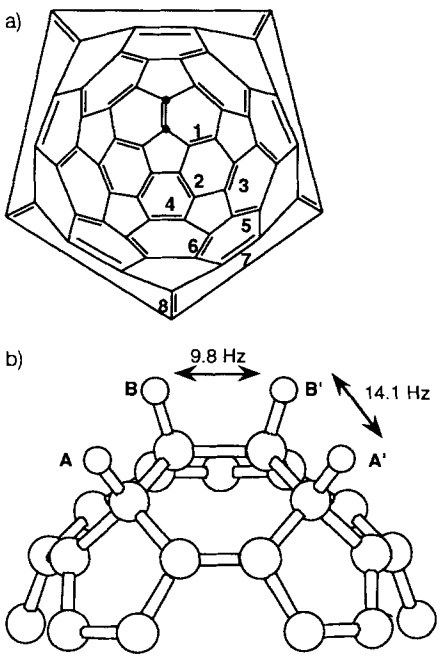

Fig. 1. a) Illustration of the eight isomers of $C_{60}H_4$ which arise from 1,2 additions to 6-6 bonds of C_{60}. The numbers correspond to those in the text for isomerically related formulae [6]. b) Part of the structure of 1,2,3,4-$C_{60}H_4$ (**1**); ^3J(H,H) values given as shown.

The theoretical methodology employed here is similiar to that described previously in our study of isomers of $C_{60}H_2$ and $C_{70}H_2$.[7] These eight isomers of $C_{60}H_4$ were investigated by using ab initio methods within the GAUSSIAN 92 series of programs.[9]

Complete geometry optimizations were performed at the Hartree–Fock (HF) level using the 3-21G and 6-31G* basis sets, the latter containing one set of spherical harmonic d functions on each carbon. The relative HF/6-31G* energies obtained are very likely to be reliable estimates of the relative free energies of the $C_{60}H_4$ isomers because this approach previously yielded relative isomer energies for $C_{70}H_2$ with chemical accuracy.[8] In marked disagreement with the MNDO-PM3 results, both levels of ab initio theory predict the lowest energy isomer to be 1,2,3,4-$C_{60}H_4$ (**1**) (Table 1). This structure is favored over the next

Table 1. Relative energies (kcal mol^{-1}) for $C_{60}H_4$ isomers **1**–**8**, based on fully optimized geometries at each level of theory.

Isomer	H on C	MNDO-PM3[6]	HF/3-21G	HF/6-31G*
1	1,2,3,4	3.3	0.0	0.0
2	1,2,7,21	3.5	6.1	6.6
3	1,2,16,17	2.4	8.1	8.5

lowest lying isomer, **4**, and the highest lying isomer, **3**, by 4.0 and 8.5 kcal mol^{-1}, respectively, at the HF/6-31G* level.[10]

The reaction of BH_3·THF (1 equiv) with $C_{60}H_2$ in toluene afforded a complex mixture of the six products (NMR data listed in Table 2), with 1,2,3,4-$C_{60}H_4$ (**1**), accounting for approximately 50% of the total $C_{60}H_4$ product. The chromatogram of the reaction mixture after chromatographic removal of most of the starting material revealed, however, only the three products shown in Figure 2. Isomer **1** (= C) is the last compound to elute on a Buckyclutcher I stationary phase[11] with a toluene/hexane (1/1) isocratic mobile phase, and is well-separated from the other $C_{60}H_4$ products. The total yield of $C_{60}H_4$ products based on uncorrected peak areas is less than 2% from C_{60}, but is 10% when $C_{60}H_2$ is used as a starting material. A mixture of $C_{60}H_4$ isomers A and B isomerizes on a Pt-contaminated Buckyclutcher I column to **1** (= C). This suggests that **1** is the thermodynamically most stable isomer, a result consistent with ab initio calculations.

Table 2. ^{1}H NMR data (400 MHz, [D$_8$]toluene, 25 °C, TMS, unless otherwise noted), structural assignments, and percent composition of the mixture for the $C_{60}H_4$ products observed by hydroboration of $C_{60}H_2$ in toluene.

Product	Spectroscopic data	Isomer	Percentage [%]	Isolable [a]
A	δ = 5.55 (AB quartet, $\Delta\delta$ = 0.18, ^3J(H,H) = 15.8 Hz)	unknown	20	yes
B	δ = 5.36 (2H, s) δ = 5.05 (AB quartet, $\Delta\delta$ = 0.24, ^3J(H,H) = 15.5 Hz)	**4**	20	yes
C	δ = 5.03 (AA'BB', $\Delta\delta$ = 0.75, ^3J(AB) = 14.1 ± 0.5, ^3J(BB') = 9.8 ± 0.5, ^4J(AB') = − 0.2 ± 0.5, ^5J(AA') = 1.7 ± 0.2 Hz)	**1**	50	yes
D	δ = 5.85 (AB quartet, 200 MHz, $\Delta\delta$ = 0.15, ^3J(H,H) = 15.5 Hz)	unknown	7	no
E	δ = 5.59 (AB quartet, 200 MHz, $\Delta\delta$ = 0.15, ^3J(H,H) = 16.3 Hz)	unknown	2	no
F	δ = 6.33 (s, 200 MHz)	**8**	1	no

[a] Nonisolable products either isomerize or decompose upon separation.

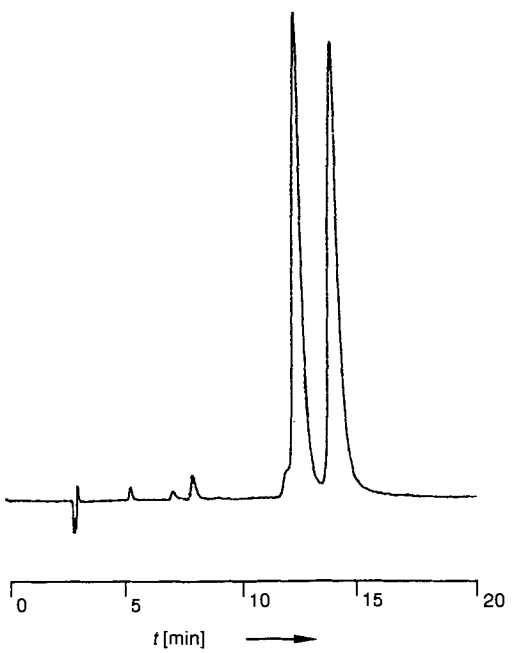

Fig. 2. Chromatogram of the product mixture resulting from the reaction of BH_3 with $C_{60}H_2$, detected at 340 nm, pre-purified to remove most starting materials (Buckyclutcher I, 10 mm × 25 cm column with hexane/toluene (1/1), flow rate 4.5 mL min^{-1}). Compound (elution time [min]): solvent spike (3.05), C_{60} (5.24), C_{70} (7.07), $C_{60}H_2$ (7.96), shoulder of product E followed by a mixture of products A and B (12.44), C (= **1**) (13.97). Products A and B were separated by using 18:82 CH_2Cl_2:hexane as the eluent *after* removal of **1**.

The 400 MHz ^{1}H NMR spectrum of **1** in [D$_8$]toluene shows an AA'BB' spin system centered at δ = 5.03 (Fig. 3a). Simulation of this spectrum led to the spectrum shown in Figure 3b, and the high quality of agreement between the two spectra provides strong evidence of the product's structure. The parameters used to simulate the spectrum are $\Delta\delta$ = 300 Hz, $^3J_{AB}$ = 14.1 ± 0.5, $^3J_{BB'}$ = 9.8 ± 0.5, $^4J_{AB'}$ = − 0.2 ± 0.5, and $^5J_{AA'}$ = 1.7 ± 0.2 Hz. Variations in these values beyond the stated error limits led to significant differences between the observed and simulated spectra.

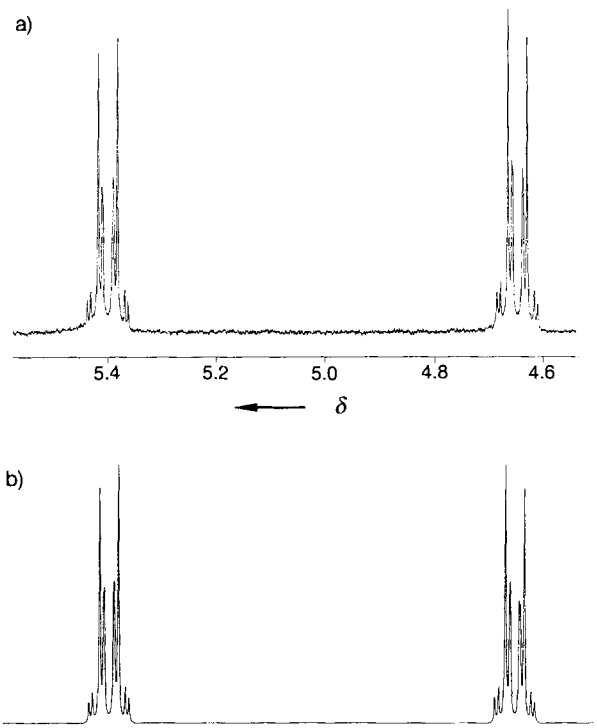

Fig. 3. a) ^{1}H NMR spectrum of **1** (400 MHz, [D$_8$]toluene, 25 °C, TMS). b) Simulated spectrum. A line broadening of 0.1 Hz was used. Coupling constants see Table 2. The related coupling constant for $C_{60}H_2$ is ^3J(A,B) = 15.7 Hz (6-6 bond).

The AB coupling between the hydrogen atoms across the 6-6 bond is 14.1 Hz, similar to the value of 15.7 Hz observed in $C_{60}H_2$. The BB' coupling between the hydrogen atoms across the 6-5 bond is 9.8 Hz. The reason for this smaller coupling constant is unclear, but the value is not unreasonable for *cis*, vicinal H_2 substitution. The AB' coupling constant at −0.2 Hz is near zero, again consistent with the assigned geometry between the two C–H bonds.[12] Finally, the terminal AA' hydrogen atoms are coupled through the double bond in the six-membered ring giving rise to a small, positive coupling constant of 1.7 ± 0.2 Hz. The observed spectrum is confidently assigned to the 1,2,3,4 isomer **1**. The only other possible structure that could lead to such a spectrum is the 1,6,7,8 isomer which would result

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0707-0787 $ 10.00+.25/0

from 1,2 H_2 additions to adjoining 6-5 bonds. The formation of this isomer is, however, unlikely because isolated X_2 addition to 6-5 bonds of C_{60} has never been observed and is calculated to be at least 20 kcal mol^{-1} less stable than addition to 6-6 bonds at all levels of theory.

The coupling constants observed in the ^{1}H NMR spectra of the isomers A–E are all consistent with 1,2 addition to 6-6 bonds. The assignment of product F with a resonance signal at $\delta = 6.33$ to **8** is tentative, but is consistent with the exceptionally low-field resonance signal of $C_{60}H_2$ at $\delta = 5.93$. All other resonance signals observed for $C_{60}H_4$ products are upfield from that observed for $C_{60}H_2$. The structure of B can be unambiguously assigned to **4**, but the structures of the products A, D, and E are consistent with any of the remaining five isomers. We plan to assign structures to these isomers through crystallographic analysis.

Experimental Procedure

To a solution of $C_{60}H_2$ [1] (10 mg, 14 μmol) in toluene (15 mL) was added BH_3 (14 μL, 1.0 M solution in THF) at 0 °C under argon. The mixture was stirred at 0 °C for 45 min, warmed to room temperature for 45 min, and quenched by addition of water (1.0 mL). The organic layer was separated, dried over $MgSO_4$, and the $C_{60}H_4$ fraction isolated by preparative chromatography on a Buckyclutcher I column (10 mm × 25.0 cm) with a toluene/hexane (1/1) mobile phase. The total yield of $C_{60}H_4$ products is 10%, less than the 20–30% yields of $C_{60}H_2$ that are obtained from C_{60} under similar conditions ($C_{60}H_4$ isomers were first obtained as side products in <1% yields in this reaction). Positive-ion FAB MS (for the mixture): observed, 724.0309, calculated 724.0313 (no evidence for $C_{60}H_6$). From this mixture three $C_{60}H_4$ isomers were separated (Table 2). The UV/VIS spectrum of C (= **1**) in toluene/hexane (1/1) tails from 290 nm with a shoulder at 342 nm and a distinct absorption at 442 nm, both of which may be diagnostic for this substitution pattern. Positive-ion FAB MS: observed, 724.0309; calculated, 724.0313. Similar for A, distinct maximum at 325 nm and weak absorption maxima at 410 and 430 nm. For B, distinct maxima are absent, shoulders at 330, 380, 425, and a broad feature at 475 nm are observed. Isolation of the materials is limited to concentrated solutions (1 mg mL^{-1}) which are handled routinely in light and air. Such solutions may be stored indefinitely at −20 °C, but removal of the solvent leads to solids which do not completely redissolve. Products A and B that were previously separated from C (**1**) were eluted on a Buckyclutcher I column that contained an unusually high amount of residual platinum from the preparation of the Buckyclutcher ligand. Repeated elutions resulted in conversion of A and B to C.

Liquid Sulfur Dioxide as a Lewis-Acidic Solvent for the Alkylation and Alkoxyalkylation of Allylsilanes**

Herbert Mayr,* Gorden Gorath, and Bernhard Bauer

The use of metal halides as Lewis acids for Friedel–Crafts and related reactions is increasingly criticized because of the nonrecyclable salts produced in the usual aqueous workup. In particular, in reactions which require stoichiometric quantities of Lewis acid, this presents an ecological and financial problem. Sulfur dioxide (SO_2) has a high ionizing power because it can act as an electron pair acceptor. Although this property has been known for a long time,[1] it has rarely been used to replace metal halides in electrophilic alkylations or acylations.[2]

Using liquid SO_2 as solvent makes an aqueous workup superfluous and should enable the recondensed SO_2 to be recycled. For these reasons we decided to study its use as a solvent for the alkylation and alkoxyalkylation of allylsilanes. In this case, reactions with acetals are of particular interest because they generally require stoichiometric quantities of $TiCl_4$[1,3] but examples with catalytic amounts of acids have been reported.[4]

If acetals **1a–1e** are treated with 1.2 equivalents of allyltrimethylsilane (**2a**) in liquid SO_2 at −60 °C the homoallyl ethers **3a–3e** are obtained in good yield (Table 1). The reaction of **1e** with **2a** shows that the reaction can also be carried out at room temperature. Due to the low vapor pressure of SO_2 at 20 °C (about 3 bar at 20 °C),[5a] thick-walled glass vessels with a screw-top were employed,[5b] which were cooled for filling and emptying and covered with a protective metal casing during the reaction. Based on the high yields for these reactions and on earlier investigations on the electrophilicity of acetals,[6] it is expected that all ordinary acetals will react under these conditions.

Table 1 shows that alkylations with the corresponding chlorides **1f–i** were also successful. The failure of 1-chloro-1-phenylethane and *tert*-butyl chloride to react under these conditions suggests that only alkyl chlorides with high S_N1 reactivities ($k_1 > 10^{-6}$ s^{-1} in EtOH, 25 °C) are reactive under these conditions.[7]

[a] Reaction times have not been optimized. [b] With a trace of I_2 present.

As shown in Table 2, other allylsilanes also react with benzaldehyde dimethyl acetal in SO_2. However, it is unclear why prenyltrimethylsilane **2c** reacts significantly more slowly than would be expected from its high nucleophilicity observed in other reactions.[8] Formation of allylsilane/SO_2 copolymers[9] was occassionally observed for which a radical chain process or an ionic mechanism could be envisaged. In the reaction of **1e** with **2a** the formation of copolymers could be suppressed by the addition of a tiny crystal of I_2, indicating the operation of a radical mechanism for copolymerization.

Table 2. Reactions of benzaldehyde dimethyl acetal (**1a**) with allylsilanes in liquid SO_2.

Reactant		Product		T[°C]	t[h] [a]	Yield [%]
	**2b**		**4b**	−60	24	85
	**2c**		**4c**	20	452	56
	**2d**		**4d**	−60	23	41

[a] Reaction times have not been optimized.

Preliminary experiments of the alkylation and alkoxyalkylation of silylenol ethers and/or electron-rich arenes were also successful. It can therefore be assumed that the solvent SO_2 could replace metal halides as Lewis acids in numerous reactions. Addition of catalytic quantities of 2,6-di-*tert*-butyl-4-methylpyridine inhibits product formation, suggesting that the ionization is catalyzed by traces of acid (possibly H_2SO_3).

Experimental Procedure

Dry SO_2 (10 mL) was condensed in a Schlenk tube at −40 °C under a nitrogen atmosphere. Benzaldehyde dimethyl acetal (1.31 g, 8.61 mmol) and allyltrimethylsilane (1.18 g, 10.3 mmol) were then dissolved with stirring and the reaction mixture allowed to stand at −60 °C. After 18 h the SO_2 was allowed to evaporate at room temperature and the residue was distilled; yield: 1.34 g (96%) *rac*-4-methoxy-4-phenyl-1-butene (**3a**).

From Aluminum Compounds to Drug Design and Action

Coordination Chemistry of Aluminum. Edited by *G. H. Robinson*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1993. XIII, 234 pp., hardcover DM 189.00, $ 115.00.—ISBN 3-527-28149-5/1-56081-059-9

This book is mainly concerned with the properties and structures of organoaluminum compounds, and constitutes an important survey of this highly topical field of research, which has grown at a remarkable rate in the last few years.

In the first chapter A. Haaland classifies the different types of interactions between atoms of Main Groups 5 and 6 and aluminum, and thereby succeeds in bringing order to the confusing variety of examples which show a remarkably wide range of bond lengths. The division into covalent and dative bonding types or mixtures of the two seems rather arbitrary at first sight, but leads to a very simple and graphic picture which, except in very few cases, affords a description of even quite small effects.

In the second chapter G. H. Robinson describes the fascinating variety of structural types that are now recognized in aluminum–nitrogen chemistry. It has been found that reacting trialkylaluminum compounds with simple amines or chelating amines yields species ranging from monomeric aluminum amides to clusters with up to eight Al–N units. In the next chapter, deviating somewhat from the mainly organo-element orientated content of the book, C. Orvig reports on the coordination chemistry of aluminum in aqueous solutions, a research topic that has been badly neglected in the current euphoria about the chemistry of Main Group 3 elements. As the author impressively shows, very interesting results continue to emerge in this area; as expected, kinetic and thermodynamic data provide the main focus of interest. In addition this relates to the highly topical theme of the transport mechanisms of aluminum ions in the human body, which are being intensively studied in connection with Alzheimer's disease.

A. R. Barron gives a very good review of compounds containing aluminum in unusual oxidation states, which were obtained in pure forms stable at room temperature only within the last few years. More remarkably, the author also reports in detail here on unstable species that can only be prepared and studied in a solid matrix, such as those formed by aluminum with CO or C_2H_4. For completeness it would have been useful to also include here a short description of species prepared and studied under extreme conditions in the gas phase. After treating compounds containing Al–Al bonds and clusters of aluminum atoms, which have only recently been isolated and characterized by crystal structure analysis, Barron moves on to paramagnetic species. Here it is found in many cases that the unpaired electrons are centered on the ligands and the aluminum atom is actually in the normal trivalent form. Here this referee takes the opportunity to suggest a minor correction. It is stated in the article, on the basis of results found for $R_2Al-AlR_2$ [where $R = CH(SiMe_3)_2$], that a criterion for the presence of an isolated Al–Al bond is a downfield shift of the α-carbon resonance in the ^{13}C NMR spectrum. This is certainly not the case, since all aluminum compounds with a three-coordinated aluminum atom and a bis(trimethylsilyl)-methyl group show a similar downfield shift.

In the remaining two chapters J. P. Oliver et al. and J. L. Atwood contribute detailed and very lucid reports on alkoxides and thiolates and on cationic and anionic organoaluminum compounds respectively. The latter chapter includes a very detailed treatment of the formation of clathrates from anionic binuclear aluminum compounds. However, cationic species are treated somewhat too briefly; although these have been known for a long time, not all have been studied by crystal structure analysis. In particular I feel that there should have been a mention of the reaction of $AlCl_3$ with pyridine, which was reported in detail (including the crystal structure of the product) as long ago as 1982.

To summarize, this easily readable book gives an excellent survey of the subject. At the cost of some loss of tidiness and clarity, it could perhaps have been enlarged to include compounds of aluminum with, for example, phosphorus, arsenic, transition metals, or alkyl groups. As someone already familiar with the subject, I found the book very enjoyable to read, leaving aside the inevitable errors. However, the book is suitable not only for specialists in the chemistry of Main Group 3 elements but also as a work of reference for more general use, as it comprehensively covers the literature in this rapidly advancing field up to 1991, with detailed and clear presentation of results, often including tables and figures.

Biosensors. Theory and Applications. By *D. G. Buerk*. Technomic, Basel, 1993. 232 pp., hardcover SwFr 187.00.—ISBN 0-87762-975-7

The title of this book leads one to expect a survey bringing together the main principles and applications of biosensors. Such a book is especially welcome in view of the wealth of literature on biosensors that has already appeared, and the progressive introduction of yet more novel physical principles into the development of biosensors. A look at the list of contents reinforces this expectation. After an introduction there are chapters on electrochemical methods and transducers, the incorporation of these into enzyme electrodes, biosensors based on optical and other principles, immunosensors, and sensors that use whole cells. The book ends with a chapter on likely future developments. Thus it appears at first glance that

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

the author has succeeded in providing an account of all the most important biosensor principles and their present and potential applications.

However, on looking through the book in more detail one discovers that many of the expectations are not fulfilled. Both the structure of the book and its detailed contents invite criticism. It consists of ten chapters, each of which is divided into sections varying in number from seven to thirteen. These are further divided into as many as nineteen subsections. Some of these consist of fewer than ten lines of text, while in other cases the first such subsection is not followed by a second one. This impression of a not always appropriate arrangement of the material is further reinforced on noting that, for example, there are three sections on glucose sensors (Sections 4.3, 4.4, and 4.5) which all employ the same principle but are applied to different problems. These are followed by sections on sensors for urea (Sect. 4.6) and for alcohols (Sect. 4.7), on multienzyme sensors (Sect. 4.9), and on carbon electrodes for enzymes (Sect. 4.10), despite the fact that the exclusion of these sensors from earlier sections was not mentioned, and without referring to the existence of glucose and alcohol sensors based on carbon electrodes. Similar inconsistencies can be found in other chapters. A clearer way of arranging the subject matter, and its inclusion in full in the list of contents, would have helped the reader considerably.

Furthermore, of the eight chapters that describe the current state of progress in biosensor developments, four are concerned exclusively with electrochemical principles and enzyme electrodes. Since immunosensors and sensors using whole cells also employ electrochemical methods, this means that these topics occupy more than half the book. Consequently the author fails to do justice to other techniques, in particular to the optical methods that are now so important in immunosensors. Thus the main emphasis in the book is on measurements using electrochemical principles. The historical survey in the introduction begins with the development of the acid–base theory, and mentions various fundamental developments in electrochemistry, whereas other detection methods are ignored. The chapters that follow contain explanations of some of the theoretical fundamentals; sometimes these are so brief that non-electrochemists will have difficulty in understanding them in detail, and in any case they are not essential for understanding biosensors. The applications described nearly all belong to the medical field; this emphasis is carried to such lengths that, for example, in relation to oxyhemoglobin and oximetry, the author describes methods that may well be important for blood investigations, but have not so far proved useful in biosensor technology. On the other hand, some important aspects of biosensors are not covered. Topics that are only treated very briefly or omitted altogether include the use of mediators as artificial electron acceptors, successful experiments on direct electron transfer from enzymes to electrodes, fabrication techniques not based on thin film technology, and optical methods such as interferometry.

Each chapter ends with a list of references, including some that are very recent, although regrettably the overwhelming emphasis is on work in the USA. Few citations of work by Japanese or European groups are included, even for groups that have developed sensors for medical applications. Moreover, there are no references to any commercial enzyme analyzers or sensors other than those made by Yellow Springs Instruments.

To summarize, the high expectations raised by the book's title fail to materialize. An indication in the title that the subject matter is restricted to medical applications and electrochemical methods would have given a better idea of the author's research interests, and would have served these topics more effectively, as they could then have been given the more detailed treatment promised by the title.

The Organic Chemistry of Drug Design and Drug Action. By *R. B. Silverman.* Academic Press, New York, 1992. XIV, 422 pp., hardcover $ 55.00.—ISBN 0-12-643 730-0

It was the author's expressed intent in writing this book to create a text through which "a student or a scientist interested in entering the field of medicinal chemistry" would learn to look at the drug development process as basically a problem in mechanistic organic chemistry. In this endeavor, Dr. Silverman has been successful and then some. A range of topics is covered and explored in a reasonable level of detail in a text of 422 pages. Specifically, there are chapters on the general principles of receptors and drug–receptor complexes, enzymes and enzyme inhibition, and DNA and drug–DNA interactions. The references are comprehensive enough for the book to serve to jumpstart a literature search in the areas that are included, although the cited literature cuts off in 1989. Interesting historical background information is included in many chapters, which enhances the reader's appreciation of why the drug discovery process evolved the way it did in certain areas. The author has also included chapters which give a reasonable overview of how a typical prototype compound is discovered, and of concepts such as bioisosterism and QSAR as they relate to structure optimization. However, there is sufficient mathematics in the discussion of physicochemical parameters to slake the typical medicinal chemist's thirst for such. The chapter on drug metabolism may perhaps overemphasize the importance of this area relative to absorption, tissue distribution, and excretion phenomena as they relate to a medicinal chemist's concerns about a compound's pharmacokinetic and pharmacodynamic behavior. However, in keeping with the book's purpose, metabolism is better understood and more easily explained in terms of the principles of organic chemistry than these other (equally important) aspects of pharmaceutical research and development. The discussion of prodrugs is an especially handy reference for browsing.

"The Organic Chemistry of Drug Design and Drug Action" is very well written, nicely indexed, and generally free of typographical errors. Naturally, since it was conceived as a text for an introductory course in medicinal chemistry, there are numerous subjects which are either treated very lightly or not at all. For the experienced medicinal chemist, this book will never replace texts such as Goodman and Gilman's "The Pharmacological Basis of Therapeutics" as a resource. Nevertheless, I believe that this book is so readable that it will prove to be a welcome addition to the library of any medicinal chemist, regardless of experience.

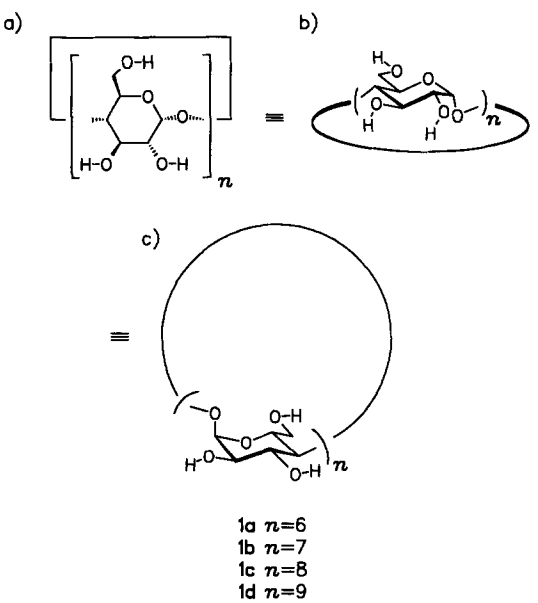
Cyclodextrins as Building Blocks for Supramolecular Structures and Functional Units

Gerhard Wenz*



Cyclodextrins are frequently used as building blocks, because they can be linked both covalently and noncovalently with specificity. Thus one, two, three, seven, fourteen, eighteen, or twenty substituents have been linked to one β-cyclodextrin molecule in a regioselective manner. Furthermore, cyclodextrins may serve as organic host molecules. Their internal cavity is able to accommodate one or two guest molecules. Conversely, suitable guest molecules can be used to thread one, two, or many (one hundred or more) cyclodextrin rings. The resulting supramolecular structures are often formed in solution, which allows characterization by high-resolution spectroscopic methods. Chemical conversion of these structures provides molecular architectures such as catenanes, rotaxanes, polyrotaxanes, and tubes, which are not readily prepared by other methods. The particular properties of cyclodextrins can also be employed, for example, for the chromatographic separation of complex mixtures of substances, even racemates, by molecular recognition. Cyclodextrins and their derivatives have been found to be remarkably active catalysts as well. Finally, since cyclodextrins can favorably influence the release of drugs, many new applications will certainly be developed in the near future.

1. Introduction

Cyclic oligomers of amylose are referred to as cyclooligoamyloses, cyclomaltooligosaccharides, or cyclodextrins (α-, β-, γ-, and δ-cyclodextrin **1a**, **1b**, **1c**, and **1d**, respectively; Scheme 1). Since their discovery by Villiers[1] in 1891, interest in these cyclic carbohydrates has increased steadily. Why?

Cyclodextrins are of interest for synthetic chemists because they are chemically stable and can be modified in a regioselective manner. Cyclodextrins are of great importance for supramolecular chemistry, since they form a homologous series of water-soluble and chiral host molecules which can be used as models for studying weak interactions. In addition, their low price provides motivation for the discovery of new applications. Thus cyclodextrins are used for the solubilization and encapsulation of drugs, perfumes, and flavorings. Their toxicity is low, and they are biodegradable. Finally, they are of interest because they are obtained from a renewable resource, starch.[2]

The last review on cyclodextrins in *Angewandte Chemie* was written by Wolfram Saenger in 1979 and entitled "Cyclodextrin Inclusion Compounds in Research and Industry".[3] Since then many (about 7000[4]) publications have appeared in this field, some of them very exciting, and it appears worthwhile to survey this field once more.[5]

2. Synthesis, Structure, and Physical Properties of the Cyclodextrins

The enzymatic degradation of starch affords a mixture of cyclic and linear maltooligosaccharides. The enzymes used are cyclodextrin glucosyl transferases (CGTases) of bacterial origin, for example from *Bacillus macerans* and *alcaliphilic bacilli*.[6] They

Hertzstrasse 16, D-76187 Karlsruhe (FRG)
Telefax: Int. code + (721)608-4421

are in general unspecific with respect to ring size.[7] The isolation of a particular cyclodextrin is carried out by the addition of selective precipitating agents.[6] Since the various cyclodextrins are interconverted by CGTases, the final product is the one that is continuously removed from the reaction mixture by selective precipitation. Thus cyclodextrins can be obtained in remarkable yields and high homologous purity (ca. 99%) (Table 1).[7, 8] Owing to the biological origin of cyclodextrins, only dextrorotatory enantiomers are formed. The levorotatory enantiomers could only be obtained by synthetic procedures, but at present an economical total synthesis does not appear feasible. D-**1a** and D-**1c** have been obtained from D-maltose in multistep procedures with overall yields of $\leq 0.3\%$.[9]

Table 1. Synthesis of cyclodextrins by enzymatic degradation of starch.

Cyclodextrin	Precipitating agent	Yield [%]	Ref.
1a	1-decanol	40	[8b]
1b	toluene	50–60	[8a]
1c	cyclohexadec-8-en-1-one	40–50	[7]

Crystalline cyclodextrins bind 6–13 wt% water, depending on ring size. The structures of **1a**·$6H_2O$,[10] **1a**·$7.57H_2O$,[11] **1b**·$12H_2O$,[12] **1c**·$13.3H_2O$,[13] and **1d**·$13.75H_2O$[14] have been determined by X-ray and neutron diffraction. These structures show that a cyclodextrin molecule resembles a hollow truncated cone (torus) and has approximate C_n symmetry (Scheme 2).

Scheme 2. Schematic representation of the shape of a cyclodextrin molecule. Two halves of two opposite glucose units are shown in cross section.

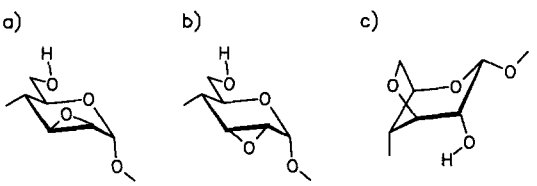
The primary hydroxyl groups are located on the narrower side of the torus and the secondary hydroxyl groups on the broader side. Because of the conical shape of the cyclodextrins and deviations from ideal C_n symmetry, their dimensions can be obtained only to within roughly ± 0.3 Å. The internal diameter increases with the number of glucose units (**1a**: 4.9 Å, **1b**: 6.2 Å, **1c**: 7.9 Å), while the height remains constant at 7.9 Å.[3, 15] All the glucopyranoside building blocks are relatively rigid and exist in a $^4C_1$ chair conformation. The secondary hydroxyl groups OH(2) and OH(3) are in equatorial positions; OH(2) groups point in towards the cavity and OH(3) groups point outwards. Since the torus bears twice as many hydroxyl groups on one side as on the other, the dipole moment is relatively large (calculated: 10–15 D,[16] found: ca. 5 D[17]) and directed along the C_n axis.

Cyclodextrins are poorly to moderately soluble in water,[18] methanol, and ethanol, and readily soluble in strongly polar aprotic solvents like dimethyl sulfoxide (DMSO), dimethylformamide (DMF), *N*,*N*-dimethylacetamide, and pyridine[19] and mixtures of these.[20] The shape of cyclodextrin molecules can be approximated by means of molecular dynamics simulations.[21] Although the torus is stabilized by intramolecular hydrogen bonds, it is still flexible enough to permit considerable deviations from regular toroidal shape.[21] However, the time-averaged structure has C_n symmetry, such that, for example, all the glucose building blocks are equivalent by ^1H and ^{13}C NMR spectroscopy.[22] Complete rotation of a glucose unit about the C(1)-O-C(4′) bonds is not possible for steric reasons. Thus protons H(3) and H(5) are always situated within the torus, whereas protons H(1), H(2), and H(4) always point outwards.

3. Synthesis of Cyclodextrin Derivatives

Cyclodextrins are derivatized in order to vary their solubility behavior, to modify their complexation properties, and to introduce groups with certain specific (e.g. catalytic) functions.

3.1. Survey of Possible Reactions



Since cyclodextrins are polyfunctional, they can undergo a wide variety of reactions;[23] these may involve cleavage of either O–H, C–O, C–H, or C–C bonds.

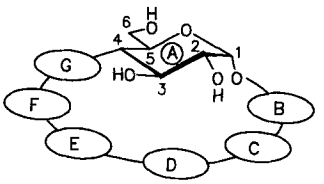
The reaction type most frequently studied is electrophilic attack at the OH groups. Reactions of **1** with alkyl halides,[24] epoxides,[25] acyl derivatives,[24a, 26] isocyanates,[26b] and inorganic acid derivatives such as sulfonic acid chlorides,[27] phosphoric acid chlorides,[28] phosphonic acid chlorides,[29] silyl chlorides,[30] and nitric acid[31] lead to cyclodextrin ethers and esters.

Gerhard Wenz was born in 1953 in Mainz, Germany, and studied chemistry from 1972 to 1979 at the Universities of Mainz and Freiburg. He received his Ph.D. in 1984 for research with G. Wegner in Freiburg on the polymerization of diacetylenes. He then spent a year as a reseach assistant at the Hermann-Staudinger-Institut, Freiburg, and studied discotic polymeric liquid crystals. During a subsequent one-year postdoctoral stay with D. J. Cram at the University of California, Los Angeles, he worked on the synthesis of a chymotrypsin model. In 1986 he moved to the Max-Planck-Institut für Polymerforschung in Mainz. In 1993 he completed his habilitation in organic chemistry at the University of Mainz and accepted a position as Professor of Macromolecular Chemistry at the University of Karlsruhe. His research focuses on the supramolecular chemistry of polymers and carbohydrates.

The nucleophilic cleavage of a C–OH bond requires activation of the oxygen atom by an electron-withdrawing group. Thus the reactions of cyclodextrin-6-*O*-sulfonates with nucleophiles such as azide ions,[32] halide ions,[33] thiols,[34] thiourea,[34b] and amines[35] generally afford the corresponding 6-deoxy derivatives.[36] 6-Azido-6-deoxycyclodextrins can be reduced to the preparatively important 6-amino-6-deoxycyclodextrins.[35, 37] The attack of imidazole on a β-cyclodextrin-2-*O*-sulfonate affords the 2-(1-imidazolyl)-deoxy-β-cyclodextrin.[38] This substitution occurs with retention, presumably due to the neighboring group effect of OH(3). In contrast, the attack of aqueous bases on cyclodextrin-2-*O*-sulfonates leads to an *intra*molecular nucleophilic substitution by OH(3) to give 2,3-anhydrocyclodextrins with *manno* configuration (Scheme 3a).[27b, 39] In analogy,

Scheme 3. a) 2,3-*manno*-, b) 2,3-*allo*-, c) 3,6-anhydrocyclodextrins.

the intramolecular substitution of sulfonate groups in position 3 by OH(2) leads to 2,3-anhydrocyclodextrins with *allo* configuration (Scheme 3b).[39c, 40] The intramolecular nucleophilic attack of OH(3) on 6-*O*-sulfonates[41] and 6-deoxyiodides[42] leads to the relatively stable 3,6-anhydrocyclodextrins (Scheme 3c). Nucleophilic attack on 2,3-*manno*-anhydrocyclodextrins opens the epoxide ring with formation of an allose unit substituted in the 3-position.[43]



Electrophilic attack at a C-O-C bond leads to decomposition of the cyclodextrin molecule. Cyclodextrins are, however, remarkably stable towards aqueous acids; for example, the half-life of **1b** in 1.15 M HCl at 80 °C is 1.6 h.[44] On the other hand, electrophilic attack by Lewis acids under aprotic conditions in the presence of a reducing agent (e.g. $BF_3 \cdot Et_2O$/triethylsilane or trimethylsilyl triflate/triethylsilane) affords smooth cleavage of the C(1)-O-C(4) bonds without affecting the glucose units and their substituents. This method is therefore used for the analytical determination of the distribution of substituents in cyclodextrin derivatives.[45] Alternatively, the C(1)–O(5) bonds can be cleaved selectively by 9-borabicyclo[3.3.1]nonyl trifluoromethanesulfonate/ethyldiborane.[46]

The H atoms are exchanged on Raney nickel for deuterium atoms (preferably in the 2-position).[47] Treatment with N_2O_4 or Pt/O_2 causes oxidation of CH_2(6) to a carboxylic acid group.[48]

All C(2)–C(3) bonds of **1b** are cleaved upon oxidation with periodate, which leads to the formation of a derivative of [35]crown-7.[49]

3.2. The Problem of Positional Isomerism

Many of the cyclodextrin derivatives described in the literature[23a] are complex mixtures of compounds, since a large number of positional isomers within the cyclodextrin framework are possible. The number of possible positions for a substituent is given by the number of possible positions at a glucose unit (three: 2, 3, and 6) multiplied by the number of different glucose units A, B, C... in the cyclodextrin (Scheme 4). The number of combinations increases rapidly with each further substituent. The number of possible positional isomers, N_i, is shown as a function of the number of substituents, N_s, in Figure 1. In the case of **1b**, N_i reaches a maximum (50388) for the substitution

Scheme 4. Labeling of the positions in the cyclodextrin molecule.

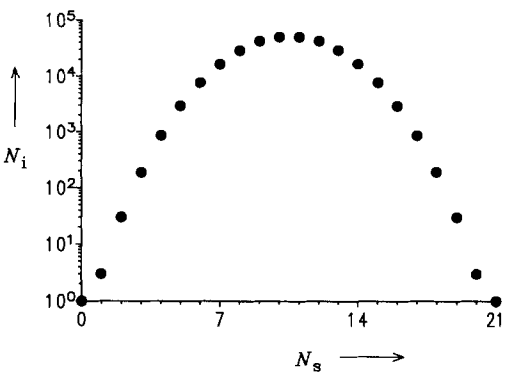


Fig. 1. Number of positional isomers, N_i, as a function of the number of identical substituents, N_s, in **1b**.

of half of the hydroxyl groups.[24a] Thus the probability of synthesizing and isolating a uniform product decreases with the increasing number of isomers. A further difficulty is that homologous derivatives with a lower or higher degree of substitution are also formed in addition to the product, and separation is required. Thus the synthesis of uniform cyclodextrin derivatives is a daunting task. Only since the advent of powerful analytical methods[45c] such as gas chromatography (after degradation),[45] high-pressure liquid chromatography,[50] mass spectrometry,[51] and high-resolution ^{13}C NMR spectroscopy has it become possible to obtain unequivocal proof of the uniformity of a reaction product. By using these methods several reaction products that had long been considered to be uniform were shown to be mixtures.[51, 52, 53]

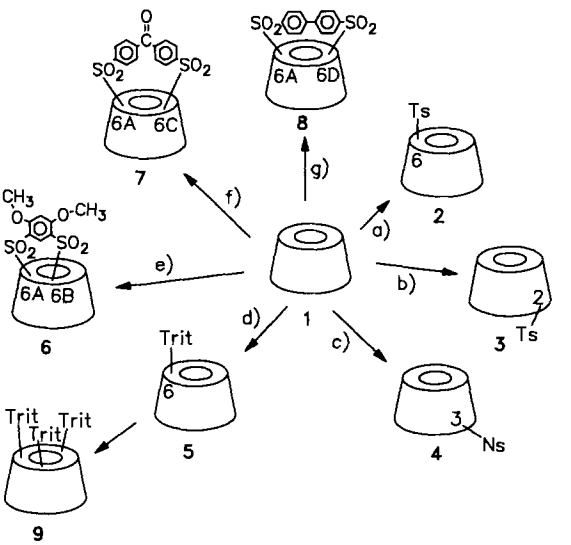
3.3. General Strategies for Regioselective Substitution

The synthesis of uniform cyclodextrin derivatives requires regioselective reagents, optimization of the reaction conditions, and good separability of the products. Bulky reagents react preferentially at the primary hydroxyl groups OH(6), since these are the most accessible. The secondary hydroxyl groups OH(2) have the highest acidity ($pK_a = 12.2$).[22c, 54] Under anhydrous conditions they can be selectively deprotonated and allowed to react with electrophilic reagents.[55] The secondary hydroxyl groups OH(3) are the least reactive and can be reacted selectively only after OH(2) and OH(6) have been blocked.[56]

The product distribution can be greatly influenced by the reaction conditions. Monosubstitution of a cyclodextrin is achieved by using less than one equivalent of the reagent, and its slow addition can also be advantageous.[57] The presence of a large excess of the reagent must be avoided when the uniform mono- or disubstitution of *all* glucose units in a cyclodextrin is required, since otherwise the reaction may go too far. The optimum reaction time is determined by carefully monitoring the reaction progress, for example by thin-layer chromatography[58] or high-pressure liquid chromatography. These reaction times are often not reproducible; this may be due to the undefined water content of the reaction mixture.[58]

The complete substitution of all hydroxyl groups requires drastic reaction conditions such as a large excess of the reagent, increased reaction temperature, and complete exclusion of water.[59]

Since mixtures of cyclodextrin derivatives are generally formed, chromatographic separation is typically required. Homologous derivatives can be separated only if the polarity of the substituent differs significantly from that of cyclodextrin. Thus the separation of derivatives with hydrophobic substituents (e.g. butyl,[58] benzoyl,[52] and tosyl[60]) is easier than that of derivatives with less hydrophobic substituents (e.g. hydroxypropyl[25b] and methyl[50a, 53]).



In the following sections we shall discuss methods for regioselective derivatization, classified according to the degree of substitution; we shall also distinguish between activating and blocking substituents.

3.4. Mono-, Di-, and Trisubstituted Cyclodextrins

A cyclodextrin bearing one, two, or three substituents gives extremely complex NMR spectra because of its low symmetry; these can be assigned only by means of multidimensional methods such as ^{1}H-^{1}H or ^{1}H-^{13}C COSY.[39b, 61]

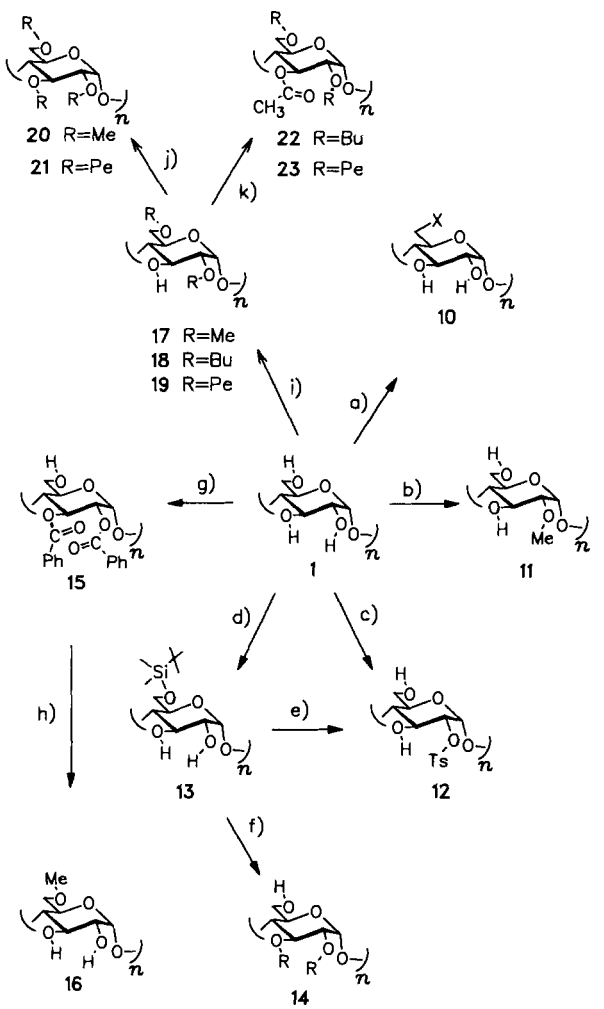
The most important cyclodextrins with *one* activating substituent (Scheme 5) are the cyclodextrin tosylates. The reaction of **1a**, **b** with tosyl chloride in pyridine affords the 6-*O*-tosylates **2a** and **2b** in 10–30% yield.[37, 60] (The ring sizes 6, 7, and 8 are denoted throughout the text by a, b, and c, respectively.) In contrast, esterification with 3-nitrophenyltosylate in DMF/water at pH 10 leads to the 2-*O*-tosylates **3a** and **3b**.[27a, 39b, 62] When **1a**, **b** is treated with tosyl chloride in aqueous NaOH,[27a] **3a** and **2b**[35] are obtained.[27a] Topochemical reaction control might be the case here. In other words, the reagent might be included in the cyclodextrin, and esterification would then occur preferentially within the inclusion compound. Therefore the orientation of the reagent in the cyclodextrin ring determines the position to be attacked. The reaction of dibutyltin oxide with **1** gives cyclic 2,3-*O*-stannates, which can be converted selectively (30% yield) with tosyl chloride into the 2-*O*-tosylates **3**.[63] The selective deprotonation of OH(2) in **1b** with NaH and subsequent reaction with tosyl chloride also leads to **3b**.[55] The 3-position of **1** can be activated by 2-naphthalenesulfonyl chloride in acetonitrile/water at pH 12 to furnish 3-*O*-(2-naphthalenesulfonates) **4a**,[40a] **4b**,[40b] and **4c**.[39c]

The etherification of **1a**, **b** with the sterically demanding trityl chloride leads to the singly blocked 6-*O*-tritylcyclodextrins

Scheme 5. Specific introduction of one, two, or three substituents to cyclodextrins. a) TsCl/Py [37,60], b) 3-nitrophenyltosylate/DMF/H_2O (pH 10) [27a,62], c) NsCl/MeCN/H_2O (pH 12) [39c,40,69b], d) TritCl/Py [37,64b,70], e) [67], f) and g) [66b], Ts = 4-toluenesulfonyl, Ns = 2-naphthalenesulfonyl, Trit = triphenylmethyl, Py = pyridine.

5a[37] and **5b**, respectively.[64] Similarly, **1b** undergoes regioselective reaction with *tert*-butyldimethylsilyl chloride at low temperatures to give 6-*O*-*tert*-butyldimethylsilyl-β-cyclodextrin.[65]

Disubstituted cyclodextrins are obtained most easily by bridging the cyclodextrin molecule with difunctional reagents. Thus Tabushi et al. allowed **1b** to react with arenedisulfonic acid chlorides; depending on the distance between the sulfonyl chloride groups, they obtained A,B-, A,C-, and A,D-disubstituted cyclodextrin sulfonates **6**, **7**, and **8**, respectively, with yields of up to 40%.[66] Such derivatives are referred to as capped cyclodextrins. The introduction of methoxy groups on the aryl residue can increase the stability of the disulfonates and thus facilitate their purification.[67] The reaction of cyclodextrins with monofunctional acid chlorides leads to mixtures of mono-, di-, and higher substituted cyclodextrins, which can be separated by preparative reversed-phase chromatography. Depending on the reaction conditions, the substituents can be directed to positions O(6),[68] O(2),[27b, 40] and O(3).[40b]



The synthesis and isolation of *trisubstituted* cyclodextrins is very difficult because of the large number of positional isomers and homologues possible. Tosylation of **1b** leads to 6^A,6^C,6^E-tri-*O*-tosyl-β-cyclodextrin in only 2.6% yield.[69] In contrast, tritylation of **1a** gives the 6^A,6^C,6^E-trityl derivative **9** in a respectable yield of 23%.[70] A remarkable alternative method should also be mentioned here: Cottaz and Driguez obtained 6^A,6^C,6^E-tri-*O*-methyl-α-cyclodextrin in 43% yield from enzymatic cyclotrimerization of 6-*O*-methylmaltose.[71]

3.5. Cyclodextrins with Uniform Mono-, Di-, and Trisubstituted Glucose Units

Since C_n symmetry is preserved if all the glucose units in cyclodextrin are substituted in the same way, these derivatives generally crystallize more easily and show simpler NMR spectra than the unsymmetrical derivatives.

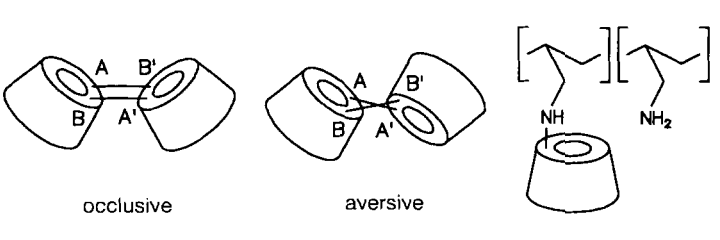
Complete tosylation of all primary hydroxyl groups is difficult; because of the increasing bulk of the cyclodextrin upon substitution, the first secondary hydroxyl groups may be attacked before the last primary hydroxyl groups have completed reaction.[41] Reactions that proceed via an intermediate with bulky substituents but lead to a final product with only small substituents are more favorable. Thus **1a** and **1b** were converted by triphenylphosphane/bromine (or iodine) into the per(6-deoxy-6-halo)-cyclodextrins **10a** and **10b** in 80 and 88% yield, respectively (Scheme 6).[42]

Selective deprotonation of all the hydroxyl groups OH(2) of **1b** with NaH and etherification with methyl iodide affords heptakis(2-*O*-methyl)-*β*-cyclodextrin **11b**.[55] Heptakis(2-*O*-tosyl)-*β*-cyclodextrin **12b** was obtained in an analogous manner.[55] All the hydroxyl groups in position 6 can be blocked by treatment with *tert*-butyldimethylsilyl chloride (formation of **13**).[30, 33, 65]

Scheme 6. Homogeneous, regioselective derivatization of all the glucose units of a cyclodextrin. a) PPh_3/X_2/DMF with X = Br, I [42], b) NaH/DMSO, MeI [55], c) NaH/DMSO, TsCl [55], d) TBDMSCl/Py [30,33,65], e) TsCl/DMAP/Py [73], f) NaH/RI/DMF (R = Me, Pe), Bu_4NF [33,74], PheCOCl/Py, *i*PrOK/*i*PrOH [24a], h) $CH_2N_2/CHCl_3$, KOH/EtOH [24a], i) $BaO/Ba(OH)_2 \cdot 8H_2O/R_2SO_4$/DMSO/DMF for R = Me [24a,75] Et [51b,76], Bz [56], otherwise NaOH/RBr/DMSO (R = Pr, Bu, Pe, Dodec) [58], j) RBr or RI/NaH/DMF [24b,77] or THF [59] (R = Me, Pe). k) Ac_2O/DMAP/Et_3N/CH_2Cl_2 [78a,c,e] or R'COCl/Py (R' = Ph, *t*Bu) [52,78b]. TBDMSCl = *tert*-butyldimethylsilyl chloride, Ts = 4-toluenesulfonyl, Bz = benzyl, Pr = propyl, Bu = butyl, Pe = pentyl, Dodec = dodecyl, Ph = phenyl, Py = pyridine, DMAP = 4-(dimethylamino)pyridine.

The remaining hydroxyl groups can be either selectively benzylated[72] or tosylated[73] at OH(2), or completely alkylated.[33, 74] The 2-*O*-tosylates **12** and the 2,3-di-*O*-alkylethers **14** are obtained after removal of the TBDMS groups.

Lehn et al. synthesized a cyclodextrin (**15**) blocked at all OH(2) and OH(3) positions by saponification of the more reactive ester groups at position 6 from per(2,3,6-tri-*O*-benzoyl)cyclodextrin.[24a] Methylation of the OH(6) hydroxyl groups with diazomethane and subsequent cleavage of the benzoyl groups furnishes the per(6-*O*-methyl)cyclodextrins **16**.[24a]



Alkylation of all OH(2) and OH(6) groups is carried out by treating **1** with alkyl halides or alkyl sulfates and a hydroxide. Thus with dimethyl sulfate, $Ba(OH)_2 \cdot 8H_2O$, and BaO in DMF/DMSO the per(2,6-di-*O*-methyl)cyclodextrins **17** are formed;[24, 75] with diethyl sulfate the analogous ethyl derivatives are obtained.[51, 76] The introduction of longer alkyl chains in positions 2 and 6 is possible by treating **1** with primary alkyl bromides and NaOH in DMSO (**18**, **19**).[58] Whereas both methylation and ethylation yield mixtures of isomers and homologous substitution products which are difficult to separate,[50, 53] the longer chain per(2,6-di-*O*-alkyl) derivatives (in particular per(2,6-di-*O*-butyl)cyclodextrins **18**) can be obtained readily in pure form. In contrast to **1** the latter are soluble in most organic solvents, even in hexane, but are completely insoluble in water.[58]

Per(2,6-di-*O*-alkyl)cyclodextrins can be completely alkylated in a subsequent step with strict exclusion of water to give per-(2,3,6-tri-*O*-alkyl)cyclodextrins (e.g. permethyl and perpentyl derivatives **20** and **21**).[24b, 59, 77] Benzyl groups serve as protecting groups for OH(2) and OH(6) in the synthesis of per(3-*O*-methyl)cyclodextrins.[56] Acylation of per(2,6-di-*O*-alkyl)cyclodextrins leads to per(3-*O*-acyl-2,6-di-*O*-alkyl)cyclodextrins such as **22** and **23**.[52, 78]

3.6. Cyclodextrin-Containing Oligomers and Polymers

Reactions of monofunctional cyclodextrin derivatives (e.g. **2a**, **b**) with difunctional nucleophiles (*α*,*ω*-diamines, *α*,*ω*-disulfides, *α*,*ω*-dicarboxylic acids) lead to singly bridged cyclodextrin dimers.[79] Breslow et al. obtained the doubly bridged cyclodextrin dimer **24** from $6^A,6^B$-diiodo-*β*-cyclodextrin and a difunctional nucleophile. Dimer **24** exists in two stable conformations: in the occlusive conformation the two rings are inclined towards each other, in the aversive conformation they tilt away from each other.[80]

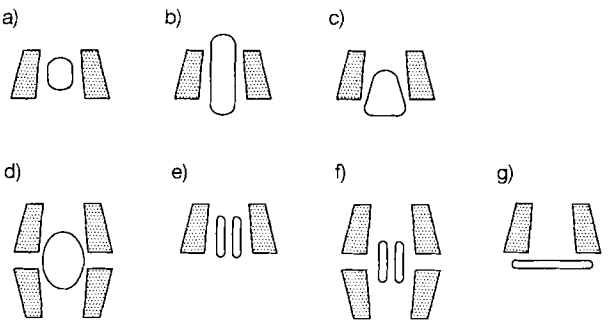
For the synthesis of linear cyclodextrin polymers, polyallylamine was treated with **2b** to give **25**;[81] the radical polymerization of vinyl-substituted cyclodextrins also provided linear cyclodextrin polymers.[82]

24 **25**

3.7. Statistically Substituted Monomeric and Polymeric Cyclodextrins for Technical Applications

There are many reasons for synthesizing uniform cyclodextrin derivatives. The procedures can be reproduced more consistently, and the products often crystallize better and are easier to identify than mixtures. However, statistical mixtures of substituted cyclodextrins also have advantages: they can be prepared much more simply, and the reactions can often be carried out in water rather than in expensive inert solvents such as DMSO. Complicated chromatographic separations are also unnecessary. In addition, statistically substituted cyclodextrins are often much more soluble than pure compounds because of their poorer tendency to crystallize.[50a] Thus until now only statistically substituted derivatives have been used industrially (see Section 8).[5c]

Hydroxypropylcyclodextrins are the statistically substituted derivatives of greatest technical interest so far. They are obtained in large quantities by adding propylene oxide to **1** in aqueous sodium hydroxide[25a, 83] and are readily soluble in water. Depending on the reaction conditions, up to two hydroxyl groups per glucose unit are etherified. Pitha et al. studied the product distribution as a function of the reaction conditions in detail.[51, 84] The substitution pattern at the glucose unit is determined most easily by degradative analysis.[45a, 45c] The hydroxypropyl substituents can be directed to certain positions by regulating the pH.[25b]



Methylation of cyclodextrins with dimethyl sulfate in aqueous solution also leads to a statistical mixture of *O*-methylcyclodextrins with a degree of substitution of 1–2 per glucose unit.[85] Enzymatic linkage of maltose oligomers to **1** leads to mixtures of branched cyclodextrins which, like the hydroxypropyl derivatives, are readily soluble in water.[51c, 86] Depending on the reaction conditions, the reaction of difunctional reagents such as epichlorohydrin,[87] diisocyanates,[88] and dicarboxylic acid dichlorides[89] with **1** affords either soluble[87b, 90] or insoluble[91] branched products.

4. Supramolecular Structures Derived from Cyclodextrins

A supramolecular structure results from defined noncovalent interactions between several individual molecules.[92] Host–guest complexes[93] are important examples of this type of structure. The host molecule offers the guest molecule a suitable environment, generally a cavity. The driving force for complexation can arise from Coulombic, dipole–dipole, van der Waals, solvatophobic, or hydrogen bonding interactions between host and guest.[94] The outer sphere of the host should be compatible with the required solvent in order to avoid aggregation or insolubility problems. In the following sections we shall distinguish between cyclodextrin derivatives, which according to their solvent compatibility are "exohydrophilic", "exolipophilic", or "amphiphilic" hosts, and describe some examples of supramolecular structures.

4.1. Cyclodextrins as Exohydrophilic Hosts

Since the exterior of cyclodextrin molecules is hydrophilic, they can form adducts with guest molecules in aqueous solution.[3, 95] These adducts can consist of one or more cyclodextrin or guest molecules. If the guest is situated within the cavity (Scheme 7a–f), these adducts are termed *inclusion compounds* according

Scheme 7. Topology of cyclodextrin adducts with a) complete, b) axial, c) partial, and d) sandwich-type inclusion; e) 1:2 and f) 2:2 inclusion compounds; g) lidlike association compound.

to the nomenclature proposed by Cramer et al.[96] On the other hand, if the guest molecule lies outside the cavity, the compounds are referred to as *association compounds* (Scheme 7g). The packing of the cyclodextrin adducts is determined predominantly by the dimensions of the guest relative to those of the cavity. The guest can be either completely or partially surrounded by the host molecule. A long, thin guest can form an axial inclusion compound, whereas a short thick guest forms a sandwichlike structure.[97] In general the stability of cyclodextrin inclusion compounds increases with the extent to which the cavity is filled by the hydrophobic part of the guest.

In order to cover the plethora of results in the literature in as brief a manner as possible, we shall first describe methods for the preparation and characterization of the cyclodextrin adducts and then consider rules for packing behavior.

4.1.1. Preparation of Cyclodextrin Adducts

Cyclodextrin adducts are usually prepared in water; the partners must only be minimally soluble. Other solvents such as DMSO are less suitable than water, since the stability of the adducts in these is much lower.[98] Even the addition of small amounts of short-chain alcohols to the aqueous solution lowers the adduct stability considerably.[99, 100] The more hydrophilic substituents on the guest or cyclodextrin molecule, the more readily soluble the adducts are in water. Thus the adducts of paraffins and **1a** are almost insoluble in water,[19, 101] while those of the short-chain alcohols,[102] acids,[103] and α,ω-diols[104] are readily soluble. Cyclodextrins with hydrophilic substituents such as sulfopropyl-α-cyclodextrin[105] or hydroxypropylcyclodextrin[25b] can solubilize even completely hydrophobic molecules such as paraffins or toluene. In heterogeneous systems the rate of adduct formation is determined by the rate of dissolution. In homogeneous solution most adducts form very quickly, generally within micro- or milliseconds.[106]

4.1.2. Methods for Determining the Topology of the Adducts

Precise information on the topology of cyclodextrin adducts can be obtained from X-ray structural analysis of single crystals (Table 2).[107] Not only the position of the guest molecule with respect to the cavity but also its mobility can be determined. Neutron diffraction also provides information on the positions and motion of the protons.

Table 2. Topology of cyclodextrin adducts from X-ray structure analysis.

Host	Guest	H:G	Type	Ref.
1a	4-iodaniline	1:1	complete	[107a]
1a	4-nitrophenol	1:1	complete	[107b]
1a	3-nitrophenol	1:1	partial	[107c]
1a	$[Rh(cod)(NH_3)_2]PF_6$ [a]	1:1	partial	[107i]
1a	ferrocene	2:1	sandwich	[107p, q]
1b	1,4-butanediol	1:1	axial	[107r]
1b	1,4-diazabicyclo[2.2.2]octane	1:1	complete	[107g]
1b	hexamethylenetetramine	1:1	complete	[107h]
1b	2-(3-phenoxyphenyl)propionic acid	1:1	axial	[107m, n]
17b	4-nitrophenol	1:1	association	[107j]
1c	[12]crown-4	1:1	complete	[107l]
1c	[12]crown-4 · NaCl	3:3:1	sandwich	[107o]
1c	1-propanol	undefined	loose	[107d]

[a] cod = 1,5-cyclooctadiene.

The topology of cyclodextrin adducts can also be determined in solution. The interactions between host and guest may lead to characteristic shifts in the ^1H and ^{13}C NMR spectra that might give information on the packing.[108] Nuclear Overhauser effects provide more precise information,[109] since their magnitudes are a measure of the distance between the protons of host and guest. As the positions of almost all the protons in the cyclodextrin molecule are well defined, the location of the guest in the cyclodextrin can be determined.

The circular dichroism induced by the chiral cyclodextrin on an achiral guest affords information on the topology of the adducts, if the orientation of the transition dipole moment of the guest is known.[108b, 110] Positive circular dichroism indicates that the transition dipole moment in the cavity lies along the C_n axis (axial).[110a, 111] Negative circular dichroism indicates that the transition dipole moment is either within the cavity and perpendicular to the C_n axis or external and parallel to the axis.[112]

The proximity of *two* chromophores included in *one* cyclodextrin molecule can favor the formation of excimers[113] or exciplexes,[114] which can be detected by fluorescence spectroscopy.[115]

4.1.3. Methods for Determining the Thermodynamic Stability of the Adducts

The formation of the adducts is described by the law of mass action. The equilibrium constant K_s, also known as the stability constant, is a measure of the thermodynamic stability of the cyclodextrin adducts. Any physical property of the host or guest that changes on formation of the adduct can in principle be used for the determination of K_s.[116]

The choice of the method to be used depends on the expected value of K_s. The larger the K_s value, the more sensitive the method must be, since the concentrations of the free species decrease with increasing K_s. The physical properties that may be used are listed in order of increasing sensitivity: solubility,[117] vapor pressure,[105b] chemical shifts of ^1H and ^{13}C NMR signals,[109e, 118], circular dichroism,[119] optical absorption,[120] acidity,[121] conductivity,[121, 122] fluorescence.[123] Common to all these methods is their limited scope of application. A much more general method, which is also more precise, is the determination of the heat of formation with the help of a microcalorimeter.[104, 124] The evaluation of the concentration dependence of the heat evolution affords not only the binding constant but also the enthalpy and entropy changes associated with the formation of the adduct.[104, 116b]

The displacement of an included probe molecule by a guest molecule can also be used for the determination of K_s.[117b, 125] Probes used in the case of α-cyclodextrin include methyl orange (detection by means of optical absorption)[117b] and 3-nitrophenyl acetate (rate of solvolysis),[126] and for β-cyclodextrin phenolphthalein,[102, 125a] methyl orange[127] (optical absorption), naphthalene derivatives (fluorescence),[128] and 3-nitrophenyl acetate (rate of solvolysis).[129]

4.1.4. Methods for Studying the Kinetics of Adduct Formation

Information on the kinetics of adduct formation can be obtained by the temperature-jump[106a, 130] and stopped-flow[131] methods; the adduct yield is detected as the change in optical absorption or conductivity. In addition, dynamic NMR spectroscopy affords at least qualitative information. Depending on whether separate[132] or averaged[109c, 118e, 133] signals are observed, the adduct formation is either slow or fast on the NMR timescale.

4.1.5. The Inclusion of Monomeric Guest Molecules

Unbranched alkyl chains fit best into α-cyclodextrin **1a**. The stability constant K_s increases rapidly with increasing chain length k and reaches values of up to $K_s = 10^4\ M^{-1}$ (Fig. 2). This indicates that hydrophobic interactions are the main driving force. Neutral hydrophilic groups at the ends of longer alkyl chains have little influence on the stability, presumably because they are situated outside the cavity in the inclusion compound. Charged

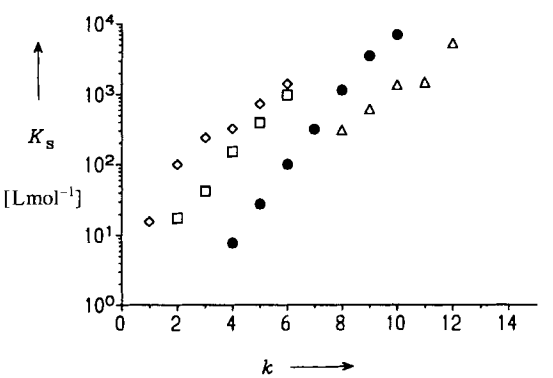


Fig. 2. Stability constants K_s of the inclusion compounds of $HOOC-(CH_2)_k-COOH$ (◇), $HOOC-(CH_2)_k-COO^-$ [134a] (□), $HO-(CH_2)_k-OH$ [104] (●), and $^-OOC-(CH_2)_k-COO^-$ [132b] (△) in **1a** as a function of the spacer length k.

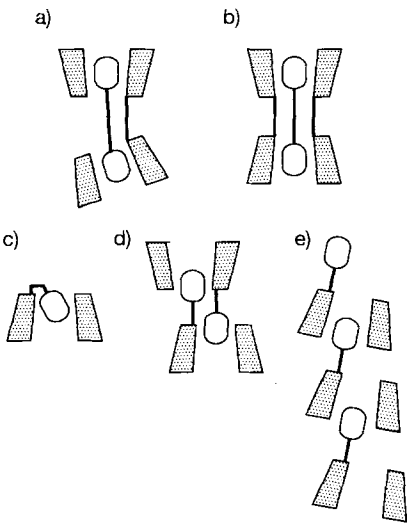
terminal groups lower the stability.[104, 121, 131, 132b, 134] If substituents are present at both ends of the chain, they can have a considerable influence on the inclusion kinetics. For example, inclusion of 1,10-decanediol and decamethylenediamine[135] is so fast that signal averaging is observed in the NMR spectra. In contrast, this process is so slow for 1,1′-decamethylenedipyridinium[132a] and 1,10-decanedicarboxylic acid[132b] that averaging is not observed. Instead, the methylene groups give rise to two sets of signals, because of the removal of mirror symmetry upon inclusion in the asymmetric host.[132a] In the case of decamethylenebis(trimethylammonium) the end groups are so large that inclusion in **1a** takes several minutes.[135] Thus the ionic end groups can provide significant steric hindrance to the inclusion and dissociation processes. When the ion passes through the ring, its hydrate shell must be shed. This also shows quite clearly that axial inclusion compounds are actually formed (Scheme 7b). This finding has been confirmed by NOE measurements[132b] and X-ray structure analysis.[107r]

Although benzene is already too large for **1a**, benzene derivatives (e.g. *p*-dibromobenzene, $K_s = 913\ M^{-1}$) can undergo inclusion.[117b, 136] The cyclodextrin apparently sticks preferentially over one of the substituents and is deformed to give an ellipse.[137] 4,4′-Bis(aminomethyl)biphenyl is already too large for **1a** ($K_s = 8\ M^{-1}$),[138] probably because the two benzene rings are not coplanar. On the other hand, azobenzene derivatives form stable axial inclusion compounds with **1a**[139] (e.g. methyl orange, $K_s = 10^{-5}\ M^{-1}$),[120b] most likely because they are planar and dumbbell-shaped.

Bulky benzene derivatives do fit into β-cyclodextrin **1b** (e.g. 4-*tert*-butylphenol, $K_s = 36300\ M^{-1}$),[140] as do naphthalene derivatives.[141] However, the cavity in **1b** is filled by molecules with a cylindrical shape better than by flat arenes. Thus derivatives of perfluoroalkyl chains,[122a] adamantane,[127] and ferrocene,[142] as well as transition metal complexes of cyclic dienes,[143, 144] form stable inclusion compounds with **1b**. Although the relatively thin, linear alkyl derivatives are included by **1b** just as well as by **1a**, virtually no spectroscopic changes occur because of the loose packing, and inclusion can be detected only indirectly, for example, by the displacement of a probe molecule.[102, 125a]



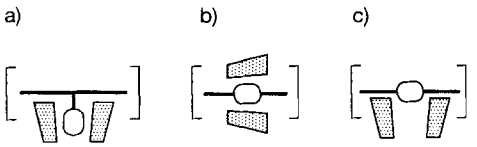
γ-Cyclodextrin **1c** is large enough to take up polyannelated ring systems such as pyrene,[145] benzpyrene,[119c] and even steroids.[146] [12]Crown-4 and its alkali metal complexes form sandwichlike inclusion complexes.[107l, o, 147] Even coronene[148] and buckminsterfullerene C_{60}[149] form stable inclusion compounds with two molecules of **1c** (Scheme 7d). **1c** is also able to take up two guest molecules (e.g. anthracene derivatives[115, 150]) simultaneously (Scheme 7e,f).

Amylose, the polymeric analogue of the cyclodextrins, often also forms similar inclusion complexes.[151] In contrast to the cyclodextrins the internal diameter of the amylose helix is not defined. The conformation of the amylose molecule can adapt itself to the size and shape of the guest molecule.[152] The selectivity of amylose is thus much lower than that of the cyclodextrins.

4.1.6. Covalently Linked Cyclodextrins and Guest Molecules

The formation of covalent bonds between building blocks provides additional possibilities for constructing supramolecular structures. Not only can two cyclodextrins or two guest molecules be linked together, equally feasible is linking a cyclodextrin and a guest molecule.

Harada et al. and Breslow et al. described the binding potential of singly[79a, 153] and doubly[80] bridged cyclodextrin dimers (Schemes 8a and 8b). Such molecules are referred to as ditopic hosts,[92b] since they are able to include two hydrophobic guests or a guest with two hydrophobic binding sites (a ditopic guest). In the latter case the stability constants can be particularly high ($K_s \geq 10^{10}\ M^{-1}$). As such systems also have a high recognition potential for guest molecules, they are also referred to as artificial receptor molecules.[80]

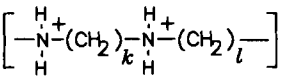


Scheme 8. Topology of inclusion compounds from a) covalently linked hosts and guests and b) ditopic host plus ditopic guest; c) monomeric, d) dimeric, and e) polymeric complexes of a host–guest conjugate.

A unique situation arises when a cyclodextrin molecule and a guest molecule are covalently linked. Such cyclodextrin–guest conjugates can organize themselves either intramolecularly to give monomeric inclusion compounds or intermolecularly to give dimeric or polymeric inclusion compounds[34a, 35, 154] (Scheme 8c–e). A covalently bonded guest molecule can be displaced from the cyclodextrin cavity by a free guest molecule. Since this displacement process can be detected spectroscopically by either optical absorption,[155] fluorescence,[156] or circular dichroism,[157] such cyclodextrin–guest conjugates can be used as sensor molecules, for example, for steroids.[155b, 156]

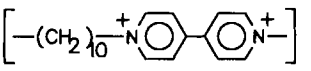
4.1.7. The Inclusion of Polymeric Guest Molecules

A polymer can by complexed by many host molecules if it has a corresponding number of binding sites, in other words, if it functions as a polytopic guest molecule. The binding sites can lie along the main chain as well as in the side chains. Since such polymers can form both inclusion and addition compounds with cyclodextrins, several arrangements are possible (Scheme 9). The axial inclusion of the main chain of a polymer (Scheme 9b) leads to a special topology: the rings are "threaded" onto a chain. This means that a threaded ring is not undergoing dynamic exchange with the free rings, unless it occupies



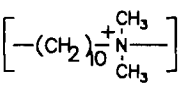
Scheme 9. Topology of cyclodextrin inclusion compounds with polymeric guest molecules. a) Inclusion of the side chain, b) axial inclusion of the main chain, c) addition to the main chain.

the position at the end of the chain. The threaded rings can only migrate along the chain or rotate about it; they are thus confined to one-dimensional space with respect to the polymer chain.



The formation of inclusion compounds with polymers has been carried out by free radical polymerization,[158] polycondensation,[159] and polyaddition[160] in the presence of cyclodextrins or hydrophilic cyclodextrin derivatives. Since the resulting polymeric adducts could not be clearly characterized owing to their poor solubility and structural heterogeneity, their topology is still unclear.

In the interactions between poly(styrenesulfonic acid)[161] or poly(*N*-alkyl-4-vinylpyridinium bromide)s[130] and cyclodextrins the side chains probably undergo inclusion (Scheme 9a). According to Harada et al., polyethylene glycol and **1a**,[162] polypropylene glycol and **1b**,[163] and poly(methyl vinyl ether) and **1c** form scarcely water-soluble adducts above a chain length of ten monomer units. The formation of these adducts is highly specific; for example, polyethylene glycol interacts only with **1a** but not with **1b** or **1c**. These adducts contain two ethylene oxide units or three ethylene units per cyclodextrin molecule. The length of these two or three repeat units (7.5 Å) and the height of the cyclodextrin torus are almost identical. Hence, it seems reasonable to suppose that the polymer chains pass through stacks of cyclodextrins. This hypothesis was supported by the X-ray powder diffractogram of the adduct of polyethylene glycol and **1a**, which is comparable to those found for axial inclusion compounds with long guest molecules like polyiodide[3, 165] in **1**. Final proof of the axial topology (Scheme 9b) of these inclusion compounds was provided by the fact that termination of the polymer chains with bulky 3,5-dinitrobenzoyl groups inhibits their formation completely.



We have used polymers with alternating hydrophobic and hydrophilic segments to construct water-soluble polymeric inclusion compounds. The hydrophobic segments (oligomethylene units) are intended to function as binding sites for **1a**. The hydrophilic segments (secondary or quaternary ammonium groups) should ensure solubility in water. The protonated poly(imino-oligomethylene)s **26**[166] and the polymeric compounds with quaternary ammonium groups, **27**[167] and **28**,[168] are sufficiently soluble in water that the interaction with **1a** occurs in a homogeneous phase. The ^{1}H NMR spectrum shows new signals due to the included oligomethylene units and the occupied rings. The induced signal shifts are independent of the concentration and resemble those of monomeric model compounds (e.g. decamethylenediamine[135] and 1,1′-decamethylenedipyridinium[132a] in **1a**). The observed signal doubling in the aliphatic range of the ^{1}H NMR spectrum is characteristic of the axial inclusion of the chain.[132a] In comparison with the formation of monomeric inclusion compounds the reaction of

26A $k = l = 6$
26B $k = l = 11$
26C $k = 10$, $l = 3$

27

28

1a with polymers **26**, **27**, and **28** is astonishingly slow; we have measured reaction times between one hour and six months. The rate of reaction decreases rapidly with the increasing bulk of the cationic groups, thus confirming the axial chain inclusion.

The polymers **26C** and **28** included in **1a** are released so slowly that excess free cyclodextrin molecules can be separated readily by dialysis or gel permeation chromatography (GPC). Like the slow threading, the slow release of **1a** is attributed to the slow migration rate of the rings along the polymer chain. This migration is probably hampered by the bulky hydrate shells around the cationic groups.

As with monomeric guest molecules, the final extent of inclusion increases dramatically with the increasing length of the hydrophobic segments. While no inclusion is observed when the chain is only six methylene units long (polymer **26A**), all water-soluble polymers with more than nine methylene groups undergo inclusion.[166–168] For example, polymer **26B** (45 mM solution in water) undergoes complexation to the extent of 68% when an equimolar amount of **1a** is added.[166] Almost complete coverage of the chain can be achieved when an excess of **1a** is used. The driving force for the threading of **1a** onto the polymer chain is a gain in enthalpy; for the polymeric inclusion compound **1a**·**26B** the enthalpy of formation is $-20\ kJ\ mol^{-1}$.[169] This value lies in the range of the enthalpies of formation of analogous monomeric systems.[104]

Our observation that the inclusion of a polymer in **1a** requires the alkyl group to be at least ten methylene groups long appears to contradict the results of Harada et al., who detected inclusion of even ethylene segments in **1a**.[162] Probably the two systems are topologically quite different. In our systems the ammonium ions form steric barriers that separate the threaded rings from each other. In contrast the neutral systems studied by Harada permit a close packing of the rings, which are linked by hydrogen bonds, along the chain.[170]

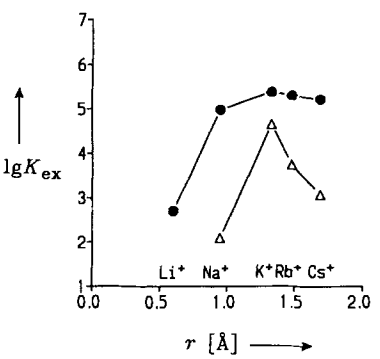
The threading of the larger host **1b** onto polymers **26C** and **28** cannot be detected by either NMR spectroscopy or microcalorimetry. In order to prove the inclusion of polymer **28** in **1b** we made use of the fact that threaded rings cannot pass one another. Polymer **28** was allowed to interact with **1b** and **1a** successively in aqueous solution; the free rings were removed afterwards by dialysis. In the product the chain is occupied up to 60% by **1b** and 7.5% by **1a**. Thus the rings **1b** are threaded rapidly onto the polymer chain, and the "slower" rings **1a** prevent them from slipping off.[168, 169]

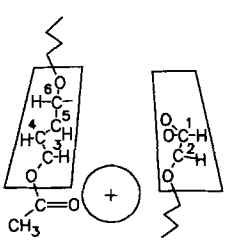
4.2. Cyclodextrins as Exolipophilic Hosts

The binding capability of lipophilic cyclodextrins was first studied by Menger and Dulany.[77] They found that a polar guest molecule such as 4-nitrophenol is complexed by heptakis(3-*O*-butyl-2,6-di-*O*-methyl)-β-cyclodextrin in organic solvents. In contrast to the hydrophilic systems here the stability constant K_s *increases* with decreasing solvent polarity; in nonpolar solvents such as heptane the stability constant for the inclusion of 4-nitrophenol is quite high ($K_s = 2600\ M^{-1}$).[77] The main driving force for the complexation is thought to be provided by dipole–dipole interactions and hydrogen bonds.[77] Thus the cyclodextrin ether behaves as an exolipophilic host.

Polar substituents directed towards the interior of the cavity increase the complexation ability of lipophilic cyclodextrins. The following values for the complexation of 4-nitrophenol in cyclohexane have been measured:[171] per(2,3,6-tri-*O*-pentyl)-β-cyclodextrin **21b** $K_s = 3560\ M^{-1}$, per(2,6-di-*O*-pentyl)-β-cyclodextrin **19b** $K_s = 6000\ M^{-1}$, and per(2,6-di-*O*-pentyl-3-*O*-acetyl)-β-cyclodextrin **23b** $K_s \geq 10000\ M^{-1}$.

The complexation of cations by the lipophilic cyclodextrins per(2,3,6-tri-*O*-acetyl)- and per(2,3,6-tri-*O*-phenylcarbamoyl)-β-cyclodextrin in organic solvents was first proven by Komiyama et al.[26b] However, the quantification of the complexation ability with the picrate extraction method[172] showed that per(di-*O*-alkyl)-, per(tri-*O*-alkyl)-, and per(tri-*O*-acyl)cyclodextrins interact only weakly with cations. In contrast, per(3-*O*-acyl-2,6-di-*O*-alkyl)-β-cyclodextrins give quite stable complexes with alkali metal ions; they are in fact even superior to the standard crown ethers,[173] though they are not as specific (Fig. 3).[174] Even very large cations such as the tetramethylammonium ion or 4,4'-bipyridinium dications[78e] are complexed by **22b**. The good complexing ability of **22b** and **23b** can be traced back to the ester carbonyl groups, which according to the *trans* rule[175] should be directed preferably towards the C_7 axis (Scheme 10). Carbonyl oxygen atoms are known to interact strongly with cations.[176]





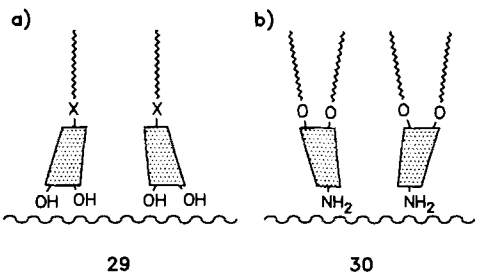


Fig 3. Complexation ability (picrate extraction coefficient K_{ex}) as a function of the cation radius r for **23b** in toluene [174] (•) and for dibenzo[18]crown-6 in benzene [173] (Δ).

Scheme 10. Possible location of an alkali metal ion in a per(3-*O*-acetyl-2,6-di-*O*-alkyl)-cyclodextrin.

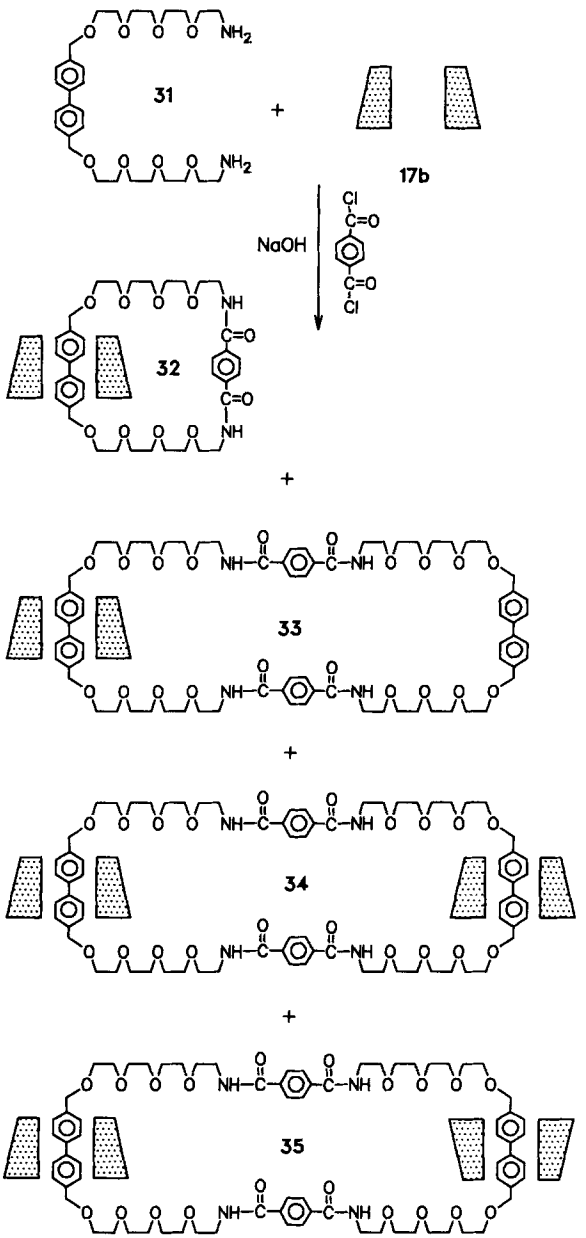
4.3. Cyclodextrins as Building Blocks for Mono- and Multilayer Systems

Apart from host–guest complexes, other supramolecular structures such as monolayers and multilayers have been derived from cyclodextrin building blocks. Kawabata et al. showed for the first time that the amphiphilic cyclodextrins **29** and **30** undergo self-organization at the air–water interface to give stable monolayers analogous to crystals.[177] The area A occupied by a molecule at the water surface increases with increasing ring size (**29a**: $A = 173$, **29b**: $A = 210$, **29c**: $A = 281\ Å^2$) but varies little with changes in the length of the alkyl chain. Consequently, the cyclodextrin rings swim flat on the water surface, and the secondary hydroxyl groups are oriented towards the water (Scheme 11). In contrast, the amphiphilic cyclodextrin **30** forms

Scheme 11. Arrangement of amphiphilic cyclodextrins at the water/air interface. X = S, NH [177, 32c].

monolayers in which the side with the primary functional groups is directed towards the water.[32c]

Guest molecules such as azo dyes can be incorporated into the monolayers formed by cyclodextrins. As the area occupied by each host molecule does not increase on complexation, the guest molecule is situated inside the host cavity.[177b, 178] Such monolayers together with their included guests can be transferred repeatedly by means of the Langmuir–Blodgett technique to planar hydrophobic substrates such as glass slides precoated with cadmium icosanate.[177a] It is thus possible to produce multilayers composed of a defined number of monolayers on such a substrate. The guest molecules incorporated into the multilayer still have enough space to undergo photochemical isomerization. For instance, included azobenzene molecules can be switched photochemically between the *trans* and *cis* configurations.[179] Such systems could in principle serve as information storage media.[180]



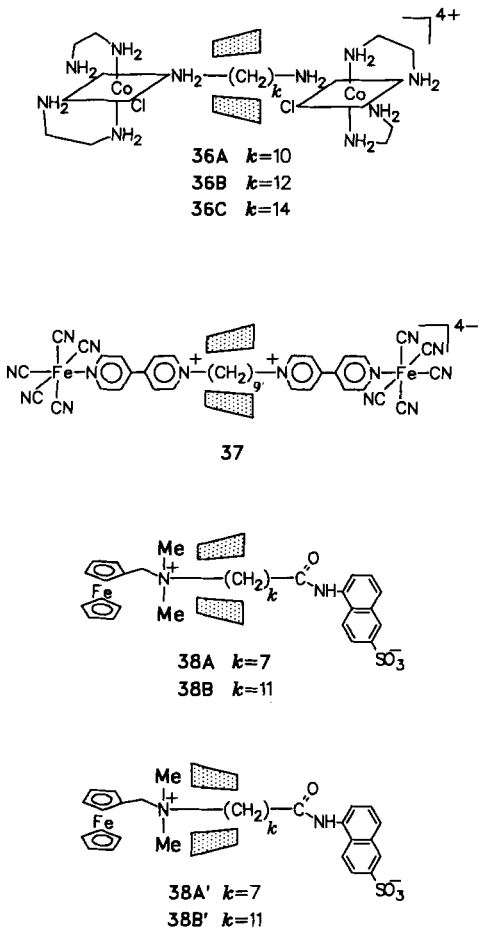
Monolayers composed of cyclodextrins are also produced by adsorption.[181] For example, cyclodextrins containing thiol groups have been adsorbed on a gold surface.[182] The formation of inclusion compounds at these monolayers can be detected by surface analysis (e.g. with plasmon spectroscopy).[182] Applications of such systems as sensors are conceivable.

5. The Construction of Molecular Architectures by Supramolecular Positioning

The great interest that supramolecular chemistry has found in the last few years arises from the idea of building up complex molecular structures from simple building blocks. The classical stepwise construction of structures by the formation of covalent bonds is replaced by the planned positioning of large units by means of secondary valence forces and their subsequent covalent linkage.[183] Whereas a large number of reactions are required in classical organic synthesis to generate, link, convert, protect, and cleave functional groups, supramolecular synthesis requires predictable forms of self-organization to bring building blocks into position in a defined manner prior to the necessary formation of covalent bonds. The tremendous power of the supramolecular approach has been demonstrated by the efficient syntheses of catenanes,[122a, 184] rotaxanes,[185] polyrotaxanes,[185] and knots[187] by Sauvage, Stoddart, and others.[92e] In the following sections we shall discuss the conditions necessary for the construction of catenanes, rotaxanes, and tubes from cyclodextrin inclusion compounds.

5.1. Synthesis of Catenanes

As early as 1957 Lüttringhaus, Cramer, Prinzbach, and Henglein attempted to synthesize a [2]catenane by ring closure of a long guest molecule included in **1a**.[188] This attempt was unsuccessful, perhaps because the guest molecule (28 bonds in length) was not long enough to circle the wall of the cyclodextrin molecule. Thirty-five years later Stoddart et al. synthesized two [2]catenanes, **32** and **33**, and two [3]catenanes, **34** and **35**, from the inclusion compound of the bitolyl derivative **31** in heptakis(2,6-di-*O*-methyl)-β-cyclodextrin **17b** (Scheme 12).[189] The cyclization of the guest was carried out by acylation of the two terminal amino groups with terephthaloyl dichloride, a reaction which also proceeds in good yields in aqueous solution. The catenanes formed can be readily separated from the reaction mixture because of their amphiphilic nature. Thus the requirements for supramolecular positioning, for the ring-closing reaction, and for the separation of the target compound were fulfilled; however, the yield of catenane **32** was only a disappointing 3% in spite of the stability of **17b**·**31** ($K_s \geq 10000\ M^{-1}$). It is possible that in **17b**·**31** the reactivity of the amino groups is diminished even though the guest **31** is 35 bonds in length. Amazingly, the catenanes **33**, **34**, and **35** with 84-membered rings could also be detected in yields of about 1%, even though their formation requires the formation of four bonds rather than two.

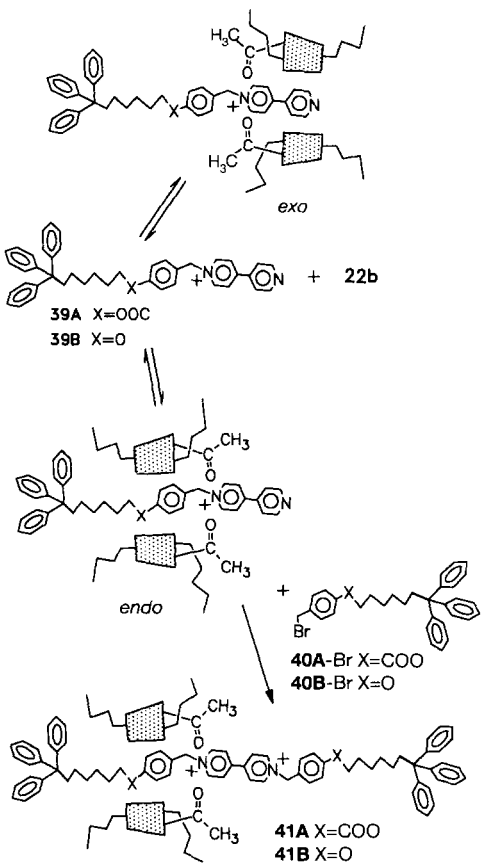


Scheme 12. Synthesis of [2]- and [3]catenanes from **17b** [189].

5.2. Synthesis of [2]Rotaxanes

In 1981 Ogino and Ohata reported that α,ω-alkanediyldiamines, included in **1a** or **1b**, react with bulky cobalt(III) complexes at both ends to give [2]rotaxanes **36** (Scheme 13).[190] The yield increased with decreasing ring size and depended on the length k of the alkyl chain, reaching a maximum of 19% at $k = 12$ (Table 3).[190b] If the chain is too short ($k = 8$), the amino groups are probably too strongly shielded by the host; if it is too long, the alkyl chains may associate. The solvent used was DMSO. Since the stability constants in this solvent are very low,[191] it is necessary to use very high concentrations of both host and guest. In a similar manner Wylie and Macartney obtained [2]rotaxane **37** by treating the inclusion compound of 1,1′-nonamethylenebis(4,4′-bipyridinium) and **1a** with a bulky iron(II)cyano complex in aqueous solution.[192] Since the iron complex formed is kinetically unstable ($k_d = 1.5 \times 10^{-3}\ s^{-1}$), there is a very slow exchange between the rotaxane **37** and the uncomplexed dumbbell-shaped compound and **1a**.[192]

Stable rotaxanes are formed only when the blocking groups are covalently linked to an included guest molecule. Isnin and Kaifer obtained a mixture of the two isomeric [2]rotaxanes **38A** and **38A′** as well as **38B** and **38B′** in 15% yield by forming an



Scheme 13. Hydrophilic [2]rotaxanes from cyclodextrins [190–193].

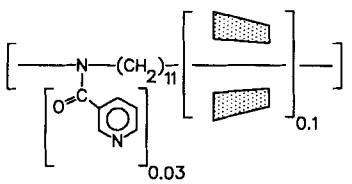
Table 3. Synthesis of [2]rotaxanes according to Ogino and Ohata [190b].

Host	k in H_2N-$(CH_2)_k$-NH_2	[2]Rotaxane	Yield [%]
1a	8	–	0
1a	10	**36A**	5.7
1a	12	**36B**	19
1a	14	**36C**	12
1b	12	**36D**	6.7

amide bond. Surprisingly isomer **38A** is stable, in other words it is a rotaxane, whereas the other isomer **38A'** dissociates slowly into the dumbbell and **1a**.[194] It seems that the steric hindrance towards unthreading depends on the orientation of the cyclodextrin.

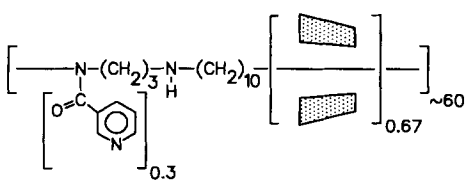
The main difficulty in these rotaxane syntheses is that the conditions for the bond-forming reaction must be favorable for the host–guest interaction as well. Although water is the best solvent for the formation of inclusion compounds, it is not very well suited as a reaction medium for the attachment of the blocking groups, as the reagents are generally only poorly soluble and can be consumed by hydrolysis. It thus appeared of interest to attempt constructing [2]rotaxanes in inert organic solvents with exolipophilic cyclodextrins. Per(3-*O*-acyl-2,6-di-*O*-alkyl)cyclodextrins such as **22b** are indeed able to complex guests such as the 4,4'-bipyridinium ions **39**, which are blocked on one side (Scheme 14). Two orientations of the host **22b** (the

Scheme 14. Synthesis of lipophilic [2]rotaxanes from *endo* complexes of bipyridinium ions blocked at one end [78e, 108e].



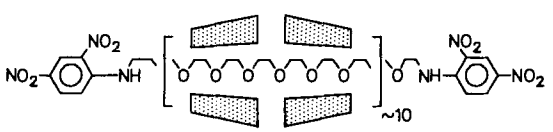
exo and the *endo* form) with respect to the guest can be distinguished in the ^{1}H NMR spectrum.[108e] Attachment of the blocking group **40A** (as the bromide) to the complexed guest **22b**·**39A** furnished the lipophilic [2]rotaxane **41A** in 19% yield.[78e] The yield of the analogous [2]rotaxane **41B** starting from the building blocks **39B** and **40B** was even better (^{1}H NMR: 50%, isolated 36%).[108e] The ^{1}H NMR spectra of both rotaxanes **41** show the distinct doubling of signals for the protons on the dumbbell axis. Together with NOE studies this signal doubling indicates that the cyclodextrin molecule is not situated in the middle of the dumbbell but towards one side of it. The two halves of the dumbbell were differentiated by deuteration of the benzylic methylene group of the blocking group **40B**. It could then be shown that in the rotaxane the host is located only on the side of the original guest molecule **39B**. Thus only the *endo* complex reacts with the blocking group **40**-Br. In the case of the *exo* complex the terminal pyridine group is probably shielded from attack of **40**-Br by the host.[108e] This selective reaction of a host–guest compound with one orientation could be used for the construction of uniform [2]rotaxanes with an unsymmetrical dumbbell component.

5.3. Synthesis of Polyrotaxanes



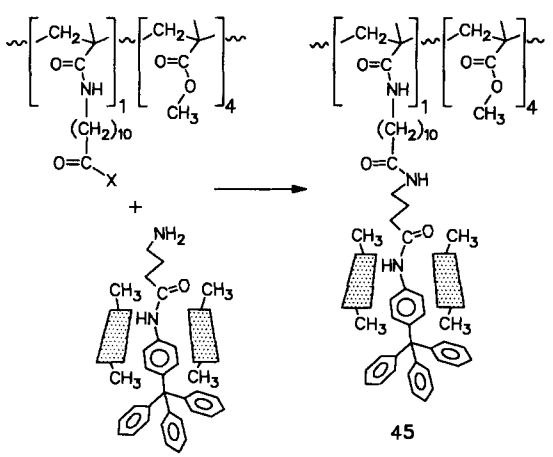
Polyrotaxanes can be prepared by reactions between axial polymeric inclusion compounds with blocking groups or by

polymer-analogous reactions of polymers with monomeric inclusion compounds. In the former case the rotaxane axes lie along the polymer main chain (main-chain polyrotaxanes), while in the latter they branch off from it as side chains (side-chain polyrotaxanes).



Starting from the inclusion compounds of the polyamines **26B** and **26C** with **1a**, we obtained the water-soluble main-chain polyrotaxanes **42** in good yields by partial polymer-analogous reaction of the amino groups with nicotinoyl chloride (Scheme 15).[166] The products were readily purified by dialysis. In the case of **42B** about forty rings were held permanently on the chain. Nicotinoyl groups are too small, however, to block the larger rings **1b**, and larger substituents such as 2,4-dinitro-5-aminophenyl groups had to be used instead.[169]

42A

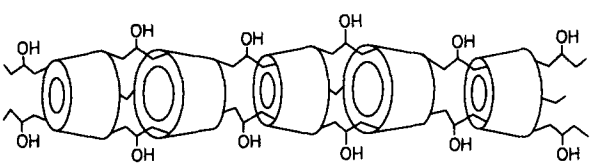


42B

43

Scheme 15. Main-chain polyrotaxanes from **1a** [166, 195].

17b·44 **45**



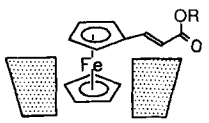
Scheme 16. A side-chain polyrotaxane from **17b** [196]. X = O-COOEt.

Harada et al. synthesized the polyrotaxane **43** with about twenty rings on the chain by reacting the terminal amino groups of a polyethylene oxide included in **1a** with Sanger's reagent.[195] This rotaxane is soluble in water at pH > 12 and in DMSO; it was purified by GPC.

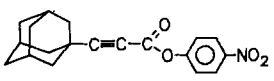
The synthesis of a side-chain polyrotaxane (Scheme 16) was achieved by Ritter et al. by the reaction between the guest in **44·17b** and the side groups of a reactive comb polymer; the polymeric product **45** was purified by multiple precipitation.[196]

5.4. Synthesis of Tubular Polymers

We have so far discussed only syntheses in which a chemical reaction was carried out at an included guest molecule. We shall now turn our attention to the covalent linkage of threaded rings to give tubular polymers. The polymeric "thread" has the function of arranging stacks of rings. Harada et al. treated a solution of polyrotaxane **43** in 10% NaOH with epichlorohydrin.[197] By using gel permeation chromatography they were able to show that cross-linking occurs only along the polymer chain with formation of hydroxypropylene bridges. The blocking groups were then cleaved with 25% NaOH and the threads removed by GPC. The final product was the tube **46** consisting of about fifteen multiply bridged cyclodextrin units.[197]

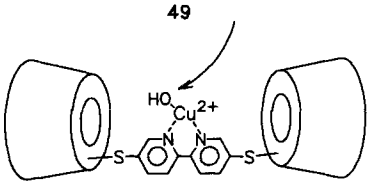


46



6. Host–Guest Catalysis

The defined spatial relationship between the building blocks of a supramolecular structure makes it possible to carry out reactions under topochemical[198] control. The influence of the host on reactions at the guest (host–guest catalysis) has been the subject of many investigations.[199] We shall now discuss the most important catalytic functions of cyclodextrins.



The term *covalent catalysis* is used when the catalysis involves a temporary covalent bond between host and guest. Most studies have focused on the catalytic activity of cyclodextrins in ester hydrolysis. Cyclodextrins accelerate the alkaline (pH > 11) saponification of esters of carboxylic acids,[200] phosphoric acids,[201] and sulfuric acid.[202] A deprotonated secondary hydroxyl group, probably OH(2), serves as the nucleophile, since it has the highest acidity. This hydroxyl group forms a cyclodextrin ester, which then hydrolyzes to the cyclodextrin and the free acid.[140, 203] The catalytic activity of the cyclodextrin increases with the stability of the inclusion compound[204] and with decreasing distance between OH(2) and the ester group of the guest in the inclusion compound.[140] Optimization of the structure of the guest leads to esters that are cleaved very rapidly by **1b**. For instance, the cleavage of ferrocene ester **47** (Scheme 17)

47 + 1b

49

48

Scheme 17. Catalysts based on cyclodextrins[205,211]. R = p-NO_2-C_6H_4.

can be accelerated by **1b** by a factor of 10^5.[205] The cyclodextrin is consumed in this process, since the cleavage of the cyclodextrin ester formed is very slow.

Cyclodextrins (pK_a = 12.2) are catalysts for ester cleavage at pH values above 11. Since it would be more useful to have such catalysis at lower pH values, functional groups that are deprotonated more easily were attached to the cyclodextrins. When the imidazole moiety (pK_a = 7.04)[206] was used, the catalytic activity of the cyclodextrin increased considerably and the optimum pH shifted to 8.[38, 203, 207] The activity depends on the position of the imidazole moiety on the cyclodextrin: an imidazole group on the side with the secondary OH groups causes a greater increase in the reaction rate than one on the side of the primary OH groups.[38, 207c] The highest activity, an increase in the rate of hydrolysis of 4-nitrophenyl acetate by a factor of 1100, was observed by Toda et al. for a heptakis(2,6-di-*O*-methyl)-β-cyclodextrin with a 4-imidazoylethyl group at O(3).[207c] Since one equivalent of this compound effected the saponification of one hundred equivalents of the ester, it is evident that the covalent intermediate is also rapidly cleaved.

Transition metal ions such as Zn^{2+} and Cu^{2+} can be coordinated to amine-functionalized cyclodextrins in order to mimic metalloenzymes. Such complexes have been used to catalyze the cleavage of esters,[208] cyclic phosphates,[209] and the hydration of carbon dioxide.[210] Very recently, the ditopic catalyst **48** was introduced, which increases the rate of hydrolysis of suitable esters like **49** at pH 7 by a factor of up to 220000.[211] Unfortunately, all such advances have so far been limited to the saponification of a few activated esters (e.g. *p*-nitrophenolates). Therefore application of these catalysts is still not feasible.[212]

Cyclodextrins can catalyze other reactions besides the saponification of esters. For example, pyridoxamine-substituted cyclodextrins catalyze the reduction of α-ketocarboxylic acids,[67] while alkenes can be converted to epoxides with porphyrin-substituted cyclodextrins.[213]

Cyclodextrins can also increase the rate of reactions without the formation of a covalent bond to the included guest; here the cyclodextrin serves as a "reaction vessel". Thus electrophilic substitution of arenes (e.g. chlorination,[214] carboxylation,[215] and azo coupling[216]) can be catalyzed by cyclodextrins. The σ complex is apparently stabilized in the inclusion compound by the donor action of the cyclodextrin. Such stabilization can even allow spectroscopic characterization of the σ complex.[217] Inclusion generally leads to a decrease in the amount of *ortho* and *meta* products because of shielding of these positions by the host.[214, 218] The regio-[219] and enantioselectivity[220] of a number of other reactions has also been influenced by the inclusion of starting materials in cyclodextrins.

When two guest molecules are included in the same cavity (cf. Scheme 7e), they are compressed, which facilitates pericyclic reactions. Inter-[221] and intramolecular[222] [4 + 2] Diels–Alder reactions and [2 + 2] photodimerizations[113b, 150b, 223] are accelerated by **1b** and **1c**, and the yields are increased. Both regio- and enantioselectivity are influenced as well.[222, 221]

7. Physical Functions of Supramolecular Structures Derived from Cyclodextrins

In addition to the chemical functions of supramolecular structures we must also mention the physical functions such as recognition[92b] and translocation (retention or transport) of guest molecules.[224] The combination of these functions is of great practical interest, since it can be employed for the separation of compounds.

7.1. Molecular Recognition

A host that forms complexes of different stabilities with two similar guests is said to display molecular recognition. Cyclodextrins detect not only the length and thickness of a guest but also distinguish between enantiomeric guest molecules owing to their chirality. Diastereomeric host–guest complexes are known both for hydrophilic[28, 141, 225] and lipophilic cyclodextrins.[226] The interactions that determine chiral recognition have been studied by computer simulations.[21, 226, 227]

7.2. Selective Retention of Guest Molecules by Immobilized Cyclodextrins

A guest molecule can be retained in a molecular current only if the host is bound to a solid substrate. The stronger the interaction between the guest and the immobilized host, the slower the guest proceeds in the current. Armstrong et al. were the first to immobilize hydrophilic cyclodextrins on silica gel and to use them for the separation of a variety of guest molecules (in particular racemates) by liquid chromatography.[228] König, Wenz, et al. showed that coatings of lipophilic cyclodextrins (e.g. **21a**,[229] **21b**,[230] **21c**,[231] **23a**,[232] and **23b**[233]) inside long capillaries form excellent stationary phases for the gas-chromatographic separation of enantiomers. The more polar permethylated cyclodextrins **20** also show very good separation performance in a lipophilic medium.[234] Immobilized permethyl-β-cyclodextrin can also be used for supercritical fluid chromatography, a method that also permits the high-resolution separation of nonvolatile substances.[234d, e] Chromatographic separation on cyclodextrin-containing stationary phases has become a widely applied analytical method for substances of general importance such as flavorings,[236] pheromones,[237] anaesthetics,[238] drugs,[239] and agrochemicals,[240] as well as for pollutants.[241]

7.3. Transport of Guest Molecules by Means of Mobile Cyclodextrins

The transport of a guest molecule in or through a liquid phase relies primarily on an increase in its solubility by the formation of a host–guest complex. This transport can be used for phase-transfer catalysis of chemical reactions[26a, 242] and for the separation of different guest molecules.[243] Hydrophilic cyclodextrins were used to transport hydrophobic guest molecules across an aqueous phase,[242a, c, 243] lipophilic cyclodextrins to transport ionic guest molecules across a lipophilic phase,[26a] and an amphiphilic derivative to transport cations across a liposome membrane.[244] Charged cyclodextrins can effect the transport of included neutral guest molecules in an electrical field.[245]

8. Applications

Cyclodextrins and their derivatives are already in use throughout the world for the formulation of drugs[83a, 246] and cosmetics[247] and for technical purposes.[248] With the exception of the latter area these applications must generally be approved by national licensing authorities. Detailed studies on the toxicity, mutagenicity, teratogenicity, and carcenogenicity of cyclodextrins, in particular hydroxypropyl-β-cyclodextrin, have thus been carried out.[249] So far cyclodextrins have been found to be non-hazardous with the exception that high concentrations of **1a**, **1b**, and **1c** cause damage to human erythrocytes.[250] However, even this can be avoided with hydroxypropyl derivatives.[7] At present cyclodextrins have general approval for use as food additives in Japan and Hungary and approval for specific applications in France and Denmark. Cyclodextrins often have advantages over starch, which might have similar inclusion properties, since they do not provide a culture medium for microorganisms.

In most of the applications, cyclodextrin inclusion compounds are formed for the modification of physical or chemical properties of the guest molecules. Analytical applications have already been mentioned. Cyclodextrins can be used for both increasing and decreasing the availability of an active substance and for protecting it from degradation.

8.1. Increasing the Availability of Drugs

The solubility of hydrophobic drugs in water can be increased by inclusion in cyclodextrins. The increase in solubility facilitates simpler formulation and an improved uptake of the drug.[251] Tensides are also used for this purpose, but cyclodextrins are more compatible with sensitive biological systems such as erythrocyte cell membranes.[249] Hydroxypropylcyclodextrins are used for solubilizing drugs that are administered parenterally.[252] Recently there has been great interest in the solubilization of insulin[253] and steroid hormones[254] as well as antiviral drugs[255] for nasal application.

Even small amounts of lipophilic cyclodextrin derivatives such as **22b** accelerate the solidification of cyanoacrylate adhesives. The acceleration of this polymerization probably results from the solubilization of ionic initiators.[256]

8.2. Reducing or Retarding the Availability of Active Substances

The formation of poorly soluble cyclodextrin derivatives, in particular starting from **1b**, can be used for removing undesired substances (e.g. cholesterol from liquid egg,[247] aromatic compounds from wastewater,[257] and nicotine and condensate from cigarette smoke[258]) and for encapsulating active substances. Encapsulation can be used to slow down the rate of release and thus increase the duration of effectiveness.[259] The vapor pressure of guest molecules can also be lowered by inclusion in cyclodextrins. This is employed for the carefully dosed long-lasting release of pleasant aromatic compounds such as chamomile, rose, lemon, and peppermint oil.[260] For this purpose cyclodextrins can also be immobilized on consumer goods such as textiles.[261] At the other extreme, unpleasant odors such as those of metabolic by-products and mercaptans in hair care products can be masked by cyclodextrins.[262]

Even the viscosity of polymeric thickening agents can be adjusted by cyclodextrins. The addition of **1** leads to readily processable solutions of low viscosity of otherwise associating polymers. The inclusion of polymer side chains probably decreases polymer–polymer interactions; however, as soon as the host is saturated by a monomeric guest, the polymer side chains are released and highly viscous solutions result.[248]

8.3. Stabilization of Active Substances

Cyclodextrins protect the included guest molecule from degradation by autoxidation, photolysis, and hydrolysis, particularly in the crystalline state. For example it is possible to stabilize sensitive flavorings such as those in onions, dill, garlic and horseradish,[262] and also vitamins[263] over a long period of time by forming cyclodextrin inclusion compounds.

9. Future Prospects

Developments shall continue at a great pace in the next few years, particularly if cyclodextrins are licensed for further applications in food and drug production.

For the synthesis of cyclodextrins the development of simpler, more easily reproducible procedures will be important. All available chromatographic and spectroscopic methods will be required for characterizing new products. Standard measurement and evaluation protocols should be developed for the determination of the stoichiometry and stability of cyclodextrin inclusion compounds to ensure the comparability of the data. Of the methods available at present, ^{1}H NMR spectroscopy and microcalorimetry are of particular importance, as they are almost universally applicable.

The boundaries drawn here, which indeed still exist, between preparative, physical, theoretical, macromolecular, biomimetic, analytic, and physiological chemistry will be fascinating to cross. For example, catalytically active catenanes and rotaxanes appear feasible. Rotaxanes and cyclodextrin catalysts could also be built into larger supramolecular structures such as monolayers and vesicles in order to carry out specific operations. Poly-

mers of defined length could be synthesized in tube-shaped polymers. The programmed release of several active substances could be achieved by the slow unthreading from polymer chains. Because of the common solvent, water, it even appears rewarding to forge a link to biochemistry. The imagination knows no limits!

I thank my co-workers and the research group of Prof. W. A. König, Universität Hamburg, for discussions and for reading this manuscript. I am also indebted to Wacker Chemie GmbH, München, and Henkel KGaA, Düsseldorf, as well as to the Bundesministerium für Forschung und Technologie (Projekt BEO 22/0319055A) and the Max-Planck-Institut für Polymerforschung for the generous support of my work in this field.

Determination of Reaction Paths for Pentacoordinate Metal Complexes with the Structure Correlation Method

Thomas Auf der Heyde*

Dedicated to Professor Hans-Beat Bürgi

Crystal structures potentially deliver far more information than is present in the average structural communication—if sufficient structural data on closely related molecules or molecular fragments are available, it may be possible to infer details of geometric changes occurring along certain reaction pathways for the species of interest. This geometric information is extrapolated from an analysis of the similarities between the structures of the fragment in the various crystalline environments, by a method that is now known as structure correlation analysis. Since it was first proposed twenty years ago, the method has been applied to a large variety of chemical systems, but none have received as much attention as the class of five-coordinate compounds. Comparative analyses of the structures of pentacoordinate complexes have yielded information about the intimate mechanisms of substitution and addition/elimination reactions at tetrahedral and square-planar complexes, and about intramolecular isomerizations of five-coordinate compounds. Since its inception, the structure correlation method has gradually adapted techniques from other branches of science, in particular group-theoretical and multivariate statistical techniques, which have been shown to be enormously powerful tools for probing geometrically complex systems. This review traces the development of the method of structure correlation and the evolution of these co-opted techniques, with a specific emphasis on studies of five-coordinate metal complexes.

1. Introduction

One of the most irksome and paradoxical shortcomings of the molecular approach to chemistry that is currently prevalent in the discipline[1] is the lack of a suitable technique for directly observing changes occurring at the molecular level during the course of a chemical reaction. In this context, the geometric characteristics of a particular reaction are usually inferred from dynamic NMR or kinetic studies, or from volume of activation measurements, for example. In some cases they may be obtained from the results of ab initio calculations, but even the unprecedented development of computational technology in the last few years has not yet enabled a quantum chemical solution for most of the real systems that the discipline has turned its attention to.[2]

Although direct *observation* of a chemical molecule along a given reaction coordinate does not seem feasible, its *visualization* at least does. The structure correlation hypothesis[3, 4] assumes that the geometric changes that a given molecular fragment would undergo along a specific reaction coordinate are mirrored by the gradual distortion or static deformation manifested by that fragment collectively over a large variety of crystalline environments. The various crystal or molecular structures are considered to constitute a series of "frozen-in" points, or snapshots, taken along the reaction pathway, which, when viewed in the correct order, yield a cinematic film of the reaction.

The rationale behind the hypothesis is enticingly simple. Crystalline structures represent stable atomic arrangements—their representative points on the Born–Oppenheimer potential energy surface will consequently tend to aggregate around local potential minima, either a "well", a "dip", or a point in a "valley". Crystal structures of closely related molecular fragments will be represented by points variously displaced from the potential minima, *along pathways of minimum energy*. Arranged in the correct sequence, then, these fragments can be assumed to map such pathways, their static deformation mirroring that expected along the coordinate. This idea has found expression in the structure correlation hypothesis: If a correlation can be found between two or more independent parameters describing the structure of a given structural fragment in a variety of environments, then the correlation function maps a minimum energy path in the corresponding parameter space.[4c]

Essentially, the method of structure correlation involves choosing a suitable data set comprising crystal or molecular structures[5] that are closely related to the fragment of interest, and then searching for correlations (similarities) between them. In the twenty years since the first paper explicitly outlining the idea of structure correlation was published,[3] the method has been applied to a wide variety of chemical systems, including organic,

inorganic, organometallic, and cluster compounds. During this time it has undergone considerable development involving the application of sophisticated multivariate statistical techniques, and group-theoretical methods. Some of the earlier studies have already been reviewed,[4a, b] and a book covering later work, with a comprehensive summary of the methods that have been developed during this time, appeared in late 1993.[6]

Undoubtedly, the class of compounds that has been most frequently and intensively studied by the technique of structure correlation is that of pentacoordinate complexes, which contains both main group elements and transition metals; indeed, the first paper in this area examined five-coordinate cadmium complexes.[3] Because these compounds have been so widely studied, the various papers offer interesting historical comparisons: 1) collectively they trace the various stages in the development of the structure correlation method (SCM), and 2) they illustrate how successively more complex methods of correlation analysis have yielded significantly greater insight into the stereochemistry of pentacoordination. This paper reviews structure correlation studies of pentacoordinate metal[7] complexes with these two aspects in mind. Papers dealing with nonmetal complexes will not be discussed here since they have received attention elsewhere[8] and in any event, do not add significant information, nor do they shed more light on the development of the SCM. We begin with a brief overview of the techniques that have proved useful in structure correlation studies.[9]

2. The Method of Structure Correlation

2.1. Representing Molecular Structures

Chemists represent molecules in many ways;[10] for the purposes of the SCM, their "depiction" in terms of a set of numbers is the most convenient for the subsequent statistical correlation analysis. This requirement necessitates an important conceptual leap in that the molecules comprising a given data set are no longer regarded as three-dimensional objects embedded in Cartesian space; they are, instead, represented by points in a multidimensional space spanned by a set of parameters (or variables) that are capable of defining the molecular geometry. In general, $3N-6$ such parameters are necessary for the complete description of an N-atom fragment.[11] Both internal coordinates (for example, bond angles and distances) and external coordinates such as fractional (crystallographic) coordinates can serve this function, but in almost all cases published thus far, the former have been used to represent the molecular geometry.[12] Bond angles and distances and other internal coordinates like them have the advantage of being easy to use and to visualize, and of appealing readily to the chemist's intuition, but they do suffer from several disadvantages that may introduce bias in comparative studies. Firstly, in general, no unique set of $3N-6$ parameters can be chosen to describe the molecular structure, so the selection will be biased by an arbitrary choice of parameters. But this choice is not always easy to make, since the larger the molecule, the greater the number of alternative parameters,[13] and the more complicated and opaque the geometric relations between them become; this complicates the identification of redundant or dependent coordinates. Secondly, in crystal structure analyses the internal coordinates are not the original refined parameters, and their errors are not directly estimated; an error in one coordinate may be coupled with errors in others, and there is no guarantee that such an effect will be obvious. Finally, the parameters are usually not all of the same type or have the same units (scale), and this can severely distort an analysis of covariance.

Where observed molecular geometries need to be referred to an idealized or a reference molecule, deformation coordinates or symmetry coordinates (SCs)—originally developed for use in vibrational spectroscopy—are very useful.[14] SCs are, for example, linear combinations of internal coordinates that transform according to the irreducible representations of the point group **G** of the chosen reference molecule; their derivation is described in most textbooks on applied group theory.[15] They are closely related to normal coordinates, and thus to the vibrational modes of the molecule.

As an example, consider an analysis of triatomic molecules that attempts to describe their deformations in relation to a reference molecule XYX with $\mathbf{G} = C_{2v}$; any such molecule is fully described by two bond-length increments (r_1 and r_2) and the increment in the bond angle ($\Delta\theta$), relative to the respective bond lengths and the bond angle in the reference structure. These (internal) coordinates transform as $2A_1 + B_2$ under C_{2v} symmetry, and the corresponding SCs are given in Scheme 1. Any given molecule would be represented by a particular point in the (three-dimensional) space spanned by S_1, S_2, and S_3. A dis-

Born in South Africa in 1958, Thomas Auf der Heyde studied chemistry at the University of Cape Town (UCT). As an undergraduate he worked for two years as a research assistant in coordination chemistry with D. A. Thornton. After obtaining his Honours degree (1981) he took up a lectureship at the University of the Western Cape (UWC), completing his Masters and Ph.D. degrees with L. R. Nassimbeni (1988). During this time he spent some months in Berne, Switzerland, with H.-B. Bürgi as pre-doctoral fellow. He returned to Berne after completing his studies, and subsequently worked with F. A. Allen in Cambridge at the Crystallographic Data Centre and with K. Mislow in Princeton. At the end of 1992 he resigned as associate professor at UWC and has since been visiting at UCT. His main research interests revolve around issues of molecular structure, incorporating areas such as the stereochemistry of coordination compounds, extraction of information about the dynamic behavior of molecules from their solid-state structure, and the quantification of chirality.

$S_1(A_1) = \Delta\theta$

$S_2(A_1) = (1/\sqrt{2})(r_1 + r_2)$

$S_3(B_2) = (1/\sqrt{2})(r_1 - r_2)$

Scheme 1.

placement along the positive S_1 coordinate would correspond to an opening of the X-Y-X angle relative to its value in the reference structure, a displacement along the S_2 axis corresponds to a symmetric stretch—both r_1 and r_2 increase or decrease simultaneously—while a displacement along S_3 represents an antisymmetric stretch.

In general, the geometry of an observed triatomic molecule would not correspond to that of the reference molecule, and its representative point in the space spanned by the symmetry coordinates would not coincide with the origin, which represents the undistorted reference. However, the coordinates of the representative point, given by its displacements (d_i) along the SCs ($\boldsymbol{S}_i$), can be used to define both the *type* of distortion and its *extent*: 1) A displacement along an S_i transforming as Γ_j under **G** would indicate that the corresponding molecule has retained the Γ_j symmetry of the reference molecule;[16] 2) the total molecular distortion can be described in terms of a displacement vector $\boldsymbol{D} = d_i\boldsymbol{S}_i$, which measures the overall displacement of the point representing the molecule from the origin, that is, the deformation of the given molecule away from the reference geometry.

Although SCs have proved extremely useful in structure correlation studies, their use does have limitations. The main restriction is that a symmetrical reference geometry needs to be chosen. This condition is not always possible to achieve, especially for large molecules, and often the choice is not straightforward, as for example when dealing with highly flexible molecules.[17]

2.2. Data Analysis: Statistical Methods[18]

Once a coordinate system has been chosen and a suitable data set comprising the fragment of interest and closely related ones in a variety of crystalline environments has been compiled,[19, 20] There may be a need to standardize or scale the data.[21, 22] The subsequent data analysis can be conveniently broken down into two stages. In the first, the behavior of individual geometric parameters, or pairs of them, is analyzed in order to identify systematic effects on the distribution of observed values, that is, to detect the existence of environmental effects. For this analysis univariate and bivariate statistics are generally sufficient. In the second stage the distributions of the molecular geometries as a whole are evaluated, that is, the types of conformation present in the data set are identified. This stage requires multivariate statistical techniques, since at this point one is dealing with complete representations of the molecules in $(3N - 6)$-dimensional parameter space.

2.2.1. *Univariate and Bivariate Statistics*

In addition to positional coordinates or bond lengths and angles and derived parameters, X-ray or electron diffraction studies yield estimated standard deviations (e.s.d.'s) that give an indication of the experimental error associated with a particular observation. A comparison of these individual e.s.d.'s with the sample variance can indicate the presence either of experimental error or environmental factors such as crystal lattice effects, or of geometric constraints on the fragment under investigation that may emanate from some residual part of the molecule.[23] Thus, if a particular squared e.s.d. is much larger than the sample variance for a given parameter, this could indicate a gross experimental error in that measurement only. On the other hand, a large sample variance relative to the e.s.d.'s indicates structural variance that may warrant further investigation. A second criterion for absence of environmental effects hinges on the calculation of the weighted sum of squares of deviations, which should approximately follow a χ^2 distribution if environmental effects are negligible.[24] (Effectively, this test evaluates whether the observations agree with one another as closely as might be expected from their e.s.d.'s.)

Histograms and two-dimensional scatter plots may be very useful in identifying clusters of data points or outliers, which may arise from experimental error, unusual structural features, or unique molecular environments. Possible linear correlations between pairs of observed parameters can be investigated through an analysis of covariance: a strong correlation would suggest that a reduction in dimensionality of the problem is possible, since some linear combination of the two parameters could adequately represent them. But since in most cases $3N - 6$ parameters are required for a molecular representation, multivariate statistical analysis should usually be performed.

2.2.2. *Principal Component Analysis*[25]

Reduction in dimensionality of the problem is generally possible only after a principal component analysis (PCA) has been performed.[9, 18, 22a, 26] Instead of breaking the data set down into two-dimensional subsets—as in covariance analysis or scatterplots—PCA searches for correlations among all $3N - 6$ parameters simultaneously, extracting linear combinations of highly correlated variables that describe, in turn, the greatest sample variance, the next greatest (orthogonal to the first), and so on. The consecutive linear combinations are called the principal components (PCs), and they appear as linear combinations of the original variables (a, b, c,...) [Eq. (1)].

$$\mathrm{PC}_n = \lambda_1 a + \lambda_2 b + \lambda_3 c + \ldots \quad (1)$$

$$n = 1, 2, \ldots, 3N - 6$$

The variables a, b, c,... that appear in any particular PC are called its components, while the coefficients λ_1, λ_2, λ_3, ... are called the loadings of the PC, and they indicate the relative importance of the corresponding variable in the PC. In addition, the technique yields the percentage of total sample variance accounted for by each PC, so it is possible to reduce the dimensionality of the problem to less than $3N - 6$ by choosing only the first k PCs ($k < 3N - 6$) that together account for, say, 90% of the variance, and ignoring the others.

Mathematically, PCA is accomplished through an eigenanalysis of the covariance or correlation matrix.[27] This process corresponds to a rotation of the original $3N - 6$ orthogonal parameter axes into $3N - 6$ new axes, the PCs, which lie along directions of maximal variance.

2.2.3. *Cluster Analysis*

The aim of cluster analysis (CA) is to cluster together similar points (observations) and/or clusters in the multidimensional parameter space, thereby yielding clusters of data points that have something in common.[9, 18, 22a, 28] Clustering algorithms differ in the criteria used for establishing similarity and in the rationale according to which clusters are fused together. They may be divided into two types: hierarchical and nonhierarchical. In hierarchical clustering each observation is initially considered either as a cluster on its own, and the most similar clusters are successively merged together in subsequent steps until all of the data points are in one large cluster; or, conversely, each point is initially considered part of the same large cluster, which is then progressively subdivided into smaller ones until, finally, each observation is again in a cluster of its own. Nonhierarchical techniques partition a data set either into some pre-set number of disjoint clusters, or into clusters situated at some user-specified locations in the multidimensional parameter space; in both cases the partitioning is done in a single step, rather than a number of hierarchical stages.

All these methods initially require the calculation of a similarity matrix whose elements are numbers indicating the similarity between each pair of observations (molecular structures) in the data set. The similarity between any two structures k and l is generally measured by a distance d_{kl} between their representative points [Eq. (2)], where x_{kj} is the value of the j-th parameter

$$d_{kl} = \left[\sum_{j=1}^{3N-6} |x_{kj} - x_{lj}|^n \right]^{1/n} \quad (2)$$

for observation (structure) k. For $n = 2$ Equation (2) yields the Euclidian distance in $3N - 6$ dimensions, while for $n = 1$ the resulting measure is called the "city-block" metric. It is important that the parameters used in a clustering analysis are suitably scaled, if not standardized, for the distance measure to be a good reflection of the relation between representative points in the multidimensional data space.[29]

CA is less objective than PCA, since the user needs to make a number of decisions, each of which could affect the outcome of a CA. Thus, once the similarity criterion has been defined, there are a large number of different linkage criteria—at what stage to link together clusters?—from which to choose. Because of the large number of user-defined variables in CA, it is good practice to apply different clustering techniques to the same body of data wherever possible.

2.3. Symmetry Considerations

For a given N-atom fragment there are, in general, $N!$ permutations of the atom labels on the molecular skeleton. This means that for each such molecule, $N!$ possible representative points exist in the parameter space.[30] Which to choose? Murray-Rust examined this problem in detail, and suggested two ways in which to deal with it.[23e] In the first a unique system of nomenclature is developed to ensure that every individual molecule is labeled in exactly the same way. In practice this may not always be possible; moreover this approach has implications for the statistical evaluation in that the distribution of the observed parameters, artificially skewed by the nomenclature, will not reflect the true distribution.

A second approach that has been widely applied in structure correlation studies makes explicit use of the symmetry of the reference molecule in generating all symmetry-equivalent permutations of the atomic labels on the molecular skeleton. This permutation has the effect of generating all symmetry-related siblings for each representative point, and it is tantamount to a symmetry expansion of the data set, in which each representative point is transformed according to the operations of the reference point group **G**.[31] While the method of symmetry expansion multiplies the number of data points by the order of **G**, it does not add any new data, but merely brings into prominence the symmetry that is implicitly assumed through the use of the group **G** as a reference group. Moreover, the explicit symmetry of the data expansion must reappear in the results of PCA and CA, thereby yielding an indicator as to the correctness of the results.

3. Proposed Reaction Paths for Five-Coordinate Metal Complexes

Complexes with the ML_5 composition (M = metal atom, L = any ligating atom) have been postulated and demonstrated to be intermediates or transition states for many ligand exchange reactions of tetracoordinate metal complexes.[32] Historically these reactions have been divided into three main groups: nucleophilic substitution, electrophilic substitution, and oxidative addition followed by reductive elimination. It has become fairly clear, though, that a relationship exists between many types of reactions previously classified quite separately.[33] Often this relationship results from geometrically similar reaction paths involving the formation of a five-coordinate species, which could be either a true intermediate in an associative nucleophilic substitution, an early transition state in an oxidative addition, or a solvento species in a dissociative substitution, for example. In this sense then, many if not most reactions of four-coordinate complexes can be deemed at some stage to involve the formation of a five-coordinate species (Scheme 2).

$$XML_3 + Y \rightarrow [XML_3Y] \rightarrow X + ML_3Y$$

Scheme 2. X and L represent any coordinated ligands, and Y is either X, L, or a solvent molecule.

Figure 1 depicts the reaction paths that have most commonly been invoked in mechanistic explanations of these ligand exchange processes at tetracoordinate metals. From a purely geometric perspective, step A maps the addition of a fifth donor to a square-planar complex—or the reverse (elimination) reaction—such as might occur for the d^8 metals. The incipient stages of this path are characterized by pentacoordinate complexes whose metal atom lies close to the base of a square pyramid (SQP); such conformers will be dubbed flattened square pyramids (fSQP). As the atom of the fifth ligand becomes more firmly bonded to the metal, the latter is drawn away from the

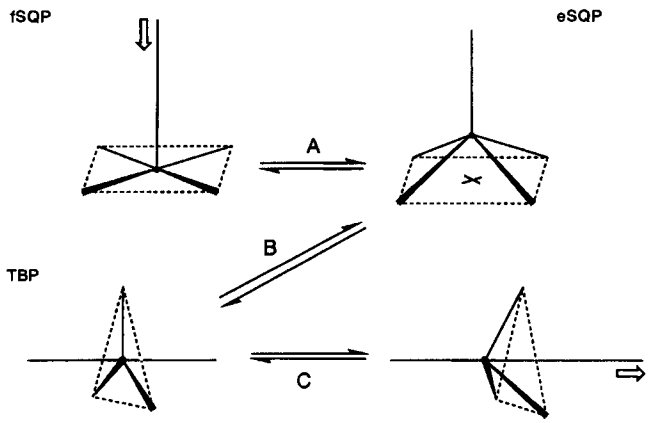

Fig. 1. Deformation and reaction pathways of five-coordinate complexes. fSQP = flattened square pyramid, eSQP = elevated square pyramid, TBP = trigonal bipyramid.[34a] Path A maps a reversible addition/elimination reaction at a square-planar metal complex, path B represents half of the Berry coordinate (Fig. 2), while path C depicts a reversible nucleophilic substitution at a tetrahedral center.

basal plane of the fSQP to form what is termed an elevated SQP (eSQP).[34a] Step B maps half of the Berry intramolecular rearrangement[35] whereby a trigonal bipyramid (TBP) deforms into a SQP by concerted bends in the axial angle and one of the equatorial angles of the TBP.[34b] The Berry mechanism[36] was originally proposed in an attempt to explain the NMR equivalence of axial and equatorial fluorine atoms in PF_5 at ambient temperature, and it offers a pathway[37, 38] for the continuous deformation of one TBP into another, through a SQP intermediate (Fig. 2). Finally, step C maps the addition of a fifth ligand

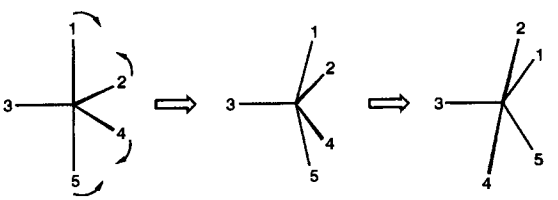

Fig. 2. The Berry intramolecular exchange mechanism. The atom labeling shown is used throughout this paper.

to a tetrahedral complex, yielding a TBP, or the reverse elimination; this path is equivalent to the S_N2 reaction coordinate of organic chemistry, and it might be expected for those metals whose tetracoordinate complexes adopt tetrahedral configurations. The two structures of highest symmetry, usually chosen as reference geometries for ML_5 complexes, are the TBP (D_{3h} symmetry) and the SQP (C_{4v}); while the angular geometry of the TBP is fixed by its symmetry, the same is not true for the SQP, which can adopt any value for the angles between *trans* ligands in the eSQP, so long as these angles are equal to each other.

4. Reaction Paths Derived from Crystal Structures

4.1. Laying the Foundations

Soon after Bürgi published the first paper outlining and explicitly employing what has since come to be known as the structure correlation method,[3] Muetterties and Guggenberger similarly applied the new idea to a study of five-coordination, but focused on a different deformation path.[39] In his paper, Bürgi viewed a series of five-coordinate metal complexes as essentially adopting TBP configuration, and then extracted an S_N2 reaction pathway (path C in Fig. 1) from correlations between them. Muetterties and Guggenberger, on the other hand, examined deformations away from TBP configuration, establishing a Berry pathway in the process (path B). Between them, the methods developed in these two papers laid the foundations for many of the subsequent structure correlation studies of pentacoordinate metal (and nonmetal) complexes, and because of their seminal importance, we shall dwell on them at some length below.

4.1.1. Bürgi's Cadmium Study—the S_N2 Pathway

The original paper examined eleven approximately trigonal bipyramidal cadmium complexes with equatorial thioglycolate ligands, and iodine, sulphur, or oxygen as axial ligands. The coordination polyhedra were simply described by internal coordinates, and correlations were mainly analyzed by means of scatterplots. The most telling correlations were those between the out-of-plane displacement (Δz) of the central Cd atom, and the distance increments[40] of the two axial bonds (Δx, Δy). This correlation is depicted in Figure 3. The results were interpreted

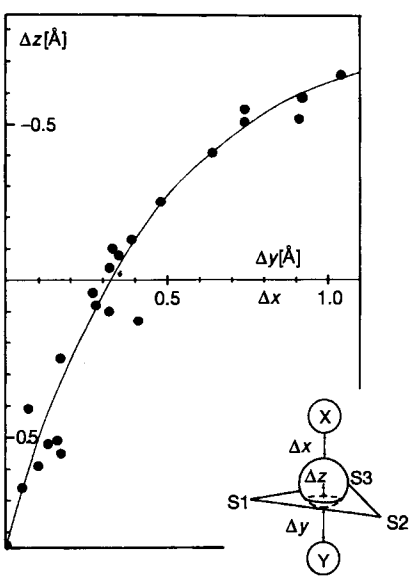

Fig. 3. The correlation between axial distance increments (Δx or Δy) and out-of-plane displacement (Δz) of the Cd atom. The distortion maps an S_N2 coordinate equivalent to step C in Figure 1.

in terms of an S_N2 distortion coordinate equivalent to step C (Fig. 1): beginning with a TBP distorted toward C_{3v} symmetry—that is, a TBP that could be viewed as a tetrahedron with a fifth ligand at one of the tetrahedral faces—one axial bond (Δx) becomes longer, as the other (Δy) shortens, while the metal is concomitantly drawn into the equatorial plane of the TBP. In the intermediate or transition state the two axial bonds are lengthened from their respective "standard" lengths by about 0.32 Å each, and the metal atom is situated exactly in the equatorial plane. An analysis of the variation in the internal angles

that accompanies the bond length changes, reveals the typical "umbrella-type" motion whereby a tetrahedron inverts during a classic organic S_N2 reaction.

An analytic expression [Eq. (3)], which parallels that proposed by Pauling [Eq. (4)],[41] was used to describe a geometric distortion coordinate along which changes in interatomic distance Δd are related to bond numbers n. On the basis of the

$$\Delta x, \Delta y = g(\pm \Delta z) = -1.5 \lg[(\pm \Delta z + 0.84)/1.68] \quad (3)$$

$$\Delta d = C \lg n \qquad 0 < n < 1 \quad (4)$$

analytic expression Bürgi was able to show that bond number n is linearly dependent on Δz, and that the sum of the axial bond numbers (n_x, n_y) equals unity at each stage of the reaction, which implies that the bond between the incoming ligand and cadmium is strengthened at the expense of that between the departing group and the metal. The bond variations observed by Bürgi have since been approximated by Burdett in an angular-overlap molecular orbital study, in which he modeled distortions with C_{3v} symmetry for ML_5 fragments with D_{3h} symmetry (corresponding to step C in Fig. 1), as well as coupled distortions along paths A and B.[42] Despite discrepancies between his calculated curves and those of Bürgi and others, Burdett[42] reports a fairly good qualitative reproduction of the observed bond shortenings and elongations.

Apart from the proposal of mapping reaction paths from crystal structures, Bürgi's initial paper also for the first time introduced the idea of using symmetry coordinates to describe molecular deformations in the solid state. He suggested that an alternative way of looking at the nucleophilic addition was to view it as the reverse of the decay of the TBP, mapped by the SCs collated in Scheme 3, where $\Delta\alpha_{nX}$, $\Delta\alpha_{nY}$ represents the deviation

$$S_2(A_1') = (\Delta y + \Delta x)/\sqrt{2}$$
$$S_3(A_2'') = (\Delta y - \Delta x)/\sqrt{2}$$
$$S_4(A_2'') = (\Delta\alpha_{1X} - \Delta\alpha_{1Y} + \Delta\alpha_{2X} - \Delta\alpha_{2Y} + \Delta\alpha_{3X} - \Delta\alpha_{3Y})/\sqrt{6}$$

Scheme 3.

of the observed angle between the n-th equatorial ligand and the axial ligands, either X or Y, from their values in the reference structure (the TBP). Figure 4 depicts the correlations between these coordinates for the eleven structures of the study. The smooth curves were obtained by regression from Equation (2) and the corresponding expressions for the SCs, and they were interpreted as follows: The decay of the TBP is initiated by antisymmetric stretching of the axial bonds (S_3, Fig. 4 top) coupled to out-of-plane bending of the CdS_3 moiety (S_4). Initially—for values of S_3 smaller than about 0.2 Å—the complex hardly deforms along the symmetric stretch coordinate (S_2, Fig. 4 bottom), but as the decay proceeds this stretch becomes more pronounced.

Another novel idea in the paper was explored in the attempt to estimate the relative magnitude of quadratic and cubic potential (force) constants for the displacement reaction, by modeling the reaction coordinate—the smooth curves in Figure 4—by equations describing a principal axis of the potential energy

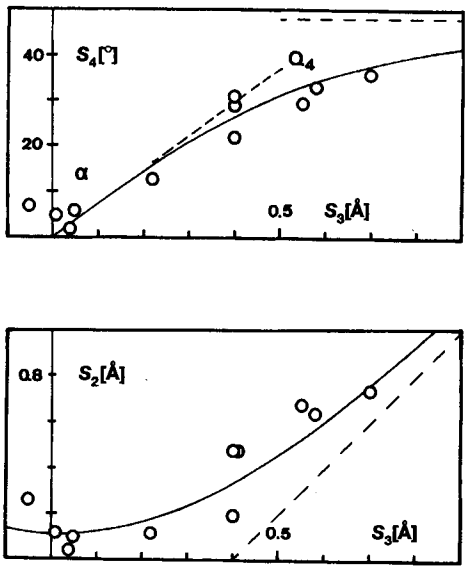

Fig. 4. Top: correlations between the SCs S_3 (XCdY, antisymmetric stretch) and S_4 (CdS_3, out-of-plane bend); bottom: correlations between S_3 (XCdY, antisymmetric stretch) and S_2 (XCdY, symmetric stretch). The solid curves were obtained by regression.

ellipsoid, and making certain simplifying assumptions. Although this approach has since been criticized,[43] it suggested the beguiling notion of extracting data on the topography of the potential energy surface of the ML_5 fragment from the experimental (crystallographic!) information at a time when such data would have been very difficult to come by computationally. Recently this idea has again been given some attention,[44, 45] though there has as yet been no further attempt to obtain empirical information on the potential energy surface for pentacoordinate metal complexes.

4.1.2. Muetterties and Guggenberger—the Berry Rearrangement

Although Bürgi's study revealed convincing correlations, it ignored certain deformations of the coordination polyhedron, by assuming that the complexes all approached at least C_{3v} symmetry. A careful analysis of the data reveals, however, that some of the complexes are quite significantly distorted away from this symmetry; the angle between axial ligands can be as low as 161°. Muetterties and Guggenberger[39] explicitly set out to deal with this problem of approximate configurations.[46] From a structural examination of a large number of coordination complexes they identified a "surprising consistency of shape", in that for compounds of the type ML_n, the n ligating atoms generally describe a polytope in which all faces are equilateral triangles or nearly so. They further found that while the fully triangulated form is always the favored one, there are alternate polyhedra (polytopal isomers[47]) for all commonly observed classes of complexes containing n ligating atoms that may be generated from the favored forms by minor bending–stretching modes. The favored form of ML_5 complexes is the TBP; the SQP is formed when two of the adjacent triangular faces of the TBP become coplanar in a square face during the (Berry) polyhedral rearrangement. As shape parameters Muetterties and Guggenberger proposed the dihedral angles between

the normals to adjacent polytopal faces, coupled with associated angles subtended at the central metal. With reference to Figure 2, the angle (δ_{24}) between the normals to the faces 124 and 524, which share the common edge 24, changes from 53.1° to zero as the TBP deforms to the SQP along the Berry coordinate. This change is accompanied by a concomitant change in the angles θ_{15} (from 180° to about 155°) and θ_{24} (from 120° to also about 155°). By correlating these three angles, Muetterties and Guggenberger were able to arrange seven pentacoordinate complexes containing six different central atoms[48] into a series convincingly mimicking the Berry path. The corresponding diagram (Fig. 5) beautifully illustrates how the individual molecular

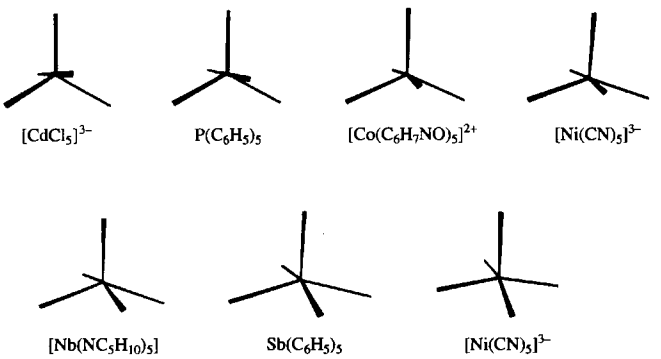

Fig. 5. Muetterties and Guggenberger's arrangement of five-coordinate complexes, which mimic the Berry mechanism, that is, the progression from D_{3h} to C_{4v} symmetry.

structures yield a cinematic film of the reaction, when they are strung together in the right order.[49]

4.1.3. Extension of the Dihedral Angle Technique

For a number of years after the two papers discussed in Sections 4.1.1. and 4.1.2. were published, little or no further attention was given to pentacoordinate metal complexes. Nonmetal compounds, however, were fairly intensively investigated by Holmes, Deiters, and co-workers (see ref. [8]), who developed an extension of Muetterties and Guggenberger's dihedral angle method, which allows a quantification of the extent to which a given molecule has traversed the TBP → SQP divide.[50] Instead of (subjectively) focusing on just two or three of the internal coordinates, Holmes and Deiters included all nine dihedral angles (between normals) in their shape parameter.[51] In their method the sum of the differences between the angles δ_{ij}(C) for each edge ij in the observed structures C and the corresponding angles in the reference polyhedra [δ_{ij}(SQP) and δ_{ij}(TBP), respectively] is determined. For the concerted axial and equatorial bends accompanying the Berry rearrangement, a plot of $217.9° - \sum_{ij}|\delta_{ij}(C) - \delta_{ij}(SQP)|$ versus $\sum_{ij}|\delta_{ij}(C) - \delta_{ij}(TBP)|$, where $217.9° = \sum_{ij}|\delta_{ij}(TBP) - \delta_{ij}(SQP)|$, should then theoretically yield a straight line with unit slope and length $(217.9°)/\sqrt{2}$. The percentage displacement of a given representative point along this coordinate—that is, the percentage displacement of the particular structure along the TBP → SQP pathway—is then easily expressed as a proportion of the length of this line.

4.2. Applications of the Early Methods

4.2.1. Nickel Complexes

The structures of 78 five-coordinate nickel complexes have been examined along similar lines to those discussed in Section 4.1.[52] The molecular geometries were described by internal coordinates (bond distances being expressed as increments relative to the respective standard bond lengths[40]), and no special account was taken of symmetry considerations of the kind mentioned in Section 2.3. The data comprised all five-coordinate nickel entries deposited in the Cambridge Structural Database at that time,[19, 20] but excluded allylic complexes.[53] Scatterplots revealed that 34 of the compounds mapped an association reaction for tetrahedral nickel complexes (path C in Fig. 1), while the remaining 44 structures lay along a reaction coordinate depicting an addition reaction at square-planar centers (path A). This finding is, of course, reconcilable with the fact that four-coordinate nickel complexes can adopt either tetrahedral or square-planar configuration, and ligand substitutions at such centers must therefore necessarily proceed at least partly by different pathways.

The reaction coordinate for square-planar complexes can be suitably described by a correlation between the angular parameters defined on the right of Figure 6; the corresponding scatter-

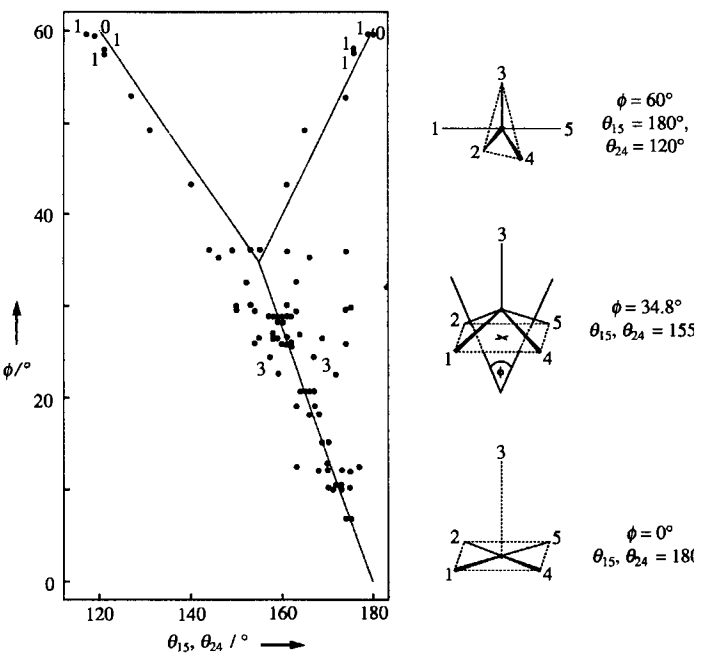

Fig. 6. Deformation of nickel complexes mapped by the bond angles θ_{15}, θ_{24} and the parameter ϕ (defined on the right of the diagram). Points on the lower right of the plot represent fSQPs, those in the center eSQPs, and those at the top right and left TBP conformers. The solid line maps the theoretical coordinate for the deformation described on the right of the scatterplot. The numbers give the oxidation state of the metal.

plot is shown on the left. The solid line represents the theoretical deformation pathway for the scheme shown on the right of the figure. In the scatterplot, points on the lower right represent compounds mapping the incipient stages of step A, that is, flattened SQPs, those at the center represent elevated SQPs, while points in the upper right and left represent TBP complexes; the

split part of the coordinate corresponds to the Berry pathway. The data are fairly evenly spread along the theoretical trajectory, which suggests that there may only be a very small energy difference between the fSQP and the eSQP, and that the activition barrier for the transformation of the one into the other is very small. However, it is not clear how to interpret the scatter about the theoretical coordinate: the phenomenon may arise from structural variations that are not adequately modeled by the method, which includes only three geometric parameters and may therefore be biased by the choice of variables.

The S_N2 pathway was mapped in reverse—that is, an axial ligand in a TBP was removed along the C_3 axis—by correlating the normalized shift parameter $s = (d_{eq} - 3z)/d_{eq}$ with the sum of the angles at the metal atom along $[\sum\theta_{1e}]$ and around $[\sum\theta_{ee}]$ the threefold axis, according to Equation (5) and Equation (6), respectively.[54] The parameter d_{eq} is the average equatorial bond length, z the displacement of the nickel atom out of the equatorial plane. Figure 7 depicts the corresponding scatterplot

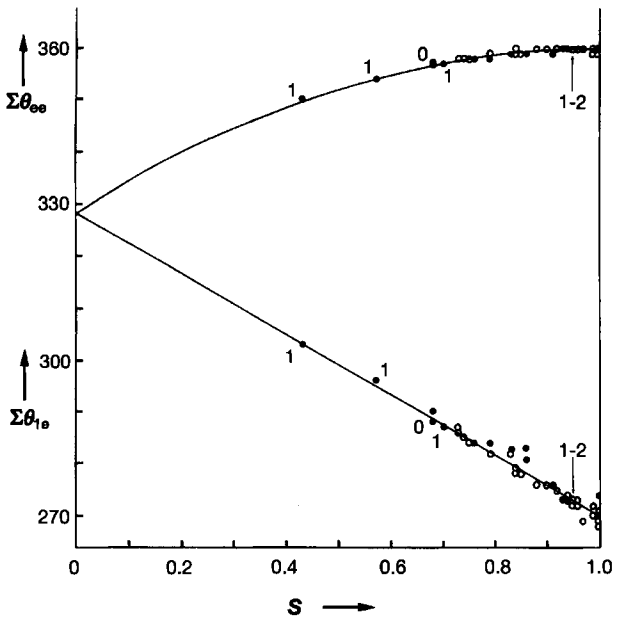

Fig. 7. Adherence of nickel compounds to the coordinate mapping the transition from C_{3v} to T_d symmetry (solid line), that is, the reverse of path C. The numbers indicate the oxidation states of the metal. $\sum\theta_{1e}$ is the sum of the angles [°] at the metal atom along the threefold axis [Eq. (5)], $\sum\theta_{ee}$ the sum of the equatorial angles [Eq. (6)], and s a normalized shift parameter (see text). The numbers indicate the oxidation state of the metal.

for the 34 complexes that mapped this pathway; the solid line represents the theoretical coordinate. Complexes containing Ni^I atoms are indicated by the numbers in the diagram, and lie furthest along the dissociation pathway. This may indicate that in those cases where homolytic bond cleavage results in Ni^I species, it will be an axial bond in a TBP that will cleave.

$$\Sigma\theta_{1e} = \theta_{12} + \theta_{13} + \theta_{14} \quad (5)$$

$$\Sigma\theta_{ee} = \theta_{23} + \theta_{34} + \theta_{24} \quad (6)$$

Finally, the Berry mechanism was found to be a viable pathway for intramolecular exchange in these complexes: a plot of

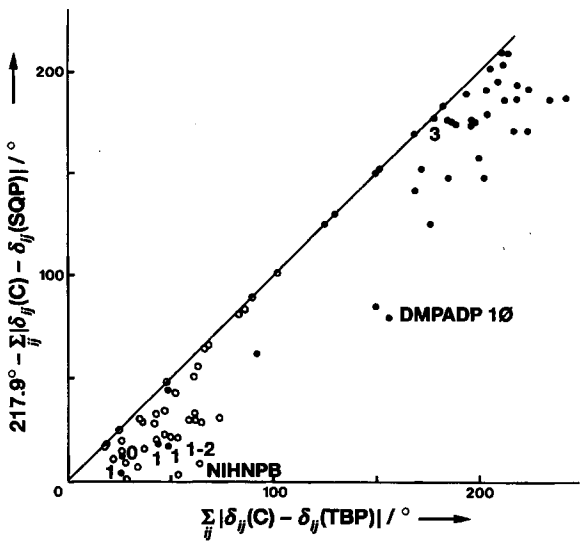

Fig. 8. Adherence of nickel complexes to the Berry coordinate (solid line). Filled circles correspond to structures mapping the association reaction at square-planar nickel, empty circles to those that do not. The numbers indicate oxidation state of the metal. NIHNPB and DMPADP are outliers.

$217.9° - \sum_{ij}|\delta_{ij}(C) - \delta_{ij}(SQP)|$ versus $\sum_{ij}|\delta_{ij}(C) - \delta_{ij}(TBP)|$ revealed a reasonable adherence of the structures to the Berry coordinate depicted by the solid line in Figure 8, in which the origin corresponds to a TBP and the upper end of the straight line at (217.9°; 217.9°) to a SQP. The fairly even clustering of the data around both ends of the coordinate suggests a small energy difference between the TBP and SQP, since a large difference would presumably result in preferred clustering of observed geometries about the lower energy conformer, and a relative paucity of points around the higher energy one. The two outliers could easily be accounted for by unique, highly restrictive structural features that would be expected to distort them away from a minimum energy pathway.

A number of different explanations could account for the scatter in Figure 8. In the paper it was suggested that the complexes that do not map the association reaction for square-planar centers (empty circles) possibly exhibit slightly less scatter than those that do (filled circles). This would make sense, since from a geometric perspective one could argue that structures distorted toward C_{3v} symmetry—that is, those lying along path C (see Fig. 1) and closer to the origin in Figure 8—would more readily undergo Berry exchange than would fSQPs, which lie along path A and at the upper right of Figure 8. Indeed, the fact that the fSQPs lie at the bottom right of Figure 6, displaced from the Berry coordinate, substantiates this suggestion. A certain amount of the scatter is also likely to arise randomly from the different crystalline environments. But another factor that complicates all studies of five-coordinate complexes is that the geometry of the SQP is not uniquely fixed by its symmetry, as is the case for the TBP. In the SQP one degree of freedom remains: the *trans*-basal angles (θ_{15} and θ_{24}, Fig. 6) can adopt any value under C_{4v} symmetry, provided that they are equal. This implies that an arbitrary choice has to be made about the constitution of the "reference SQP" and the values of its angles. Clearly, this affects the calculation of Holmes and Deiters's shape parameters; specifically, the length of the Berry coordinate in plots like

that of Figure 8 and the coordinates of the representative points in these diagrams would be affected.[55]

4.2.2. Zinc, Molybdenum, and Iron Complexes

Scatterplots and the application of the dihedral angle method to a sample of 33 pentacoordinate zinc compounds (represented by their internal coordinates) has enabled a mapping of steps B and C in Figure 1.[56] Results are similar to those for the cadmium complexes and the 78 nickel complexes described earlier, with the exception that in the S_N2 pathway the TBP intermediate was shown to be distorted (with an axial angle of about 163°), as a consequence of the directional preferences of the substitution pathway. There are two extreme approach trajectories of the incoming nucleophile N with respect to the ZnL_4 tetrahedron: for an ideal 'face' approach (F) one N-Zn-L angle would be 180° and three 70.5°, while an ideal 'edge' attack (E) gives rise to two pairs of angles of 125.3° and 54.7°. Figure 9 reveals that the nucleophile approaches the tetrahedron at an oblique angle, midway between F and E, which may well cause the observed distortion of the intermediate. An absence of correlations for the more square pyramidal configurations of the data set suggests that in the case of Zn^{II} complexes any dissociation must occur from the axial positions of a TBP (path C), as opposed to the apical position of an SQP (path A): hence, for the substitution reaction, Berry deformation of a complex towards an SQP leads into a cul-de-sac.

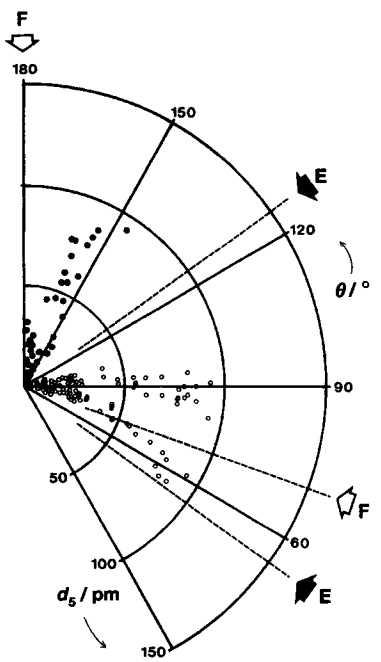

Fig. 9. Scatterplot showing the dependence of the angle of nucleophilic attack on the distance increment [40] of the Zn-to-nucleophile bond. Filled circles plot θ_{15}, open circles θ_{25}, θ_{35}, and θ_{45} (see Fig. 2 for nomenclature). F = face attack, E = edge attack.

A sample of 44 five-coordinate molybdenum complexes has been very similarly treated, and coordinates for an S_N2 reaction and a Berry exchange were obtained.[57] A Berry coordinate has also been mapped from an analysis of nine structures of the type $[Fe(CO)_3P_2]$, where P_2 represents either a bidentate or two monodentate phosphane ligands.[58] In this case, the data were symmetry-expanded according to C_s symmetry. The distribution of the resulting 18 data points was fairly even along the TBP → SQP pathway, again suggesting a low energy barrier for this deformation; indeed, two of the compounds are fluxional even at temperatures as low as −80 °C. This result was not reproduced in a study of twelve $[Fe(CO)_4L]$ complexes (L = monodentate ligand), which found that most of them clustered around the TBP configuration, though some displacement along the Berry coordinate was observed.[59] The aim of the latter study was to establish correlations between the geometric deformations of these complexes and certain Mössbauer parameters, in an attempt to relate their electronic nature to their structure. The results of the study led the authors to predict that axial ligands whose π-acceptor qualities are similar to those of CO would facilitate the Berry mechanism, whereas strong σ-donor ligands would present barriers to the intramolecular exchange. Kinetic and dynamic NMR data to verify this speculation are yet to be forthcoming.

4.2.3. Copper Complexes

Complexes of copper(II) exhibit a wide variety of regular and nonregular stereochemistries, partially as a result of the lack of spherical symmetry of this d^9 ion. In particular, it is often impossible to distinguish between penta- and hexacoordination. This feature has led to attempts[60] to classify these complexes as (4 + 2) when there are four short and two long bonds, or as (4 + 1 + 1*) when there are four short bonds, one long bond, and one (1*) of intermediate length. These configurations could alternatively also be considered as a perturbed ML_4 geometry (4 + 2 or 4 + 1 + 1*), perturbed ML_5 (4 + 1 + 1*), or distorted ML_6 (4 + 2 or 4 + 1 + 1*). Such a structural spectrum invariably invites attempts to map deformation pathways. But it might also frustrate those attempts, since the broad range of configurations could be indicative of a flat potential energy surface, in which case correlations may not be easily identifiable. In the following we concentrate only on those complexes that are readily identifiable as pentacoordinate.

The geometry of the $[Cu(bpy)_2Cl]^+$ ion (bpy = 2,2′ bipyridyl) has been shown to be closer to TBP, though distorted towards SQP, in a series of five complexes with various anions.[60–63] Correlations between some of the internal parameters of the CuN_4Cl chromophore led Hathaway et al. to suggest that these structures map out a TBP → SQP transformation. In terms of the Berry mechanism there are three possible deformations of a trigonal bipyramidal CuN_4Cl polyhedron, of which two are equivalent (Fig. 10). The data for the five $[Cu(bpy)_2Cl]^+$ complexes seemed to map pathway E (or the symmetry-equivalent path F), but not path D. Since the distortion along path E does

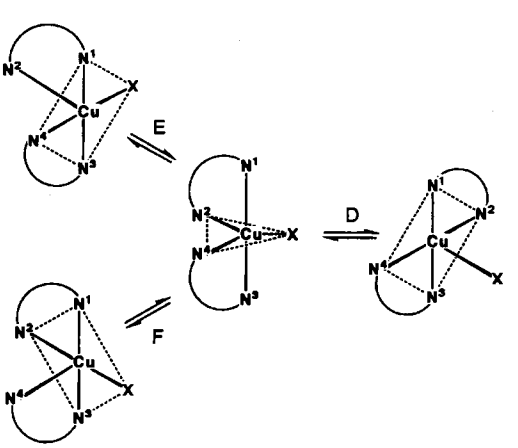

Fig. 10. Possible deformation modes of trigonal bipyramidal complex $[Cu(bpy)_2X]^+$. Path D maintains C_{2v} symmetry, while the symmetry-equivalent paths E and F do not.

not maintain C_2 or C_{2v} symmetry, Hathaway rationalized the deformation as a linear combination of the normal modes of vibration of a trigonal bipyramidal $[CuN_4Cl]^+$ ion, rather than as a Berry mechanism. Path D, however, retains C_2 symmetry, and can hence "be considered as a Berry twist-type mechanistic pathway"; the latter path is mapped by three out of four $[Cu(bpy)_2(OH_2)]^{2+}$ complexes.[61]

Extended Hückel molecular orbital calculations were then used to estimate the relative total energies for a $[Cu(NH_3)_4Cl]^+$ ion as a function of one of the N-Cu-N angles, defined as α_3 (equivalent to the angle N2-Cu-N4 in Fig. 10).[62, 63] The resulting energy profile is shown in Figure 11. Plotted onto the profile

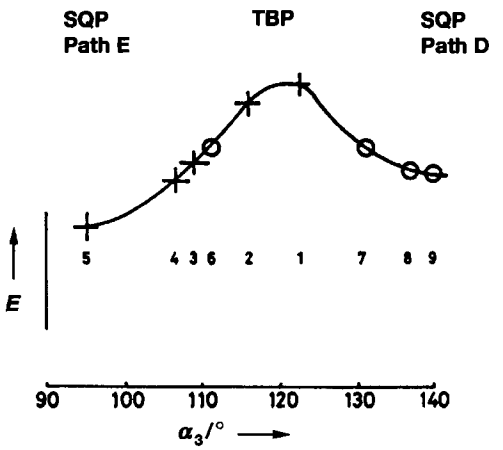

Fig. 11. The extended Hückel energy profile for the model complex $[Cu(NH_3)_4Cl]^+$, as a function of the N2-Cu-N4 angle (α_3) in Figure 10. The crosses represent the observed values of α_3 for complexes $[Cu(bpy)_2X]^+$ in which X = Cl, the circles those in which X = OH_2.

are the values of α_3 for the chloro complexes (crosses) and the aqua complexes (circles). The diagram should not be misconstrued as the correlation between the observed values of α_3 and the energy of the complex, but it does serve to illustrate one possible approach to empirical potential energy surfaces: if a large enough sample pertains, it might be possible to model the data distribution density along the reaction coordinate and thereby perhaps obtain information about the topography of the energy well (or minimum energy path). However, in this case the calculations tellingly revealed the TBP to be of slightly higher energy than the SQP, even though most of the structures approximate more closely to the TBP than the SQP; perhaps this illustrates the point that the potential energy surfaces for the various observed structures and the model complex are significantly different, even though the complexes have similar compositions.[43] In a subsequent paper the results of variable temperature NMR experiments on the $[Cu(bpy)_2X]^+$ ions (X = Cl or I) are reported, and it is shown that they exhibit no fluxionality;[64] in view of this, it is not clear how to interpret the structural correlations obtained for these molecules in the earlier reports. In another study, Hathaway et al. have proposed that three related complexes the CuN_5-containing chromophore may be viewed as stationary points along a Berry pathway, but no further reports have emerged for this system.[65] All of the studies discussed so far in this section suffer from the drawback that they included only very limited numbers of structures, and the conclusions—as far as there are any—must therefore be treated with a certain amount of caution.

In a separate report,[66] brief mention is made of a principal component analysis (PCA) of 26 $[Cu(L)_2X]$ complexes (L = bpy or 1,10-phenanthroline (phen)), which revealed that the structural variance for these compounds essentially lies in a plane in the 15-dimensional data space[67] that was analyzed. The plane is described by two axes that correspond to the eigenvectors for the two deformations depicted in Figure 10, that is, the symmetric (Berry) pathway (path D), and the asymmetric (non-Berry) deformation (path E). Hathaway's conclusion that the structures of this type of complex can be discussed in terms of these two deformation paths has therefore been borne out by the PCA. A more recent study[68] suggests, however, that the true deformation pathway for complexes of this kind is intermediate between the symmetry-equivalent paths E and F. In the latter case, 36 bpy and phen complexes were analyzed on the basis of their internal coordinates, specifically the equatorial angles around the metal atom. The conclusion about the nature of the deformation path may be doubtful though, because of certain problems in the geometric treatment.[69] In a slight contradiction of the above suggestion, the study also concluded that $[Cu(L)_2X]$ complexes do not readily distort toward SQP through the symmetric deformation, whereas they do through path E. This observation was rationalized by the argument that the $Cu(L)_2$ chromophores cannot be planar—as they would be along path D—because of steric hindrance between the hydrogen atoms near the pyridinic nitrogen atoms.

The studies on five-coordinate copper complexes that have been mentioned here barely scratch the surface of the data that are available: less than forty, highly select complexes have been examined. It seems that the complexity of the problem—emphasized by the confused results and conclusions from the different studies—calls for the application of far more sophisticated methods of analysis than have thus far been brought to bear on these structures.

4.3. The Application of Multivariate Techniques: d^8 Metal Complexes

Perhaps the most comprehensive analysis of an ML_5 system to date can be found in a study involving the multivariate analysis of a data set comprising 196 pentacoordinate d^8 complexes containing the metals nickel, palladium, platinum, rhodium, and iridium.[70, 71] Bond distances were expressed as increments,[40] and angles were all scaled to the approximate dimension of the average bond distance in the data set.[21] The coordination geometries were expressed by means of a complete set of symmetry coordinates for both TBP and SQP configurations. Each ML_5 fragment was thus represented by a point in two different 12-dimensional parameter spaces: *T-space*, where each structure is related to a TBP, and *S-space*, where each is related to a SQP. A novel feature of this analysis is that no "ideal" value of the *trans*-basal angle (θ_{15} and θ_{24}, Fig. 2) in the reference SQP had to be assumed, since the evaluation of the SCs does not require a value for this angle: even though it is the increments r or deviations Δ of the observed values from the reference values that appear in the SC expressions (see Section 2.1), the

reference values cancel for all but the totally symmetric representations.[72, 73] The atom labeling problem (Section 2.3) was explicitly discussed: the 120 (= 5!) possible permutations of the labels give rise to ten and fifteen groups, respectively, of twelve and eight so-called permutationally equivalent isomers—structures that are represented by identical lengths, but different senses, of the total distortion vector (Section 2.1), that is, they are equally deformed from the reference TBP or SQP, but their atom labels are permuted according to the symmetry of the reference point groups.

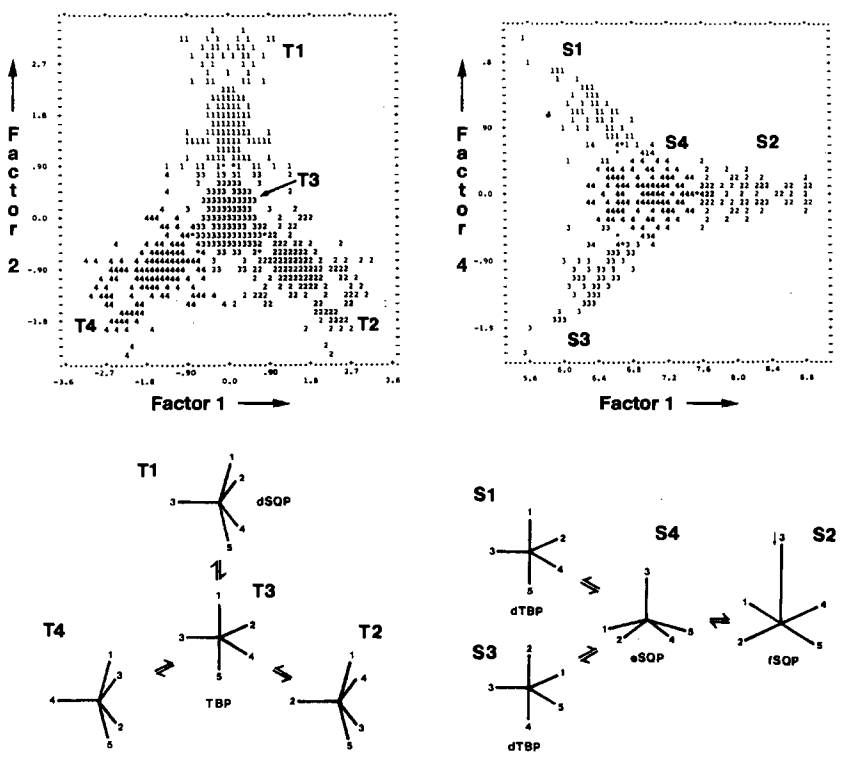
For both spaces the data were symmetry-expanded (D_{3h} and C_{4v} symmetry), leading to 2352 and 1568 data points in T- and S-space, respectively. Univariate and bivariate statistics (analysis of variance and covariance) suggested the importance of deformations along paths B and C (Fig. 1) for the data in T-space, while in S-space deformations along paths A and B predominated.

The resultant twelve-dimensional data distributions were then analyzed by both hierarchical and nonhierarchical cluster analysis (CA), and the Euclidian distance was chosen as a measure of similarity. The method of nonhierarchical CA classified the data set into a user-specified number of clusters, while hierarchical CA employed a method called "Ward's method".[74] The search for the "ideal" number of clusters was fairly random in the initial stages, but a solution was soon found by use of the symmetry criterion, namely that the symmetry of the data distribution made explicit by the symmetry expansion must reappear in the results of CA. An additional criterion, implementable because two different clustering algorithms were employed, was that the classification of data points had to be identical, or very nearly so, for both methods.[75] Four clusters were identified in both spaces (see Fig. 12): in T-space a central cluster (cluster T3) representing an ideal TBP is surrounded by three identical clusters (T1, T2, T4) whose median configurations (archetypes) are distorted SQPs. Interestingly, the three SQPs represented by these clusters correspond to the alternate SQPs that could be obtained from the central TBP (cluster T3) by means of the Berry mechanism. In S-space, the data cluster about an fSQP and an eSQP archetype (S2 and S4), as well as two permutationally equivalent TBP archetypes (S1, S3)—the latter again correspond to the two TBPs that could ideally be formed from the eSQP. Note how the symmetry of the data distribution reflects the symmetry of the reference point groups.

The study interestingly revealed a strong homogeneity of the clusters. Histograms displaying the distance of each observation from the cluster center in most cases revealed no more than two or three outliers, and for all of these it was possible to rationalize why they appeared on the fringes of the clusters: in some cases the points corresponded to structures that were intermediate between SQP and TBP, or between fSQP and eSQP, while in others peculiar structural features of the compounds deformed them away from the minimum energy path.

An interesting comparison can be made between the scatterplots for the addition reaction at a nickel center in a square-planar environment in the earlier study[52] (Fig. 6) and the corresponding diagram for the study discussed here (Fig. 12, right). In the former, where only three geometric parameters are employed in the analysis, a distinction between the eSQP and the fSQP is hardly possible, whereas the clustering algorithm has been able to subdivide the group of square-pyramidally disposed structures into the two classes automatically. This speaks volumes for the power of this form of analysis, since the distinction between these two forms would appear to be a totally arbitrary one on the basis of a graphical analysis only: the representative points for the eSQP and the fSQP are likely to be separated by only a very small potential barrier on the Born-Oppenheimer potential energy surface for the ML_5 fragment, and the spread of observed molecular structures around these points can be expected to be large and diffuse, with no clear boundaries between the two distributions. Purely graphical techniques would consequently be unlikely to suffice as a means of differentiation. This point becomes clear when one compares the average sizes[76] of S2 and S4 (0.697 and 0.932 Å) with the distance between them (0.833 Å)—possibly the clouds of data points diffuse into each other. Despite this, the statistical technique evidently succeeded in fixing the positions of the archetypal configurations somewhere in the center of the cloud of data points surrounding them.

Principal component analysis did not enable a dramatic reduction in dimensionality, but it did reveal chemically meaning-



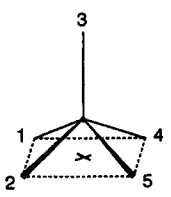


Fig. 12. Results of cluster analysis of d^8 metal complexes. The scatterplot on the left shows the clusters formed in T-space, that on the right those formed in S-space. Below each scatterplot is a qualitative interpretation of the cluster archetypes, and the deformation coordinates relating them.

ful results. For the TBP the two most important distortions are the S_N2 and the Berry deformations (steps C and B in Fig. 1), accounting for 15 and 24% of the variance, respectively. The eSQP was shown to distort along both the addition/elimination pathway (step A, 14%) and the Berry coordinate (12%). In an interesting contrast, the fSQP maps only the incipient stages of the addition/elimination reaction (14% of variance), and was not seen to distort along the Berry path. In this analysis, symmetry considerations also played an important role, in that only SCs of identical symmetry appeared together in the same PC. As an example, consider the first two PCs for the eSQP [Eq. (7a, b)]

$$PC1 = 0.888S_1 - 0.879S_2 + 0.879S_3 \quad (7a)$$

$$PC2 = 0.837S_4 + 0.837S_5 \quad (7b)$$

where the SCs (S_i) are defined as in Figure 13. The component SCs of PC1, mapping the addition/elimination deformation, are all of A_1 symmetry, while those of PC2, describing the Berry coordinate, all have B_1 symmetry, that is, no mixing of symmetries is observed.

$S_1(A_1) = r_3$

$S_2(A_1) = \frac{1}{2}(r_1 + r_2 + r_4 + r_5)$

$S_3(A_1) = (1/\sqrt{2})(\Delta\theta_{15} + \Delta\theta_{24})$

$S_4(B_1) = \frac{1}{2}(r_1 - r_2 - r_4 + r_5)$

$S_5(B_1) = (1/\sqrt{2})(\Delta\theta_{15} - \Delta\theta_{24})$

Fig. 13. Examples of some of the SCs used to represent the structures of observed pentacoordinate complexes. SCs shown are those derived for the SQP reference geometry; the atom numbering scheme is indicated. Their symmetries are given in the brackets.

Chemically, the results suggested interesting new possibilities: 1) the fact that the TBP cluster distorts along the S_N2 coordinate suggests that five-coordinate Rh and Ir compounds, which are significantly represented in this cluster, may undergo dissociation by an S_N2 mechanism via a (short-lived) tetrahedral intermediate, even though this may not be evident from the chemistry of their (square-planar) tetracoordinate complexes; 2) since the fSQP is not seen to map the Berry coordinate, other mechanisms may be operable in fluxional pentacoordinate Pt and Pd complexes (which are principally represented in this cluster), or at least, the complexes may have to undergo a considerable distortion of their coordination sphere to an eSQP before this mechanism can operate. This observation may be the reason for the lack of unambiguous experimental results that indicate Berry fluxionality in complexes of these metals.[70c]

5. Comparison of Structural Results with Theoretical Models

Ab initio calculations on compounds of the type dealt with in this paper are—arguably—only just becoming computationally feasible, and no real comparisons are yet possible between that type of theoretical approach, and the results of the structural analyses. However, studies involving simpler theoretical models are available. Kepert et al. have developed a simple repulsion model in which the ligand donor atoms, regarded as point charges, are assumed to be distributed on the surface of a hard sphere at the center of which the metal is sited.[77] The main purpose of this model is to classify, rationalize, and predict the stereochemistries of $[ML_n^x]$ complexes, where L represents either unidentate ($x = 1$), bidentate ($x = 2$), or less commonly, tridentate ligands ($x = 3$). For the composition $[ML_5^1]$, for instance, the data, which include both transition and nontransition metals, appear to fall into two categories: those that map the TBP → SQP transition, and those that do not; the latter to a large extent map the departure of an apical ligand from a SQP instead.[77, 78] This finding was later[52] corroborated in the analysis of 78 five-coordinate nickel complexes discussed in Section 4.2.1, where just under half the complexes were found to lie along paths B and C of Figure 1, while the rest map paths A and B.

In their study of $[ML_5^1]$ complexes, Favas and Kepert[78] defined an axis in the TBP, such that the angles between this axis and each of the ligand atoms A, B, and C, are all equal; angles ϕ_D and ϕ_E are then measured between this axis and the bonds to D and E. Figure 14 depicts the potential energy surface (PES)

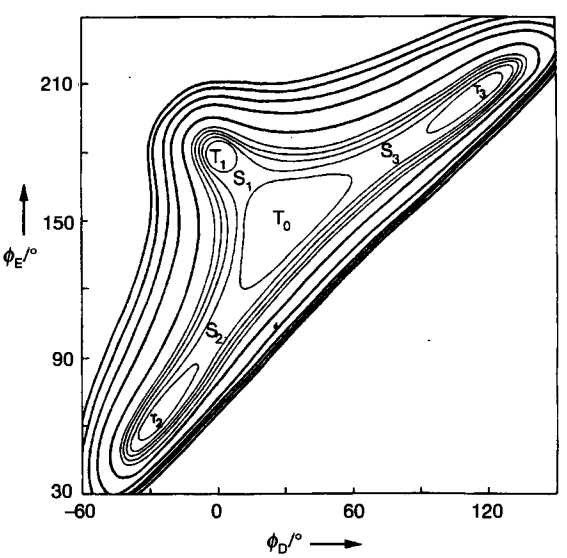

Fig. 14. Potential energy surface for $[ML_5^1]$ complexes. T_0, T_1, T_2, and T_3 represent TBP conformers that may be interconverted through SQP intermediates, represented by S_1, S_2, and S_3. The angular parameters ϕ_D and ϕ_E are described in the text.

for $[ML_5^1]$ molecules with C_s symmetry, projected onto the ϕ_D/ϕ_E plane. The positions of the TBPs and SQPs are shown by T and S, respectively, and the PES is symmetrical about the line $\phi_E = 180° - \phi_D$. The topography of this PES is mirrored in a scatterplot (Fig. 15, left) of the structural data for 33 zinc complexes (Section 4.2.2), in which the data have been projected onto a plane that is almost equivalent to the ϕ_D/ϕ_E plane, but is defined in terms of bond angles in the structures.[56]

For complexes of the type $[MA_2B_3]$, where A and B are unidentate, the PES has similar general features to those shown in Figure 14, but the relative energies of stereochemically distinct TBPs and SQPs, that is, of the potential minima (T_0, T_1,

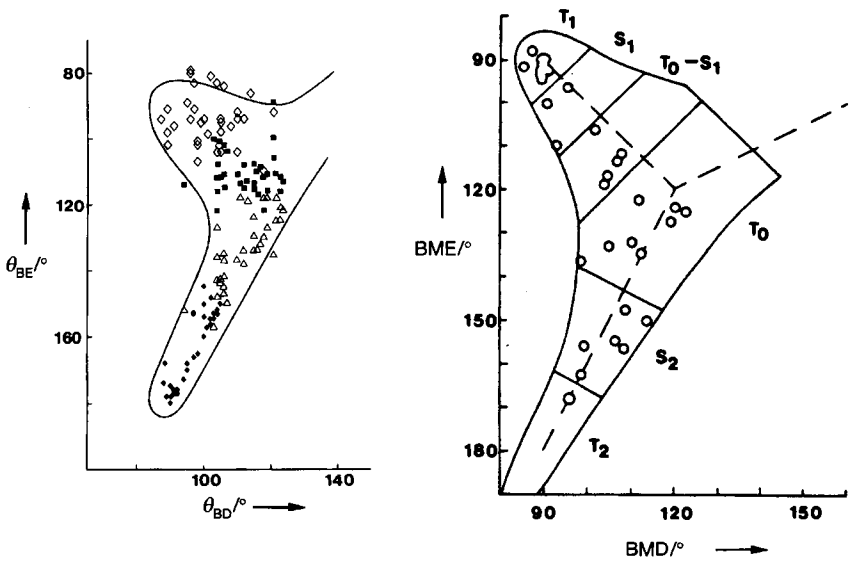

Fig. 15. Left: scatterplot of bond angles θ_{23} (equivalent to θ_{BE}) and θ_{34} (θ_{BD}) (see atom numbering in Fig. 2) for 33 zinc complexes [56]. The different symbols represent different permutations of the atom labels on the same molecular skeleton. Right: the same angular data for 51 mixed $[MA_2B_3]$ complexes (A, B = monodentate ligands) [78]. Note the similarity between the outlines of the distributions in these diagrams, and those of the potential energy surface in Figure 14.

T_2, T_3) and the saddle points (S_1, S_2, S_3), depend on the relative lengths of the M–A and M–B bonds. It is therefore not possible to obtain a unique representation of the PES for this model. Nonetheless, a plot of the angular data for 51 mixed complexes of this kind[78] reproduces the broad outlines of the PES for these $[ML_5]$ complexes (Fig. 15, right).[79] An analysis, along similar lines, of 16 $[ML^3L_2^1]$ compounds with a variety of transition and nontransition metals has provided an empirical mapping of a stereochemical interconversion of two distorted TBPs via a SQP intermediate, that maintains C_s symmetry.[80] The process is not equivalent to the Berry mechanism and has no readily recognizable counterpart among postulated $[ML_5]$ reaction mechanisms. Nevertheless, the data partially lie along troughs in the PES for this system, as established by using Kepert's model. Lastly, the amount of square-pyramidal distortion of eleven $[Cu(planar\text{-}L^3)L_2^1]$ complexes has been analyzed and quantified with the dihedral angle method of Muetterties and Guggenberger (Section 4.1.2), and the data distribution compared to the PES for this system according to Kepert's model.[81] A comparison of results showed that the ordering of the complexes along the TBP → SQP coordinate from the approach of Muetterties and Guggenberger was similar to the ordering that emerged from Kepert's model.

It has long been suggested that the geometry of ML_5 conformers will be dependent on the metal's d electron configuration;[82, 83] specifically the degree of 'flatness' of the SQP, and the ratios of the apical/basal and axial/equatorial bond lengths[84] in the SQP and TBP, respectively, are influenced by this factor. On the basis of an extended Hückel molecular orbital analysis of a $[PtL_5]^{3-}$ model, and considering only σ-bond strength,[85] Rossi and Hoffmann[83] predicted that the apical bond in a square-pyramidal d^8 complex would be longer than the basal bonds, while in the corresponding TBP the axial bonds would be shorter than those in equatorial positions. An empirical analysis by Holmes[86, 87] confirmed these predictions, but in that instance only fairly small samples were analyzed.[88] In the case of the multivariate analysis discussed in Section 4.3, the average axial bond in the TBP was found to be 0.030 Å longer than its usual reference value, while the equatorial bonds were 0.025 Å shorter, in contradiction to both the earlier empirical analysis and the theoretical predictions. In the case of the SQP, however, the results for the larger data set corresponded with those of Holmes, and with those of the theoretical prediction: for the eSQP the apical bond will be 0.030 Å longer, the basal bonds 0.008 Å shorter than the references, while the fSQP will have apical bonds that are on average 0.692 Å longer and basal bonds 0.165 Å shorter than their standard lengths.

According to Rossi and Hoffmann's calculations the "ideal" *trans*-basal bond angle (θ_{tb}) for a SQP environment of a d^8 metal center is 164°, but their model did not include the effect of spin. In his analysis, Holmes subdivided the compounds for which the spin state was known into low-spin and high-spin complexes (fourteen and nine compounds, respectively) and showed that low-spin complexes have a preference for the fSQP configuration (average $\theta_{tb} = 173°$), and high-spin complexes for the eSQP (average $\theta_{tb} = 161°$). The multivariate analysis revealed $\theta_{tb} = 171°$ for the fSQP (cluster S2 in Fig. 12; 39 structures), and $\theta_{tb} = 163°$ for the eSQP (S4; 88 structures), but it was not possible to correlate these values with spin state, since for most of the structures in the data set spin was not measured or reported. In addition, Holmes predicted that high-spin d^8 complexes would preferentially adopt SQP configuration over TBP, and his data seem to agree with this assertion. In the more recent study (Section 4.3) approximately twice as many compounds were classified as SQP than as TBP, and when regarding the individual metals, it is obvious that this tendency for the second- and third-row elements, which are more likely to be low-spin, is more pronounced than for nickel. Once again, without more knowledge of the spin states of the complexes, little can be definitely said about the conformational preferences of different spin states.

6. Discriminating Between Reaction Mechanisms: Metal Cluster Rearrangements

In previous sections we have focused on complexes in which the central metal atom is surrounded by five ligand donor atoms; here we shall be looking at one example of a metal cluster, where, although the metal atoms are not five-coordinate, the cluster framework nevertheless adopts regular polyhedral shapes known from pentacoordinate metal complexes. Metal clusters containing trigonal bipyramidal M_2Ru_3 fragments (M = Cu, Ag, Au) have been shown to exhibit dynamic behavior in solution, involving an intramolecular site exchange of the M atoms in the TBP.[89] In the absence of any geometric information about the interconversion pathways, Rodger and

Johnson have put forward three hypotheses concerning possible mechanisms for such polyhedral rearrangements.[90] They postulate that there are only two possible mechanisms[91] for site exchange in pentaatomic clusters: the first involves the stepwise cleavage and subsequent formation of a polyhedral edge, with an edge-bridged tetrahedral intermediate, while the second involves a concerted process and a SQP intermediate, akin to the Berry process. These alternative mechanisms are depicted in Figure 16.

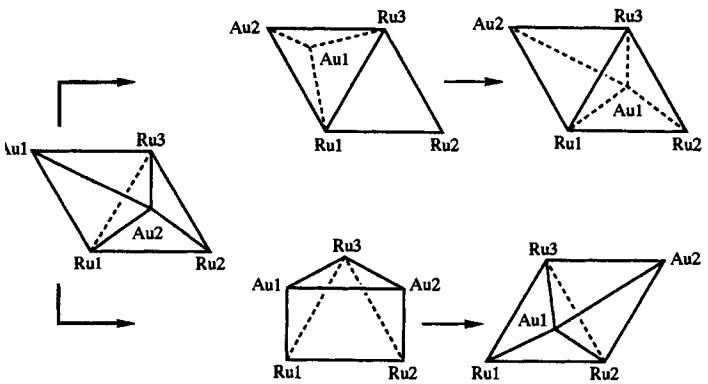

Fig. 16. Possible mechanisms for site exchange in Au_2Ru_3 clusters. Top: stepwise mechanism with edge-bridged intermediate; bottom: Berry process. The molecular fragments were defined by the lengths of the nine edges indicated for the TBP on the left, plus the distance Au1–Ru2.

An examination[92] of the structures of 19 Au_2Ru_3 fragments contained in clusters with a variety of carbonyl, phosphane, and μ_3-ligands (e.g. S, COMe) has revealed that site exchange most likely occurs by the Berry process. It proved possible to rule out tetrahedral edge-bridged intermediates and the alternative turnstile mechanism[37, 38] on the basis of the structural evidence. The data, composed of interatomic distances and selected bond and dihedral angles, were symmetry-expanded according to the C_s symmetry group common to the idealized TBP and SQP clusters, and the analysis included multivariate techniques and scatterplots. A dihedral angle plot, in which the dihedral angle between the planes Au1-Ru1-Au2 and Ru2-Ru1-Au2 (Fig. 16) —equivalent to the dihedral angle δ_{24} of Section 4.1.2. and Figure 2—is plotted against the corresponding bond angles θ_{15} and θ_{24}, reveals the typical 'V-shaped' Berry coordinate (Fig. 17). Corroborating evidence comes from the PCA, which yielded one PC accounting for 92% of the variance in the ten metal–metal distances chosen to represent the fragments (Fig. 16); the major components of this PC are the symmetry equivalent distances Au1–Ru2 and Au2–Ru1. The proposed mechanism is fully consistent with the results of NMR studies on the dynamic behavior of these fragments in solution.[89]

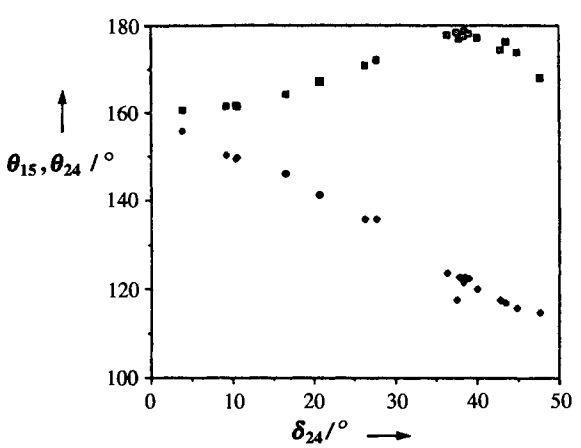

Fig. 17. Dihedral angle plot for Au_2Ru_3 clusters. The angles δ_{24} and θ_{15}, θ_{24} are described in the text.

7. Summary and Outlook

In retrospect, by and large the various structure correlation studies on pentacoordinate complexes have served to substantiate earlier hypotheses (made on the strength of (indirect) evidence from solution studies) about the likely geometric route that reaction pathways of ML_5 or (ML_4 + L) systems might take. Whereas those studies employing simpler two- or three-dimensional methods of analysis may not have significantly deepened our understanding of the mechanisms even though they have lent support to the structure correlation hypothesis, the multidimensional analysis revealed geometric details which suggest that these reaction mechanisms require more careful study with techniques that extend to shorter time-scales. Questions remain, for example, about the viability of the Berry pathway for isomerization reactions of platinum and palladium complexes, or about the possible existence of short-lived tetrahedral rhodium and iridium intermediates in substitution reactions of (square-planar) compounds of these metals. There may also be a need to reinvestigate the possible correspondence (or lack of it) between theoretical predictions[83] about ratios between axial/equatorial and apical/basal bond lengths and the empirical results.[70]

Even the application of the structure correlation method to ML_5 complexes has not yet been exhausted, since pentacoordinate copper complexes still seem to offer a fruitful field of research, for example. Another area of great interest would be an analysis of site preferences for various classes of ligands,[93] particularly in complexes of the d^8 metals; this could yield information about the *trans* effect in square-planar complexes, since five-coordinate intermediates are often invoked in mechanistic explanations of this phenomenon. Future work might focus more on obtaining energetic information along with geometric detail by combining kinetic and structural data to construct individual reaction-path and energy profiles.[45] It might also take advantage of the recent dramatic increases in availibility of computers with high performance to compare structural results with ab initio calculations on some of the systems discussed here. Connected to this is the use of results from structure correlation studies in the optimization of molecular modeling software: the averaged geometries obtained from structure correlation studies represent, at least, local potential minima, and can therefore be used in the process of minimization.[94]

Finally, without being able to offer an answer but in the hope that it may spur more work in the area, I wish to close with what appears to me a fundamental paradox. No single molecular Hamiltonian exists for the series of [ML_n] complexes, and hence there can be no potential energy surface for this "system". Why

is it, then, that these complexes exhibit such consistent correlations, when at most what they have in common is a metal atom surrounded by n coordinated ligand atoms?

I wish to thank the Chemistry Department, University of Cape Town, for hosting me so generously, thereby affording me the opportunity to do what most academic chemists can only dream of—completing unfinished manuscripts.

[1] This approach allows us to represent a molecule in terms of classical concepts of shape and structure, that is, as an ensemble of nuclei that vibrate with small amplitudes around well-defined positions in space. From this notion arises the possibility of depicting a molecule by a model in which the time-averaged nuclear positions are made to coincide with well-defined points in space. Notwithstanding its success, it should not be forgotten that this molecular theory has its origin in the Born–Oppenheimer approximation to the molecular Hamiltonian, according to which electronic and nuclear motions may be separated—and the latter largely ignored—or that there may also be other molecular theories that give rise to nonclassical interpretations and models; see S. [11] Under specific constraints, such as those imposed by symmetry considerations or those resulting from limitations on certain geometrical parameters, it may be possible to reduce the number of degrees of freedom from $3N-6$. For example, the imposition of T_d symmetry on a five-atom fragment reduces the number of parameters needed from nine to only one (the bond length); see J. D. Dunitz, *X-Ray Analysis and the Structure of Organic Molecules*, Cornell University Press, Ithaca, **1979**, Chapter 9.

[12] For one example of a structure correlation analysis involving positional coordinates see P. Murray-Rust, J. Raftery, *J. Mol. Graphics* **1985**, *3*, 50–59.

[13] For example, the number of internal distances of $N(N-1)/2$ is much larger than the number of degrees of freedom $(3N-6)$.

[16] With reference to the case cited in the text, for example, any molecules whose representative points fall exactly onto the S_1 or S_2 coordinates would exhibit full C_{2v} symmetry, since these coordinates transform as A_1. Expressed differently, any such molecules would differ from the reference structure only in their bond angle (S_1), or in the length of the two $X-Y$ bonds (each being shortened or lengthened by the same amount; S_2); both of these deformations maintain C_{2v} symmetry.

[17] In such cases it may be necessary to refer to the group theory of "nonrigid" molecules, see H. C. Longuet-Higgins, *Mol. Phys.* **1963**, *6*, 445–460; H. Frei, A. Bauder, H. H. Günthard, *Top. Curr. Chem.* **1977**, *81*, 1–97; R. L. Flurry, *J. Chem. Educ.* **1984**, *61*, 663–665.

[18] Statistical methods suitable for structure correlation studies have been reviewed in T. P. E. Auf der Heyde, *J. Chem. Educ.* **1990**, *67*, 461–469 and in ref. [9a, b].

[19] Crucial tools for this stage are the Cambridge Structural Database [20], which contains crystallographic data for a large number of organic and organometallic compounds, or the Inorganic Crystal Structure Database [G. Bergerhoff, R. Hundt, R. Sievers, I. D. Brown, *J. Chem. Inf. Comput. Sci.* **1983**, *23*, 66–69], housing data on inorganic structures. The databases allow the user to define a search fragment, and then retrieve all crystallographic structures that contain that fragment. The choice of a search fragment needs to be a judicious compromise between a definition that is too narrow in its scope, thereby precluding the retrieval of entries whose distortions might be of extreme interest and importance, and one that is so broadly stated as to include fragments which add nothing to the analysis—apart, that is, from time and effort spent on it.

[21] Angular and distance measurements, for example, are not directly comparable. Angles may be *scaled* to about the same range as distances, by expressing them as radial displacements α on a circle whose radius r is equal to the average bond distance in the data set: $\alpha = 2\pi r\,(\theta/360°)$. Alternatively, the data may be *standardized* to unit variance and zero mean, by using the z-transformation; see ref. [22] for other suitable scaling and standardization techniques. For an example of the z-transformation applied to crystallographic data in a structure correlation study, see R. Taylor, *J. Mol. Graphics* **1986**, *4*, 123–131.

[25] Principal component analysis is often referred to as factor analysis, a generically related, but distinct, method: C. Chatfield, A. J. Collins, *Introduction to Multivariate Analysis*, Chapman and Hall, London, **1980**.

[26] E. R. Malinowski, D. G. Howery, *Factor Analysis in Chemistry*, Wiley, New York, **1980**.

[27] The matrix (**E**) composed of the normalized eigenvectors is multiplied by the diagonal matrix ($\mathbf{\Lambda}^{1/2}$) of the square roots of the eigenvalues: $\mathbf{P} = \mathbf{E}\cdot\mathbf{\Lambda}^{1/2}$. The PCs are then obtained from the columns of the resulting $(3N-6)\times(3N-6)$ matrix (**P**), while the eigenvalue associated with each PC represents the proportion of the total sample variance accounted for by that PC.

[28] D. L. Massart, L. Kaufman, *The Interpretation of Analytical Chemical Data by the Use of Cluster Analysis*, Wiley, New York, **1983**; J. Zupan, *Clustering of Large Data Sets*, Research Studies Press (Wiley), Chichester, **1982**.

[29] For instance, a pair of otherwise identical structures may differ by 0.5 Å in a particular bond distance, while another pair differs only by 10° in a given bond angle. Without suitable scaling or standardization, the representative points for the first pair will be closer to each other than those of the second pair, even though the molecules of the first pair differ more than those of the second in a chemical sense.

[30] In crystallographic terms this is equivalent to the problem of ensuring that wherever possible all the atoms listed for a given molecule are found within the same asymmetric unit and not distributed over symmetry-equivalent positions throughout the crystal lattice, which would give rise to a disjoint molecule.

[31] In the case of the triatomic molecules discussed in Section 2.1, for example, this means that four points would be generated for any given structure, one for each of the four operations of the point group (C_{2v}). However, in this instance, the permutations for the operations E and $\sigma(xy)$ will generate the same coordinates for the representative point because the molecules are planar; the same goes for

the permutations brought about by the operations C_2 and $\sigma'(yz)$. The points will all be equidistant from the origin, that is, equally distorted with respect to the reference molecule, since they represent symmetry-equivalent permutations of the labeling of the atoms on the same molecular skeleton.

[32] See, for example, a) F. Basolo, R. G. Pearson, *Mechanisms of Inorganic Reactions*, 2nd ed., Wiley, New York, **1967**; b) G. K. Anderson, R. J. Cross, *Chem. Soc. Rev.* **1980**, *9*, 185–215; c) *Mechanisms of Inorganic and Organometallic Reactions*, Vol. 2 (Ed.: M. V. Twigg), Plenum, New York, **1984**; d) R. J. Cross, *Adv. Inorg. Chem.* **1989**, *34*, 219–292.

[33] G. K. Anderson, R. J. Cross, *Acc. Chem. Res.* **1984**, *17*, 67–74; R. J. Cross, *Chem. Soc. Rev.* **1985**, *14*, 197–223; R. J. Cross in ref. [32c], Chapter 5.

[34] a) Clearly, when the ligands are not all identical in the tetravalent complex the symmetry of the SQP will be lower (than C_{4v}). The term SQP then implies that all apical equatorial angles are only approximately equal. b) The SQP → TBP rearrangement implies that pairs of opposite apical-equatorial angles remain approximately equal during the process.

[35] R. S. Berry, *J. Chem. Phys.* **1960**, *32*, 933–938.

[36] The Berry deformation has been inappropriately called a "pseudorotation"; the latter term was borrowed from work on the fluxional puckering motion of cyclopentane (see J. E. Kilpatrick, K. S. Pitzer, R. Spitzer, *J. Am. Chem. Soc.* **1947**, *69*, 2483–2488), where it denotes an *equipotential* process in which the motion of the atoms is *perpendicular* to the direction of pseudorotation. As early as 1970 Muetterties pointed out that "the terminology is imprecise and should be dropped" (see footnote [44] in E. L. Muetterties, *Acc. Chem. Res.* **1970**, *3*, 266–273).

[37] Another mechanism proposed for such an intramolecular exchange process is the turnstile rearrangement [38]. However, two independent ab initio examinations, one on the model compound PH_5 (J. A. Altmann, K. Yates, I. G. Csizmadia, *J. Am. Chem. Soc.* **1976**, *98*, 1450–1454), and the other on PF_5 (P. Russegger, J. Brickmann, *Chem. Phys. Lett.* **1975**, *30*, 276–278), have shown that this mechanism requires a considerably higher activation energy and is not a strictly different pathway, but can be regarded as a distortion away from the minimum energy path of the Berry coordinate. Both studies conclude that a turnstile mechanism will only be realized for structurally restricted systems, and that the true saddle point corresponds to the square-pyramidal intermediate with C_{4v} symmetry. For the remainder of this paper we shall focus on the Berry process, referring to the turnstile mechanism only where explicit mention is made of it in the study under review.

[38] I. Ugi, D. Marquarding, H. Klusacek, P. Gillespie, F. Ramirez, *Acc. Chem. Res.* **1971**, *4*, 288–296.

[39] E. L. Muetterties, L. J. Guggenberger, *J. Am. Chem. Soc.* **1974**, *96*, 1748–1756.

[40] The increment in the observed bond distance between two atoms A and B is established relative to the length of a "standard" covalent A–B bond length. Standard bond lengths can be obtained from any number of tables, such as those compiled by L. Pauling, *The Nature of The Chemical Bond*, 3rd ed., Cornell University Press, Ithaca, **1960**. A comprehensive set of bond distances has recently been collected in A. G. Orpen, L. Brammer, F. H. Allen, O. Kennard, D. G. Watson, R. Taylor, *J. Chem. Soc. Dalton Trans.* **1989**, S1–S83; F. H. Allen, O. Kennard, D. G. Watson, L. Brammer, A. G. Orpen, R. Taylor, *J. Chem. Soc. Perkin Trans. 2* **1987**, S1–S19.

[41] L. Pauling, *J. Am. Chem. Soc.* **1947**, *69*, 542–553.

[42] J. K. Burdett, *Inorg. Chem.* **1979**, *18*, 1024–1030.

[43] Insofar as the reaction coordinates are obtained from a correlation analysis of all the structures comprising the data set, the underlying assumption behind this kind of approach (see also ref. [44]) is that the potential energy surface for each observed structure has exactly the same topography. This is clearly an untenable assumption, given the widely divergent compounds involved; the shortcomings of this approach have since been discussed in H.-B. Bürgi, J. D. Dunitz, *Acta Crystallogr. Sect. B* **1988**, *44*, 445–448.

[44] F. Pavelcik, E. Luptakova, *Collect. Czech. Chem. Commun.* **1990**, *55*, 1427–1434.

[45] H.-B. Bürgi, K. C. Dubler-Steudle, *J. Am. Chem. Soc.* **1988**, *110*, 4953–4957.

[46] They complained of the "irksome phrase...'the molecule is a *distorted* trigonal bipyramid'...encumbered with imprecise English and often encountered in structural papers" [author's emphasis], while admitting to using such language themselves.

[47] The term "polytopal isomer" was first coined by Muetterties in 1969 (E. L. Muetterties, *J. Am. Chem. Soc.* **1969**, *91*, 1636–1643), and it refers to a class of stereoisomers "of idealized polygons or polyhedra whose vertices are defined by the ligand atom positions in coordination compounds".

[48] Cadmium, phosphorus, cobalt, nickel, niobium, and antimony.

[49] This diagram has even found its way into an inorganic chemistry textbook; see J. E. Huheey, *Inorganic Chemistry*, 2nd ed., Harper and Row, New York, **1979**, p. 196.

[50] R. R. Holmes, J. A. Deiters, *J. Am. Chem. Soc.* **1977**, *99*, 3318–3326.

[51] A critique that might be raised here is that the nine dihedral angles described by the shape of the TBP polyhedron are not all independent.

[52] T. P. E. Auf der Heyde, L. R. Nassimbeni, *Inorg. Chem.* **1984**, *23*, 4525–4532.

[53] Allylic compounds were excluded from all the papers reviewed here, because it is difficult to identify a definite atom or point of ligation in such structures.

[65] N. J. Ray, L. Hulett, R. Sheahan, B. J. Hathaway, *J. Chem. Soc. Dalton Trans.* **1981**, 1463–1469.

[66] E. Müller, C. Piguet, G. Bernardinelli, A. F. Williams, *Inorg. Chem.* **1988**, *27*, 849–855.

[67] This representation included 15 parameters (five distances and ten angles), of which only twelve are independent.

[68] O. Carugo, C. B. Castellani, *J. Chem. Soc. Dalton Trans.* **1990**, 2895–2902.

[69] The main problem in this study lies with the conceptualization of the parameter space, which is defined in terms of "three coplanar axes at 120°", and yet is treated as an orthogonal "three-dimensional" space. The three axes are defined by the differences between the observed angles and the values they would adopt in a presumed SQP, each axis corresponding to a different permutation of the ligand labels in the complex. It is not clear that the three coplanar axes represent truly independent coordinates, and, moreover, in the hypothetical case of an observed complex having exactly the same geometry as the reference SQP, the denominator in the shape parameter becomes zero, rendering the parameter space ill-defined.

[70] a) T. P. E. Auf der Heyde, H.-B. Bürgi, *Inorg. Chem.* **1989**, *28*, 3960–3969; b) *ibid.* **1989**, *28*, 3970–3981; c) *ibid.* **1989**, *28*, 3982–3989.

[71] The data were retrieved from the July 1984 version of the CSD [20] and comprised 113 nickel, 15 palladium, 9 platinum, 28 rhodium, and 31 iridium structures.

[72] With regard to the SCs of Section 2.1, for instance, the length of the reference bond (in the calculation of the distance increment [40]) would cancel in S_3, which transforms as B_2, but not in S_2, which is totally symmetric (A_1).

[73] The fact that no "ideal" SQP needs to be defined also means, however, that there is no single representative point for this conformer in the corresponding 12-dimensional parameter space. Instead, all allowed SQPs with C_{4v} symmetry will lie along a continuous line, which reflects the one degree of freedom that this symmetry allows the SQP (see Section 3).

[74] L. Nørskov-Lauritsen, H.-B. Bürgi, *J. Comput. Chem.* **1985**, *6*, 216–228.

[75] A given structure whose representative point is clustered together with the points for all the other SQPs in the data set should, in general, be classified in this way, irrespective of the kind of algorithm employed.

[76] The size is defined as the average distance [Å] of cluster members from the center of the cluster.

[77] D. L. Kepert, *Inorganic Stereochemistry*, Heidelberg, Springer, Berlin, **1982**, and references therein.

[78] M. C. Favas, D. L. Kepert, *Prog. Inorg. Chem.* **1980**, *27*, 325–463.

[79] The angles BME and BMD are defined within the same plane in the structures as the angles ϕ_D and ϕ_E; the two pairs of angular parameters are therefore geometrically related.

[80] D. L. Kepert, E. S. Kucharski, A. H. White, *J. Chem. Soc. Dalton Trans.* **1980**, 1932–1938.

[83] A. R. Rossi, R. Hoffmann, *Inorg. Chem.* **1975**, *14*, 365–374.

[84] In line with our use of these terms in earlier papers [70], we refer to the apical bond in a SQP, and the axial bonds in a TBP.

[85] Rossi and Hoffmann also include π-donor and -acceptor effects in their analysis, but insofar as most of the complexes in the studies considered here would have minimal π-bonding ligands (see ref. [53]), these effects will not be discussed at this point.

[86] In these papers [87], Holmes presents a comprehensive overview of his structural work specifically with compounds containing pentacoordinate phosphorus and other main-group elements, as well as a compilation of studies on five-coordinate transition metal complexes. He compares the observed structures to those predicted by Rossi and Hoffmann [83] for a variety of different

d-orbital configurations, and interprets the observed conformations in terms of repulsions between nonbonding electrons in d-orbitals and electrons in bonding orbitals.
[87] a) R. R. Holmes, *Prog. Inorg. Chem.* **1984**, *32*, 119–235; b) R. R. Holmes, *J. Am. Chem. Soc.* **1984**, *106*, 3745–3750.
[88] Twenty-eight nickel, four platinum, five iridium, and seven rhodium complexes.
[89] See, for example, C. P. Blaxill, S. S. D. Brown, J. C. Frankland, I. D. Salter, V. Sik, *J. Chem. Soc. Dalton Trans.* **1989**, 2039–2047, and references therein; S. S. D. Brown, I. D. Salter, V. Sik, I. J. Colquhoun, W. McFarlane, P. A. Bates, M. B. Hursthouse, M. Murray, *ibid.* **1988**, 2177–2185; L. J. Farrugia, M. J. Freeman, M. Green, A. G. Orpen, F. G. A. Stone, I. D. Salter, *J. Organomet. Chem.* **1983**, *249*, 273–288.
[90] A. Rodger, B. F. G. Johnson, *Polyhedron* **1988**, *7*, 1107–1120.
[91] See also D. Britton, J. D. Dunitz, *J. Am. Chem. Soc.* **1975**, *97*, 3836.
[92] A. G. Orpen, I. D. Salter, *Organometallics* **1991**, *10*, 111–117.
[93] How do the π and σ properties of ligands affect their positions in the TBP and SQP, and how do they correlate with the stereochemistry of the complexes? Such an analysis would require algorithms capable of handling categorical variables (for the different sites or the different kinds of ligands) as opposed to continuous variables. For example, the influence of σ-donor capability on the dynamic stereochemistry of $[Ni(CH_3)_2A_3]$, where A is a weaker σ donor than CH_3, has been examined in K. Tatsumi, A. Nakamura, S. Komiya, A. Yamamoto, T. Yamamoto, *J. Am. Chem. Soc.* **1984**, *106*, 8181–8188.
[94] A. Vedani, D. W. Huhta, *J. Am. Chem. Soc.* **1990**, *112*, 4759–4767.

X-Ray Structure Analysis of Methane Monooxygenase: An Important Step toward Understanding the Oxidation of Methane in Biological Systems

Bernt Krebs* and Norbert Sträter

Metalloenzymes catalyze a variety of elementary chemical transformations in biological systems. Frequently the task of these highly active and efficient catalysts is to activate small and often also quite unreactive substrates like CO, CO_2, H_2, CH_4, NO, N_2, O_2, and H_2O. Besides the fundamental increase in knowledge about the construction of the active site, the determination of the structure of these proteins often also provides the key to the mode of action of the enzyme. In addition, the metal centers in biological systems can be imitated by synthetic biomimetic coordination compounds and thus serve as models for new, more active or more specific technical catalysts. Whereas the inference of exact structural information from spectroscopic data—with the exception of the data from multidimensional NMR spectroscopy—is very difficult, the complete three-dimensional structure of a biomolecule can be determined with crystal structure analysis. With the X-ray structure elucidation of the hydroxylase component of the methane monooxygenase (MMO) from *Methylococcus capsulatus* (Bath), the comprehensive characterization of an interesting active site that contains two iron atoms has now been achieved.[1] The structural basis for the mechanism of the difficult transformation of the nonpolar molecules CH_4 and O_2 under physiological conditions could be clarified.

The element iron is ubiquitous in virtually all living systems and performs very different functions, which, apart from its abundant availability in the biosphere, can be attributed to its redox behavior (most often Fe^{II}/Fe^{III}) and its varied coordination chemistry. The binuclear iron proteins have formed a particular research priority in recent years, arousing interest because of their broad distribution and the diverse modes of action. They participate in the reversible binding of oxygen (hemerythrin), in DNA synthesis (ribonucleotide reductase), in phosphate ester hydrolysis (purple acid phosphatases), in electron transport (rubrerythrin), and in hydroxylation of alkanes (methane monooxygenase). The crystal structures of hemerythrin[2] and ribonucleotide reductase[3] have already been elucidated (Fig. 1), and also the crystallization of rubrerythrin[4] and the purple acid phosphatase from kidney beans[5] has been achieved as a first step toward the X-ray structure analysis of these proteins that is underway.

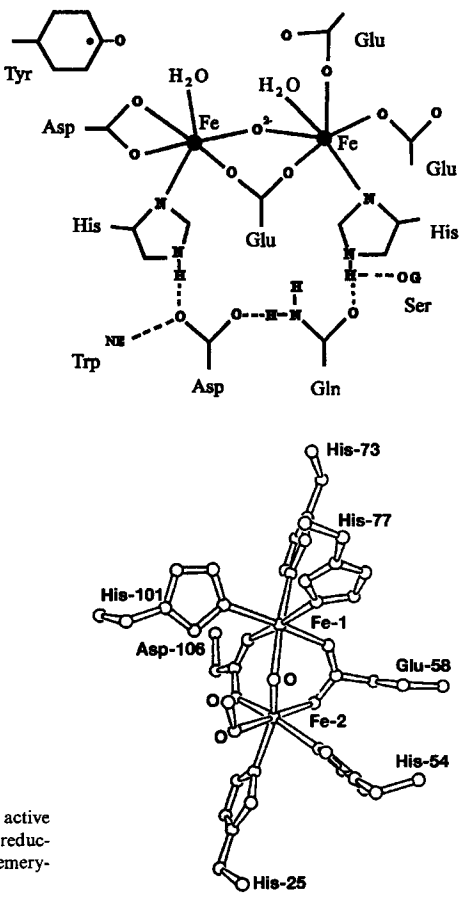

Fig. 1. Structure of the active site of ribonucleotide reductase [3] (top) and oxyhemerythrin [2] (bottom).

Methanotrophic bacteria can exploit methane as the only source of energy and carbon. They play an important role in the carbon cycle of the biosphere, because they limit the release of this greenhouse gas into the atmosphere. Apart from methane, monooxygenases can, however, also oxidize longer hydrocarbons. The methanotrophic bacteria have become technically important for the biological regeneration of ground polluted with oil[6] and for the oxidative removal of trichloroethylene from potable water.[7]

In the conversion of methane to methanol MMO catalyzes the first and indeed the most difficult step of the oxidation of hydrocarbons to carbon dioxide under physiological conditions [Eq. (a)]. The catalytic function of the metal center may be seen

$$CH_4 + NADH + H^+ + O_2 \longrightarrow CH_3OH + NAD^+ + H_2O \quad (a)$$

as the activation of the oxygen molecule for the reaction with the likewise rather inert C–H bond of methane. The MMO from *M. capsulatus* consists of three proteins: the hydroxylase (protein A, $M_r \approx 251$ kDa) that incorporates the iron-containing active center, the reductase (protein C, 38.6 kDa) that transfers the electrons from NADH to the hydroxylase, and a regulatory protein (B) with a molecular weight of 15.5 kDa. The hydroxylase in turn consists of three peptide chains with $\alpha_2\beta_2\gamma_2$ stoichiometry.

The structure of the hydroxylase complex was determined at a crystallographic resolution of 2.2 Å, which allows details to be discussed on an atomic level. Two αβγ protomers are linked through a noncrystallographic twofold rotation axis and form a relatively compact heart-shaped molecule of dimensions 60 × 100 × 200 Å. At the interface between the αβγ protomers is a large canyon; this, however, does not provide direct access to the active site. The secondary structures of the three subunits are strongly dominated by α-helices. The structure of the α and β subunits closely resembles the ribonucleotide reductase in terms of the arrangement of the secondary structure elements. The active site containing two iron centers is completely integrated into the α subunit (Fig. 2), with the result that four iron atoms are present per $\alpha_2\beta_2\gamma_2$ dimer. This result contradicts studies by atomic absorption spectroscopy, which yield an iron content of 2.3 mol per dimer.[8]

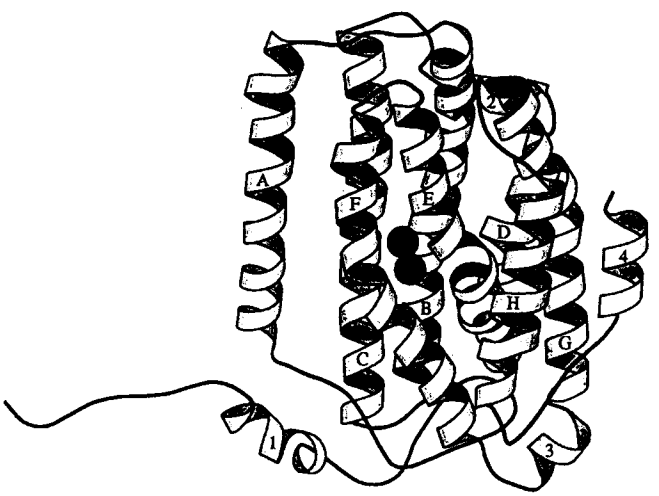

Fig. 2. Secondary structure of the α-subunit of the hydroxylase component of methane monooxygenase [1].

A model for the active site, proposed after determining and comparing the amino acid sequences of MMO from *M. capsulatus* with that of ribonucleotide reductase, was confirmed by structure elucidation.[9] The Fe^{III}–Fe^{III} distance was refined to 3.4 Å and is thus in good agreement with the interpretation of EXAFS data, which yield a distance of 3.42 Å.[8] In comparison, the metal–metal distances in the ribonucleotide reductase and in hemerythrin are 3.3 and 3.32 Å, respectively. Both iron atoms are in an approximately octahedral environment and are bridged by two exogenic ligands, which the authors interpret as a hydroxide and a bidentate acetate ion (Fig. 3). Since ammonium acetate was also present in the crystallization buffer, this ligand may not be coordinated to the enzyme in the cell. Possibly the methoxide ion binds as an oxidized substrate at this position before it is protonated and leaves the active site. A terminal aqua ligand is bound to the Fe(1) atom. The binding site for the oxygen molecule may also be localized here. This picture of the diiron site of hydroxylase is in agreement with EXAFS, ENDOR, UV/VIS, EPR, and Mössbauer studies that have been performed on the enzyme in solution.

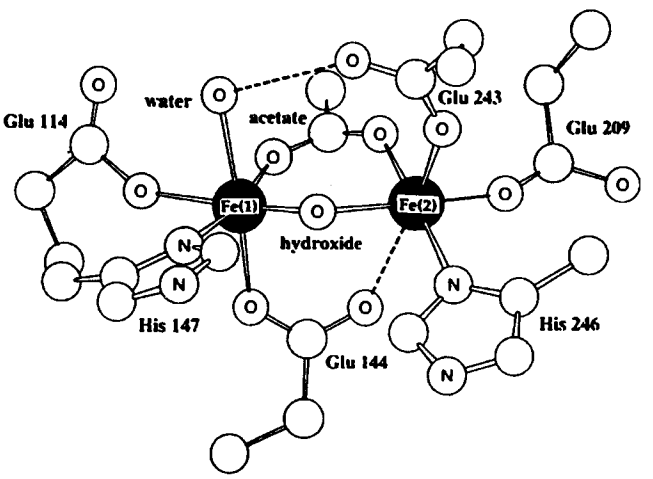

Fig. 3. Structure of the active site of methane monooxygenase [1].

Interestingly, the tyrosine radical important for the reaction mechanism of the structurally similar ribonucleotide reductase is replaced in MMO by a cysteine unit. A redox-active role for this SH group has been proposed, and the authors announce that further evidence will be published soon. Besides this cysteine unit, a threonine group is the only other protonated side chain in the vicinity of the active site. This group might thus have the function of providing the proton in the reaction. A cavity close to the active site is formed by predominantly hydrophobic side chains. Possibly the alkanes are preoriented here for conversion with the activated oxygen molecule at the Fe(2) atom. Because no direct access from the surface of the protein to the active center is present, the binding of the substrate must be made possible by a change in conformation of the enzyme, which is probably induced by interaction with the regulatory protein B. The presence of this protein also causes large changes in the spectroscopic properties of the hydroxylase, the rate of conversion, and the regioselectivity of substrate oxidation. This influence of protein B on the active site is probably transmitted through the helices E and F exposed to the large cavity at the αβγ dimer interface (Fig. 2); thus the binding of the B component in this cavity can be postulated.

This structure elucidation is a decisive step on the way to understanding the molecular mechanism of the oxidation of methane to methanol in biological systems. The structure provides the basis for a deeper interpretation of the available spectroscopic measurements and gives important impetus to further investigations. Also interesting is the structural relationship between MMO and ribonucleotide reductase, which gives us a new instructive example of how nature employs available structural

features—here both the tertiary structure and the active site—in the catalysis of completely different reactions. The future will certainly bring further structural analyses: for example, if samples crystallized in another buffer or containing the active site in a reduced state were to be analyzed, more detailed hypotheses of the reaction mechanism could be proposed. Possibly a larger complex of proteins A, B, and C could be crystallized, above all to study the immense influence of the regulatory protein on the structure of the active site.

Fullercages without Carbon—Fulleranes, Fullerenes, Space-filler-enes?

Reinhard Nesper*

Is the fullerene structural principle, revealed in recent years with the new modifications of carbon, of far more wide-ranging significance than has previously been assumed? Can the special geometry of fullercages form the basis for energetically favorable, or at the very least kinetically stable structures, with elements quite different from carbon? Such questions relate not only to derivatives of carbon fullerenes with metallic or organometallic species but also to what has previously been known as incorporation, or the replacement of carbon in fullerenes with heteroatoms. A new study by Corbett and Sevov entitled "Carbon-Free Fullerenes" has now provided further food for thought in a quite different direction.[1]

The two authors describe the ternary indides $Na_{172}In_{197}Ni_2$ and $Na_{96}In_{97}Z_2$ (Z = Ni, Pd, Pt), in which $Na_{12}In_{48}$, In_{70}, and In_{74} cages, each with fullerene-type structures, form characteristic structural elements. The fullercages are present, however, not as isolated clusters, but as two-dimensional layers in a quasi-closest-packed arrangement, connected through In–In bonds. The spaces between the layers are filled by the Na and Z atoms.

The fullercages in these indides are not empty. They contain additional interesting polyhedra, whose corners are located beneath the surface of the larger external polyhedra, in accord with the duality principle. These enclosed polyhedra can be designated endohedral units, thereby leading to the formulations $Na_{32}@[Na_{12}In_{48}]$, $Na_{37}@In_{70}$, and $Na_{39}@In_{74}$. The inner polyhedra are still fairly large and are each filled with one additional smaller polyhedron. In this way one of the most important structural principles of the intermetallic phases is also adhered to: a quasi-closest-packed arrangement in every sense. For the larger cages the overall structure of the multilayered polyhedra can, with respect to the central atom Z, be represented as $In_{10}@Na_{32}@[Na_{12}In_{48}]$, $Ni@In_{10}@Na_{37}@In_{70}$, and $Z@In_{10}@Na_{39}@In_{74}$ (Fig. 1c). The discrepancies with the overall formulas are due to additional interstitial atoms.

Substitution of spheres for the large cages in $Na_{96}In_{97}Z_2$ gives rise to an arrangement that corresponds very well to the nickel arsenite structure. The expression "hierarchical structures" was recently used by von Schnering et al. to describe arrangements in which large units containing many atoms, in this case fullerspheres, take the place of smaller, topologically similar species, here, simple atoms.[2] This comparison points to the fact that compounds that differ both in terms of stoichiometry and chemistry can apparently exist in similar arrangements, if these arrangements prove to be particularly favorable in a number of respects. Thus, a kind of fractal behavior or scale-symmetry is indicated in structural chemistry.[3]

We now come to the question as to whether fullercages are among the more favored arrangements. I believe so. Upon close scrutiny of the literature, it becomes clear that such polyhedra have indeed been frequently detected in chemical compounds since the 1950s; the first unambiguous example was β-rhombohedral boron.[4] However, intermetallic compounds may also contain fullercages (Table 1) formed between the more electronegative components in each compound, in which homopolar bonds are preferred.

In β-rhombohedral boron a B_{60} fullercage is present as the doubly endohedrally filled unit $B_{12}@B_{12}@B_{60}$ with connections in three dimensions (Fig. 1a).[4] As all the atoms are of the same type, all the bonds are covalent, even the shorter, stronger bonds between the B_{12} polyhedra. It is therefore difficult to consider the B_{60} polyhedra as distinct units in a chemical bond-

[a] VEC = valence electron number = average number of electrons per atom. [b] see Fig. 1b.

ing sense. Quantum mechanical investigations have not yet been carried out for the fullerpolyhedra in this boron modification—an additional challenge for courageous theoreticians.

What is certain is that the average number of valence electrons—three per boron atom—does not suffice for the formation of a fullerene or hence a system with VEC = 4. At first glance, the inwardly and outwardly orientated terminal bonds present a confusing picture (see Fig. 1a). Upon closer examination, however, multicenter and two-electron/two-center bonds can be assigned, in accordance with the Wade rules for electron-deficient polyhedra. All the five-membered rings, and hence all the bonds in the five-membered rings, comprise constituent parts of icosahedra, and thus Wade polyhedra. All other bonds, in other words those joining the five-membered rings, bridge the icosahedra and are thereby among the stronger two-electron/two-center bonds. It may be coincidental that the shorter and longer bonds in C_{60} and B_{60} are topologically equivalent.

On the basis of these considerations and by analogy with boranes the B_{60} polyhedron may be considered an electron-deficient fullerane with free terminal valences rather than a fullerene. Fulleranes constructed with single bonds and terminally linked on all sides have the same theoretical electron requirement as isolated fullerenes—VEC = 4. Thus, the boron structure has too few electrons for either structural form. However, boron may compensate for this through the formation of electron-deficient polyhedra, in this case icosahedra, which as a consequence must be integrated into the fullerane surface. Should β-rhombohedral boron therefore be perceived as a polymeric, electron-deficient variation of C_{60}? As is the case for the boron fullercage, N_{60} polyhedra are present in many of the compounds shown in Table 1. These polyhedra should correspond to the stronger covalent interactions, as in each case they are composed of the more electronegative components Al and Ga and display relatively short edge-dimensions.

Although all the phases listed in Table 1 display intermetallic character, the partial transfer of charge from the more strongly electropositive alkali and alkaline earth elements should be taken into account. But the charge transfer should be less pronounced than that in Zintl phases. Thus, it is not clear how many electrons are available for a given fullercage, in other words, how many electronic states are occupied. For the novel indides[1] and $LiMgAl_2$[5] only simplified theoretical investigations have been conducted to date with the extended-Hückel method. The maximum average number of electrons possible for the electronegative components, VEC_{max}, is attained when all the valence electrons are assigned to these atoms (see Table 1). Thus for N_{60} fulleranes (N = Al, Ga) $VEC_{max} = 3.0-3.3$; for the In_{70}, In_{74}, and $(Na,In)_{60}$ fulleranes in $Na_{96}In_{97}Z_2$ and $Na_{172}In_{197}Ni_2$ $VEC_{max} \approx 4$; and finally for Al_{76} in $LiMgAl_2$, the largest metal fullerane known to date, $VEC_{max} = 4.5$.

The indium atoms in these phases can thus formally obtain up to about four valence electrons, thereby permitting fullerane- or fullerene-type structures. No inward homopolar interactions are present, because no indium atoms are contained within the middle inner polyhedron; however, there are many terminal In–In bonds to the neighboring cages. Multiple bonding should be absent here, as a consequence of the low tendency towards such interactions among the heavy main-group elements, and thus, in analogy to the boron polyhedron, a fullerane formulation is proposed.

The largest cages to date are the doubly endohedrally filled Al_{76} fulleranes in $LiMgAl_2$, $Al_3M_7@M_{40}@Al_{76}$, where M = Li, Mg (Fig. 1d).[3, 7] Its size is compared to that of C_{60} in Figure 1f. The Al_{76} cages form a quasi-cubic-closest-packed arrangement, again in line with the hierarchical structure relationship. Since all the Al_{76} cages are linked through Al–Al bonds, there should be no double bonding contribution, and the large cage can be termed a fullerane. The results of simplified band structure calculations indicate that the fullerane Al atoms have an electron requirement of VEC $\approx$ 4 to achieve optimal bonding.[5] The electronic prerequisites for this are derived from the stoichiometry (see Table 1). In this way, only a single formal transfer of charge, $(Li,Mg)^+$ Al^-, is required per formula unit.

With this relatively simple classification of such phases by means of a more or less estimated valence electron count, it is clear that only a limited understanding of the chemical bonding can be achieved; however, this may still be useful for the synthesis of new compounds of similar type. In support of this preliminary qualitative hypothesis, we should emphasize that the structures of many aluminides, gallides, and indides can be rationalized by simple, formal charge-transfers and the Wade rules. Thus, the phases discussed here are not exceptional.[6–8]

The formation of metal fulleranes appears to begin with an icosahedral cluster which forms the innermost shell of a three-layer cluster that is typically completed by a fullerane sphere. For phases that obey this construction principle the term "icosogene" has been coined.[9] The shell-like construction, in which electropositive and electronegative atoms are segregated into different layers, is strongly reminiscent of tenside emulsions and micellar systems. For the two metal fulleranes the formation of the inner surfaces seems to be of considerable significance. Viewed superficially, the phases NaIn and $Na_{96}In_{97}Z_2$ scarcely differ from one another in stoichiometry and valence electron count; however, the latter phase contains Z atoms as nucleation centers.

This leads to the obvious question: when does growth from nucleation centers of icosahedral or pentagonal symmetry result in classical crystals and when in quasi-crystals? Interestingly, quasi-crystalline $LiMgAl_2$ has also recently been reported[16] (see also ref.[3]). One wonders whether fullerenes can also serve as nuclei for the growth of quasi-crystals.

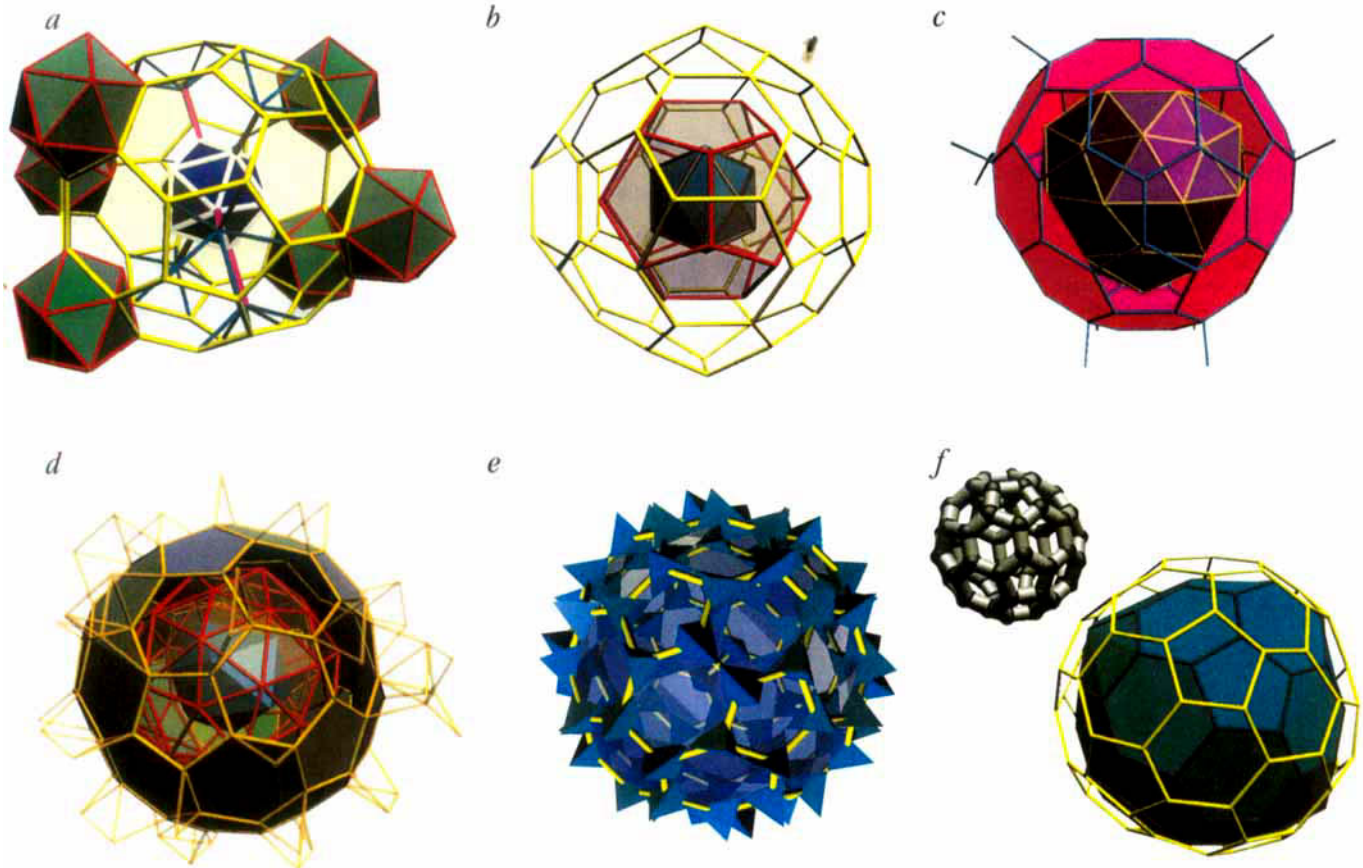

Fig. 1. Structures of endohedrally filled fullercages: a) β-rhombohedral boron. In the fullercage B_{60} all the five-membered rings form part of B_{12} icosahedra (red and blue rods; yellow rods for the corresponding fullerene five-membered rings), of which only half are represented completely. The central icosahedron (white rods) is linked through terminal bonds (thick magenta rods; only half are depicted for clarity) to all the icosahedra in the B_{60} surface. b) $(Al,Zn)_{49}Mg_{32}$ with $(Al,Zn)_{60}$ fullerane cage. The pentagon dodecahedron shown in red corresponds to the layer of atoms between the fullercage and the inner icosahedron. The fullercage shows distinct deformations which displace the atoms from the mean plane of the surface of the sphere. c) Multiply endohedrally filled $Na_{96}In_{97}Z_2$: $Z@In_{10}@Na_{39}@In_{74}$. Only the middle inner polyhedron Na_{39} is visible as depicted. The outwardly bridging In–In bonds are indicated. d) $LiMgAl_2$ with a doubly endohedrally filled Al_{76} fullerane: $Al_3M_7@M_{40}@Al_{76}$ (M = Li, Mg). The outwardly bridging Al–Al bonds (transparent golden rods) are shown on the fullerene surface (yellow rods). e) $Al_{84}O_{210}$ polyhedra in $Sr_{36}Bi_{22}Al_{48}O_{141}$ with AlO_4 tetrahedra (violet). This polyhedron is also filled by two further polyhedron shells, but these are not shown here. Since the polyhedron surfaces of the fullercage are depicted as transparent, the tilting of the AlO_4 tetrahedra can be discerned clearly. f) Comparison between C_{60} (left) and, Al_{60} (in $(Al,Zn)_{49}Mg_{32}$, solid, blue-green) in Al_{76} (right, yellow rods). The average sphere radii are 3.4, 6.8, and 7.4 Å.

Fullercages have already been identified in the structures of insulators, again in an arrangement in which distinct interactions lead to onion-skin-like constructions on the molecular scale. The compound $Sr_{36}Bi_{22}Al_{48}O_{141}$ is a complex oxide composed of a doubly endohedrally filled $Al_{48}O_{210}$ polyhedron with 12 five-membered rings and 32 six-membered rings[17] (Fig. 1e). Here, each O atom is situated not quite midway between two Al atoms ($Al_{84}O_{116}$). The three-way coordination of the Al atoms on the surface of the fullercage is increased to tetrahedral ($Al_{84}O_{210}$) through a further, terminal oxygen atom, whereby the linked AlO_4 tetrahedra give rise to a complex fullercage. It is therefore reasonable to anticipate more such structures in the chemistry of heteropolyanions.

Multiply endohedrally filled units are likewise known for the larger C_n fullerenes, for example, the "onion-skin fullerenes" constructed entirely from carbon atoms.[19] It is, however, also possible to include here other molecular species that form van der Waals complexes with C_n fullerenes, in other words, host–guest compounds. Access to clathrates of this type is not very likely with the Krätschmer process,[18] as few potential guest molecules have sufficiently high thermal stability. Rather, fullerenes must first be synthesized at significantly lower temperatures before such inclusion compounds would appear completely conceivable.

Finally, there remains the question as to whether other heavy elements are able to form fullerenes or fulleranes. Since silicon and germanium tolerate a greater range of bond angles, they would be expected to form cages that would be geometrically stabilized by endohedral filling. Whether a multiply bonded structure would have any energetic chance over a singly bonded fullerane is another open question. For the tricoordinate elements phosphorus, arsenic, antimony, and bismuth, endohedrally stabilized fulleranes seem entirely imaginable.

But why should we stop here? A great number of multicomponent compounds can be discussed in this manner and may even have been prepared in a few laboratories. Binary compounds are suitable only with certain preconditions because of the unavoidable frustration in the five-memberd rings. Perhaps other large polyhedra with rings having an even number of members and whose geometry and solid-state structure are also

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0808-0845 $ 10.00+.25/0

known are more favorable—they do not always have to form fullercages!

Organoplatinum Dendrimers Formed by Oxidative Addition**

Sudhir Achar and Richard J. Puddephatt*

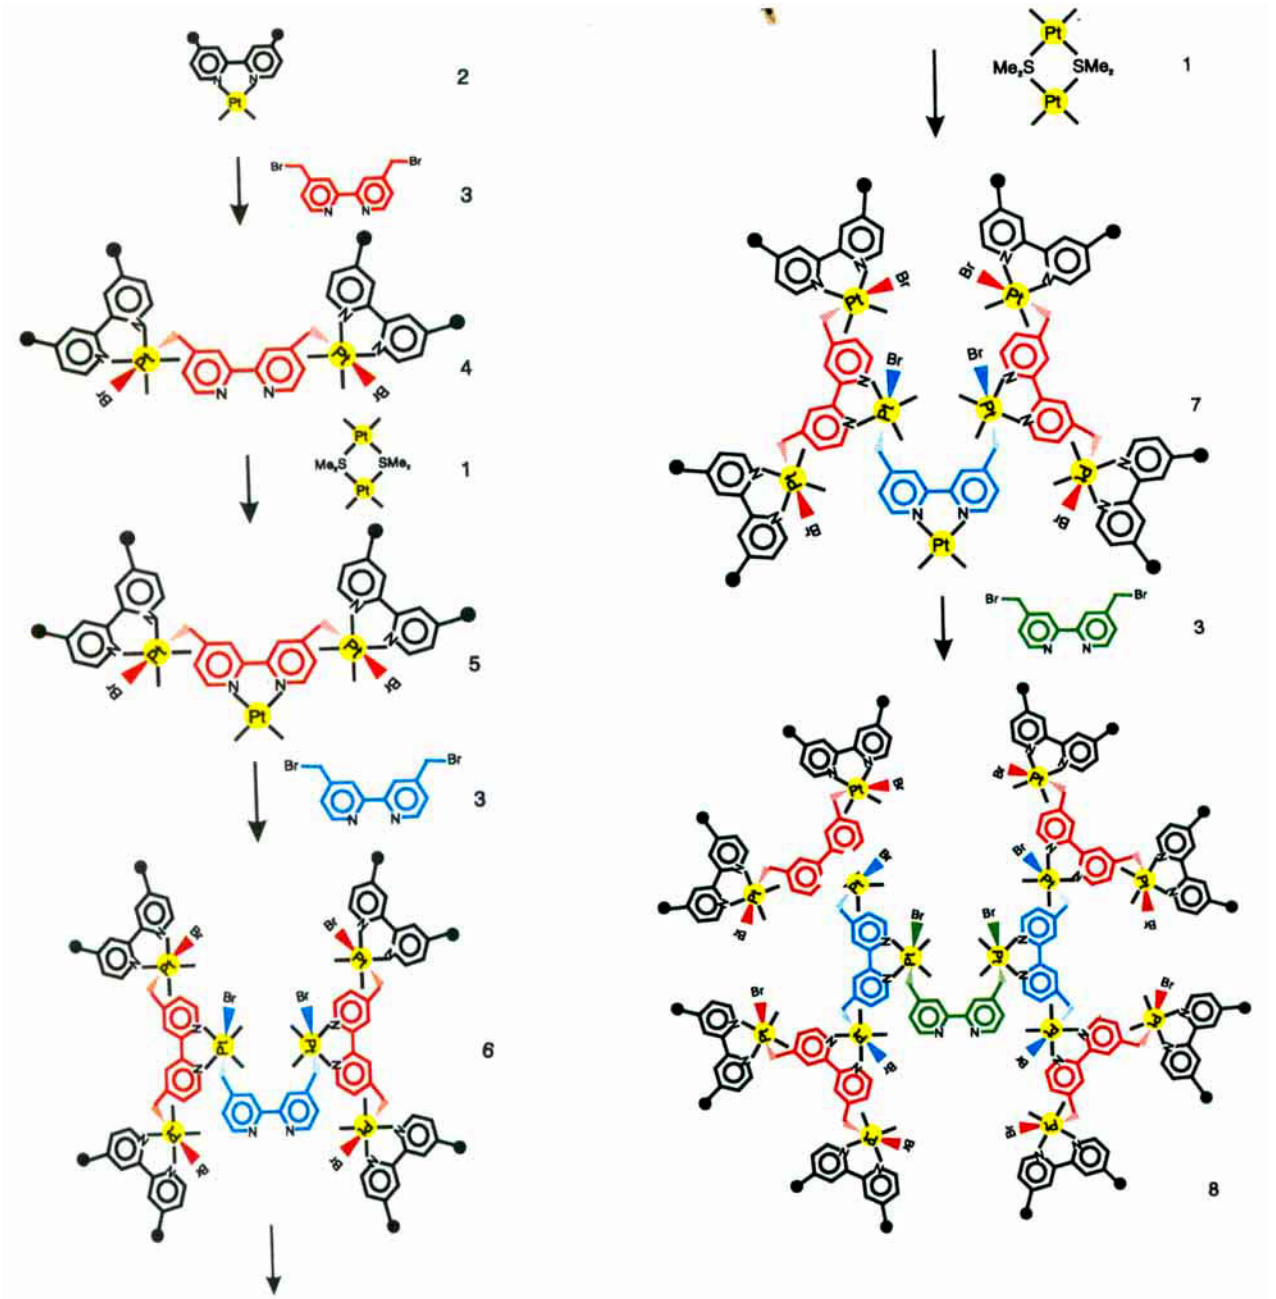
Dendrimers are branched molecules the synthesis and characterization of which are of great current interest.[1-7] Most known dendrimers are organic compounds, but those containing inorganic functional groups are also of interest. Recently dendrimers containing ruthenium(II) coordination centers,[6] organosilicon centers,[4] and (η-arene)η-cyclopentadienyliron centers[4] have been reported but there appear to be no examples of dendrimers containing alkyltransition metal groups.[1,7] Hitherto, dendrimers were synthesized by one of two stepwise approaches, namely the divergent method[1] (construction from the center outwards) and the convergent method[2,3] (construction from the outside to the center). To be successful, both methods require that very high yields are obtained for the individual steps and this is difficult to achieve in many organometallic reactions. We report here a new method of synthesis which has yielded the first polynuclear, dendritic organotransition metal complexes. This synthetic method is based on two known reactions. First, the displacement of the SMe_2 ligands from $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (**1**) by diimines is easy and essentially quantitative and yields $[PtMe_2(diimine)]$.[8] Second, oxidative addition of benzyl bromide and related molecules to $[PtMe_2(diimine)]$ occurs quantitatively to give $[PtBrMe_2(benzyl)(diimine)]$.[9,10] In particular, $[PtMe_2(bu_2bpy)]$ (**2**), (bu_2bpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine) is very reactive towards oxidative addition and the products are more soluble than those obtained by using $[PtMe_2(bpy)]$, (bpy = 2,2′-bipyridine).[10] The oxidative additions are readily monitored by a change in color from orange-red for the platinum(II) complexes such as **2** to pale yellow for the platinum(IV) products,[11] and by a decrease in the coupling constant $^2J(Pt,H)$ for the methylplatinum groups in the ^1H NMR spectrum from 84–86 Hz in **2** to 69–70 Hz in the platinum(IV) products.[8-10]

The reaction sequence leading to the organoplatinum dendrimer is shown in Scheme 1 (the black circles represent the *tert*-butyl groups). Oxidative addition of the C–Br bonds of 4,4′-bis(bromomethyl)-2,2′-bipyridine (**3**)[12] to the platinum(II) centers of **2**[11] gave the binuclear platinum(IV) complex **4**, which was isolated as a pale yellow solid. Complex **4**, which contains two stable platinum(IV) centers and a free diimine functionality, is formed selectively by *trans* oxidative addition.[13] The subsequent reaction of **4** with **1** occurred with displacement of $PtMe_2(SMe_2)_2$ to give the trinuclear complex **5**.[13] Complex **5** is orange-red and contains a new, reactive platinum(II) center with similar reactivity to that in **2**. This represents the end of the first growth cycle in which the platinum nuclearity is first doubled, then increased by one with regeneration of the platinum(II) center required to participate in the next cycle (in Scheme 1, the new diimine derived from **3** is color-coded red to aid identification in later steps).

In the second growth cycle, trinuclear **5** reacted in a 2:1 molar ratio with **3** (color-coded blue in the Scheme 1), with doubling of the nuclearity to give the pale yellow hexanuclear platinum(IV) complex **6**,[14] which again contains a free diimine group. Reaction of **6** with **1** adds a new platinum(II) center and leads to the orange-red heptanuclear **7**.[14]

In the third growth cycle, heptanuclear **7** reacted cleanly in a 2:1 molar ratio with **3** (color-coded green in Scheme 1) to give the pale yellow Pt_{14} cluster **8**.[15] After this stage the reactions occurred less cleanly. Thus, reaction of **8** with **1** did not occur quantitatively, and reaction of this impure product with more **2** failed to give the desired Pt_{30} complex. This limit to growth can be understood in terms of steric hindrance. Thus the synthetic method shown in Scheme 1 is convergent[2,3] with the result that the reaction center becomes more sterically hindered with each growth cycle until a limit is reached at which further reaction is suppressed. In our sequence, modification of the reagents to reduce steric hindrance is required to achieve growth beyond the Pt_{14} dendrimer.

An uncontrolled dendrimeric growth is observed on reaction of **1** with **3**. The first step is substitution of the SMe_2 ligands of **1** by the diimine to give the red $[PtMe_2(\mathbf{3})]$ which then reacts by intermolecular oxidative addition of the C–Br bonds to give an insoluble yellow polymer.



The new dendrimers are characterized by several methods. The formation and reaction of the platinum(II) centers can be monitored by UV/VIS spectroscopy by the growth and decay, respectively, of the metal to ligand charge transfer band [5d(Pt^{II}) to π^*(diimine)] at 430–470 nm in acetone solution. Analytical and NMR spectroscopic data are particularly useful. The NMR spectra become more complex as the molecular size increases. For complexes **4** and **5**, complete assignments including $^{195}Pt,^1H$ coupling constants can be made; for complexes **6** and **7**, almost all proton resonances can be assigned but peak broadening makes assignment of $^{195}Pt,^1H$ couplings difficult; for complex **8**, peaks are further broadened but peak integration is still useful and the interpretation of the spectra is fully consistent with the proposed structure. The increase in molecular weight on going from **7** to **8** can be monitored by gel permeation chromatography (GPC). The apparent molecular weight by GPC referenced to polystyrene standards was 1700 for **7** and 2900 for **8**, fully consistent with a doubling of molecular size.[16] The solubilities of the complexes follow the sequence **8** $\gg$ **7**, **6** $\gg$ **5**, **4** $\ll$ **1**, as expected since the greater solubility associated with the branched dendrimeric structures is only expected at the second growth cycle.[1-7]

In summary, it is clear that the methodology described above has succeeded in the synthesis of the first alkyltransition metal dendrimers. The highest nuclearity obtained is Pt_{14} but modification of the method should lead to controlled synthesis of even higher nuclearity dendrimers. The stuctures of these molecules not only have considerable aesthetic appeal but add a new dimension to the range of potentially useful dendrimers.[1-7]

[14] Complex **6**: ^{1}H NMR (300 MHz, $CDCl_3$): δ: 1.2–1.37 (72H, *t*Bu), 1.12, 1.4–1.6 (36H, Pt^{IV}-CH_3), 2.1–3.0 (12H, Pt^{IV}-CH_2), 8.40, 8.68 (d, 4H each, H-6, H-6′ of bu_2bpy); 8.05 (s, 8H, H-3, H-3′ of bu_2bpy); 7.28, 7.58 (d, 4H each,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0808-0848 $ 10.00+.25/0

H-5, H-5′ of bu_2bpy)], [5.71 (d, 4H, H-5, H-5′ of first generation diimine), 6.83 (s, 4H, H-3, H-3′ of first generation diimine), 8.11 (d, 4H, H-6, H-6′ of first generation diimine)]; [6.65 (d, 2H, H-6, H-6′ of second generation diimine); 6.48 (s, 2H, H-3, H-3′ of second generation diimine), note that the signals of H-5 and H-5′ of second generation diimine are obscured. Complex **7**: ^{1}H NMR (200 MHz, [D_6]acetone): $\delta = 0.65$ (s, Pt^{II}-CH_3), 1.1–1.7 (108 H, *t*Bu and Pt^{IV}-CH_3), 2.5–3.4 (12 H, Pt^{IV}-CH_2); UV/VIS (CH_3CN): $\lambda_{max} = 430$ nm.

[15] Complex **8**: ^{1}H NMR (200 MHz, $CDCl_3$): δ: 1.0–1.8 (228 H, 144 in *t*Bu and 84 in Pt^{IV}-CH_3), 2.5–3.1 (28 H, Pt^{IV}-CH_2), 6.0–8.8 (m, 90 H, aromatic CH). Note the absence of a CH_2Br resonance, which would be present if only partial oxidative addition occurred, and the absence of a MLCT band in the UV/VIS which would be present if some Pt^{II} centers remained unreacted.

[16] GPC analysis was performed in THF employing polystyrene standards. The absolute molecular weights cannot be expected to be correct since the standards are linear and organic, while **7** and **8** are more spherical with heavy metal content. Nevertheless, GPC is shown to be useful for characterization of organometallic dendrimers.

[17] Editorial note: Y.-H. Liao and J. R. Moss recently reported on organoruthenium dendrimers with Ru–C bonds (*J. Chem. Soc. Chem. Commun.* **1993**, 1774). In these dendrimers the organoruthenium units are, however, exclusively functional groups on the dendrimer surface.

$[Mo_{57}Fe_6(NO)_6O_{174}(OH)_3(H_2O)_{24}]^{15-}$: A Highly Symmetrical Giant Cluster with an Unusual Cavity and the Possibility of Positioning Paramagnetic Centers on Extremely Large Cluster Surfaces**

Achim Müller,* Winfried Plass, Erich Krickemeyer, Stephan Dillinger, Hartmut Bögge, Anja Armatage, Anna Proust, Christian Beugholt, and Ulf Bergmann

Dedicated to Professor Otto Scherer on the occasion of his 60th birthday

How is it possible to synthesize larger and larger molecular constructions, for example clusters, in a range we shall call mesoscopic? It certainly would be of considerable importance if one could obtain relatively large intermediates by a self-assembly process;[1] these quasi-preorganized building blocks could then be combined to giant molecules, a step that, of course, requires a detailed knowledge of the system. Significant in this context is that extraordinary and novel properties—for example magnetic and electronic—can be expected for mesoscopic compounds. This is especially true, if the relevant compounds do not represent a section of a solid-state structure.

The following novel route can be pursued for this: Substitution of more positive by less positive metal centers M′—for example, molybdenum(VI) by vanadium(IV) centers in oxometalates of the α-Keggin type anion $[Mo_{12}XO_{40}]^{3-}$ (X = P, As)—results in highly negatively charged (that is, nucleophilic) intermediates. These can either be stabilized by cationic species or, as here, connected to give larger moieties. In the case of $[Mo_{12}AsO_{40}]^{3-}$ the intermediate $[Mo_8^{VI}V_4^{IV}As^{V}O_{40}]^{11-}$, formed according to above formalism, can be stabilized in aqueous solution, for example by As^{3+}, affording the $[As_2^{III}Mo_8^{VI}V_4^{IV}As^{V}O_{40}]^{5-}$ cluster.[2] In the absence of arsenic further condensation occurs;[2] hence, it stabilizes the α-Keggin ion. As intended, a large polymolybdate is formed as an intermediate that, as a reactive, highly negatively charged ligand can be connected in various ways by metal cations M′ or cationic groups (e.g., $VO^{2+}/Fe^{3+}/MoO_2^{2+}$) to yield large molecular constructions. In this way one arrives at giant (metal) clusters with open d-shells and/or novel band structures and probably also at compounds with unusual material properties.

Heating an aqueous, hydrochloric acid solution of sodium molybdate dihydrate and iron(III) nitrate nonahydrate with hydroxylammonium chloride under reflux results in the formation of **1**. This highly symmetrical ($\bar{6}m2$; D_{3h}) torus-like giant cluster anion with a size in the nanometer range comprises 276 atoms (excluding H atoms) and has a molecular weight of 9250.9 Da (Fig. 1). Six Fe^{3+} centers and three (formally) cationic $[Mo\text{-}(\mu\text{-}H_2O)_2(\mu\text{-}OH)Mo]^{9+}$ moieties connect three Mo_{17} ligands, $[Mo_{15}^{VI}(MoNO)_2^{3+}O_{58}(H_2O)_2]^{20-}$. This now allows for exchange and positioning of cationic centers M′ with open d-shells while at the same time retaining the Mo_{17} moieties as spacers.

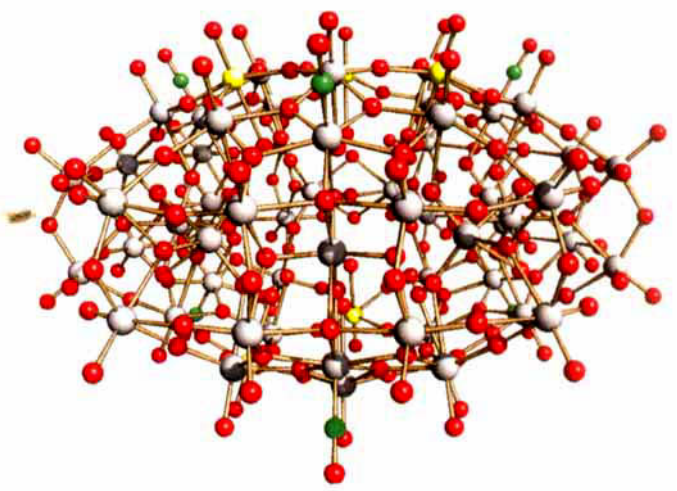

Fig. 1. Ball-and-stick model of the cluster anion of **1** viewed (approximately) along one of the $2(C_2)$ axes (outer diameter: ca. 2.5 nm; color code: Mo light gray, Fe yellow, O red, and N green).

$Na_3(NH_4)_{12}[Mo_{57}Fe_6(NO)_6O_{174}(OH)_3(H_2O)_{24}] \cdot 76H_2O$ **1**

Characterization—especially determining the kind of protonation and the oxidation states of the metal centers—has, due to the size of **1**, required the application of numerous methods: elemental analysis (including determination of NH_4^+ by Kjeldahl nitrogen analysis), single-crystal X-ray structure analysis,[3] calculation of the bond valence sum for the metal and oxygen atoms, redox titration (manganometric), thermogravimetry, magnetochemical measurements as well as UV/VIS/NIR, IR, Raman, ^{57}Fe Mössbauer, and ESR spectroscopy.[4] Limiting oneself to the results of the X-ray structure analysis can lead to extreme possibilities for mistakes as work by Zhang et al.[5] clearly shows. For compounds **2** and **3** the authors published completely wrong results: for **2** a cluster charge of 6– instead of 21– and incorrect cations were reported, while for the highly negatively charged cluster in **3**, the structure was

$(NH_4)_{21}[Mo_{57}V_6(NO)_6O_{180}(OH)_3(H_2O)_{18}] \cdot 65H_2O$ **2**

$(NH_4)_{12}[Mo_{36}(NO)_4O_{108}(H_2O)_{16}] \cdot 33H_2O$ **3**

incorrectly described and was formulated as a neutral unit.[5] This is a particularly serious error since different formulations correlate with completely different expectations for the important magnetic and electronic properties.

Compound **1** exhibits a multitude of different coordination polyhedra (Fig. 2). In the Mo_{17} moieties a central heptamolybdate fragment is discernible, which contains two $(MoNO)^{3+}$ groups as pentagonal bipyramids. An additional interesting

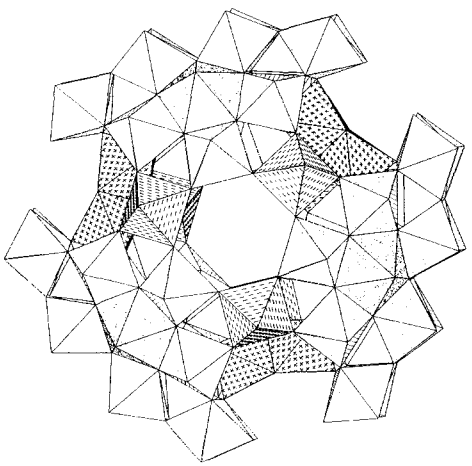

Fig. 2. Polyhedral representation of the cluster anion of **1** showing the three Mo_{17} units. The $Fe^{III}O_4(OH_2)_2$ octahedra are shown with broken lines, the $[Mo(\mu\text{-}H_2O)_2(\mu\text{-}OH)Mo]$ moieties with crosses, the pentagonal $Mo(NO)_6$ bipyramids are randomly dotted and the MoO_6 octahedra have a regular pattern of dots (selected distances: Mo–N 171.4(11); N–O 126.2(16); Fe–$(OH_2)_{term}$ 204.1(9); 217.7(9); Fe–O_{6r} 194.0(7), 195.0(7) pm); the distances for M=O- and Mo-O-Mo moieties are within the expected range.

structural element are two alternating Fe-O-Mo-O twelve-membered rings perpendicular to the $\bar{6}(S_3)$ axis. Inside the cluster anion is a relatively large cavity, which is formed by a central O_{33} polyhedron (cf. Fig. 3). Two planar H_2O six-membered

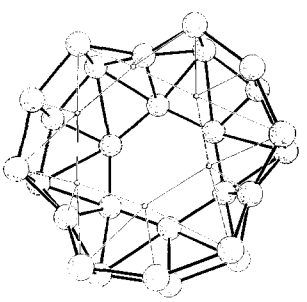

Fig. 3. Characterization of the cavity in the cluster anion of **1** (diameter normal to the $\bar{6}(S_3)$ axis ca. 0.9 and parallel ca. 0.5 nm, without taking the hydrogen atoms into account), formed by the central O_{33} polyhedron (consisting of twelve terminal H_2O molecules, three μ_2-OH groups of the $[Mo(\mu\text{-}H_2O)_2(\mu\text{-}OH)Mo]$ moieties and eighteen μ_2-O atoms).

rings each lying beneath the Fe-O-Mo-O twelve-membered rings are integrated in the O_{33} polyhedron. Since, here similar structural elements are observed as for a modification of ice, the H_2O six-membered rings possibly have a template effect for the formation of the shell structures (remarkable in this regard is the observation that the cluster anion in **1** is apparently *not* formed in D_2O as the reaction medium). Furthermore, the formation of hydrogen bonds of the H_2O molecules which border the cavity points to an interesting relation with clathrates (Fig. 3).[7] Clathrates are namely crystalline framework inclusion compounds whose host structures are constructed in such a way that isolated or bound cavities form, which can contain partly or completely small, in general, uncharged guest species. Since in the main only weak van der Waals interactions exist between the host matrix and the guests, it often happens that the guest species are disordered.[7] Evidently, in connection with the possible presence of H_2O molecules,[3] **1** can be classed as a molecular model for clathrates.

Magnetic measurements for compound **1** at room temperature gave a value of $\mu_{eff} = 15.1\ \mu_B$, as expected for the presence of six high-spin iron(III) centers (expected spin-only value for six uncorrelated $S = 5/2$ centers: $\mu_{eff} = 14.5\ \mu_B$).[8] The temperature-dependence of μ_{eff} between room temperature and 80 K is indicative of a weak, but significant exchange interaction of antiferromagnetic type with small coupling constants. The interpretation of the ESR spectrum recorded at room temperature is consistent with this small exchange interaction. The presence of iron(III) centers can also be confirmed by Mössbauer data (at 100 K: isomer shift $\delta = 0.50 \pm 0.02\ mm\,s^{-1}$ vs. α-Fe and quadrupole splitting $\Delta E_Q = 1.14 \pm 0.01\ mm\,s^{-1}$) as well as by bond valence sum calculations.

Vibrational spectra (IR and Raman spectra) of **1** show the characteristic bands for the Mo_{17} moieties,[4] as well as the characteristic band for the ν(NO) stretching vibration, which proves the presence of a linear $(MoNO)^{3+}$ moiety.[9] On the basis of this data **1** can be described as follows:

$$Na_3(NH_4)_{12}[\{Fe^{III}(H_2O)_2\}_6\{Mo(\mu\text{-}H_2O)_2(\mu\text{-}OH)Mo\}_3\text{-}\{Mo^{VI}_{15}(MoNO)^{3+}_2O_{58}(H_2O)_2\}_3]\cdot 76H_2O \quad \mathbf{1}$$

From bond valence sum calculations the cationic group can be approximately formulated as a $[Mo^{V}(\mu\text{-}H_2O)_2(\mu\text{-}OH)Mo^{V}]$ moiety. This implies that the 4d electrons are only predominantly located on the relevant Mo centers. The results of additional spectroscopic investigations, the interpretation of which with regard to the electronic properties is extremely difficult due to the size of the cluster, will be correlated with the interesting material properties in the future.

It is especially efficient, if the range of nanostructures that is of interest to molecular materials becomes, as here, accessible by a self-assembly process.[10] Polyoxometalates are premier objects of investigation, since between the limiting cases of "molecular" systems (type MO_4^{n-}) and oxidic solids, there are mesoscopic forms with a fascinating structural variety and unusual material properties.[11] It must be emphasized that the last two classes of compounds are formed by the same chemical process, that is acidification of a solution containing MO_4^{n-} anions.[11]

Another interesting aspect of the underlying concept is the possibility of positioning several, especially paramagnetic, metal centers M′ at well-defined locations, employing the Mo_{17} moieties as ligands or spacers. This allows one to influence the topology or structure of the M'_n polyhedron due to the different coordination behavior of M′. In turn insights into interesting exchange interactions—for instance, in polyoxometalates and specifically across the Mo_{17} moiety—can be obtained. This particular aspect is also of relevance to comparable arrangements of paramagnetic metal centers on molybdenum oxide surfaces (cf. the model function of **1** for the Fe^{III}/polymolybdate catalyst used industrially in the Formox process for the oxidation of methanol to formaldehyde[12, 13]).

Finally, it is worth pointing out the possibility of developing an interesting host–guest chemistry in connection with the relatively large cavity in **1**[3]—however, also its model character for clathrates. It will be the goal of a future synthesis plan to produce even larger clusters. Since, however, with increasing cluster size their solubility (and thus possible growth) decreases, at-

tempts will be made to produce even more highly negatively charged species, whose solubility is increased as a result of large hydration.

Experimental Procedure

A mixture of $Na_2MoO_4 \cdot 2H_2O$ (12.00 g, 49.6 mmol), $Fe(NO_3)_3 \cdot 9H_2O$ (9.50 g, 23.5 mmol), $NH_2OH \cdot HCl$ (16.00 g, 230.2 mmol), H_2O (250 mL), and 3.5% HCl (12.5 mL) was stirred rapidly and heated to reflux (The initially formed precipitate, redissolved: the solution changed color from brown to dark green, brown to green-brown; intermittently strong effervescence) until brown vapors appeared at the upper end of the reflux condenser (duration: ca. 20 min). The beige-brown precipitate was filtered hot and the filtrate, after cooling to 20 °C, was allowed to stand for 2 d in an open 400-mL beaker and was then filtered again. Brown, hexagonal crystals (stroke color: green-brown) of **1** precipitated within 3–4 d from the solution, which was stored in a closed vessel at 5 °C. Yield: 0.6 g (ca. 6.0% based on the amount of Mo used).

Received: September 17, 1993
Revised: December 23, 1993 [Z 6365 IE]
German version: *Angew. Chem.* **1994**, *106*, 897

[1] J. S. Lindsey, *New J. Chem.* **1991**, *15*, 153.

[2] A. Müller, E. Krickemeyer, S. Dillinger, unpublished results. In that case compound **2** is formed.

[3] Crystal structure analysis: $P6_3/mmc$, $a = 2380.6(5)$, $c = 2763.4(7)$ pm, $V = 13563(5) \times 10^6$ pm^3, $Z = 2$, $\rho_{calcd} = 2.67$ g cm^{-3}; temperature: 193 K; structure solution with direct methods, $R = 0.063$ for 3377 independent reflections ($F_0 > 4\sigma(F_0)$). Details of the crystal structure and particularly of the complex cation lattice (particularly spectacular and grave errors in [5], which cannot be discussed in this work) of **1** are to be published in detail elsewhere. An important piece of information is, for example, that there is a significantly low occupation of the Na positions. No significant residual electron density could be located inside the cavity. The question of whether possibly "water" is present in the cavity, cannot be answered conclusively either with the help of the X-ray crystal structure analysis (possible disorder) or hy taking into consideration the thermogravimetric data (mass contribution per H_2O molecule is only ca. 0.2%). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-57983.

[4] Additional characterization of **1** not mentioned in the text: correct elemental analysis for $H_{251}N_{18}Fe_6Mo_{57}Na_3O_{283}$ (H,N,Fe); IR (KBr pellet, some characteristic bands): $\tilde{\nu} = 1600$ (m, $\delta(H_2O)$ and $\nu(NO)$), 945 (m), 910 (sh), 880 (vs, all $\nu(Mo{=}O)$); characteristic bands in the Raman spectrum ($\lambda = 1064$ nm): 960 (vs), 930 (m), 880 cm^{-1} (m, all $\nu(Mo{=}O)$). The presence of (formally) six Mo^V and six $(MoNO)^{3+}$ centers can be deduced from the redox titration with permanganate. An increasing delocalization of the 4d electrons, which are obviously influenced in large species of the type **1** by the cation lattice, seems to reduce the degree of protonation of the μ-OH group in the $[Mo(\mu\text{-}H_2O)_2(\mu\text{-}OH)Mo]$ moieties. The balance of charges might then take place by an increase of the number of cations—in the present case by further occupation of the Na positions [3].

[5] S. Zhang, G. Huang, M. Shao, Y. Tang, *J. Chem. Soc. Chem. Comm.* **1993**, 37; *ibid.* **1986**, 835. The compound "$[H_3O^+]_6[Mo_{57}V_6O_{183}(NO)_6(H_2O)_{18}]^{6-} \cdot 89H_2O$" given there is obviously false with respect to its composition, structure, and the oxidation states of the metal centers. Also, the synthesis of this compound was not reproducable following the procedure provided by the authors: personal communication by P. Gouzerh, University Pierre et Marie Curie, Paris. The correct formulation for a compound obtained by us: $(NH_4)_{21}[\{V^{IV}O(H_2O)\}_6\{Mo^V(\mu\text{-}H_2O)_2\text{-}(\mu\text{-}OH)Mo^V\}_3\{Mo^{VI}_{15}(MoNO)^{3+}_2O_{58}\text{-}(H_2O)_2\}_3] \cdot 65H_2O$ (**2**)) [6]. The compound formulated as a neutral (!) complex by Zhang et al. $(NH_4)_{12}[(Mo^{VI}O_2)_2\{H_{12}Mo^{VI}_{15}(MoNO)^{3+}_2O_{58}(H_2O)_2\}_2] \cdot 33H_2O$ (**3**), which contains the same Mo_{17} ligand was described—unlike **2**—even with a false macrostructure. Compounds **2** and **3** were recently obtained by us in relatively high yields following a different route [6].

[6] A. Müller, E. Krickemeyer, S. Dillinger, H. Bögge, A. Proust, W. Plass, R. Rohlfing, *Naturwissenschaften*, **1993**, *80*, 560 (a provisional formulation for compounds **2** and **3**, without physical data and justification, has already been given here); for more recent details see A. Müller, E. Krickemeyer, S. Dillinger, A. Bögge, W. Plass, A. Proust, L. Dloczik, C. Menke, J. Meyer, R. Rohlfing, *Z. Anorg. Allg. Chem.* **1994**, *620*, 599.

[7] A. F. Wells, *Structural Inorganic Chemistry*, 5th ed., Clarendon, Oxford, **1984**; F. Vögtle, Supramolekulare Chemie, Teubner, Stuttgart, 1989; A. Müller, H. Reuter, S. Dillinger, unpublished results.

[8] Within in the range of measurement the Mo centers do not make a significant positive contribution to the χ value, that is, the 4d-electrons are spin-paired as observed for the two- and fourfold reduced Keggin ions (A. Müller, E. Krickemeyer, M. Penk, V. Wittneben, J. Döring, *Angew. Chem.* **1990**, *102*, 85; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 88).

[9] $(MoNO)^{3+}$ [electron configuration $(MoNO)^4$] has a considerable tendency of formation in mono- and polynuclear chalkogometalate systems: P. Gouzerh, Y. Jeannin, A. Proust, F. Robert, *Angew. Chem.* **1989**, *101*, 1377; *Angew. Chem. Int. Ed. Engl.* **1989**, *28*, 1363; A. Müller, W. Eltzner, S. Sarkar, H. Bögge, P. J. Aymonino, N. Mohan, U. Seyer, P. Subramanian, *Z. Anorg. Allg. Chem.* **1983**, *503*, 22; A. Müller, W. Eltzner, H. Bögge, E. Krickemeyer, *Angew. Chem.* **1983**, *95*, 905; *Angew. Chem. Int. Ed. Engl.* **1983**, *22*, 884; A. Müller, W. Eltzner, W. Clegg, G. M. Sheldrick, *ibid.* **1982**, *94*, 555 and **1982**, *21*, 535. Some of the compounds described herein have been used as models or standards in the aforementioned titration.

[10] An essential aspect is that clear quality and property changes or jumps (incidentally a fundamental problem in science) and, furthermore, also an increase in information in the sense of the definition given by C. F. von Weizsäcker emanate starting from a simple molecular region. This applies even more, if the resulting systems do not represent a section of a typical solid-state structure with approximated translational symmetry, which also—according to von Weizsäckers approach—reduces the number of decision points. It is referred here to the concept of information as defined by von Weizsäcker since it will become important for the classification of molecular materials in the future (C. F. von Weizsäcker: a.) "Information is the measure of amount of *form*. . . .matter has form. . ." b.) "The more decisions can be made about an object, the more form in a general, not necessarily spacial sense of the word can he recognized about it. This amount of form is, as just stated, a property of the object. . ." (From C. F. von Weizsäcker, *Aufbau der Physik*, 1st ed., dtv, Stuttgart, **1988**, p. 167 with the authentic definition in German.)). In this context the following statement by R. Feynman is of interest: "I can hardly doubt that when we have some control of the arrangement of things on a small scale we will get an enormously greater range of possible properties that substances can have." (cited from: R. W. Siegel, *Physics Today* **1993**, *46* (October), 64). These statements are of special relevance to polyoxometalates with their structural and functional variety and with respect to the resulting numerous possible applications [11].

[13] In addition, it should be mentioned that studies regarding the interaction of the Co^{II} centers in hydrodesulfurization (HDS) catalysts (nanometer-size molyhdenum disulfide crystallites with Co^{II} centers on the edges) have been carried out in order to understand the electronic/magnetic state of the catalyst system in correlation to its activity. In this system the Co^{II}—Co^{II} distances of the catalyst, which regularly shows a high degree of saturation for edge sites, are of the same magnitude as the Fe^{III}—Fe^{III} distances in **1** (H. Topsøe, R. Candia, N.-Y. Topsøe, B. B. Clausen, *Bull. Soc. Chim. Belg.* **1984**, *93*, 783). Remarkably, the size of the crystallites of the HDS catalyst is comparable to that of the cluster anion in **1** [14].

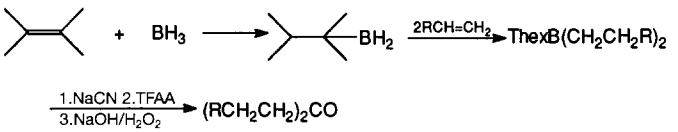
Synthesis and Properties of 2,4,6-Trimethylphenylborane (Mesitylborane), a Stable Alternative to Thexylborane**



Keith Smith,* Andrew Pelter,* and Zhao Jin

Thexylborane[1, 2] (1,2,2-trimethylpropylborane)[***] has been extensively used in synthesis. This is due to a combination of its ability to add two alkenes of little or moderate steric hindrance and the low migratory aptitude of the thexyl group in such important reactions as the cyanoborate process[3] and carbonylation[4] of organoboranes [Eq. (a), TFAA = trifluoroacetic anhydride]. However, thexylborane suffers from some major disadvantages. It must be made at low temperatures and used immediately or else the boron group wanders, by retrohy-

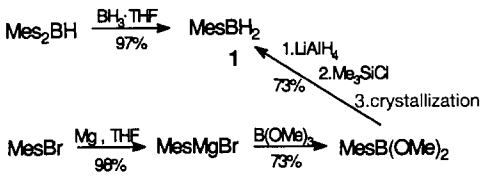
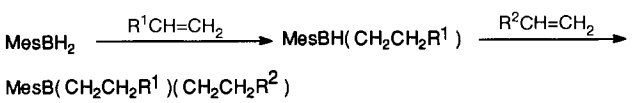
[***] For convenience monoorganoboranes are referred to as though they were monomers although in fact all are dimers.



(a)

droboration–hydroboration, to the primary carbon atoms. Two different alkenes can be added sequentially only if the first is somewhat hindered; on the other hand two slightly hindered alkenes cannot be added without substantial displacement of tetramethylethene. These disadvantages limit the variety of products that can be made using thexylborane.

Monoarylboranes cannot undergo retrohydroboration and could possibly be stabilized by 2,6-disubstitution.[5] They thus present attractive possibilities and we have previously reported on 2,4,6-triisopropylphenylborane (tripylborane).[6] We now record that 2,4,6-trimethylphenylborane, mesitylborane (**1**), is a readily available, crystalline, stable borane that can replace thexylborane for most purposes. In addition **1** has special properties not shared by thexylborane and also shows significant advantages compared with tripylborane.



Mesitylborane (**1**) (m.p. 46 °C) is made by either of the two routes shown in Scheme 1. Commercially available dimesitylborane[7] undergoes ready redistribution with borane–THF to give **1**. Alternatively mesityl dimethoxyborane, a useful relay compound, may be converted to **1** by conventional methods.[6]

Scheme 1. Synthesis of mesitylborane **1**.

Crystalline **1** showed no sign of decomposition, isomerization, or redistribution after 24 h at room temperature, and after 10 days retained 93% of its original hydride activity. In THF after seven days at room temperature there was a 16% loss of hydride activity, but no redistribution or isomerization. From a two week old solution of **1** in THF, pure crystalline **1** is readily recovered in 75% yield. This is in great contrast to methylborane[8] or thexylborane,[1, 2] both of which must be made in solution and used at once.

The first notable point about the chemistry of **1** is that it hydroborates 1-alkenes in a sequential fashion (Eq. (b), Table 1, exp. 6; also exp. 1, 2, 7 were carried out in a sequential fashion).

(b)

The second is that the regioselectivity of each step of the hydroboration is around 99%. Furthermore, there is no displacement of the aromatic group even on addition of two secondary alkyl groups (exp. 3–5, 8) though it was noted that α-pinene was displaced by cyclohexene during the final hydroboration step following initial hydroboration of α-pinene by mesitylborane (exp. 9).

Table 1. Hydroboration of alkenes with $MesBH_2$ (**1**).

Exp.	Alkene A	Alkene B	Yield [%] [a] MesOH	R^AOH	R^BOH
1	1-octene	1-octene	88	91	
2	1-hexene	1-hexene	94	91

6	1-octene	1-hexene	92	93	91
7	1-octene	cyclohexene	93	89	91
8	α-pinene	1-hexene	93	88	93
9	α-pinene	cyclohexene	91	[b]	43

[a] Yield after oxidation of the triorganoboranes determined by gas chromatography. [b] 81% α-pinene.

To show that the organoboranes $MesBR^1R^2$ can be put to synthetic use, examples were transformed to ketones by the cyanoborate process [Eq. (c)].[3] The results (Table 2) show that ketones are produced in yields at least as good as those obtained by using thexylborane[3] and in higher purity due to the greater regiospecificity shown by mesitylborane in hydroboration reactions. There was no evidence of scrambling of alkyl groups, nor

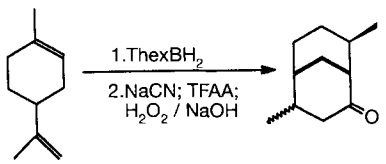
were there any ketone products derived by migration of the mesityl group. The synthesis of unsymmetrical linear ketones (previously only available by circuitous routes[9, 10]) greatly enlarges the scope of reactions such as the cyanoborate process.

Cyclic hydroboration followed by replacement of the boron atom by a carbonyl group is an important process.[3] This is readily accomplished by hydroboration with mesitylborane followed by the cyanoborate process as illustrated by the reaction of vinylcyclohexene to give the bicyclic ketone **2** with only a trace of the alternative product **3** [Eq. (d)]. The corresponding



(d)

reaction using thexylborane gave about the same yield of ketonic product but this consisted of approximately equal amounts of **2** and **3**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0808-0852 $ 10.00+.25/0

The cyanoborate process on limonene [Eq. (e)], successful with thexylborane,[3] essentially failed for mesitylborane. This might be due to the greater facility of thexylborane, as compared to mesitylborane, for the hydroboration of more hindered alkenes. It defines at least one area in which thexylborane will retain an advantage over mesitylborane.

(e)

We next examined the displacement of the mesityl group from dialkylmesitylboranes, and found two unusual and highly selective processes that further enhance the usage of mesitylborane. The first method consisted of the addition of bromine in methanol to the dialkylmesitylboranes [Eq. (f)]. This caused cleavage of the mesityl group with production of bromomesitylene and dialkylmethoxyboranes, oxidation of which gave the corresponding alcohols in overall yields of 82–87%.

$$MesBR^1R^2 \xrightarrow[MeOH]{Br_2/} MesBr + MeOBR^1R^2 \xrightarrow{[O]} R^1OH + R^2OH \quad (f)$$

More importantly, the intermediate dialkylmethoxyboranes can be reacted directly with a Grignard reagent to give fully mixed organoboranes, in which all the alkyl groups can be primary. These in turn can be readily converted to the corresponding tertiary alcohols[11] [Eq. (g)]. When R^1 = *n*-octyl, R^2 = *n*-hexyl, R^3 = *n*-butyl, the overall yield of isolated carbinol, based on $MesBH_2$ is 69%, which implies a highly efficient process given the seven steps involved.

$$MesBR^1R^2 \xrightarrow{Br_2/MeOH} MeOBR^1R^2 \xrightarrow{R^3MgBr} BR^1R^2R^3 \xrightarrow[H_2O_2 / NaOH]{NaCN; TFAA;} HOCR^1R^2R^3 \quad (g)$$

A different method of releasing the mesityl group is through direct reaction with an alkyl or aryllithium (e.g. Eq. (h)). Butylhexyloctylborane produced from the initial reaction was converted to the corresponding carbinol by the cyanoborate process in 78% yield showing that there had been little, if any, scrambling of the alkyl groups. The mesityl group, presumably displaced as mesityllithium, was recovered as mesitylene in 88% yield.

$$MesB(Oct)(Hex) \xrightarrow{BuLi} BuB(Oct)(Hex) \xrightarrow[H_2O_2 / NaOH]{NaCN; TFAA;} HOC(Bu)(Hex)(Oct) \quad (h)$$

Our studies show that mesitylborane is readily available and its hydroborating properties, as well as the properties of the derived organoboranes, should render it a useful addition to the armoury of organic reagents.

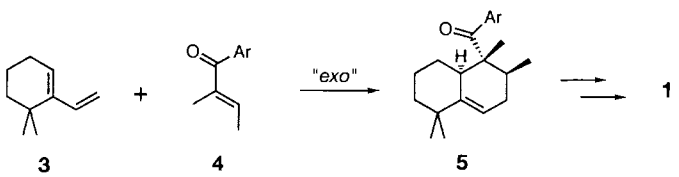
A Concise Total Synthesis of (±)-Mamanuthaquinone by Using an *exo*-Diels–Alder Reaction**

Taeyoung Yoon, Samuel J. Danishefsky,* and Susan de Gala

An interesting class of sesquiterpenoid quinones and hydroquinones has been isolated from various marine sponges.[1] Certain members of this family exhibit profiles of cytotoxity,[2] antimicrobial activity,[2b, 3] and inhibition of reverse transcriptase action.[4] Among the novel compounds in this subgroup is mamanuthaquinone **1**[5] isolated from *Fasciospongia sp.*, a sponge isolated from Mamanutha Island in the Fiji chain. Mamanuthaquinone exhibits moderate cytotoxity toward human colon tumor cell lines (HCT-116). Also, the structurally related avarol **2** and its quinone analogue have been proposed as promising anti-AIDS drugs,[4a] though their clinical usefulness is far from demonstrated.[6]

1 mamanuthaquinone



2 avarol

In considering a total synthesis of mamanuthaquinone **1** an obvious, if speculative possibility presented itself (Scheme 1). In

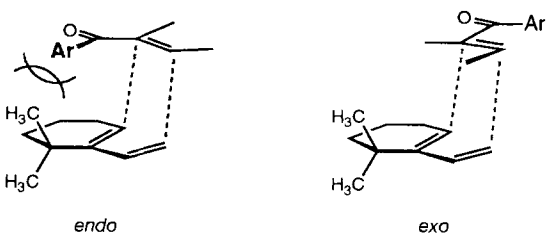
principle, the generalized system **5** can be assembled from diene **3** and dienophile **4**. With a properly chosen aroyl function, **1** might well be quickly derivable from the adduct **5**. However, in such a Diels–Alder reaction an *exo* transition state is required to reach the stereochemistry required for **1**.

Scheme 1. *Exo*-Diels–Alder approach for **1**.

The well-known preference for *endo* topology in the Diels–Alder reaction[7] is most pervasive with relatively unhindered cyclic dienophiles (e.g., maleic anhydride, *p*-benzoquinone, etc.) and homoannular dienes.[8] Nevertheless, *endo* orientation is still preferred in most intermolecular processes and if it is not dominant, the cycloadditions tend toward stereorandomness. However, the attractive forces of secondary orbital interaction to which the selectivity is generally attributed[9] are rather weak and can be easily overridden by seemingly minor structural changes.[10] Indeed, almost exclusive *exo* additivity has been exhibited by the reaction of cyclopentadiene and acyclic dienophiles having an alkyl substituent on the carbon bearing the activating group (e.g., methacrolein).[11] While the origin of this "abnormal" tendency is not clear, the anomaly had been mostly confined to reactions utilizing cyclopentadiene as the diene partner. Conceivably, it could be the consequence of the steric repulsion between the methylene group of cyclopentadiene and the α-substituent of dienophiles in the transition state leading to *endo* adduct.[12] For instance, the same catalytic system that produces only *exo* adduct from the cycloaddition of methacrolein with cyclopentadiene[11e] gave rise to nearly complete *endo* preference with acyclic dienes such as 1-methoxybutadiene.[13]

We were also mindful, on the other hand, that with the parent 1-vinylcyclohexene, Diels–Alder reaction had been reported to yield cleanly the *endo* product.[14] However, in the case at hand (**3** + **4**), we hoped to extend the "cyclopentadiene effect" by taking particular advantage of the quaternary carbon of the diene in conjunction with a sterically demanding aroyl group on the dienophile. In such a cycloaddition, the *endo* mode might be highly disfavored due to repulsion of the aryl group with the dimethylcyclohexenyl array (Fig. 1). Thus, the use of a maximally substituted aroyl function in the Diels–Alder reaction seemed to be in keeping with the stereochemical rationale, while holding promise for simplifying the late stages of reaching **1**. In this communication we describe the first total synthesis of mamanuthaquinone in a remarkably concise way drawing upon this reasoning (Scheme 2).



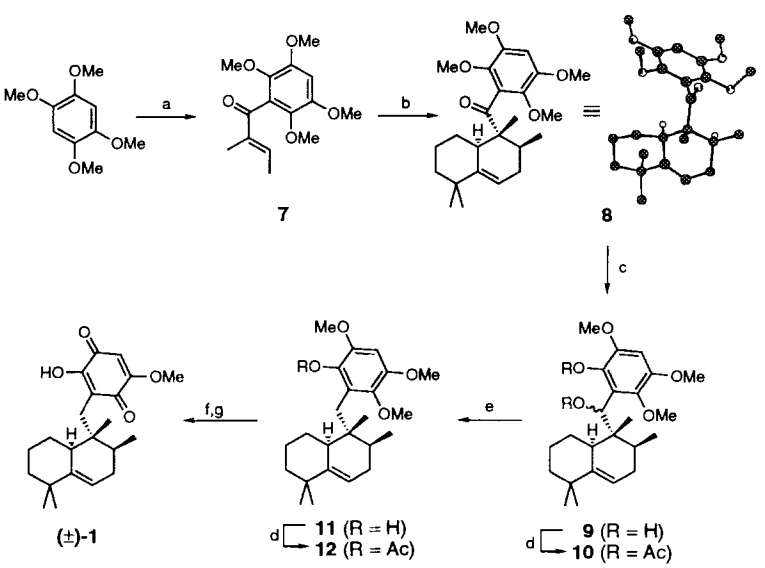


Fig. 1. *Exo* addition of **3** to **4** is favored over *endo* addition.

The requisite dienophile **7** was obtained in one step (77% yield) from the reaction of the aryl lithio derivative of 1,2,4,5-tetramethoxybenzene[15] and **6**, which was in turn prepared from the reaction of tigloyl chloride with *N*,*O*-dimethylhydroxylamine following the protocols of Weinreb.[16] Cycloaddition of **7** with **3**[17] under mediation by ethylaluminum dichloride/THF in dichloromethane afforded an 85% yield of a single cycloadduct. The presence of THF resulted in a doubling of the yield; without it, decomposition of the diene competed quite significantly, which was so extensive with other Lewis acids such as boron triflouride etherate or titanium tetrachloride that the desired cycloaddition did not proceed at all. The regiochemistry of the cycloaddition was well compliant with the precedents and no other regio- or stereoisomers were detected. Compound **8** was characterized by X-ray crystallography.[18]

Scheme 2. Synthesis of (±)-mamanuthaquinone **1**. a) *n*BuLi, LiCl, THF, 0 °C → room temperature, 1 h; then (*E*)-$CH_3CH{=}CCH_3CON(CH_3)OCH_3$ **6**, −78 °C → room temperature, 12 h; b) **3** (2 equiv), $EtAlCl_2$ (1.5 equiv.), THF (1 equiv), CH_2Cl_2, room temperature, 6 h; c) $LiAlH_4$, THF, reflux, 2.5 d; d) Ac_2O, Et_3N, cat. 4-dimethylaminopyridine, CH_2Cl_2, room temperature, 4 h; e) Li (10 equiv), NH_3, −78 °C, 10 min; NaOBz; NH_4Cl; f) $(NH_4)_2Ce(NO_3)_6$ (2.5 equiv), aq. MeCN; g) K_2CO_3, MeOH, room temperature, 1 h.

With the three stereogenic centers installed in the required configuration, a straightforward end game sequence was implemented. Treatment of **8** with lithium aluminum hydride resulted, not only in reduction of the ketone, but also in demethylation of one of the *ortho* methoxy groups. Acetylation of diastereomers **9** gave **10**, whose de-acetoxylation as shown afforded **11**, which was then acetylated to give **12** (55% based on **8**). Oxidative demethylation of **12** with ceric ammonium nitrate followed by de-acylation (K_2CO_3 in MeOH) afforded (±)-mamanuthaquinone (85% based on **12**; m.p. 114–116 °C, the enantiomerically pure natural product:[5] m.p. 108.5–109.5 °C).[19]

In summary, the total synthesis of **1** has been accomplished in eight steps in 32% yield from 1,2,4,5-tetramethoxybenzene. We hope to sort out the factors which were responsible for the apparent *exo* selectivity of this Diels–Alder reaction. For instance, assigning the relative importance of the geminal dimethyl center of **3** and the two vinyl methyl groups of **7**

would be helpful in planning extensions of these findings. Studies addressed to such issues as well as to proposals relating to the mode of action of mamanuthaquinone are in progress.

Experimental Procedure

8: To an ice-cold solution containing **7** (208 mg, 0.74 mmol) and THF (0.06 mL, 1 equiv) in CH_2Cl_2 (5 mL) was added 1.8 M $EtAlCl_2$ in toluene (0.60 mL, 1.5 equiv), followed by slow dropwise addition of **3** (0.20 g, 2 equiv) in CH_2Cl_2 (2 mL). After the addition was complete, the mixture was allowed to warm to room temperature and stirred for 6 h. The reaction was quenched by cautious addition of saturated NH_4Cl at 0 °C. The aqueous layer that separated was extracted with CH_2Cl_2 and the combined organic phases were dried (Na_2SO_4), concentrated in vacuo, and chromatographed on silica (10/1 to 4/1 hexane/EtOAc) to give 263 mg of **8** as a white solid (84%): m.p. 122–124 °C (CH_2Cl_2/hexane); IR ($CDCl_3$): $\tilde{\nu}_{max}$ = 2939, 1680, 1484, 1465, 1424, 1257, 1225, 1197 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$): $\delta \approx 6.55$ (s, 1 H, phenyl), 5.43 (d, J = 4.3 Hz, 1 H, vinyl), 3.87 (s, 6 H), 3.73 (s, 3 H), 3.70 (s, 3 H), 2.60 (d, J = 12.3 Hz, 1 H), 2.25 (m, 1 H), 2.0–1.7 (m, 3 H), 1.2–1.0 (m, 3 H), 1.07 (s, 3 H), 1.02 (s, 3 H), 0.92 (d, J = 6.9 Hz), 0.89 (s, 3 H); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 213.2, 149.2, 148.8, 145.7, 138.9, 138.5, 132.8, 115.6, 99.6, 62.0, 61.5, 56.6, 54.9, 42.5, 41.2, 36.5, 33.9, 31.2, 30.3, 29.8, 28.0, 22.7, 17.1, 12.0; MS (20 eV EI): *m/z* (rel. int.): 416 (1) [M^+], 280 (1), 225 (100) [aroyl$^+$], 210 (6), 191 (4); high-resolution FAB MS for $C_{25}H_{36}O_5$, calcd 416.2564, found 416.2540; correct elemental analysis.

[12] The concept of a specific *endo*-orienting preference of methyl groups by a σ interaction has been suggested [11a]. However, the explanation given in the text, which is based on steric interactions, seems more likely in the light of the fact that a similar *exo* preference is exhibited by α-haloacrylic acids (see [10]). Also, quite recently, Lewis acid controlled variation of *endo*/*exo* selectivity in a hetero-Diels–Alder reaction has been reported: L. F. Tietze, C. Schneider, *Synlett* **1992**, 755.

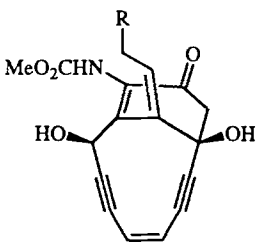
On the DNA Recognition Role of the Carbohydrate Sector in Calicheamicin: A Comparison of DNA Cleaving Capacity of Enantiomeric Calicheamicinones**

Jayshree Aiyar, Stephen A. Hitchcock, Derek Denhart, Kevin K. C. Liu, Samuel J. Danishefsky,* and Donald M. Crothers

The antitumor activity of the naturally occurring drug calicheamicin γ_1^I (**1**) is believed to operate through its efficient cleavage of duplex DNA in a double-stranded, highly sequence-selective fashion.[1, 2] The drug is comprised of an aryl tetrasaccharide carbohydrate region tethered to an enediyne-containing aglycone moiety. The latter, which is termed calicheamicinone, was synthesized first in our laboratory as its racemate[3] (**2**/**3**) and subsequently in the enantiomerically pure form corresponding to the natural product, by Nicolaou et al.[4]



1

Calicheamicin γ_1^I reacts with supercoiled phage DNA to produce a ratio of double- to single-stranded cuts of 1:2.[5] The

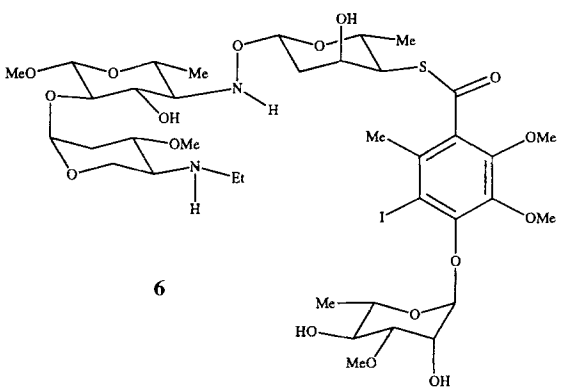
propensity for this enediyne drug to exact double-stranded cuts is more pronounced than that of many other DNA cleaving agents.[6] In contrast, racemic calicheamicinone (**2**/**3**), which lacks the carbohydrate sector, exhibits sharply reduced capacity to effect such double-stranded cleavage[5] and furthermore exhibits none of the sequence selectivity displayed by the intact drug itself. Nonetheless, quantifiable genuine double-stranded cutting events are detected with the aglycone racemate (the ratio of double-stranded to single-stranded cuts is about 1:30).[5] In addition, reaction of DNA with racemic calicheamicinone, under conditions where the enediyne sector suffers reductive cyclization, leads to only 10% hydrogen incorporation into the aglycone by direct transfer from DNA.[5] This is in contrast to the situation in **1**, where 80–90% hydrogen incorporation by transfer from deoxyribose residues is observed in the course of reductive aromatization.[7]



2 R = SSSMe
4 R = AcS

3 R = SSSMe
5 R = AcS

Preincubation of linear duplex DNA with the carbohydrate domain of calicheamicin in the form of its methyl glycoside **6**,[8] followed by incubation with racemic calicheamicinone led to modulation[9a] of the virtually uniform cleavage pattern observed in the absence of the carbohydrate.[9] A similar capacity is exhibited by the racemic *S*-acetate (**4**/**5**), a precursor of calicheamicinone. However, in contrast to calicheamicinone, which relies on a trisulfide trigger, the racemic *S*-acetate **4**/**5** has the advantage of being readily activated for diyl formation at pH 8 without recourse to exogenous reducing agents.[5]

6

The experiments described herein assess the contributions of each of the aglycone *S*-acetate enantiomers (**4** and **5**) to the double-stranded cutting and sequence selectivity observed in our previous studies with the racemate.[5] Compounds **4** and **5** have been prepared in enantiomerically pure form by total synthesis and converted to the two antipodes of calicheamicinone (**2** and **3**).[10, 11]

The kinetics of supercoiled phage DNA cleavage were monitored in experiments in which *S*-acetate enantiomers of natural (**5**) and unnatural absolute configuration (**4**) were incubated with DNA. Figure 1 shows that the two enantiomers displayed different degrees of double-stranded cleavage. Surprisingly, the unnatural enantiomer, **4**, with a double- to single-stranded cutting ratio of about 1:20 is four to five times more efficient in this sense than is the natural enantiomer (ratio of about 1:90 at the same concentration). On the other hand, the overall cleavage rate, the sum of single- and double- stranded cutting rates, does not differ detectably for the two enantiomers.

The absolute amount of double-stranded cutting measured in these experiments using the *S*-acetates **4** and **5**, though still formidable relative to conventional reagents, is small compared with calicheamicin itself. Therefore we do not presently propose a detailed model to explain the significant and reproducible difference in the double-stranded cleaving capacities of the two enantiomers. A possible direction for interpretation of the trend could be the presence of hydrophobic pockets in the minor groove which favor the free unnatural *S*-acetate **4** over its natural counterpart **5** in certain conformations, which allow for double-stranded cleavage.[12] We note that the possibility of enantioselective bias in the interaction of ligands with oligonucleotide hosts has been addressed in the elegant investigations of Barton et al.[13] and more recently by Boger et al.[14] However, this is the first such finding in the enediyne drug area.

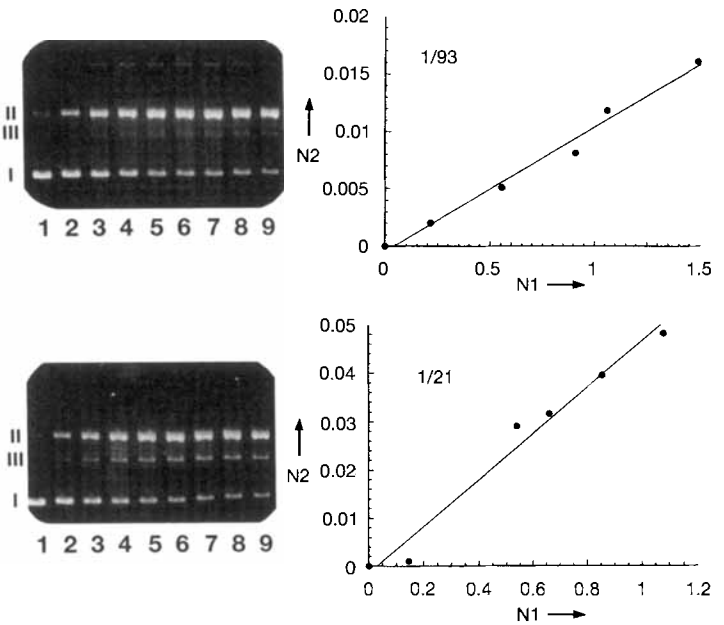


Fig. 1. Agarose gels illustrating the different degrees of double-stranded cleavage displayed by the enantiomeric aglycones **4** (bottom) and **5** (top). Supercoiled ΦX174(RFI) DNA (40 μM in nucleotides) was incubated with 0.2 mM **4** or **5** in 50 mM tris(hydroxymethyl)aminomethane (Tris), pH 8.0 at room temperature. At various times, 3 μL aliquots of each reaction mixture were added to 3 μL loading dye (0.02% bromophenol blue in 80% glycerol) and resolved on a 1% agarose gel in 1X TAE buffer (40 mM Tris acetate/2 mM EDTA) run at 6–8 Vcm^{-1}. The gels were stained in a 1.3 $\mu g mL^{-1}$ ethidium bromide solution and photographed with Polaroid 665 film. Negatives were scanned by using a model 1650 scanning densitometer (Hoefer). The average number of single-stranded (N1) and double-stranded (N2) cuts per molecule were calculated as discussed earlier [5], assuming a Poisson distribution for the formation of Form II (nicked circular) and Form III (linear) cleaved products from Form I (supercoiled) DNA. The data from the first 5–7 min of the reactions can be fitted to a linear equation (top and bottom right, respectively), giving the ratio of the average number of double- to single-stranded cuts per molecule. For both gels, lane 1: untreated DNA, lanes 2–9: extent of the reaction at 1, 2, 3, 5, 7, 10, 15, and 20 min, respectively.

When the DNA was preincubated with the methyl glycoside of the aryl tetrasaccharide domain of calicheamicin γ_1^I **6** (5 μM), prior to addition of the aglycone, it was found that the double- to single-stranded cutting ratios decreased in both **4** and **5** (to ca. 1:50 and 1:200 respectively, Fig. 2). Possibly the carbohydrate preferentially binds the phage DNA at sites which would otherwise be targeted for double-stranded cutting by the aglycone.[12] However, the unnatural *S*-acetate enantiomer **4**, retained its greater efficacy as a double-stranded cleaving agent relative to the natural antipode **5** even under these conditions.

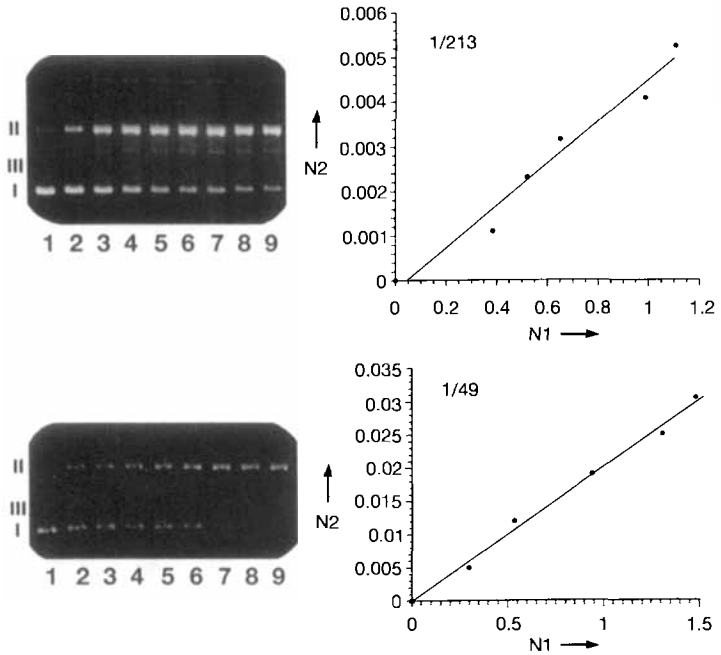

Fig. 2. Chiral preference of the aglycones **4** (bottom) and **5** (top) in the presence of the saccharide **6** in the double-stranded cleavage of DNA (agarose gel chromatographs, left). Reactions were carried out as described in Figure 1, except that the DNA was preincubated with 5 μM **6** for 15 min prior to addition of **4** or **5**. Data were analyzed as described in Figure 1, and are represented quantitatively in the top and bottom right panels. For both gels, lane 1: untreated DNA + **6**, lanes 2–9: extent of the reaction at 1, 4, 7, 10, 15, 20, 25, and 30 min, respectively. The ratio of double to single-stranded cuts is equal to the slope of the line, and is accurate to about ±15%.

Thus, the carbohydrate domain, when bound to DNA, does not appear to modulate the relative binding characteristics of the two *S*-acetate aglycone enantiomers. In addition, preincubation of the linear duplex DNA used in earlier studies[5, 9a] with methyl glycoside **6** prior to addition of either **4** or **5** gave rise to the same enhanced cutting sites flanking the carbohydrate-protected regions as were found with the racemate (Fig. 3). As before, the most prominent of the enhanced sites is at the underlined G in the CGGA sequence (marked by the lower bracket on the right side of Fig. 3). This sequence serves as one of the calicheamicin recognition domains included in the design of the DNA fragment.[5] Quantitative analysis of the gel chromatographic data (not shown) gives enhancement patterns for the two enantiomers (lanes 9–12, 14–18) which are indistinguishable from the results we reported earlier[9a] for the racemic mixture (lanes 1–4). Note that the enhanced sites (marked by arrows) are adjacent to, but frequently do not correspond exactly to calicheamicin γ_1^I cleavage sites, which can best be seen in lane 13.

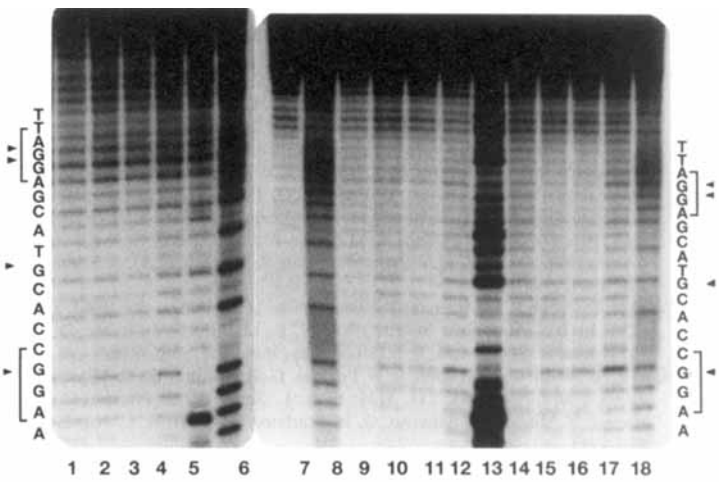

Fig. 3. Sequence selectivity of the aglycones in the presence of aryl tetrasaccharide **6** bound to DNA. The DNA sequence [5,9a] was designed to include several calicheamicin cleavage sites. Oligosaccharide and [3′-^{32}P] bottom-strand labeled DNA duplex ("bottom" with respect to orientation of calicheamicin γ_1^I at the recognition sites) were preincubated in 10 mM Tris·HCl (pH 8.0), 1 mM EDTA, 2% THF for 15 min at 25 °C. Aglycones **4**, **5**, or a racemic mixture of **4** and **5** (3.2 mM) were added to the reactions, and incubation continued for 2 h. The DNA in each reaction was ethanol-precipitated, resolved by electrophoresis on a 10% denaturing polyacrylamide gel, and autoradiographed. Lanes 1–4, reaction with racemic mixture of **4** and **5**: lane 1, DNA + aglycone; lane 2, DNA preincubated with 20 μM oligosaccharide + aglycone; lane 3, same as lane 2, but with 0.1 mM oligosaccharide; lane 4, same as lane 2, but with 0.5 mM oligosaccharide; lane 5, DNA + 5 μM **1** + (dithiothreitol) DTT, reacted at room temperature for 5 min; lane 6, A + G marker ladder. Lanes 9–12 and 14–18, reactions with individual enantiomers **5** and **4**, respectively: lane 7, untreated DNA; lane 8, A + G marker ladder; lane 9, DNA + **5**; lane 10, DNA preincubated with 20 μM oligosaccharide + **5**; lane 11, same as lane 10, but with 0.1 mM oligosaccharide; lane 12, same as lane 10, but with 0.5 mM oligosaccharide; lane 13, DNA + 5 μM **1** + DTT, reacted at room temperature for 15 min; lane 14, DNA + **4**; lane 15, DNA preincubated with 20 μM oligosaccharide + **4**; lane 16, same as lane 15, but with 0.1 mM oligosaccharide; lane 17, same as lane 15, but with 0.5 mM oligosaccharide; lane 18, A + G marker ladder. Brackets indicate strong calicheamicin γ_1^I recognition sites within the DNA sequence used in these experiments. Arrows point to strong aglycone-mediated cleavage sites adjacent to protected regions, in the presence of the oligosaccharide.

In summary, it is clear that the carbohydrate sector provides the bulk of the DNA recognition of the drug. Yet, in the absence of a covalent link between the recognition and effector (enediyne) domains, the carbohydrate is unable to override or measurably modify the inherent differences of the antipodal *S*-acetate:DNA interactions. It would therefore be of great interest to determine whether the carbohydrate domain when covalently joined to each of the enantiomeric aglycone antipodes, could modulate the characteristics of the drugs through their enediyne sectors.

Clearly the covalent attachment of the *ent* effector to the natural recognition domains can only be accomplished through the medium of organic synthesis. Another fascinating synthetic goal is that of creating hybrid agents where the effector domains of established clinically useful drugs are joined to the powerful carbohydrate recognition domain of calicheamicin.[15] On the basis of ongoing experiments, we have reason to believe that such goals are not unrealistic.

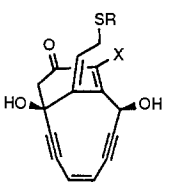
A Convergent Total Synthesis of Calicheamicin γ_1^I**

Stephen A. Hitchcock, Serge H. Boyer, Margaret Y. Chu-Moyer, Steven H. Olson, and Samuel J. Danishefsky*



We have been concerned with the total synthesis of the enediyne antibiotic calicheamicin γ_1^I (**1**).[1, 2] In 1988 we described the first construction of a functionalized core structure corresponding to the aglycone sector of the drug. This synthesis showed the feasibility of assembling such structures by a cyclization of the type **a** → **b**, and the stereochemical ramifications of such a process at the emerging secondary alcohol.[3] Subsequently, related cyclizations have found application in a variety of other programs in the enediyne area.[4] Exploiting these findings, we accomplished the synthesis of descarbamoylcalicheamicinone (**2**)[5] and, finally, calicheamicinone (**3**)[6] both in racemic form. It was shown that these systems, lacking the carbohydrate domains,

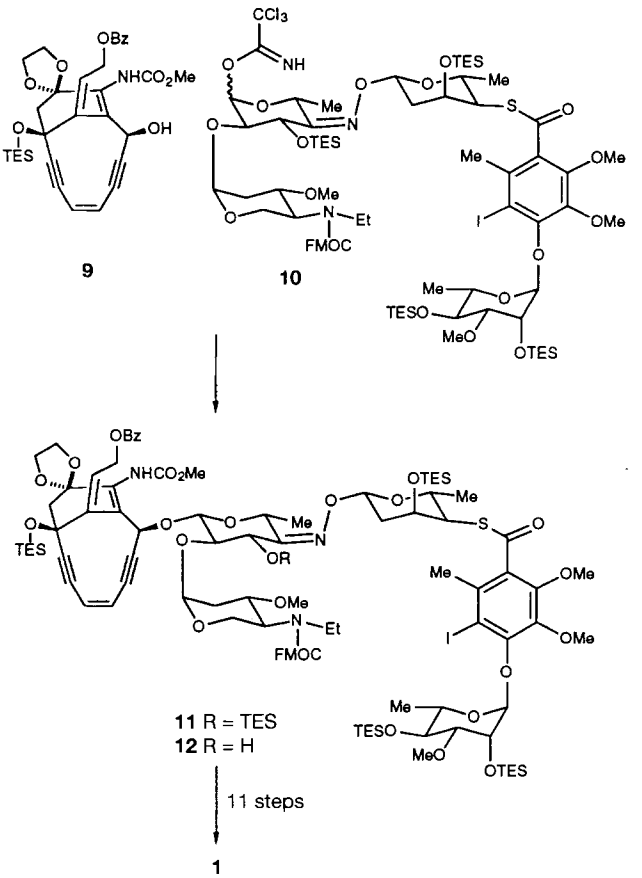
[**] This research was supported by National Institutes of Health (Grant No. CA 28824). A NATO/SERC (Science and Engineering Research Council (UK)) Fellowship to S. A. H., a Kent Fellowship to S. H. B. and M. Y. C.-M., and an NSF Predoctoral Fellowship to M. Y. C.-M. are gratefully acknowledged.

still retain significant double-stranded DNA-cleaving capacity, albeit in significantly reduced potency relative to the drug and with no appreciable sequence selectivity.[7, 8] During the course of these studies,[7] it was also demonstrated that S-acetates **4** and **5** were more readily actuated for Bergman cyclization[11] and diyl formation than were the corresponding trisulfide aglycones **2** and **3**, respectively.

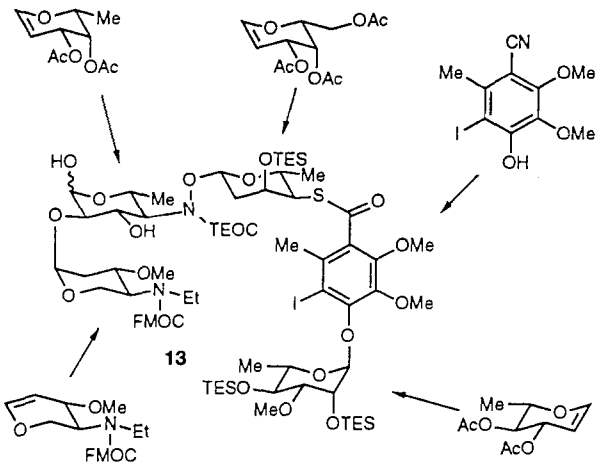
From these studies we undertook a program to access enantiomerically pure versions of these aglycone derivatives. This effort culminated in the synthesis of (−)-calicheamicinone (having the absolute configuration corresponding to the natural product), as well as its (+)-enantiomer.[9, 10] As a consequence of this initiative,[9] aglycone analogues bearing the unnatural absolute configuration also became available for the first time with some surprising implications. The double-stranded DNA-cleaving capacity of these unnatural aglycone congeners was demonstrated to be significantly more effective than that of their counterparts in the natural series; thus providing the incentive to attach the enantiomeric effectors to the carbohydrate region of the natural drug.



As for the carbohydrate sector, we showed (by analogy with esperamicin) that coexistence of the reducing hydroxyl and the NH function of the hydroxylamine connector would be extremely unlikely.[11] We demonstrated that the free "reducing" hydroxyl could be sustained and activated if the hydroxylamine NH group were protected, for instance, as a 2-trimethylsilylethoxycarbonyl (TEOC) function. Using these principles, we effected coupling of calicheamicinone precursor **6** with a fully functionalized pentacyclic aryl tetrasaccharide domain (see trichloroacetimidate **7**, Scheme 1).[12, 13] While this was, at the

Scheme 1. a) $BF_3 \cdot OEt_2$, Et_2O, CH_2Cl_2, −78 °C (25%). Phth = phthaloyl; TBS = *tert*-butyldimethylsilyl.

time, the most advanced coupling of its kind, it transpired that the chemistry of the steps required to get from **8** → **1** was too extensive and complex to allow for survival of the aglycone sector and the various glycosidic bonds.

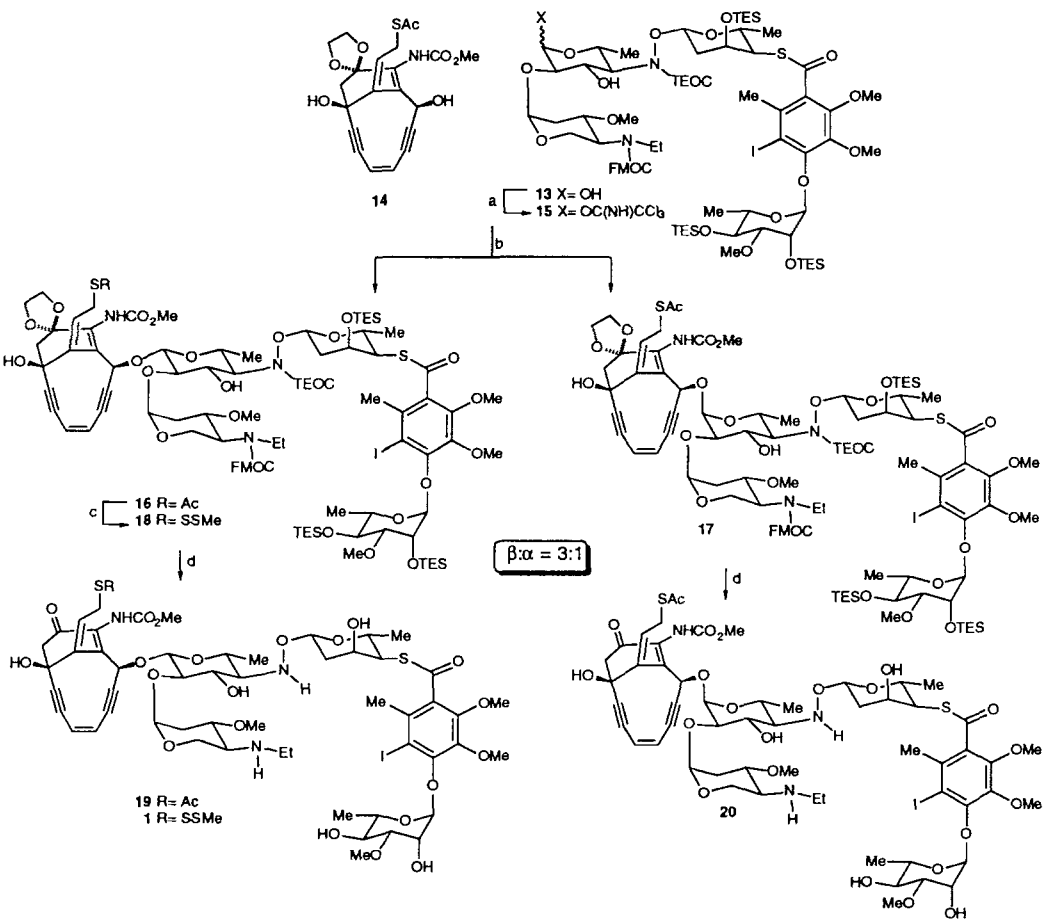


In the interim, Nicolaou et al. succeeded in coupling aglycone precursor **9** with the oxime-linked donor **10** (Scheme 2). In an experimental tour de force, adduct **11** was converted to calicheamicin (**1**) in an 11-step sequence. In that way the first total synthesis of calicheamicin was accomplished.[2]

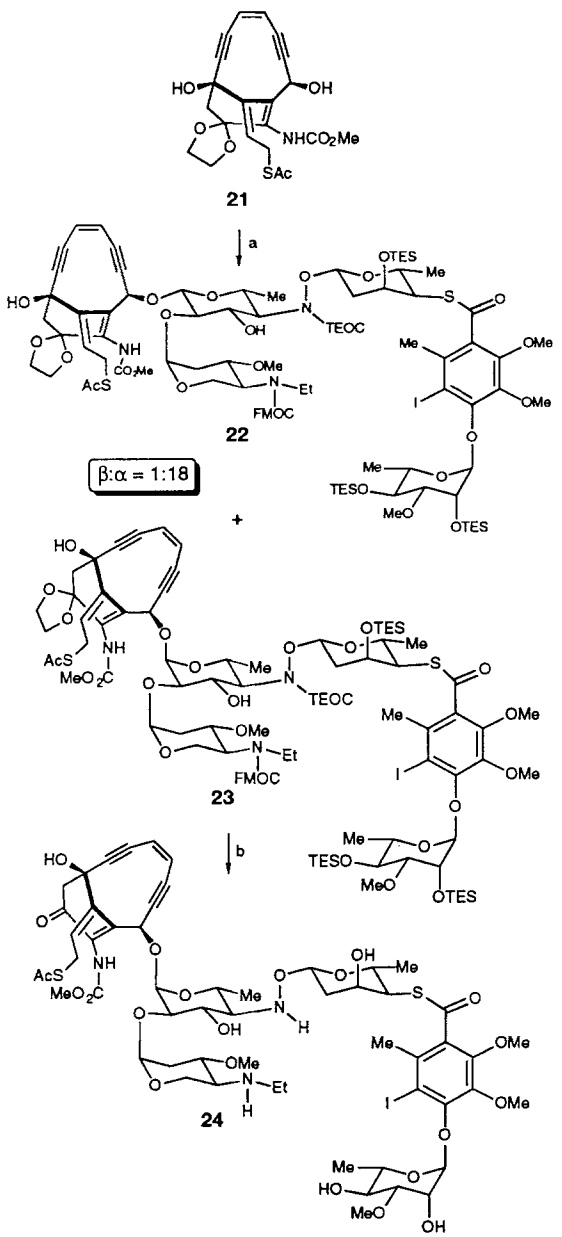
Scheme 2. a) $BF_3 \cdot OEt_2$, CH_2Cl_2, −40 °C (40% of **11** plus 36% of **12**). TES = triethylsilyl.

Our own efforts were deployed toward determining the latest point in the synthesis in which coupling could be accomplished. For ultimate convergence, it would be necessary to fashion a glycosyl donor containing the fully functionalized pentacyclic domain at the required oxidation level. The blocking group strategy had to take into account the need to protect the hydroxylamine nitrogen, as discussed above. It was also necessary to protect the amino function of the E-ring with something other than a phthalimide since it was found that deprotection of such a nitrogen (by hydrazinolysis) would not be compatible with the labile functionality present in the aglycone. Experience gathered in our synthetic program had revealed that liberation of the axial alcohols in the B- and D-rings, from the corresponding *tert*-butyldimethylsilyl derivatives, would also not be possible in the latter stages of the synthesis for the same reason. With these considerations in mind, and with helpful precedents from the Nicolaou synthesis available,[2] donor **13** was synthesized and employed. The construction of **13** (Scheme 3) followed very closely from the glycal assembly method used in the related construction of the previously mentioned donor **7**.[12]

To achieve maximum convergency we employed a very mild trichloroacetimidate glycosylation promoter which, we hoped,



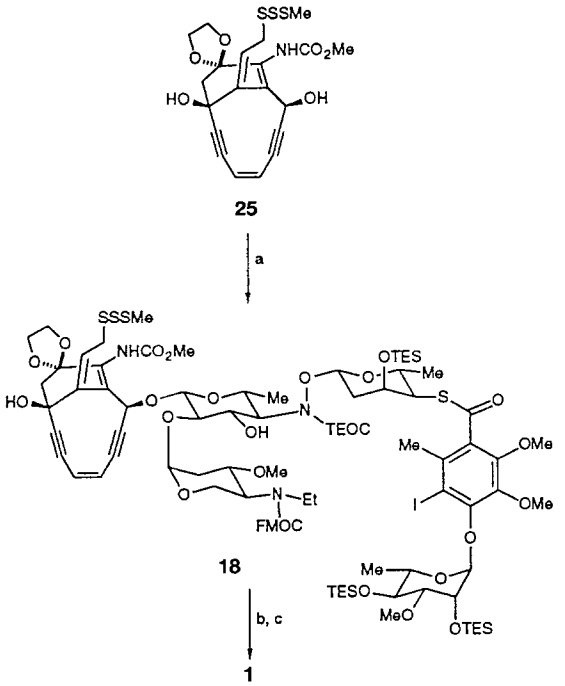
Scheme 3. Synthesis of the carbohydrate domain from four glycals and an aryl iodide.



would be compatible with the highly sensitive functionality which would be contained in the acceptor (vide infra). A gratifying success was realized in the coupling of **15** with the optically pure (−)-S-acetate intermediate **14** prepared en route to **3**, as discussed above (Scheme 4). Under mediation by silver(I) triflate, in the presence of molecular sieves, a 58% yield of a separable 3:1 mixture of **16** and the corresponding α-anomer **17** was obtained.[14] Compound **16** was transformed to the corresponding trisulfide **18** as shown. Deketalization of **18**, which was accompanied by partial desilylation, was followed by tetra-*n*-butylammonium fluoride (TBAF)-induced removal of all remaining silyl groups as well as the TEOC *and* 9-fluorenylmethoxycarbonyl (FMOC) urethane protecting groups in a single step. This concise two-step deprotection sequence afforded calicheamicin γ_1^I (**1**) identical with an authentic sample[15] of the natural product by physical and spectroscopic data (TLC, $[\alpha]_D^{25}$, ^{1}H NMR, MS, and IR).

A similar two-step deprotection of **16** itself, led to **19** which is the S-acetate congener of **1**. As an additional source of corroboration for this structure, the high-field ^{1}H NMR spectrum of our synthetically prepared compound compared identically with a spectrum kindly provided by Professor K. C. Nicolaou.[16] By the same token, treatment of α-glycoside **17** afforded **20** which differs from the drug congener **19** only at the anomeric center at the A-ring of the carbohydrate sector.

A most remarkable finding was encountered in the glycosylation of the *ent*-version of **15** (i.e., **21**)[9] with the same glycosyl donor **15** (Scheme 5). The hope had been to construct a system which would be comprised of the carbohydrate domain of calicheamicin in its natural configuration, glycosidically linked to an *ent*-aglycone sector either as a trisulfide (corresponding to the *ent*-aglycone version of **1**) or as an S-acetate corresponding to the *ent*-aglycone version of **19**. Coupling of **15** with **21** gave a 38% yield of a separable mixture of two anomers (in a ratio of 1:18). Amazingly, the minor product corresponded to the β-glycoside **22** while the major product was the α-glycoside



Scheme 4. Coupling of **15** with the (−)-S-acetate **14**. a) Cs_2CO_3, Cl_3CCN, CH_2Cl_2, 25 °C, 4 h (91%); b) AgOTf (Tf = trifluoromethanesulfonyl), 4 Å molecular sieves, CH_2Cl_2, 25 °C, 12 h (58%); c) diisobutylaluminum hydride (DIBAL), CH_2Cl_2, −78 °C, 0.5 h, then *N*-(methyldithio)phthalimide, CH_2Cl_2, 25 °C, 0.5 h (54%); d) camphorsulfonic acid (CSA), THF, H_2O, 25 °C, 96 h, then TBAF, THF, 0 °C, 15 min, R = Ac (40% overall), R = SSMe (37% overall).

Scheme 5. Coupling of **15** with the (+)-S-acetate **21**. a) **15**, AgOTf, 4 Å molecular sieves, CH_2Cl_2, 25 °C, 12 h (38%); b) CSA, THF, H_2O, 25 °C, 96 h, then TBAF, 0 °C, 15 min (40% overall).

23.[17] This compound was deprotected in the usual two-step sequence giving rise to **24** which is seen to be the α-glycoside version of **20** bearing the *ent*-effector domain. The evaluation of the *ent*-aglycone α-glycoside and α- and β-glycoside versions of the S-acetate drugs is now under way.

Finally, we were emboldened to attempt glycosylation at an even more advanced stage, that is, that of trisulfide **25** (Scheme 6). In the event, a 34% yield of **18** was obtained.[18] The feasibility of this coupling with the allylic trisulfide in place is eloquent testimony to the mildness of the conditions which have been devised. We note that the route communicated herein embodies ultimate convergence for the synthesis of **1**. The aglycone portion is unveiled in a single deketalization step. The entire carbohydrate domain of calicheamicin is delivered in a form where it is retrieved in a single *step* (TBAF). The success of these experiments suggests that it will be possible to attach a

Donor-Stabilized Aluminum(II) Bromide**

Mario Mocker, Christian Robl, and Hansgeorg Schnöckel*

Dedicated to Professor Helmut Werner on the occasion of his 60th birthday

Boron and gallium dihalides have been known for a long time; however, hitherto no evidence could be found for AlX_2 compounds (X = halogen) in the condensed phase.[1] AlX_2 structures are of particular interest: whereas boron dihalides, such as BCl_2, exist as dimers with a boron–boron bond (B_2Cl_4), solid $GaCl_2$ must be formulated, for example, as $Ga^I[Ga^{III}Cl_4]$. The latter compound, however, can be converted into a molecular species with a Ga–Ga bond (e.g. $Cl_2GaGaCl_2 \cdot 2$dioxane) by addition of suitable bases.[4, 5] Thus, boron and gallium are similiar to each other with regard to their ability to form element–element bonds. Hence corresponding base-stabilized species $Al_2X_4 \cdot 2$donor with an Al–Al bond are to be expected also in the case of aluminum. This expectation was intensified by the characterization of an Al–Al bond in Al_2R_4 (R = $CH(SiMe_3)_2$) by Uhl et al.[7] We report here on the preparation and structure of the first base-stabilized Al^{II} halide.

The title compound was prepared by depositing the high-temperature molecule AlBr[8] together with anisole on a surface cooled with liquid nitrogen.[10] By warming this mixture above the melting point of anisole a red solution of AlBr is obtained, which on further warming to room temperature decomposes within a few days. This process is, however, so slow at −30 °C that $AlBr_2$ can form continuously from AlBr and the $AlBr_3$ (max. 10%) which is present as a consequence of the method of preparation. $AlBr_2$ crystallizes in the form of yellow needles of the composition $Al_2Br_4 \cdot 2$anisole **1** on slow condensation of pentane into the mixture [Eq. (a)]. In this way the major product AlBr is deposited as a red oil on the walls of the flask.[13]

$$AlBr + AlBr_3 \xrightarrow[-30\,^\circ C]{\text{anisole}} \underset{\mathbf{1}}{Al_2Br_4 \cdot 2\,\text{anisole}} \qquad \text{(a)}$$

In the solid state **1** can be stored at room temperature and can be prepared in a glove box for additional investigations (e.g. X-ray diffraction, Raman spectroscopy). On warming solid **1** above 100 °C, however, significant decomposition takes place. In toluene or C_6D_6, **1** disproportionates at room temperature within a few hours. The ^{27}Al NMR spectrum of a freshly prepared sample of **1** shows a broad signal at $\delta \approx 130$ as well as an additional signal at $\delta = 95$, which is assigned to the adduct $AlBr_3 \cdot$anisole and which indicates the beginning of the disproportionation.[14] In the Raman spectrum the totally symmetric $AlBr_2$ stretching vibration is found at 188 cm^{-1} and the Al–Al vibration at 510 cm^{-1}.[15] In the mass spectrometer **1** cannot be vaporized without decomposition, the heaviest fragment to appear is $[M^+ - OCH_2]$.[18]

The molecular structure of **1** resulting from the X-ray structure analysis is illustrated in Figure 1.[19] The Al–Br distance

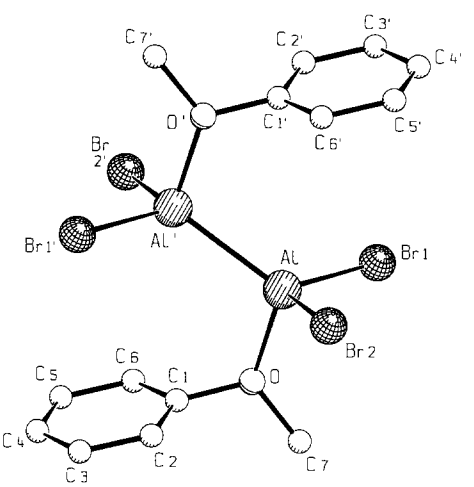

Fig. 1. Molecular structure of **1** in the crystal (hydrogen atoms are not shown). Selected bond lengths [pm] and angles [°] (standard deviations in parentheses): Al–Al' 252.7(6), Al–Br1 229.9(4), Al–Br2 231.2(4), Al–O 193.0(8); Br1-Al-Br2 108.4(1), Br1-Al-O 100.6(3), Br2-Al-O 100.8(3), Br1-Al-Al' 119.2(2), Br2-Al-Al' 117.8(2), O-Al-Al' 106.9(3).

(230 pm) is, as expected, longer than the Al–Br distance found in $AlBr_3$.[20] The $Br_2AlAlBr_2$ framework has approximate C_{2h} symmetry; the $AlBr_2$ planes are each bent by 35° away from the line through the bond between the two aluminum centers. The coordination of anisole results in a distorted tetrahedral environment for each Al atom. The Al–O bond (193 pm) is short in comparison to the Al–O bond of $AlMe_3 \cdot Me_2O$ (201 pm[23]). There is no corresponding structural data available for an adduct $AlBr_3 \cdot R_2O$ which would be more suitable for comparison.[24] A comparison of the dissociation enthalpies ($AlBr_3 \cdot Et_2O$: 36.5/39.1 kcal mol^{-1}, $AlMe_3 \cdot Et_2O$: 20.2 kcal mol^{-1}[26]), however, indicates a strengthening of the Al–O bond in the adduct $AlBr_3 \cdot$ether.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The most remarkable structural feature of **1** is the short Al–Al bond (252.7 pm). This bond is comparable in length to the Al–Al bond in the radical anion $[R_2AlAlR_2]^{\bullet-}$ (R = $CH(SiMe_3)_2$) (253 pm) which is strengthened by π bonding contributions.[27] The single occupation of a bonding π orbital for R_2AlAlR_2 ($d_{(Al-Al)}$ = 266 pm[7]) thus leads to the same increase in bond strength as the replacement of the substituents R by bromine atoms and at the same time to donor stabilization by anisole. Apparently, in both cases repulsive Al–Al interactions, which arise from positive partial charges, are weakened in the same way. In contrast, the Al–Al bond in the radical anion $[Trip_2AlAlTrip_2]^{\bullet-}$ (Trip = 2,4,6-*i*$Pr_3C_6H_2$) of 247 pm is significantly shorter than that of **1**; the Al–Al bond length in the neutral $Trip_2AlAlTrip_2$ of 264.7 pm differs only slightly from that in R_2AlAlR_2 (R = $CH(SiMe_3)_2$).[28] Comparable relationships are also observed in the analogous gallium compounds. For instance, the Ga–Ga distance in the radical anion $[Trip_2GaGaTrip_2]^{\bullet-}$ (234.3 pm)[29] is considerably shorter than that in $Ga_2Br_4 \cdot 2$dioxane (239 pm[30]).

The preparation and characterization of **1** shows that with this synthesis strategy both additional R_2AlAlR_2 species and additional aluminum(II) halides and chalcogenides should be accessible.

[1] Molecular $AlCl_2$ has been detected in low concentrations in addition to AlCl and $AlCl_3$ in high-temperature equilibria [2]; in noble gas matrices it is formed from aluminum atoms and Cl_2 [3]. It is questionable whether, as described in [3], $AlCl_2$ and $AlBr_2$ can be prepared at temperatures from 120 °C to 570 °C. According to our observations a rapid disproportionation into aluminum and AlX_3 (X = Cl, Br) occurs under these conditions.

[8] AlBr was prepared analogously to AlCl [9] from Al and HBr.

[9] M. Tacke, H. Schnöckel, *Inorg. Chem.* **1989**, *28*, 2895.

[10] The deposition of gaseous $AlBr_2$ is not suitable for the preparation of solid $AlBr_2$ in preparative quantities, since the concentration of this species in comparison to the concentration of AlBr under our preparation conditions is very low (in earlier experiments for the preparation of AlBr in matrices no indications of $AlBr_2$ were found [11]). If the equilibrium distribution is roughly estimated for $AlCl_2$ (only for this species are thermodynamic data known [12]), it is shown that in the presence of AlCl and liquid aluminum at about 1200 K, the concentration of $AlCl_2$ is only about 0.1 % of the concentration of AlCl.

[13] We also expect a structure stabilized by the formation of Al–Al bonds or by coordination of anisole for AlBr. We are currently trying to further purify and to fully characterize this compound.

[14] NMR spectra (Jeol-GSX-270, C_6D_6, 25 °C): $\delta(^{27}Al)$ = 130 ($\omega_{1/2}$ = 3000 Hz), 95 (based on $[Al(H_2O)_6]^{3+}$ as external standard); $\delta(^1H)$ = 3.52 (3 H), 6.81, 6.92 (5 H) (based on TMS).

[15] This assignment is based on a comparison of the observed bands of stronger intensity [16] in the low-frequency region between 510 and 85 cm^{-1} with the Raman frequencies of Si_2Br_6: ν(SiSi) 562, $\nu_s(SiBr_3)$ 229, $\delta_s(SiBr_3)$ 80, $\nu_{as}(SiBr_3)$ 479, $\delta_{as}(SiBr_3)$ 134, ρ($SiBr_3$) 89 cm^{-1} [17]. After an additional comparison with a section from the Raman spectrum of anisole (108, 266, and 444 cm^{-1}) the following assignment seems plausible for several of the remaining bands: 85 cm^{-1}: ρ($AlBr_2$) or $\delta_s(AlBr_2)$; 137 cm^{-1}: $\delta_{as}(AlBr_2)$; 492 cm^{-1}: $\nu_{as}(AlBr_2)$.

[16] Raman spectrum: Bruker FT Ramanscope IFS66/FRA 106, Nd: YAG laser, 1064 nm. $\tilde{\nu}$[cm^{-1}] (rel. int.) = 3066(6.5), 3042(1.5), 2955(3), 2832(0.5), 1599(1.5), 1585(1.5), 1449(0.5), 1428(0.5), 1205(0.5), 1168(1), 1156(1), 1138(2), 1069(0.5), 1021(1), 1005(5), 945(1.5), 792(1), 760(2), 691(0.5), 612(1), 510(2), 492(0.5), 392(0.5), 300(1), 236(0.5), 220(2), 188(10), 137(6), 109(5), 85(7).

3,6-Diazaxanthylium Salts: Dyes with a New Chromophore**

Lutz Eggers, Walter Grahn,* Wolfgang Lüttke, Burkhard Knieriem, Peter G. Jones, and Axel Chrapkowski

Amongst xanthene dyes[1] rhodamines (**1**) are of scientific interest[2] and have found diverse commercial applications[3] (e.g., since 1967 as laser dyes[2b, 4]); this is particularly so for rhodamine B (**1a**) and rhodamine 6G (**1b**).[2, 3] We were interested in potential changes in the properties of **1** if the nitrogen atoms were not bonded peripherally to the xanthylium framework as in **1**, but instead formed part of the tricyclic framework as in the 3,6-diazaxanthylium salts (**2**). Heterocycles with the parent framework of **2** were previously unknown.

[a] Calculated by the PPP method [5]. [b] Quantum corrected.

Scheme 1. Compounds **1**, **2**, and **8a**: Chemical shifts δ of the methine C atoms and π-charge densities q_π (numbers in italics) at the centers of the tricyclic frameworks in the ground state, calculated by the PPP method [5] (except for **8a**). [**1**: q_π : **1'** (X = H); δ(^{13}C NMR): **1a**(X = 2-COOH-C_6H_4) [6]. **2**: q_π : **2'** (X = H); δ(^{13}C NMR): **2a**(X = Ph)].

We found that **2**, despite its smaller π-electron system, should absorb at considerably longer wavelengths than **1** (**2**: λ_{max}(PPP) = 649 nm, **1**: λ_{max}(PPP) = 495 nm; **2**: 16 π electrons, 14 π orbitals, **1**: 18 π electrons, 16 π orbitals). This unexpected prediction prompted us to synthesize two compounds of type **2**, and to investigate them by X-ray crystallography, spectroscopically, and with regard to their reactivity.

Starting materials for the synthesis of **2** were the 3,4-disubstituted pyridines **3** and **4** (Scheme 2). In addition to the pyridine nitrogen atom, potassium-4-benzyl-3-pyridinolate (**3**)[7] contains two further nucleophilic centers, namely the pyridinolate oxygen atom and (in the latent form) the methylene group. 3-Bromo-4-nitropyridine-1-oxide (**4**) undergoes regioselective nucleophilic attack by **3** at the 3-position with formation of 3,3'-oxybispyridine (**5**) at room temperature in dimethylformamide (DMF). Subsequent heating of **5** with phosphorus trichloride yields the ether **6** by deoxygenation[8] and replacement of the nitro group by chlorine. The dicationic salt **7**, the methylene protons of which are more acidic than those of **6**, is produced by forming two quaternary nitrogen atoms using Meerwein's reagent. If **7** is treated with triethylamine in a polar solvent such as acetonitrile, the reaction solution turns blue. The initially formed benzyl anion nucleophilically attacks the C atom bearing the chlorine substituent. After elimination of HCl, the salts **2** can be isolated as violet crystals with a metallic luster. Attempts to obtain the parent compound **2** (X = H) from the dication **7** with X = H have as yet been unsuccessful.[9]

Scheme 2. Synthesis of the 3,6-diazaxanthylium salt **2**. [a] Yield for X = phenyl; [b] the structure of **8** is shown in Scheme 1.

The cations of **2a** and **2b** contain a previously unreported heterocyclic central framework. The structures of **2a,b** may be deduced from spectroscopic and X-ray data: In the FAB^+ mass spectra (matrix: 3-nitrobenzyl alcohol) of **2a** and **2b**, the base peaks occur at the expected m/z values of 289 and 357, respectively. The ^{1}H and ^{13}C NMR spectra of **2a** and **2b** differ significantly from those of their respective precursors **7** and are only consistent with a symmetrical structure.

The structures of both dyes **2** were confirmed by X-ray structural analyses at −130 (**2a**) and −100 °C (**2b**).[10] Suitable crystals were obtained by using tetraphenylborate as counterion.

The chemically equivalent bonds of **2a** and **2b** are the same length as those of **1b**[11a] to within about 1 pm. Unlike the exactly planar tricyclic parent framework of the xanthene dye **1b**,[11a] both cations are clearly tilted about the central axis O10 · · · C9; the left and right halves are planar to within 1 pm and form an interplanar angle of 5°. The phenyl substituents are positioned similarly as for xanthenes (**1**), approximately perpendicular to the best plane through the tricycle (interplanar angles 83° and 75°, respectively; cf. Fig. 1). The following aryl torsion angles were observed for xanthenes (**1**): **1b**: 82°,[11a] **1** (X = 2-(fluorosulfonyl)-4-sulfophenyl): 86°.[11b]

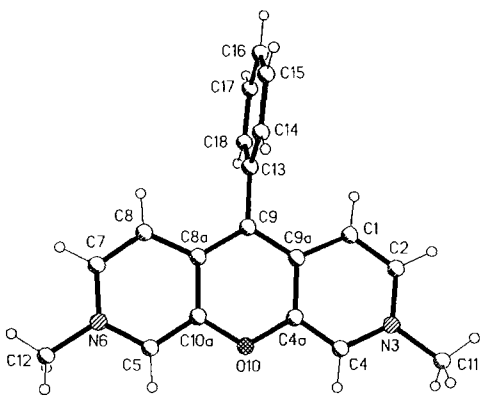

Fig. 1. Structure of the cation of **2a** in the crystal. Selected distances [pm]: N3–C2 134.8(3), C2–C1 136.1(3), C1–C9a 141.4(3), C9a–C9 140.2(3), N3–C4 136.6(3), C4–C4a 134.6(3), C4a–C9a 142.0.

The signals of the equivalent protons 1-H and 8-H which appear in the ^{1}H NMR spectra of **2a,b** at remarkably high field (δ = 5.50 and 5.58, respectively) imply that they lie in the shielding region of the anisotropy effect originating from the phenyl substituents X. This is only possible if the phenyl ring in solution is also positioned orthogonally to the chromophore for **2a,b**. The ^{13}C chemical shifts correlate with the π-charge densities q_π obtained by PPP calculations and show alternating π densities which are inverted for corresponding centers of **1** and **2** (see Scheme 1).

The UV/VIS spectra of **2** are of particular interest compared to those of the rhodamines **1** (**1a**: λ_{max} = 554 nm). The intense band of **2a** with the longest wavelength (Fig. 2) appears at 630 nm (ε = 24100); its position corresponds very well to the theoretical prediction (Table 1). The absorption of **2** at considerably longer wavelength than **1** is explained by the fact that the ether bridge, as a donor, influences the chromophores differently at different positions in the framework according to the Dewar rules.[12] Thus, a donor at C-4a (or C-10a) should cause hypsochromism for **1**, and bathochromism for **2**, in comparison to their respective basic chromophores.

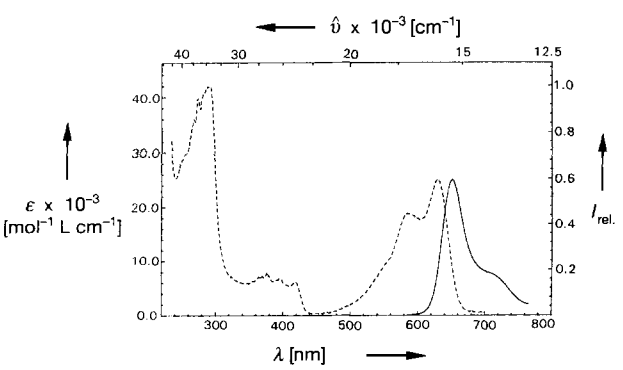

Fig. 2. Absorption (· · ·) and fluorescence (—) spectrum of **2a** where A = BF_4^- in dichloromethane; $c = 1.40 \times 10^{-6}$ mol L^{-1}; λ_{EX} = 390 nm.

The extinction coefficients of the absorption maxima of **2** with the longest wavelengths are considerably lower than those of **1** (Table 1). Differences in the transition moments of **1** and **2** are responsible for this. According to the PPP calculations of the π-charge densities q_π for the S_0 and S_1 state, a strong shift of charge takes place from both of the amino nitrogen atoms in the tricyclic framework following excitation of **1**. This is not possible for compounds **2**, since their nitrogen atoms are incorporated into the aromatic system. On excitation of **2**, a markedly smaller shift of charge, polarized perpendicular to the long axis of the molecule, results within the xanthylium ion.

Since many xanthene dyes such as **1a,b** show intense fluorescence with a mainly small Stokes shift (Table 1), the fluorescence of **2a,b** was determined. For each of the dyes **2** we also observed a fluorescence band, which was only slightly shifted compared to the absorption band with the longest wavelength; the quantum yields ϕ_F are considerably smaller than for rhodamines (**1**) (Table 1).

The dyes **2** have high melting points and are stable for a few months in the crystalline form and in solution, but only with the exclusion of oxygen. As crystals, they decompose and decolorize in air (without exposure to light) within days or weeks, but in solution within a few minutes or hours. The constitution of the non-analytically pure oxidation product **8a** of **2a**, which can be isolated as a colorless substance, indicates why these dyes are sensitive to oxygen. The ^{1}H and ^{13}C NMR spectra of **8a** are consistent with a symmetrical structure. The NMR signal of the central atom C-9 experiences a distinct high-field shift from 103.0 in **2a** to 67.6 in **8a**; the oxygen therefore attacks at C-9, which has a high π-electron density according to the PPP calculations (see Scheme 1). In contrast to **2**, oxidation of rhodamines (**1**) occurs preferentially when exposed to light; a structurally asymmetrical oxidation product results by attack at C-3 or C-6.[13]

Experimental Procedure

2a: The following operations were all carried out using N_2 as the inert gas (strict O_2 exclusion). Triethylamine (0.25 mL, 1.7 mmol) was added to a solution of **7a** (360 mg, 0.72 mmol) in dry acetonitrile (25 mL) and heated under reflux with stirring for 2 h. The solution was then concentrated and chromatographed on about 50 g neutral Al_2O_3 (activity 90) with dichloromethane/acetone ≈ 3:2. After the solvents were distilled off, the residue was dissolved in dichloromethane (50 mL) and extracted once with water (20 mL); yield: 243 mg (90%). Analytically pure **2a** was obtained by recrystallization from chloroform [14].

2a: M.p. 219–222 °C (BPh_4^- as anion); ^{1}H NMR (CD_2Cl_2): δ = 3.33 (s, 6H; CH_3), 5.50 (d, ^3J(H,H) = 6.8 Hz, 2H; 1/8-H), 6.28 (d, ^4J(H,H) = 1.7 Hz, 2H; 4/5-H), 6.59 (dd, ^3J(H,H) = 6.8, ^4J(H,H) = 1.7, 2H; 2/7-H), 6.99–7.01 (m, 2H; 14/18-H), 7.25–7.27 (m, 1H; 16-H), 7.35–7.39 (m, 2H, 15/17-H); ^{13}C NMR (CD_2Cl_2): δ = 44.33 (C-11/12), 103.00 (C-9), 110.36 (C-1/8), 121.92 (C-4/5), 128.40 (C-16), 129.93 (C-14/18), 130.33 (C-15/17), 132.99 (C-13), 140.65 (C-2/7), 144.13 (C-8a/9a), 149.74 (C-4a/10a).

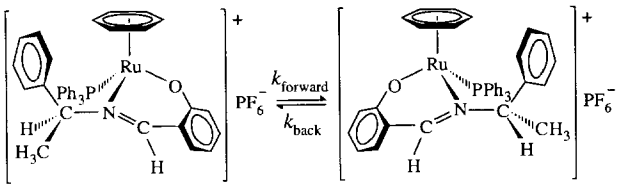
Propeller Isomerism of the Triphenylphosphane Ligand in Half-Sandwich Ru^{II} Complexes**

Henri Brunner,* Ralf Oeschey, and Bernd Nuber

Dedicated to Professor Helmut Werner on the occasion of his 60th birthday

The phenyl rings of triphenylphosphane adopt a propeller-like arrangement in both the free and the complex-bound state.[1, 2] In organometallic complexes, the configuration of the three phenyl rings in the crystal is primarily determined by intramolecular interactions and not by packing forces.[3–6] Here, the phenyl rings in half-sandwich complexes deviate from a staggered conformation with respect to the other ligands in a characteristic way (Scheme 1); one phenyl ring is arranged face-exposed (Ph 1) and the other is arranged edge-exposed (Ph 3) to the π-bound arene ligand.[3–6] The *gauche* angles α_{1-3} therefore lie in the ranges 24–58°, 145–179°, and 262–302°.[3, 4, 6] The sign of the torsion angles ω_{1-3} of the phenyl rings about the C_{ipso}–P axes determines the configuration of the two possible enantiomeric propeller arrangements *M* (Scheme 1) or *P*.[3, 4]

Scheme 1. Left-handed helical *M* configuration of PPh_3 on the complex fragment [(arene)MLL'].



The energy barriers for the rotation of the PPh_3 ligand about the M–L axis (determined by variable-temperature $^{13}C\{^1H\}$ NMR spectroscopy) for the complexes $[CpFe(CO)(COMe)PPh_3]$[5] and $[(\eta^6\text{-}C_6Me_6)Cr(CO)_2PPh_3]$[7] are 43.1 and 28.2 kJ mol^{-1}, respectively. Complex fragments with a stereogenic metal atom of given configuration form diastereomers with triphenylphosphane which only differ in terms of the sense of the propeller of the PPh_3 ligand. Although the calculated energy difference between the two diastereomers is small, in all of the previously reported cases only one of the two possible diastereomers occurs in the solid state, probably the more stable one.[4–6] We report here on half-sandwich Ru^{II} complexes containing the triphenylphosphane ligand. In the synthesis of these complexes initially the diastereomer with the more unstable propeller arrangement forms (kinetic product), which is subsequently converted into the diastereomer with the more stable propeller arrangement (thermodynamic product) at higher temperatures. Both isomers were characterized by X-ray crystal structure analyses.

In the cation, compound **1** contains the anion of *S*-(+)-1-phenylethylsalicylaldimine (pesa) as a chirally modified N,O chelate ligand. In accordance with the synthesis of the corresponding *p*-cymol complexes,[8] **1** is obtained from the neutral complex $[(\eta^6\text{-}C_6H_6)Ru(pesa)Cl]$ by halogen abstraction with $AgPF_6$ and subsequent addition of PPh_3 at −35 °C. Compound **1** forms two diastereomers (R_{Ru},S_C) and (S_{Ru},S_C), which differ from each other in terms of the configuration at the ruthenium

atom (Scheme 2). At room temperature the equilibrium ratio determined by the integration of the ^{1}H NMR signals of the η^6-arene protons is 93:7 in [D$_6$]acetone and 95:5 in $CDCl_3$.

(R_{Ru}, S_C)-**1** (S_{Ru}, S_C)-**1**

Scheme 2.

Compound **1** crystallizes in a diastereomerically pure form from $CHCl_3$/petroleum ether as deep red, air-stable tetrahedra (**1a**), if, after synthesis at $-35\,^\circ C$, the solution is kept at $5\,^\circ C$. If, on the other hand, the initially bright red solution of **1a** in $CHCl_3$ is warmed to higher temperatures, epimerization takes place, which can be followed by ^{1}H NMR spectroscopy and occurs first order,[9] the solution changing color to red-brown, only observable in thick layers. If the solution is cooled to $5\,^\circ C$, after a period of more than ten half-lives, red-brown tablets of **1b** crystallize.[9] Both modifications, **1a** and **1b**, show the same ^{1}H, ^{31}P{^{1}H}, and ^{13}C{^{1}H} NMR spectra in solution up to $-90\,^\circ C$.[10] Also no differences in the chemical shifts of the phosphorus signals were observed in the ^{31}P CP/MAS solid-state NMR spectra (CP/MAS = cross polarization/magic angle spinning),[11] and the IR spectra of **1a** and **1b** were identical both in a KBr matrix and in $CHCl_3$ solution. Within the error limits the same is true for the angle of rotation as well as the circular dichroism and UV spectra.[12]

The X-ray structure analyses of the tetrahedral and tablet modifications, **1a** and **1b**, respectively, revealed both to have the (R_{Ru},S_C) configuration (Fig. 1). They differ only in terms of the chirality of the propeller of the PPh_3 ligand; the rest of the complex cation is almost the same in both cases.[13]

Noteworthy in the structures is that in **1a** the P1–Ru1 bond is 0.037(4) Å longer and the N1–Ru1 bond 0.04(1) Å shorter than in **1b**. Furthermore, the P1-Ru1-N1 angle in **1b** is 2.6(4)° smaller than in **1a**. The shape of the thermal ellipsoids for the η^6-arene carbon atoms in **1b** indicates a disorder in terms of a rotation about the sixfold Ru1–arene axis. In **1a** the arene ring is not planar, since the distances Ru1–C36 and Ru1–C37 are up to 0.06(2) Å longer than the other Ru1–C(arene) distances because of the *trans* effect of PPh_3.[14]

(R_{Ru},S_C)-**1a** and (R_{Ru},S_C)-**1b** differ with respect to the propeller configuration of the PPh_3 ligand. In comparison to **1a**, the PPh_3 fragment in **1b** is rotated anticlockwise about the M–L axis by 53°. This is accompanied by a rotation of the phenyl "rotor blades" about their C_{ipso}–P axes, which causes the inversion of the propeller from the *M* arrangement in **1a** to *P* in **1b**. The edge arrangement of the phenyl ring C16–C21 relative to the arene ligand in **1a** changes into the face arrangement in **1b**; the opposite is true for the phenyl ring C10–C15. For the edge-exposed phenyl rings the dihedral angle C21-P1-Ru1-arene(centr) in **1a** (− 82°) is slightly smaller than the dihedral angle C15-P1-Ru1-arene(centr) of 89° in **1b**.[15] Thus, the distance of the *ortho* proton at C20 in **1a** (2.34 Å) to the protons of the arene ligand is slightly smaller than for the corresponding proton at C14 in **1b** (2.40 Å). The difference between the minimum H···H distances of the methyl protons at C3 and the next- nearest protons on the phenyl rings of the PPh_3 ligand is significantly greater, namely 2.43 Å for H3···H8 in **1a** and 3.20 Å for H3···H5 in **1b**.[15] These intramolecular interactions provide an explanation why the initially formed **1a** is thermodynamically unstable in comparison to **1b**.

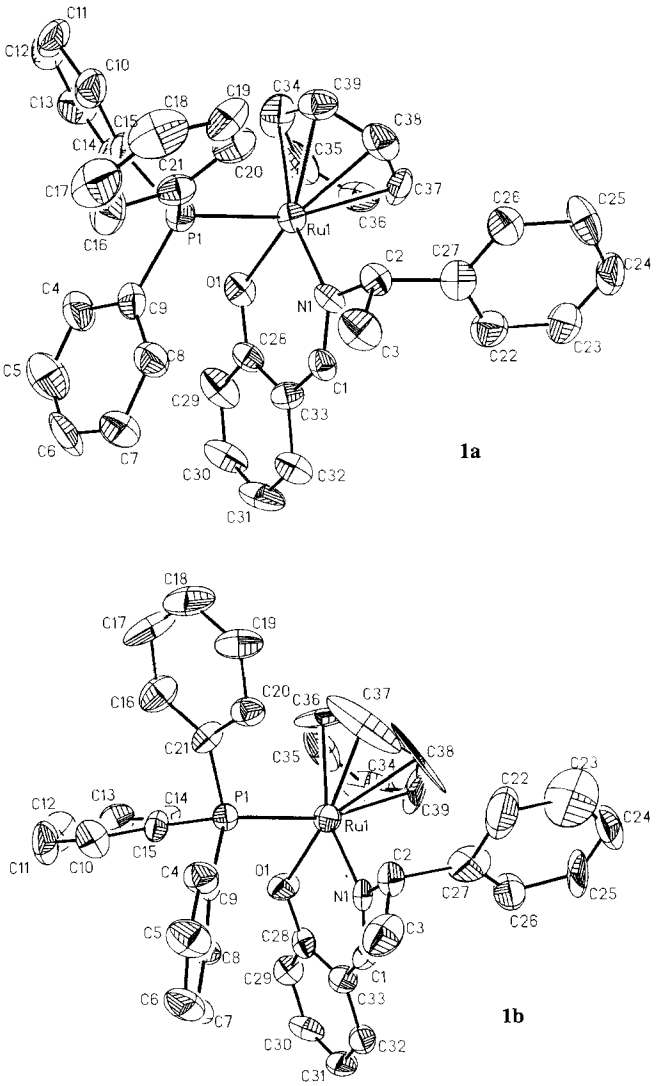

Fig. 1. Crystal structures of **1a** and **1b** (thermal ellipsoids at 50% probability level). The PF_6 anions and the hydrogen atoms were omitted for clarity. Selected distances [Å] and angles [°] in **1a**: Ru1-P1 2.392(4), Ru1-O1 2.063(8), Ru1-N1 2.063(8), Ru1-N1 2.09(1), Ru1-C34 2.22(2), Ru1-C35 2.21(2), Ru1-C36 2.28(2), Ru1-C37 2.27(2), Ru1-C38 2.24(1), Ru1-C39 2.21(1), N1-C1 1.28(2); P1-Ru1-N1 88.8(5), P1-Ru1-O1 82.3(4), O1-Ru1-N1 89.4(4); **1b**: Ru1-P1 2.355(4), Ru1-O1 2.057(9), Ru1-N1 2.13(1), Ru1-C34 2.18(3), Ru1-C35 2.20(3). Ru1-C36 2.18(4), Ru1-C37 2.21(2), Ru1-C38 2.28(3), Ru1-C39 2.17(4); P1-Ru1-N1 90.6(3), P1-Ru1-O1 82.3(2), O1-Ru1-N1 86.8(4).

The conformations found in the molecular structures of **1a** and **1b** in regard to the stereogenic center C2 are also preferred in solution. This is revealed by the ^{1}H NMR signals of the methyl protons at C3 and of the methine proton at C2, which, in comparison to those of the likewise (R_{Ru},S_C)-configurated starting material [(η^6-C_6H_6)Ru(pesa)Cl], are shifted by more than $\Delta\delta = 0.8$ to higher field. The molecular structures in the crystal clearly show that the methyl and methine protons are situated within the anisotropy cone of the phenyl ring C16–C21 of **1a** and of the phenyl ring C4–C9 of **1b**. The weak attraction between the π-bound six-membered ring and the phenyl group C22–C27 of the 1-phenylethyl group, known as the "β-phenyl effect", seems to determine the conformation.[16]

Red tetrahedra of **1a** crystallize at 5 °C from a $CHCl_3$ solution of **1a**, which has been kept at −25 °C for several days. In this case, neither the helicity of the PPh_3 nor the Ru configuration has changed. If crystallization is effected after adjustment of the diastereomeric equilibrium $(R_{Ru},S_C) \rightleftharpoons (S_{Ru},S_C)$, red-brown tablets of **1b** are obtained containing the thermodynamically more stable propeller configuration of the triphenylphosphane ligand. The course of the exchange experiments with tri(*p*-tolyl)phosphane can be followed by ^{1}H NMR spectroscopy. The results suggest that the epimerization of **1a** and **1b**, and therefore also the change of the propeller configuration, occurs by a rate-determining dissociation of the PPh_3 ligand.[9, 17]

Inversion of the propeller configuration in the complexes $[CpFe(CO)(COMe)PPh_3]$[5] and $[(\eta^6\text{-}C_6Me_6)Cr(CO)_2PPh_3]$[7] occurs rapidly and intramolecularly; this inversion is hindered, but not prevented, by the Cp and arene ligands and, depending on their size, also by the other ligands. In **1a**, in contrast, the $CHCH_3$ group of the 1-phenylethyl group blocks the intramolecular propeller inversion, which is only made possible by the triphenylphosphane dissociation.

Experimental Procedure

$[(\eta^6\text{-}C_6H_6)Ru(pesa)Cl]$: Synthesis in accordance with the preparation of the analogous cymol complex [8] (synthesis at room temperature, workup by repeated precipitation from CH_2Cl_2/acetone/hexane). The compound was obtained crystalline and diastereomerically pure in 45% yield with (R_{Ru},S_C) configuration [18] in the crystalline state; in contrast, in $CDCl_3$ solution a diastereomeric ratio of 86:14 is found. ^{1}H NMR (250 MHz, $CDCl_3$, 25 °C, TMS) (values for the (S_{Ru},S_C) diastereomer in parentheses): δ = 7.99 (s, 1H, N=CH), 7.67–6.39 (m, 9H, arene-H), 5.97 (5.68), (q, ^3J(H,H) = 6.9 Hz, 1H, CH), 5.31 (5.54) (s, 6H, C_6H_6), 1.77 (2.00), (d, ^3J(H,H) = 6.9 Hz, 3H, CH_3); correct elemental analysis.

$[(\eta^6\text{-}C_6H_6)Ru(pesa)PPh_3]PF_6$ **1**: $AgPF_6$ (429 mg, 1.7 mmol) was added to a suspension of $[(\eta^6\text{-}C_6H_6)Ru(pesa)Cl]$ (744 mg, 1.7 mmol) in acetone (120 mL) at −35 °C and stirred (N_2 atmosphere). Subsequently, after 45 min PPh_3 (525 mg, 2.0 mmol) was added which caused the mixture to turn yellow immediately. After the mixture had been stirred for 30 min at −35 °C, it was filtered through Celite, concentrated to a few mL, and precipitated by the addition of petroleum ether. Several precipitations from CH_2Cl_2/petroleum ether gave **1** as an orange-yellow, microcrystalline powder in almost quantitative yield. The crystallization of each 100 mg **1** from 1.9 mL $CHCl_3$/0.4 mL petroleum ether at 5 °C after 3 d yielded red, air-stable tetrahedra of **1a** (73%). Tablets of **1b** were formed after warming a solution of **1** at 40 °C for 50 min or 5 h stirring at 12 °C and subsequent crystallization at 5 °C (80% yield of red-brown, air-stable tablets within 3 d). ^{1}H NMR (250 MHz, $CDCl_3$, 25 °C, TMS) (values for (S_{Ru},S_C)-**1** in parentheses): δ = 7.78 (d, ^4J(H,P) = 0.7 Hz, 1H, N=CH, 7.65–6.44 (m, 24H, arene-H), 5.33 (5.83) (d, ^3J(H,P) = 0.7 Hz, 6H, C_6H_6), 5.21 (q, ^3J(H,H) = 7.0 Hz, 1H, CH), 1.04 (1.93) (d, ^3J(H,H) = 7.0 Hz, 3H, CH_3); $^{31}P\{^1H\}$ NMR (161.8 MHz, [D$_6$]acetone, 25 °C, 85% H_3PO_4 ext.): δ = 35.8 (28.8) (s, 1P), −142.6 (sept, ^1J(P,F) = 707 Hz, 1P, PF_6); $^{13}C\{^1H\}$ NMR (100.6 MHz, $CDCl_3$, 25 °C): δ = 165.7 (s, C1), 164.8 (s, C28), 142.6 (s, C33), 135.9, 134.8 (s, C30, C31), 133.9 (d, ^2J(C,P) = 10 Hz, C4/8/10/14/16/20), 131.5 (d, ^4J(C,P) = 2.4 Hz, C6/12/18), 130.2 (d, ^1J(C,P) = 47.5 Hz, C9/15/21), 129.8 (s, C23/25), 129.1 (d, ^2J(C,P) = 10 Hz, C5/7/11/13/17/19), 128.5 (s, C24), 125.7 (s, C22/26), 122.6 (s, C32), 121.7 (s, C27), 115.8 (s, C29), 90.3 (90.8) (d, ^2J(C,P) = 3 Hz, C34/35/36/37/38/39), 77.6 (d, ^3J(C,P) = 1.8 Hz, C2), 25.0 (s, C3); correct elemental analysis.

[9] The kinetics of the epimerization is followed based on the decrease of the η^6-C_6H_6 signal of **1a** in $CDCl_3$ at 12 ± 2 °C. The analysis of the data affords $k_{rate} = (2.28 \pm 0.02) \times 10^{-2}$ min^{-1}, which corresponds to a half-life $\tau_{1/2}$ = (30.4 ± 0.4) min. By using the equilibrium constant $K = [(S_{Ru},S_C)\text{-}\mathbf{1}]/[(R_{Ru},S_C)\text{-}\mathbf{1}] = 0.046 \pm 0.003$, the rate constants of the forward and back reaction can be calculated: $k_{forward} = (1.00 \pm 0.08) \times 10^{-3}$, $k_{back} = (2.18 \pm 0.03) \times 10^{-2}$ min^{-1}. The kinetic parameters determined with **1b** ($k_{rate} = 2.31 \pm 0.03) \times 10^{-2}$ min^{-1}, $\tau_{1/2}$ = (30.1 ± 0.3 min) correspond with those determined for **1a** within the limits of error.
[10] On cooling, a reversible signal broadening of the ^{13}C resonances of the triphenylphosphane ligand, particularly the C_{ortho} signals, occurs.
[11] ^{31}P CP/MAS NMR (121.5 MHz, ν_{rot} = 3340 Hz for **1a**, 3266 Hz for **1b**): **1a**: δ = 33.5 (s, 1P), −143.7 (sept, ^1J(P,F) = 712 Hz, 1P, PF_6); **1b**: 33.4 (s, 1P), −143.8 (sept, ^1J(P,F) = 712 Hz, 1P, PF_6). We thank Prof. Dr. A. Sebald, Bayreuth, for recording the spectra.
[12] UV/VIS (−10 °C, $CHCl_3$): **1a**/**1b**: λ_{max} (ε = 418 (3000); by raising the temperature to 25 °C after 30 min: 410 (2600); angle of rotation: **1a**/**1b**: $[\alpha]_D^{-18}$ = −1076°, $[\alpha]_{578}^{-18}$ = −1276°, $[\alpha]_{546}^{-18}$ = −2072°; CD (−20 °C, CH_2Cl_2): **1a**/**1b**: λ_{max}; λ_0 ($\Delta\varepsilon$ [° L mol^{-1} cm^{-1}]) 443 (−14.6), 393 (12.2), 352 (−5.8), 305 (5.1); 414, 369, 327.
[13] Crystal structure analyses: Syntex-Nicolet R3 four-circle diffractometer, $Mo_{K\alpha}$ radiation (λ = 0.71073 Å), empirical absorption correction, SHELXTL-PLUS program on a Microvax II workstation, structure solution by Patterson Fourier and least squares methods, positions of the H atoms were calculated with the option HFIX. **1a**: $C_{39}H_{35}F_6NOP_2Ru$, M_r = 810.72, crystals: red tetrahedra, 0.2 × 0.2 × 0.2 mm^3, monoclinic, space group $P2_1$, a = 10.436(5), b = 19.39(1), c = 10.518(5) Å, β = 119.62(4)°, V = 1850.7 Å^3, Z = 2, ρ_{calcd} = 1.45 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 0.56 mm^{-1}; transmission factors: 0.92–1.00, ω scan, 3.0° < 2σ_i < 52.5°. 2198 independent reflections with $I > 2.5\theta$, refinement with 451 variables: R = 0.051, R_w = 0.043, GOF = 1.63, residual electron density 0.43/−0.38 eÅ^{-3}, determination of the absolute configuration by comparison of the R values for the two possibilities. The refinement of the variables η according to Sheldrick did not result in any reliable conclusion. PF_6 slightly disordered. **1b**: $C_{39}H_{35}F_6NOP_2Ru$, M_r = 810.72, crystals: red-brown tablets, 0.02 × 0.1 × 0.6 mm^3, monoclinic, space group $P2_1$, a = 10.01(1), b = 18.073(9), c = 10.472(7) Å, β = 96.78(7)°, V = 1881.2 Å^3, Z = 2, ρ_{calcd} = 1.43 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 0.55 mm^{-1}; transmission factors: 0.92–1.00, ω scan, 3.0° < 2σ_i < 42.0°. 2743 independent reflections with $I > 2.5\theta$ (h,k,l: min: 0/0/−11, max: 11/19/11), refinement with 451 variables: R = 0.060, R_w = 0.049, GOF = 1.48, residual electron density 0.50/−0.62 eÅ^{-3}, determination of the absolute configuration by measurement of a section of Friedel pairs (20.0° < 2θ < 45.0°, $h/k/l$: min: 0/−20/−12, max: 11/−1/12) and refinement up to η = 1.2 ± 0.2, since, because of the small size of the crystal, the reflection intensities of the crystallographically independent unit were relatively weak. The arene ligand is disordered in terms of a rotation about the sixfold Ru1-centr axis. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57948.

[17] The exchange experiment was carried out with **1a** at 11 ± 2 °C in $CDCl_3$ by addition of a fivefold molar excess of tri(*p*-tolyl)phosphane. The decrease in the concentration of (R_{Ru},S_C)-**1** occurs first order and gives a rate constant $k = (2.26 \pm 0.01) \times 10^{-3}$ min^{-1}, which correlates well with the rate-determining $k_{forward}$ of the epimerization [9].

Substantial electronic interactions have been evidenced in per-*gem*-dimethyl-substituted macrocyclic oligoalkynes ("pericyclynes")[1-3] and oligoalkadiynes[4] such as **1** and **2**. Since the highest occupied molecular orbitals (HOMOs) of a cyclopropane ring[5] are much closer in energy to the π MOs of an acetylene unit than the σ MOs of a *gem*-dimethyl group are, we thought that considerably stronger homoconjugative effects ought to be shown by perspirocyclopropanated pericyclynes[6] and perspirocyclopropanated macrocyclic oligoalkadiynes such as **3** and **4**. This expectation is based on the observation that the splitting between the π MOs parallel to the plane of the ring in 1,1-diethynylcyclopropane is much larger (1.4 eV) than in 3,3-dimethylpenta-1,4-diyne (0.6 eV).[7]

3,3:8,8:13,13-Trisethanopentadecahexayne (**10**) should be a more appropriate building block than 1,1-diethynylcyclopropane[8] for compounds of type **3** and **4**. Hexayne **10** was assembled in six steps from (trimethylsilylethynyl)cyclopropane (**5**).[9] The sequence began with the deprotonation of **5** with butyllithium in diethyl ether and subsequent formyl group transfer with dimethylformamide. The resulting aldehyde was converted into the dibromoethenyl derivative **6** by treatment with a mixture of carbon tetrabromide, triphenylphosphane, and zinc[10] (70% overall yield) and this in turn dehydrobrominated to give the 1,1-diethynylcyclopropane derivative **7** (95%). This compound was desilylated to provide **8**, which was first treated with two equivalents each of butyllithium, then cuprous chloride, and finally diethynylcyclopropane derivative **7**. This Cadiot–Chodkiewicz coupling[11] led to the silylated acyclic dehydrotrimer **9** of 1,1-diethynylcyclopropane in 54% yield, and desilylation gave **10** (84%) (Scheme 1). When a solution of **10** in pyridine was added over a period of three days to a slurry of cuprous chloride and cupric acetate in pyridine,[12] and the mixture was stirred at ambient temperature for an additional four days, three cyclic dehydro oligomers of 1,1-diethynylcyclopropane were isolated in 6, 39, and 8% yield, respectively, by column chromatography and/or recrystallization. All three were characterized by their diagnostically simple ^1H and ^{13}C NMR spectra (Table 1). Attempts to determine their molecular masses by mass spectrometry with common ionization methods (electron ionization, chemical ionization, direct chemical ionization, field desorption) failed, as the compounds apparently decompose irreproducibly in the inlet system of the mass spectrometer.[13] The relative molecular masses of the two major compounds were, however, determined by vapor pressure osmometry in dichloromethane solution to be 529 and 783 g mol^{-1}, which indicated that they correspond to the cyclic dehydrohexamer **4** (calcd for $C_{42}H_{24}$: 528 g mol^{-1}) and the cyclic dehydrononamer **12** (calcd for $C_{63}H_{36}$: 793 g mol^{-1}) of 1,1-diethynylcyclopropane. While attempts to grow high-quali-

4: White crystals, decomp > 130 °C. ^1H NMR: $\delta = 1.27$ (s); ^{13}C NMR: $\delta = 21.02$ (CH_2), 3.91, 62.52, 77.77 (C).
12: White powder, decomp > 100 °C. ^1H NMR: $\delta = 1.29$ (s); ^{13}C NMR: $\delta = 21.30$ (CH_2), 3.87, 62.41, 77.73 (C).

ty crystals of the unidentified product **11** and nonamer **12** failed, "expanded [6]rotane" **4** crystallized well from chloroform and benzene. The structure of the crystals containing two molecules of chloroform per molecule of **4** was analyzed by X-ray diffraction at 200 K and refined to $R = 0.047$ (Fig. 1).[14]

The thirty-membered ring of compound **4** has a chair conformation (Fig. 1 bottom), but with an average torsional angle of $\varphi = 41.4(4)°$ it is less puckered than cyclohexane ($\varphi = 55.1°$)[15] and [6]rotane ($\varphi = 54.6°$).[16] Therefore, a maximum overlap between the Walsh orbitals of the spirocyclopropane units and the π orbitals of the adjacent ethynyl groups is not realized. In fact, the bond angle in the "expanded" six-membered ring of **4**

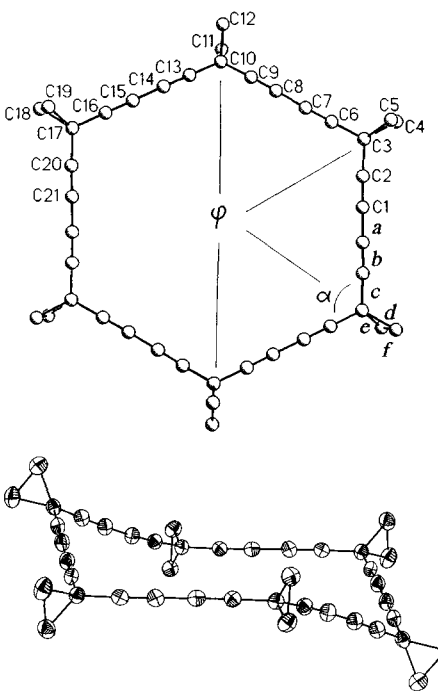

Fig. 1. Crystal structure of hexaspiro[2.4.2.4.2.4.2.4.2.4.2.4]dotetraconta-4,6,11,13,18,20,25,27,32,34,39,41-dodecayne $C_{42}H_{24}$ (**4**)[14]. The numbering in the upper part of the figure does not follow that recommended by IUPAC. Bond lengths [Å] and angles [°] (averaged over D_{3d} symmetry): $a = 1.379(4)$, $b = 1.190(3)$, $c = 1.443(2)$, $d = 1.529(4)$ (axial position), $e = 1.523(3)$ (equatorial position), $f = 1.467(3)$; $\alpha = 115.5(4)$, $\varphi = 41.1(4)$. In the bottom section **4** is shown with thermal probability ellipsoids (50% probability level) and without hydrogen atoms.

($\alpha = 115.5°$), which is also the exocyclic angle of the spirocyclopropanes, is virtually the same as that between the two exocyclic carbon–carbon bonds in 1,1-diethynylcyclopropane (115.5°).[17] This causes the macrocycle **4** to be less puckered than the six-membered rings in cyclohexane ($\alpha = 111.4°$)[15] and in [6]rotane ($\alpha = 111.5°$).[16] The ethynyl groups on the cyclopropane rings in **4** apparently exert an electron-withdrawing effect, as the lengths of the proximal and the distal bonds in the three-membered rings are found to be significantly different [1.526(4) versus 1.467(3) Å]. This lengthening of the proximal and the shortening of the distal bond is also observed in 1,1-diethynylcyclopropane [1.526(1) versus 1.483(1) Å],[17] and it is consistent with the known effects of electron-withdrawing substituents on a cyclopropane[18] as put forward by MO theory.[19] This type of bond differentiation is not observed in [5]- and [6]rotane,[16] and it is opposite to that in [3]rotane, in which the proximal bonds are shortened and the distal bonds are lengthened.[20] The electron donor action of the spirocyclopropane groups in **4**, on the other hand, does not affect the C≡C bond lengths.

Surprisingly, the UV spectra for the basic chromophore 1,4-dicyclopropylbutadiyne, the acyclic dehydrotrimer **10**, and macrocycles **4** and **12** look quite similar in the long-wavelength region, with bathochromic shifts of about 2 nm for the absorption maxima of **4** and **12** (Fig. 2). The intense main absorptions

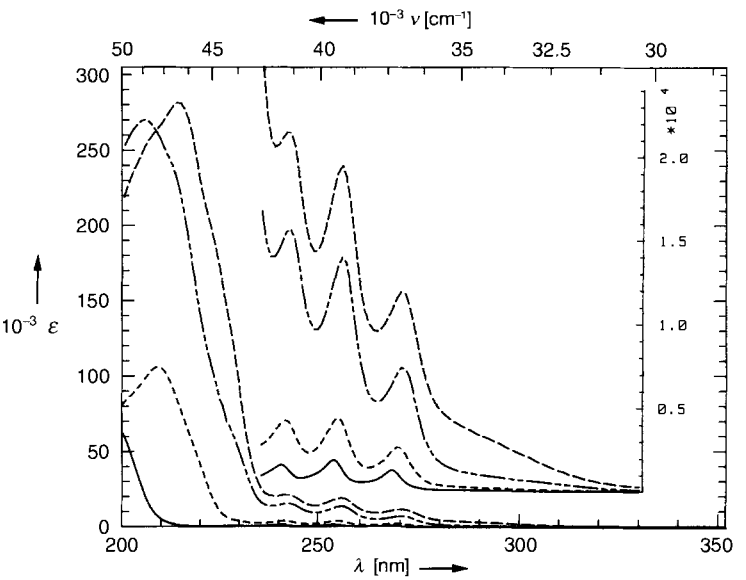

Fig. 2. UV spectra of 1,4-dicyclopropylbutadiyne (—) in methanol, 3,3:8,8:13,13-trisethanopentadecahexayne **10** (----), hexaspirodotetracontadodecayne **4** (— —), and nonaspirotrihexacontaoctadecayne **12** (– –) in *tert*-butyl methyl ether.

at 200–220 nm ($\varepsilon = 250000$–450000), however, are strikingly different. A distinct bathochromic shift is observed on going from 1,4-dicyclopropylbutadiyne to **10** and, more interestingly, this absorption splits into two bands for both macrocycles **4** and **12** but with different magnitudes. This is most likely linked to the expected increased homoconjugative interaction between ethynyl units in **4** and **12**, as corresponding effects are not observed in the UV spectra of the analogous permethylated macrocycles **1** and **2**.

Another striking feature of the "expanded [6]rotane" **4** is its shock sensitivity: When a sample was struck hard with a spatula, a pestle, or a falling metal ball, it flared and turned into black soot. This unusual behavior must be attributed to the presence

of the six three-membered rings, as analogous behavior has not been observed for the permethylated derivative **2**.[4]

Enzymatic Grooming of Organic Thin Films**

James K. Whitesell,* Hye Kyung Chang, and Christopher S. Whitesell

We recently described the preparation of new materials consisting of helical peptides arranged nearly vertically and unidirectionally from the surface of gold and of indium–tin oxide (ITO) glass.[1] These layers were produced by polymerization of the N-carbonic anhydride of amino acids, and although they are composed of essentially completely helical structures, the polypeptide chains appeared not to be monodisperse. We report here that these synthetic, oriented peptide layers can be manipulated enzymatically to clip selectively the longer peptide chains, providing a more uniform layer without concurrently destroying bulk material or adversely influencing the high levels of helicity of the layers. These results are significant from two perspectives. First, we have demonstrated that enzymes can be used to manipulate the macroscopic features of bulk materials, in this case resulting in the smoothing of an uneven polymer surface. Second, we have shown that bulk materials comprised of natural substrates for enzymes are resistant to natural enzymatic degradation when formed in a tightly organized array.

Through the use of suitable starting "seeds" of different size, we have been able to define an area on the surface that is appropriate for the helical secondary structure of polyphenylalanine, polyethylglycine, and polyleucine on gold (as a thin layer on chromium-coated silicon) and of polyalanine on both ITO glass and gold (Fig. 1).[1, 2] Possible applications of these polypeptide

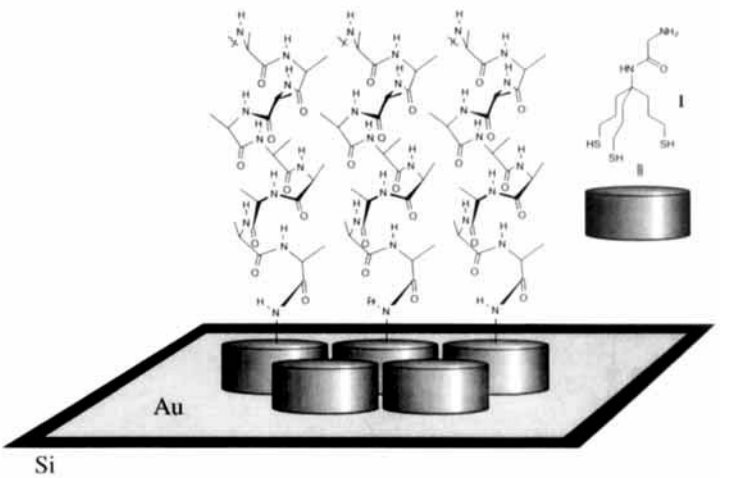

Fig. 1. Schematic representation of a layer of helical polyalanine formed by polymerization of the N-carbonic anhydride starting with a monolayer of aminotrithiol **1** as a "seed" bound to a gold layer on silicon with an intervening layer of chromium. For clarity, **1** is shown as a cylinder on the surface.

layers include waveguide optical switches based on nonlinear optical properties inherent in materials with unidirectional alignment of polarizability vectors.[3–6] Our method for constructing relatively thick layers of highly ordered and directionally aligned materials complements other techniques that depend upon a discrete, layer-by-layer assembly, and has the distinct advantage that the layers are constructed in a single operation; it has the disadvantage that there is no inherent means to produce material composed of chains of all the same length. Thus, although the layers formed in this way are composed almost exclusively of helical peptide units oriented nearly perpendicular to the surface, the lengths of the individual chains (and, therefore, the height above the surface) are uneven. Indeed, attempts to measure thickness of these polypeptide layers using ellipsometry[7] were unsuccessful as the data was highly variable across the surface and not interpretable. Nonetheless, we were able to make an estimate of average thickness of the layers by comparing their IR absorbance with that of a layer consisting of 24 alanines prepared by the sequential addition of trialanine units using Merrifield-like technology. Each amino acid residue in a helical

polypeptide contributes approximately 1.5 Å to the length of the helix, and thus with our system and measurement technique (80°, grazing angle reflection IR spectroscopy with vertically polarized light), each 0.1 absorbance unit (for the amide I band) corresponds to approximately 300 Å of thickness. We have thus far been able to grow layers thicker than 3000 Å that are optically clear.

For practical use as waveguide materials, it is desirable that the surface be as uniform as possible to minimize light loss. Thus, we began to examine methods which allow the longer chains to be selectively shortened. Because the bulk of the layer is apparently composed of tightly packed, helical polypeptide polymers, we reasoned that only the longer chains protruding above the surface of the bulk layer would be exposed to possible hydrolytic cleavage. However, attempted hydrolysis with aqueous sodium hydroxide led to rapid attack of the silicon–chromium interface and physical destruction of the gold overlayer.

Thus, we turned to the use of enzymes in order to achieve hydrolysis under conditions that would be more selective for cleavage of only the peptide amide bonds exposed to the solution. Indeed, treatment of a layer of polyalanine on gold with alanine aminopeptidase[8] led to rapid removal of a small fraction of the peptide layer. A plot of absorbance versus time (Fig. 2) reveals that the initial rapid rate of loss of material dropped dramatically and stopped after approximately 12% of the material was removed. (Fresh enzyme was added at 10 h intervals to insure that the decrease in removal rate did not result from inactivation of the enzyme by either denaturation or product inhibition.[9])

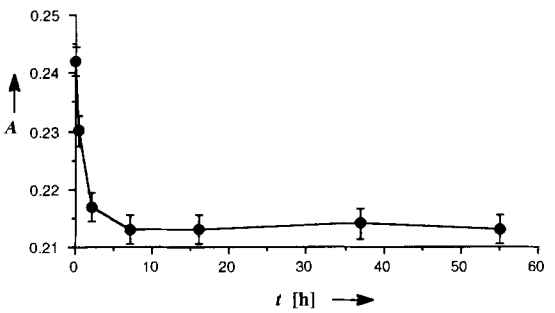

Fig. 2. Plot of absorbance A (amide I band) versus time t for a 300 Å thick layer of polyalanine on gold upon treatment with alanine aminopeptidase in water at pH 6.8 and 37 °C.

By modification of the procedure used to prepare polyalanine layers, we have also been able to construct thin films of peptides derived from other amino acids, including phenylalanine and leucine.[11] Treatment of the layer of polyleucine with leucine aminopeptidase[10] also resulted in a rapid decrease in IR absorbance with no further change observed after 1 h; approximately 11% of the total thickness was removed by the enzyme.

These results are consistent with the selective removal of residues only from the longer chains, a process that must stop when the amino terminus of the peptide can no longer reach the active site of the enzyme. We have represented this concept schematically in Figure 3. Indeed, after enzymatic treatment, the layers were amenable to ellipsometry. We conclude that the longer chains form a disordered mass on the surface and that this overlayer of helical peptides contributes dramatically to the degree of rotation of the laser beam used in the ellipsometric measurement. After enzymatic grooming, thickness values of about 300 Å per 0.1 absorbance units were obtained for the polyalanine films, in reasonable agreement with the estimate made above based upon the discretely prepared, 24-mer of polyalanine.[11] Furthermore, measurement of the contact angle with water[12] before treatment gave values that ranged from 23–61°, consistent with a highly variable surface. After enzymatic grooming, the contact angle was 55–56° uniformly over the surface.

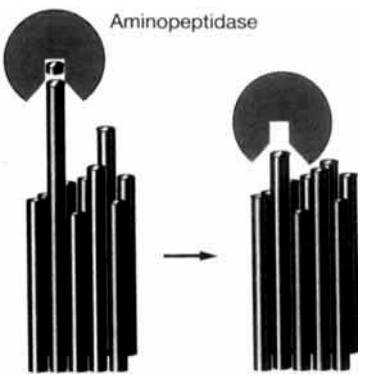

Fig. 3. Schematic representation of the selective action of alanine and leucine aminopeptidases on those polypeptide chains that extend significantly above the bulk layer.

Leucine aminopeptidase is the only aminopeptidase for which a crystal structure has been obtained.[13] The distance of the active site of this enzyme from the surface is approximately ten amino acid residues (in an extended, β-conformation). In the α-helical conformation, ten residues contribute 15 Å to the length of the peptide. However, we hesitate to suggest that variation in lengths of our surface-bound peptide layers have been reduced to this amount, because the mode of action of leucine aminopeptidase is not yet known in detail.[14] It is interesting that the same percentage of the surface-bound peptide is removed from both the polyalanine and polyleucine layers.

Experimental Procedure

Polyalanine and polyleucine layers on gold were prepared as previously described [1]. A solution of tris(hydroxymethyl)methylamine (3 mM) and $CoCl_2$, $MnCl_2$, and $MgCl_2$ (each 5 mM) was prepared and adjusted to pH 6.8 with dilute HCl. Alanine aminopeptidase (5 mg) was added and the solution was warmed at 37 °C for 20 min. The plate coated with the polyalanine layer was immersed in this solution, and periodically removed, rinsed with water and then ethanol, and analyzed by grazing angle IR spectrospcopy. Additional enzyme was added at 10 h intervals. The commericial solution of leucine aminopeptidase was used as obtained from Sigma at 37 °C. Fresh solution was used after each measurement.

[11] This comparison is not ideal because the layers that we have built by sequential addition do not exhibit as high a level of helicity as those prepared by polymerization. We rationalize this difference as resulting from low levels of partial racemization during the multistep operations, where a single amino acid of the opposite hand inhibits formation of the helical secondary structure for several residues to both sides of the defect.

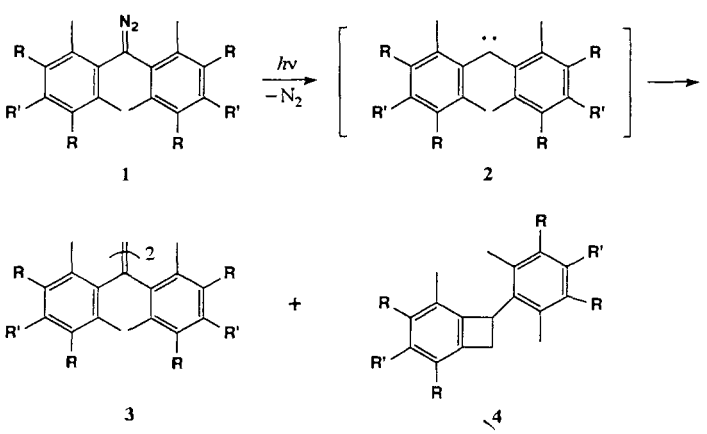
An Extremely Long-Lived Triplet Carbene; Reactivity, Optical Absorption Spectrum, and Kinetics of Highly Congested Diarylcarbenes**

Hideo Tomioka,* Hidetsumu Okada, Tetsuya Watanabe, and Katsuyuki Hirai



In contrast to the long history of persistent radicals,[1] which started with the work of Moses Gomberg in 1890, that of persistent carbenes is much shorter. Only a few years ago "bottleable" carbenes were first isolated.[2, 3] These carbenes are stabilized not only by bulky protecting groups but also by heteroatom substituents directly connected to the carbenic carbon atom. Owing to these substituents, these carbenes have singlet ground states. But their electronic configurations are still a topic of debate.[4] The next challenge is the stabilization of a carbene hopefully having a triplet ground state by all-carbon substituents. The most persistent triplet carbene known so far is dimesitylcarbene (**2a**), which was first generated by Zimmerman and Paskovich[5] in 1964. The congestion at the carbene center in **2a** is reflected in its unique behavior, for example its proclivity to dimerize and reluctance to attack secondary carbon–hydrogen bonds. Carbene **2a** was not stable enough to be isolated, and systematic kinetic studies were also not conducted for further characterization. If four additional methyl groups are introduced at the *meta* positions, the carbenic center would be more crowded, because of the "buttressing effect" on the four *ortho* methyl groups.[6] In view of the scarcity of the data in this field despite recent growing interest in triplet carbenes as potential organic ferromagnets,[7] we became interested in designing and generating persistent triplet carbenes. Thus, we have generated a series of polymethylated diphenylcarbenes **2a–c** and investigated their reactivities by flash photolysis techniques. We have found that they are exceptionally long-lived for diarylcarbenes with lifetimes on the order of seconds.

The new precursor diazomethanes **1b, c** were prepared by essentially the same procedure[5, 8] employed for dimesityldiazomethane. The polymethylated diphenylcarbenes were then generated either by thermolysis or by photolysis of the diazomethanes, and the products were analyzed by conventional methods (Table 1). The reactions observed with didurylcarbene

Table 1. Conditions and product distribution for the decomposition of diazo compounds **1** [a].

Diazo cmpd	Conditions	Yield [%] [b] 3	4
1a	C_6H_6/140 °C	14	63
1b	C_6H_6/140 °C	0	96
1c	C_6H_6/140 °C	0	90
1a	$h\nu/C_6H_6$/10 °C	61	0
1b	$h\nu/C_6H_6$/10 °C	29	41
1c	$h\nu/C_6H_6$/10 °C	5	79

[a] Irradiations were carried out on a 20 mM solution of **1** in degassed benzene with a 300 W Hg lamp and a Pyrex filter. Thermolyses were performed in degassed benzene and in a sealed Pyrex tube. [b] Determined by gas chromatography and NMR spectroscopy.

(**2b**) and decamethyldiphenylcarbene (**2c**) were analogous to those observed with dimesitylcarbene (**2a**). These carbenes did not react with the diazomethane precursors to give ketazines. Instead they reacted either by dimerization to form tetraarylethylene **3** or by attack at an *ortho* methyl group to give 1,2-dihydrocyclobutabenzene ("benzocyclobutene") **4**. A key difference is found, however, in the formation of **4**. In the case of **2a**, **4a** was produced only by thermolysis at 140 °C, and **2a** underwent mainly dimerization when photolyzed at room temperature. On the other hand, in the case of **2b**, benzocyclobutene **4b** was produced not only by thermolysis but also by photolysis along with the dimer. Compound **2c** produced **4c** as major product at the expense of **3a** even in the photolytic run.

Irradiation ($\lambda > 300$ nm) of **1a** in a 2-methyltetrahydrofuran (MTHF) glass at 4 K gave a paramagnetic species readily characterized from its EPR spectrum as triplet didurylcarbene **2a**. The EPR signals from **2** were stable for at least several hours at this temperature and survived even at 110 K. These observations established the triplet as the ground state of this carbene.[9]

Optical spectroscopy in the frozen medium gave analogous but more intriguing results. Figure 1b shows the absorption spectrum obtained after irradiation of **1b** in a MTHF glass at 77 K. The spectrum displays two distinct features: two sharp, intense UV bands with maxima at 321 and 335 nm, and in the

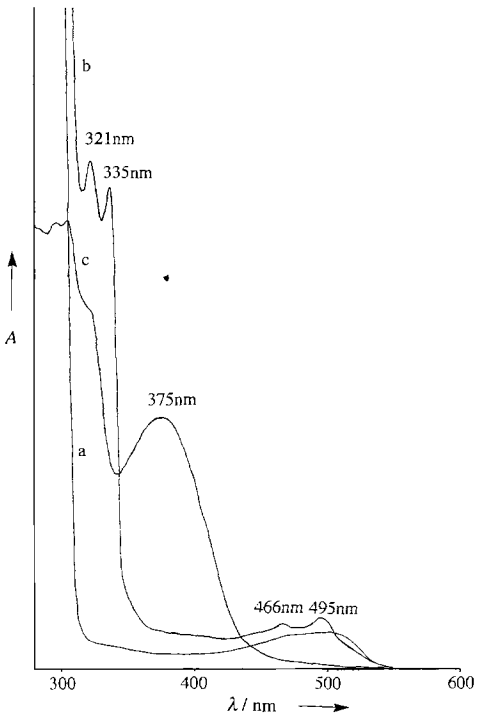
[**] This work was supported by the Japanese Ministry of Education, Science, and Culture.

visible portion of the spectrum two weak, broad, overlapping bands with apparent maxima at 466 and 495 nm. The glassy solution did not exhibit any changes in its absorption spectrum for several hours when kept at 77 K. However, when it was allowed to warm to room temperature and then cooled to 77 K, the characteristic absorption bands disappeared (vide infra). The absorption spectra of several aryl carbenes in frozen media have been reported.[10] Typically, they display an intense UV band and a weak visible transition. These features are present in the spectrum obtained in the photolysis of **1b**. Moreover, the product analysis of the reaction solution showed the presence of dimer **3b** as well as benzocyclobutene **4b**. Thus, the absorption spectrum can be attributed to didurylcarbene (**2b**) generated by the photodissociation of **1b**.



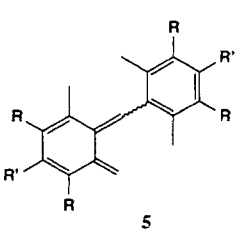


Fig. 1. a) UV/VIS spectrum of **1a** in MTHF at 77 K. b) Same sample after 6 min irradiation ($\lambda > 300$ nm). c) Same sample after the matrix was warmed to 110 K.

The spectral changes of the matrix were carefully monitored as a function of temperature as the matrix thawed. At higher temperatures a new broad absorption at 375 nm appeared and increased as carbene absorption bands decreased (Fig. 1c). The species responsible for this new absorption showed appreciable thermal stability; even at room temperature it persisted a few seconds before decaying. These observations suggest that the absorption at 375 nm must be due to an intermediate formed from the initially generated triplet carbene that leads to the final products.

A plausible candidate for the intermediate, which also explains the formation of benzocyclobutene, is *o*-xylylene **5b**, formed by intramolecular 1,4 H shift from an *ortho*-methyl group to the carbenic center of **2b**. Coincidently, the formation of *o*-xylylene from *o*-tolylmethylene and its subsequent cyclization was demonstrated by matrix isolation spectroscopy in inert gas matrices at low temperature both upon photolysis and upon thawing the matrix.[11] Moreover, several *o*-xylylenes have been reported to exhibit a broad absorption band centered at around 350 to 460 nm depending on the substituents.[12]

5

Flash photolysis of **1b** (1.0×10^{-4} M) in a degassed benzene solution at room temperature with a xenon flash lamp (pulse width of 10 μs) produced a transient species absorbing at 310–350 nm; the apparent maximum at around 335 nm was coincident with the xenon pulse (Fig. 2). The decay kinetics of the

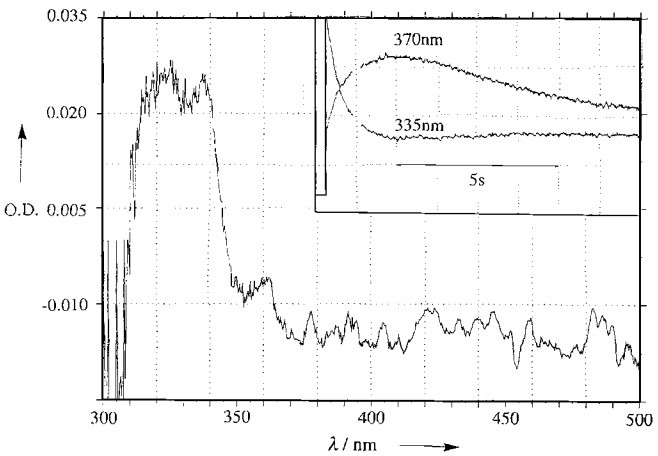

Fig. 2. Absorption spectra of the intermediates formed by irradiation of **1b** in degassed benzene, recorded 50 μs after the photolysis pulse. The inset in the upper right shows the time course of the absorptions at 335 and 370 nm (oscillogram traces). O.D. = optical density.

transients indicates that the absorption at 335 nm decays within 1 s and a new species with an absorption maximum at around 370 nm arises, which is too long-lived to be monitored by our system. Product analysis of the spent solution showed the presence of **3b** and **4b**. Thus, on the basis of the low-temperature spectrum coupled with chemical analysis, we assign the initially formed transient with a maximum at 335 nm to carbene **2b** and the second to *o*-quinodimethane **5b**. This interpretation is supported by the trapping experiments using oxygen. In the flash photolysis of an oxygen-saturated benzene solution of **1b** a broad absorption band with a maximum at 390 nm appeared at the expense of the absorption due to the carbene. The reaction mixture was found to contain octamethylbenzophenone as the main product. It is well documented that diarylcarbenes with triplet ground states are readily trapped by oxygen to generate the corresponding diarylketone oxides.[13] Thus, our observation can be interpreted as indicating that the triplet carbene **2b** is trapped by oxygen to form the carbonyl oxide, which confirms that the transient absorption quenched by oxygen is due to **2b**. The rate constant for the quenching of **2b** by oxygen was determined to be $7.1 \times 10^7\ M^{-1} s^{-1}$. The inset in Figure 2 shows the decay of **2b** and the formation of **5b** over time and indicates that the decay of **2b** is kinetically correlated with the growth of **5b**. The decay rate constant was determined to be $2.1 \pm 0.1\ s^{-1}$, while the growth rate constant was $1.8 \pm 0.2\ s^{-1}$. Since the product analysis shows that carbene **2b** decays not only by intramolecular H abstraction but also by dimerization, the difference in the rate constants can be ascribed to the dimerization rate constant (k_d) under the assumption that the rate constant for the formation of **5b** is identical with that for H abstraction (k_i). Since the difference in the rate constants, $0.3\ s^{-1}$, is equal to $k_d[\mathbf{2b}]$, k_d is determined to be $6.4 \pm 0.7 \pm 10^4\ M^{-1} s^{-1}$ by

using [**2b**] obtained from the extinction coefficient of **2b** and absorbance after the pulse. A half-life ($t_{1/2}$) of roughly 310 ms was determined for **2b** from the decay curve, while the lifetime based on k_i was estimated to be 555 ± 62 ms. Similar measurements for the carbenes **2a** and **2c** gave values of k_d, k_i, and $t_{1/2}$ (τ) for **2a** of $7.3 \pm 1.5 \times 10^5\ M^{-1} s^{-1}$, $3.1 \pm 0.4\ s^{-1}$, and 210 (323 ± 42) ms, respectively, while **2c** decayed unimolecularly with $k_i = 6.9 \pm 0.5\ s^{-1}$ ($\tau = 145 \pm 10$ ms).

These results indicate that when four methyl groups are introduced at the *meta* positions of the *ortho*-methylated diphenylcarbene, the carbenic center is more effectively blocked by the four *ortho* methyl groups presumably owing to the buttressing effect exerted by the *meta* substituents. Didurylcarbene is found to be some five orders of magnitude longer lived than the parent diphenylcarbene (2 μs in cyclohexane).[14] However, when two more methyl groups are introduced at the *para* positions, the carbenic center is forced to react with the *ortho* methyl groups, which are brought much closer to the carbene, and the carbene is shorter lived.

Support is lent to this explanation by semiempirical calculations. Optimized geometries calculated for a series of polymethylated phenylcarbenes with the programm PM3-ROHF/CI (4×4)[15] indicate that the distances between carbenic carbon and *o*-methyl carbon atom for mesityl-, duryl-, and pentamethylphenylcarbenes are 2.8461, 2.7942, and 2.7778 pm, respectively.

The present study reveals that polymethylated diphenylcarbenes are exceptionally long-lived for diarylcarbenes, although they are not persistent enough to be isolable. The buttressing effects effectively strengthen the *ortho* effect that protects the reactive center. This strategy may prove successful in the preparation of a "bottleable" triplet carbene.

Ether-Solvated Sodium Ions in Salts Containing π-Hydrocarbon Anions: Crystallization, Structures, and Semiempirical Solvation Energies**

Hans Bock,* Christian Näther, Zdenek Havlas, Andreas John, and Claudia Arad

Dedicated to Professor Heinz Nöth on the occasion of his 65th birthday

In numerous reactions in solution, the solvation of cations[1] can exert influence on the multidimensional network of interrelated equilibria of electron transfer, ion pair formation, or aggregation[1e] and, therefore, control processes from a geochemical[1f] to a biochemical[1g] nature. The selection of the $Na^{\oplus}$ ion is advantageous for the investigation of the complex interdependencies, because, due to its small ionic radius and high solvation enthalpy[2] together with the relatively low reduction potential of sodium metal,[2] this cation forms countless salts[3a] and compounds[1e, 3b] of impressive structural diversity. Using $Na^{\oplus}$ as example, we report on a method to specifically prepare optimally ether-solvated metal cations by one-electron reduction of unsaturated hydrocarbons with alkali metals in ether solution and to crystallize the solvent-separated π-hydrocarbanion salts (Scheme 1).

Under aprotic reduction conditions the π-hydrocarbons (Scheme 1) selectively form their radical anions, which, due to the extensive delocalization of the negative charge in their rather large π-systems, no longer possess negatively charged centers[1e, g] suited to form contact ion pairs **A**, and therefore crystallize as solvent-separated ion pairs **B**[4]. One of the many possible variations is demonstrated by fluorene (Scheme 1), the sodium reduction of which leads to H_2 formation.[4]

$[Met^{\oplus}\{RO(CH_2CH_2O)_{x-1}\}_y C_n H_m^{\bullet\ominus}]$ **A**

$[Met^{\oplus}\{RO(CH_2CH_2O)_{x-1}\}_y][C_n H_m^{\bullet\ominus}]$ **B**

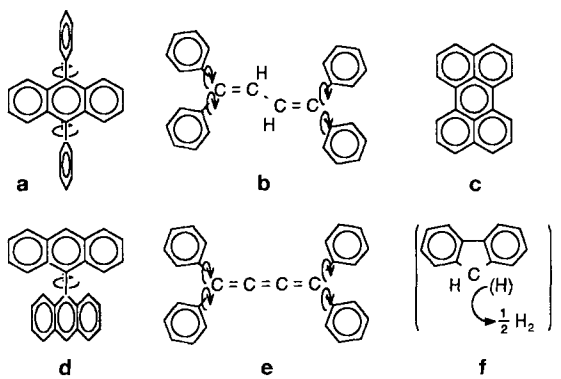
[**] Structures of Charge-Perturbed and Sterically Overcrowded Molecules as well as Interactions in Crystals, Part 31. The investigations have been supported by the A. Messer Foundation, the Bundesland Hessen, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. – Part 30: H. Bock, I. Göbel, C. Näther, Z. Havlas, A. Gavezzotti, G. Filippini, *Angew. Chem.* **1993**, *105*, 1823; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1755.



Redox half-reaction I:

$$[Met]_{\infty} + y\ solvent \rightleftharpoons [Met^{\oplus}(solvent)_y] + e^{\ominus}$$

Redox half-reaction II:

$$C_nH_m + e^{\ominus} \rightleftharpoons [C_nH_m^{\bullet\ominus}]$$

$[C_nH_m^{\bullet\ominus}]$:

Scheme 1. Preparation of solvent-separated radical anion salts $[Met^{\oplus}(solvent)_y][C_nH_m^{\bullet\ominus}]$ with optimally solvated metal cations $Met^{\oplus}$ by one-electron transfer from alkali metals $[Met]_x$ to unsaturated hydrocarbons C_nH_m containing extended π-systems, partly sterically shielded because of twisting effects, for example, in ether as solvent. (For $Met^{\oplus} = Na^{\oplus}$, see Fig. 1 and text). **a**: 9,10-diphenylanthracene$^{\bullet\ominus}$, **b**: 1,1,4,4-tetraphenyl-1,3-butadiene$^{\bullet\ominus}$, **c**: perylene$^{\bullet\ominus}$, **d**: bianthryl$^{\bullet\ominus}$, **e**: 1,1,4,4-tetraphenylbutatriene$^{\bullet\ominus}$, (**f**: fluorenyl$^{\bullet\ominus}$).

In the solvates **1**–**5** with various ethers (Fig. 1), the coordination number n of the $Na^{\oplus}$ center increases from the frequently observed[3] 6 in **1**, **2**, and **3** to 7 in the cryptand-221-solvate **4** and to 8 in the bis(triglyme) solvate **5**. Despite largely comparable dihedral angles ω(OC-CO) = 59 ± 2° in polyethers,[5] the average contact distances $Na^{\oplus} \cdots O$ increase with the coordination number from 239 ± 4 pm for $n = 6$ to 248 ± 9 pm for $n = 7$ and to 262 ± 13 pm for $n = 8$. An almost octahedral arrangement is observed only in the solvent complex $[Na^{\oplus}(thf)_6]$ (**1**, Fig. 1), which exhibits angles $ONa^{\oplus}O$ of 90 ± 3°. All the other coordination polyhedra $Na^{\oplus}O_n$ are distorted: The angles $ONa^{\oplus}O$ vary in $[Na^{\oplus}(dme)_3]$ (**2**) between 69 and 104°, in $[Na^{\oplus}(diglyme)_2]$ (**3**) between 80° and 138°, in $[Na^{\oplus}$(cryptand-221)] (**4**) between 68° and 124°, and in the eight-coordinate $[Na^{\oplus}(triglyme)_2]$ (**5**) between 61 and 93° (Fig. 1).

The different solvent shells around the $Na^{\oplus}$ ions (Fig. 1) can be discussed with regard to MNDO enthalpies of formation (Table 1), which have been approximated from the structural coordinates[6] (Scheme 2).

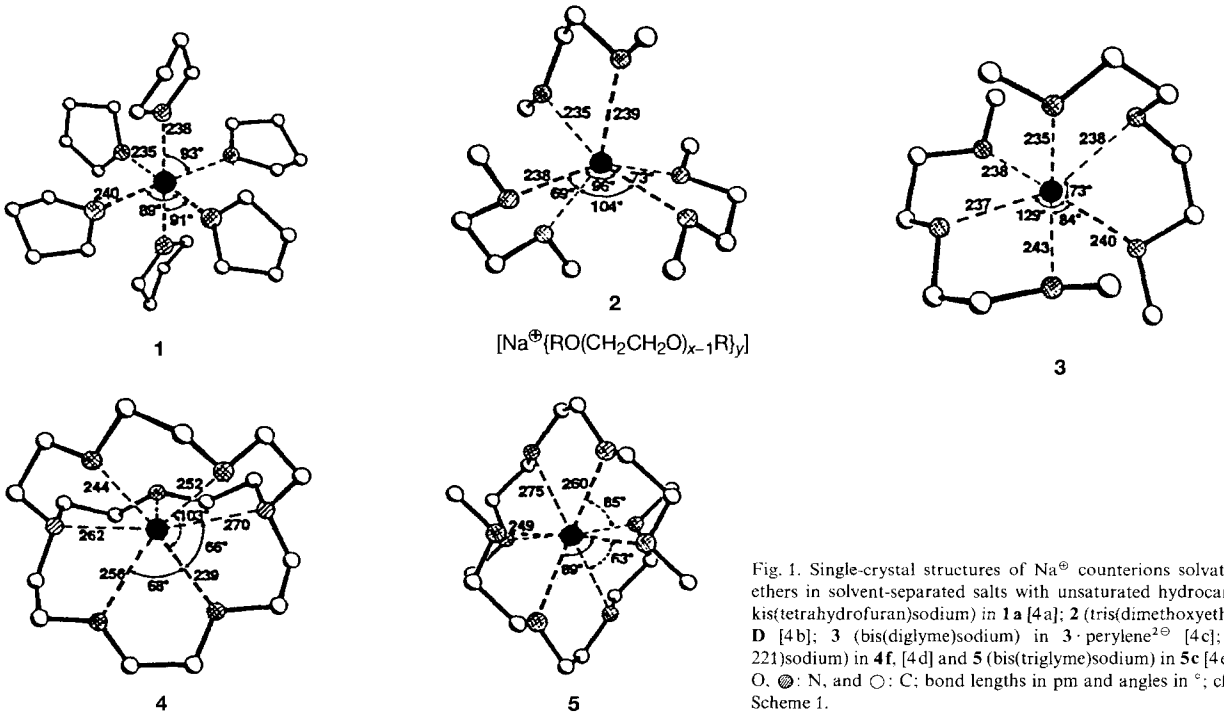
Table 1. Characteristic MNDO differences in heats of formation, $\Delta\Delta H_f^{MNDO}$, [6c] and average bond energies BE^{MNDO} [$Na^{\oplus} \cdots O(N)$] (each in kJ mol^{-1}) for the solvated complexes $[Na^{\oplus}\{RO(CH_2CH_2O)_{x-1}R\}_y]$ (cf. Scheme 2).

Cation	$n_{Coord.}$	Ether	(Solvent shell)	$\Delta\Delta H_f^{MNDO}$ (Solvent repulsion)	(Free ether)	BE^{MNDO} [$Na^{\oplus} \cdots O$]
1	6	6 THF	−830	+243	−587	−98
2	6	3 DME	−771	+100	−671	−112
3	6	2 Diglyme	−743	+66	−677	−113
4	7	1 Cryptand-221			−804	(−115)
5	8	2 Triglyme	−859	+151	−708	−89

The MNDO heats of formation[6] (Scheme 2 and Table 1) for the solvent complexes $[Na^{\oplus}\{RO(CH_2CH_2O)_{x-1}R\}_y]$ provide, in particular, the following information:

1) The best complexing agent for $Na^{\oplus}$ is the cryptand-221 (Table 1; $\Delta\Delta H_f^{MNDO}$ (free ethers) = − 804 kJ mol^{-1}), as expected.

2) If the coordination number of the cation is kept constant, the repulsive interactions within the solvent shell are clearly



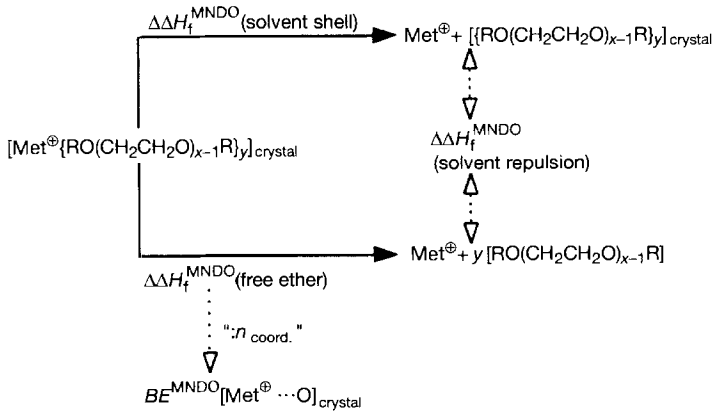


Fig. 1. Single-crystal structures of $Na^{\oplus}$ counterions solvated by different ethers in solvent-separated salts with unsaturated hydrocarbons: **1** (hexakis(tetrahydrofuran)sodium) *in* **1a** [4a]; **2** (tris(dimethoxyethane)sodium) *in* **D** [4b]; **3** (bis(diglyme)sodium) in **3**·perylene$^{2\ominus}$ [4c]; **4** ((cryptand-221)sodium) in **4f**, [4d] and **5** (bis(triglyme)sodium) in **5c** [4e]. ●: $Na^{\oplus}$, ◍: O, ◎: N, and ○: C; bond lengths in pm and angles in °; cf. text. **a**–**f**: See Scheme 1.

Scheme 2. Approximate calculation of MNDO heats of formation from the crystal structure data (Fig. 1): Removal of the cation $Met^{\oplus}$ from the solvated complex $[Met^{\oplus}\{RO(CH_2CH_2O)_{x-1}R\}_y]$ yields the heats of formation difference $\Delta\Delta H_f^{MNDO}$ (solvent shell) if the solvent shell does not change, and analogously if the shell breaks up into individual ether molecules, $\Delta\Delta H_f^{MNDO}$ (free ethers); the difference between them can be defined as $\Delta\Delta H_f^{MNDO}$ (solvent repulsion). An average bond energy BE^{MNDO} $[Met^{\oplus} \cdots O]$ in the solvated complexes can be estimated from the value $\Delta\Delta H_f^{MNDO}$ (free ether) on dividing it by the coordination number $n_{coord.}$.

noticeable: Thus $Na^{\oplus}$ is encapsulated by three molecules of dimethoxyethane energetically more favorably than by six molecules of tetrahydrofuran (Fig. 1, **1** and **2**, as well as Table 1, $\Delta\Delta H_f^{MNDO}$ (solvent repulsion) = +100 and +243 kJ mol^{-1}). This further substantiates the laboratory experience that DME is better suited than THF to crystallize thermally stable $Na^{\oplus}$ salts of organometallic anions.

3) For comparable solvation, the size of the cation plays an important role. For instance, for the solvent complex $[Li^{\oplus}(dme)_3]$[7] the MNDO bond energy ($Li^{\oplus} \cdots O$) is estimated to be only −42 kJ mol^{-1} (cf. Table 1, $[Na^{\oplus}(dme)_3]$ with BE^{MNDO} ($Na^{\oplus} \cdots O$) = −112 kJ mol^{-1}), and the repulsion between the surrounding dimethoxyethane molecules, which is enhanced by the decrease of the cation radius from 97 to 68 pm,[2] increases by about 90 kJ mol^{-1}.[8]

The last remark also reveals that the method for preparation and crystal growth of salts with optimally solvated cations (Scheme 1) exemplified here for $Na^{\oplus}$ can be applied to other metals that can reduce unsaturated hydrocarbons. The same holds for other solvents such as ethylenediamine derivatives $R_2N(CH_2CH_2NR)_xR$.[9]

For the fascinating phenomenon of cation solvation, (macroscopic) thermodynamic data dominate the literature to date. For a 'microscopic' structural picture, serendipitous discoveries such as the simultaneous 1:1 crystallization of tetraphenylbutadiene disodium from dimethoxyethane both as a solvent-sharing contact ion aggregate **C** as well as a solvent-separated ion triple **D**[1k] can add novel and essential facets: The equilibria

$[\{Na^{\oplus}(dme)_2\}_2C_{28}H_{22}^{2\ominus}]$ **C**

$[\{Na^{\oplus}(dme)_3\}_2][C_{28}H_{22}^{2\ominus}]$ **D**

between the multiple solvation of metal cations and the competing formation of contact ion triples with a shared solvent shell is further affected by an energetically favorable lattice packing.[10]

Experimental Procedure

For the preparation of solvent-separated ion pairs freshly cut sodium (0.5 to 1 mmol, about 12 mg) degreased with *n*-hexane was placed in a Schlenk trap under argon, and a sodium metal mirror was generated at 10^{-4} mbar by heating with a hot air blower. Thereafter, an equimolar amount of the hydrocarbon was weighed into the trap under Ar, and the appropriate solvent, carefully dried ($c_{H^{\oplus}} < 1$ ppm) and repeatedly degassed at 10^{-4} mbar was added dropwise. The quantity is selected so that the hydrocarbon concentration essential for the crystal growth amounts to approximately 1 to 2×10^{-2} mol L^{-1}. Under the above conditions crystals of $[Na^{\oplus}(thf)_6]$[9,10-diphenylanthracene$^{\cdot\ominus}$] and of $[Na^{\oplus}(dme)_3][9,9'$-bianthryl$^{\cdot\ominus}]$ with dimensions between 0.3 and 0.5 mm and a reflection profile suited for structure determination grow within 2 to 20 days. Advisable for reactions with perylene is a sixfold metal surplus and for those requiring lithium metal for reaction activation an initial ultrasonic treatment (50 W) of 2 to 5 minutes. For the crystal growth of the sodium salts, the solutions have to be covered by a 5 to 10 mL layer of carefully purified *n*-hexane.

[2] According to transference measurements, $Li^{\oplus}$ and $Na^{\oplus}$ move in aqueous solution as the ions $[Li^{\oplus}(H_2O)_{25}]$ and $[Na^{\oplus}(H_2O)_{17}]$ surrounded by presumably up to three solvent shells; their ionic radii increase from 68 and 97 pm for the "naked" ions to 340 and 276 pm [1 f]. The different enthalpies of hydration of −500 kJ mol^{-1} for $Li^{\oplus}$ and of −390 kJ mol^{-1} for $Na^{\oplus}$ contribute to the reason why the metal reduction potentials in water [$E(Li/Li^{\oplus}_{aq}) = -3.05$ V and $E(Na/Na^{\oplus}_{aq}) = -2.71$ V [1 f]] have a reversed sequence to the atomic ionization potentials $IE_I^V(Li) = 5.39$ eV and $IE_I^V(Na) = 5.14$ eV.

Preparation of Chiral Nitroxide Radicals and Spontaneous Optical Resolution by Recrystallization**

Rui Tamura,* Shinsuke Susuki, Nagao Azuma, Akira Matsumoto, Fumio Toda, Akio Kamimura, and Kenzi Hori

Nitroxides protected by bulky substituents continue to play an important role not only as stable free radicals for spin-labeling experiments[1] and trapping reactions[2] but also as spin sources for the elaboration of organic magnetic materials[3] and more recently as organic oxidants.[4] The vast majority of nitroxides have been synthesized by oxidation of secondary amines or hydroxylamines.[5] We describe here the preparation, properties, and crystal structure of nitroxide radicals that are obtained as conglomerates (racemic mixtures); the synthesis is based upon the mechanistic studies of a newly found $S_{RN}1$ reaction.[6] Furthermore, we discuss the formation of the radical conglomerates in terms of the unique molecular and crystal structure. To the best of our knowledge no report has appeared to date on the preparation of stable free radical as conglomerates and their spontaneous optical resolution, although two types of optically active nitroxide radicals were obtained from an optically active compound[7] and from diastereomeric derivatives after optical resolution.[8]

When nitroenones **1** ($E^{red}_{1/2} = -1.68$ V)[6] and **2** were treated with 3.0 equiv of SmI_2 ($E^{ox}_{1/2} = -1.55$ V)[9] in THF/Et_2O (3/1, v/v) at $-50\,^{\circ}C$, the fairly stable radical anion **3**[10] was produced (Scheme 1). Subsequent addition of powdered 3,5-dinitrobenzoyl chloride (**4**) all at once at $-50\,^{\circ}C$[11] and warming to $25\,^{\circ}C$ resulted in the O-acylation of the enolate moiety of **3**. Analytically pure cyclic nitroxides **5** and **6** were obtained in 75 and 70% yield, respectively (Table 1), after purification by flash column chromatography on silica gel (hexane/EtOAc, 19/1) and recrystallization from Et_2O. An X-ray analysis of a single

crystal of **5** established the nitroxide structure unequivocally (Fig. 1),[12] which is in accord with the consumption of 3.0 equiv of SmI_2. Both the X-ray structure[13] and the ab initio molecular orbital calculations[14] of **1** show short intramolecular contacts (3.20–3.26 Å) between one of the nitro oxygen atoms and ethylenic carbon atoms of the enone moiety. This conformation and the reducing power of SmI_2 toward **1** and **2**[15] should be responsible for the efficient formation of the cyclic nitroxides, although the detailed mechanism is not yet fully understood.

Spontaneous optical resolution occurred during recrystallization of **5** and **6**[12]. The properties of **5** and **6** are summarized in Table 1. The single crystal of **5** that was examined consisted of a single enantiomer, as was evident from its point and space group ($P3_1$ or $P3_2$, $Z = 3$) and was indeed optically active. The melting points of the pure enantiomers of **5** and **6** were higher than those of the respective mixtures. Moreover, the pattern of the X-ray powder diffraction spectra of mixtures of the enantiomeric crystals of **5** and **6** obtained by recrystallization was identical with those of the respective unrecrystallized materials.

[**] This work was supported by the Japanese Ministry of Education, Science and Culture (Grand-in-Aids for Scientific Research on Priority Area "Molecular Magnetism", No. 228/05234220), the Yamada Science Foundation (R. T.), and the Computer Center at the Institute for Molecular Science, Okazaki National Research Institute (Japan) (use of the HITAC M-600 and S-820/80 computers). We also thank Prof. K. Mukai, Ehime University, and Prof. T. Takui, Osaka City University, for helpful discussions.

Consequently, we conclude that nitroxides **5** and **6** form conglomerates consisting of a mixture of two enantiomeric crystals.

In the chiral molecule **5** (Fig. 1) the mean plane of the fused rings forms an angle of 76° with the 3,5-dinitrobenzoyl group so as to avoid steric repulsion; the dihedral angle between the mean plane of the nitroxide portion (C-NO-C) and the 3,5-dinitrobenzoyl group is 51°. More interesting is the crystal structure of **5** with two threefold screw axes along the *c* axis in the trigonal unit cell (Fig. 2). The molecules are arranged around one axis be-

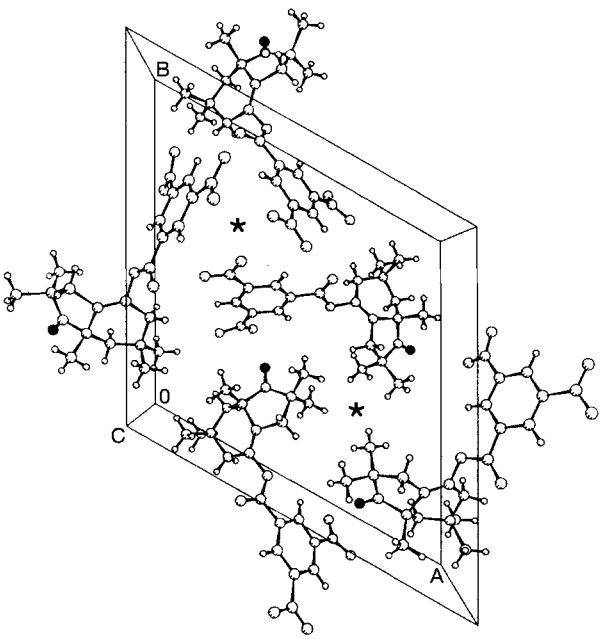

Fig. 2. Crystal structure of **5**. ⋆: Points corresponding to the threefold screw axes; •: O atoms of the NO groups.

cause of the electrostatic intermolecular interaction between the nitroxide oxygen atom and the nitrogen atom of one of two nitro groups on the benzene ring (2.87 Å), whereby a head-to-tail arrangement results. The other axis is surrounded by the other nitro group owing to another electrostatic intermolecular interaction between the nitro groups (3.02 Å), giving a tail-to-tail arrangement. Thus, the unique molecular asymmetry and arrangement seems to be responsible for the helical crystal structure and hence leads to the formation of conglomerates of the stable free radical.

Solutions of **5** and **6** in THF display an intense 1:1:1 triplet in their ESR spectra at 25 °C (Table 1), and the powdered materials exhibit exchange-narrowed spectra (**5**: $\Delta H \approx 12$ G, $g = 2.007$; **6**: $\Delta H \approx 16$ G, $g = 2.007$) at 25 °C. The radical purity of **5** and **6** was determined to be approximately 100% by magnetic susceptibility measurements by means of a Faraday balance (55 K $\leq T \leq$ 250 K); in other words, the temperature dependence of the static magnetic susceptibility of **5** and **6** follow the Curie–Weiss law; the Curie constants are approximately 0.38 ± 0.01 K emu mol^{-1} (theoretical value, 0.377).

The methods described here have provided conglomerates of stable radicals with a unique crystal structure that leads to spontaneous optical resolution. The scope, limitations, and the reaction mechanism of this synthetic method along with the precise magnetic properties of the newly prepared nitroxides are under investigation.

Cyclotrimerization of Ethyne on the Complex Fragment [(η^1-*t*Bu$_2$PCH$_2$P*t*Bu$_2$)Ni^0] with Formation of an η^6-Benzene–Nickel(0) Complex**

Thomas Nickel, Richard Goddard, Carl Krüger, and Klaus-Richard Pörschke*

For a number of years we have directed our efforts to modifying the properties of nickel(0) centers with mono- and bidentate ligands, for example, with the phosphanes PR_3 (R = Me, Et, Ph, *i*Pr),[1] $Me_2PCH_2PMe_2$,[2] and *t*Bu$_2$PC$_2$H$_4$P*t*Bu$_2$.[3] Ethene and ethyne are especially interesting coligands. For the ligand combination *t*Bu$_2$PCH$_2$P*t*Bu$_2$ (dtbpm)[4] and stilbene or diphenylacetylene, activated by electron-withdrawing substituents, Hofmann et al. first obtained nickel(0) complexes with dtbpm as a chelating ligand.[5] We report here on novel nickel(0) complexes in which only *one* phosphorus atom of the bidentate dtbpm ligand is coordinated to the nickel(0) center.

When a solution of equimolar amounts of $[Ni(C_2H_4)_3]$[6] and $tBu_2PCH_2PtBu_2$ in ether is cooled from $-10\,^{\circ}C$ to temperatures between -30 and $-78\,^{\circ}C$, large yellow cubes of **1** form in 65% yield [Eq.(a)]. When heated rapidly, **1** decomposes at $70\,^{\circ}C$; the compound can be stored for longer periods only below $0\,^{\circ}C$. Complex **1** is stabilized in solution by addition of ethene.

$$[Ni(C_2H_4)_3] + tBu_2PCH_2PtBu_2 \longrightarrow [(\eta^1\text{-}tBu_2PCH_2PtBu_2)Ni(C_2H_4)_2] + C_2H_4 \quad (a)$$

In the 300 MHz ^1H NMR spectrum ([D$_8$]THF) of **1** at $-80\,^{\circ}C$ two signals are observed at $\delta = 2.60$ and 2.51, which are assigned to the "inner" and "outer" protons, respectively, of two equivalent ethene ligands in a trigonal-planar L-Ni$(C_2H_4)_2$ complex.[7] The phosphane ligand gives rise to two equally intense methyl signals; the broad signal ($\delta = 1.35$) is attributed to a coordinated $PtBu_2$ group, the sharp one ($\delta = 1.18$) to a noncoordinated $PtBu_2$ group. Corresponding signals are found in the ^{13}C NMR spectrum (75.5 MHz, $-80\,^{\circ}C$). In the ^{31}P NMR spectrum ($-80\,^{\circ}C$) the coordinated and the noncoordinated phosphorus atoms of the dtbpm ligand give rise to an AX system [$\delta = 63.5, 23.8$; $^2J(PP) = 17$ Hz]. In the ^1H and ^{13}C NMR spectra at $-30\,^{\circ}C$ the ethene signals are coalesced, and both $PtBu_2$ signals are sharp. Apparently, for solutions of **1** the rotation of the ethene ligands about the bond axis to the nickel atom is restricted at low temperatures, and in addition the mobility of the *tert*-butyl groups of the coordinated phosphorus atom is reduced; when the temperature is increased the ethene ligands and the *tert*-butyl groups undergo facile rotation. A (fast) exchange of the phosphorus atoms is not observed at $-30\,^{\circ}C$.

The results of the crystal structure analysis of **1**[8a] are summarized in Figure 1. The Ni atom is coordinated in a trigonal-planar fashion by two ethene molecules and one P atom of the diphosphane ligand [Ni–P1 2.238(1) Å]. The second P atom of the phosphane ligand is far enough from the Ni center [Ni···P2 4.696(1) Å] that both intramolecular and intermolecular Ni···P2 interactions in the crystal lattice can be discounted. The fact that the dtbpm ligand in **1** does not act as a chelating ligand with formation of a NiPCP ring, even though the Ni center is unsaturated (16e), is explained by the high conformational strain connected with this coordination mode.[9]

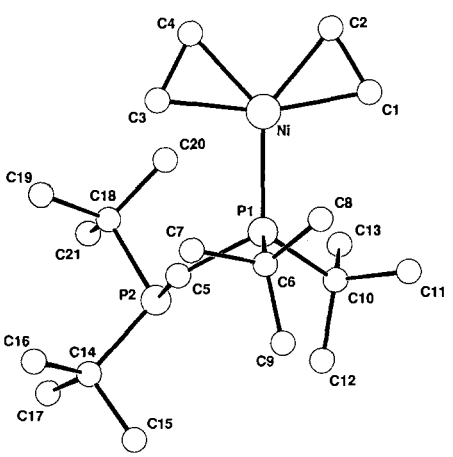

Fig. 1. Crystal structure of **1**. Selected bond lengths [Å], angles [°], and torsion angles [°] (Ca,b: midpoint between atoms Ca and Cb): Ni-P1 2.238(1), Ni-C1 2.013(2), Ni-C2 2.000(2), Ni-C3 2.016(2), Ni-C4 1.999(2), P1-C5 1.872(2), P2-C5 1.877(2), Ni-C1,2 1.883(4), Ni-C3,4 1.886(4), C1,2···C3,4 3.319(6), Ni···P2 4.696(1), Ni-P1-C5 116.5(1), P1-C5-P2 125.9(1), C5-P2-C14 98.2(1), C5-P2-C18 104.7(1), P1-Ni-C1,2 120.3(1), P1-Ni-C3,4 116.0(1), C1,2-Ni-C3,4 123.5(1), Ni-P1-C5-P2 89.7(2), C3,4-Ni-P1-C5 29.5(2).

When a yellow solution of **1** in pentane with an excess of ethyne is warmed from -78 to $-55\,^{\circ}C$, it becomes dark and a few flakes of red-colored polyacetylene precipitate. At $-78\,^{\circ}C$ and in the course of several days, orange rosette-shaped crystals of the benzene–nickel(0) complex **2** form in 50% yield.[10a] According to these results, the ethene ligands of **1**[10b] are displaced, and ethyne is cyclotrimerized on the 12e $[(\eta^1\text{-}tBu_2PCH_2PtBu_2)Ni]$ complex fragment to give a benzene ligand [Eq.(b)].[10c,d]

$$1 + 3\,HC{\equiv}CH \longrightarrow [(\eta^1\text{-}tBu_2PCH_2PtBu_2)Ni(\eta^6\text{-}C_6H_6)] + 2\,C_2H_4 \quad (b)$$

Crystalline **2** melts at $83\,^{\circ}C$ with decomposition. In the EI mass spectrum ($80\,^{\circ}C$) the molecular ion (440) undergoes cleavage of benzene to give the complex fragment $[(dtbpm)Ni]^+$ (362); benzene cation gives rise to the base peak. Complex **2** decomposes in solution (THF) above $-30\,^{\circ}C$, presumably by release of the benzene ligand.[11] In the 400 MHz ^1H and 75.5 MHz ^{13}C NMR spectra at $-80\,^{\circ}C$ very sharp singlets at $\delta(H) = 5.95$ and $\delta(C) = 92.0$ are observed for the benzene ligand; the chemical shifts and the coupling constant $J(CH) = 168$ Hz are comparable to those of $[(C_6H_6)Cr(CO)_3]$ [$\delta(H) = 5.67$; $\delta(C) = 95.5$; $J(CH) = 175$ Hz].[12] Thus for **2** in solution the benzene ligand is η^6-coordinated to the nickel atom. Since the ^1H and ^{13}C NMR signals of the *tert*-butyl groups occur in pairs, only *one* phosphorus atom of the bidentate dtbpm ligand in **2** is bound to the nickel(0) center [^{31}P NMR ($-80\,^{\circ}C$): $\delta = 53.4, 19.1$; $^2J(PP) = 37$ Hz]. Within the temperature range at which the complex is stable the phosphorus ligand was not observed to change hapticity (accompanied by plausible η^4-coordination of the benzene ligand), nor could an exchange of the benzene ligand with free benzene be proved by NMR spectroscopy.

The crystal structure of **2**[8b] is shown in Figure 2. The benzene ligand is planar [maximum deviation (C2): 0.005 Å] and symmetrically coordinated to the Ni atom [average Ni–C bond length: 2.138(6) Å]; the center D of the C_6 ring is 1.606(5) Å away from the Ni atom.[13] The C–C bonds within the six-membered ring [1.41(1) Å] are all the same length within the margin of error. In addition the P1 atom of the dtbpm ligand is coordi-

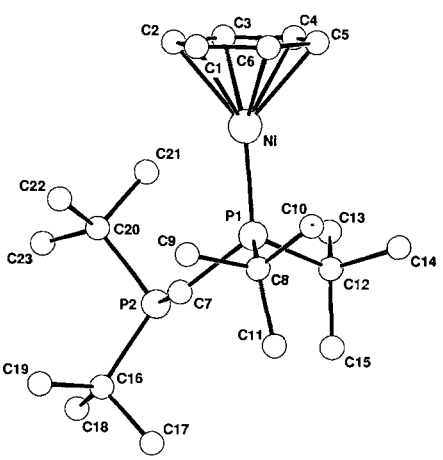

Fig. 2. Crystal structure of **2**. Selected bond lengths [Å], angles [°], and torsion angles [°] (D: center of the six-membered ring (C1–C6): Ni-P1 2.111(1), Ni-C1 2.140(4), Ni-C2 2.128(5), Ni-C3 2.136(5), Ni-C4 2.143(5), Ni-C5 2.142(5), Ni-C6 2.136(5), Ni-D 1.606(5), Ni···P2 4.507(1), P1-C7 1.867(4), P2-C7 1.867(4); D-Ni-P1 174.2(2), Ni-P1-C7 122.2(1), P1-C7-P2 123.6(2), Ni-P1-C7-P2 74.6(7).

nated to the Ni center. The Ni–P1 bond of 2.111(1) Å is relatively short, and the D-Ni-P1 angle is 174.2(2)°. The coordination geometry of the nickel atom can be considered pseudo-linear. The torsion angle Ni-P1-C7-P2 [74.6(7)°] is smaller than the related angle in **1** [89.7(2)°]; this can be explained by the reduced spatial requirement of the (η^6-C_6H_6)Ni unit in comparison to that of the $(C_2H_4)_2$Ni unit. The P-C-P angles in **1** [125.9(1)°] and **2** [123.6(2)°] are similar and markedly larger than the P-C-P angles in transition metal complexes with a tBu$_2$PCH$_2$PtBu$_2$ chelating ligand [95.5(2)–99.2(2)°].[5, 14] Force field calculations[15] on the uncomplexed tBu$_2$PCH$_2$PtBu$_2$ molecule indicate a P-C-P angle of 122.3° [P–C 1.89 Å, P···P 3.30 Å]. The calculated molecule has a twofold rotational axis that bisects the P-C-P angle. In the related diphosphane (c-C_6H_{11})$_2$PCH$_2$P(c-C_6H_{11})$_2$ this angle is determined to be 120.5(1)°[16] (calcd: 120.6°).[15]

Nickel(0) complexes with benzene or other arene ligands have been relatively uncommon. Jonas prepared the first complexes of the type [{R$_2$P(CH$_2$)$_n$PR$_2$}Ni(arene)] by reducing [{R$_2$P(CH$_2$)$_n$PR$_2$}NiCl] (R = c-C_6H_{11}; n = 2, 3) with lithium in the presence of benzene (or other arenes).[17] The bidentate phosphane ligand is presumably bound to the nickel(0) center in a chelating fashion and the arene ligand like an alkene (η^2 or η^4) (NMR data are not available). This coordination mode was proven for the analogous naphthalene[18] and anthracene complexes[19] by NMR spectra and crystal structures. In contrast, the benzene ligand in **2** serves as a six-electron ligand for the nickel atom, which attains an 18e configuration including the electron pair of the coordinating phosphorus atom. Complex **2** completes the series of complexes of the type [L$_n$M(η^6-C_6H_6)], n = 2–4, with the parent structure, n = 1. The reaction providing **2** [Eq.(b)] at temperatures below −50 °C (!) may serve as a model[10c] for a reaction step in Reppe's nickel(0)-catalyzed cyclotrimerization of ethyne to benzene.[20]

Experimental Procedure

1: A solution of [Ni(C_2H_4)$_3$][6] in ether (30 mL), prepared from [Ni(*trans*,*trans*,*trans*-1,5,9-cyclododecatriene)] (1.165 g, 5.0 mmol) and ethene, was combined with a solution of dtbpm (1.522 g, 5.0 mmol) in ether (20 mL) at −10 °C. The solution was filtered through a cooled D4 frit to remove insoluble impurities; large yellow cubes formed at −30 °C. The crystallization was completed at −78 °C; the mother liquor was removed from the crystals with a capillary, and the crystals were washed twice with cold pentane and dried at −30 °C under vacuum (oil pump). Yield 1.36 g (65%). – Correct elemental analyses; m.p. 70 °C (decomp); ^{1}H NMR (300 MHz, −80 °C): δ = 2.60, 2.51 (4H each, H_2C=CH_2'); 2.05 (2H, PCH_2P'), 1.35 (d, 18 H, PtBu$_2$ complexed), 1.18 (d, 18H, PtBu$_2$ free); (− 30 °C): 2.58 (8H, C_2H_4), 2.07 (2H, PCH_2P'), 1.37 (d, 18H, PtBu$_2$ complexed), 1.17 (d, 18H, PtBu$_2$ free); ^{13}C NMR (75.5 MHz, −80 °C): δ = 54.3, 50.5 (2C each, H_2C=CH_2); 38.1 (2C, sharp, PCMe_3), 34.0 (2C, br. P'CMe_3), 30.2 (12C, br, CH_3 and CH_3'), 18.0 (1C, ^1J(PC) = 50; 2 Hz, PCH_2P'); (− 30 °C): δ = 52.7 (4C, C_2H_4); 38.1, 34.0 (2C each, sharp, PCMe_3 and P'C'Me_3), 30.7, 30.5 (6C each, CH_3 and CH_3'), 18.2 (1C, PCH_2P'); ^{31}P NMR (121.5 MHz, −80 °C): δ = 63.5, 23.8 (^2J(PP) = 17 Hz).

2: A yellow solution of **1** (419 mg, 1.0 mmol) in pentane (25 mL), which was prepared at 0 °C, was exposed to ethyne (100 mL, 4 mmol) at −78 °C. The reaction mixture was stirred and warmed to −55 °C. Any **1** that had precipitated then redissolved. The solution became dark, and a red precipitate of polyacetylene formed. At −78 °C orange, rosette-shaped crystals form over the course of several days, which were washed twice with ether at −78 °C and dried under vacuum (oil pump) at −30 °C. Yield 220 mg (50%). – Correct elemental analyses, m.p. 83 °C; EI-MS (80 °C): m/z = 440 ([M]$^+$, 2), 362 ([(dtbpm)Ni]$^+$, 4), 78 ([C_6H_6]$^+$, 100); IR (KBr): 3060 (ν(=C-H)), 1748, 1585 cm^{-1} (ν(C=C); C_6H_6); ^{1}H NMR (400 MHz, −80 °C): δ = 5.95 (s, 6H, C_6H_6), 1.58 (2H, PCH_2P), 1.24, 1.18 (each 18H, C(CH_3)$_3$ and C(CH_3')$_3$); ^{13}C NMR (75.5 MHz, −80 °C): δ = 92.0 (6C, ^1J(CH) = 168 Hz, C_6H_6), 35.9 (2C, PCMe_3), 33.1 (2C, P'C'Me_3), 34.0, 32.2, 30.7 (2C each, C(CH_3)$_3$), 30.8 (6C, C(CH_3')$_3$), 15.6 (1C, PCH_2P); ^{31}P NMR (121.5 MHz, −80 °C): δ = 53.4, 19.1 (^2J(PP) = 37 Hz).

Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57884, the names of the authors, and the journal citation.
[9] The monoethene complex [(dtbpm)Ni(C_2H_4)] with dtbpm as a chelating ligand can be prepared from **1** by a laborious procedure. This complex converts back to **1** immediately upon treatment with ethene. This implies that bidentate coordination of dtbpm on the nickel(0) center with ethene as a coligand is possible but high in energy. In contrast, activated alkenes acting as strong acceptors stabilize the chelating coordination of dtbpm on nickel(0)[5], since they take up the excess charge pushed onto the nickel(0) center by the two phosphorus atoms.
[10] a) Uncomplexed benzene in the reaction mixture was evident in the ^{1}H and ^{13}C NMR spectra. b) The mixed ethene/ethyne complex [(η^1-tBu$_2$PCH$_2$PtBu$_2$)-Ni(CH$_2$=CH$_2$)(HC≡CH)] was isolated in crude form as an intermediate in the displacement reaction at −78 °C and characterized by ^{1}H and ^{31}P NMR spectroscopy. c) It was shown qualitatively (^{1}H, ^{31}P NMR) that the benzene complex **2** catalyzes the cyclotrimerization of ethyne at −50 °C to give benzene. d) For comparison [(tBu$_2$MeP)Ni(C_2H_4)$_2$] was prepared as a model compound for **1** and treated with ethyne under the same conditions. The formation of benzene was also observed, but a benzene complex analogous to **2** was not found. Benzene is also formed as a side product in the synthesis of the bis(ethyne) complexes [(R$_3$P)Ni(HC≡CH)$_2$] (R = Me, Et, etc.)[1b].
[11] Upon warming to −30 °C the red solutions of **2** turn yellow. According to the ^{31}P NMR spectrum a number of compounds are formed, which have not yet been identified.
[12] The ^{1}H and ^{13}C NMR signals of [(C_6H_6)Cr(CO)$_3$] are shifted upfield from those of uncomplexed benzene [δ(H) = 7.35; δ(C) = 129.0; J(CH) = 159 Hz]; this is explained by the increased charge density on the C atoms as a result of backbonding. This is apparently accompanied by an increase in the s character of the C–H bonds, which leads to a stronger coupling J(CH). R. Aydin, H. Günther, J. Runsink, H. Schmickler, H. Seel, *Org. Magn. Reson.* **1980**, *13*, 210.
[13] The corresponding distances in the Ni^{II} complexes [(C_6F_5)$_2$Ni(η^6-toluene)] [13a] and [(C_6F_5)$_2$Ni(η^6-mesitylene)][13b] are considerably longer (1.693 and 1.691 Å, respectively); moreover, the η^6-bound six-membered rings are not planar. a) L. The Absolute Configuration of (+)-α-1,2,3,4,5,6-Hexachlorocyclohexane, and Its Permeation through the Seal Blood–Brain Barrier**

Kattrin Möller, Cornelia Bretzke, Heinrich Hühnerfuss,* Roland Kallenborn, Jochen N. Kinkel, Jürgen Kopf, and Gerhard Rimkus

Because of its ubiquitous nature and its relative persistence, α-1,2,3,4,5,6-hexachlorocyclohexane (α-HCH) plays an important role in most studies of the "fate" of organic pollutants in marine and terrestrial ecosystems. In Western Europe its direct application mixed with the insecticide γ-hexachlorocyclohexane (γ-HCH, lindane) is no longer permitted, but in other parts of Europe, especially in eastern Europe, it may still be entering the environment by way of such formulations. In the marine environment γ-HCH is also transformed to α-HCH by marine microorganisms. The amounts involved are very low, but they may be significant over longer periods of time.[1]

In the last two years, α-HCH has received additional attention in process studies, because it is the only one of the eight possible HCH isomers which is chiral, and can therefore be studied by chiral gas chromatography. The cyclodextrin separation phases which have recently been developed[2] have made it possible to distinguish between enzymatic and nonenzymatic degradation processes.[3] This method has been used to study the pathways of microbial degradation of α-HCH in North Sea water, and its enzymatic degradation in marine and terrestrial organisms from various trophic levels.[3–5] In the liver of the common eider duck, for example, preferential degradation of (−)-α-HCH was demonstrated.[6]

During analysis of brain tissue from the harbor seal (*Phoca vitulina*) we encountered a surprising phenomenon. In brain samples from eight Icelandic seals we detected almost exclusively (+)-α-HCH (the values for the enantiomer ratio (+)-α-HCH/(−)-α-HCH were 55.6, 66.2, and six values of 100:0; Fig. 1). In contrast, blubber tissue from the same animals yielded enantiomer ratios of only 1.2 to 1.4. This finding is especially interesting because of the widespread hypothesis that the blood–brain barrier is also partially effective towards certain fat-soluble organic pollutants. The "blood–brain barrier" is normally understood as mechanisms which greatly inhibit the transport of *non*-lipid-soluble substances such as proteins from blood vessels into the surrounding interstitial nervous system tissue (glia) and the capillary endothelium. These mechanisms thus ensure a constant environment for the neurons.[7] The respiratory gases carbon dioxide and oxygen, however, can cross the capillary walls with ease. The exact mechanisms involved, especially for the selective inhibition of entry for certain lipid-soluble pollutants into the brain tissue, still require more detailed study. Whether the barrier effect is enhanced by enzymes in the endothelial cells (enzyme barrier) also still appears controversial.

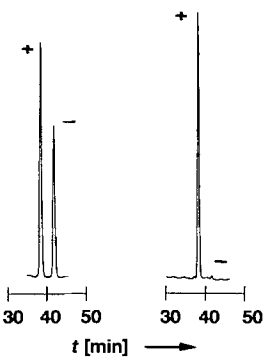

Fig. 1. Comparison of chromatograms for *n*-hexane extracts of blubber (left) and brain tissue (right) from the harbor seal (*Phoca vitulina*). For experimental conditions see Experimental Procedure.

Concentrations of polychlorinated biphenyls (PCBs) in brain tissue have been found to be a factor of ten lower than those found in other organs of the same animals.[8] This well-known effect is also often ascribed to the influence of the blood–brain barrier. Other authors, however, have shown that α-HCH is accumulated very efficiently in the brain tissue of mice and rats[9] and of fur seals.[10] The brain samples from rats[9a] and two of the fur seal samples[10] also revealed the first indications of preferential accumulation of (+)-α-HCH. The systematic investigation of eight Icelandic seals carried out in the present study shows that this phenomenon can obviously be generalized, at least for the less pollutant-exposed Icelandic animals. In addition, our studies show that as for the PCBs, γ-HCH is present at much lower concentrations in the brain samples than in other organs of the same animals. Such extreme concentration differences between γ-HCH and α-HCH, when comparing values from brain and other organs, have also been reported by Mössner et al. for fur seals.[10] However, these results are difficult to reconcile with our previous experience with enzymatic and nonenzymatic degradation processes for HCH isomers. We therefore interpret the enantioselective enrichment of (+)-α-HCH in seal brain tissue less as the result of enzymatic degrada-

[**] Chromatographic Separation of Enantiomers of Chiral Organic Pollutants, Part 7. This work was supported by the Ministry of Research and Technology. Part 6: [4].

tion processes, and rather as a "preferential permeability of the blood–brain barrier" for (+)-α-HCH. However, we can not of course exclude the possibility that enzyme processes acting in the same direction also enhance this effect.

Preliminary studies with brain tissue from the common eider duck and sheep also indicated preferential enrichment of (+)-α-HCH, and support the findings obtained in this study.[11] A similar protective mechanism is also presumed for humans, though a systematic study at this trophic level has yet to be carried out.

A more detailed discussion of this phenomenon has been impossible until now, because the absolute configurations of the α-HCH enantiomers were unknown. A first step in this direction required development of a method for separating sufficient quantities of the α-HCH enantiomers for crystallization. X-ray crystal structure analysis should then permit assignment of absolute configuration to the (+)-α-HCH enantiomer.

Attempts to separate the α-HCH enantiomer with an optically active base, (+)-brucine, using the method described by Cristol[12] proved to be very time-consuming. After several weeks and repeated workup of the reaction mixture, (−)-α-HCH was obtained in 96% purity. The (+)-α-HCH enantiomer was lost in this procedure. By modifying the reaction and using the (−)-enantiomer of an optically active base it may have been possible to synthesize the (+)-α-HCH enantiomer in an analogous manner.

The two α-HCH enantiomers were accessible by high performance liquid chromatography (HPLC) in a much more elegant manner, in a matter of hours. The enantiomer separation was carried out using a preparative column with the chiral stationary phase ChiraDex (Merck). An HPLC chromatogram of α-HCH obtained with an analytical version of this column is shown in Figure 2.

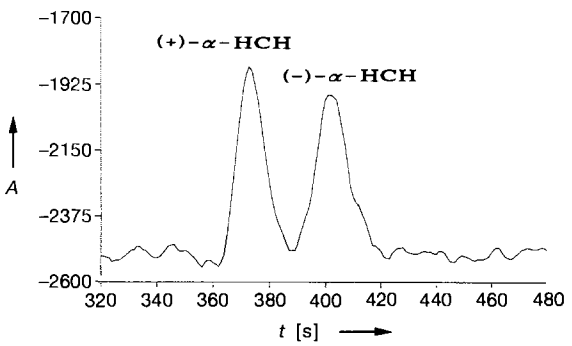

Fig. 2. HPLC chromatogram (Absorption A versus time t) for enantiomer separation of *rac*-α-HCH . For experimental conditions see Experimental Procedure.

Five cycles with a preparative Chiradex 250–50 column yielded about 20 mg of α-HCH of ≥99% purity. Recrystallization from ether at 277 K afforded single crystals of this enantiomer which were suitable for X-ray analysis. Figure 3 shows the SCHAKAL representation of the α-HCH structure thus obtained.[13] Following the extended priority rules of Cahn, Ingold, and Prelog,[14] the absolute structure of (+)-α-HCH was therefore assigned the configuration (+)-α-1*S*,2*R*,3*R*,4*S*,5*S*,6*S*-hexachlorocyclohexane.

In summary, we conclude that (+)-α-1*S*,2*R*,3*R*,4*S*,5*S*,6*S*-hexachlorocyclohexane is enantioselectively accumulated in the brain tissue of seals. From the data so far available, we assume that the blood–brain barrier of the seal is enantioselectively permeable for this α-HCH enantiomer. Further studies will be required to determine whether other pollutants can also cross the blood–brain barrier enantioselectively, whether similar structural elements are required, and to what extent this finding can be extended to all organisms of higher trophic levels, including humans.

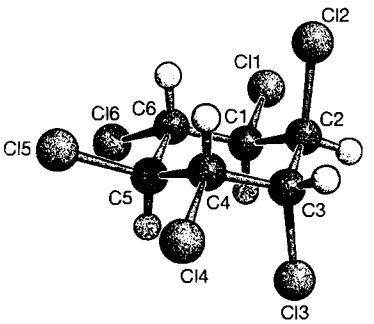

Fig. 3. The molecular structure of (+)-α-1*S*,2*R*,3*R*,4*S*,5*S*,6*S*-hexachlorocyclohexane. Bond lengths [pm] and selected bond angles [°]: Cl1-C1 178.3, Cl2-C2 179.3, Cl3-C3 178.5, Cl4-C4 179.3, Cl5-C5 178.5, Cl6-C6 178.8, C1-C2 152.3, C2-C3 151.6, C3-C4 152.8, C4-C5 152.1, C5-C6 153.1, C6-C1 151.7, all C–H bond lengths are 98.0 pm; Cl1-C1-C2 110.0, Cl2-C2-C3 108.0, Cl3-C3-C4 112.0, Cl4-C4-C5 109.9, Cl5-C5-C6 109.8, Cl6-C6-C1 109.9.

Experimental Procedure

Preparation of brain samples (homogenization, extraction, chromatographic purification, fractionation by HPLC) was carried out by the procedures described for the common eider duck [6]. The (+)-α-HCH fraction was measured by gas chromatography under the following conditions: fused silica capillary column: 25 m, i.d. 0.25 mm, stationary phase 50% octakis(3-*O*-butyryl-2,6-di-*O*-pentyl)-γ-cyclodextrin and 50% OV-1701, carrier gas helium 60 kPa, Vega gas chromatograph Carlo Erba, 2 μL on-column injection, ^{63}Ni-ECD with nitrogen as make-up gas.

The HPLC separation of the (+)-α-HCH enantiomers was carried out on an LiChrocart 250-4 ChiraDex (5 μm) analytical column from Merck, Darmstadt, under the following conditions: eluent MeOH/H_2O 75/25 (v/v): flow rate 0.8 mL min^{-1}; pressure 1.27×10^7 Pa, 3 μg *rac*-α-HCH sample; sample loop 200 μL; detector spectrophotometer. For the preparative 250-50 column with the same stationary phase, the following conditions were used; pump L-6200 (Merck–Hitachi), equipped with a preparative pump head; eluent MeOH/H_2O 75/25 isocratic; flow rate 15 mL min^{-1}; 16.5–20 mg *rac*-α-HCH sample; after five applications of sample, about 20 mg of (+)-α-HCH was isolated, purity ≥99%. Recrystallization from ether at 277 K afforded single crystals of this enantiomer which were suitable for X-ray analysis. The optical rotation in hexane solution was determined with a Perkin–Elmer polarimeter 243 (c = 2.5 mg L^{-1}): $[\alpha]_D^{20}$ = 117.4.

CAS Registry numbers: α-HCH , 319-84-6; (+/-)-α-HCH, 60291-32-9; (+)-α-HCH, 119911-69-2; (−)-α-HCH, 119911-70-5.

Cellulose in Schweizer's Reagent: A Stable, Polymeric Metal Complex with High Chain Stiffness**

Walther Burchard,* Norbert Habermann, Peter Klüfers,* Bernd Seger, and Ulf Wilhelm

Cellulose is the biogenic raw material that nature provides us with the largest quantities of. The search for solvents for cellulose has always been closely associated with the development of new applications and has also served in the chemical and physical characterization of cellulose. One of the longest known solvents for cellulose is Schweizer's reagent, an aqueous ammoniacal solution of copper(II) hydroxide ("cuoxam"). This reagent was discovered in the middle of the 1800s[1] and has been employed since the turn of the century in the cuprammonium process. The alkaline variant is used today, in particular for the preparation of membranes from (modified) cellulose for hemodialysis and hemofiltration.[2] In polymer analysis both cuoxam and "cuen" (copper(II) hydroxide in aqueous ethylenediamine (en)) are used for the determination of the degree of polymerization of cellulose.

The numerous conjectures regarding the fundamental molecular aspects of the cuprammonium process and the applications in polymer analysis are, for the most part, not backed up by experiment. Recently we showed that carbohydrates in aqueous alkaline solution are multiply deprotonated in the presence of copper(II) ions and form chelate complexes.[3] We report here on our first investigation of the solution equilibria in the systems polyol/Cu^{II}/NH_3 and polyol/Cu^{II}/en, on preliminary light-scattering experiments on cellose in cuoxam, and on a structural model of the cellulose–copper complex, which can be used to link the values from coordination chemistry with parameters from polymer chemistry.

The formation constants of polyolato–copper complexes were determined for the polyols anhydroerythritol (*meso*-oxolane-3,4-diol; AnEryt) and methyl-4-*O*-methyl-β-D-glucopyranoside (Me-β-D-Glc*p*4Me) by spectral photometry.[4] (The latter polyol was included because of its close structural resemblance to cellulose.) The structural formulas show both polyols along with a monomeric unit from cellulose from the middle of the chain (anhydroglucose, Glc_C).

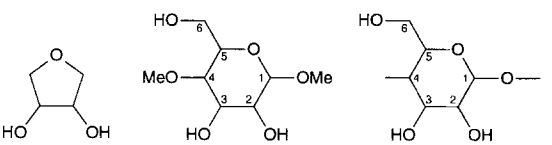

Table 1 lists the constants for the system Cu^{II}/NH_3/AnEryt (1/500/3), $c_0(Cu) = 1$ mM, that are used in the calculation of the distribution curves. The distribution of species[5] as a function of the pH value is shown on the left side of Figure 1. The known amminecopper complexes are the dominant species up to pH ≈ 11; the polyol is doubly deprotonated at higher pH values, and the resulting *meso*-oxolanediolate(2−) ion displaces ammonia with formation of the ternary complex $[(NH_3)_2Cu(AnErytH_{-2})]$. The formation of the $AnErytH_{-2}$ ligand in aqueous solution is in accord with the observed formation of crystalline oxolanediolato(2−)cuprates from aqueous media.[3]

Table 1. Indices of the formula $Cu_i(NH_3)_j(AnErytH_{-2})_kH_l$, mixed stability constants ("Brønsted constants") as $\log\beta$ and λ_{max} [nm], in parentheses: ε_{max} [M^{-1}cm^{-1}][a]. The following relationship holds (without charges):

$$\beta = \frac{c([Cu_i(NH_3)_j(AnErytH_{-2})_kH_l])}{c^i(Cu)\,c^j(NH_3)\,c_k(AnErythH_{-2})\,c^l(H)}$$

The constants used for the calculation of the distribution of noncolored species: 0101 9.53[b], 0011 13.6 (estimated), 0012 27.0 (first step determined by the Michaelis method[c]), 000−1 14.0; $I_0 = 0.75$ M (ammonium sulfate).

ijkl	$\log\beta$	$\lambda_{max}(\varepsilon)$
1100	4.0	752 (19)
1200	7.4	702 (30)
1300	10.2	642 (42)
1400	12.0	583 (55)
1500	11.1	653 (130)
1210	18.2	611 (44)
1020	22.0	632 (37)
102 − 2	−5.8	687 (38)

[a] The values for the five amminecopper ions were determined in the binary ammonia–copper system; in the evaluation of the ternary system fixed values were used and variables were also refined. Maximum deviations between the two calculations: 0.1 for $\log\beta$, 2 nm for λ_{max}, and 2 M^{-1} for ε. [b] I. Nagypál, F. Debreczeni, *Inorg. Chem. Acta* **1984**, *81*, 69–74. [c] L. Michaelis *Ber. Dtsch. Chem. Ges.* **1913**, *46*, 3683–3693.

The unexpected thermodynamic stability of polyolatocopper complexes is emphasized on the right side of Figure 1. In an excess of components AnEryt and en, $AnErytH_{-2}$ displaces ethylenediamine from the stable $[Cu(en)_2]^{2+}$ complex above pH ≈ 11 with formation of the ternary complex; above pH ≈ 13 en-free bis(polyolato)cuprates are formed despite the excess of en. In the investigation of the system Cu^{II}/NH_3/Me-β-D-

[**] Polyol–Metal Complexes, Part 7. This work was supported by the Bundesministerium für Forschung und Technologie (Förderkennzeichen 0319368A) and Akzo AG, Wuppertal (FRG). We thank Prof. Dr. A. Zuberbühler, Basel (Switzerland), for supporting our work and for an expanded version of the program SPECFIT. – Part 6: M. Klaassen, P. Klüfers, *Acta Crystalogr. Sect. C*, **1994**, 50, 175–178.

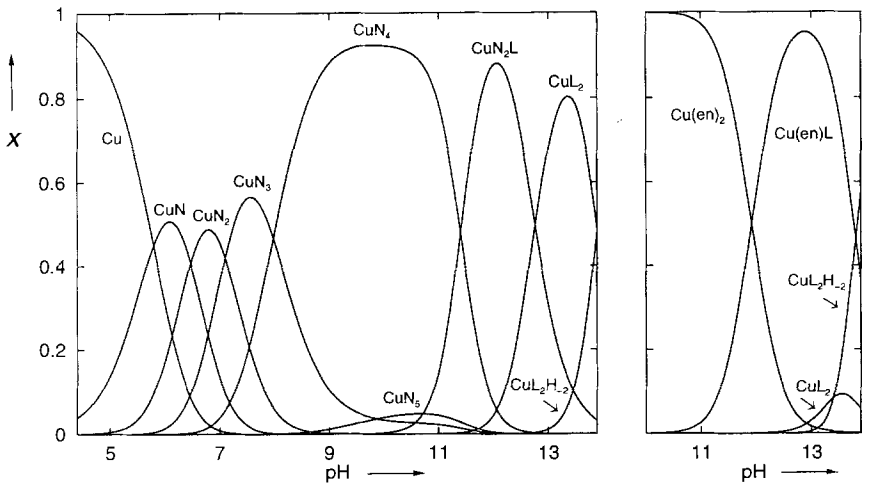

Fig. 1. Left: Plot of the molar ratio x of a species relative to the total amount of copper as a function of the pH for the system Cu^{II}/NH_3/AnEryt (1/500/3); $c_0(Cu) = 1$ mM and ionic strength $I_0 = 0.75$ M; in the notation used for the individual species N stands for NH_3 and L for anhydroerythritol. Right: Species distribution for the system Cu^{II}/en/AnEryt (1/3/3); $c_0(Cu) = 1$ mM and $I \approx 0$; values of logβ (indices based on the formula $Cu_i(en)_j(AnEryrH_{-2})_kH_l$): 0101 9.93, 0102 16.78 [16]; 1200 18.95, 1110 21.9, 1020 21.6, 102−2 −5.2.

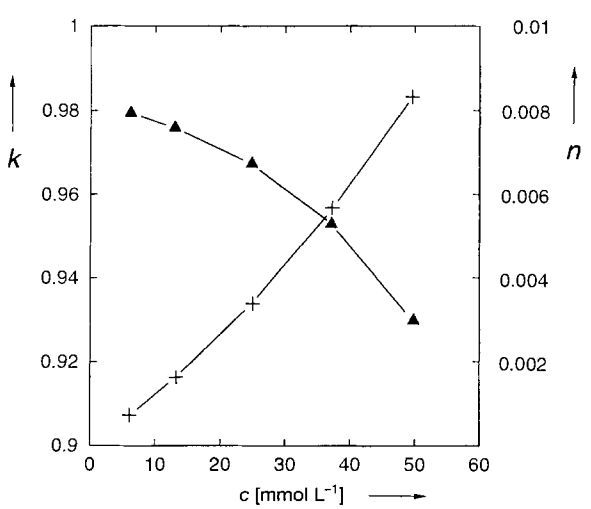
Glc$p$4Me (1/100/1), $c_0(Cu) = 1$ mM, an equimolar copper:polyol ratio was chosen so as to model the cellulose-saturated cuoxam solutions. No new species of particular stability were found, and the constants of the complexes formed with doubly deprotonated glucoside are comparable to those with AnEryt.[6]

What form does cellulose take in Schweizer's reagent? Investigations with simple polyols suggest that the monomer should be formulated as $(NH_3)_2Cu(Glc_c2,3H_{-2})$ with deprotonated O-2 and O-3. Owing to the high stability of polyolatocopper complexes, it is expected that in not-too-dilute solutions of sufficiently high pH most anhydroglucose units are complexed. Rough numerical approximations for solutions with concentrations typically used in polymer characterization can be obtained by transferring the formation constants from dilute solution. For the conditions given in Figure 2—these concentrations are also used in the dilution series in the light-scattering experiments described below—almost complete complexation occurs even in concentrated ammonia solutions, and complexation increases as the diol concentration decreases. Thus cellulose forms a stable polymeric metal complex in cuoxam.



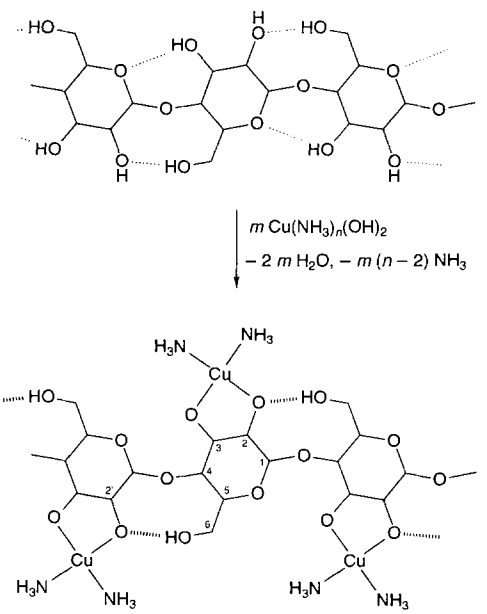


Fig. 2. Plot of the degree of complexation k (k = proportion of the metal-bound diol units [triangles] and degree of cross-linking n ($n = 0.5 \times$ proportion of diol units in bis(diolato) complexes [crosses]) versus AnEryt concentration c; calculated from the values of logβ from Table 1 and for the concentrations used in the light scattering measurements (0.1025 M $Cu(OH)_2$, 14.7 M NH_3, 0.0063–0.0496 M diol).

A preliminary model for the structure of the polymeric complex can be sketched in which the monomeric units are disposed following a construction principle that we observed recently for a related cyclodextrin complex. There, the alkoxide functions serve as acceptors in intramolecular hydrogen bonds of the type $O-H\cdots O^-$.[7] In the bottom part of Scheme 1 a cellulose chain is shown in which the monomer units are linked by O-6–$H\cdots$O-2′ bonds in addition to the glycosidic bond. The special

Scheme 1.

characteristic of cellulose is obvious: in the cyclodextrin complex a compromise is drawn between the complexation of as many copper ions as possible and the stabilization of the alkoxide functions by the formation of hydrogen bonds. In contrast, in the cellulose complex *all* the diol functions are engaged in complexation and *also* in formation of hydrogen bonds of the type $O-H\cdots O^-$. Remarkably the conformation of the cellulose chain generally assumed[8] (Scheme 1, top) does not change upon complexation. According to our model the number of hydrogen bonds in the complex is less than in cellulose, but these remaining hydrogen bonds are stronger owing to the deprotonation of the acceptor.

One should bear in mind that the notion that the polymer is fixed in *one* conformation by strong hydrogen bonds holds only for those sections of the macromolecule in which adjacent anhydroglucose units bind copper ions. However, as the degree of complexation k is less than 1, copper-free monomeric units occur which can be considered to be flaws. In these positions more than one conformation with $O-H\cdots O^-$ bonds is possible, and the complexed cellulose chain has a "joint" at this point. The degree of complexation under the chosen experimental conditions is thus an important parameter for characterizing the polymer and should correlate with chain stiffness.

A second parameter that connects coordination and polymer chemistry is the degree of cross-linking, also defined in Figure 2. Analysis of the solution equilibria show that even with an excess of copper and ammonia a small amount of the polyol exists as bis(polyolato) complexes, which corresponds to the cross-linking of cellulose strands or sections of strands through copper.

Our proposed model can be tested by light-scattering (LS) experiments. Up until now LS experiments were not possible because of the deep-blue color of the copper complexes. We were able to conduct the first analyses of this type with a strong Ar ion laser (absorption correction, $\lambda_0 = 457.9$ nm). With modern LS techniques the mean geometrical molecular radius R_g can be ascertained as well as a molecular radius determined by hydrodynamics R_h.[9] These two radii and the angle dependence of the scattering intensity are used to determine chain stiffness. The measurements were conducted with cellulose of different molecular weights; a polydispersity of $M_w/M_n = 2$ was assumed.

The term "chain stiffness" can be understood by examination of Figure 3. A chain with unrestricted mobility forms a relatively tight knot. If the mobility of individual members of the chain (here the anhydroglucose units) is hampered, the knot expands to a wormlike chain. In a mathematical description in 1934

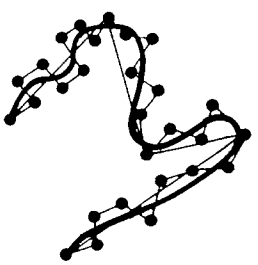

Fig. 3. Schematic representation of chain stiffness (flexible chains: short lines connecting the dots; chain in the Kuhn model: long, thin lines; wormlike chain: long, thick lines.

Kuhn[10] introduced the concept of a statistically preferred length, which is referred to today as the Kuhn segment length l_k (long lines in Fig. 3). This extended length, which joins a number of monomeric units into an almost rigid segment, requires free and independent mobility of the new segments. Identical results were obtained from the analysis of the scattering data[11] by three methods employing: 1) the radius of gyration R_g defined by Benoit and Doty,[12a] 2) the characteristic ratio C_∞ according to Flory,[12b] and 3) the angle dependence of the scattering intensity with application of the Koyame theory.[12c] The analysis (for details see ref.[12d]) yielded a Kuhn segment length of $l_k = 26(\pm 6)$ nm; in other words, approximately 50 monomeric units form a relatively rigid segment. These results become more meaningful upon comparison to the known values for polystyrene: $l_k = 2$ nm and roughly 10 units per segment.[13] Thus cellulose in cuoxam shows an unexpectedly high chain stiffness, in accord with the proposed model.

A further question was whether cross-linkage through the formation of bis(polyolato) complexes can be proved by LS experiments. Figure 4 shows a plot of the radius of gyration R_g and the hydrodynamic radius R_h versus chain length. Polymers with constant segment densities give straight lines over the entire range in such plots. In Figure 4 the plot clearly deviates from linearity for samples with greater molecular weights. This implies an increase in the segment density with high degree of polymerization and is an indication of intramolecular cross-linking. This type of exclusively intramolecular cross-linking is possible only in highly dilute solution.[14] Intermolecular cross-linking between chains should occur at higher concentrations, especially when the so-called overlap concentration c^*[15] is exceeded. Indeed, this effect is observed: cluster formation and finally gelling take place.

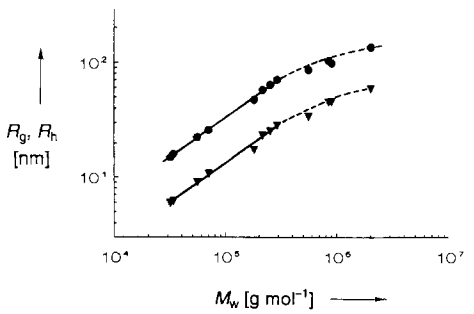

Fig. 4. Plot of the molecular radii R_g (circles) and R_h (triangles) versus molecular weight M. The anomalies at high molecular weights result from the contraction of the molecular knot as a consequence of intramolecular cross-linking.

These results show that a structural model of cellulose derived from single-crystal data from cyclodextrin complexes links values from coordination chemistry with parameters from polymer chemistry. It should be noted that the model itself and the values shown in Figure 2 are preliminary. For a more precise description of the complex equilibria further investigations that include the concentration range of the polymer analysis are necessary. The compensation of various errors is likely to be crucial in the uniform values we obtained (50 anhydroglucose units in the rigid sections versus an extent of complexation of 98% at high dilution).

[14] The degree of cross-linking n is the sum of an intramolecular and an intermolecular term. It should be noted that the extrapolation to $c = 0$ in the polymer analysis does not imply an analogous extrapolation in the $n(c)$ diagram. The limiting case there corresponds to infinitesimally few diol units near the amminecopper units and thus to $n \rightarrow 0$ for $c \rightarrow 0$. In contrast, extrapolation in polymer analysis allows a description of the behavior of isolated cellulose molecules in solution; however, in this case a finite number of diol units are available for complex equilibria. Under these conditions n corresponds to the extent of *intra*molecular cross-linking.

A Mixed-Valent, Unsymmetrical $Fe^{II}Fe^{III}$ Complex with a Terminal Phenolato Ligand as a Model for the Active Site of Purple Acid Phosphatases**

Elisabeth Bernard, William Moneta, Jean Laugier, Sylvie Chardon-Noblat, Alain Deronzier, Jean-Pierre Tuchagues, and Jean-Marc Latour*

Purple acid phosphatases (PAP) are non-heme proteins with an active site containing two iron atoms; these enzymes catalyze the hydrolysis of activated phosphoric acid esters.[1] Two forms of the diiron unit have been characterized: the oxidized inactive $Fe^{III}Fe^{III}$ center and the reduced active $Fe^{II}Fe^{III}$ unit. The diiron(II) form of the protein is unstable, and release of Fe^{II} ions is observed upon reduction of the oxidized protein with dithionite.[1] X-ray structure analysis has not yet been possible for any PAP enzyme; however, EXAFS[2] and NMR[3] studies indicate that the Fe_2 center has an oxygen-rich coordination environment similar to that in ribonucleotide reductase.[4] A bridging hydroxo ligand has been proven in the reduced form of the protein, but some controversy still exists on the nature of the bridging ligands at the oxidized center.[1, 5] A distinctive feature of these proteins is the tyrosine residue bound to one of the iron atoms, which contributes to their color through a Tyr-to-Fe^{III} charge transfer transition at 550 nm in the oxidized protein. Upon one-electron reduction the charge transfer band moves to 510 nm while retaining its intensity, which indicates that the Tyr residue is bound to the nonelectroactive Fe^{III} ion.

Two approaches have been used for modeling the PAP active site. The dinuclear iron(III) complex with a phenolato ligand has been used to mimic the coordination of the tyrosine residue. But a symmetrical complex was obtained in which each Fe^{III} atom is ligated by a phenolato ligand.[6] In another approach phosphate bridges have been incorporated into μ-oxodiiron(III) cores[7] and into mixed-valent $Fe^{II}Fe^{III}$ complexes of μ-phenolato ligands containing four pyridine rings.[8] In all instances symmetrical complexes were obtained.

In this communication we describe the structural and magnetic characterization of the unsymmetrical mixed-valent $Fe^{II}Fe^{III}$ complex **1**. This complex is the first to reproduce the coordination of a terminal tyrosine residue to a diiron center as found in the PAP enzymes. This compound was derived from a new unsymmetrical heptadentate ligand (H_2L) constructed by introducing two different complexing "arms" (bis(2-pyridylmethyl)aminomethyl and (2-pyridylmethyl)(2-hydroxyphenyl)-aminomethyl) at the *ortho* positions of *p*-cresol.[9] In addition, the results of an electrochemical study of **1** help explain the instability of the reduced diiron(II) form of the PAP enzymes.

Reaction of one equivalent of H_2L with two equivalents of $Fe(NO_3)_3 \cdot 9H_2O$ and one equivalent of disodium 1,3-benzenedipropionate (Na_2mpdp) affords a violet solution, which yields a violet precipitate of **1** upon addition of sodium tetraphenylborate. Elemental analysis of **1** shows that it is the

$[Fe^{II}Fe^{III}L(mpdp)]BPh_4$ **1**

mixed-valent complex with the above formulation, which is confirmed by solid-state magnetic studies. Recrystallization of this powder from acetonitrile/ethanol affords violet crystals suitable for X-ray structure analysis.[10] The structure of **1** is represented in Figure 1. The complex consists of discrete diiron complex

cations and tetraphenylborate counterions. The two iron atoms have substantially different coordination environments. Fe1 is surrounded by a distorted N_3O_3 octahedron consisting of three nitrogen atoms from one "arm" of L and two oxygen atoms from two carboxylate groups of mpdp, and the oxygen atom from the cresolato ligand. Fe2, on the other hand, is in an N_2O_4 environment made up of two nitrogen atoms from the other "arm" of L, two oxygen atoms from two carboxylate groups of mpdp, one from the cresolato ligand, and one from the terminal phenolate group (terminal with respect to coordination to the iron center and the ligand system). The two iron atoms are bridged by the two carboxylate groups and the oxygen atom of the cresolate. The Fe–Fe distance amounts to 3.417 Å, which compares favorably with those determined in symmetrical bis-μ-carboxylato-μ-phenolato complexes [3.39(3) Å][11] and in reduced uteroferrin [3.52 Å] from EXAFS measurements.[2] It is worth noting that the Fe-O-Fe unit is strongly asymmetric; the Fe2–O1 distance is 0.124 Å shorter than Fe1–O1 separation. The same trend is observed for the other metal–ligand distances and leads to the conclusion that the valences of the iron ions are localized; the Fe2 center is in the +III oxidation state, Fe1 in the +II oxidation state.

The localization of valences in **1** is supported by the Mössbauer spectra (range 300–80 K), which at 80 K exhibit two doublets split by quadrupole interactions with isomer shifts of 0.490 and 1.124 mm s^{-1} (relative to metallic iron at room temperature), splittings of 0.594 and 2.376 mm s^{-1}, and relative areas of 50.6 and 49.4%, respectively. The first doublet is attributed unambiguously to the trivalent Fe2 center, while the second one corresponds to the divalent Fe1 center. Similar Mössbauer parameters have been obtained for various PAP enzymes. Magnetization studies have been performed over the temperature range 2–300 K. The product of the molar susceptibility and the temperature is equal to 6.8 μ_B at 300 K and decreases slightly with temperature to 5.4 μ_B at 100 K. It then decreases more abruptly to reach roughly 0.4 μ_B at 2 K. This behavior is consistent with the occurrence of a moderate antiferromagnetic interaction between the Fe^{II} and Fe^{III} centers. The data were fitted to the equation deduced from application of the Heisenberg spin Hamiltonian $\mathcal{H} = -2JS_1S_2$ to a pair of spins $S_1 = 5/2$ and $S_2 = 2$. The best fit was obtained with the values $g = 2.0$ and $J = -3.8$ cm^{-1}.[12] This exchange interaction compares more favorably with that calculated for the phosphate derivative ($J = -3.0$ cm^{-1}) than that determined for the uncomplexed form ($J = -9.9$ cm^{-1}) of the PAP from porcine uterus.[13]

The electrochemical properties of **1** were investigated in 0.1 M tetrabutylammonium perchlorate in acetonitrile. In this medium the electronic absorption spectrum of **1** comprises three bands in the range 300–800 nm: at 374 nm ($\varepsilon \approx 2200$), 405 nm ($\varepsilon \approx 2000$), and 535 nm ($\varepsilon \approx 1700$) (Fig. 2, curve a). Comparison of this spectrum with those of complexes of μ-phenolato ligands leads to the tentative assignment of the bands at 405 and 535 nm to charge-transfer transitions from the terminal and the bridging phenolates to the Fe ion, and the absorption at 374 nm to a charge transfer from the Fe^{II} ion to the pyridine groups.[11]

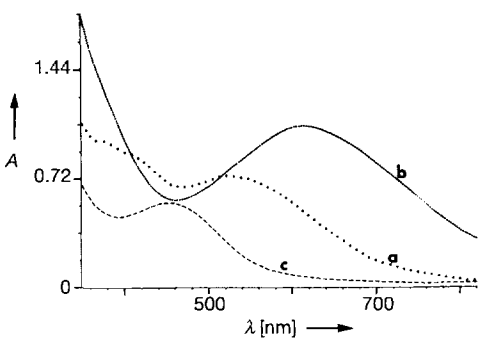

Fig. 2. Electronic absorption spectra in a 0.1 M solution of tetrabutylammonium perchlorate (TBAP) in acetonitrile at ambient temperature: a) solution of **1** (0.97 mM); b) solution from a) after one-electron oxidation; c) solution from a) after one-electron reduction.

A reversible oxidation wave is observed in the cyclic voltammogram of **1** (Fig. 3, curve a) at $E_{1/2} = 0.12$ V. Coulometric analysis shows that this process is a one-electron transfer, and it is therefore assigned to the $Fe^{II}Fe^{III}/Fe^{III}Fe^{III}$ transition (e.g. the oxidation of the Fe^{II} ion). The solution of the oxidized complex shows an enhanced charge-transfer band at 618 nm ($\varepsilon \approx 2600$; Fig. 2, curve b). The reduction of **1** at $E_{1/2} = -0.88$ V is reversible, but following this reduction a second wave appears at a slightly less negative potential $E_{1/2} = -0.72$ V (Fig. 3, curve b). Exhaustive electrochemical reduction of **1** at −1.2 V requires one electron per molecule, and the resulting solution shows the presence of the two $Fe^{II}Fe^{II}$ species in roughly a 1:1 ratio (Fig. 3, curve c). The electronic spectrum of the reduced

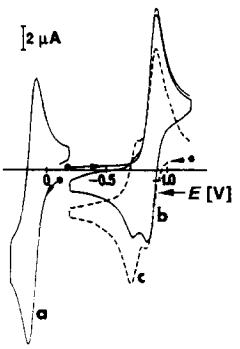

Fig. 3. Cyclic voltammetry with a glassy carbon electrode (diameter 3 mm) of a 0.84 mM solution of **1** versus Ag/10 mM Ag^+ reference in acetonitrile/0.1 M TBAP; $v = 100$ mV s^{-1}. Curve a: Scan between −0.10 V and +0.30 V; curve b: two successive scans between −0.20 V and −1.20 V; curve c: obtained after controlled potential reduction at −1.20 V of the initial solution.

solution presents an absorption at 452 nm ($\varepsilon \approx 1100$). Reoxidation at −0.45 V or at −0.8 V (the potential at which only the most readily oxidized species is oxidized) regenerates essentially the starting solution. This behavior is consistent with the existence of two $Fe^{II}Fe^{II}$ compounds **2** in equilibrium; **2b** results from a chemical transformation of **2a** [Eq. (a)].

$$\underset{\mathbf{1}}{Fe^{II}Fe^{III}} + e^- \rightleftharpoons [\underset{\mathbf{2a}}{Fe^{II}Fe^{II}} \rightleftharpoons \underset{\mathbf{2b}}{(Fe^{II}Fe^{II})}] \qquad \text{(a)}$$

Several hypotheses can be made about the nature of the chemical transformation **2a** → **2b**. Comparison of the structures of the mixed-valence and diiron(II) complexes with the μ-phenolato ligand containing four pyridine units indicates that the structures do not change greatly upon reduction.[14] This indicates that a drastic structural change is also unlikely to occur in the reduction of **1**. On the other hand, the electrochemical study shows that the high electron density resulting from both the coordination of the second phenolato ligand and the transfer of an electron strongly destabilizes the diiron(II) center.[15] The dissociation of an anionic ligand (carboxylate or phenolate) would therefore release some electron density from the diiron site. The small stabilization of the second reduced species (160 mV) is more consistent with dissociation of a carboxylato than that of the terminal phenolato ligand. This ligand would bind again when the diiron(II) center is reoxidized, making the

overall process chemically reversible. Further work is in progress to fully characterize the second reduced species **2b**.

In summary, complex **1** is the first structurally characterized model complex of a PAP enzyme that reproduces the unsymmetrical coordination of a terminal phenolato ligand to a diiron center. Solid-state magnetic studies have shown that the electronic structure of complex **1** is similar to that of the active site of the enzyme. Electrochemical studies have demonstrated that **1**, like the PAP enzymes, has stable $Fe^{III}Fe^{III}$ and $Fe^{II}Fe^{III}$ forms, and that the terminal phenolato ligand destabilizes the diiron(II) state, both in terms of electrochemical potentials and of chemical reactivity. The latter finding rationalizes the observation that reduction of porcine PAP is accompanied by release of iron ions.[1]

Experimental Procedure

To a solution of 1 g (1.88 mmol) of H_2L in 75 mL of CH_3OH were added successively a solution of 1.52 g (3.76 mmol) of $Fe(NO_3)_3 \cdot 9H_2O$ in 50 mL of CH_3OH and a solution of 550 mg (2.48 mmol) of Na_2mpdp [16] in 50 mL of CH_3OH. Addition of a solution of 2.6 g (7.6 mmol) of sodium tetraphenylborate in 30 mL of CH_3OH induced the precipitation of **1** (1.25 g) as a black powder. Recrystallization from acetonitrile/ethanol gave black crystals suitable for X-ray analysis.

[12] In cases where the exchange integral J is as small as here, the zero-field splitting parameter of the Fe^{II} ion is likely to be of the same order of magnitude and should be taken into account. Accordingly, the Heisenberg spin Hamiltonian furnishes only a crude estimate of J. A more sophisticated treatment of the field and temperature dependences of the magnetization of **1** is currently underway and will be reported in due course.

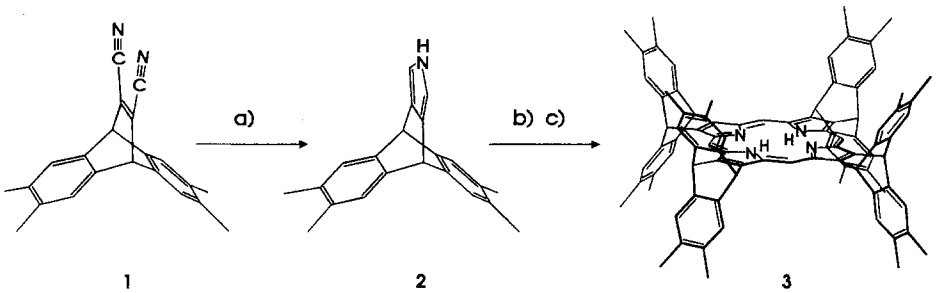
Porphyrins with Biconcave Frameworks**

Yvan Ramondenc, Reinhold Schwenninger, Thao Phan, Karl Gruber, Christoph Kratky, and Bernhard Kräutler*

Dedicated to Professor Hans Gruber on the occasion of his 65th birthday

Recently new porphyrin-like compounds such as Franck's "vinylogous" porphyrins,[1] the "extended" porphyrins, for example, those of Woodward et al., Sessler et al., and Gossauer et al.,[2] and Vogel's "porphycenes"[3] have drawn attention to the considerable number of possible forms which can arise just from their two-dimensional structures. However, the structuring of the third dimension through covalently bonded, peripheral substituents was of crucial importance in Collman's "picket fence" porphyrin.[4] In the *meso*-aryl porphyrin used there, the aryl substituents were the basis for the buildup of the framework in the third dimension. This construction principle was used in (nearly) all[5] three-dimensionally structured porphyrins prepared later[6] (Scheme 1 left).



We report here on a second, widely applicable strategy for the synthesis of three-dimensionally structured porphyrins, using porphyrins with "biconcave" frameworks as examples (Scheme 1 right). Cycloadditions provided access to new bulky pyrroles with an oligocyclic structure. The synthesis of the β,β'-disubsti-

[**] We would like to thank Dr. W. Amrein and R. Häfliger (ETH, Zürich) and E. Williams (Fisons Instruments) for measuring mass spectra. This work was supported by the Jubiläumsfonds der Österreichischen Nationalbank (Proj. Nr. 4194).

Scheme 2. Preparation of pyrrole **2** and its tetramerization to porphyrin **3**. a) DIBAH, −20 °C; b) 30% formaldehyde solution, acetic acid, room temperature, 7 d; c) DDQ, room temperature, 2 h.

tuted pyrroles necessary for this was achieved with oligocyclic-substituted maleic acid dinitriles whose reduction provided a new route to pyrroles.[7, 8] The dinitrile **1** (from acetylenedicarbonitrile and 2,3,6,7-tetramethylanthracene analogous to ref. [9]) could be reduced with diisobutylaluminum hydride (DIBAH) to give pyrrole **2** (Scheme 2) in about 33% yield. Pyrrole **2** has a framework similar to that of triptycene. According to an X-ray crystal structure analysis (Fig. 1), the angle between the planes of the two central phenyl rings in **2** is 115.5°; the distances C2–C7 and C2′–C7′ are 6.52 and 8.68 Å, respectively.[10]

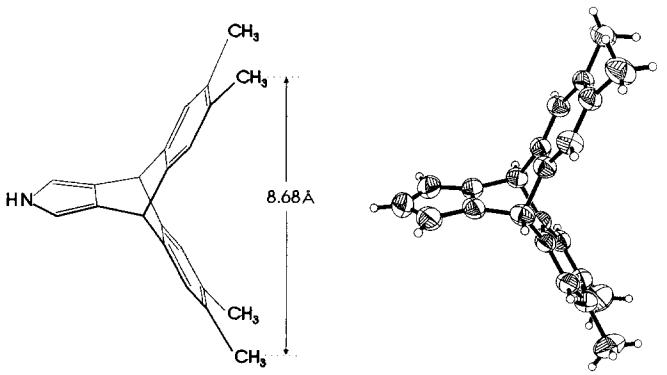

Fig. 1. Left: Structural formula of pyrrole **2**; right: Crystal structure of **2** (projection of one of the three crystallographically independent molecules; thermal ellipsoids at 50% probability level).

Tetramerization of pyrrole **2** by condensation with formaldehyde and subsequent oxidation gave, analogous to a well-known method,[11] reddish, fluorescent, biconcave tetrakis-(9,10-dihydro-9,10-anthraceno)porphyrin **3** in 72% yield. The structure of **3** was deduced from UV/VIS, FAB-MS, and ^{1}H NMR spectra (Table 1).

Compound **3**, like other porphyrins, is an excellent ligand for transition metal ions; for example, in the successful preparation[12] of the Co^{II}-porphyrinate **4**. In the NMR spectrum of the paramagnetic Co^{II} complex **4**, the signals of the hydrogen atoms of the porphyrin ligands show characteristic anisotropic shifts.[13] The light-sensitive, diamagnetic 8-iodooctylporphyrinatocobalt(III) **5** could be prepared from **4** by reduction and subsequent reaction with 1,8-diodooc-

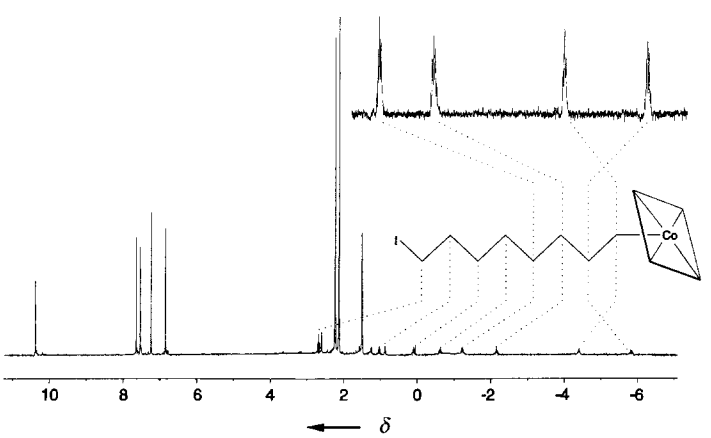

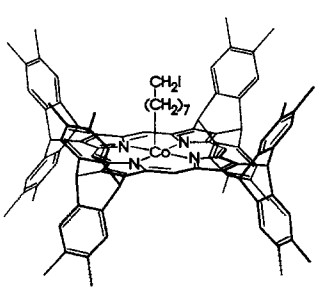

Fig. 2. ^{1}H NMR spectrum of 8-iodooctylporphyrinatocobalt(III) **5** (300 MHz, $CDCl_3$, $\delta(CHCl_3)$ = 7.24; signal assignment in the high-field region from H,H-COSY spectra).

tane. In the NMR spectrum of **5**, the signals of the alkyl groups bonded to cobalt show a characteristic high-field shift (to $\delta \approx -5.8$, Fig. 2).

In metalloporphyrins like **4** and **5**, which are derived from biconcave porphyrins, the peripheral ring of substituted phenyl rings shields the central metal ion from both sides. The biconcave framework prevents dimerization and can be used for a spatially controlled uptake of organic guest molecules. According to preliminary investigations,[14a] in the solid, large guest molecules (such as fullerenes) are incorporated into the structured cavities.[14b]

5

The new approach for the preparation of β,β'-disubstituted pyrroles presented here opens up a rational, and multifacetted direct route to porphyrins with a three-dimensionally structured periphery. This has led to the preparation of the first biconcave metalloporphyrins, whose frameworks promise interesting catalyst properties.

Experimental Procedure

1: Acetylenedicarbonitrile (234 mg, 3.08 mmol) in benzene (5 mL) was added dropwise over 4 h (under N_2) to a heated (80 °C) suspension of 2,3,6,7-tetramethylanthracene (452 mg, 1.93 mmol) [15] in benzene (5 mL). The reaction mixture was heated under reflux for an additional 10 h. After cooling and concentration of the mixture, column chromatography (silica gel, CH_2Cl_2/petroleum ether 1/1) and crystallization from CH_2Cl_2 yielded 562 mg (1.81 mmol, 94%) **1**.

2: DIBAH (12 mmol, 1 M in hexane) was treated with **1** (0.60 g, 1.93 mmol) in dry CH_2Cl_2 (20 mL) under N_2 at −20 °C and stirred. The mixture was stirred at −20 °C for 3.5 h, treated with aqueous citric acid (0.5 M, 16 mL) and diluted with aqueous citric acid (0.5 M, 12 mL) and CH_2Cl_2 (12 mL) at room temperature. The organic phase was concentrated and purified by column chromatography (silica gel, CH_2Cl_2/petroleum ether 1/1). The colorless pyrrole **2** (190.5 mg, 0.64 mmol) crystallized from CH_2Cl_2/hexane (1:5) in 33% yield.

3: A solution of **2** (81 mg, 0.27 mmol) in CH_2Cl_2 (0.6 mL) was treated under N_2 with CH_3OH (0.84 mL), acetic acid (78 μL), and 30% formaldehyde solution (111 μL). The mixture was protected from light, stirred for 7 d at room temperature under N_2, and then concentrated. The residue was dissolved in benzene (2 mL) under N_2 and treated with dichlorodicyanobenzoquinone (DDQ) (42.3 mg, 0.18 mmol) in benzene (4 mL). After 2.5 h at room temperature, the solution was diluted with CH_2Cl_2 (2 mL) and shaken with phosphate buffer (pH 7) (0.1 M 3 mL). The organic phase was separated by column chromatography (CH_2Cl_2). Microcrystalline **3**, 60 mg (72%), was obtained from the red porphyrin fraction after concentration and precipitation from CH_2Cl_2/hexane.

4: **3** (90 mg, 74 μmol) was dissolved in dry THF (20 mL) under N_2 and treated with anhydrous Co^{II} bromide (283 mg, 1.3 mmol) and triethylamine (200 μL, 1.4 mmol) in THF (15 mL). The mixture was stirred at room temperature for 6 h, concentrated under vacuum, and the residue was extracted with CH_2Cl_2 (200 mL). The extract was worked up in water, concentrated, and filtered through an aluminum oxide column. The red fraction (**4**) was concentrated under vacuum and dried. The Co^{II} porphyrinate **4**, 83 mg (88.9%), was obtained as a red-brown powder.

5: This was obtained with a yield of 48% by the reduction of **4** and alkylation with 1,8-diiodooctane (analogous with ref. [16]).

Electrostatic Activation of Hypervalent Organo-Iodine Compounds: Bis(onio)-Substituted Aryliodine(III) Salts

Robert Weiss* and Jörg Seubert

The massive use of electrostatic effects is an option for the control of structure and reactivity which has to date been used remarkably little. Using organic π systems we have already been able to demonstrate that the complete conversion of a set of neutral ligands to a set of a cationic ligands (e.g. by poly(onio) substitution) confers a dramatically increased electrophilicity and electron affinity on the π template.[1] This effect is predominantly caused by the electrostatic effect (field effect)[2] of the positively charged ligands and should thus not show a saturation effect nor be limited to organic π systems. The latter conclusion has already been confirmed for poly(onio)-substituted derivatives of phosphorous in several oxidation states.[3] In view of the current significance of hypervalent organo-iodine(III) compounds[4] as multifaceted redox reagents in organic synthesis, the question was now posed as to whether their reactivity and synthetic potential could not also be increased by electrostatic activation. We report here on the first synthesis of bis(onio)-substituted aryliodine(III) salts and demonstrate their potential in organic synthesis with a few examples.

The starting point of modern organo-iodine(III) chemistry is still Willgerodt's (dichloro-iodo)benzene **1**.[5] A large number of publications have reported on the transformation of this system into reagents of type **2** using O, C, or N nucleophiles within the framework of $S_N(I)$ reactions.[4] Onio-substituted aryliodine(III) salts were, however, not accessible by this route. However, the first examples of this new class of compounds can be prepared under mild conditions and in high yields according to the various syntheses shown in Scheme 1.[6]

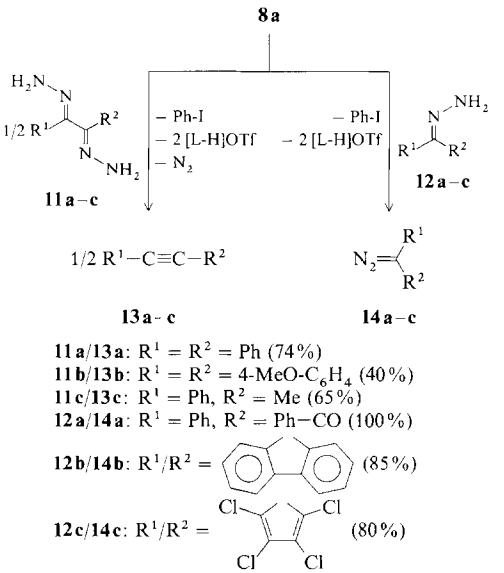
Scheme 1. OTf = O_3SCF_3.

(L) in a mol ratio of 1:2 leads, within a few minutes at room temperature, to the precipitation of the title compounds **8–10** as triflate salts which are sparingly soluble in CH_2Cl_2. They are completely stable in the absence of moisture and can be stored. According to this procedure their synthesis is coupled in a thermodynamically favorable way with the simultaneous (practically quantitative) formation of the products **6** and **7** containing low-energy Si–O bonds. This is crucial for the success of the synthesis, since **3** does not react with ligands such as L without the addition of **5**; incidentally, **1** does not react even with the addition of **5**. The formation of **6** and **7** can easily be controlled by ^{1}H NMR spectroscopy.[7]

Table 1. Yields and spectroscopic data for the compounds **8–10** [a]. Correct C,H,N analyses were obtained.

8a: Yield: 98%; ^{1}H NMR: δ = 7.65 (dd, ^3J = 6.6, 6.0 Hz, 2H; H-3/H-5 Ph), 7.80 (m, 5H; H-4 Ph, H-3/H-5 pyridine), 8.36 (t, ^3J = 7.7 Hz; 2H; H-4 pyridine), 8.69 (d, ^3J = 7.7 Hz, 2H; H-2/H-6 Ph), 9.00 (d, ^3J = 4.9 Hz, 4H, H-2/H-6 pyridine); ^{13}C NMR: δ = 121.86 (q, ^1J(C,F) = 320 Hz; CF_3), 124.67 (C-1 Ph), 129.87 (C-3/C-5 pyridine), 134.37 (C-3/C-5 Ph), 135.95 (C-4 Ph), 136.73 (C-2/C-6 Ph), 146.14 (C-4 pyridine), 148.58 (C-2/C-6 pyridine)



8b: Yield: 80%; ^{1}H NMR: δ = 3.08 (s, 12H, NMe_2), 7.47 (AA'BB', ^3J = 7.7 Hz, 8H; DMAP), 7.59 (dd, ^3J = 8.2, 7.7 Hz, 2H; H-3/H-5 Ph), 7.72 (t, ^3J = 7.7 Hz, 1H; H-4 Ph), 8.48 (d, ^3J = 8.2 Hz, 2H; H-2/H-6 Ph); ^{13}C NMR: δ = 40.28 (NMe_2), 109.66 (C-3/C-5 DMAP), 122.00 (q, ^1J(C,F) = 320 Hz; CF_3), 123.60 (C-1 Ph), 133.77 (C-3/C-5 Ph), 134.88 (C-4 Ph), 135.15 (C-2/C-6 Ph), 145.94 (C-2/C-6 DMAP), 157.14 (C-4 DMAP)

9: Yield: 93%; ^{1}H NMR: δ = 3.76 (s, 6H; Me), 7.27 (d, ^3J = 89.6 Hz, 4H; H-4/H-5 imidazole), 7.61 (dd, ^3J = 8.2, 7.7 Hz, 2H; H-3/H-5 Ph), 7.76 (t, ^3J = 7.7 Hz, 1H; H-4 Ph), 8.42 (s, 2H; H-2 imidazole), 8.52 (d, ^3J = 7.7 Hz, 2H; H-2/H-6 Ph); ^{13}C NMR: δ = 36.38 (Me), 122.00 (q, ^1J(C,F) = 320 Hz; CF_3), 124.80 (C-1 Ph), 126.30 (C-4/C-5 imidazole), 133.74 (C-3/C-5 Ph), 134.97 (C-4 Ph), 135.66 (C-2/C-6 Ph), 140.11 (C-2 imidazole)

10: Yield: 81%; ^{1}H NMR: δ = 7.45 (dd, ^3J = 8.2, 7.7 Hz, 2H; H-3 quinoline), 7.58 (dd, ^3J = 7.7, 7.1 Hz, 2H; H-3/H-5 Ph), 7.89 (m, 3H; H-4 Ph, H-6 quinoline), 8.17 (d, ^3J = 7.7 Hz, 2H; H-5 quinoline), 8.24 (dd, ^3J = 8.8, 7.1 Hz, 2H; H-7 quinoline), 8.72 (d, ^3J = 7.7 Hz, 2H; H-2/H-6 Ph), 8.80 (d, ^3J = 8.8 Hz, 2H; H-8 quinoline), 8.96 (d, ^3J = 8.2 Hz, 2H; H-4 quinoline), 10.00 (d, ^3J = 5.5 Hz, 2H; H-2 quinoline); ^{13}C NMR: δ = 121.86 (q, ^1J(C,F) = 320 Hz; CF_3), 124.61 (C-3 quinoline), 125.10 (C-1 Ph), 125.89 (C-6 quinoline), 131.13 (C-5 quinoline), 131.49 (C-4a quinoline), 134.12 (C-3/C-5 Ph), 135.66 (C-4 Ph), 135.99 (C-7/C-8 quinoline), 136.69 (C-2/C-6 Ph), 141.71 (C-4 quinoline), 147.93 (C-8a quinoline), 153.94 (C-2 quinoline)

[a] ^{1}H NMR (400 MHz, CD_3CN, 25 °C, TMS), ^{13}C NMR (100 MHz, CD_3CN, 25 °C, TMS).

Because of the irreversibility of the electron acceptance in the new bis(onio)iodine(III) compounds, no cyclic voltametric redox potentials could be determined for **8–10**. A clear indication of the efficiency of the electrostatic increase of the electron affinity by poly(onio) substitution is given by a comparison of polarographic measurements on **3** and **8a**. According to these, the $E_{1/2}$ value for the acceptance of the first electron in the transition from **3** to **8a** is shifted by about 1.3 V) towards more positive potential (from −1.0 to +0.34 V)![8] This severely increased oxidation power of **8a** relative to **3**, combined with the basic nature of the free ligand, pyridine, enables the valuable use of this reagent in synthesis. Thus, 1,2-bishydrazones **11** could be cleanly oxidized to alkynes **13** by using **8a** (Scheme 2).[9] Under analogous conditions, and using **3** as oxidant, this reaction leads to totally unsatisfactory results with respect to yield, reaction time, and the formation of by-products.[10] This is, therefore, further proof of the electrostatic activation in compounds **8–10**. In several cases the dehydrogenation of monohydrazones **12** afforded the diazo compounds **14** (Scheme 2).[11]

Scheme 2.

Both reactions occur spontaneously at room temperature in mainly good to very good yields[12] and are notable for the ease of workup of the reaction mixture and the avoidance of toxic heavy metal reagents (e.g. HgO), which are used, in general, in the conventional dehydrogenations of this type.

We have obtained many new bis(onio)-substituted aryliodine(III) salts by structural variation of the parent iodoarene and the N-heteroarene. The synthetic potential of these new reagents is currently under investigation.[13]

Experimental Procedure

All reactions were carried out under nitrogen in dried solvents (exception: workup of **13** and **14**). No melting points were determined on account of the extreme hygroscopic nature of compounds **8–10**. Compounds **13** and **14** were characterized by comparison of their physical data with those in the literature.

8–10: **3** or **4** (2.5 mmol) in CH_2Cl_2 (20 mL) was treated with **5** (5 mmol). The N-heteroarene (5 mmol) in CH_2Cl_2 (10 mL) was added dropwise to this solution. The colorless (**8b** beige) precipitate was filtered, washed with CH_2Cl_2, and dried at 0.01 Torr.

13: **8a** (3 mmol) was suspended in CH_2Cl_2 (40 mL) and was treated with a solution of **11a–c** (1.5 mmol) in CH_2Cl_2 (10 mL) with strong evolution of N_2. After 1 h the solution was treated with petroleum ether and the residue filtered off. After distilling off the solvent, the product was purified by sublimation at 0.01 Torr (**13a, b**) or by Kugelrohr distillation (**13c**) (**13c** was obtained as a 1:2 mixture with iodobenzene).

14: **8a** (2 mmol) was suspended in CH_2Cl_2 (30 mL) and treated dropwise with a solution of **12a–c** (2 mmol) in CH_2Cl_2 (10 mL). After 1 h the solvent was removed at 20 Torr and the residue taken up in Et_2O. After filtration and renewed removal of the solvent at 20 Torr, the product was recrystallized from petroleum ether (**14b**) or MeOH (**14c**). Crude **14a** was transferred on to a silica gel column and washed with a large quantity of petroleum ether. Subsequently the product was eluted with CH_2Cl_2 and dried after removal of the solvent at 20 Torr.

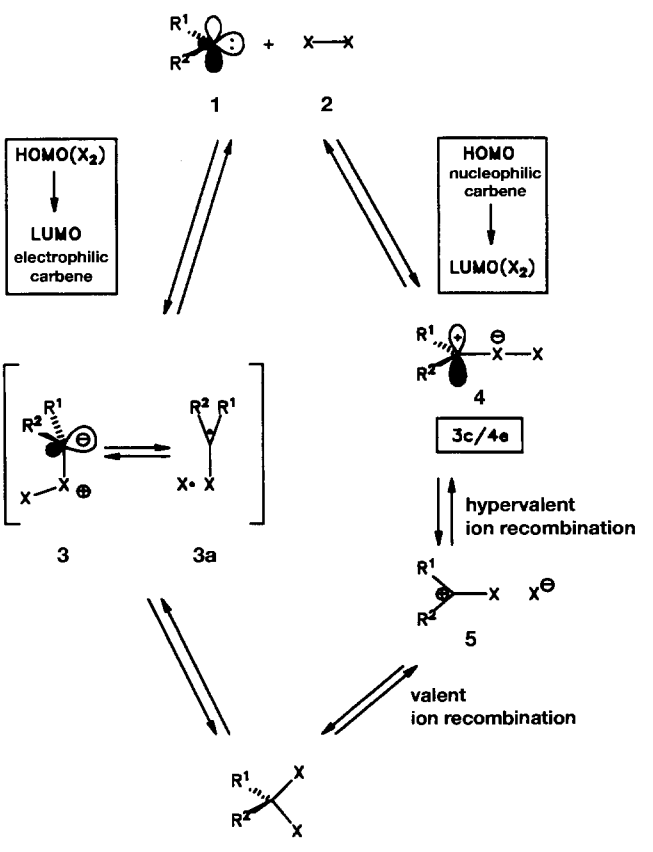
The dehydrogenation of a monohydrazone with **3** has so far only been reported for one example: P. A. S. Smith, E. M. Bruckmann, *J. Org. Chem.* **1974**, *39*, 1047.

[12] The yields were not optimized.



[13] In preliminary experiments electron-deficient hydroquinones, for example *o*- and *p*-tetrachlorohydroquinone and even 2,3-dichloro-5,6-dicyano-1,4-hydroquinone could be oxidized to the corresponding quinones. In reactions with activated arenes (e.g. anisole) under mild conditions (room temperature) the corresponding diaryliodonium systems were obtained.

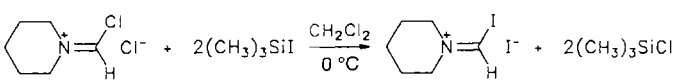
Concerning the Mechanism of α-Elimination: Hypervalent Ion Pairing in an Iodocarbenium Iodide**

Robert Weiss,* Michael Rechinger, and Frank Hampel

Although the α-addition of a halogen to a carbene and the corresponding α-elimination are important basic reactions in organic chemistry, little experimentally confirmed information is available concerning the thermal pathway of these reactions.[1] From a mechanistic point of view a general reaction coordinate, which is characterized by two electronically complementary limiting cases, can be formulated for these processes. R. Hoffmann et al. have considered (qualitative theory) one of these limiting cases by using the example of chlorine addition to difluorocarbene (Scheme 1, left branch).[2] According to these studies the polar α-addition of the halogen molecule X_2 **2** is initiated by a valent (i.e. 2c/2e) LAB (Lewis Acid Base) interaction between the π^* orbital of the halogen (HOMO) and the $2p_z$ orbital of the (S)-carbene **1** (LUMO), from which primarily the halonium ylide **3** should result.[2] Its conversion to the methane derivative **6** can now proceed by the familiar route of sigmatropic 1,2-shifts in ylides. As in the Stevens rearrangement the latter process could also involve radical pairs (in our case **3a**)—a mechanistic option not discussed by Hoffmann.[3]

In this case the reaction between **1** and **2** would be initiated by a hypervalent LAB-interaction between the sp_2 lone pair of the carbene and the σ^* LUMO of the halogen (Scheme 1, right branch). This interaction should initially lead to the hypervalent 3c/4e situation **4** within the framework of an S_N2 reaction at the halogen X. Depending on the substituents R^1/R^2 as well as the

Scheme 1.



halogen X, the latter structure should either have the character of an intermediate or a transition state on the way to the inner ion pair **5** and/or the methane derivative **6**. If one uses the relative stabilities of the structurally related trihalides X_3^- as a guide,[4] the formal combination of a nucleophilic carbene with molecular iodine should give the best chance of obtaining systems of the type **4** and thus of being able to study them experimentally. In earlier work we have repeatedly pointed out the possibility that certain anomalies in the chemical behavior of

[**] Iodocarbenium Ions, Part 4. This work was supported by the Fonds der Chemischen Industrie. Part 3: [5c].

donor-substituted iodocarbenium iodides of the general type **5** might be explained by the assumption of n-σ* contacts between the oppositely polarized iodine centers.[5] However, the experimental material did not allow any statements about the nature and structural consequences of these hypervalent contacts. We have now for the first time succeeded in obtaining a crystalline simple donor-substituted iodocarbenium iodide and in answering, with the aid of a crystal structure analysis, some of the questions raised above.

N-(Iodomethylene)piperidinium iodide (*N,N*-pentamethylene(iodomethylene)iminium iodide) (**8**) served as a model system. This compound could be obtained readily from the corresponding dichlorine system 7 by a halogen exchange reaction with Me_3SiI in CH_2Cl_2 and subsequent precipitation with Et_2O.[6]

7 **8**

On cooling the reaction mixture to −18 °C, **8** precipitates as yellow needles, suitable for X-ray structure analysis.[7] The structure of **8** is shown in Figure 1.

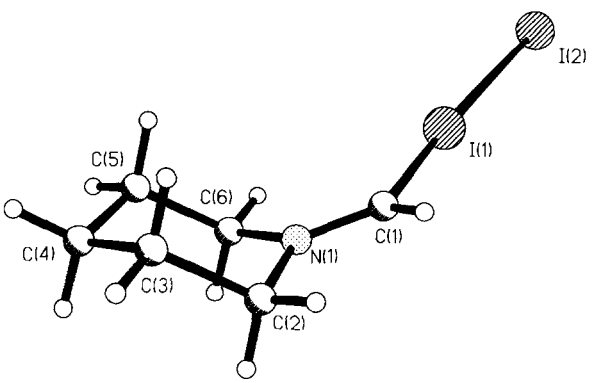

Fig. 1. Crystal Structure of **8**. Important distances [Å] and angles [°]: C1–I1 2.132, I1–I2 3.330, C1–N1 1.461; C1–I1–I2 176.8, N1–C1–I1 125.7

The asymmetric unit consists of four molecules whose C–I and I–I distances differ somewhat (C–I: 2.063–2.132 Å; I–I: 3.330–3.440 Å). The C-I-I bond angles vary between 171.3 and 177.5°. The C–I distances in **8** are clearly longer than the typical vinylic C–I bond lengths of approximately 2.03 Å.[8] With an average length of 3.37 Å, the I–I bond lengths in **8** almost correspond to the arithmetic mean of the I–I distance in molecular iodine (2.66 Å)[9] and the I–I distance of 4.3 Å[9] of the inner ion pair expected on the basis of the sum of the van der Waals radii. Accordingly, with its almost linear C-I-I sequence, the structure has the characteristics of a new type of hypervalent 3c/4e bonding system. The latter corresponds to a "frozen transition state" of I_2-elimination from a donor-stabilized diiodomethane and marks for the first time a characteristic point on the reaction coordinate of the polar α-elimination. An ab initio calculation on the structural analogue *N,N*-dimethyl(iodomethylene)iminium iodide confirms, in principle, our experimental findings.[10] The difference between the I–I distances calculated for the gas phase (3.01 Å) in $Me_2\overset{+}{N}{=}CHI\ I^-$ and the crystallographically determined I–I bond lengths in the analogous system **8** can be explained by the occurrence of additional secondary donor–acceptor interactions in the crystal, between an available lone pair at the terminal iodine and the empty p_z orbital at the carbenium center of the unit lying underneath it (C–I distance: ≈3.5 Å). These intermolecular interactions should cause a weakening of the n–σ* contacts discussed above. This again results in a shorter experimental C–I bond length than that calculated ($C-I_{calculated}$: 2.25 Å). The system calculated for the gas phase is thus already more advanced on the reaction coordinate of the α-elimination. A further consequence of this association is the low solubility of **8** in common organic solvents, which we have already observed with other iodocarbenium iodides.[5]

G. Maier et al. reported in 1986 on the photochemical generation and matrix isolation of the parent compound of the iodocarbenium iodides, $CH_2I^+\ I^-$.[11] The authors concluded from spectroscopic studies that this species has the character of a contact ion pair of type **5**, and not that of a hypervalent system of type **4**. These results contrast markedly to our findings on the donor-substituted iodocarbenium iodide **8**, for which one would a priori expect ion pair character rather than for $CH_2I^+I^-$ due to its internal mesomeric stabilization. Effects of the medium could be responsible for this divergence, alternatively the possibility exists that the species produced by Maier et al. rather has the character of a halonium ylide of type **3**. Theoretical calculations by these authors in a later publication also indicate this possibility.[12]

Experimental Procedure

All manipulations were carried out under nitrogen in dried N_2-saturated solvents. A solution of Me_3SiI (0.9 mL, 1.22 g, 6.1 mmol) in CH_2Cl_2 (5 mL) was added dropwise to a solution of 7 [13] (0.512 g, 3.05 mmol) in CH_2Cl_2 (20 mL) at 0 °C. After stirring at 20 °C for 12 h, **8** was precipitated as a yellow solid from the solution with diethyl ether. Subsequently the product was dried for 8 h under high vacuum. Yield: 0.984 g (92%). Single crystals of **8** were obtained after storing the filtrate at −20 °C for two months. Correct C,H,N elemental analyses. ^{1}H NMR (400 MHz; SO_2, −60 °C, [D_6]acetone): δ = 10.56 (s, 1H; CHI), 4.45 (br, s, 4H; CH_2), 2.18 (br, s, 6H; CH_2); ^{13}C NMR (100 MHz; SO_2, −60 °C, [D_6]acetone: δ = 143.4 (CHI), 66.3 (CH_2), 61.8 (CH_2), 26.8 (CH_2), 26.2 (CH_2), 22.6 (CH_2); IR (KBr): ν[cm^{-1}] = 2947m, 2863m, 1695s, 1608m, 1443m, 1370m, 1347m, 1295m, 1021m, 1000s, 954m, 909m, 859m, 843m, 805m, 767m, 634m, 605m, 559br, 434s, 335m.

Reductive Disproportionation of NO Mediated by Copper Complexes: Modeling N_2O Generation by Copper Proteins and Heterogeneous Catalysts**

Christy E. Ruggiero, Susan M. Carrier, and William B. Tolman*

Copper ion-mediated reduction of nitric oxide (NO) to nitrous oxide (N_2O) or dinitrogen (N_2) is important in biological denitrification, whereby anaerobic organisms utilize nitrogen oxides as electron acceptors for metabolism,[1] and in heterogeneous catalytic processes useful for pollution control.[2] Although mechanistic investigations have implicated copper/NO interactions in the generation of N_2O and/or N_2 by metalloenzymes (e.g., nitrite reductase)[3] and heterogeneous catalysts (e.g., copper-exchanged zeolites),[4] there is a general lack of knowledge of the chemistry of $Cu-N_xO_y$ species with which to evaluate the plausibility of postulated reaction pathways.[5] As part of our efforts to provide such a chemical foundation, we have isolated and determined the geometric and electronic structures of mononuclear copper nitrosyl complexes ([$Tp^{RR'}$CuNO], where R = *t*Bu, R′ = H, or R = R′ = Ph, and $Tp^{RR'}$ refers to the tris(1-pyrazolyl)hydroborate anion; R and R′ denote the substituents at the 3- and 5-positions of the pyrazole rings, respectively),[6] that provide the chemical precedent for NO binding to single copper ions in proteins and in zeolites.[7] These novel compounds were reversibly formed upon treatment of [$Tp^{RR'}Cu^{I}$] precursors with NO (g). In the presence of excess NO and in the absence of dioxygen or added ligands such as CH_3CN or CO, [Tp'^{BuH}CuNO] exists unchanged in solution for longer than a day. Here we report that when Cu^{I} complexes of the less sterically hindered supporting ligands Tp^{Ph2} or Tp^{Me2} are allowed to stand under an excess of NO (1 atm), the initially formed NO adducts cleanly convert to Cu^{II} nitrite complexes and N_2O in a well-defined disproportionation reaction that models possible copper-mediated N_2O formation routes in biological and heterogeneous catalytic systems.

Exposure of colorless solutions of [$Tp^{Me2}Cu]_2$ (**1**)[8] or [$Tp^{Ph2}Cu(CH_3CN)$] (**2**)[9] in CH_2Cl_2 to excess NO (1 atm) resulted in the rapid (within 5 min) formation of equilibrium quantities of [$Tp^{R2}Cu(NO)$] (**3**, R = Me, or **4**, R = Ph), which were identified by diagnostic metal-to-ligand charge transfer (MLCT) features at 494 nm or 478 nm in their respective UV/VIS spectra.[7] Upon standing, the NO-saturated solutions of **3** or **4** turned green or yellow, respectively, and generated one equivalent of N_2O [90–95% yield, based on copper; determined by GC; Eq. (a)]. The colored products were identified as nitrito

$$\underset{\text{or}}{\tfrac{1}{2}[(Tp^{Me2}Cu)_2]\ \mathbf{1}} \quad \underset{[Tp^{Ph2}Cu(CH_3CN)]\ \mathbf{2}}{} \quad + 3\,NO \longrightarrow [Tp^{R2}Cu(NO_2)] + N_2O \qquad \begin{matrix}\mathbf{5}\ (R = Me)\\ \mathbf{6}\ (R = Ph)\end{matrix} \qquad (a)$$

complexes (**5**, R = Me; **6**, R = Ph) by comparison of their spectroscopic properties to independently synthesized samples, and were shown by UV/VIS and EPR spectroscopies to be produced in quantitative yields. When $^{15}N^{18}O$ was used as substrate in the reaction with **1**, fully labeled products predominated,[10] a result that argues against involvement of other N- or O-containing species in the reaction (for example, possible contaminants N_2, N_2O, or O_2) and confirms that both N_2O and NO_2^- arise from NO. Although NO-disproportionation reactions are known for other transition metals,[11] to our knowledge well-defined examples of such a transformation mediated by copper complexes have not been reported.[12]

An X-ray crystal structure determination of **5** revealed symmetric, bidentate binding of nitrite to a square-pyramidal Cu^{II} ion (Fig. 1).[13] The coordination geometry of **5** contrasts with

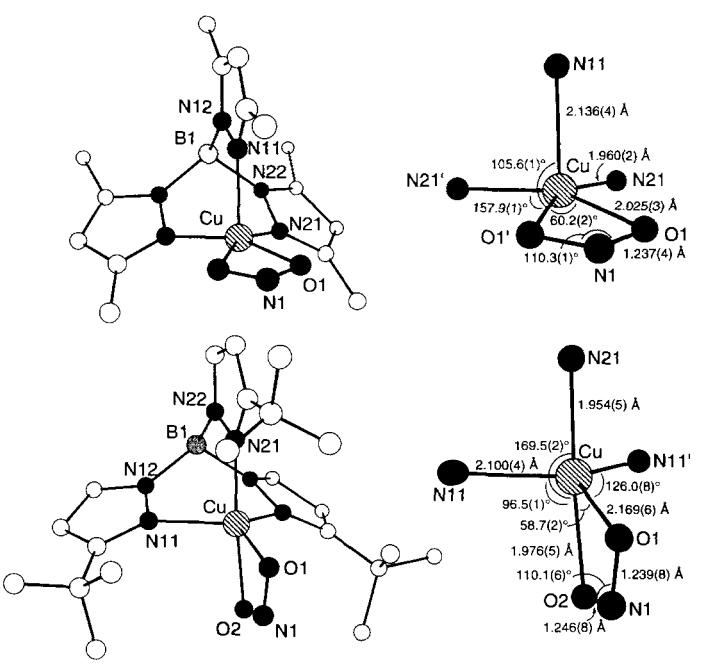

Fig. 1. X-ray crystal structures of **5** (top) and [$Tp'^{BuH}Cu(NO_2)$] (bottom, from ref. [5b]), with full views on the left and views of the copper coordination spheres on the right (selected bond distances [Å] and angles [°] given; hydrogen atoms omitted for clarity).

that of the previously characterized analog $[Tp^{tBuH}Cu(NO_2)]$,[5b] reproduced for comparison in Figure 1, which exhibits differing $Cu^{II}-O_{nitrite}$ bond lengths and a distorted trigonal-bipyramidal structure. These structural differences, which presumably result from divergent steric influences of the Tp substituents, are reflected in disparate EPR spectroscopic properties for the two complexes; the signal of **5** is axial ($g_\perp = 2.09$, $g_\parallel = 2.32$, $A_\parallel = 128$ G, $A_{N\perp} = 14$ G) while that of $[Tp^{tBuH}Cu(NO_2)]$ is distinctively rhombic.[5b] Either complex can be envisioned as a speculative model for the substrate adduct to the monocopper site of nitrite reductases,[5b, 14] and we suggest on the basis of the observed differences between the synthetic analogues that similar variability in nitrite orientation and/or Cu^{II} coordination geometry is possible in the enzymes.

Mechanisms for the copper-mediated disproportionation reaction may be envisioned that involve binding of a second NO molecule to the copper ion of the initial nitrosyl complex to afford a *cis*-dinitrosyl compound (**A**, path 1, Scheme 1), direct attack on the coordinated nitrosyl to form a monocopper N_2O_2 adduct (**B**, path 2), or dimerization of the copper nitrosyl compound to generate a μ_2-$(NO)_2Cu_2$ unit (**C**, path 3). An intermediate like **C** was previously suggested to be involved in the reaction of a Cu^I_2 compound with NO that afforded N_2O and a $Cu^{II}-O-Cu^{II}$ complex.[5a] Subsequent N–N bond formation from **A** or **C** could generate mono- or dinuclear $Cu-N_2O_2$ species like **B**. Analogous complexes with $N_2O_2^{n-}$ ligands ($n = 0$, 1, or 2) have been generated from NO[15] and have been proposed as intermediates in NO disproportionation reactions catalyzed by other transition metals[11, 16] and by zeolites,[4] as well as in the formation of N_2O by both iron and copper nitrite reductases.[17] Rapid electron transfer from Cu^I to generate Cu^{II} and a $N_2O_2^-$ adduct, elimination of N_2O, and reaction with a third NO molecule to give NO_2^- may be envisioned to occur subsequently in all cases (paths 1–3) in some (undefined) order.

Scheme 1. Possible mechanisms for the disproportionation reaction (R = R′ = Ph or Me; $Tp^{RR'}$ refers to the tris(1-pyrazolyl)hydroborate anion, and R and R′ denote the substituents on the 3- and 5-positions of the pyrazole rings, respectively). Oxidation states of the metal and nitrogen oxide ligands are not shown due to potential ambiguities inherent in such assignments for these redox active species (see ref. [7]).

Monitoring UV/VIS spectroscopic changes as a function of time allowed calculation of a pseudo-first-order rate constant for the reaction of **4** (R = Ph) with excess NO ($k_{obs} = 1.3(2) \times 10^{-4}$ sec^{-1} at 24 °C; $t_{1/2} = 1.5$ h), which remained constant within experimental error when the copper concentration was varied (10-fold range) and when either loss of **4** ($\lambda_{max} = 478$ nm) or gain of **6** ($\lambda_{max} = 798$ nm) was followed (Fig. 2). Thus, the order of the reaction with respect to the copper nitrosyl precursor is one, clearly ruling out dimerization of copper species as a rate limiting step and, assuming that the subsequent steps are relatively fast, supporting the initial mononuclear paths 1 or 2 (Scheme 1). Kinetic analysis of the faster ($t_{1/2} \approx 8$ min) reaction of **3** (R = Me) was complicated by the similarity between the rate at which the **1**/**3** equilibrium (K) was reached (k_1 step) and the rate of formation of **5** and N_2O (k_2 step). Nonetheless, reasonable preliminary fits of the data to yield pseudo-first-order rate constants $k_{obs(1)} \approx k_{obs(2)} \approx 3 \times 10^{-3}$ sec^{-1} at 24 °C were obtained using a kinetic scheme involving preequilibrium formation of **3** followed by irreversible reaction with additional NO molecules, consistent with paths 1 or 2 (Scheme 1).[18] Further work directed toward isolation of possible reaction intermediates and acquisition of more detailed kinetic information is underway.

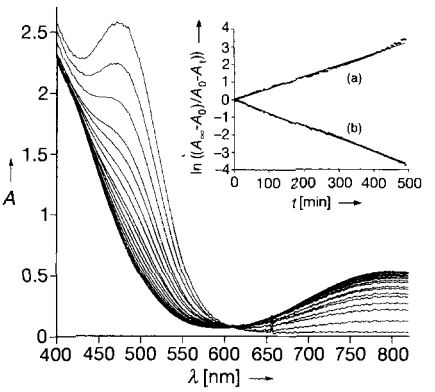

Fig. 2. Electronic absorption spectra showing the loss of **4** (478 nm) and the formation of **6** (798 nm) as a function of time. Spectra are shown at 30 min intervals. Inset: First-order plots for loss of **4** (a) and gain of **6** (b).

Experimental Procedure

5: Solutions of $CuCl_2 \cdot 2H_2O$ (490 mg, 2.90 mmol) in MeOH (1 mL) and $NaNO_2$ (399 mg, 5.79 mmol) in MeOH (5 mL) were simultaneously added to a solution of KTp^{Mc2} [8] (650 mg, 1.93 mmol) in CH_2Cl_2 (15 mL). The solution immediately turned green, and a precipitate formed. After stirring for 10 min, the solution was filtered, the filtrate was concentrated to 5 mL, and 1 mL MeOH was added. The solution was further concentrated until green microcrystals formed. The crystals were collected by filtration (408 mg, 52% yield). X-ray quality crystals were obtained in 50% yield by recrystallization from CH_2Cl_2/Et_2O. IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2931, 2518 (B-H), 1541, 1450, 1419, 1386, 1351, 1291, 1197, 1067, 1048, 982, 877, 846, 805, 768, 689, 669, 644; UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 260 (800), 306 (1000), 370 (420), 800 (110); EPR (9.47 GHz, CH_2Cl_2/toluene, 77 K): $g_\perp = 2.06$, $g_\parallel = 2.33$, $A_\parallel = 145$ G, $A_{N\perp} = 14$ G, $A_{N\parallel} = 12$ G; correct C,H,N analysis.

6: This complex was prepared analogously to **5**, except anhydrous $CuCl_2$ was used, and the product was initially precipitated from cold (−20 °C) CH_2Cl_2 prior to CH_2Cl_2/Et_2O recrystallization (53% yield). **6**: IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3062, 2623 (B-H), 1546, 1474, 1426, 1364, 1283, 1283, 1234, 1173, 1070, 1011, 917, 878, 808, 762, 570; UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 258 (19000), 300 (sh, 1500), 400 (400), 798 (100); EPR (9.47 GHz, CH_2Cl_2/toluene, 77K): $g_\perp = 2.09$, $g_\parallel = 2.32$, $A_\parallel = 128$ G, $A_{N\perp} = 14$ G; correct C,H,N analysis.

Evidence of Room-Temperature Superconductivity in the Bi-Sr-Cu-O System**

Richard S. Burrows, Darl H. McDaniel*

In 1988, H. G. von Schnering et al.[1] reported the observation of superconductivity with an onset temperature of 140 K and zero resistivity at 80 K in a sample of $Bi_2Sr_2(Ca_{trace})CuO_x$ (Bi2202, $x = 6 + \delta$). No repetitions of this observation have been reported until now. Using a sol-gel preparative route,[2] we have observed the 140 K superconducting phase a number of times, with evidence of both higher T_c and lower T_c phases being present as well. We describe here the preparation and characterization of these samples and present a possible explanation for the evolution of the superconducting phases. Figure 1 shows the magnetic susceptibility vs. temperature with significant abrupt decreases below 150 K and 50 K, Figure 2 shows a magnetization curve at 130 K displaying hysteretic behavior characteristic

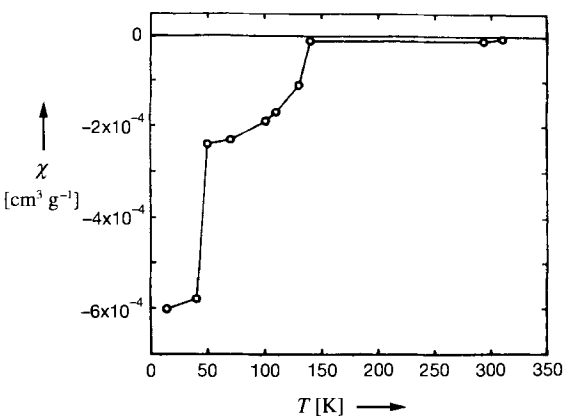

Fig. 1. Magnetic susceptibility vs. temperature of a nominal $Bi_2Sr_2CuO_6$ prepared by a sol–gel route indicating a negative susceptibility at 300 K.

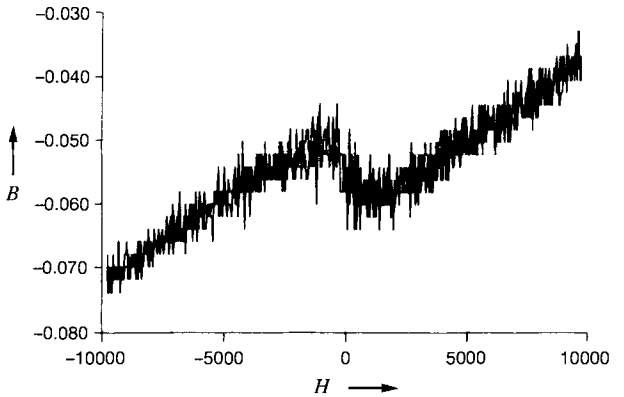

Fig. 3. A magnetization curve at room temperature showing the persistence of diamagnetism with induced paramagnetic behavior at higher field strength (B and H, see Fig. 2).

of flux pinning of Type II superconductors, and Figure 3 shows a room temperature curve displaying the persistence of diamagnetism with induced paramagnetic behavior at higher field strength. The observed phenomena in this sample persisted for over one month, during which time the sample was kept in a Kel-F holder. The sample was removed at that time to check the background of the holder, which was found to be very slightly paramagnetic. On returning the sample to the holder, the previously observed diamagnetic signal had disappeared.

Figure 4 depicts a hysteresis loop obtained by vibrating sample magnetometry for another nominal Bi2201 sample at room temperature, the thermal limit of our instrument (EG & G ORTEC). Using a thermogravimetic analyzer (Perkin

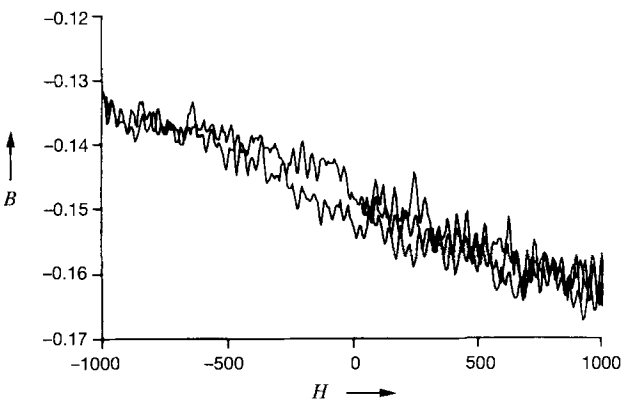

Fig. 4. A magnetization curve obtained at 300 K displaying hysteretic behavior for a second sample of nominal $Bi_2Sr_2CuO_6$ composition (B and H, see Fig. 2).

Elmer), we determined what we believe to be the superconducting critical temperature of this second sample. By placing a magnet just below the sample, we observed an apparent weight loss which was reversible after removing the magnet from the sample proximity and which was not due to interactions of the platinum cup or stirrup with the magnetic field. Upon warming the sample, we observed a weight increase until 350 K whereupon, the sample began to lose weight. We interpret the weight gain as a loss of superconducting volume fraction as a function of temperature until the T_c was achieved at 350 K. We have now prepared a total of eight Bi2201 samples (some with Pb or Li doping) showing evidence of room temperature superconductivity, and an additional 14 samples showing superconductivity between 25 and 110 K. (The literature T_c values for Bi2201 range from 4 to 18 K.[3–7]) All of our high-temperature superconducting samples exhibit temporal instability with the superconducting signal disappearing within hours to days.

The following procedure has shown a success rate of about 10% in yielding superconducting samples with T_c above 50 K. Chemicals used in this work were commercial reagent grade materials (Aldrich, Fisher Scientific, and Baker) and were used as received. Oxides and carbonates were individually dissolved in near stoichiometric amounts of 8 M nitric acid (slight excess in the case of bismuth) and each metal solution subsequently diluted to 0.1 M. Half-molar ethylenediaminetetraacetic acid (EDTA) solution was prepared by adding enough 6 M aqueous ammonia to bring about dissolution. Each solution of metal ions was individually chelated with stoichiometric amounts of EDTA solution. The chelated-metal salt solutions were then mixed and the pH adjusted to near 7.0, after which, the solution was evaporated at 40–60 °C until a blue gel formed. The gel was then charred between 250 and 300 °C in a 250 mL crucible in an electrically heated sand bath. The crucible mouth was covered by a watch glass to prevent excessive air flow over the hot char material. (**Caution:** Excess acid in the dissolution stage should be avoided as ammonium nitrate which is formed upon neutralization leads to flashing of the sample near 160 °C.) After charring, the cooled ash was ground using an agate mortar and pestle to reduce the sample volume and increase sample homogeneity. The ashed sample was then transferred to a combustion boat and annealed at temperatures between 795 and 840 °C under air. Although char colors varied from black to yellow/green, the yellow/green samples were discarded due to the presence of phase-separated Bi_2O_3. Dark brown colored chars gave the most favorable results. Annealed samples which were black with a slight brown tint gave the best magnetic characteristics. Annealing and cooling conditions used in this work are summarized in Table 1. We had no success in preparing superconducting pellet samples from previously calcined material. Pellets were made from pressed precursor ash, but exhibited microcracks and porosity. On two occasions, metal-like conductivities were measured, but neither sample indicated temperature dependence between 77 and 300 K. On one of these trials, the temperature sensor failed on attempting a 400 K measurement.

Table 1. Annealing conditions for the nominal Bi-Sr-Cu-O samples.

Nominal stoichiometry	T [°C]	Duration [h]	T [°C]	Duration [h]	Cool cycle [a]
Bi2201	800	10.00	320	12	p/q
$Bi_2Sr_{1.9}Li_{0.1}CuO_6$	805	4.75	–	–	f/c A
Bi2201	813	0.50	–	–	quench
Bi2201	796	1.33	–	–	quench
Bi2201	750	6.20	–	–	B
$Bi_2Sr_{1.8}Pb_{0.2}CuO_6$	840	22.00	–	–	f/c
$Bi_2Sr_{1.8}Pb_{0.2}CuO_6$	825	2.50	844	22	f/c
$Bi_2Sr_{1.8}Pb_{0.2}CuO_6$	840	17.83	–	–	quench

[a] P/q: A partial quench from 300 °C. f/c: Samples cooled over a period of nearly 30 min. A: Cooled under an oxygen atmosphere. B: Slow cooled to 560 °C under O_2 and to room temperature under nitrogen over a seven hour period.

Powder X-ray patterns (Siemens) made from 10-hour scans of the superconducting samples were assigned to five different phases. The majority phase was the Bi2201 material; the signals of the minority phases (three of which were strontium cuprates) were nearly equivalent in intensity. Our findings are consistent with the conclusions of Schlichemaier et al.[8] who reported that

Bi2201 cannot be prepared phase pure. Lattice parameters for the alkaline-earth metal cuprate systems in this work closely match those previously reported for alkaline-earth metal cuprates.[9–12] Table 2 summarizes the phases fit to the X-ray diffraction patterns. The unknown phase is believed to be a "doubling" of the Bi2201 unit cell along the c axis. This c axis length is approximately the same length reported by Michel et al.[3]

Table 2. Lattice parameters for the phases fit to nominal $Bi_2Sr_2CuO_6$ samples.

Phase	a [Å]	b [Å]	c [Å]	Ref.
Bi2201	5.392	5.394	24.45	[3–7]
$SrCuO_2$ [a]	3.56	16.32	3.92	[13, 15]
$SrCuO_2$ [b]	3.90	3.90	3.35	[15, 17]
Sr_2CuO_3	12.7	3.5	3.9	[14, 16–18]
[c]	–	–	47.6	[3]

[a] Orthogonal phase. [b] Tetragonal phase. [c] This unknown phase was fit with only lattice parameters of (00l).

Although the crystal structures of alkaline-earth metal cuprates[9, 10] have been known for some time, reports of new synthetic routes, solid solutions, and defect studies have recently appeared.[11–14] Azuma et al.[15] indicate that the tetragonal $Sr_{1-x}Ca_xCuO_2$ phase is responsible for superconducting behavior observed up to 110 K, which has been improved to 180 K by Li et al. in $Ca_{1-x}Sr_xCuO_2$.[16] Undoped $SrCuO_2$ has also been reported by Hiroi et al.[17] to superconduct at 100 K. Since we have observed reflections of tetragonal $SrCuO_2$ in all but one of our high-temperature superconducting samples by X-ray diffraction, the tetragonal $SrCuO_2$ is a good candidate for the high-temperature superconducting component produced in our samples. The $SrCuO_2$ may grow selectively on the surface of a Bi2201 template. Strain would be introduced by the mismatch in the lattices between the two phases at their interface. The $SrCuO_2$ superconducting properties would therefore be subject to the stresses of the aging Bi2201 template as well as any degradation caused by the ambient atmosphere, resulting in temporal instability. While von Schnering found superconductivity at 140 K in Bi2201 containing a trace of calcium, we found no evidence of calcium incorporation in our samples to form $Bi_2Sr_2CaCu_2O_8$ by X-ray diffraction and believe that the presence of calcium in von Schnering's 140 K sample may be coincidental to its superconductivity. Hagberg et al.[18] described the observation of a "hyper-diamagnetic" signal at 240 K in nominal $Bi_{1.9}Pb_{0.4}Sr_{1.9}Ca_{2.0}Cu_{3.2}O_x$. Some very low intensity reflections in powder X-ray diffraction patterns reported by Hagberg et al.[18] appear to be assignable to phase-separated strontium cuprate which might be responsible for their observed signal. Laguës et al.[19] have recently found evidence of superconductivity at 250 K in an artificially layered BiSrCaCuO system. Their high-temperature superconductor also appears to be a small volume fraction of their sample.

History of Chemistry

Histoire de la chimie. By *B. Bensaude-Vincent* and *I. Stengers*. La Découverte, Paris, 1992. 360 pp., paperback FF 180.00.—ISBN 2-7071-2192-4

The Fontana History of Chemistry. By *W. H. Brock*. Fontana Press, London, 1992. 744 pp., paperback £ 8.99.—ISBN 0-00-686173-3

We chemists are fascinated by our history. An historical approach to teaching gives depth and perspective to the subject. It provides role models and helps to start vocations. It brings in the human element, indeed a humanistic touch. In research, the historical dimension reframes one's own efforts. It can give ideas. A paper by Naumann in the 1904 *Berichte* helped us to devise the new reagent "clayfen." Furthermore, there may be lessons in the constantly reshuffling history of the subject that we never learned from, or were never taught by our mentors. And, now that we live in a global village, past histories, centered on Europe in the ninetheenth century, are too restrictive.

Before reading the two books reviewed, I drew up a check-list consisting of these ten items: coverage of ancient Chinese alchemy and chemistry; of Arabic alchemy; chlorine bleaching (Scheele, 1773; Berthollet, 1785); Humphrey Davy's diamond combustion; Ampère and representative shapes for molecules (1814); Faraday's isolation of benzene; Ostwald's role in the birth of physical chemistry; Ehrlich's devising of drugs for tropical diseases; the phase rule; Bayer's invention of the polyurethanes. Then I graded each book, from 0 (no mention) to 10 (adequate coverage) on each item. By this method, coverage by the French book scores 20%, that by the British book 47%. To be fair, however, *History* gave itself, justifiably, twice the space of *Histoire*.

Chemists are being eased out from their own history. In spite of the living tradition of chemists as historians of their own discipline—contemporary examples include Joseph Needham, Joseph S. Fruton, and the ACS books edited by Jeffrey I. Seeman—historians of chemistry claim the field as their own. The strategy can be blunt, or it can be more subtle. *Histoire* states emphatically that chemists in our century are no longer engaged in history of chemistry. Counter-examples include J. R. Partington, as well as the above short list! *Histoire* denies an identity to chemistry. It claims conversely that chemistry reduces to its history alone. And this history is defined, prior to being set in concrete by the pure historians. *Histoire* tells the same traditional and rather boring history that originates with Partington and overemphasizes such topics as nomenclature, the Leblanc and Solvay processes, and the Berthelot contributions to organic synthesis; to the detriment of stereochemistry, coordination chemistry (*Histoire* does not even mention Werner's name), catalysis, rare gas chemistry, or the Dow chlorine chain. An additional ploy of historians to wrest the field from the chemists is to end the narrative in the 1930s, so as to avoid tempting living chemists to jut in and to set the record straight.

Histoire is marred by careless mistakes: *Roger* B. Woodward and Ro*n*ald Hoffma*n*: Kekul*e*; *V*an't Hoff. The tone of ironic condescension, such as the constant reference to "professorial chemistry", grates.

Histoire is organized in 32 tripartite chapters. Such segmentation makes for easy reading; each episode is narrated and analyzed in a couple of pages. Some are done in an exemplary manner: the reception in France of Dalton's atomic theory, for example. These discursive segments were composed, it appears, almost exclusively from secondary sources; virtually all quotations from primary material are borrowed from other historians rather than from the properly acknowledged original.

History is a very different book, delightful to read, with little one can take issue with. The author not only avoids denigrating chemists, he understands chemistry. The format he has chosen explains his success: each chapter is centered on a seminal textbook. Thus, Brock goes in succession through Multhauf's and Partington's histories, Boyle's *Sceptical Chymist*, Lavoisier's *Traité Élémentaire*, Dalton's *A New System of Chemical Philosophy*, Liebig's *Anleitung zur Analyse organischer Körper*, Laurent's *Méthode de chimie*, James Sheridan Muspratt's *Chemistry: Theoretical, Practical and Analytical as applied and relating to the Arts and Manufactures*, Mendeleev's *Principles of Chemistry*, John Servos's *Physical Chemistry from Ostwald to Pauling: The Making of a Science in America*, Cannizzaro's *Sketch of a Course of Chemical Philosophy*, Pauling's *Nature of the Chemical Bond*, Ingold's *Structure and Mechanism in Organic Chemistry*, and Nyholm's *Renaissance of Inorganic Chemistry*. This organization gives autonomy to the chapters; each reads like a small essay (plus the final bibliographical essay, hard to fault in coverage).

The writing is consistently pleasurable, with the occasional chuckle (arsole, p. 603). Some features are genuine finds, such as the parallel between Australian and Japanese chemistries, or the percipient note on the dominance of the teaching market by American books since the 1960s. Conversely, *History* is a bit fastidious on academic moves, and exaggerates the importance of University College, London, in 20th century chemistry. I felt that Brock struggled with the problem of fitting into his intricate patchwork at least a passing mention of every crucial name. I did not find howlers, only irritants. Carothers's suicide had reasons more complex than feelings of inadequacy as a scientist: he had been aggrieved by his sister's death, and his new director of research at DuPont was giving him a hard time. Mukaiyama's name is misspelt. An obsolete graphical symbol for benzene is still used (p. 622). And C_{60} can be argued to be a natural molecule (soot, rocks, interstellar matter) rather than an "invented" one.

To sum up on these two books: condescension backlashes, admiration does not err.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

New Books

Dynamics of Excited Molecules. Edited by **K. Kuchitsu.** Elsevier, Amsterdam, **1994.** 620 pp., hardcover, Dfl. 495.00.—ISBN 0-444-81796-4

Theories and Mechanism of Phase Transitions, Heterophase Polymerizations, Homopolymerization, Addition Polymerization. (Advances in Polymer Science, Vol. 112). Edited by **A. Abe, H. Benoit, H.-J. Cantow et al.** Springer, Heidelberg, **1994.** 307 pp., hardcover, DM 198.00.—ISBN 3-540-57236-8

Polymer Synthesis. (Advances in Polymer Science, Vol. 111). Edited by **A. Abe, H. Benoit, H.-J. Cantow et al.** Springer, Heidelberg, **1994.** 227 pp., hardcover, DM 188.00.—ISBN 3-540-57198-1

Luftreinhaltung, 3rd Ed. By **G. Baumbach.** Springer, Heidelberg, **1994.** 461 pp., paperback, DM 78.00.—ISBN 3-540-56823-9

Ab Initio Variational Calculations of Molecular Vibrational-Rotational Spectra. (Lecture Notes in Chemistry, Vol. 61). By **D. J. Searles, E. I. v. Nagy-Felsobuki.** Springer, Heidelberg, **1993.** 186 pp., paperback, DM 58.00.—ISBN 3-540-57465-4

Stereoselective Synthesis. Edited by **E. Ottow, K. Schöllkopf, B.-G. Schulz.** Springer, Heidelberg, **1993.** 136 pp., hardcover, DM 128.00.—ISBN 3-540-57202-3

TA-Siedlungsabfall. Kommentar unter Berücksichtigung der aktuellen Gesetzeslage. Edited by **Bundesverband der Deutschen Entsorgungswirtschaft e. V.** Merz Verlag, Bonn, **1994.** Paperback, DM 32.50.—ISBN 3-926108-26-6

Metalloporphyrins Catalyzed Oxidations. (Catalysis by Metal Complexes, 17). Edited by **F. Montanari, L. Casella.** Kluwer, Dordrecht, **1994.** 368 pp., hardcover, Dfl. 240.00. —ISBN 0-7923-2657-1

Cyclodextrins in Pharmacy. (Topics in Inclusion Science, 5). By **K.-H. Frömming, J. Szejtli.** Kluwer, Dordrecht, **1993.** 228 pp., hardcover, Dfl. 160.00.—ISBN 0-7923-2139-1

Conceptual Trends in Quantum Chemistry. Edited by **E. S. Kryachko, J. L. Calais.** Kluwer, Dordrecht, **1994.** 264 pp., hardcover, Dfl. 165.00.—ISBN 0-7923-2621-0

Oxygenates by Homologatin or CO Hydrogenation with Metal Complexes. (Catalysis by Metal Complexes, 16). Edited by **G. Braca.** Kluwer, Dordrecht, **1994.** 240 pp., hardcover, Dfl. 160.00.—ISBN 0-7923-2628-8

Spectra for the Identification of Monomers in Food Packaging. By **J. Bush, J. Gilbert, X. Goenaga.** Kluwer, Dordrecht, **1993.** 448 pp., hardcover, Dfl. 320.00.—ISBN 0-7923-2400-5

Fluorescent Chemosensors for Ion and Molecule Recognition. (ACS Symposium Series No. 538). Edited by **A. W. Czarnik.** American Chemical Society, Washington (USA), **1993.** 243 pp., hardcover, $ 69.95.—ISBN 0-8412-2728-4

Thermally Generated Flavors. (ACS Symposium Series No. 543). Edited by **T. H. Parliment, M. J. Morello, R. J. McGorrin.** American Chemical Society, Washington (USA), **1993.** 488 pp., hardcover, $ 109.95.—ISBN 0-8412-2742-X

Silk Polymers. (ACS Symposium Series No. 544). Edited by **D. Kaplan et al.** American Chemical Society, Washington (USA), **1993.** 253 pp., hardcover, $ 94.95.—ISBN 0-8412-2743-8

The Anomeric Effect and Associated Stereoelectronic Effects. (ACS Symposium Series No. 539). Edited by **G. R. J. Thatcher.** American Chemical Society, Washington (USA), **1993.** 290 pp., hardcover, $ 74.95.—ISBN 0-8412-2729-2

Physical Properties of Polymers, 2nd Ed. By **J. E. Mark et al.** American Chemical Society, Washington (USA), **1993.** 409 pp., hardcover, $ 59.95.—ISBN 0-8412-2505-2

Polymers for Microelectronics. (ACS Symposium Series No. 537). Edited by **L. F. Thompson, C. G. Willson, S. Tagawa.** American Chemical Society, Washington (USA), **1993.** 554 pp., hardcover, $ 119.95.—ISBN 0-8412-2721-7

Thin-Layer Chromatography, 3rd Ed. (Chromatographic Science Series, 66). By **B. Fried, J. Sherma.** Marcel Dekker, New York, **1994.** 464 pp., hardcover, $ 165.00.—ISBN 0-8247-9171-1

NMR Techniques in Catalysis. (Chemical Industries Series, 55). Edited by **A. T. Bell, A. Pines.** Marcel Dekker, New York, **1994.** 448 pp., hardcover, $ 165.00.—ISBN 0-8247-9173-8

Stoffe E-O. Hagers Handbuch der Pharmazeutischen Praxis, Vol. 8, 5th Ed. Edited by **F. v. Bruchhausen et al.** Springer, Heidelberg, **1993.** 1293 pp., hardcover, DM 610.00.—ISBN 3-540-52640-4

Solid-State NMR I: Methods. (NMR - Basic Principles and Progress, Vol. 30). Edited by **B. Blümich.** Springer, Heidelberg, **1994.** 281 pp., hardcover, DM 248.00.—ISBN 3-540-57189-2

Solid-State NMR II: Inorganic Matter. (NMR - Basic Principles and Progress, Vol. 31). Edited by **B. Blümich.** Springer, Heidelberg, **1994.** 215 pp., hardcover, DM 248.00.—ISBN 3-540-57190-6

Turning Points in Catalysis**

John Meurig Thomas*

This personal journey through the enlarging landscape of heterogeneous catalysis, pure and applied, starts with the discovery in 1823 of a dramatic example of the synthesis of water that was to serve as the basis of the first commercial exploitation of catalysis, Dobereiner's lighter (tinder box). The quickening pace of successive industrial innovations and of academic insight during the intervening 170 years are summarized and the turning points, both major and minor, identified. Although new concepts and new ideas emerged in relative profusion, few exhibited the longevity predicted for them at birth by their proponents. Some concepts, like broken milestones on a vanished road, have ceased to retain their significance. Some have survived, even flourished. But in catalysis, as in most other branches of natural science, new tools and new techniques, rather than new concepts, tend to hold sway. And just as experimental advances in enzymology and immunology have led to the design of remarkable new biocatalysts so also, but not yet at the same level of delicate control, have the tools and techniques of solid-state chemistry (including novel preparative and computational procedures), generated many powerful rationally designed inorganic catalysts.

1. Introduction

It is not an excess of multinational European fervor but a sense of innocent pride mingled with a respect for historical exactitude that prompts me to begin by recalling that Europe has been the crucible and fulcrum for change in the science and technology of catalysis for more than two centuries. Nowadays, however, catalysis has been so extensively woven into the fabric of life in all the industrialized nations that the practice and pursuit of the subject transcends both national and continental boundaries.

Although *concepts* and *ideas* occupy a central place in the grand sweep of our understanding of the nature of the world around us, it is a mistake to imagine that they play a greater role than *tools* and *techniques* in achieving scientific progress. Few scientific revolutions are concept-driven. They invariably grow and are ultimately accomplished through the agency of experiment. In the tortuous paths from genesis to maturity in most disciplines and topics, more profound influences are exerted by the arrival of new instruments, new techniques, and the discoveries that they engender, than by the formulation of new ideas.

Galileo's telescope played as crucial a role in the consolidation of the heliocentric view of the universe as did Copernicus's theory, which was, in any case, based on prior observations. Likewise, the optical micoscope of Leeuwenhoek, no less than the electron microscope of Ruska, and all the dazzling succession of microscopes now at our disposal, have revolutionized our appreciation of the architecture and texture of the invisible. And when Röntgen discovered X-rays and W. H. Bragg invoked a mathematical tool (invented by a famous Frenchman) to represent the intensities of diffraction spots in terms of Fourier series, machinery was set in motion that now gives us the means to derive electron distributions in solids and molecules and in individual chemical bonds—the very essence of our present-day interpretations of catalysis.

Mathematical tools such as the transform and series associated with Fourier's name, like the more tangible tools of the chemist such as chromatography and spectroscopy, can set us off in new directions. And even the identification of simple physical phenomena can, in certain contexts, constitute major turning points.[1]

So much for general observations. When we focus on catalysis we have to cope with a vast corpus of information. Besides the simple and complicated facts pertaining to its occurrence and practice—as well as the impressive armory of tools and techniques with which to pursue manifestations of the phenomenon—we have, in addition, another factor which is so pervasive and so much taken for granted that we tend to discount it as a determinant in the growth of the subject. This is the desire to exploit catalysis for practical purposes. The urge to gain mastery over, or to harness the forces of, nature and to exploit one's discoveries for practical or commercial ends is

irrepressible.[2] This urge is itself the engine of change, which brings forth new turning points.

1.1 The Early Days of Heterogeneous Catalysis and the First Commercial Exploitation: Döbereiner's Lighter

Even before Berzelius in 1835 coined the word catalysis in its modern connotation, applied catalysis was already a reality (Table 1). The writings of the Arabic alchemist, Jabir ibn Haiyan (Geber) in the eighth century reveal that mineral acid was then used as a catalyst for the production of ether by the dehydration of alcohol. Davy's discovery (at the Royal Institution, in 1817) consisted essentially in the observation that a pre-heated length of fine platinum wire could be made to glow in a mixture of air with coal gas, carbon monoxide, alcohol vapor, or similar substances, and that the glowing continued until all the inflammable material was consumed.[5]

Table 1. Historical overview of applied catalysis up to about 1900.

Jabir Ibn Haiyan (Geber)	8th Century	ether from alcohol (sulfuric acid catalyzed)
Kirchhoff	1814	acid-catalyzed hydrolysis of starch
Davy	1817–26	hot platinum, air, and coal gas
Döbereiner	1820s	tinder box (Feuerzeug)
Grove	1840	electrocatalysis, fuel cell
Phillips	1840s	$SO_2 \rightarrow SO_3$; sulfuric acid synthesis (Pt on montmorillonite as catalyst)
Mége-Mouries	1869	catalytic hydrogenation of oils
Normann	1901	octadecenoic acid to stearic acid

Over a period of seven days in late July–early August 1823 Döbereiner produced a dramatic example of the catalyzed synthesis of water. He directed a fine jet of hydrogen at a powdered platinum catalyst from a distance of four or so centimeters. The finely divided catalyst instantly became white hot and, with a strong jet, the hydrogen caught fire. This was the scientific principle that led Döbereiner in due course to produce his famous lighter—the forerunner of the matchstick—the so-called "feuerzeug" or tinder box.[6, 7] Scientific aspects of Döbereiner's discovery were pursued by Michael Faraday;[6] but another Englishman, one Alexander Garden, "a scientific chemist in Oxford Street, London"[7] was more concerned about its practical applications and, specifically, in "the idea of employing it for the instantaneous production of fire and light". By 1828, hundreds of thousands of Döbereiner's lighters had been mass produced by Gottfried Piegler in Schleiz (on the edge of the Thüringer Wald between Hof and Gera): some 20000 were in use in England alone that year.[7] One of them, which was received as a gift from Döbereiner by Faraday,[8] and which is now a treasured antique in the Director's flat at the Royal Institution, is shown in Figure 1. Döbereiner's lighter is reminiscent of the Kipp's apparatus for the generation of hydrogen sulfide: hydrogen is produced by the action of sulfuric acid on granules of zinc. The pressure of hydrogen that builds up stops the acid from continuing to fall on the zinc until a stopcock, releasing the hydrogen which impinges upon the platinum catalyst, is opened.

His lighter brought Döbereiner great fame.[7] It might also have brought him considerable fortune, but he characteristically refused to take out a patent, published all his designs, and spurned a large offer from an Englishman named Robinson for monopoly rights with the words "I love science more than money".[9] (Humphry Davy a little earlier had refused to patent his invention of the miners' safety lamp for similar reasons.[10] The desire to make money is not the only stimulus for technological enterprise!) Robinson prospered from the manufacture of Döbereiner tinder boxes (lighters), as did many others throughout Western Europe. This was the first example of the commercial exploitation of heterogeneous catalysis. And in spite of the invention of the safety match in 1848, by one of his former pupils, Böttger, the Döbereiner lighter retained its popularity for a long time and was still in use at the beginning of the First World War.[11]

John Meurig Thomas was born in South Wales in 1932 and took his initial degree in the University College of Swansea. For twenty years, after completing his Ph.D. in London, he taught in the University of Wales, first at Bangor, later as Professor and Head of Chemistry in Aberystwyth where his work in solid-state and surface chemistry led to his election as Fellow of the Royal Society in 1977. Called to the University of Cambridge to succeed Jack Linnett in 1978 he headed the Department of Physical Chemistry and was Professorial Fellow of King's College for nine years before taking over the Directorship of the Royal Institution of Great Britain in London where, as Fullerian Professor he continues his researches. He has received numerous awards, both nationally and internationally, including the premier one awarded every three years (Faraday medal) of the Royal Society of Chemistry, and the Messel Gold Medal of the Society of Chemical Industry. He has been elected honorary foreign member of six national academies and is the recipient of many honorary degrees. He has lectured extensively overseas, and gave the Baker Lectures at Cornell University on Solid State Chemistry in 1983. Author of several books (including one on 'Michael Faraday and the Royal Institution: the Genius of Man and Place') and over 700 articles, he was knighted for his services to chemistry and the popularization of science in 1991. For the last three years he has served as Deputy Pro-Chancellor of the University of Wales, and in 1993 was elected Master of the oldest College in Cambridge, Peterhouse. The book entitled "Principles and Practice of Heterogeneous Catalysis", which he wrote together with W. John Thomas, Bath, is due to be published at the end of 1994 by VCH.

Fig. 1. Michael Faraday received this "tinder box" (fire lighter) from Döbereiner, its inventor, in the late 1820s. In Döbereiner's lighter, the first example of the commercial exploitation of heterogeneous catalysis, a jet of hydrogen, which is generated by the action of acid on zinc, is allowed to impinge upon divided platinum. The catalyst becomes white hot and so the hydrogen catches fire.

In the late 1830s my countryman Grove pioneered the use of platinum as an electrocatalyst. He also demonstrated that platinum could equally readily catalyze the thermal decomposition of water vapor into hydrogen and oxygen as it could the combustion of hydrogen to water. Grove described his famous "gas battery" or fuel cell, of which he was the inventor, in a charming letter to Michael Faraday written in October 1842.[12]

W. R. Grove to M. Faraday
London Institution
Saturday Oct 22 1842
My dear Sir

I have just completed a curious voltaic pile which I think you would like to see, it is composed of alternate tubes of oxygen and hydrogen through each of which passes platina foil so as to drop into separate vessels of water acidulated with sulphuric acid the liquid just touching the extremities of the foil as in the rough figure below [see ref. [8]].

The platina is platinized so as to expose by capillary attraction a greater surface of liquid to the gas. With 60 of these alternations I get an unpleasant shock and decompose not only iodide of potassium but water so plainly that a continuous stream of thin bubbles ascends from each electrode. Thus water is decomposed by its composition—no oxidable metal is employed. I have reversed the tubes and tried all the counter expts but the phenomena are too marked I think to render any mistakes possible. Mr Gassiot was with me today and saw the Expts. Can you spare me an hour next week on Tuesday if it suits you or any day except Wednesday at any hour from 11 to 3— at the Laboratory of the London Institution. I cannot but regard the experiment as an important one both as to the chemical and other theories of the pile and as to the catalytic effects of the combination of the gases by platina.
I remain my dear Sir
yours very sincerely
W. R. Grove

In the early 1830s, Peregrine Phillips, an enterprising Englishman, patented a catalyst consisting of finely divided platinum supported on montmorillonite clay for the conversion of sulfur dioxide to the trioxide, thereby paving the way for the manufacture of sulfuric acid.

We must not forget, in France of all places, that it was a Frenchman, rejoicing in the name Hippolyte Mége-Mouries, who, in 1869, was the recipient of Napoleon III's prize for the best substitute for butter: he succeeded in catalytically hydrogenating natural oils thereby inventing margarine. Processes of this kind were to benefit greatly from the catalytic investigations of the German worker Normann more than thirty years later. It was Normann who, inter alia, succeeded in converting octadecanoic acid to stearic acid. Such processes were also much facilitated by the techniques of catalytic hydrogenation using metallic nickel pursued by Sabatier in France in the 1900s.

1.2. Heterogeneous Catalysis from the End of the Last Century to the End of the Second World War

Of the various landmarks summarized in Table 2, one notes that many of these processes are of vital importance even today. Working from the bottom up, the significance of the achievements of Lewis and Gilleland in the USA was that they introduced a fundamentally new kind of chemical engineering process, namely *fluidized catalytic cracking*. This certainly marked a turning point, not only because of its commercial efficiency and repercussions, but because it drew particular attention to the need in such operations for the catalyst particles used in the fluidized bed to possess an irreducible minimum attrition resistance. *Catalytic cracking* itself, using a fixed-bed reactor, had been introduced in 1936 by Houdry, a motor-racing enthusiast obsessively motivated by the desire to produce better -higher octane-rating- -fuel.

Table 2. Historical overview of applied catalysis 1900–1945.

Haber	1909	ammonia synthesis
Ostwald	1910...	nitric acid from ammonia
BASF	1920...	methanol synthesis
Fischer and Tropsch	1922	syngas chemistry
Union Carbide	1937	ethylene oxide (Ag)
Houdry	1930–40	fixed-bed catalytic cracking of oils → fuels
Ipatieff and Pines	1940	solid acid catalysts
Lewis and Gilleland	1941	fluidized catalytic cracking

The "*solid acid catalysts*" produced in the early 1940s in the USA by the Russian emigre Ipatieff and his coworker Pines, consisted of diatomeceous earth (kieselguhr) laced with concentrated phosphoric acid. This catalyst proved remarkably effective in a variety of isomerizations, oligomerizations, and alkylations, which, in turn, greatly improved the quality of aviation fuel.

Fischer–Tropsch chemistry is still of primary concern in the chemical and petrochemical industry. It represents a milestone in applied catalysis in that it opened the way for the conversion of essentially all sources of carbon —coal, oil, biomass, and natural gas— via synthesis gas ("syngas", i.e. $CO + H_2$ mixtures) to alkanes, alkenes, and alkanols, depending upon the choice of

catalyst. With the need to minimize the sulfur and nitrogen content of fuels, Fischer–Tropsch catalysis is nowadays an attractive means of producing environmentally clean fuels, quite apart from its pivotal role in the generation of chemical commodities.

The success of *the Haber process*, initiated in 1909, for the *synthesis of ammonia*,[12] and subsequent improvements to it, is in large measure responsible for the feeding of mankind. In 1990 over 100 million tonnes of ammonia were synthesized worldwide. This figure grows annually by some two per cent. The vast majority of the ammonia ends up as fertilizer, and the onset of the use of this *fertilizer* is now and will forever be inscribed in the biological record- -see the striking dendochronological picture of growth rings in the trunk of a tree from a Norwegian forest (Fig. 2).

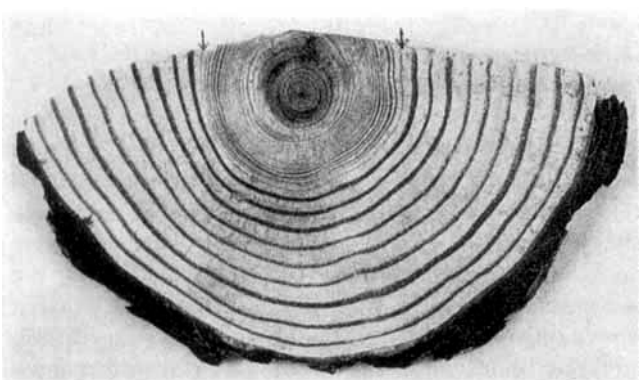

Fig. 2. An eloquent illustration of the impact of ammonia on the biological record. This section is of a tree from a Norwegian forest after about 35 years growth. Nitrogenous fertilizer was administered annually from the air after about 25 years initial growth. The enormously increased rate of growth under fertilization is apparent from the much wider spacing of the annual growth ring from the start of fertilization (indicated by arrows).

It has frequently been argued that the success of applied catalysis owes very little to pure, laboratory-based research and much more to industrial innovation. Paraphrasing a well-known aphorism among engineers—that science owes more to the steam engine than the steam engine does to science—the tacit implication among proponents of this view is that "science owes more to industrial catalysts than industrial catalysts owe to science". Indeed, in the context of the ammonia synthesis the case has recently been made[13] that the best catalysts were arrived at "by purely empirical methods and countless screening experiments". Whilst there is some truth in this statement for the development of ammonia (as well as other) industrial catalysts, one must not conclude that the design and practice of industrially viable modern catalysts is bereft of scientific principle. To be sure, it is undeniable that the majority of the catalysts appearing in Tables 1 and 2 were the product of largely empirical investigation. It is, however, equally indisputable[4] that a high proportion of the industrial catalysts of the last fifty years (see Tables 3 and 4) and especially of the catalysts introduced from 1980 onwards (see Table 9) emerged from pre-meditated scientific analysis and application.[14–18] Later in this article (see Section 5) several examples of designed heterogeneous catalysts are given.

To revert to Table 2, the mechanism of the copper-based methanol synthesis (ICI process) is now reasonably well understood, as are the broad features of catalytic cracking of hydrocarbons and their synthesis by Fischer–Tropsch reaction—even to the extent that the Shell Company could recently (and rapidly) set up a manufacturing facility for sulfur-free hydrocarbon fuels from syngas using a "formulated" Fischer–Tropsch catalyst based on cobalt. Major progress, much of it based on pre-meditated formulation and dextrous chemical synthesis, has also been achieved in the development of new solid acid catalysts.[16]

2. Highlights in Industrial Catalysis 1945–1985

Many of the key industrial catalytic processes introduced in this period have themselves served as turning points, judging by the considerable intellectual and technological stimulus that they have provided. Taking the enumerations of Tables 3 and 4, we first note the major impact of the independent work of Barrer and colleagues[19] in England and of Breck,[20] Rabo,[21] Milton, and others in the USA in preparing highly pure and highly crystalline analogues of naturally occurring, as well as uniquely new, *zeolitic molecular-sieve catalysts*. Mordenite is a typical example in the first category, zeolites X, Y, and L in the second. Zeolites constituted an impressive new kind of cracking, alkylation, and isomerization catalyst, much more active, and appreciably more specific than the acidic silica-alumina gel catalysts that they supplanted. In the hands of Plank and Rosinsky, zeolite-Y preparations were fine-tuned to be powerful fluidized cracking catalysts. A second generation of zeolitic catalysts, nowadays termed pentasils and typefied by ZSM-5, were brought forth by Weisz, Kerr, Haag,[22–24] and co-workers in the early 1970s. Their hallmark was shape-selectivity, a key quality to which we return later in Section 5.

Table 3. Historical overview of applied catalysis after 1945, part 1.

Rabo, Barrer, Breck, Milton	zeolites for isomerization and as replacement
Plank and Rosinsky	for silica-alumina in catalytic cracking.

Grätzel...	photocatalysis
	alkane activation
	new acid catalysts
	catalytic distillation and reverse configuration reactors

Haensel's introduction of *reforming catalysts*, in which, inter alia, linear alkanes were converted to branched ones (with improved octane ratings), brought into the arena of catalysis the notion of *bifunctionality*. Not only did the comminuted platinum, supported on high-area oxides such as alumina, provide the platform for such processes as hydrogenation and dehydrogenation, but the acidic support, the other functionality, facilitated both the formation and rearrangement of cationic organic moieties present as intermediates at the catalyst surface.

Ziegler (in Mülheim) and Natta (in Milan) were responsible for a major advance in 1953 with their discovery of *stereoregular polymerization*. This marked the introduction of the control of tacticity of synthetic polymers. It was Natta who first realized that the precise nature of the catalyst crucially governed the type of polymer that was produced. An appropriate choice of catalyst could, for example, increase the polymer density and tensile strength. The length of the polymer chain determines such properties as the transparency, stiffness, brittleness, and strength of the material. The catalyst used by Ziegler consisted of $TiCl_4$ and alkylaluminum compounds. The modern version of the Ziegler–Natta catalyst is a $MgCl_2$-supported $TiCl_3$ complex, and a great deal is now known about the individual steps in the overall catalytic process.

In the 1980s Kaminsky, Ewen, Brintzinger, and Sinn produced an impressive new family of homogeneous organometallic *metallocene catalysts* for the stereoregular polymerization of propene. Catalysts such as [ethylenebis-(4,5,6,7-tetrahydro-1-indenyl)]zirconium dichloride in the presence of an aluminum compound such as methyl alumoxane ($(CH_3AlO)_n$) were shown by Kaminsky et al. to be highly efficient for stereoregular polymerization.[25, 26] They regarded this as a key advance from the heterogeneous Ziegler–Natta catalysts in that, being homogeneous, the new catalysts are relatively straightforward to study because every one of the active sites has the same molecular structure, and, more important operationally, there is a well-defined chiral center in each catalytic molecular entity so that stereopreference inevitably ensues during chain growth as implied in the schematic representation of Figure 3. It is energeticallly favored for the monomer to be bound to the zirconacene catalyst in one of the two possible modes.

Of more ancient lineage but of no lesser importance at present than stereoregular polymerization is catalysis by *immobilized enzymes*. A pioneeering paper by the American workers Nelson and Griffin in 1916 showed that when invertase is grafted on to a high-area microporous charcoal, no loss of enzymatic activity is observed. In the mid 1940s invertase immobilized on high-area solids was used as an industrial biocatalyst for the decolorization of golden syrup (by the inversion of sucrose). Katchalski and coworkers[27] in Israel and many other investigators, including the groups of Lilly and Dunnill in London and of some industrial companies in Japan, Europe, and North America brought immobilized enzymes into a high degree of performance. Noteworthy achievements were the use of immobilized penicillin amidase to convert benzylpenicillin to 6-aminopenicillanic acid (thereby leading to the production of semi-synthetic penicillins), and of immobilized glucose isomerase for the isomerization of glucose to fructose. These two examples led the way to the ever-increasing use of immobilized biocatalysts in the food and pharmaceutical industries, uses that are now burgeoning.[28]

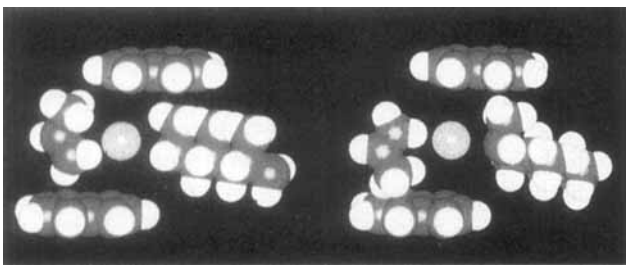

Fig. 3. On the left is shown the energetically favored, on the right the unfavored manner for a propylene molecule to be attached to the central atom of the zirconium catalyst. This energetic preference is the root cause of the stereoregular polymerization of propylene with a Brintzinger–Kaminsky catalyst. The growing polymer is on the right of the central atom (see text). (Picture by R. S. Bell and J. M. Thomas based on F. Kübor *New Sci.* **1993**, *139* (1986), 28).

Auto-exhaust catalysts have been fashioned on the basis of steadily increased knowledge of the individual mechanistic steps associated with the combined objective of eliminating nitric oxide, carbon monoxide, and incompletely combusted hydrocarbons from the exhaust. As well as utilizing rhodium, palladium, and platinum, which are well known for their ability to cope catalytically with the above gases, advantage has been taken of the propensity exhibited by some metal oxides, of which CeO_2 is a notable example, to *release* oxygen from its structure in a sacrificial manner when gas-phase oxygen is depleted, as is often the case, in the exhaust environment.

Catalytic, enantioselective synthesis of organic compounds of increasingly impressive specificity was introduced in the interval in question by adroit choice of transition metal or noble metal complexes typefied by the rhodium complexes of Knowles in the US, the BiNAP reagent developed by Noyori,[29] and the elegant work of Sharpless, Collman, and others on regio- and enantioselective epoxidations.[30] Efforts to perfect *selective oxidation* of methane on an industrial scale were not successful. It is easier to find catalysts for the more effective complete combustion of this hydrocarbon than for its selective transformation to C_2 building blocks and higher homologues. Likewise laboratory (model) systems for the activation of the C–H bond in alkanes depend heavily on pointers provided by biological catalysts.

Catalytic distillation, a relatively new chemical engineering strategem, utilized early on by the Enichem Company in Italy, combines distillation and catalysis into one operation. The aim here, as in the use of *catalytic membranes* pioneered by Gryaznov in Moscow, is to increase the efficiency of the overall operation. Other strategies entailing new chemical engineering practices were incorporated into the so-called *catalytic heat generator* (CHG) developed in Novosibirsk.[31, 32] This specially designed heat generator greatly reduces emission of carbon dioxide in the burning of fuel. The CHG combines in one reactor various energy-consuming processes (such as heating or evaporation of water and other liquids, drying, and thermal treatment of solid powders) with catalytic oxidation (combustion) of the fuel in a fluidized bed. Catalytic heat generators, like the rapidly expanding field of solid acid catalysts,[33] are likely to play an ever-increasing role in the *clean technology* of the future.

3. Everything Is Interesting: Not Everything Is Important

On contemplating the vast canvas of catalysis and the enormous and growing wealth of facts pertaining to the phenomenon, it is prudent to remind ourselves that, in catalysis, almost everything we investigate is interesting. But not everything is important. It is also salutory to recall that we have had conspicuously more success in discovering new catalysts than in explaining old ones.

These thoughts came forcibly to mind when, in preparing this lecture, I consulted the monograph published by Georg-Maria Schwab in 1931 (Fig. 4). This book was an important milestone.

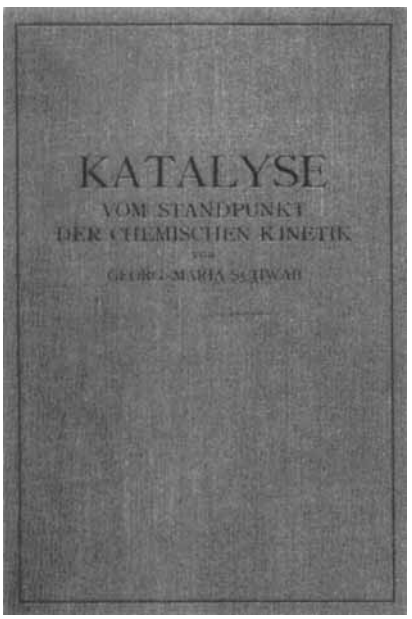

Fig. 4. Title page of the English of Georg-Maria Schwab's monograph on "Catalysis From The Standpoint of Chemical Kinetics" (published by Macmillan, London) translated by H. S. Taylor and R. Spence.

It was composed by the thirty-year-old Schwab with all the scholarship and authority associated with teutonic thoroughness. The fact that H. S. Taylor, a major figure in catalysis at that time and head of a thriving school in Princeton, saw fit immediately to translate it into English with R. Spence[34] testifies to the esteem with which Schwab's work was held by his scientific peers. Schwab's book makes fascinating reading even now, and I take comfort from one of his early caveats:

"*In this section particularly, a certain subjectivity of standpoint can be excused as essentially unavoidable*"

In catalysis, as in many other subjects, it was ever thus! Overwhelmingly, Schwab's book views the world of catalysis, as his title made explicit, from the perspective of chemical kinetics. He attempts to encompass all aspects of the subject, including processes in the homogeneous gas phase as well as in the homogeneous liquid phase. But he says very little about biological catalysis, evidently because of its then bewildering nature. He highlights the contributions of Langmuir especially and of Hinshelwood in the domain of kinetics. He also focuses on the "active sites" concept proposed by H. S. Taylor in the early 1920s. He underlined the importance of many other topics that are still relevant to discussions of the subject: heats of adsorption (and the value of calorimetry and thermodynamics in retrieving such heats), intermediate "compounds" of various kinds as envisaged by Van't Hoff, Arrhenius, and Sabatier, and the "activation" of a catalysts or the conversion of a precursor solid into an active catalyst by heating.[35]

It is interesting to reflect that biological catalysis, which seemed to Schwab to be of such complexity that it was omitted from his monograph, has been so greatly clarified in the intervening years that it is now perhaps better understood, and certainly more amenable to subtle modification and prior design than any other form of heterogeneous catalysis (see Section 5.1). Schwab also wrote:

"*The somewhat pessimistic conclusion which we have already reached from the present conditions of our knowledge, that there is not a single mechanism of catalysis, naturally does not exclude the possibility that a quite general correlation of the pertinent phenomena covering a whole series of items, can be given*".

It still remains true –and not unexpectedly so in view of the wide spectrum of different reactions amenable to catalysis– that there is no single, all-embracing theory of catalysis, in the sense that we have other comprehensive theories (of evolution or relativity, for example). Schwab's reminder about general correlations is therefore relevant.[36]

3.1. Important Tools and Techniques

In the intervening years since the appearance of Schwab's seminal work, enormous power has been added to the armory of those who investigate the science and technology of catalysis (Table 5). On the spectroscopic front, as well as in the field of imaging and in numerous aspects of diffraction, *ultrasensitivity of detection* or *identification* and *ultrarapidity of operation* have been the hallmarks, and there has been a concomitant florescence in *computation and simulation*. Particular examples, be they spectroscopic, diffractive, or concerned with imaging, are of greatest value when they can be applied to catalysts operating under realistic conditions. In situ studies, including the use of chemical reactions themselves as probes of catalytic performance, have been rather slow in reaching maturity. If we concern ourselves excessively with model systems operating under rarefied conditions –both in the literal and metaphorical

Table 5. Modern equipment for the study of catalysts.

Tools	Sensitivity and speed
Instruments for	
spectroscopy	ultra-high structural and spatial resolution
diffraction	extraordinary sensitivity of detection
imaging	
computation	fast retrieval from data bases
simulation	

sense—we run the risk of abandoning studies of catalysis per se in favor of pursuing phenomena such as adsorption, surface structure, and the dynamics and physics of two-dimensional arrays. So tempting and seductive are the appearance of meretricious new methods and so tantalizing is the glamor of new techniques that we can be readily diverted from our original intentions. So intoxicated do we become by the lure of the new that we tend to jettison our long-term policy and replace it by a perpetual programme of improvisation.

In contemplating the choice of tools currently at our disposal, it is chastening to recall that, whereas spectroscopic and all other experiments can fail as well as succeed, in the practices of computation and simulation the criteria—even the awareness—of failure are less sharply defined.[37]

It is a little difficult to identify the precise turning points in the recent explosive growth of computational techniques. Several factors have converged to change the overall climate: the integrated circuit, the fast Fourier transform, the parallel processor, each have had their part to play. All this has meant that ab initio and other quantum mechanical calculations have become more manageable if not routine. Monte Carlo and molecular dynamics (MD) calculations are now regularly performed by non-experts. A major turning point in this area was the introduction by Car *and* Parrinello[38] in 1985 of the *ab initio molecular dynamics* method, based on the local density approximation.[39] Car and Parrinello procedures now permit us to "test" the existence of vast new ranges of solids not hitherto prepared (or imagined). Nesper et al.,[40] for example, have recently explored the stability of hypothetical, microporous modifications of carbon derived from zeolitic frameworks.

Table 6 lists some of the more important tools and techniques that have been the agents of progress in catalysis. But this list is not complete; electron microscopy in all its numerous modes[41–43] and scanning tunneling and atomic force microscopy, Raman spectroscopy as well as other powerful tools[44] are omitted. Working upwards in Table 6, one recognizes that photoelectron and high-resolution electron-energy-loss spectroscopy (*with or without angular variation*[45]), as well as conventional or tensor low-energy electron diffraction (LEED and TLEED, respectively) are not suited for in situ studies of catalysts because of limitations imposed by the mean free path of the electron. Nevertheless these tools are admirable for the investigation of model systems, and they yield invaluable pointers pertaining to the performance of real catalysts. Brief statements summarising the contributions of each of the items listed in Table 6 are as follows:

Table 6. Impetus of some new techniques and tools.

Brunauer–Emmett–Teller (BET) theory
calorimetry
H/D and o/p-H_2 exchange
radio and stable isotopic labeling (^{14}C, ^{13}C, ^{18}O)
multinuclear NMR spectroscopy with high-resolution (MAS-NMR, DOR, ^2H, and 2D)
IR, FT-IR, DRIFTS, spectator species
synchrotron (rotating-anode) sources, combined X-ray absorption and diffraction, NEXAFS
neutron scattering
transient kinetics and in-situ methods
molecular dynamics, Monte Carlo methods
(XPS-UPS, HREELS, TLEED, etc, suitable only for model systems)

[a] Abbreviations see text.

- *X-ray induced photoelectron spectroscopy* (XPS) made it possible to study submonolayer amounts on solids of exceptionally low area (ca 1 cm^2),[46–48] and in so doing revealed the nature of the bonding of the bound state and set limits on its sticking coefficient. The same, essentially, can be said of high-resolution electron-energy loss spectroscopy (HREELS).[44, 49]
- *UV-induced photoelectron spectroscopy* (UPS) and its angular dependence[45] in association with XPS, definitively established that those metals active as Fischer–Tropsch catalysts facilitated dissociative chemisorption of carbon monoxide. Metals that were not active favored adsorption of CO in the molecular state.[48]
- *Monte Carlo* and *MD*, together with other computational techniques such as docking and energy-minimization calculations, are now so well advanced that they can yield diffusivities of reactant and product species (in zeolitic catalysts, for example[50]) with a precision rivalling that of direct measurement. Computer simulation in catalysis is a burgeoning field.[51, 52]
- *Transient kinetics* studies, using isotopically labeled reactants in interrupted flow, as carried out by Tamaru[53] in Japan, offers access to both turnover number and the concentration of active intermediates at a particular catalyst surface.
- *Neutron scattering* has broadly two major advantages to offer in the in situ study of catalysts. First, since neutrons freely penetrate stainless steel yet are readily scattered by hydrogen and deuterium, in situ high-pressure studies of, for example, hydrodesulfurization (HDS) (MoS_2) catalysts, may be made by inelastic neutron scattering.[54] Second, by focusing on elastic neutron scattering (diffraction that is), the detailed atomic structure of a working catalyst, along with the subtle changes it undergoes during activation, may be refined by the Rietveld method from the profile of the powder diffraction pattern recorded under operating conditions.[55, 56]
- *Synchrotron radiation* with its unparalleled angular resolution, monochromaticity, polarization, and wavelength tunability has had a profound impact on our knowledge of catalysis;[57, 58] and again is usable under working conditions. Not only does it make it possible to record ultra-high-resolution diffractograms of working catalysis prior to, during, and after activation[16, 59]—and thereby yield (by Rietveld analysis) unique insights into the delicate structural changes accompanying the conversion of an inert, precursor solid into an active catalyst—it also affords direct information on the valence state, the environment, and coordination numbers in the first and second coordination spheres of a metal center. Furthermore, it is now possible to chart both the short-range order and properties of a key element in a particular catalyst while at the same time obtain information about long-range (crystallographic and related) order by doing combined X-ray diffraction analysis and X-ray absorption spectroscopy (the so-called XRD/EXAFS approach).[60–65] Near-edge X-ray absorption spectroscopy (NEXAFS), employing fluorescence emission from light elements (such as C, N, and O) in

small molecular species undergoing adsorption at metal surfaces, has yielded[66, 67] quantitative data about bond lengths in the chemisorbed state.

- The analytical value of infrared (IR) spectroscopy, rendered much more sensitive by Fourier transform (FT) operation, is incontestable. It has uncovered modes of bonding hitherto unknown. It has shown (by the reflection-absorption procedure) that even an atomically flat single crystal metal surface is energetically nonuniform. It has proved invaluable in the identification of acidic and other sites at catalyst surfaces. But it must not be thought that a well-defined surface species identified by IR is directly implicated in the act of catalytic turnover. One must be wary of *spectator species*: the ethylidene species formed at metal surfaces during catalytic hydrogenation of ethene for example thought to be is no more than a spectator, as was demonstrated by J. T. Yates by using a combination of surface spectroscopy, isotopic labeling, and transient kinetics.
- *Multinuclear NMR spectroscopy* is an indispensable tool to monitor the progress of solid-catalyzed gas-phase or liquid-phase reactions.[68, 69] The advent of FT methods (by Ernst, who demonstrated that natural-abundance ^{13}C NMR measurements largely dispensed with the need for the use of ^{14}C radio-labeled compounds) as well as magic-angle spinning NMR,[70] and other sophisticated variants like double-rotation NMR developed jointly by Lippmaa in Tallinn and Pines in Berkeley, makes it possible to devise elegant in situ experiments in heterogeneous catalysis.
- *Deuterium exchange* and labeling experiments were devised by H. S. Taylor and members of his school of acolytes at Princeton shortly after Urey discovered the isotope. These experiments did much to confirm the reality of dissociative absorption of polyatomic species and the atomic-scale scrambling within intermediates at catalyst surfaces. The ortho/para hydrogen exchange, especially in the hands of Farkas and Eley, shed light on the magnetic properties and degree of chemical unsaturation of various surfaces.
- *Calorimetry*, as noted by Schwab in his book, directly reveals the energetic uniformity or, more usually, heterogeneity of a catalyst surface. Nowadays, extremely minute areas of catalyst can be quantitatively investigated, as shown by King et al[71] using their novel micro-calorimeter for Ni surfaces.

The *Brunauer–Emmett–Teller (BET) theory* introduced in the late 1930s of multilayer adsorption gave rise to a reasonably reliable method of measuring the true area of a catalyst (or any solid) from the uptake of gas as a function of pressure. Modest as it may, at first sight, seem, this marked a turning point in the progress of catalysis for it provided a quantitative means of comparing one catalyst, in terms of its genuine surface activity, with another.

Other techniques, not listed in Table 6, are also of great value in investigating model or real-life catalysts. These include a family of temperature-programmed procedures (desorption, reduction, sulfidation, etc) the majority of which are applicable to operating, practical catalysts. There are also a variety of techniques better suited—or even solely suited, owing to their intrinsic character—to probe the properties of model catalysts. These encompass Auger electron spectroscopy (AES), ion scattering spectroscopy (ISS), and secondary ion mass spectrometry (SIMS) and most variants of electron microscopy. These days, X-ray diffraction, thanks to the availability of powerful (rotating-anode) laboratory X-ray sources, may be routinely deployed to identify and characterize mono- or multiphasic solid catalysts under operating conditions[72, 73] and to do so with essentially immediate computer access to powder-diffractogram data bases. Specialist techniques, based on Mössbauer spectroscopy or Rutherford back-scattering, are also available.[74]

I wish to draw attention to the special status occupied by zeolitic and some other solid catalysts. These are best described as *uniform heterogeneous catalysts*[14, 75] and are monophasic crystalline solids in which the active sites are distributed in a spatially uniform manner throughout their bulk. Shape-selective catalysts, discussed further in Section 5, also fall into this category. Because such catalysts have the overwhelming fraction of the surface area *inside* the bulk (being microporous and crystalline), the surface and the bulk of such solids are effectively synonymous. It follows that the techniques of solid-state chemistry and solid-state physics are also applicable for the study of the surfaces of these uniform heterogeneous catalysts. All the panoply of spectroscopic, diffraction-based, and computational techniques deployed for the solid state are therefore appropriate for uniform heterogeneous catalysts. It follows, for example, that when the surface is inside the bulk, as in a zeolitic catalyst, a projected high-resolution image of the solid, as shown in Figure 5, faithfully reflects the projected surface characteristics of this catalyst.

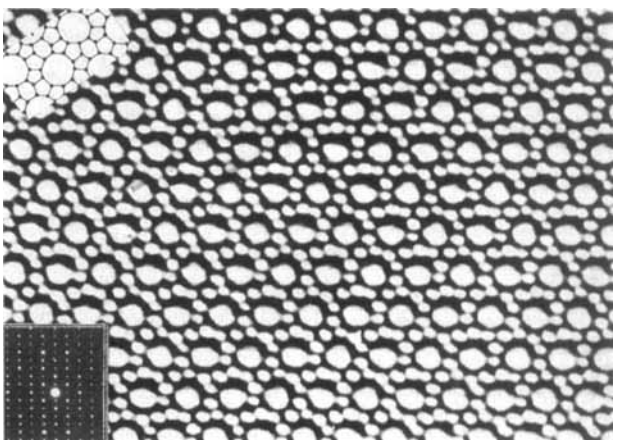

Fig. 5. High-resolution electron micrograph of a zeolitic acid catalyst (see also section 5) showing projected structure of pores lined with active sites. Large pores are 5.5 Å in diameter (from J. M. Thomas, P. L. Gai-Boyes, *Nature* **1993**, *364*, 478).

Zeolitic and other molecular-sieve crystalline solids occupy a unique place in the science and technology of catalysis in that they can function equally as faithful models for, and as actual examples of, practical catalysts.[76]

3.2. Important Concepts and Phenomena

Several concepts of ancient vintage in the surface chemistry of solids are still central to contemporary catalysis (see Table 7 for

Table 7. Concepts and phenomena of surface chemistry and catalysts as well as their proponents.

monolayers	Langmuir
kinetics of reactions involving monolayers	Langmuir Hinshelwood Rideal, Eley

a catalyst for the forward reaction is also one for the reverse	Grove

several examples). The notion of chemisorbed *monolayers*, first introduced by Langmuir nearly eighty years ago, is an integral part of the language and interpretations of catalysis, and it is through this notion that reaction mechanisms for kinetically zero, first, or fractional order are formulated.

Langmuir–Hinshelwood mechanisms of surface-catalyzed reactions predicate the co-adsorption of two (or more) reactants. The *Rideal–Eley mechanism*, on the other hand, requires only one of the reactants to be chemisorbed: the other reactant simply suffers a rather sticky collision with the bound species (or with the interstices in the incomplete adsorbed layer) thereby leading to reaction. Experiment indicates that the majority of catalytic reactions comply more with the Langmuir–Hinshelwood than with the Rideal–Eley mechanism. It is also a great convenience in chemical engineering practice to express overall rate equations in the format associated with Langmuir–Hinshelwood mechanisms.[77] Such rate equations facilitate the scale-up of laboratory and pilot-plant studies into their mature, industrial-scale operation.[78, 79]

There were (comparatively sterile) periods in the history of catalysis when too much emphasis was placed on kinetic and not enough on structural studies. These periods have now passed.[80, 81] It is, however, surprising that, notwithstanding the preoccupation with kinetic studies that dominated catalysis research for so long, it was not until quite recently that chemical oscillations and instabilities, of the kind now recognized to be so pervasive and responsible for nonlinear behavior in chemical phenomena generally,[82] were discovered (see Section 4).

The term *active site* in heterogeneous catalysis by solid is inextricably associated with the work of H. S. Taylor in the 1920s. Such sites were initially regarded as those of high heats of adsorption. Nowadays, recognizing that a bound state needs to be neither too strongly nor too weakly bound to a catalyst surface, active sites have almost the opposite connotation from that originally propounded by Taylor. Of key significance and lasting validity was Taylor's view, subsequently confirmed by experiment, that at a particular catalyst there could be different types of active sites for different catalyzed reactions. This neatly explained why different poisons or inhibitors[83] exert different effects on different reactions. In biological catalysis, the active site is so central a concept that its structure and accessibility are the principal objectives in its study.

Surface heterogeneity in inorganic, especially metallic catalysts, originally implied the topographical irregularities of terraces, kinks, corners on or point defects and emergent dislocation at a crystal face, or different kinds of crystallographic faces.[84] Whilst such a description is still valid and logically leads to the notion of coordinative unsaturation, it is now recognized that even an atomically flat solid surface has intrinsic energetic heterogeneity because of the scope for a multiplicity of different kinds of bonding.

Potential energy diagrams entered the literature of catalysis soon after they were introduced in 1932 by Lennard-Jones to explain the peculiarities of adsorption isobars and, in particular, the observed differences in amounts adsorbed at a fixed external pressure (of, typically, hydrogen in contact with a polycrystalline metal) as the temperature rose from that of liquid air upwards.

Prior to the explosion of information that ultimately occurred following the seminal work of Germer in the USA on low-energy electron diffraction (LEED) from surfaces, and prior to the appreciation of all the surface structural subtleties that LEED subsequently revealed—supermeshes, commensurate and incommensurate two-dimensional repeats, surface Debye–Waller factors, and the like—it had long been realized that:

1) The position of equilibrium for a given reaction was unaffected by the presence or not of an appropriate catalyst. Lemoine, a French chemist, had established this fact in 1877 by elegant work on the system $2HI \rightleftharpoons H_2 + I_2$.
2) A catalyst for a forward reaction is also one for the back reaction. The principle of microscopic reversibility demands this. But before that principle was explicitly enunciated, Grove in the 1840s, had demonstrated it for $2H_2O \rightleftharpoons 2H_2 + O_2$.

Table 7 is selective rather than comprehensive. It omits the not unimportant mechanism of oxidation first identified by Mars and van Krevelen[85] who observed that certain oxides readily release their structural oxygen to an incoming reactant and subsequently make good the loss by assimilating oxygen from the gas phase. For reasons that are not clear, metal oxides that possess the perovskite, fluorite, or pyrochlore structures are prone to exhibit this property. Such *sacrificial mechanisms* often loom large in the catalytic oxidation of some hydrocarbons[86] and carbon monoxide.[87] Another omission from Table 7 is the useful subdivision, introduced by Boudart,[88] by which supported catalysts are termed either *structure-sensitive* or *structure-insensitive*.[89] A catalytic reaction is said to be structure-sensitive if its rate changes markedly as the particle size of the (supported) catalyst is changed, or as the crystallographic face of a (single-crystal) catalyst is altered. Conversely, the rate of a structure-insensitive reaction is not significantly modified by such changes. The hydrogenolysis of ethane ($C_2H_6 + H_2 \rightarrow 2CH_4$) and the synthesis of ammonia are good examples of structure-sensitive reactions:[90] the hydrogenation of ethene or benzene and the oxidation of carbon monoxide, on the other hand, are examples of structure-insensitive reactions.[91]

3.3. Broken Milestones on a Vanished Road

Blessed with the wisdom of hindsight it is easy to see which of the teeming variety of concepts, hypotheses, and principles for

mulated in earlier eras have stood the test of time. Some have survived, some have been resuscitated and injected with renewed vitality, others have died and now appear like broken milestones on a vanished road. Notions such as the "dislocation hypothesis" and "disruptive action of catalysts", propounded by Boeseken, no less than the "spatial factors" proposed by Biltz, along with suggestions pertaining to the mechanical or magnetic effects of catalysis and many other notions[92] are heard no more.

Of those that have survived it is instructive to elaborate their usefulness.

4. Some Illustrative Examples and Summarizing Statements

The idea that some solid catalysts possess *bifunctional* or *multifunctional* character is an important one. The recognition that supported metal catalysts (e.g., Pd or Pt on Al_2O_3 or zeolites) behave in a clearly identified dual fashion has greatly assisted designers of catalytic reactors. In the hydro-processing of petrochemicals, for example, the metal serves to dissociate H_2 as well as to facilitate the equilibration of alkanes, alkenes, and alkynes, whereas the acid support serves to catalyze the build-up of vital carbocationic intermediates. We note that the support functions not only to stabilize the highly dispersed catalyst (thereby retaining high surface area), to prevent poisoning by facilitating removal of deposited coke for example, and to activate the metal by electron transfer between it and metal, but it also can be directly involved in crucial elementary steps in overall reactions such as that shown in Figure 6.[93] Implicit in this picture is the "*spillover*" of hydrogen atoms that are generated by dissociation of H_2 at the metal particle. The dissociated atoms are mobile on the support, to a degree that depends on the nature of the latter—the H atoms are more mobile on WO_3 than on SiO_2 for instance—and play an important role in many heterogeneously catalyzed hydrogenations.

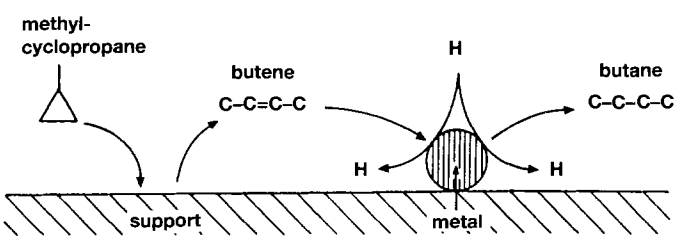

Fig. 6. A bifunctional catalyst such as platinum on silica facilitates the isomerization of methylcyclopropane to but-2-ene as well as the hydrogenation of the latter to butane. Dissociated hydrogen, facilitated at the metal, "spillover" on to the support (after Boudart [93]).

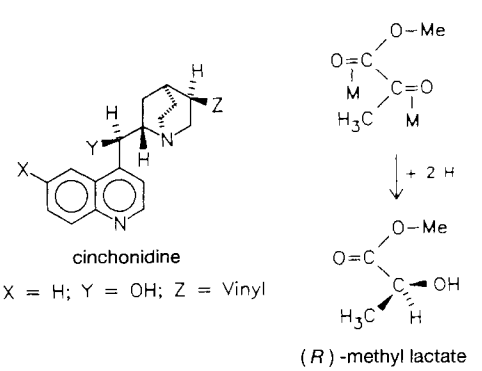
Consideration of bifunctional catalysts raise other relevant issues. *Metal-support interaction*, for example, influences both the electronic state of the metal along with its precise morphology. When finely divided chromium is dispersed over either SiO_2 or Al_2O_3 high area supports, there is little doubt (from the observed magnetic properties) that the chromium exists predominantly in the Cr^{II} state. Whereas the SiO_2 support provides a strong ligand field, thereby favoring the low-spin configuration for the octahedrally bonded $3d^4$-Cr^{II} ion, the Al_2O_3 support provides a weak ligand field, thereby favoring the high-spin state of the Cr^{II}. Metal-support interaction can be very strong, as was first recognized by Schwab and Solymosi.[94a] It has been further studied by Tauster et al.,[94b] who found that the catalytic activity for alkane hydrogenolysis, for example, can be suppressed if the supported catalyst is subjected to high-temperature pretreatment in H_2. The probable cause of the diminution in catalytic activity is the migration of species from the oxide support on to the exposed surface of the otherwise active metal. This is an example of strong-metal-support interaction (SMSI) about which a great deal is heard these days. Supported rhodium, for example, is a component of the automotive exhaust catalyst[95] (the three-way one) responsible for the reduction of NO by CO. It is also a viable catalyst for the conversion of syngas to oxyproducts such as ethanol and acetaldehyde.[96] This catalyst exhibits strong-metal-support interaction following high-temperature treatment in H_2, and minute particles of it tend to disintegrate further in atmospheres of CO. The morphology of supported metals can take up a multiplicity of types, from discrete, well-defined polyhedral, to discrete fluxional (though still polyhedral) to monolayer form. All this has emerged from a combined use of high-resolution electron microscopy,[97-99] EXAFS,[90] and X-ray diffraction.[99]

The realization that surfaces could be pre-treated so as to endow them with properties that they lacked in their pristine state constitutes another turning point in catalysis, and it is especially well-reflected in the development of *solid enantioselective catalysts*. The scope for tailoring metal catalysts by pre-adsorbing upon their surfaces bulky organic molecules which create prochiral cavities for the incoming reactant is considerable.[100] Wells et al.[101] have re-examined the Orito reaction[102] in which platinum, modified by the presence of presorbed cinchonidine becomes active for the stereoselective hydrogenation of an α-ketoester (e.g. methyl pyruvate) to an optically active product, for example, (*R*)-(+)-methyllactate (Fig. 7). My colleagues and I have explored, by computer graphics, the way in which this stereoselective process might proceed. The plausible assumption here is that cinchonidine forms an ordered, well spaced out array of interstices in the adsorbed layer. The interstices permit ingress of the methyl pyruvate in a preferred fashion so as to pre-ordain the formation of a given enantiomer.[15] There is little doubt, however,



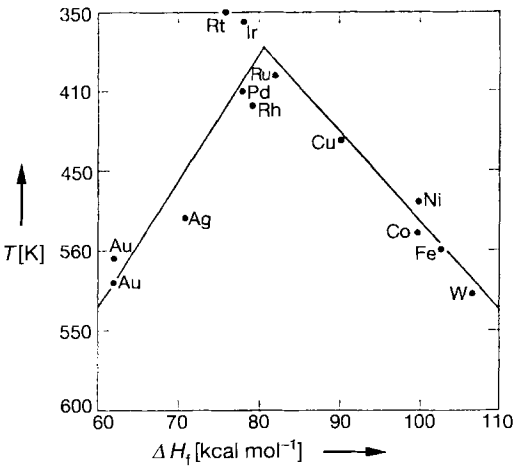


Fig. 7. Cinchonidine preadsorbed on a platinum catalyst favors the steroselective hydrogenation of a co-adsorbed α-ketoester to the optically active (*R*)-methyl lactate. See also ref. [15] and there particularly Figure 4.

that enantioselective catalysts of this kind will soon be superseded by more reliable, active, and selective ones, such as chiral metal complexes and a wide variety of stereoselective biocatalysts (see Section 5).

Another concept, stemming originally from the Russian worker Balandin, and later taken up by the Dutch school (notably Schuit and Sachtler) in the early 1960s is that of the use *volcano plots* (Figs. 8, 9). In reality, this concept encapsulates

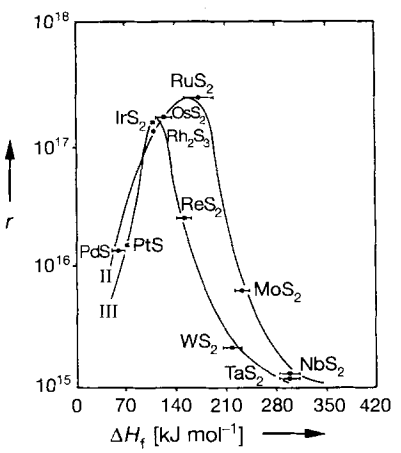

Fig. 8 (top) and 9 (bottom). Volcano plots, first proposed by the Russian worker Balandin, emphasize that catalytic activity is optimal when the enthalpy of formation ΔH_f of the surface intermediate compound is neither too great nor too small (see text). The dependence of the formation enthalpy of the formate on the temperature at which a certain rate of reaction is achieved is plotted in Figure 8. Details of Figure 9 are given in ref. [103].

the view that an intermediate surface compound, a metal formate, for example, when formic acid is catalytically decomposed at metal surfaces, is formed on the catalyst. This view, in a sense, is an updated version of Sabatier's original idea. The stability of this two-dimensional compound should be neither too high nor too low to secure maximal activity. Volcano plots have wide applicability. That reproduced in Figure 9 is taken from the work of Chianelli et al.[103] whose work on metal sulfides has done much to elucidate the mechanisms of hydrodesulfurization. This topic is one in which the Topsøe group[104, 105] in Denmark has made valuable contributions.

Whilst the idea of the *electronic factor* in catalysis, espoused by Hauffe, Wolkenstein, Weisz, and Stone in the 1950s, proved valuable for the interpretation of catalysis at oxide semiconductors,[106, 107] and whilst it served[108] as a useful basis for rationalizing trends for catalytic performance among families of alloy and bimetallic phases, it is now recognized that the term as such lacks precision and provides little predictive power in handling the massive corpus of inorganic catalytic phenomena.[109] Specific interactions between solid surfaces and molecules that impinge upon it are now handled quantum mechanically at various levels of sophistication from semi-empirical to rigorous ab initio treatments.[110–113]

Band theory tended to dominate discussions on catalysis by solids in the period 1950 to 1965. Far less is heard of it nowadays, chiefly because the local density of states at individual atoms or small clusters is now demonstrably more appropriate. There is, however, one area of catalysis, of growing practical importance, where band-structure considerations hold sway, and this is in *photocatalysis*. Gerischer, Parmon, Cunningham, and others have carried out a great deal of research in this field.

A knowledge of the magnitude of the electronic band gap and precise positions of the top of the valence band and the bottom of the conduction band edges—the analogue for an extended system of the HOMO–LUMO gap in a molecule—together with estimates of band bending that inevitably occurs owing to space-charges at the subsurface of a semiconductor, permits one to assemble an appropriate photoelectrolytic cell of the type schematized in Figure 10. The desired oxidation ensues as a

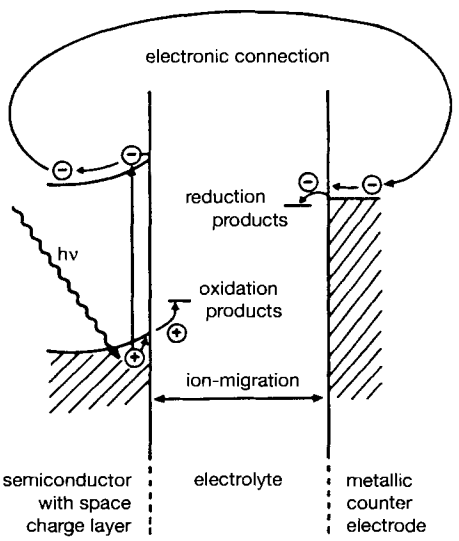

Fig. 10. In photoelectrolysis light is used to create electrons and holes which then serve to effect reduction and oxidation, respectively.

result of the electronic hole created by photo-absorption at the semiconductor–electrolyte interface and reduction by the mobile electron at the counter-electrolyte–electrolyte interface. Microcapsules and other appropriate miniature devices housing a tailored photocatalyst, like the one shown sandwiched between colloidal platinum and RuO_2 microelectrodes in Figure 11 can be so structured, as outlined by the Swiss worker M. Grätzel, for the continuous photocleavage of water, or indeed of a wide range of undesirable pollutants in fresh waters.

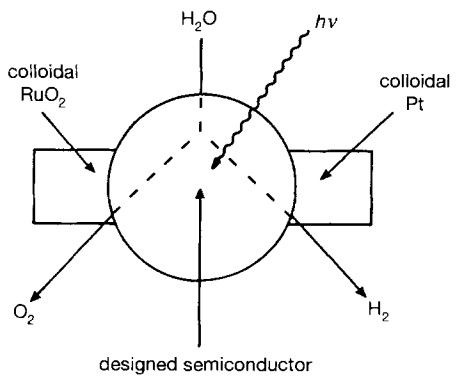

Fig. 11. It should be feasible to design a semiconductor catalyst microcapsule for the photocleavage of water and other abundant meterials (see text).

TiO_2 and ZnO are popular photocatalysts since they each efficiently absorb long wavelength ultraviolet light and are also chemically stable to the reaction conditions. Other semiconductor particles, notably CdS and GaP, absorb larger fractions of the solar spectrum and can form chemically activated surface-bound intermediates: they do, however, tend to degrade during the repeated catalytic cycles that prolonged heterogeneous photocatalysis demands.[114–126] Heterogeneous photocatalysis is used not only for degradation of pollutants and other unwanted organic materials, it can be harnessed for synthetic purposes. Bard et al.[116] have, for example, photocatalytically synthesized methane from acetic acid, and Lehn et al.[127] and Grätzel et al.[123] have demonstrated numerous other syntheses. Semiconductor-catalyzed photoaddition of cyclic enol ethers to 1,2-diazenes to afford hitherto unknown hydrazine derivatives can be effected by using ZnS and CdS.[125]

In designing a good photocatalyst for solar energy conversion of water to hydrogen and oxygen, the band gap between the conduction band and valence band edges must straddle the redox potentials—shown as dashed horizontal lines in Figure 12. The sulfide and selenide of zinc satisfy this condition as bulk solids; silicon and gallium arsenide do not, and neither do the sulfide and selenide of cadmium. However, it is a quantum mechanical fact (see Brus,[128] Nozik et al.,[129] and Henglein and Weller et al.[130]) that the width of the band gap for a given semiconductor widens as the particle size is decreased. Micro- and ultramicrocrystalline specimens of semiconductors may therefore be "tuned" —by the recently developed techniques of nano-technology—so as to yield the required band gap for the solar-driven (or any other light-induced) chemical process, be it synthesis or degradation.

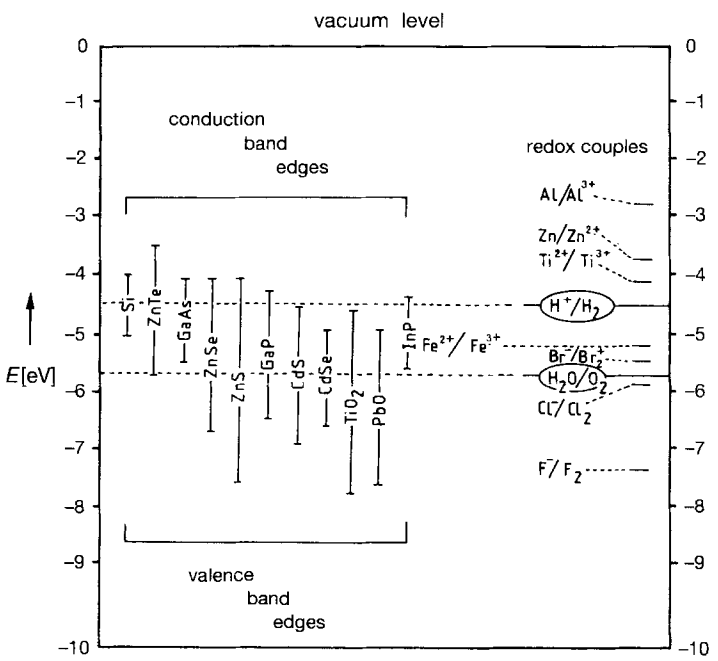

Fig. 12. The lower and upper extremities of the vertical lines denote respectively the top of the valence band and the bottom of the conduction band for several binary photocatalysts. For comparison, the band gap of silicon, as well as the electrochemical potentials of several familiar redox couples are also given (see text).

Elegant work by Parmon and his colleagues[131–133] in Novosibirsk has led to an effective means of harnessing solar energy so as to photosplit naturally occurring impurity hydrogen sulfide in the Black Sea. By ingeniously fashioning a heterojunction between minute particles of the sulfide of copper and the sulfide of solid solutions of zinc and cadmium (Fig. 13) light from the entire solar spectrum may be fruitfully harnessed for the separation of H_2S into hydrogen and water.

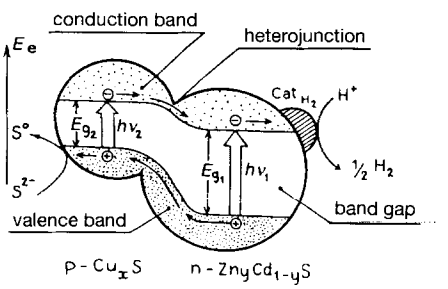

Fig. 13. Energy diagram and scheme (after Parmon et al. [131]) for the photoseparation of charges and catalytic processes in a suspended particle of a semiconductor with microheterojunction $CuS_x/Zn_{1-y}S$, which is one of the most efficient photocatalysts for H_2S cleavage in aqueous solutions. E_e is the electrochemical potential of the electron, E_{g_1} and E_{g_2} are the widths of the band gaps of the respective n- and p-type semiconducors and $h\nu_1$ and $h\nu_2$ are the corresponding light quanta.

Periodic variation in animal and insect population with the passage of time was recognized several decades ago by biologists such as the Australian worker May. In numerous predator–prey situations populations undergo regular bursts of growth followed by rapid decline on time-scales that vary from days to years. May's own work on lemming population (Fig. 14) shows that the mathematics of this periodic or oscillatory phenomenon is well understood. So far as chemists in general are concerned, the most renowned *oscillatory reaction* is the remarkable liquid phase one discovered by Belousov around 1950 and re-discovered by his Russian compatriot Zhabotinokii.[134] (But work at Brooklyn Polytechnic in the 1920s had already identified the

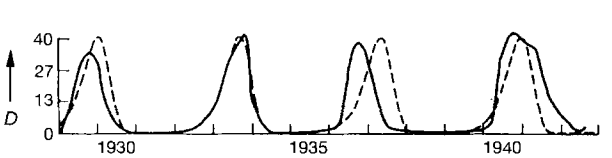

Fig. 14. Variation of the lemming density (D) (solid line) between 1929 and 1943. The dashed curve is the theoretical fit (after R. M. May, *Theoretical Ecology: Principles and Applications*, 2nd ed., Blackwells, Oxford, **1981**, p. 5.

reality and the mathematical basis of oscillatory reactions in chemical phenomena generally.)

Oscillatory reactions in heterogeneous catalysis are now of great interest as the recent reviews of L. D. Schmidt et al., Ertl, and others reveal. Although the existence of such oscillations was not firmly identified until the late 1960s and early 1970s (by Wicke et al.[135, 136] in Germany) it is now believed[137] that probably all bimolecular oxidation reactions catalyzed by transition metals will exhibit oscillations under some sets of experimental conditions. Whereas on the practical side it is rightly felt that oscillatory states of (large-scale) catalytic reactors are potentially dangerous—making it all the more necessary to understand the fundamentals of such processes—it is also appreciated that practical benefits can accrue by operating reactors under unstable regimes (with 'oscillating' input of feed reagents as demonstrated by Matros[138, 139] and Hegedus et al.[140]).

Chemical reactions far from equilibrium on solid catalysts may exhibit the phenomena of nonlinear dynamics, as exemplified by the oxidation of CO on a platinum(110) single-crystal surface (studied by Ertl et al.[141]). Depending on the precise temperature and partial pressure of the reactants, the temporal variation of the reaction rate may become oscillatory and even chaotic. And in a parallel way, the concentration distributions of the adsorbed species on the surface form so-called *spatio-temporal patterns* including propagating and standing waves, rotating spirals, as well as irregular and rapidly changing structures best denoted as "*chemical turbulence*".

The mechanism of the reaction $2CO + O_2 \rightarrow 2CO_2$ as catalyzed by noble metal surfaces is well understood thanks to the work of Engel and Ertl.[142] For the two reactants to be chemisorbed they compete, as it were, on an equal footing. For dissociative chemisorption of O_2, a fairly large ensemble of neighboring unoccupied surface sites is required, and any preadsorbed CO (since it can be bound to every available metal site) acts as an inhibitor for oxygen adsorption. The adsorbed atoms of oxygen, on the other hand, form a relatively open adlayer into which adsorption of CO is still quite feasible. Thus, there is comparatively little influence of preadsorbed oxygen on the adsorption probability for CO. The formation of CO_2 proceeds through recombination of CO_{ad} with O_{ad} (see Fig. 15), which is followed by immediate release into the gas phase. The sticking coefficients of CO and O_2 are functions of the surface coverages of the respective adsorbed species. The kinetics for the overall reaction are described by a set of nonlinear ordinary differential equations for the state variables u_1 and u_2 (which denote the surface coverages of adsorbed CO and O, respectively), the solutions of which depend on the control parameters, temperature, and the partial pressures of the CO and O_2.[143]

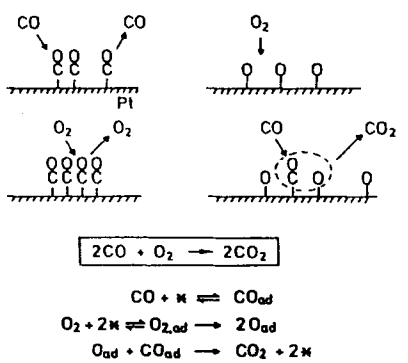

Fig. 15. Schematic representation of the mechanism of the reaction: $2CO + O_2 \rightarrow 2CO_2$ on a platinum surface. The asterisk denotes a free site on the surface [141].

Ertl has shown[141] that, with the Pt(110) surface, when operated under strictly isothermic low-pressure conditions, the reaction rate for a narrow range of control parameters is not stationary but becomes oscillatory as found experimentally[144] (see Fig. 16). The variation of the work function $\Delta\Phi$ (which is proportional to the oxygen coverage, u_2), parallels the oscillatory reaction rate, as indeed does the partial pressure of CO. All this reflects the fact that, with this system, kinetic oscillations are confined to conditions under which adsorption of oxygen is rate-limiting. This observation holds the key for rationalizing the physical mechanism underlying these phenomena.

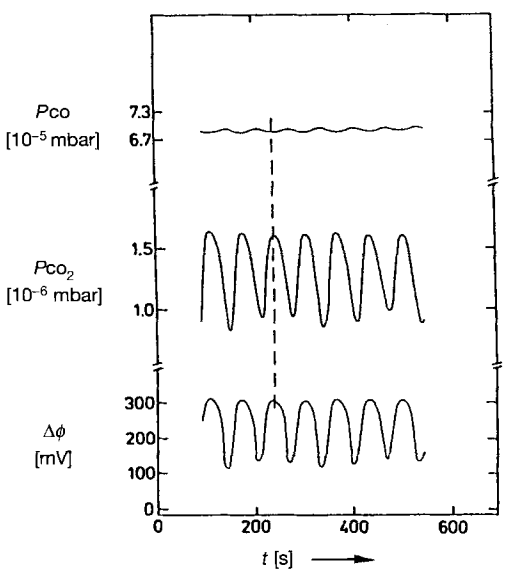

Fig. 16. Oscillatory kinetics with the catalytic CO oxidation at a Pt(110) surface. The recorded CO_2 partial pressure pCO_2 is proportional to the reaction rate; the work function change $\Delta\Phi$ parallels the oxygen coverage u_2. Temperature is 480 K, $pO_2 = 2.1 \times 10^{-4}$ mbar, and $pCO = 6.8 \times 10^{-5}$ mbar as in Figure 10 of ref. [141].

The clean Pt(110) surface does not possess the atomic structure that would correspond to the bulk termination (1×1 mesh as in Fig. 17) but is reconstructed into a 1×2 mesh with a "missing row" that is ostensibly energetically more stable. The heat of adsorption of CO on a 1×1 surface exceeds that on a 1×2 surface so that, as a consequence, a $1 \times 2 \rightarrow 1 \times 1$ transformation—brought about by homogeneous nucleation and

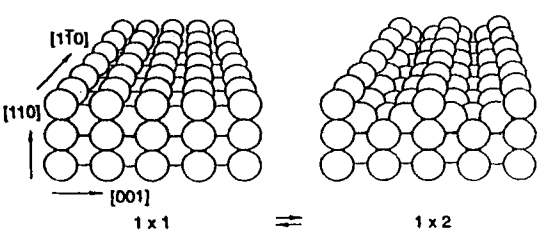

Fig. 17. The two structural modifications of the Pt(110) surface; see text and ref. [141].

minute but spontaneous local displacements of Pt atoms in the topmost layer[145]—takes place as soon as the CO coverage exceeds a critical value of about 0.2. The 1×1 surface exhibits a higher oxygen sticking coefficient than the 1×2 surface. Hence, for a narrow range of control parameters, the surface structure will continuously switch between states of low (1×2) and high (1×1) reactivity.

This is just one explanation for oscillatory phenomena in heterogeneous catalysis. The recent review by Schüth, Henry, and Schmidt,[137] which admirably summarizes over 300 publications dealing with oscillatory phenomena exhibited by a wide range of catalysts in many different forms (films, foils, powders, supported crystallites, and single crystals), gives other, equally valid qualitative and in many cases quantitative explanations for oscillatory reactions in heterogeneous catalysis. Concepts such as "strange" attractors and deterministic chaos, bifurcations, standing and travelling waves as well as turbulence are, it seems, an inherent feature of heterogeneous catalysis. Just as it is recognized for catalysis generally, there is probably no single mechanism that explains all known oscillatory behavior for every heterogeneous system so far studied.

In drawing this section to a close, one may, at the risk of grotesque oversimplification, enumerate some of the key summarizing statements pertaining to the behavior of solid heterogeneous catalysts as in Table 8.

Table 8. Some key generalizations.

In photocatalytic degradation and photocatalytic synthesis there is scope for considerable design by varying both the composition and the physical dimension of appropriate semiconductors.
Bifunctional catalysts, consisting of finely divided metals on oxide or sulfide supports, are of central importance in petrochemical, especially hydro-treating, processes.
Surface reconstructions can be both extensive and ubiquitous; and incommensurate overlayers are by no means rare.
Oscillatory kinetics and spatio-temporal phenomena are widespread in the realm of heterogeneous catalysis; and they encompass propagating or standing waves, bifurciations, determinative chaos and chemical turbulene.
Gross non-stoichiometry within the bulk and at the surfaces of mixed-valence solid catalysts, especially oxides, is of frequent occurrence.

5. Shape-Selective Catalysts

There is overwhelming evidence that molecular biologists and organic chemists concerned with the appreciation and design of biological catalysts are in a much more commanding position than those of us whose pursuits are devoted to the performance and the understanding of the inorganic catalyst.

5.1. Why Are Enzymologists and Immunologists So Well Placed?

Fifty years ago it seemed to Schwab,[146] and doubtless to all his contemporaries, that the complexity of biological catalysis could barely be properly described, let alone adequately explained. It was much easier, as his book revealed (see Fig. 4), to describe and to seek to explain how inorganic catalysts worked. Now, however, the situation is vastly different; and it is instructive for a physical chemist like me, interested in rationally designing inorganic, shape-selective catalysts functioning on principles that have more than a superficial kinship with enzymes and catalytic antibodies, to enquire why.

In a nutshell, it is because the nature of the catalytically active site and its immediate environment along with the geometry of the attachment of the reactant (substrate)[147] in an enzyme or an antibody is known to a high degree of precision. And this has arisen chiefly because of major advances in:

- the (crystal) structure determination of large numbers of enzymes (and an increasing number of antibodies[148–153]);
- the technique of site-specific mutagenesis and
- sophisticated kinetic studies of 'tailored' enzymes.

This has meant that the atomic detail of the active site and the manner in which it undergoes subtle changes upon uptake and conversion of a reactant, or as a result of the delicate modification (by mutagenesis) of the active site, is extraordinarily well appreciated. But enzymes as a class of catalyst are also more amenable to study by a panoply of available techniques and tools because of the convenient (if not anthropomorphic!) fact that chemical conversions occur within them at low temperatures (even at $-20\,^{\circ}C$), highly suited for in situ high-resolution X-ray crystallographic study.

But how has all this come about? A convenient place to begin our answer is by examining recent remarks by one of the founders of molecular biology, Max Perutz[154]:

> *In a Friday Evening Discourse at the Royal Institution in 1948, Linus Pauling said: "I think that enzymes are molecules that are complementary in structure to the activated complexes of the reactions that they catalyse, that is, the molecular configuration that is intermediate between the reacting substances and the products of the reaction".*
>
> *His prediction was borne out in 1965 by lysozyme, the first enzyme structure to be solved. That structure showed the transition state of the substrate to be stabilized by the strong electric field of two carboxylates on either side of the active site cleft. I generalized that finding with the statement: "We may now ask ourselves why chemical reactions, which normally require powerful organic solvents or strong acids and bases, can be made to proceed in aqueous solution near neutral pH in the presence of enzyme catalysts. Organic solvents have the advantage over water of providing a medium of low relative permitivity, in which strong electrical interactions between the reactants can take place. The non-polar interiors of enzymes provide the living cell with the equivalent of the organic solvents used by the chemists. The substrate may be drawn into a medium of low relative permitivity in which strong electrical interactions between it and specific polar groups of the enzyme can occur".*

Perutz's statement in the second half of the citation (taken from ref. [157]) extends well beyond the realm of electrostatics and their role in the catalytic conversion of organic reactants. The notion that the active site of an enzyme is complementary in character to the atomic detail of the activated complex of the reaction catalyzed carries echoes of Paul Ehrlich's proposition, almost a hundred years ago, and Emile Fischer's idea somewhat

later, of a "lock and key" fit between certain molecules. More relevant perhaps is the classic notion that enzymatic action hinges upon transition-state complementarity, a proposition first made by the polymathic English geneticist, J. B. S. Haldane in 1930[158] and then further extended by Linus Pauling (see above and in ref. [155]).

The structure of lysozyme,[156, 159] a proteolytic enzyme closely analogous in its mode of catalytic operation to a solid acid catalyst (see Section 5.6), contains a cleft—a well-defined cavity. Numerous structural determinations of enzymes done subsequently (about 300 in all) show that the cavity active site (which is often synonymous with a hydrophobic pocket) is a recurring structural motif in the architecture of their constitution.

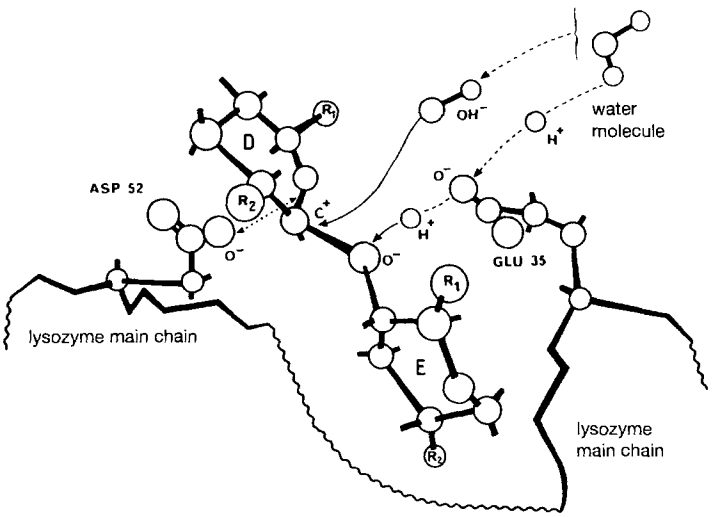

Fig. 19. Schematic illustration of the mechanism of the catalytic action of lysozyme derived from the crystallographic studies of Phillips et al. [156,159].

5.2. Shape-Selectivity in Biocatalysis

The cavity active site, so it has emerged from numerous detailed crystallographic and other structural studies (including NMR spectroscopy and mapping with fluorescence resonance energy transfer[160]), is also a characteristic of central functional importance throughout the immune system (and therefore a major determinant in antibody-antigen interaction[161, 162]) as well as in the behavior of ribozymes.[163]

Figure 18 is a computer graphic representation (to scale) of how a substrate molecule (a polysaccharide) is held as a "tortured victim" (to use Perutz's[154] phrase) inside the cavity active site of lysozyme. A clearer structural picture, based on Phillips' classical study,[156, 159] is shown in Figure 19. In the language of modern enzymology,[162] recognizing that it is a cardinal feature of enzymatic action for the enzyme to bind the substrate rather weakly but for the transition state to be appreciably stabilized by it, we expect there to be physical distortion (hence the torture) of the bound substrate at the cavity active site. The great triumph of X-ray crystallography, and a major turning point in enzymatic catalysis dating from Phillips' work, is that in situ structural studies with substrate and with a range of inhibitor molecules, directly revealed this distortion and, in so doing, suggested a mechanism for the enzyme's action. Catalysis of the hydrolysis of glycosides by lysozyme is brought about by stabilization of a planar, carbenium-ion-like transition state at the anomeric carbon atom for glycoside cleavage by the enzyme. This transition state is also stabilized by the electrostatic interaction between the carboxylate anion at the active site and the developing positive charge on the oxocarbenium ion in the transition state.

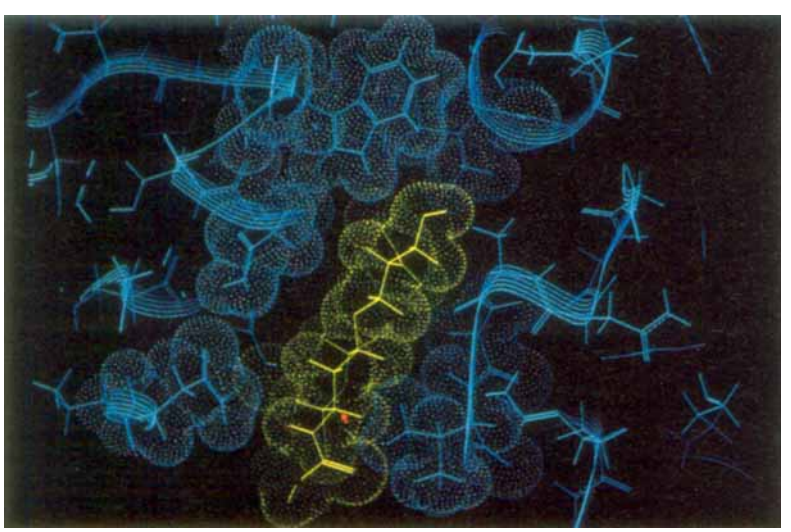

Fig. 18. Computer graphic representation of cavity active site in lysozyme. The polysaccharide (yellow) fits snugly into the hydrophobic pocket of the enzyme (see text). The dotted surfaces represent the surface of the molecule based on the van der Waals radii (prepared by C. M. Freeman, Biosym Inc., San Diego, based on data in [159]).

The elucidation of the mode of catalytic action of lysozyme serves as the archetype for all other proteolytic enzymes, and the majority of all enzymes. Thanks to site-selective mutagenesis, the critical amino acids lining the cavity active site can be precisely identified and the atoms within these fragments, in some instances, located to within a few tenths of an Ångstrom unit. More often than not, it is at a mere triad of amino acids—those that do indeed line the cavity and participate in general acid–base catalysis by the donation and acceptance of protons—where the whole competence of the catalysis resides.

Changing the surface charge of the cavity active site in enzymes by site-directed mutagenesis produces new variants with significantly different catalytic performance. For example, Russell and Fersht[164] were able, by this method, to shift the pH-activity profiles of the enzyme subtilisin, generate higher catalytic activities, and alter the specifities of the enzyme. Their work also afforded insight into the dielectric properties of water in the enzyme, the role of ions in electrostatic shielding and the high-field effects on catalysis. From all this they were able to suggest rules for tailoring pH-activity profiles in enzymatic catalysts.

Armed with site-selective mutagenesis and the consequential power to change the atomic structure of the cavity active site in an enzyme by the merest amount, the enzymologist is able to pinpoint the geometry and entire catalytic apparatus of the critical part of the enzyme in extraordinary

detail. In Knowles'[165] studies of the manner in which triosephosphate isomerase catalyzes the interconversion of the two triosephosphates, dihydroxyacetone phosphate (DHAP), and (*R*)-glyceraldehyde-3-phosphate (GAP) through the intermediate formation of *cis*-enediol, all the skills of structural and kinetic elucidation were brought to bear. A deeper understanding of the mode of catalytic action, to a degree that greatly surpasses what is understood about the mechanism of any reaction catalyzed by a solid inorganic catalyst, is thus achieved. From the crystal structures of the triosephosphate isomerases of both chicken and yeast, with either the substrate or a substrate analogue at the active site, it is clear that the basic catalytic group B^- (Fig. 20) is the oxygen atoms of the carboxylate of

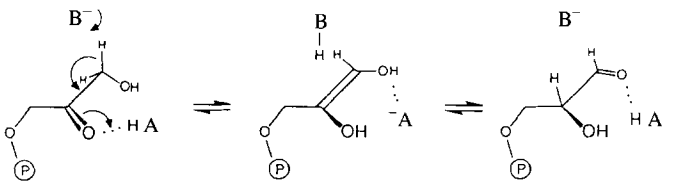

Fig. 20. The reaction catalyzed by triosephosphate isomerase. B is a basic catalytic group which abstracts the pro-(*R*) proton on the carbon of dihyroxyacetone phosphate (DHAP), assisted by an acidic catalytic group HA, to produce the intermediate enediol. This intermediate then collapses to give the product glyceraldehyde 3-phosphate (GAP) and regenerates the enzyme. The same enediol is produced by the enolization of DHAP or of GAP, and the overall reaction simply puts the two enolizations back-to-back (see ref. [165]).

Glu 165, since, in Knowles' words, they "are beautifully positioned for the proton abstraction required".[166] Indeed, when this group is moved by about 1 Å, as in the mutant enzyme where Glu 165 is changed to Asp, for which the structure (determined by X-ray crystallography) shows no other significant alterations, the catalytic power of the enzyme falls by nearly a thousandfold.[167] And when Glu 165 is completely removed and replaced by water, catalytic activity drops by more than a million times. Structural investigation of the crystalline triosephosphate isomerase and its bound substrate also reveal that the electrophile, the proton attached to A in DHAP, is histidine 95. The position of the imidazole ring (that contains the proton) with respect to the substrate being strategically placed for the donation.

Considerable advances[168] towards a detailed understanding of the catalytic mechanism of the zinc enzyme carbonic anhydrase[169] have been made very recently as a result of the application of crystallographic and kinetic methods to wild-type and mutant enzymes. The importance of directed hydrogen bonds for stabilizing the transition state of the catalyzed reaction and for inhibitor selectivity is here again particularly apparent. Thus histidine 64 (His 64) serves as an efficient proton shuttle between the metal center and buffer species (B/BH^+) in the reaction:

$$\begin{array}{ccccc} \text{E-Zn}^{2+}\text{-H}_2\text{O} & \rightleftharpoons & \text{E-Zn}^{2+}\text{-OH}^- & \overset{\text{B}}{\underset{\text{BH}^+}{\rightleftharpoons}} & \text{E-Zn}^{2+}\text{-OH}^- \\ | & & | & & | \\ \text{His} & & \text{His-H}^+ & & \text{His} \end{array}$$

Moreover detailed analysis reveals that His 62, His 67, and His 200, but not His 65, can function as proton shuttles but do so much less efficiently than His 64. The conclusion is inevitable: not only does His 64 have a favorable location providing facile proton transfer pathway but also a physico-chemical environment leading to appropriate acid–base properties.[168] (Just to emphasize the value of spectroscopic as well as crystallographic techniques in elucidating biological catalysis, Krebs et al.[170] were able to observe bound CO_2 by IR spectroscopy.[171])

Looking back, therefore, at the turning point that came with Phillips's work on lysozyme and at the course of events in enzymology subsequently, we may identify some key messages about biocatalysis. Effective enzymatic action entails:

1) accommodating the substrate (reactant) in a stereochemically precise fashion, governed by shape and distances, within the hydrophobic pocket (cavity active site); and
2) having just the right acid–base properties —that is, right pK values and requisite location—as between the lining of the pocket and the bound substrate.

To some degree these desiderata are mirrored in solid acid catalysts of the molecular-sieve kind described in Section 5.5.

5.3. Catalytic Antibodies

But it is not only enzymes that convey significant messages to those of us interested in inorganic shape-selective catalysis, catalytic antibodies do so also. It is a fundamental feature of the immune system that high-specificity binding sites are created spontaneously within the immunoglobin (antibody) protein to eliminate foreign invaders (antigens). The remarkable fact is that the binding sites of the antibody are effectively programmable. The immune system creates within the folds of the polypeptides (immunoglobins) cavity active sites that can recognize a vast array of chemically different invading molecules: each antigen stimulates a specific binding site in the antibody.[161, 173] With the development of *monoclonal antibodies* and genetic engineering techniques antibody catalysts, the creation of which certainly signifies a turning point, are now poised to make major contributions in organic chemistry, biotechnology and medicine, and especially in:

1) Assembling catalysts for disfavored chemical reactions.
2) Devising highly regio- and stereospecific catalysts for the synthesis of enantiomerically pure compounds.
3) The development of catalysts for highly stereoselective proton transfers.

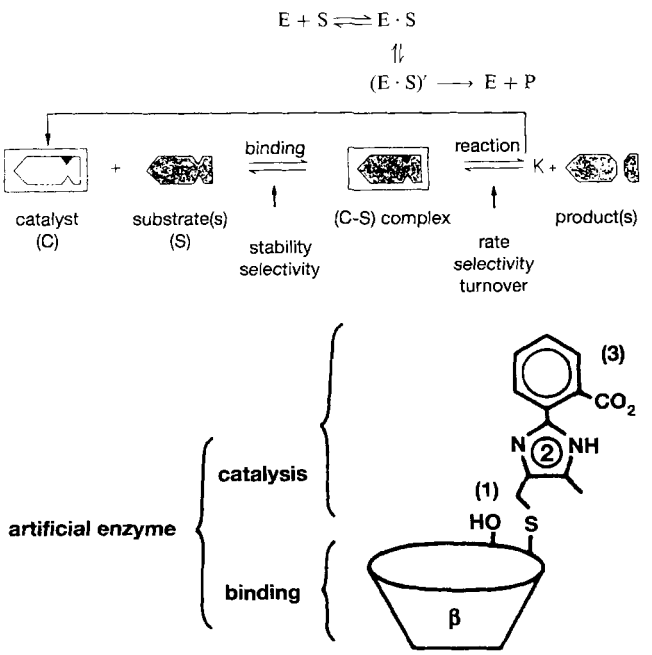
The strategy each time is to choose the right starter molecule, the so-called hapten, to generate an antibody with the appropriate disposition of catalytic groups. The whole philosophy behind catalytic antibodies is that an antibody raised against a transition state will bind it, and thus be a catalyst for the reaction that passes through that state. The haptens are effectively the transition state analogues.

Enzymes and antibodies are self-evidently biological catalysts. In enzymes, molecular evolution over aeons of time has yielded the cavity active site; in the antibodies, because the immune system is 'programmable', the binding site has been forcibly created in a very short time span by the hapten. There

is a third kind of fashioned molecular catalyst, the artificial miniature enzyme (enzyme mimetica) which we consider next.

5.4. Miniature, Artificial Enzymes

In 1985, Bender et al.[174] published a paper of compelling pedagogic elegance describing how, with the aid of a β-cyclodextrin, they assembled a miniature, artificial enzyme, the catalytic performance of which rivalled that of the parent, chymotrypsin, which it mimicked. Chymotrypsin itself is a large (MW 24800 Da) and complicated (245 amino acids) enzyme, the function of which is to catalyze the hydrolysis of a variety of esters and amides. From an X-ray analysis of its structure, the constituents of its active site—the lining of the hydrophobic pocket—were determined. These are an imidazolyl group, a carboxylate group, and a hydroxyl group. These were grafted by Bender et al.[174] in the correct sequence on to the rim of the β-cyclodextrin, which serves as the binding site (Fig. 21).



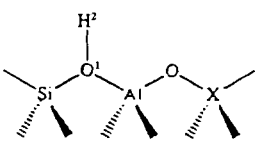


Fig. 21. Top: Schematic representation of the enzymatic process. The enzyme E processes the substrate (reactant) S into product P via the transition state E·S (after Lehn). Bottom: Strategy for the construction of an artificial chymotrypsin (miniature enzyme), based on cyclodextrin (see text; after ref. [174a]).

The artificial chymotrypsin has a relative molecular weight of only 1365, yet the real and artificial enzyme have approximately the same catalytic activity. The development of this miniature enzyme is an example of *supramolecular chemistry*, an area in which Jean-Marie Lehn has played a leading role. The nub of the message is that a sizeable molecular entity, which is nevertheless very much smaller in size and complexity than the natural enzyme, can be so fashioned as to mimic the catalytic performance of the enzyme. It is to be noted that there is a created cavity as well as a created and strategically located Brønsted acid site in this artificial enzyme.[174b]

5.5. Shape-Selective Inorganic Catalysts: Not only Interesting, but also Important

As well as being a crucial determinant of the catalytic performance of enzymes and abzymes (catalytic antibodies), shape-selectivity is also a key feature of molecular-sieve inorganic catalysts described briefly earlier (Sections 2 and 3.1). They are examples of *uniform heterogeneous catalysts*, in the sense previously outlined, and they represent one of the most rapidly growing categories of inorganic catalyst. The dimensions of the pores of the particular molecular sieve under consideration govern the size and shape of the reactant molecules that may enter it, the product molecules that may leave it, and the nature of the reactive intermediates that can form within it. Molecular-sieve solids, typefied by zeolites, are very high-area catalysts (typically 400–500 m^2g^{-1}), with over 99%, depending upon crystallite size, of the surface area inside the bulk. An acidic zeolite such as H^+-ZSM-5[133, 175] may be viewed as a three-dimensional network of corner-sharing SiO_4 tetrahedra, the spaces between these forming molecular-scale micropores of variable shape and dimension dependent upon the precise architecture. A few silicon ions, about one in ten to one in fifty, are replaced by aluminum ions (i.e. AlO_4 replace SiO_4 tetrahedra) and protons are required locally for electroneutrality. The protons are localized at one of the four oxygen atoms of the AlO_4 tetrahedron forming bridging hydroxyl groups. These Brønsted sites, sketched in Scheme 1, have been established to be active in a wide range of catalytic conversions of alkanes, alkenes, and alkanols.

Scheme 1. X = Si, P.

A striking example of the efficacy of solid acid molecular-sieve catalysts is shown in Figures 22 and 23. In Figure 22 the work of Le Bel in France in 1880 on the $ZnCl_2$-assisted dehydration of methanol is set alongside that of the shape-selective catalysis reported by the Mobil Research group nearly a hundred years later. One notes that, with H^+-ZSM-5, no polynuclear aromatic can be formed because the pore dimension (diameter ca. 5.5 Å) does not permit it. Contrast the distribution of products with another molecular-sieve catalyst, mordenite, the pores of which are large enough (diameter ca. 7.5 Å) to accommodate naphthalene and other polynuclear arenes.

Inorganic molecular-sieve catalysts with built-in shape selectivity are of great fundamental interest for a variety of reasons:

1) Microporous microcrystalline catalysts based on the naturally occurring zeolites[19, 20, 176]—an enormously large and growing family— form an open network possessing a porosity such that 30–50% of the solid is void space. About a quarter of the elements of the periodic table can now be incorporated into the framework structure of this kind of solid.
2) By controlling, during or after synthesis, the number of heteroatoms in the framework, finely adjustable concentrations of active sites may be placed, in a spatially uniform fashion, within the inner surface of the catalyst.
3) The precise location and environment of the active sites—be it a proton loosely attached to a framework oxygen, or a

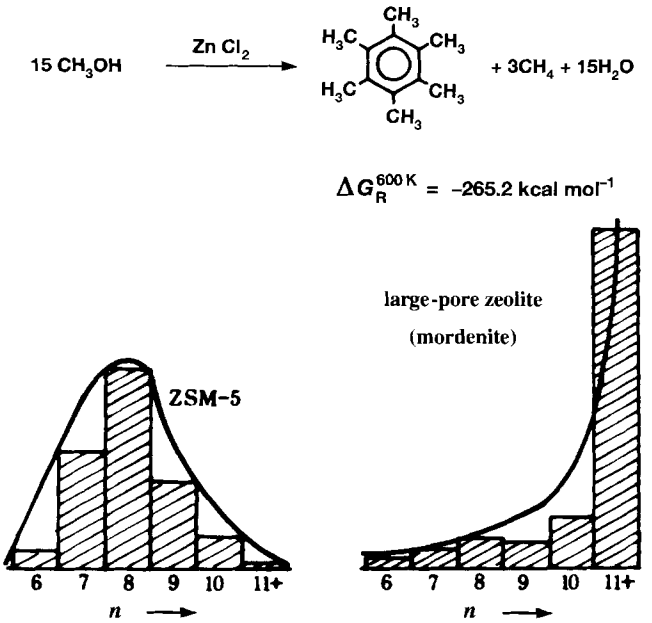

Fig. 22. It has long been known that the dehydration of methanol yields interesting hydrocarbons. Le Bel and Greene, in 1880, using molten $ZnCl_2$, produced hexamethylbenzene this way, along with a soup of other products. With the shape-selective solid acid H^+-ZSM-5, benzene, toluene, and xylene (important constituents of petrol) are among the principal products. With larger pore, molecular-sieve acid catalysts such as mordenite, polynuclear aromatics are also formed.

redox element such as titanium—can be determined experimentally.

4) In situ studies of bound reactants (or inhibitors) within the channels and cavities of the catalysts may be quantitatively followed by IR spectroscopy,[177–179] solid-state NMR,[180–182] X-ray diffraction,[72, 183] X-ray absorption and fluorescence,[60, 184, 185] neutron-scattering,[186, 187] and a range of other techniques (see Table 6).
5) Computational methods[188–194] are very productive and revealing for such catalysts, partly because of the power of quantum chemical techniques allied to classical methods of lattice-energy minimization.

Details are given elsewhere of the considerable progress in deepening our understanding of such factors as catalyst activation;[75] catalytic selectivities,[195] diffusivities and binding energies[50] of reactants and products in molecular sieves, as well

Table 9. Several innovations in applied catalysis since 1980. All processes marked with an asterisk utilize crystalline molecular-sieve catalysts.

Process	Catalyst
1980–1989	
conversion of ethene and benzene to ethyl benzene*	H^+-ZSM-5
methanol to gasoline (petrol)*	H^+-ZSM-5
conversion of ethene and acetic acid to vinyl acetate	Pd
oxidation of *tert*-butyl alcohol to methylmethacrylate	Mo oxides
improved means of liquefying coal	Co, Ni sulfides
production of diesel fuel from CO + H_2 (syngas)	Co
hydrotreating of hydrocarbons*	Pt/zeolite Ni/zeolite H^+ ferrierite
catalytic distillation (in methyl tertiary butyl ether (MTBE) production)	acidic ion exchange resins
vitamin K_4 production	Pd membrane
dehydrocyclization ('Cyclar') of alkanes* conversion of light alkanes to aromatics*	Ga-ZSM5
oxidation of methacrolein hydration of isobutene	Mo-V-P heteropolyacid
polymerization of tetrahydrofuran	phase-transfer catalysis
1990–1993	
production of dimethyl carbonate from acetone	CuCl
conversion of phenol to hydroquinone and catechol*	Ti-silicalite
isomerization of but-1-ene to 2-methylpropene*	H-ferrierite, H-Theta-1 (acidic zeolites)
isomerization of oxime of cyclohexanone to ε-caprolactam*	silico-alumino-phosphate molecular sieve (SAPO-11)
ammoxidation of cyclohexanone to its oxime using H_2O_2*	Ti-silicalite
production of acrylamide from vinyl cyanide	immobilized nitrile hydratase
complete combustion of natural gas (at ca. 1300 °C)	noble metals and/or mixed oxides
'sweetening' of natural gas by selective oxidation of H_2S to S	mixed oxides
oxidation of benzene to phenol via cyclohexene*	zeolites
methanol to light alkenes*	silico-alumino-phosphate molecular sieve
olefin oligomerization ("Shell" polygasoline and kerosene process)*	zeolite
production of L-aspartic acid and L-analine from NH_4 fumarate	immobilized micro-organisms
conversion of toluene to toluene *cis*-1,2-dihydroxy-3-methylbenzene	*Pseudomonas putida*
production of 2,6-diisopropylnaphthalene using propene as alkylating agent*	acidic zeolite (mordenite)
decomposition of hypochlorite	NiO
dehydration of alkanols	heteropolyacid salts

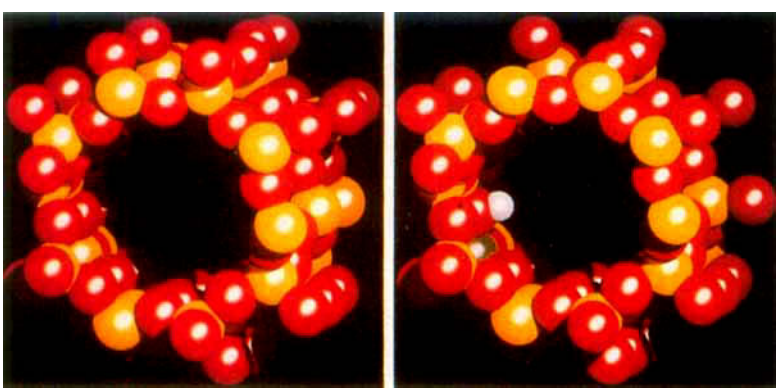

Fig. 23. Scalar representation (left) of the pure, siliceous molecular sieve known as silicalite (SiO_2) the pore diameter of which, as in ZSM-5 (right) is 5.5 Å. H^+-ZSM-5 is a protonated form of the siliceous analogue but with one in ten to one in fifty or so of the silicon atoms in the framework replaced by aluminum atoms. There is one proton loosely attached to framework oxygen atoms for every Al^{3+} ion (or rather trivalent ion such as Fe^{3+}) that substitutes for a Si^{4+}. See also Figures 5 and 24.

as descriptions of fundamentally new types of catalyst structures—some of which can be determined only by a stochastic combination[196] of interlocking techniques such as X-ray powder diffraction, high-resolution electron microscopy,[197, 198] and energy minimization procedures[194] using appropriate interatomic potentials.[199]

Zeolite and related solids now play a very significant role in industrial catalytic processes as may be gleaned from Table 9, where it is seen that a substantial fraction of the innovations in applied catalysis in recent years are based on molecular-sieve catalysts.[18]

5.6. Solid Acid Catalysts and Clean Technology

Clean technology[33] nowadays provides the stimulus for a multitude of new developments and initiatives in applied catalysis, not the least important of which is the growing environmental concern about the use of corrosive liquid acids (such as hydrofluoric acid and 96 percent sulfuric acid) as catalysts for the alkylations or isomerizations of hydrocarbons. Selective and active solid acids are therefore attractive as replacements; and the ever-growing family of molecular-sieve catalysts, with strong proton-donating sites distributed uniformly within the pores and cavities, offer a promising range of viable alternatives.[200–203]

Apart from the substantial family of aluminosilicate zeolitic acids (typefied by H^+-ZSM-5, HY, H-mordenite), the large family of microporous aluminum phosphates[200–205] (ALPOs, signifying $AlPO_4$ polymorphs in a wide range of open tetrahedral network structures) can be controllably modified, usually at synthesis, so as to yield acid SAPOs or acid MAPOs. In a SAPO, silicon atoms replace some of the phosphorus atoms (in tetrahedral coordination) thereby yielding $H[AlP(Si)]O_4$, whereas in the MAPOs, a divalent element M, typically Mg, Zn, Mn, Co, etc, replaces aluminum atoms, giving $H^+[Al(M)P(Si)]O_4$ (metal aluminum phosphate silicate). In a MAPO, such as the fascinating, double-barrelled so-called DAF-1 structure,[206] a divalent atom (Mg) replaces Al. DAF-1 is a very strong solid (Brønsted) acid and has a framework composition $Mg_{0.22}Al_{0.78}PO_4$, the counterbalancing ions being protons loosely bound to the framework oxygen atoms. SAPO-18,[207] on the other hand has a framework composition of typically one silicon per twenty tetrahedral sites. MAPO-18, with M = Mg, Zn, Co, has recently been shown to be highly efficient in converting methanol to mixtures of ethene and propene (Table 10).[208]

Fundamental studies, both experimental and theoretical, of the origins of Brønsted acidity in solid acid catalysts and the nature of the reactive intermediates formed when alkanes are converted by them in processes such as isomerization or cracking, have intensified[209–212] in recent years. It is becoming increasingly apparent from analyses on materials of identical stoichiometry but different framework structures (such as H^+ faujasite and H^+-ZSM-5) that the difference in value of the proton affinity for the bridging hydroxyl oxygen atom,[191] (Fig. 24), and the next oxygen atom is the key to determining the Brønsted acidity of these catalysts. Hydrogen–deuterium exchange reactions, along with dehydrogenation and cracking of

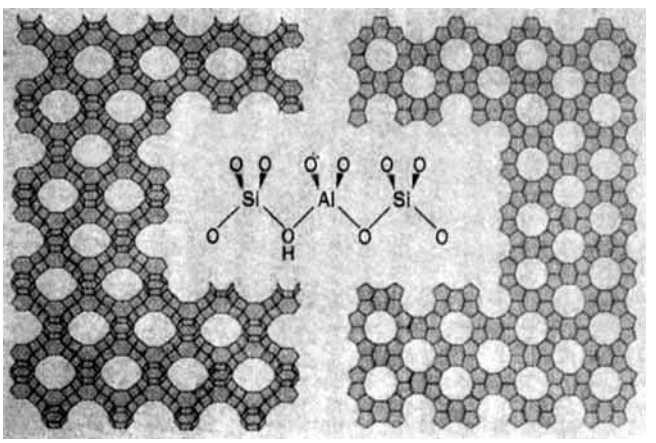
n-alkanes on Brønsted acid zeolitic catalysts point to the dominance of pentacoordinated carbocations (carbonium ions) as the crucial intermediates for monomolecular conversions of alkanes.[212]



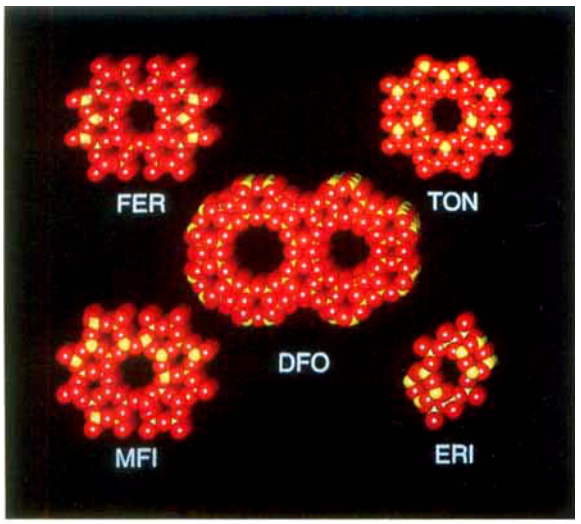


Fig. 24. The acidity of the zeolite catalysts originate from bridging hydroxyl groups (see formula in the center). Zeolite-Y (which has the same framework structure as the mineral faujasite) (left), and ZSM-5 (right) are different structural forms, but can be synthesized with identical compositions. But even with exactly the same number of active sites (Brønsted acid centers as in Fig. 23) they exhibit different catalytic activities. This is because of differences in the proton affinities of bridging hydroxyl oxygen atoms in their framework (see text and refs. [191, 192]).

Given the wide (and subtle) variety of molecular-sieve solids upon which Brønsted acidity may be conveniently conferred,[203, 213, 214] instructive catalytic comparisons may be made between a suitable subset of solid acid catalysts ranging from aluminosilicates to MALPOs (see Fig. 25) using an important isomerization as a probe: the conversion of but-1-ene to 2-methylpropene.[213, 215] (There are powerful factors, again related to "clean technology", why the quest for catalysts for this reaction is so important, see also ref. [216].)

The framework of inorganic molecular sieves of the type discussed here is remarkably flexible: even though these solids do not collapse until very high temperatures are reached, they quiver like a jelly—this was established from ^{29}Si solid-state NMR spectroscopy and molecular dynamics simulation[16, 51]

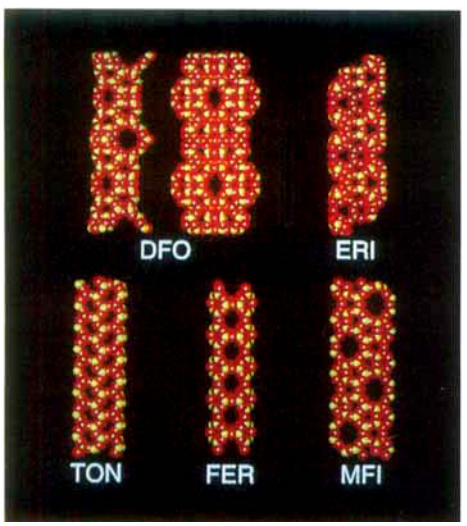

Fig. 25. Plan view (top) and elevation (bottom) of five distinct types of shape-selective molecular-sieve solids that function as solid acid catalysts for the skeletal isomerization of but-1-ene. FER ≡ H^+-ferrierite, TON ≡ H^+ = Theta one, MFI ≡ H^+-ZSM-5 (Mobil five), ERI ≡ H^+-erionite, and DFO ≡ H^+Davy-Faraday One. (DFO (DAF-1) has two distinct kinds of pores [206].)

(Fig. 26) at liquid nitrogen temperature. Using a blend of Monte Carlo and molecular dynamics calculations,[195] we compared the mobility and the binding energy of all four isomers of butene (Fig. 27) inside ZSM-5 and Theta-1, a zeolitic catalyst discovered[217] at the British Petroleum Company. We found that it is much easier for 2-methylpropene than for any of the three other isomers to be released from both these two catalysts. Taking account of spatial considerations, we would expect undesirable by-products—that is, unneeded dimers—to form in the larger cavities where channels intersect. We therefore predicted Theta-1 would be superior to ZSM-5 for the isomerization of but-1-ene to 2-methylpropene (Fig. 28). Our predictions proved true;[213]

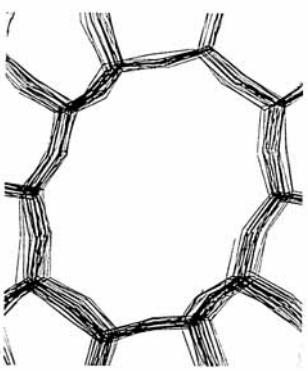

Fig. 26. Superimposed snapshots of a portion of a molecular dynamics simulation of the silicalite framework indicating the degree of structural flexibility [217].

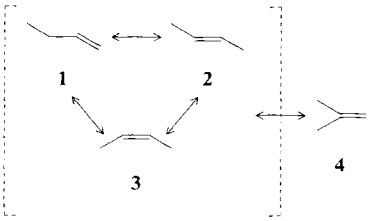

Fig. 27. The four isomers of butene. But-1-ene (**1**) is plentifully available from catalytic oil crackers. 2-methylpropene (**4**) is the desirable product as it may be converted, over another solid acid catalyst, to methyl tertiary butyl ether (MTBE), a replacement for lead-containing constituents of petrol.

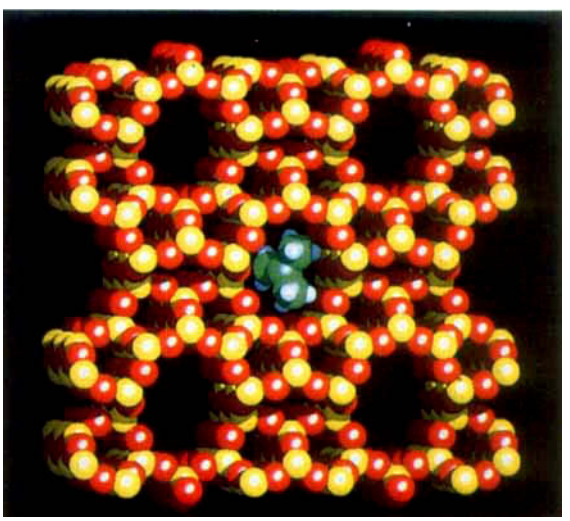

Fig. 28. Using an automated method [195] of blending energy-minimization procedures and Monte Carlo and molecular dynamics calculations it is possible to predict that Theta-1, and other similar molecular sieves with non-intersecting pore structures such as ferrierite, are superior catalysts for the isomerization of but-1-ene to 2-methylpropene than ZSM-5, which has intersecting pores. A 2-methylpropene molecule, shown here in one of the pores of Theta-1, is less strongly bound by, and diffuses more readily out of, the catalyst than any of the other three isomers [33]. (see also Fig. 27).

and they would be equally valid for ferrierite. (We now know [218] that the Shell Company is using H^+ ferrierite and that the BP and Mobil Companies are using H^+ Theta-1 as the basis of their pilot plants for the large-scale production of 2-methylpropene as the precursor for production of methyl tertiary butyl ether (MTBE), that boosts octane rating of (and which dispenses with the need for environmentally harmful lead-containing additives in) petrol.

Less sophisticated computations and modeling suffice to reveal that, in the design of a new solid acid catalyst for the

formation of a valuable precursor for a wide range of polymers and liquid crystals, 2,6-diisopropylnaphthalene (from naphthalene and propene), H^+-mordenite is the catalyst of choice. This is elegantly illustrated in the work of Cusumano et al.,[219] (Fig. 29).

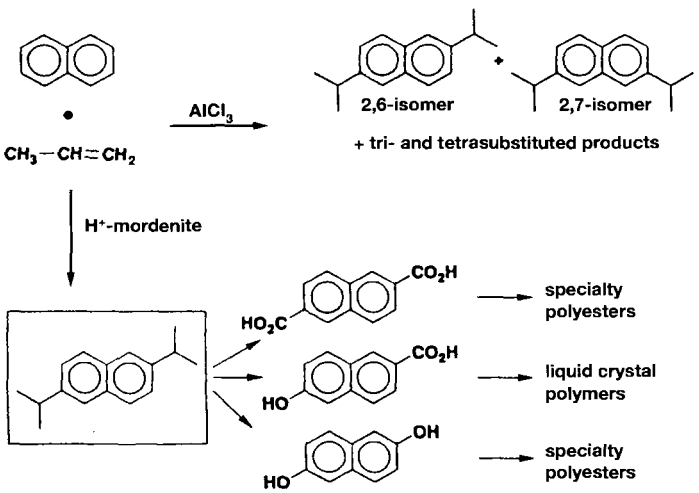

Fig. 29. When naphthalene is alkylated by propene in the presence of aluminum trichloride catalyst, a mixture of the 2,6- and 2,7-diisopropylnaphthalene isomers as well as many tri- and tetrasubstituted naphthalenes is produced. Cusumano [219] has shown that there is overwhelming preference for the 2,6-diisopropyl derivative when H^+-mordenite is used as the acid catalyst, the shape-selectivity of this catalyst being illustrated here.

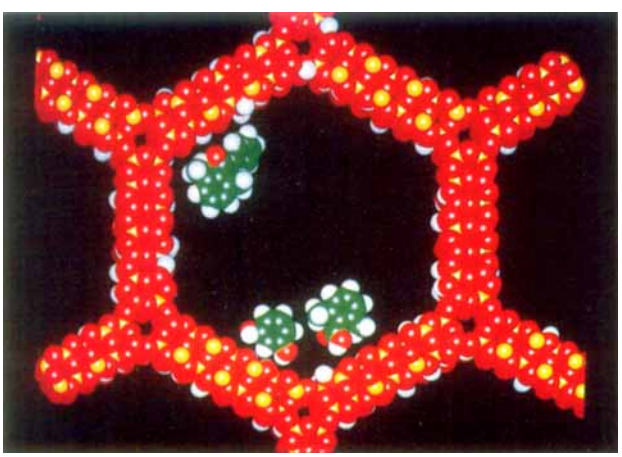

This design strategy for the selection of an optimal catalyst from an already available set of potential molecular-sieve, uniform heterogeneous catalysts or the creation (first on computer and then in the laboratory!) of an altogether new one is likely to gain pace in the near future. As ever, the technical virtuosity of the preparative chemist, now nourished by the input of modeling and computation, will reap rewards. The good news for catalyst engineers in this context as it is for the enzyme designer "is that proper placement of appropriate groups in the right environment seems to be enough".[165] One may now, with optimism, look forward to the day when the degree of prior control required for tailor-made catalysts, such as the water-soluble homogeneous ones now in commercial use[221] for hydrogenation and hydroformylation, will also be achievable with molecular-sieve heterogeneous catalysts. Indeed, as Kirill Zamaraev and I have shown elsewhere[4] there are already industrially demonstrated successes in this regard.

There are definite indications that very many novel microporous solids[220]—like the molecular-sieve cobalt phosphate,[222] or the MCM large-pore structures recently prepared by Beck et al[223] and Stucky et al.,[224] (see Fig. 30) and already used so imaginatively by van Bekkum et al.,[225]—will appear in the near future, providing yet further likely turning points.

In concluding my ruminations here in France, I cannot but reflect the sentiment with which, I believe, everyone would agree, namely that firm and sturdy foundations have been laid for the growth of heterogeneous catalysis (see Fig. 31). There is only one way to go now: upwards!

Fig. 31. A postcard showing the Eiffel Tower under construction. Copyright: Collection Viollet, 1988 (Editions Gerndre, 65 Boulevard Masséna, F-75013 Paris).

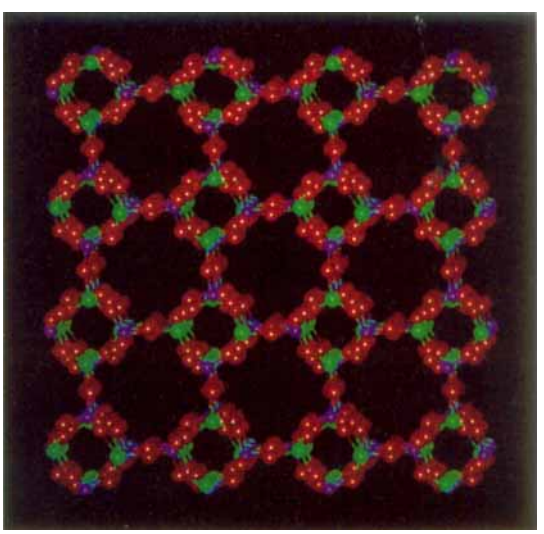

Fig. 30. Left: Graphic illustration of how van Bekkum et al. [225] have used individual members of the newly developed families of large-pore (20 to 50 Å diameter) microcrystalline siliceous solids [222,223] to inject shape-selectivity into organic processes such as the Fries reaction. This hexagonal pore of 31 Å diameter houses various functionalized arenes some of which are initially anchored by pendant Si–OH groups to the walls of the pore (2,6-dimethylbenzoic acid and resorcinol which, by Fries reaction yields a benzophenone derivative). Right: DAF-2 (Davy–Faraday 2) is a recently designed molecular sieve in which the tetrahedral bonded ions of the framework are cobalt (green) and phosphorus (purple) in 1:1 ratio (red: oxygen) [222].

I am grateful to all my colleagues here and to collaborators from other laboratories for their continued cooperation and enthusiasm. Almost all the work bearing my name that is reported in this review was the result of SERC rolling grants.

Received: December 22, 1993. [A 441E]

[1] Consider how our understanding of the mode of action of biological catalysts was revolutionized by two seemingly trivial discoveries. The first of these, made by the American biochemists J. B. Sumner (in 1926) and J. H. Northrup (in 1931), that enzymes could be crystallized: the second, made in 1934 by Dorothy Crowfoot (as she then was) and J. D. Bernal in England, that crystals of enzymes (notably pepsin) give rise to a glittering profusion of sharp X-ray diffraction spots. These discoveries meant that no longer could the view be sustained, popular until then, that enzymes were a mixture of convoluted macromolecules of variable length, assembled spaghetti-like to yield colloidal dispersions. These two phenomena implied that molecules of enzymes, however complicated, have an extremely well-defined structure, otherwise they would not self-assemble to form a crystal; moreover, the diffraction spots gave the clue, later brilliantly exploited, that the structure, and hence the active site as well as the mode of operation, of an enzyme could be deduced from X-ray crystal analysis. Consider also the simple phase changes that lie at the heart of the humble cloud and bubble chambers and the absolutely pivotal role that they have played in cosmic ray and particle physics.

[2] The intensity and nature of this so-called commercial pressure varies with the passage of time. In one era, the need to produce sulfuric acid or ammonia may stimulate invention or innovation in a given direction. In other eras, production of fuel, fertilizers, foodstuffs, fabrics, or pharmaceuticals lead us to new and hitherto unexplored pastures. These days, environmental issues loom large and there are increasing demands for better catalysts to create a cleaner world [3,4].

[5] During the first thirty or so years of the post-phlogiston era several examples of catalytic reactions were discovered or re-examined. These encompassed both homogeneous and heterogeneous reactions. And among the former, the Clément and Desormes mechanism for the manufacture of sulfuric acid by the land chamber process was reported in 1806, and Kirchhoff's investigation of the conversion of starch to sugar by dilute acid in 1814. Dutch chemists studied the catalytic dehydration of alcohol to ethylene as early as 1796, and Thenard's detailed examination of the abilities of five different heated metals to decompose ammonia was published in 1813. Of the metals he studied, iron proved the most effective and platinum the least. It was about 1910 before iron was found (by researchers at BASF) to be the most efficient catalyst for the synthesis of ammonia.

[6] News of Döbereiner's discovery reached England through the French mathematician and physicist, Hachette who wrote to Michael Faraday. Faraday's notebooks (kept at the Royal Institution) contain an entry on 27 September 1823 showing that he verified Döbereiner's discovery. Faraday, with his characteristic thoroughness [8], demonstrated that air was essential to the glowing of the platinum and proved that the powder had the ability to take up hydrogen.

[34] R. Spence ended his distinguished career in the UK as Director of the Atomic Energy Research Establishment, Harewell.

[35] Schwab had an eye for significant developments. He spotted L. H. Germer's important paper in *Z. Phys.* **1929**, on low-energy-electron diffraction of a nickel single crystal exposed to hydrogen; and he reported his fellow countryman's (E. Rupp's) work (*Z. Electrochem.* **1929**) on the same system.

[36] To put things into comparable perspective, it is chastening to recall that theory and experiment in certain realms of astronomy and astrophysical phenomena have recently been reported to agree to eleven significant figures. No theory in chemical kinetics and catalysis can boast such correspondence with experiment.

[37] Present-day novitiates in catalysis need to be constantly reminded of these truths.

[74] A discriminating account of these and other related techniques is given in the admirable monograph by Niemantsverdriet [44].
[75] J. M. Thomas, J. Chen, A. R. George, *Chem. Br.* **1992**, 991.
[76] In industrial practice zeolitic catalysts are very often fashioned into composite particles with the zeolite itself embedded in an amorphous silica (or silica-alumina) matrix. The composite can however be treated as two interpenetrating continua (see P. G. Smirniotis, E. Reicherstein, *Chem. Eng. Sci.* **1993**, *48*, 585) that constitute a uniform whole.
[77] For example, in the synthesis of methanol from $H_2 + CO$ or from $H_2 + CO + CO_2$ mixtures at 10 bar in the 200 to 250 °C range it is convenient to express the rate of methanol formation in Langmuir–Hinshelwood form (see A. Cateron, A. N. Hayhurst, *Chem. Eng. Sci.* **1994**, *49*, 209). Thus, the rate of synthesis of methanol r_M from H_2 and CO is written:

$$r_M = \frac{k_{f1} K_{CO} K_H^2 K_{CH} p_{CO} p_{H_2}^2}{1 + K_{CO} p_{CO} + K_{CO} K_H^{3/2} K_{CH} p_{CO} p_{H_2}^{3/2}}$$

And the rate of synthesis of methanol from $H_2 + CO + CO_2$ is of the form:

$$r_M = \frac{k_{f2} K_{CO_2} K_H K_{HCO_2} p_{CO_2} p_{H_2}^2}{1 + K_{CO_2} p_{CO_2} + K_{CO_2} K_H^{1/2} K_{HCO_2} p_{CO_2} p_{H_2}^{1/2} + \dfrac{K_{CO_2} p_{CO}}{K'_{CO} p_{CO}}}$$

[99] See ref. [44], there particularly chapter 6..
[100] In 1956, Japanese workers, using palladium supported on natural silk, obtained optical yields of about 36 per cent in the hydrogenation of oximes and oxazolones. More recently, W. M. H. Sachtler and Y. Izumi (see *Adv. Catal.* **1983**, *32*, 215) have shown that Raney nickel catalysts, when first modified so as to effect corrosive chemisorption of (*R*,*R*)-tartaric acid, can then smoothly hydrogenate methyl acetoacetate to methyl-3-hydroxylbutyrate:

$$CH_3COCH_2COOH_3 + H_2 \longrightarrow CH_3CH(OH)CH_2COOCH_3$$

American workers using a catalyst similarly modified with chiral tartaric acid "template", hydrogenated 2-methylpyridine to optically active 2-methylpiperidine; and workers at the Zelinskii Institute in Moscow showed that metallic copper, cobalt, and palladium, when modified with chiral amino acids, are also good catalysts for a number of enantioselective hydrogenations.

[143] The state variables u_1 and u_2 are determined by the sequence of reaction steps in Figure 15 as:

$$du_1/dt = s(CO)p_{CO} - k_d u_1 - k_r u_1 u_2$$

$$du_2/dt = s(O_2)p_{O2} - k_r u_1 u_2$$

and the overall reaction rate R is given by $R = k_r u_1 u_2$, where k_r is the rate coefficient for the surface recombination rate at a particular temperature, and $s(CO)$ and $s(O_2)$ are the sticking coefficients for adsorption of CO and O_2 (normalized to the impingement rates from the gas phase determined by the partial pressures p_{CO} and p_{O2}). k_d is simply the rate coefficient for desorption of CO.

[147] Biologists, especially biochemists, mean by the word *substrate* the species that is bound to and converted by the enzyme. To the physical scientist, especially physical chemists, the *substrate* (or substratum) generally means the solid upon which a catalyst (or other material) is supported. To conserve conventions and to avoid confusion, we shall in our discussions of biocatalysts gradually adopt the biochemists' use of substrate.
[148] The structure at 3.5 Å resolution of a complete anti-canine lymphoma antibody in which all parts of the distorted Y-shaped molecule with two arms (the so-called Fab fragments) are localized in the crystal and visible in the electron density map has recently been published by L. J. Harris, S. B. Larson, K. W. Hasel, J. Day, A. Greenwood, A. McPherson, *Nature* **1992**, *360*, 369. In the last five years many Fab structures have been crystallographically determined, see, for example, refs. [149–153].

[166] According to Knowles [165] this arrangement is exquisite for several reasons. First, the fit is snug, the distance from the nearer carboxylate oxygen to the substrate's C-1 or C-2 atom being only 2.8 or 3.4 Å. Second, the carboxylate group is bidentate, which means that the proton can be removed from either C-1 or DHAP (from left to right in Fig. 20) or from C-2 of GAP (right to left), with minimal motion of the catalytic base. Third, the stereoelectronic requirement for rapid enolization is nicely satisfied by the active site arrangement of triosephosphate isomerase. And last, advantage is taken of the fact that a *syn* orbital of a carboxylate ion is much more basic than an *anti* orbital.

Scales of Nucleophilicity and Electrophilicity: A System for Ordering Polar Organic and Organometallic Reactions

Herbert Mayr * and Matthias Patz

Contrary to widely held opinion, for many reactions in organic and organometallic chemistry it is possible to define nucleophilicity and electrophilicity parameters that are independent of the reaction partners. This phenomenon, discovered by Ritchie during the early 1970s for reactions of highly stabilized carbenium and diazonium ions with n-nucleophiles, also occurs with reactions of carbenium ions with aliphatic and aromatic π-electron systems and in hydride transfer reactions. With the aid of the scales of nucleophilicity and electrophilicity set out here, which extend over eighteen orders of magnitude, forecasts can be made about the feasibility and rate of a given CC bond formation, ionic reduction, or diazo coupling. Linkage with the reactivity scales of Ritchie and Sweigart/Kane-Maguire enables a unified treatment of a large number of polar reactions.

1. Introduction

The foundations of our modern understanding of the course of organic chemical reactions were laid in the mid-1920s, when Lewis's electron theory of valency[1] and the general acid–base theory of Lowry and Brønsted were developed.[2] On this basis, Ingold, in the 1930s, introduced the concepts of "electrophiles" and "nucleophiles", signifying electron-seeking and nucleus-seeking species, respectively.[3]

The first systematic attempt to quantify the kinetic term "nucleophilicity" was reported by Swain and Scott, who investigated the rates of S_N2 reactions in 1953.[4] They defined nucleophilicity n as an inherent property of a substance according to Equation (a), in which s represents the sensitivity (specific to

$$\lg(k/k_{H_2O}) = sn \qquad \text{(a)}$$

each electrophile) of the rate constants to variations in the nucleophile. The S_N2 reactions of nucleophiles with CH_3Br in water were used as reference reactions ($s = 1$).

One year later, Edwards proposed a four-parameter equation in which the basicity and polarizability of the nucleophile were weighted differently according to the electrophile,[5] but this equation also did not find wide application. Parker demonstrated the great influence of solvation, reporting that, with S_N2 reactions, an increase in nucleophilicity by as much as a factor of 10^8 can be observed on changing from a solvent that forms hydrogen bonds to a dipolar aprotic solvent.[6] When Bunnett reviewed this field in 1963 he listed seventeen factors that must be considered in a quantitative representation of nucleophilicity.[7] Because the reactivities of nucleophiles towards *trans*-$[Pt(py)_2Cl_2]$ did not correlate with nucleophilicity parameters known at the time, Pearson et al. concluded that "at present (in 1968) it was not possible to predict quantitatively the rates of nucleophilic displacement reactions if a number of substrates of widely varying properties are considered."[8]

2. Constant Selectivity Relationships

In view of these complexities, a discovery by Ritchie in 1972 attracted much attention. He found that in reactions of carbocations and diazonium ions with nucleophiles, a particular nucleophile system can be characterized by one constant parameter N_+ which is independent of the nature of the electrophile [Equation (b)].[9]

$$\lg(k/k_0) = N_+ \qquad \text{(b)}$$

This relationship (Fig. 1) is also referred to as the "constant selectivity relationship", because the relative reaction rate of two nucleophiles (= selectivity) does not depend on the reactivity of the electrophile. Conversely, the relative reactivity of two electrophiles (= selectivity) is independent of the strength of the nucleophile. Deviations from this behavior are only observed at the diffusion limit.

It was later shown that Equation (b) is not strictly valid, and that better correlations are obtained when different families of electrophiles are treated separately.[10] However, in view of the range of the nucleophilicity scale (approximately 13 orders of magnitude), these discrepancies are negligible to a first approx-

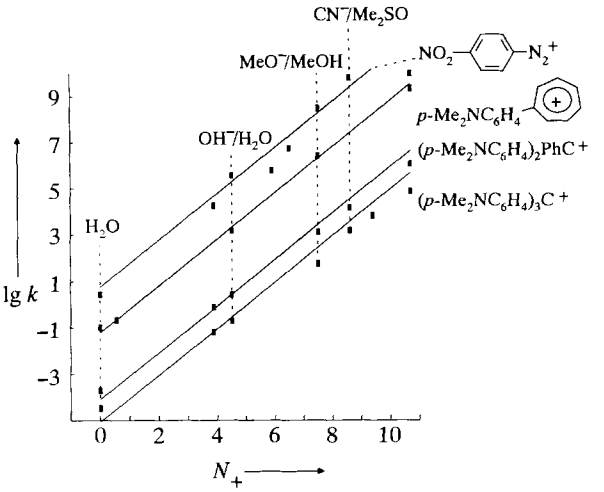

Fig. 1. Constant selectivity relationship according to Ritchie [9].

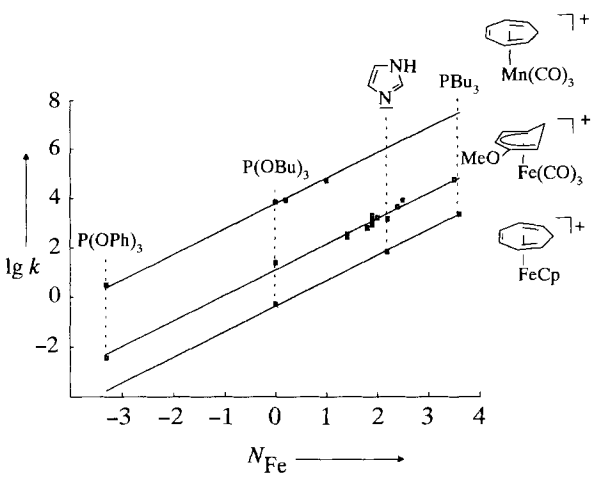
imation. Furthermore, since the behavior of uncharged electrophiles such as esters,[11] acceptor-substituted ketones,[12] and 2,4-dinitrohalobenzenes[13] is also consistent with Equation (b), its impact increases significantly.

Kane-Maguire, Sweigart et al. observed similar correlations in nucleophilic additions to metal-coordinated π-electron systems.[14] As shown in Figure 2, the relative reactivity of the organometallic complexes $[Mn(CO)_3(C_7H_8)]^+$, $[Fe(CO)_3(2\text{-}MeOC_6H_6)]^+$, and $[Fe(Cp)(C_7H_8)]^+$ is independent of the absolute reaction rates of the reference nucleophiles. Since the relative reactivities of phosphorus and nitrogen nucleophiles towards free carbocations and metal-coordinated π-electron systems are equal,[15] the Kane-Maguire and Sweigart N_{Fe} scale can be considered representative for both classes of electrophiles.

Constant selectivity relationships are also observed in the addition of diarylcarbenium ions (abbreviations defined in Scheme 1) to terminal double bonds, where the new CC bond is



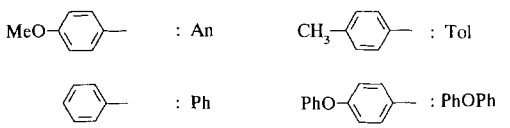


Fig. 2. Constant selectivity relationship according to Kane-Maguire and Sweigart et al. [14].

Scheme 1. Abbreviations used for aryl groups.

formed in the rate-determining step.[16] The relative reactivity of π-nucleophiles is independent of the electrophilicity of the carbenium ions, although the absolute reaction rates vary by more than five orders of magnitude (Fig. 3). If the results of competition experiments[17] are included, it can be shown that, in reactions of compounds containing terminal double bonds with diarylcarbenium ions, the constant selectivity relationship applies over a reactivity range of at least eight orders of magnitude.[16] Diarylcarbenium ions were therefore used as reference electrophiles to establish a scale of nucleophilicity for π-electron systems. As the diarylcarbenium ions so far used, from the bis(*p*-chloro)- to the bis(*p*-dimethylamino)-substituted diphenylcarbenium ion, cover a reactivity range of more than thirteen orders of magnitude, nucleophiles of very different reactivities

Herbert Mayr, born in 1947 in Weilheim, Oberbayern, studied chemistry at the Universität München and gained his doctorate in 1974 under R. Huisgen. After working for one year with G. A. Olah at the Case-Western Reserve University in Cleveland, Ohio, he joined P. von R. Schleyer in Erlangen where he habilitated in 1980. From 1984 to 1991 he headed the Institut für Chemie der Medizinischen Universität at Lübeck. In 1991, he was appointed Professor at the Institut für Organische Chemie in the Technische Hochschule, Darmstadt. His fields of research include syntheses via carbocationic intermediates, kinetics of ion–molecule reactions, linear free energy relationships, carbocationic telomerizations, and unusual cycloadditions.

H. Mayr

M. Patz

Matthias Patz was born in 1965 in Kiel. During his chemistry studies at the University of Hamburg, he spent six months at the University of Southampton. In 1990, he completed his Diploma thesis at the Institut für Anorganische und Angewandte Chemie at Hamburg on anionic effects in potassium crown ether complexes. Early in 1991 he began his doctorate studies in the research group of H. Mayr at the Institut für Chemie der Medizinischen Universität at Lübeck, and moved at the end of 1991 together with the research group to the Technische Hochschule, Darmstadt.

can be compared while the steric conditions of the electrophilic centers are kept exactly identical.

3. Rates of Electrophile–Nucleophile Combination Reactions

3.1. Methods of Determination

The majority of the rate constants quoted here have been determined by preparing solutions of stable carbenium ions (or other electrophiles) and monitoring the decrease in concentration after adding the nucleophile. If n-nucleophiles are used, there is a single reaction step (Scheme 2, first reaction), sometimes followed by a deprotonation step. On the other hand, the attack of carbenium ions on alkenes, arenes, allylsilanes, allylgermanes, allylstannanes, or hydrosilanes is the first step in a multiple stage reaction cascade (Scheme 2). The rate constants quoted in this article relate to the first step of this reaction sequence, namely bond formation between electrophile and nucleophile ("electrophile–nucleophile combination"), which is usually rate-determining. In these reactions there is no difference between the reaction rates of free and paired carbenium

Scheme 2. Single-step and multistep reactions of electrophiles (R^+) with nucleophiles. M = Si, Ge, Sn.

ions, which was at first surprising. This observation was explained[18] by the fact that the Gibbs free energy of paired carbocations is more favorable than that of the free ions by an approximately constant amount (about 14 kJ mol^{-1} in CH_2Cl_2, for example) independent of their structure. As this energy difference can also be assumed for the activated complexes, the reaction rate is the same for free and paired carbocations.[18] The reason for the different situation in the chemistry of carbanions has been discussed.[18b]

We determined rate constants of $k < 10^4$ L mol^{-1} s^{-1} conductometrically or photometrically using fiber optics, so that low temperatures and inert gas atmosphere could be employed without problems.[19] The research groups of Ritchie[20] and Kane-Maguire[21] mainly applied stopped-flow techniques (UV/VIS), allowing the measurement of more rapid reactions. In the investigation of carbonyl complexes, IR spectroscopy was also used.[21] With laser pulse methods the diffusion limit could be approached; the carbenium ions are produced by 20 ns laser pulses in the presence of nucleophiles,[22] and the dependence of their decomposition rate on the nucleophile concentration yields the rate constants of the electrophile–nucleophile combination reactions.

Furthermore, the relative reaction rates of alkenes and allylsilanes were determined by competition experiments in which carbenium ions were produced in situ in the presence of a pair of π-nucleophiles.[17, 23] The relative rate constants determined from the ratios of the products agree with the results of absolute rate measurements.[18]

The azide clock technique [24, 63] developed by Jencks exploits the fact that many carbenium ions undergo diffusion-controlled reactions with N_3^- ($k = 5 \times 10^9$ L mol^{-1}s^{-1}).[25] Hence, experiments in which carbenium ions are produced in situ in aqueous azide solutions enable the determination of absolute rate constants from the ratios of the capture products. However, the rate constants calculated from these competition reactions sometimes depend on the azide concentration, so rate constants determined with the azide clock are not always reliable.[26]

For the π-nucleophiles on which this review focuses, we have shown that measurements of absolute rate constants using either salts of stable carbenium ions or carbenium ions produced by laser flash photolysis give consistent results,[27] which have furthermore been verified by product studies in competition reactions. Hence for these nucleophiles there are three completely independent sets of data, whose agreement confirms that the electrophile–nucleophile combination reaction is the rate-determining step.

3.2. Reaction Rate as a Function of Nucleophile, Electrophile, Temperature, and Solvent

The rate constants of the electrophile–nucleophile combination reactions described in this paper are mainly dependent on the four factors mentioned in the heading of this section. A strict separation of these four factors is not possible. In particular, the magnitude of the nucleophilicity and electrophilicity parameters is often linked with the type of the solvent. For the reactions of carbocations with uncharged nucleophiles such as alkenes,[19] neutral hydride donors,[28] and phosphanes,[14] the reaction rate

Table 1. The effect of the solvent on the rate of reaction of carbenium ions with uncharged nucleophiles.

Electrophile (T[°C])	Nucleophile	Solvent	k [L mol^{-1} s^{-1}]	Ref.
An_2CH^+ (−30)	2-Methyl-1-pentene	CH_3NO_2	2.63	[19]
		$(CH_2Cl)_2$	0.958	[19]
		CH_2Cl_2	0.632	[19]
		$CHCl_3$	0.543	[19]
$AnPhCH^+$ (−20)	$HSiMe_2Ph$	CH_3NO_2	71.4	[28]
		CH_3CN	67.5	[28]
		CH_2Cl_2	47.7	[28]
$[Fe(CO)_3(C_6H_7)]^+$ (20)	$PTol_3$	CH_3NO_2	4.1×10^4	[21]
		$(CH_3)_2CO$	2.8×10^4	[21]
	Pyrrol	CH_3NO_2	0.89 [a]	[37]
		CH_3CN	1.34 [a]	[37]

[a] At 45 °C.

is hardly affected by the nature of the solvent (Table 1), because electric charges are neither "created" nor "destroyed" in the rate-determining step. Even the change from the slightly polar chloroform ($\varepsilon = 4.81$) to nitromethane ($\varepsilon = 35.94$) causes the rate of the reaction of bis(*p*-methoxyphenyl)carbenium ion (An_2CH^+) with 2-methyl-1-pentene to increase by a factor of only 4.8. Since the polarities of the solvents used in electrophile–nucleophile reactions normally lie between these two extremes, the influence of the solvent on the rate of such reactions can be neglected to a first approximation.

Reaction rates strongly dependent on the solvent are found, for example, when the reactivities of n-nucleophiles are compared in protic and aprotic solvents (see Section 1). For azo couplings, on the other hand, a correlation between the reaction rate and the donor number[73a] of the solvent is observed.[73b] In such cases, nucleophilicity and electrophilicity is more rationally defined with respect to a particular solvent (see Section 3.3.3).

3.3. Nucleophiles

3.3.1. *Introduction*

Nucleophiles can be classified according to the type of orbital in which the electrons that are available for the new bond with the electrophile are located. Thus, π-nucleophiles (e.g., alkenes), n-nucleophiles (e.g., phosphanes), and σ-nucleophiles (e.g., hydrides) may be distinguished. As it is easier to discuss differences and similarities within these groups, the three classes of nucleophiles are first treated separately.

3.3.2. *Reactivity of π-Nucleophiles*

3.3.2.1. *Alkenes, Dienes, and Alkynes*

Figure 4, which illustrates representative compounds from Table 2, shows that the alkyl-substituted ethenes fall into two groups: those that give secondary carbenium ions on electrophilic attack, and those that give tertiary carbenium ions. *Iso*-butene is 25000 times as reactive as propene, whose reactivity is hardly different from that of the *cis*–*trans* isomers of 2-butene. The steric effect of the *tert*-butyl group causes 2,3,3-trimethyl-1-butene to be 20 times less reactive than *iso*-butene. Consequently, its reactivity is similar to that of norbornene, which is intermediate in reactivity between precursors of secondary and tertiary carbenium ions, in accordance with the S_N1 reactivity of 2-norbornyl derivatives.

[a] The nucleophilicity parameters N and s are defined in Section 4.2 (approximate values in parentheses). [b] From relative reactivities towards Tol_2CH^+ [17, 30d]. [c] Estimated values in parentheses. See Section 3.5.

Unexpectedly large reactivity differences have been observed between the various methylenecycloalkanes.[30c] We found a correlation between the rates of the carbenium ion additions to methylenecycloalkanes and the solvolysis rates of the corresponding cycloalkyl derivatives in S_N1 reactions. Previously the trend in solvolysis was rationalized by a change in the strain (during in $sp^3 \rightarrow sp^2$ hybridization) for the rate-determining step.[31] In the addition reactions discussed here, none of the carbon atoms in the ring undergoes a change in hybridization in the rate-determining step, which throws doubt[30c] on Brown's I-strain theory[32] of the solvolysis of cycloalkyl compounds.[32]

The reactivities of the conjugated dienes and styrenes also reflect the stabilities of the allyl and benzyl cations produced by the electrophilic attack relative to alkylcarbenium ions (as derived from solvolysis data).[30a] In nonconjugated dienes, the additional double bond always causes a decrease in the nucleophilicity; no examples of nucleophilic assistance of the reaction by the second π-bond were found.[30b]

Whereas the nucleophilicities of the CC double-bond systems hitherto studied correlate with the S_N1 reactivities of the addition products, the triple bonds of 1-hexyne and phenylacetylene react much more rapidly than would be expected on the basis of the solvolysis rates of the corresponding vinyl chlorides.[30d] As a consequence of the large energy gain on conversion of a CC triple bond into one CC double bond and one CC single bond (compared with the change C=C → 2 C–C), alkynes are attacked by carbenium ions only slightly more slowly than the correspondingly substituted alkenes, although the vinyl cations produced from alkynes are intermediates of higher energy. Only relative to bridging electrophiles, for example, halogens do alkynes show a significantly lower nucleophilicity than alkenes.[33]

3.3.2.2. *Allylsilanes, Allylgermanes, and Allylstannanes*

The reactivities of allyl–element compounds (Table 3) and alkenes (Table 2) are compared in Figure 5, which shows that

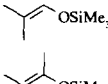
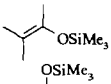
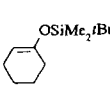
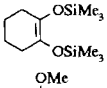
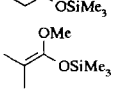
the replacement of an allylic hydrogen by a trimethylsilyl group increases the nucleophilicity of the double bond by the factor 200000. A comparison of allyltrimethylsilane with *iso*-butene indicates that a β-trimethylsilyl group in the intermediate carbenium ion increases the reactivity more than an α-methyl group. The series of allyltriphenyl–element compounds shows an increase in nucleophilicity in the order Si < Ge ≪ Sn. The low rates often observed for Lewis acid catalyzed reactions of allylstannanes are therefore a result of the rapid reaction of the allylstannanes with the Lewis acids and the weak nucleophilicity of the intermediates so obtained.[34]











The great influence of the substituents at silicon is apparent on comparing allyltrimethylsilane with allyltriphenylsilane. The difference between the inductive effects of methyl and phenyl causes the triphenylsilyl compound to be a factor of 58 less reactive. A still greater difference in reactivity is observed if a methyl group on the silicon is replaced by chlorine. Thus, allylchlorodimethylsilane is about three orders of magnitude less reactive than allyltrimethylsilane. Finally, replacement of an allylic hydrogen atom by a trichlorosilyl group causes deactivation by a factor of 350 (last two compounds in the right-hand column of Figure 5).[35]

Both columns of Figure 5 show an increase in nucleophilicity along the series $SiPh_3 < GePh_3 < SiMe_3 < SnPh_3 < SnBu_3$. The reactivity differences are smaller in the right-hand group of compounds, because the additional methyl group reduces the electron deficiency in the carbenium center of the intermediate.

3.3.2.3 Alkyl Enol Ethers and Silyl Enol Ethers

Because of the high nucleophilicity of enol ethers, their reactivity towards strong electrophiles such as $(p\text{-}ClC_6H_4)_2CH^+$ and $(p\text{-}MeC_6H_4)_2CH^+$ was determined by the rapid laser flash method (Table 4).[27] As shown by the comparison of 1-(methoxy)cyclopentene with 1-(trimethylsiloxy)cyclopentene, alkyl enol ethers and silyl enol ethers differ only slightly in reactivity. Many of the rate constants measured by laser flash spectroscopy are leveled by the proximity of the diffusion limit, and the differences in reactivity due to activation become more pronounced if the reactivities towards the less electrophilic bis(p-dimethylaminophenyl)carbenium ion are compared.[36] Since alkyl enol ethers polymerize under these conditions, so far only data for silyl enol ethers have been determined against this carbenium ion.

Table 4. Rate constants of the reactions of alkoxy- and siloxy-substituted ethenes with the bis(p-chlorophenyl)methyl cation **A** (CH_3CN), and the bis(p-tolyl)methyl cation **B** (CH_3CN) [27], and the bis(p-dimethylaminophenyl)methyl cation **C** (CH_2Cl_2) [36] at 20 °C.

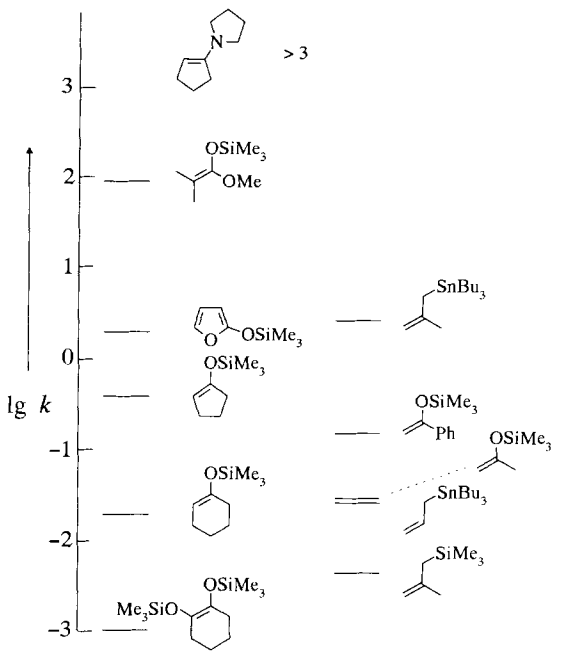

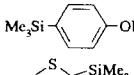

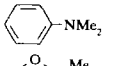

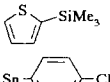

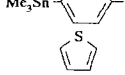

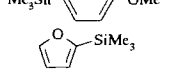

Fig. 6. Rate constants of the reactions of $(p\text{-}Me_2NC_6H_4)_2CH^+$ with electron-rich double-bond systems (CH_2Cl_2, 20 °C) [36, 88].

In Figure 6 the reactivities of silyl enol ethers are compared with those of allylsilanes and allylstannanes. For structurally analogous compounds ($H_2C{=}CMe{-}CH_2{-}SiMe_3$ < $H_2C{=}CMe{-}OSiMe_3 \ll H_2C{=}CMe{-}H_2SnBu_3$), the nucleophilicity of silyl enol ethers lies between that of allylsilanes and allylstannanes.

3.3.2.4. Arenes

The reaction of arenes with the tricarbonylcyclohexadienyl iron cation often does not follow a second order rate law. This behavior has been explained by the reversible formation of an intermediate π-complex.[37] However, second order rate constants were measured for a series of electron-rich arenes (Table 5).

Table 5. Rate constants of the reactions of arenes with the tricarbonylcyclohexadienyl iron cation in nitromethane at 45 °C [14]. Activation parameters $\Delta H^{\neq}$ [kJ mol^{-1}] and $\Delta S^{\neq}$ [J mol^{-1} K^{-1}] in parentheses.

We also observed complex kinetics in the reactions of diarylcarbenium ions with benzene derivatives,[38] but attributed this finding to the reversible formation of a σ-complex. In agreement with this assumption, we obtained second order kinetics (Table 6) by adding a tetraalkylammonium salt: the anion, present in high concentration, acts as a base, rapidly deprotonating the intermediate benzenium ion. The relative reactivities of the arenes correlate with their basicities (Fig. 7), as was concluded earlier from the relative arene reactivities determined in competition experiments.[39]

3.3.3. Reactivity of n-Nucleophiles

Amines, phosphanes, phosphites, and a number of anions are the most widely investigated representatives of n-nucleophiles. Many reactions with water and hydroxide ions were followed to classify the electrophilicities of carbocations (see Section 3.4.2).

As described in Section 3.2, the rates of the reactions of carbocations with uncharged nucleophiles in aprotic solvents are almost independent of the solvent polarity. Hence the rate constants given in Table 7 for reactions with the tricarbonylcyclohexadienyl iron cation[40] reflect the intrinsic nucleophilicity of phosphanes and phosphites.

Table 7. Rate constants of the reactions of phosphanes and phosphites with the tricarbonylcyclohexadienyliron cation (20 °C, acetone).

The higher reactivity of tris(p-tolyl)phosphane and tris(p-anisyl)phosphane relative to triphenylphosphane suggests that the electron density on the phosphorus atom is increased by mesomeric interactions with the substituents. Phosphites are significantly less reactive than phosphanes, because in this case the mesomeric effect is outweighed by the marked negative inductive effect of the oxygen.

Because the rate constants in Tables 7 (phosphanes in acetone) and 8 (amines in acetonitrile) are fairly independent of the solvent, the two sets of data can be compared directly. Amines and phosphanes are thus seen to be similarly nucleophilic in aprotic solvents.

As shown, for example, by McClelland, Steenken et al.,[48] in water-acetonitrile mixtures the nucleophilicity of amines decreases on changing from aprotic to protic solvents, because hydrogen bonds to the nitrogen are formed. For this reason, the nucleophilicity series of amines in water determined by Ritchie (Table 9) differs considerably from the reactivity series in aprotic solvents (Table 8).

Table 8. Rate constants of the reactions of amines with the tricarbonylcyclohexadienyliron cation (20 °C, acetonitrile).

The difference in the reactivity of anionic nucleophiles in protic and aprotic solvents, described by Parker for S_N2 reactions,[6] is also observed in the electrophile–nucleophile combination reactions discussed here. Ritchie's N_+ parameters for the azide ion in water (7.6) and in dimethylsulfoxide (DMSO, 10.07) imply, for example, that the azide ion reacts with carbocations in water almost 300 times more slowly than in DMSO.[11] In contrast to the situation for combinations of carbocations with amines discussed above, hydrogen bond formation is not the only factor responsible for the reduced nucleophilicity of anions. Since cation–anion combinations neutralize charge, large reactivity differences on varying solvent polarity are also observed in aprotic solvents.[52] The rates of the combination reactions greatly increase with decreasing solvent polarity, so the reactivity of anionic nucleophiles towards cations can only be defined with respect to a given solvent.

3.3.4. *Reactivity of σ-Nucleophiles (Hydrides)*

In this section, discussion is limited to the abstraction of H^- from hydrides of Main Group 4 elements, which have been studied in detail. In most investigations of hydride abstractions from CH bonds, the triphenylcarbenium ion (= trityl cation) has been employed as the hydride acceptor.[53] Because of their importance in biochemistry, hydride transfers from NADH analogues have been extensively investigated, in particular, N-benzyl-1,4-dihydronicotinamide.[54] Bunton et al. showed that the reactions of cations with this hydride donor obey the N_+ relationship of Ritchie.[55] As these data are primarily used for the characterization of the electrophilicity of carbenium ions, they are discussed in Section 3.4.2.

The reactivity of silanes, germanes, and stannanes towards the hydride acceptor AnPhCH$^+$ increases with increasing metallic character of the central atom and the associated increasing hydride character of the hydrogen (Fig. 8, Table 10). The influence of substituents on the reactivity of the silanes shows that conjugative and hyperconjugative effects assist the formation of the intermediate silicenium ions to a much lesser degree than the formation of carbenium ions. An earlier claim that hydride abstraction from silanes involve a rate-determining one-electron transfer[53a] could be clearly disproved by the H–D isotope effects on reaction rates and products.[28] The transfer of hydride from the silicon to the carbenium center in the rate-determining step was thus confirmed.

The reducing power of *N*-benzyl-1,4-dihydronicotinamide (BDHNA) in water lies between that of BH_4^- and that of BH_3CN^- (Table 11). In less polar solvents the reactivities of the

Table 11. Rate constants of the reactions of the ferrocenyl–anisyl–carbenium ion with 1-benzyl-1,4-dihydronicotinamide (BDHNA) and borohydride anions (25 °C, water) [55].

Nucleophile	k [$L\,mol^{-1}\,s^{-1}$]
BH_4^-	1.5×10^{6}
BDHNA	1.5×10^{5}
BH_3CN^-	7.4×10^{3}

anionic hydride donors BH_4^- and BH_3CN^- are more enhanced than that of BDHNA, with the result that in such solvents the uncharged hydride donor shows the lowest reaction rate of these three reducing agents.[55]

3.4. Electrophiles

3.4.1. The Reactivity-Selectivity Principle as a Basis for Scales of Electrophilicity?

Because of the difficulties in determining absolute reaction rates, the selectivity S_F of electrophiles has been used as an indicator of their reactivity.[39b] S_F expresses the ability of an electrophile to differentiate between the *meta* and *para* positions of a monosubstituted benzene [Eq. (c); m_f, p_f: partial rate factors; b: proportionality constant]. According to the reactivity–selectivity principle, reactive electrophiles are characterized by low selectivity, and less reactive electrophiles by high selectivity. The proportionality between intra- [$\lg(p_f/m_f)$] and intermolecular [$\lg p_f$] selectivity, which is described by Equation (c), is well documented. It is a necessary consequence of the linear free

$$S_F = \lg(p_f/m_f) = b\lg p_f \qquad (c)$$

energy relationships that hold for electrophilic substitutions in the *meta* and *para* positions of a monosubstituted benzene.

The relationship between selectivity S_F and reactivity is less clear, as both slow reactions with low selectivity (mercurations) and rapid reactions with high selectivity (acylations) are known.[57] After the fall of the reactivity–selectivity principle,[58–60] these examples are now no longer exceptions to the rule, and it has become clear that electrophilic reactivities cannot be derived from selectivity data.[16, 26, 59, 60] Scales of electrophilicity must be determined by other means.

3.4.2. Scales of Electrophilicity from "Constant Selectivity Relationships"

Ritchie's N_+ relationship [Equation (b)] contains not only the nucleophilicity parameter N_+, which has been discussed, but also the electrophilicity parameter $\lg k_0$, which is independent of the nucleophile and is the rate constant of the reaction of a given electrophile with water.[9] The parameter $\lg k_0$ can therefore also be represented by E_+ [Eq. (d)].

$$\lg k = E_+ + N_+ \qquad (d)$$

Kane-Maguire, Sweigart et al. analogously obtained a scale of electrophilicity for complexes between transition metals and π-hydrocarbons (Table 12) by using phosphanes and phosphites as reference nucleophiles.[14]

The π-nucleophiles that we have investigated are mostly less reactive than the n-nucleophiles studied by Ritchie, Kane-Maguire, and Sweigart, and are therefore suitable for the characterization of strong electrophiles. Just as the electrophilicity scale of Table 12 is obtained from the y-intercepts in Figure 2, we now obtain the relative electrophilicities of diarylcarbenium

Table 12. Relative reactivities of metal π-complexes towards phosphorus nucleophiles (in acetone, acetonitrile, and nitromethane at 20 °C) [14]. See also Fig. 2.

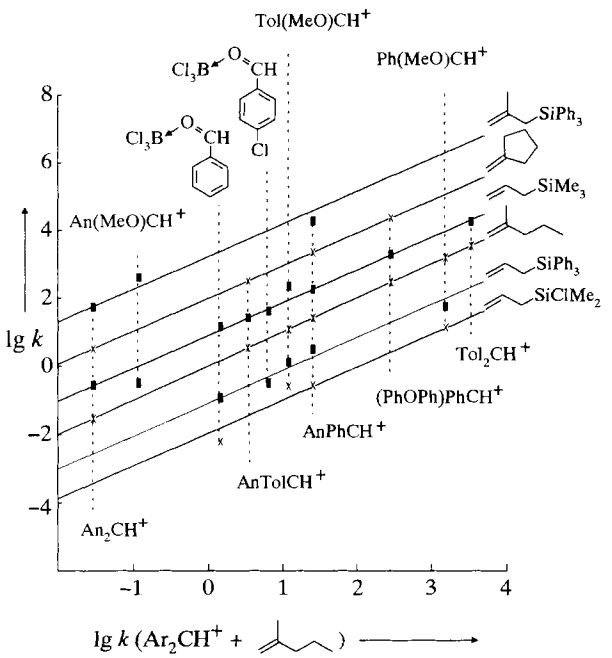
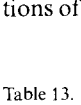
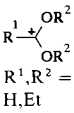
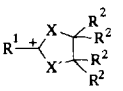
$[W(CO)_3(C_7H_7)]^+$	5.77		

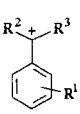
ions from the x-intercepts in Figure 3 and related plots. Since the constant selectivity of diarylcarbenium ions towards terminal vinyl derivatives is also valid for other types of C-electrophiles (Fig. 9),[61] the positions of these electrophiles in Figure 9 reflect their relative electrophilicities.











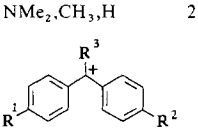


Fig. 9. Rate constants for the reactions of diaryl- and methoxycarbenium ions, and of complexes between aldehydes and Lewis acids with alkenes and allylsilanes (CH_2Cl_2, −70 °C). The rate constants for the reactions of the Lewis acid complexes and the anisyl(methoxy)carbenium ion with 2-methyl-1-pentene were extrapolated from the linear free energy relationship. To facilitate the discussion, the line defined for 2-methyl-1-pentene is also depicted (unity line).

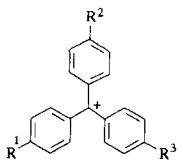

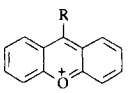

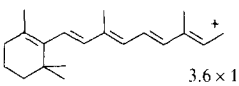

Although the validity of the N_+ relationship has been demonstrated for reactions of some carbenium ions with water, it does not follow that the reactivity order of the electrophiles towards water given in Table 13 exactly reflects their relative reactivity towards other nucleophiles, especially as the k values relate to various mixtures of solvents. The α-methoxybenzyl cation, for example, reacts approximately two orders of magnitude more rapidly with water than the bis(*p*-tolyl)carbenium ion, whereas these two electrophiles hardly differ in their reactivity towards π-nucleophiles (Fig. 9). Possibly the anomeric stabilization of the hemiacetals already affects the transition state of the reactions of carboxonium ions with water. In spite of this discrepan-

cy, the data in Table 13 provide valuable information about the approximate reactivities of numerous synthetically important electrophiles, as shown by the correlation discussed in Section 4.2.

As mentioned in Section 3.3.4, the rate of hydride transfer from *N*-benzyl-1,4-dihydronicotinamide (BDHNA) to many electrophiles has been investigated (Table 14).[54] Because this compound is a relatively strong nucleophile, the investigations focused on electrophiles of very low reactivity, which do not react with water, or do so only sluggishly.

The reaction rates of carbocations with BDHNA were usually determined in water. Because of the possibility of hydrogen bond formation, only the order of magnitude of these rate constants can be compared with those obtained in reactions of BDHNA with cations in aprotic solvents.

3.5. Effect of Temperature

The effect of temperature on selectivity in radical and carbene reactions has been extensively discussed by Giese.[59, 87] The selectivity order of various radicals for a pair of competing reagents above the isoselective temperature is exactly the reverse of that below it, while at the isoselective temperature all the radicals of tbe reaction series show the same selectivity. The isoselective temperature for the reaction of diarylcarbenium ions with the pair allyltrimethylsilane/2-methyl-2-butene, is about 1000 K (Fig. 10), which is far outside the experimental range. In the ideal case of isentropic reaction series, the isoselective temperature is $T = \infty$.

In some cases, the reaction at a particular temperature is completely unselective ($\lg \kappa = 0$), and the relative nucleophilicity of two reaction partners is reversed above and below this temperature. Below -57 °C, for example, the *p*-anisyl(phenyl)carbenium ion reacts more rapidly with 2-methyl-2-butene than with allyltrimethylsilane, while above -57 °C the allyltri-

methylsilane is more reactive. At $-57\,^{\circ}C$, the electrophile does not differentiate between the two nucleophiles, and the intersection point with the zero line is termed the aselective temperature.[16b]

A further problem for the construction of reactivity scales is thus encountered. The relative reactivity of the two nucleophiles considered in Figure 10 depends not only on the electrophile but also on the temperature. At low temperatures, 2-methyl-2-butene is always the stronger nucleophile, but above the aselective temperature, which depends on the electrophile, allyltrimethylsilane is more reactive than 2-methyl-2-butene.

The effect of temperature is certainly relatively small in general, with the result that large changes in the electrophilicity and nucleophilicity order do not occur with variations in temperature. If nucleophiles of very similar reactivity but different activation enthalpy (and entropy) are compared, however, a transposition on the reactivity scale may result. How can one judge whether relative reactivities are likely to be affected by such a temperature-dependent reversal?

In almost all the reaction series so far investigated, we have found that the activation entropy is largely dictated by the structural type of the nucleophile, but is influenced only slightly by the nature of the carbocationic electrophile, even when its reactivity changes by about six orders of magnitude (Table 15). If

rate constants for electrophile–nucleophile combination reactions are known at only one temperature, the activation parameters and hence the temperature dependence of the reaction rate can therefore be derived from the known rate constant and the estimated activation entropy; $\Delta S^{\neq}$ is assumed to be identical to that for the reaction of the nucleophile concerned (or of a structurally related nucleophile) with any carbocation.

4. Construction of Averaged Scales of Electrophilicity and Nucleophilicity

4.1. The Coexistence of Constant Selectivity Ranges and of Domains of the Reactivity–Selectivity Principle

Strictly speaking, the construction of scales of electrophilicity and nucleophilicity is only meaningful in regions of constant selectivity, as only then is the nucleophilicity series, determined with respect to one electrophile, transferable to another electrophile and vice versa. This situation is almost realized for the systems studied by Ritchie and by Kane-Maguire, Sweigart et al. (cf. Section 2).

In reactions of diarylcarbenium ions with compounds with terminal CC double bonds, the relative reactivity of the π-nucleophiles remains the same while the electrophilicity of the carbenium ions changes by six orders of magnitude ($k = 10^{-2}$–$10^{4}\,L\,mol^{-1}\,s^{-1}$, Fig. 3). For trimethylsiloxycyclohexene and 2-methyl-1-pentene (Fig. 11), the constant selectivity relation-

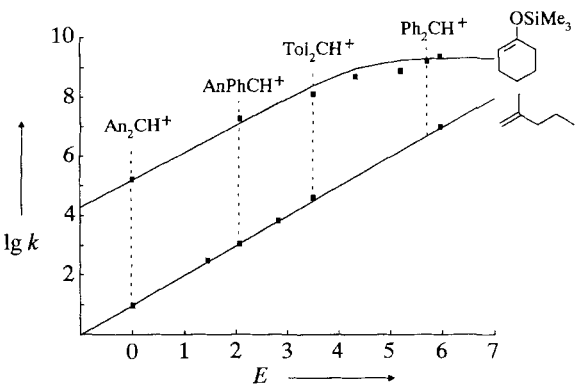

Fig. 11. Comparison of the rate constants of the reactions of diarylcarbenium ions with 2-methyl-1-pentene and trimethylsiloxycyclohexene (20 °C). The electrophilicity parameter E plotted on the x-axis is introduced in Section 4.2.

ship is valid up to rate constants of about $5\times10^{7}\,L\,mol^{-1}\,s^{-1}$. On use of even stronger electrophiles this value of k is exceeded, and the diffusion limit is approached. Then deviations from the linear free energy relationships result, and the ability of the electrophiles to differentiate between the two π-nucleophiles is reduced. An inverse proportionality between reactivity and selectivity can, therefore, only be expected with confidence (see Section 3.5) if the rate constant for at least one of the pair of competing substances is greater than $5\times10^{7}\,L\,mol^{-1}\,s^{-1}$. As the rate constants of the reactions of many reactive intermediates are of this magnitude, the success of the reactivity-selectivity principle in rationalizing the observed carbene and radical reactivities can be explained. Nevertheless, Giese has shown that, even with these systems, violations of the reactivity-selectivity principle often occur.[59]

Our observation that deviations from the linear free energy relationships only occur when the diffusion limit is approached is basically in agreement with the conclusions reached from selectivity studies with carbenium ions produced in solvolysis reactions.[26, 90, 91] It should, however, be noted that in these reactions a narrow transition region has been postulated[91] in which the selectivity is expected to decrease with increasing reactivity because the transition state becomes more similar to the reactants (Hammond region). Our data give no indication of such a region, so in these reactions we question whether a shift of the transition state on the reaction coordinate is the origin of the decreasing selectivity with increasing reactivity.

The relationships between reactivity and selectivity in reactions of carbenium ions with π-nucleophiles do not always have

the simple form shown in Figures 3 and 11. In general, we find that π-nucleophiles with a methyl group at the carbon which forms the new CC bond react more sensitively to a variation in the electrophile than the corresponding unsubstituted compounds. The lines for 2-methyl-2-butene and *trans*-β-methylstyrene in Figure 12, for example, have a greater slope than

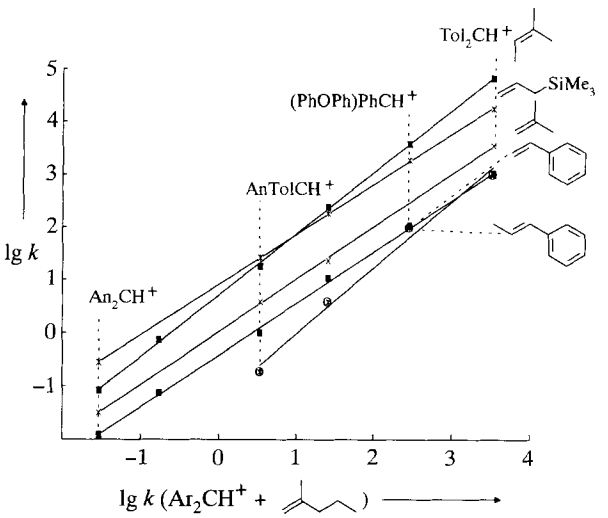

Fig. 12. Rate constants for the reactions of diarylcarbenium ions with various double-bond systems (CH_2Cl_2, −70 °C).

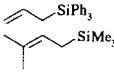

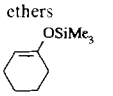

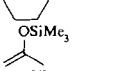

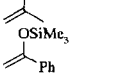

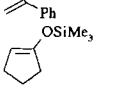

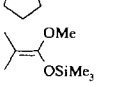

those for *iso*-butene and styrene. Although the reason for the different slopes is not yet clear, it can be excluded that steric factors alone are the cause. Tetramethylethene, 2-methyl-4-trimethylsilyl-2-butene, and 1-methoxy-2-methyl-1-trimethylsiloxy-1-propene, for example, are affected quite differently by variation of the electrophile (Table 16) in spite of the same substituent at the point of attack of the electrophile.

Because of the different slopes (Fig. 12), different types of reactivity-selectivity relationships result in the linear region of the free energy relationships. The bis(*p*-methoxyphenyl)carbenium ion, for example, reacts only a little more rapidly with 2-methyl-2-butene than with *iso*-butene. With increasing electrophilicity of the carbenium ion, the reactivity difference between the two π-nucleophiles initially increases (increasing selectivity) before the approach to the diffusion limit (not shown in Fig. 12) causes it to decrease.

Two reversals of the reactivity–selectivity relationship are observed for the 2-methyl-2-butene/allyltrimethylsilane pair. Carbenium ions with low electrophilicity react more rapidly with allyltrimethylsilane than with 2-methyl-2-butene (Fig. 12). With increasing reactivity of the carbenium ions the selectivity decreases, and the correlation lines cross; on further increase of the electrophilicity, the selectivity increases, now in favor of the 2-methyl-2-butene. If very strong electrophiles are used, the selectivity eventually decreases because the diffusion limit is approached.

The styrene/β-methylstyrene pair behaves similarly. Carbenium ions with low electrophilicity show a preference for styrene; an increase in electrophilicity leads to a reduction in the reactivity difference, the bis(*p*-methylphenyl)carbenium ion reacting with both nucleophiles at equal rates. On further increase in electrophilicity, the reaction rate of the methylated styrene increases to a greater extent, with the result that in competition experiments with the unsubstituted diphenylcarbenium ion, *trans*-β-methylstyrene is favored over styrene by a factor of 4.4.[17b] In this region the selectivity is enhanced in proportion with reactivity, but is reduced on further increase in reactivity, because the two nucleophiles again react with equal rates when the diffusion limit is reached.

[a] For pseudo-first-order rate constants with nucleophile as solvent. [b] In water. [c] For the formulas of the electrophiles, see Table 17.

These examples highlight the problems of a single parameter scale of nucleophilicity. If a nucleophilic series is based, for example, on the bis(*p*-methoxyphenyl)carbenium ion as a reference electrophile, the sequence β-methylstyrene < styrene and 2-methyl-2-butene < allyltrimethylsilane is found. If a stronger electrophile (Ph_2CH^+) is used, the sequence becomes styrene < β-methylstyrene and allyltrimethylsilane < 2-methyl-2-butene, and Ph_2CH^+ cannot differentiate at all between strong nucleophiles such as reactive enol ethers.[27] In summary, also for simple electrophile–nucleophile combination reactions, constant selectivity relationships are not strictly fulfilled if a large structural variety of electrophiles and nucleophiles is allowed.

While the problem of diffusion-controlled reactions can be circumvented by using weaker electrophiles for the characterization of strong nucleophiles, the examples discussed above show that even for the electrophile–nucleophile combination reactions illustrated in Figure 12, one single parameter is not sufficient for the characterization of nucleophilic properties. It should rather be borne in mind that in certain cases the *relative* strength of nucleophiles also depends on the electrophile.

4.2. Correlation Analysis

In view of the intersection of correlation lines demonstrated in Section 4.1, it seems expedient not to base the construction of scales of electrophilicity and nucleophilicity on the two-parameter equation of Ritchie [Equation (b)], but also to take into account the different slopes of the correlation lines.

In many investigations of the reactions of diarylcarbenium ions with nucleophiles, the observed rate constants could be represented extremely well by Equation (e) (see also Figs. 3, 9, 12).[16, 28, 35]

$$\lg k = s\lg k_0 + c \qquad \text{(e)}$$

The quantity $\lg k_0$ (rate constant of the reaction of the electrophile with 2-methyl-1-pentene) is a measure of the strength of the electrophile, while the nucleophile is characterized by the quantities c (= 0 for 2-methyl-1-pentene) and s (= 1 for 2-methyl-1-pentene). For nucleophiles stronger than 2-methyl-1-pentene, c adopts a value greater than 0,[92] and for nucleophiles more sensitive than 2-methyl-1-pentene to changes in the electrophile, s is greater than 1.

Problems arise, however, if Equation (e) is used for systems with large absolute values of $\lg k_0$ (very strong or very weak electrophiles), because uncertainties in the value of s have a large effect on the calculated rate constant. We avoid this problem by replacing Equation (e) by Equation (f), which contains,

$$\lg k = s(E + N) \qquad \text{(f)}$$

in addition to an electrophilicity parameter E and a nucleophilicity parameter N, the nucleophile-specific slope parameter s already used in Equation (e). Differences between the s values given in Table 16 and in the literature[16, 28, 35] are mainly due to different reference temperatures.

As most of the experimental values ($\lg k$) used for calculating the correlation lines lie between −4 and +4, inaccuracy in the value of s (= 0.5–1.5) is less serious if Equation (f) is used, because the expression in parentheses ($E + N$) to be multiplied always has a small absolute value. The advantage of using Equation (f) rather than Equation (e) is shown graphically in Figure 13. If the electrophilicity scale is plotted on the x-axis, the nucleophilicity parameter c is obtained, according to Equation (e), from the point of intersection of the correlation lines with perpendiculars at $E = \lg k_0 = 0$, which is sometimes far outside the experimental range. On the other hand, the nucleophilicity parameter N [Eq. (f)] is obtained from the point of intersection of the correlation lines with the horizontal line de-

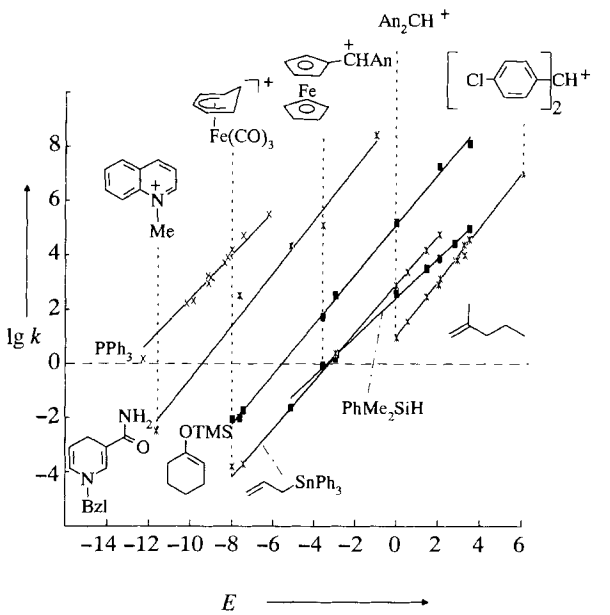

Fig. 13. Rate constants for electrophile–nucleophile combination reactions at 20 °C. Graphical representation of 6 of the 56 correlations listed in Tables 16 and 17.

fined by $\lg k = 0$, which usually lies within or close to the experimental range. The nucleophilicity parameter N then corresponds to the negative value of E for that electrophile with which the nucleophile concerned reacts with a rate constant $k = 1$.

For the correlation analysis, the electrophilicity E of the bis(*p*-methoxyphenyl)methyl cation was set at 0, and the slope parameter s of 2-methyl-1-pentene at 1. Then, the rate constants ($\lg k$) for the combination reactions of diarylcarbenium ions with nucleophiles that have been investigated in detail were subjected to least-squares fitting. The parameters so obtained were kept constant, and other systems were then incorporated by minimizing the squares of the deviations of observed and calculated logarithms of rate constants to yield the data of Table 16.

A standard temperature of 20 °C was chosen for the correlations. In cases where reactions were investigated at another temperature, and activation parameters are not known, the conversion to 20 °C was carried out by estimating the activation entropy (see Section 3.5) which in combination with $\lg k$ allows the activation enthalpy to be calculated.

As the solvent has only a small effect on the rates of most of the electrophile–nucleophile combination reactions discussed here (see Section 3.2), the solvents used in Table 16 are generally not explicitly reported. This information is only given in the case of n-nucleophiles, whose reactivity was frequently investigated in protic solvents, if the nucleophilicity parameters are based on a protic solvent.

Figure 13 illustrates 6 of the 56 lines obtained by correlation analysis. Over the whole reactivity range from very slow reactions ($k \approx 10^{-5}\,\mathrm{L\,mol^{-1}\,s^{-1}}$) up to rate constants of $5 \times 10^{7}\,\mathrm{L\,mol^{-1}\,s^{-1}}$, there are linear relationships. Deviations from linearity only occur as the diffusion limit is approached (see Section 4.1). The series of cationic electrophiles extends from the highly reactive bis(*p*-chlorophenyl)methyl cation ($pK_{R^+} = -14$),[105] which requires very strong Lewis or Brønsted acids for its formation, up to the *N*-methylquinolinium ion ($pK_{R^+} \approx 16.5$),[106] which exists as a cation even in dilute sodium hydroxide solution. A similar reactivity range is covered by nucleophiles, extending from the slightly nucleophilic toluene, through alkylethenes and enol ethers, up to the strongly nucleophilic amines and phosphanes.

Steric effects, which naturally also affect the rate of these reactions, were neglected in our analysis. This is possible because, relative to the enormous reactivity range, the corrections are mostly only small. However, triarylcarbenium ions are excluded from our analysis for the time being to avoid an explicit treatment of the steric effects. It is known that these react significantly more slowly than expected from their Lewis acidity, because of steric shielding.[28, 107]

If the observed pseudo-first-order rate constants for reactions with water (Table 13) are plotted against the electrophilicity parameters E (Table 17), a linear correlation (Eq. (g), and Fig. 14, $r = 0.996$, 13 points plotted) is obtained, from which only the value for the α-methoxybenzyl cation deviates significantly.

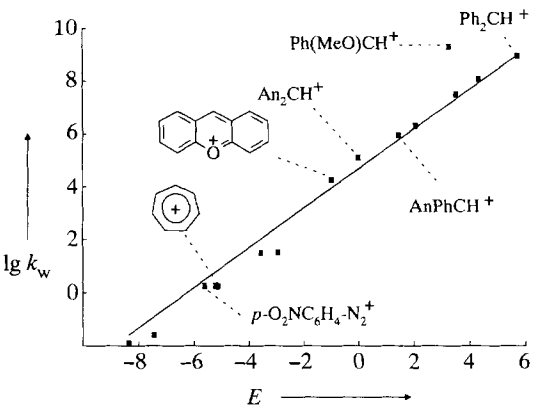

Fig. 14. Correlation between the rate constants of the reactions of electrophiles with water (pseudo-first-order rate constants, Table 13) and the electrophilicity parameters of Table 17.

This correlation equation (g) enables the electrophilicity parameters E to be roughly estimated from known rate constants for the reaction with water. The limits of this method are illustrated by the scatter of the points about the correlation line in Figure 14. As some of the k_w values given in Table 13 are identical to Ritchie's k_0 values, Equation (g) represents the link between our E scale and Ritchie's electrophilicity series.

$$E = 1.24 \lg k_w - 5.80 \quad (k_w \text{ from Table 13}) \qquad \text{(g)}$$

From the overlap of the data in Tables 12 and 17, the correlation equation (h) can be derived, with which Kane-Maguire's k_{rel} values for metal complexes (Table 12) can be converted to electrophilicity parameters E.

$$E = 1.38 \lg k_{rel} - 18.2 \quad (\lg k_{rel} \text{ from Table 12}) \qquad \text{(h)}$$

As the k_{rel} values of Table 12 and the corresponding E values of Table 17 are for the most part based on the same experimental data, the correlation coefficient for Equation (h) is meaningless.

Table 17. Electrophilicity scale for nonprotic solvents (20 °C).

[a] In dichloromethane. [b] In acetonitrile. [c] For the formulas of the nucleophiles, see Table 16.

In the same way, from the overlap of the entries in Tables 7 and 8 with those in Table 16, Equation (i) is calculated, which

$$N = 1.51 \lg k + 7.53 \ (k \text{ from Tables 7 and 8}) \qquad \text{(i)}$$

represents a link between the nucleophilicity series of Sweigart/Kane-Maguire[14] and the N scale introduced in this article.

Finally, comparison of the data in Table 16 with those in Table 1 of ref. [11] gives Equation (k), which combines Ritchie's N_+ scale with the N scale of Table 16.

$$N = 1.20N_+ + 6.18 \quad \text{(k)}$$

When nucleophilicity parameters derived from Equations (i) and (k) are used in the calculation of rate constants according to Equation (f), the best error compensation is obtained if the slope parameters $s = 0.66$ [Eq. (i)] or $s = 0.83$ [Eq. (k)] are used, these being the reciprocals of the slopes in these equations.

5. Predicting Polar Organic Reactions

If it is assumed that Equation (f) is also valid for combination reactions of nucleophiles and electrophiles given in Tables 16 and 17, but not yet investigated, the rate constants for 2408 electrophile–nucleophile combination reactions can be calculated. If Ritchie and Sweigart/Kane-Maguire scales are incorporated by using Equations (g) to (k), and the extrapolated nucleophilicity parameters of Tables 2, 3, and 6 are included, the forecasting potential is considerably increased.

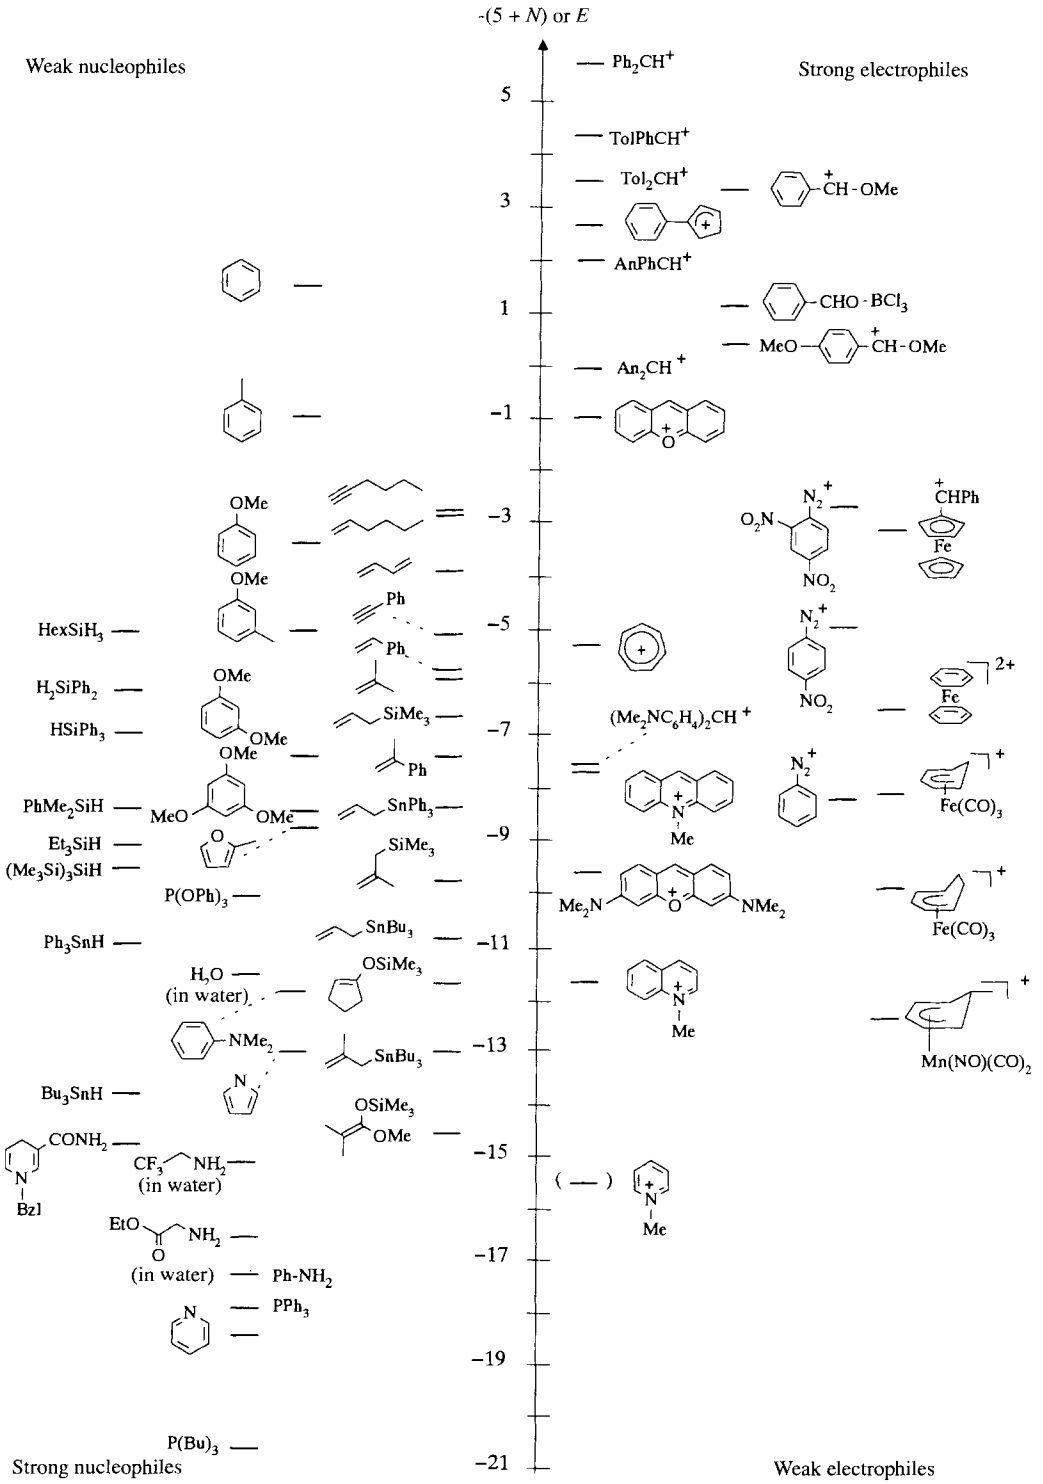

Fig. 15. What reacts with what? Graphical representation of the averaged nucleophilicity and electrophilicity series.

Which electrophile–nucleophile combination reactions take place at 20 °C? In Figure 15 the reaction partners are plotted in such a way that the equation $E = -(5 + N)$ is valid for electrophiles and nucleophiles that are opposite each other. That is, the electrophilicity scale is arranged counter to the nucleophilicity scale. According to Equation (f), for electrophile–nucleophile pairs that are on the same level, $\lg k = -5s$. For most nucleophiles, the limits of s are $0.6 < s < 1.2$ (Table 16); thus for adjacent electrophile–nucleophile pairs, combination rate constants at 20 °C of 10^{-3}–10^{-6} L mol^{-1}s^{-1} are to be expected. If the concentration of the component in excess is 1 mol L^{-1}, half-lives are 12 min to 8 days. To a first approximation, electrophiles will react at 20 °C with all nucleophiles that appear below them in Figure 15. Clearly this can only give a rough picture, and Equation (f) must be used for more precise predictions.

Some examples will illustrate this procedure:

In Figure 15, anisole lies above the tropylium ion; a rapid reaction is unlikely. From Equation (f), a rate constant 10^{-8} L mol^{-1}s^{-1} is calculated, in agreement with the observation that this reaction does not take place at room temperature. Even if tropylium tetrachloroaluminate is heated with anisole to 85 °C, no substitution product is obtained, and the reaction of tropylium chloride with anisole at 85–90 °C for five hours yielded 0.8% *p*-anisylcycloheptatriene.[108] On the other hand, tropylium tetrafluoroborate reacts smoothly at room temperature with allylsilanes,[109] *iso*-butene, and α-methylstyrene,[110] as expected from Figure 15 and Tables 2, 16, and 17.

The tricarbonyl(cyclohexadienyl)iron cation reacts rapidly with silyl enol ethers and allylstannanes even at room temperature.[111] However, the reaction with allyltrimethylsilane required heating for six hours.[112] We are not aware of any reactions of this cation with alkylated ethenes. If these take place at all, they must require more extreme conditions.

Diazo couplings with the benzenediazonium ion are usually carried out with aromatic amines or phenolate ions, whereas phenol ethers are inert. However, the strongly electrophilic 2,4-dinitrobenzenediazonium ion also reacts with anisole, and reaction with the 4-nitrobenzenediazonium ion occurs if the more electron-rich *m*-methylanisole is used.[113] Coupling of 1,3,5-trimethoxybenzene even occurs with the benzenediazonium ion.[113] Likewise, reactions of the 2,4-dinitrobenzenediazonium ion with numerous 1,1-dialkylethenes,[114] styrene,[114] and allylsilanes[115] have been described, but there was no reaction with monoalkylated ethenes.

Equation (f) and the simplified form of Figure 15 not only answers the question whether a reaction proceeds at all, but also helps determine chemoselectivities. If, for example, values of $\lg k$ are calculated to be greater than 8, the diffusion limit is being approached, and hence selectivities in competition reactions will decrease or disappear.

As evident from the derivation, this analysis only considers the kinetic aspects of electrophile–nucleophile combination reactions. Thermodynamic factors are not included, and it is well known that, especially in the coordination of electrophiles with n-nucleophiles, an unfavorable equilibrium often prevents a process that would be expected to take place on kinetic grounds.

6. Conclusions and Future Prospects

The statement made by Pearson 25 years ago that it was then impossible to predict rates of nucleophilic substitutions quantitatively if substrates with very different properties were used is still relevant today.[8] An all-embracing theory of electrophile–nucleophile reactions is still not in sight.

Nevertheless, we have shown in this review that the constant selectivity relationships discovered in the early 1970s by Ritchie, and further developed by Sweigart and Kane-Maguire, are valid with minor modifications in broad areas of organic and organometallic chemistry. These particularly include reactions of cationic carbon electrophiles with nucleophiles in which only one bond is formed in the rate-determining step (no cycloadditions!) and no σ-bonds are broken. However, the fact that hydride transfers (M–H cleavage) and reactions of metallic π-complexes (C–metal cleavage) also obey these simple relationships demonstrates that this is not an indispensable precondition. The behavior of complexes of carbonyl compounds and Lewis acids (Fig. 9) indicates that a positive charge on the electrophile is not essential, in agreement with Ritchie's observation that carboxylic esters or acceptor-substituted ketones show constant selectivity relationships.[11]

We cannot yet offer a conclusive theoretical interpretation of the reactivity relationships presented here. From the MO perturbation method[116] or the configuration-mixing model of Pross and Shaik,[117] a correlation between electron affinity and reactivity of electrophiles would be expected, and also between the ionization potential and the reactivity of nucleophiles. We have shown, however, that in slow reactions ($k = 10^{-4}$–10^{4} L mol^{-1}s^{-1}) of diarylcarbenium ions with π-nucleophiles there is no correlation between ionization potential and nucleophilicity, even if steric factors are held constant.[18a] Nevertheless, we observed a linear relationship between the kinetics ($\Delta G^{\neq}$) and the thermodynamics (ΔG°) of the electrophile–nucleophile combination reactions.[30a]

On the other hand, in rapid reactions ($k \approx 10^{8}$ L mol^{-1}s^{-1}), the relative reactivity of enol ethers is determined mainly by their ionization potential and not by the thermodynamics of the rate-determining step.[27] The transition between the two regions could be explained by a shift of the transition state on the reaction coordinate. According to the Hammond postulate, an early transition state is expected for the more rapid reactions, which accounts for the correlation with the energy of the frontier orbitals. In the slow reactions with a later transition state, the free energy ΔG° of the rate-determining step would play a dominant role. On the other hand, in Section 4.1 we have deduced a constant position for the transition state, based on the absence of the Hammond curvature. This assumption is supported by the observation that the activation entropies, which according to Houk et al. depend on the position of the transition state,[118] are practically constant in our reaction series. Hence, a contradiction arises which we are not able to solve at the present time.

The value of Equation (f) for predicting reactivity is largely dependent on the number of available reactivity parameters. As shown in this review, reliable reactivity data already exist for the most important classes of nucleophiles. Since, for some arenes, absolute rate constants for attack by carbenium ions are now

also known (Tables 5 and 6), the abundant data on electrophilic aromatic substitution reactions can be incorporated into this nucleophilicity scale.[57b, 119] The benefit of this correlation for synthesis design will increase enormously when the well-researched heteroarenes are included.[94]

Our knowledge of the strengths of electrophiles is comparatively scanty. Reliable reactivity data (Table 17) are available for only a few electrophiles, some of which are unimportant for preparative purposes. For some electrophiles whose reaction rates with water are known (Table 13) E-parameters can be estimated, but the range in which Equation (g) is valid is not yet clear. A relationship between electrophilic reactivity and pK_{R^+} values has been reported on several occasions,[54, 72, 120] but the connection between electrophilicity and thermodynamic stability was called into question in a series of more recent papers, which mainly dealt with acceptor-substituted carbocations.[121] For many classes of preparatively important electrophiles, no quantitative reactivity data whatever exists yet, so the determination of more electrophilicity parameters is of the utmost importance for further developments in this area.

Many of the results reported here were obtained by members of this research group during the last decade. Our special thanks are due to them. We thank the Deutsche Forschungsgemeinschaft, not only for support of our work in the past, but also for recently undertaking to fund the continuation of this research within the framework of the "Electrophilicity" project. Financial assistance from the Volkswagen-Stiftung has enabled the expansion into the study of organometallic electrophiles within the framework of the principal program "Organometallic Reactions for Organic Synthesis". Finally, we thank the Fonds der Chemischen Industrie for the general research grant and also for the award of a Kekulé Stipendium to M. Patz.

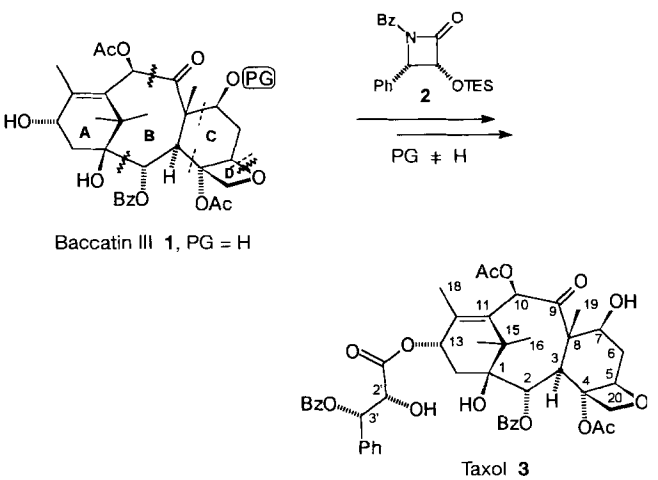
The First Total Syntheses of Taxol



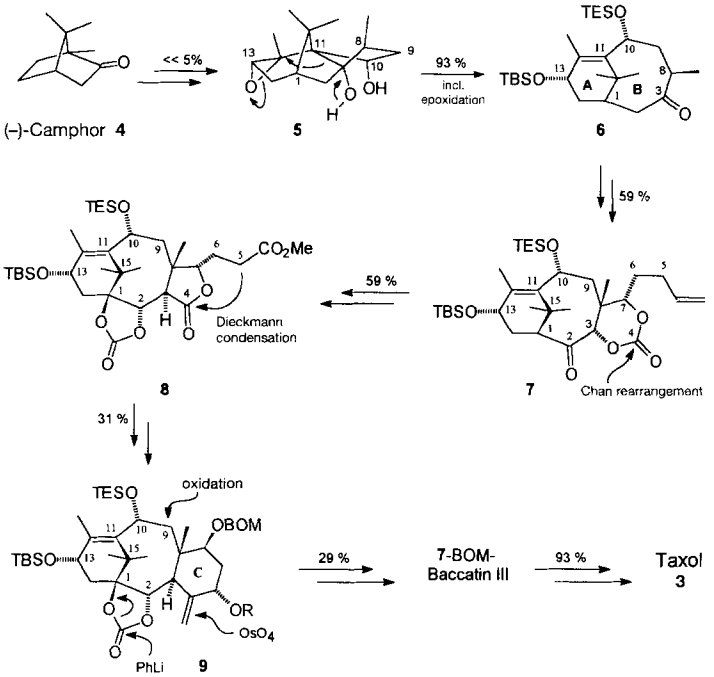
Ludger Wessjohann*

In modern chemistry it is a considerable rarity for the total synthesis of a medicinally and commercially significant natural product not to appear till 22 years after its complete structural elucidation. Though taxol (**3**)[1] is currently the most promising agent against breast cancer and other types of cancer, it took some time before synthetic chemists became interested in it, for several reasons. Thus, nearly a decade elapsed before taxol's biological mode of action—an unusual stabilization of the microtubuli—and its significance for novel cancer therapy were recognized (cf. ref. [1]).

However, from the middle of the 1980s onwards, the number of synthetic attempts increased in an almost explosive manner. Intense competition developed to complete the first total synthesis of this unusual and demanding molecule, a race which involved (and involves) over forty of the best known research groups in the field of natural product synthesis. Taxol and the efforts to complete its synthesis gave rise—at least in the USA and amongst natural product chemists—to at least as much excitement as did fullerenes in physical chemistry, though with the decided difference that taxol did not possess just "potential" applications. Indeed, because of problems with supply and limited possibilities to synthesize derivatives, its full medicinal potential has still only been investigated to a limited extent. For studies of structure–function relationships, the total synthesis is of great importance, especially in preparing the way for the synthesis of derivatives.

An initial highpoint has now been reached with the first two total syntheses by R. A. Holton et al.[2] (Florida State University) and K. C. Nicolaou et al.[3] (University of California, San Diego and Scripps Research Institute).

What was it that made the synthesis of taxol so difficult? For a while, the assertion that every molecule that can exist can today be made, given enough manpower,[4] was almost called into question. To analyse the problem, it is useful to concentrate on the tricyclic A/B/C-ring system of Baccatin III (**1**), which can be treated with **2**, for example, by the method of Holton and Ojima (Scheme 1) to give taxol.[1–3] The oxetane ring (D) is usually treated as a functional group. Apart from this group, the most remarkable feature is the unusual anti-Bredt double bond of the A-ring. However, in contrast to normal doctrine, in this case it leads to a reduction in the total strain (ca. -1.5 kcal mol^{-1}), whereas the very rigid, arched structure of the entire molecule is highly strained from the steric effect of the bridgehead dimethyl groups at C15 (strain energy $\approx +10$ kcal mol^{-1}), in cooperation with the C8-methyl group, which also projects outwards.



Scheme 1. Semisynthesis of taxol from protected Baccatin III according to Holton and Ojima (cf. ref. [1]); strategic bond cleavages for the syntheses of Holton et al. [2] (– – –) and Nicolaou et al. [3] (∿∿) are indicated. PG = protecting group.

The main problem in taxol synthesis is, then, the construction of the highly functionalized, central, eight-membered ring (B). Although the methyl groups (C16/C19) projecting into this ring are not too close to each other (convex face) in taxol, most reactions with prefabricated A/C rings bring them into too close a proximity during the B-ring closure reaction. In addition, the possibilities for subsequent stereoselective functionalization of the central eight-membered ring are very limited, because of its rigidity and steric shielding, and because of the lability of the oxetane ring and the C7 stereocenter (retroaldol/aldol reaction to the more stable epimer). Till recently, in most syntheses of the taxane skeleton (A/B/C rings) one of the two (or three) central methyl groups have been missing. If all of them were indeed present, it has not been possible to introduce the necessary functional groups afterwards. The two successful research groups have solved these problems very differently, but in part with almost identical reactions.[5]

Holton et al.[2] first constructed the A and B rings, in a linear strategy using the elegant fragmentation of the [3.3.0] system **5** derived from β-patchoulene oxide (Scheme 2), which they had previously used for the synthesis of *ent*-taxusine. However, to

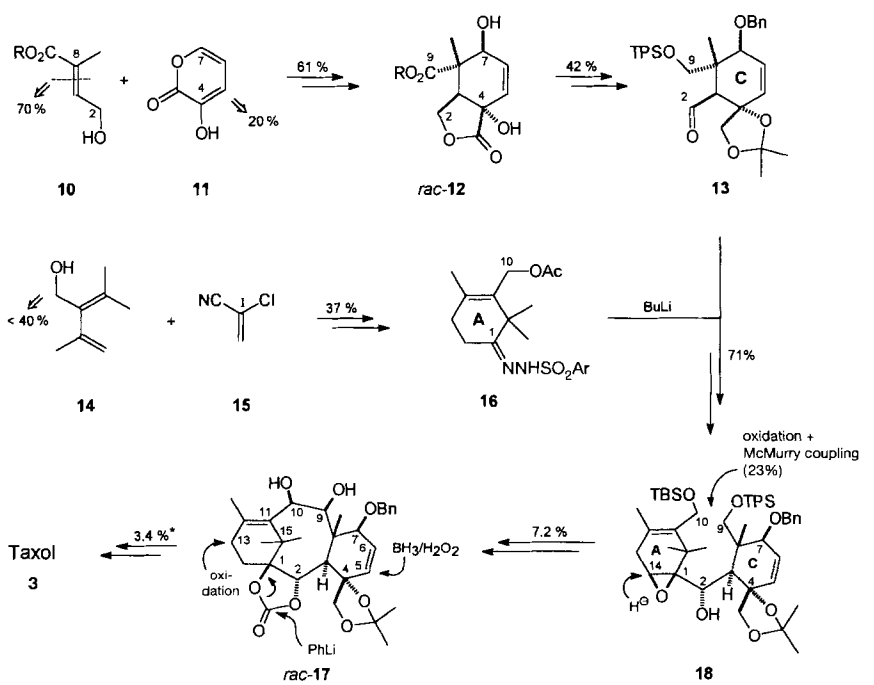

Scheme 2. Total synthesis of taxol according to Holton et al. [2]. Taxol numbering (Scheme 1) used.

obtain the correct enantiomeric series, they had to start extravagantly, using (–)-camphor. The resulting A/B fragment **6** contains the complete, homochiral A-ring and all the methyl groups, as well as one oxygen functional group in both the upper and lower regions for further modifications.

The difficult stereocenter at C7 was constructed early, by using a diastereoselective aldol reaction with magnesium diisopropylamide and 4-pentenal. Since three of the four missing C-ring atoms could be introduced here in a simple manner, derivatizations will later presumably be easy at this step. C4 was provided by a carboxylic ester—also used as a protecting group in intermediate **7**—by an unusual Chan rearrangement. This was followed by a few less elegant steps for deoxygenation at C3 (SmI_2) and oxidation at C1. The latter was only possible with the B/C-*cis* compound, by an unusual, selective enolate formation to the bridgehead C1 rather than to the doubly activated C3—further proof for the unusual steric and conformational characteristics of taxoids. After reduction and isomerization to the *trans* compound, the resulting C1/C2 diol was quantitatively protected with phosgene (cf. **8**) to prepare for the later formation of the benzoate at C2 by addition of phenyllithium and selective fragmentation[6](cf. **9**). First, however, the vinyl group had to be degraded oxidatively to give the ester **8**. The C-ring was then closed by an effective Dieckmann condensation, and decarbalkoxylated.

The remaining keto group at C4 makes possible the oxidation of C5, and conversion to the methylene compound **9**. This last step is sterically problematic and was achieved in moderate yield by a methyl Grignard addition in dichloromethane (instead of ether) and elimination with Burgess' reagent. Dihydroxylation afforded the precursor to the oxetane, which was obtained by nucleophilic substitution of the secondary mesyl or tosyl group at C5, followed by acetylation of the tertiary OH group. These steps, with substitution at the secondary carbon rather than at the primary one (as suggested by the textbooks), were almost identical to those also used by Nicolaou et al.[3] (38%; Holton: 48%). In principle they correspond to the biosynthesis proposed by Halsall and Potier (see ref. [1]). Finally, the upper bridge in the B-ring had to be oxidized, for which benzeneselenic anhydride was very cleverly employed. On the route to 7-BOM-Baccatin III, one should also mention the unusual release of the TBS-protected C13-OH group with tris(dimethylamino)sulfur(difluorotrimethylsilanide).

Nicolaou et al., who only worked on the synthesis of taxol for about two years,[3] follow a much more convergent route (Scheme 3), which begins, however, with achiral precursors. The A-ring precursor was constructed by a Diels–Alder reaction (**14** + **15**) and refunctionalized to the sulfonylhydrazone **16**. This reacted according to Shapiro to give the corresponding alkenyllithium nucleophile, a procedure which is reminiscent of Funk's synthetic route (see ref. [1]). The C2 aldehyde group of **13** served as the electrophile and reacted diastereoselectively in excellent 82% yield to give the A–C coupled alcohol. Chelate-directed epoxidation of this alcohol then led to **18**. Compound **13** was accessible from racemic **12**, the product of the Diels–Alder reaction between 3-hydroxypyrone **11** (from mucic acid) and the dienophile **10**. The epoxide **18** was selectively hydrogenated at C14, and the resulting C1/C2 diol protected as the carbonate (see above).[6]

Scheme 3. Total synthesis of taxol according to Nicolaou et al. [3]. Taxol numbering (Scheme 1) used. * = yield obtained without enantiomer separation. The percentages above the retrosynthetic arrows for the compounds **10**, **11**, and **14** relate to their yields from readily available precursors according to the literature given in reference [3].

After oxidation of C9 and C10 to the aldehyde level, the key step followed. This was a well-established step in constructing strained structures, a McMurry–pinacol coupling to the top B-ring bridge, which afforded the diol **17** in 23% yield. The only other successful eight-membered ring closure starting from an "advanced" A/C system *with* methyl groups is also based on a McMurry reaction at this step, and also led to yields in the lower 20% region. (Kende, also cf. Pattenden). Nicolaou et al., however, only carried out this reaction as far as the diol **17**, permitting further functionalization and enantiomer separation. With Kende's alkene, this is clearly not easily possible.

In order to construct the oxetane ring, the C5–C6 double bond is hydroborated and oxidized with moderate regioselectivity and yield. Oxetane ring closure and benzoate formation at C2[6] follow as already discussed. The late oxidation at C13, the linkage point to the taxol sidechain, is unusual.

When the total yields are directly compared, the more convergent method of Nicolaou et al. is clearly less efficient, especially since the difficulties of enantiomer separation or an—presumably less favorable –asymmetric synthesis are not taken into account (ca. 0.07% compared with 2.7%, or, starting from commercially available materials, about 0.01% against 0.1%).[5] Holton's synthesis shows quite good yields throughout, whereas that of Nicolaou et al. still has room for improvements. At least for the McMurry reaction, these will be very difficult to achieve. In the end, however, a comparison of number of steps and yields in this case is senseless, since for such complex syntheses it tells us very little about the total effort required, or about the practicability of the synthesis.

A more important question concerns which procedure will allow directed synthesis of taxol derivatives. Derivatizations should take place as late as possible in the reaction sequence, in order to minimize the additional labor required. This requirement is better met by a more convergent synthesis such as that of Nicolaou et al. It also more easily permits permutations in the building blocks and the synthesis of A-ring derivatives. C-ring derivatives can, in principle, be provided by both procedures. With Nicolaou's procedure, however, the problem arises that increased steric hindrance with more complex derivatives may lead to even worse yields for the ring closure or in the carbonate formation.[7] Experience has taught us that with taxanes even the tiniest changes in the substituents or the skeleton can cause great problems with the synthesis. It remains to be seen whether the syntheses presented can provide novel taxol derivatives quickly and in significantly improved yields.

A comparison with other syntheses which have not yet been completed must not be forgotten. It is apparent that the route which has probably been chosen most often, fragmentation of bicyclo[4.2.0] systems to yield the B-ring, was not involved in the first success, even though it represents the quickest and, with respect to the reagents, probably simplest (cheapest) entry to the tricycle. As examples I would like to emphasize the elegant synthetic routes of Blechert et al.[8] and of Wender and Mucciaro.[9] The former leads from simple starting materials primarily by aldol and photochemistry to model compounds which are already active. The latter resembles the Holton synthesis in the construction of the A/B ring system, but makes use of a 4/6 precursor of the B-ring instead of a 5/5 one. This allows the use of inexpensive α-pinene to produce the enantiomerically pure tricycle in only six steps. A combination of this procedure with Holton's C-ring annelation is conceivable.

In spite of the fantastic successes from the groups of Holton and Nicolaou, much excitement remains in the race for a total synthesis which is superior to semisynthetic and biological procedures not only with respect to variability, but also to yield, and commercial feasibility.

German version: *Angew. Chem.* **1994**, *106*, 1011

[1] Recently, several excellent review articles on the chemistry and biology of taxol have been published, as well as its history and even politics with the compound. For this reason I have not quoted all the preliminary work and synthetic routes of other authors individually in the text; they are found in K. C. Nicolaou, W.-M. Dai, R. K. Guy, *Angew. Chem.* **1994**, *106*, 38–69; *Angew. Chem. Int. Ed. Engl.* **1994**, *32*, 45; C. S. Swindell, *Org. Prep. Proced. Int.* **1991**, *23*, 465–543; G. M. Gragg, S. A. Schepartz, M. Suffness, M. R. Grever, *J. Nat. Prod.* **1993**, *56*, 1657–1668; T. P. Mucciaro, Dissertation, Stanford University, USA, **1992**.

Molecular Distortion in Reactive Chemical Intermediates

Terry A. Miller*

Chemists have long recognized the intimate connection between a molecule's geometric structure and its reactivity, or in other words the connection between form and function. Historically, the definitive determination of structure, from that of the regular hexagon of benzene to that of the double helix of DNA, has often been followed by significant advances in the understanding and utilization of a molecule's reactivity. Over the years, the structures of most classes of molecules (in their ground electronic state) have been characterized by spectroscopic or crystallographic means.

A major exception to this statement is the class of transient chemical intermediates, which are formed in one step of a complex chemical reaction only to be consumed in a later one. Since it is just these species whose reactivity determine the overall result of the chemical reaction, an accurate understanding of their structure is often critical. Yet their transient nature generally thwarts any structural determinations by crystallographic, or even many spectroscopic, techniques. For lack of better information, the chemical intermediate, often an open-shell radical or radical ion, is typically assumed to be structurally comparable to a closely related "stable" molecule. For example, radical anions or cations, formed by addition or removal of an electron, respectively, are assumed to have roughly the same geometry as their neutral parent. However, such assumptions are inherently dangerous since geometric form ultimately follows electronic structure. Indeed, long ago Jahn and Teller[1] demonstrated by using group theory that any symmetric polyatomic species with an open-shell, degenerate electronic state, such as that of many neutral and charged radicals, would geometrically distort to a configuration of lower energy.

An example of particularly compelling interest is the prototypical aromatic molecule, benzene, and its cation. The closed-shell electronic ground state of benzene has been thought to have the structure of a regular hexagon with the symmetry elements of the D_{6h} point group, since the popularization of the Kekulé electronic structure over a century ago. All reliable experimental observations are consistent[2a] with that structure, the most definitive of which is probably the recently obtained[2b] microwave spectrum of asymmetrically deuterated benzene.

However, matters are much less conclusive concerning the structure of the reactive open-shell radical ions of benzene. Consider, in particular, its radical cation, $C_6H_6^+$, formed by the removal of one of benzene's six π electrons. Since, for D_{6h} benzene, the highest occupied molecular orbital is of e_{1g} symmetry, the ground state of its cation would be expected to be the electronically doubly degenerate $^2E_{1g}$ state, which fulfills the criteria of the above-mentioned Jahn–Teller theorem for distortion. Thus, group theory guarantees that the geometry of $C_6H_6^+$ will not be precisely that of a regular hexagon (D_{6h} in group-theoretical language), but it is the task of experiment to determine whether the molecule's distortion is significant. (Clearly whether a quantity is significant or not depends largely upon the beholder, but pragmatically it is useful to consider that something is significant if it has an observable effect upon a given experiment's results.)

Unlike neutral benzene, the geometry of its cation has been something of a mystery, lacking a definitive experiment owing to its extremely transient existence, or even a real theoretical consensus, due to the unknown magnitude of its Jahn–Teller effect. As will be discussed below, laser-induced fluorescence (LIF) experiments on halo-, particularly fluoro-substituted, derivatives of the benzene cation have given us our best experimental guidance to the structure of $C_6H_6^+$, but similar LIF experiments on the benzene cation $C_6H_6^+$ itself are impossible because of the vanishingly small quantum yield for emission from any of its known excited electronic states. Rather the best *direct* experimental evidence for the structure of the benzene radical cation comes from the photoelectron spectroscopy (PES) of gas-phase benzene[3–5] and from electron paramagnetic resonance (EPR) spectra of $C_6H_6^+$ isolated in a freon matrix.[6] In both studies, the Jahn–Teller distortion of $C_6H_6^+$ was significant, that is, experimentally observable. In the EPR experiment, the H atoms of benzene were found to be not all magnetically equivalent, which would imply chemically, that is, structurally, different environments, which of course is inconsistent with their being attached to equivalent carbon atoms located at the vertices of a regular hexagon. Similarly, the photoelectron spectrum showed a splitting of the components of the lowest excited vibrational level (ν_6 of e_{2g} symmetry), whose motion could lead to distortion of the moleule. Had $C_6H_6^+$ maintained precisely the D_{6h} symmetry of a regular hexagon, these components would be degenerate.

These two direct experiments may seem rather decisive, but they have two major shortcomings. First, although they unambiguously indicate a significant distortion, they do little to quantify it or identify its origin. Second, they do not clearly distinguish between a dynamic and a static distortion. In a static distortion, $C_6H_6^+$ in its vibrationless level would be distorted at all times, that is, permanently. For a dynamic Jahn–Teller effect, at any given instant, $C_6H_6^+$ is distorted from a regular hexagon, but it dynamically samples a number of group-theoretically proscribed distortions, with the mean or average being the undistorted hexagon of D_{6h} symmetry. In principle, the PES experiment could distinguish between these two possibilities by measuring the splittings in a number of excited vibrational levels. In practice, these additional measurements have not been made, primarily because of the spectral congestion at these higher excitations, coupled with the relatively poor spectral resolution (50–100 cm^{-1}) of conventional PES. In principle, the EPR experiment is unambiguously indicative of a *permanent*

distortion. However, it is unclear whether this permanent distortion is a property of $C_6H_6^+$ itself or is caused by the freon matrix environment in which the experiment is performed.

The mystery surrounding the structure of $C_6H_6^+$ has recently been diminished significantly by Müller-Dethlefs et al.[7, 8] They have applied the exciting new technique of zero kinetic energy (ZEKE)-PES;[9] as with conventional PES, ZEKE allows the measurement of a cation's quantum levels. However, the resolution of the ZEKE spectrum (ca. 0.2 cm^{-1} in these studies) is 10^2-10^3 higher than conventional PES, allowing the resolution of even the rotational energy levels of the cation.

Observation of rotational structure in the ground state of $C_6H_6^+$ offers an entirely new avenue for determining its structure. In their first work, Lindner et al.[7] show that all the observed rotational transitions are consistent with D_{6h} symmetry for the cation. If distortions reduced the cation's symmetry to D_{3h} or D_{2h}, additional, strong lines would be expected in the rotational spectrum which were not observed. Qualitatively this finding can be interpreted as showing that on the time scale of molecular rotation, the benzene cation has, on average, D_{6h} symmetry.

The result is, of course, consistent with any distortion of $C_6H_6^+$ simply being insignificant (unobservably small in this experiment) and implies that the EPR measurements, on an even slower time scale, have observed a distortion of $C_6H_6^+$ at least in part attributable to its environment. However, this finding does *not* rule out a significantly, but dynamically, distorted cation whose nuclei sample, by pseudorotation, a number of non-D_{6h} configurations whose average does possess D_{6h} symmetry. Indeed if we use the results of LIF investigations[10-12] of 1,3,5-trifluorobenzene ($C_6H_3F_3^+$) and the hexafluorobenzene cation ($C_6F_6^+$), we would expect the latter situation to hold. In those two cases, significant stabilization energy was gained (800–1000 cm^{-1}) through Jahn–Teller distortion, with most of it being apportioned to changes in the C–C bond lengths and C-C-C bond angles. (The Jahn–Teller effect cannot distort any of the benzenoid cations from planarity, though conceivably other effects could.) However, for both fluorobenzenes, it was shown that there are insignificantly small barriers to pseudorotation through configurations averaging to D_{6h} symmetry. Theoretical calculations,[13] shown to be rather accurate for $C_6F_6^+$, predicted a very similar situation for $C_6H_6^+$, that is, the Jahn–Teller distortion of the cations is basically a property of the benzenoid ring and is only affected in a minor way by substituents. Later theoretical predictions for $C_6H_6^+$ would seem to confirm this result.[14]

In principle, even if a dynamic Jahn–Teller distortion is averaged on the rotational time scale, its effects do not entirely vanish from the rotational spectrum. These effects manifest themselves as relatively small, additional terms in the rotational Hamiltonian. In a related five-electron system, the cyclopentadienyl radical, C_5H_5, which similarly pseudorotates, high-resolution LIF spectra have precisely determined the magnitude of these terms and hence the radical's distorted structure.[15] Similar rotational observations are, in principle, possible with $C_6H_6^+$, but the spectral resolution required will severely challenge even the very impressive resolution of the ZEKE variant of PES.

The second paper by Lindner et al.[8] offers an alternative and probably better approach for learning about the likely dynamic Jahn–Teller distortion of $C_6H_6^+$. A direct way to observe this distortion is simply to measure the positions and splittings in a number of Jahn–Teller active vibrational levels. Such results, coupled with the appropriate theory[12] can give a complete description of the geometric distortion of the molecule and the resulting energy stabilization.

As noted earlier, conventional PES typically lacks the resolution to enable an analysis of the congested vibrational structure of a molecule with a number of fundamental, overtone, and combination bands. However, simply being able to resolve all the individual vibrational transitions is not necessarily sufficient. In fact, a recent experiment[16] on $C_6H_6^+$, with a variant of ZEKE in which mass-resolved cations rather than electrons are detected,[17] resolved clearly much of the cation's vibrational structure. Nonetheless, considerable ambiguity remained as to the proper assignment of these distinct vibrational transitions. In the second paper by Lindner et al.,[8] they resolve the rotational structure of an excited vibrational band. This rotational structure serves as a fingerprint of the vibration mode, because rotational selection rules and hence structure depend upon vibronic symmetry.[18] By this approach they positively identify the components of the first excited level of the e_{2g} ν_6 mode of $\tilde{X}^2E_{1g}$ $C_6H_6^+$. In perfect D_{6h} symmetry this level should be fourfold degenerate. However, they find it is strongly split into a doubly degenerate e_{2g} component and b_{1g} and b_{2g} components, the latter two being split by a much smaller amount. These observations clearly indicate that the benzene radical cation is significantly and dynamically distorted along the ν_6 normal coordinate but that it has only a smallish barrier (indicated by the b_{1g}–b_{2g} splitting) to rapid pseudorotation which results in a structure, which is on average a regular hexagon.

The authors do not report in their work any values for the magnitude of the Jahn–Teller geometric distortion nor the energy stabilization derived therefrom. However, continued measurements of a number of rotationally resolved vibrational levels, coupled with the appropriate anaysis, will surely yield such results. At that point another long standing mystery of molecular structure will be solved.

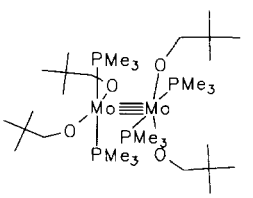
Heterodimetallic Complexes with an Unbridged, Polar Metal–Metal Bond

Max Herberhold* and Guo-Xin Jin



Among the numerous complexes with a direct metal–metal bond[1, 2] those that are stable without bridging ligands are especially fascinating. *Homo*dinuclear complexes with an unsupported metal–metal linkage are known in particular for metals in lower (− I, 0, I) and intermediate oxidation states (II, III). The first group includes dinuclear complexes like **1** and **2** and the cyclopentadienyl metal complexes **3**, **4**, and **5**.

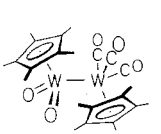
10, R = Me, Et [11]

11, M = Tc, Re [12]
R = $iPr_2C_6H_3$



The second group is dominated by dinuclear complexes with metal–metal multiple bonds.[1, 8] Complexes that have been intensively studied owing to their formal quadruple bond—include the homonuclear dirhenate ions $[X_4Re{\equiv}ReX_4]^{2-}$ **6**, whose molecular halves are eclipsed, and the alkoxidomolybdenum complexes **7a**, **b**. The d^3-d^3 dimers **8** and **9**, which contain a formal triple bond, also display a rich chemistry.[2] A related compound with a metal–metal single bond is the alkyne complex **10**. Homodinuclear complexes with unbridged metals in higher oxidation states such as Tc^{VI} and Re^{VI} in complexes **11** are uncommon.

Homodinuclear complexes are generally symmetrical "dimers" with a nonpolar metal–metal bond. Polarity can be introduced to a certain degree, while maintaining the oxidation state of the metal, by "one-sided" exchange of a ligand in homoleptic complexes, which results in compounds like **12** and **13**. The metal–metal bond is yet more polar when the same metal is in different oxidation states in the two centers, as is found in the unexpected products **14** and **15** and in the bis(dithio ether) complexes **16**.

For a number of years dinuclear complexes with different metals have been popular subjects of study owing to the reactivity and potential catalytic activity of compounds with metal–metal bonds. The two metals may be adjacent d-block elements as in **17** and **18** or may come from opposite ends of the periodic table as in **19**–**23**.

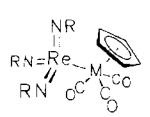
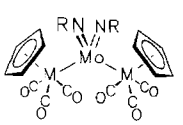
23, M = Fe, Ru[25]

The concept of "early–late" heterodimetallic compounds, which are formed by combination of a d electron-poor and a d electron-rich transition metal complex fragment, has proved to be especially worthwhile;[26] however, products in which the metal–metal bond is further stabilized by bridging ligands are usually obtained.



Trinuclear heterodimetallic complexes like **24**–**26** have also been prepared and structurally characterized.

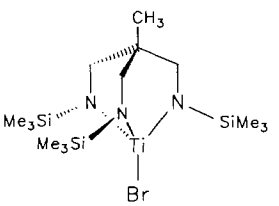
$[Cp(CO)_2Ru-Zr(Cp)_2-Ru(CO)_2Cp]$ **24**[23]



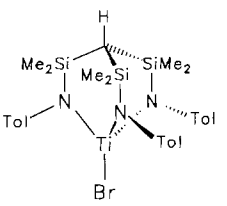
$[(Ph_3P)_2Cu-Fe(CO)_4-Cu(PPh_3)_2]$ **25**[27]

$[(ArN)_3Re-Hg-Re(NAr)_3]$
26, Ar = 2,6-iPr$_2$C$_6$H$_3$[28]

Strongly polar metal–metal bonds can apparently be expected for heterodimetallic complexes in which the metal centers are present in significantly different oxidation states. The importance of the difference in oxidation state for the preparation of unsupported di- and trinuclear complexes with polar metal–metal bonds seems to have been underestimated so far. However, several recent papers[29–32] have focused on the deliberate construction of complexes with polar bonds by the combination of complex fragments with metals in higher and lower oxidation states. Thus the research group of J. Sundermeyer[29] has treated imidometal compounds such as $[Re(N$$t$$Bu)_3Cl]$ and $[Mo(N$-$t$$Bu)_2Cl_2]$ with carbonyl metalate salts like $K[Mn(CO)_5]$ and $K[M(CO)_3Cp]$ (M = Mo, W) to obtain di- and trinuclear complexes of type **27** and **28**, respectively.



27, M = Mo, W [29]
R = tBu

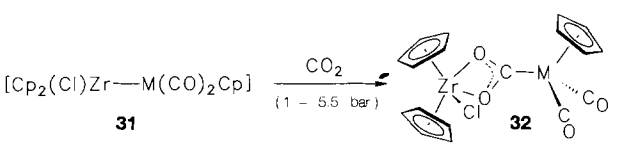


28, M = Mo, W [29]
R = tBu

The synthetic approach of combining a hard "metal acid" ($[Re(N$$t$$Bu)_3]^+$, $[CpM(N$$t$$Bu)_2]^+$ (M = Mo, W), $[Cp_2Nb(N$$t$$Bu)]^+$, $[M(N$$t$$Bu)_2]^{2+}$ (M = Mo, W), $[CpM(N$$t$$Bu)]^{2+}$ (M = Nb, Ta)) with a soft "metal base" ($[Mn(CO)_5]^-$, $[Co(CO)_4]^-$, $[M(CO)_3Cp]^-$ (M = Mo, W), $[Fe(CO)_2Cp]^-$) can certainly be expanded, since plenty of precursors are available for both the high- and the low-valent components.[30] In comparison to the analogous oxometal complexes, imido metal compounds have the advantage that the steric demands of the imido ligand RN can be varied by the choice of the appropriate R group. It remains to be seen whether the subsequent hydrolysis of the metal–imido bonds gives oxometal complexes without affecting the unsupported, polar metal–metal bond.

The significance of steric shielding is also evident in the heterodimetallic complexes synthesized by L. H. Gade et al. starting from the amido-substituted titanium(IV) monobromides **29a**, **b** (Tol = $C_6H_4CH_3$).[31, 32] The tripodal protecting ligand

29a [31]



29b [32]

(L_3) stabilizes the titanium(IV) component $[(L_3)TiBr]$ so well, that its reaction with the carbonyl metalates $Na[Co(CO)_3(PPh_3)]$ and $K[M(CO)_2Cp]$ (M = Fe, Ru) leads to stable heterodimetallic complexes with a polar, unsupported metal–metal bond. The Ti–Fe complex of type **30** is much more robust than the related complex **23**.

$[(L_3)Ti-M(CO)_2Cp]$ **30**, M = Fe, Ru[32]

$L_3 = CH_3C(CH_2NSiMe_3)_3$, $HC[SiMe_2N(Tol)]_3$

These new complexes allow the systematic investigation of the chemical reactivity of compounds with a strongly polar, unsupported metal–metal bond. Hitherto there have been few studies on the reactivity of heterodimetallic complexes without bridging ligands, for example the trinuclear compound $[Cp_2Zr\{Ru(CO)_2Cp\}_2]$ analogous to **21**.[22b] A more recent example is the observed insertion of CO_2, but not CS_2, under mild conditions into the metal–metal bond of **31**, which results in the carboxylato complexes **32**.[33] The shielding cyclopentadienyl ligands are apparently important in protecting the metal–metal bond in **31**. In complexes like **27**, **28**, and **30** the bulky ligands

guarantee the kinetic stability of the compounds and apparently prevent the direct electron transfer from the low- to the high-valent component, but they also block access to the metal–metal bond.

Reactions of $[(C_5Me_5)ZrF_3]$ with $AlMe_3$—Synthesis and Structure of a Zirconium–Aluminum–Carbon Cluster**

Axel Herzog, Herbert W. Roesky,* Zdirad Zak, and Mathias Noltemeyer

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

Organometallic fluorides of the elements of Group 4 have been studied very little to date. Our investigations into the reactivity of $[Cp^*ZrF_3]$ (**1**)[1] ($Cp^* = C_5Me_5$) synthesized for the first time recently by us showed that this compound together with methylaluminoxane (MAO) as cocatalyst is suitable for the polymerization of ethylene.[2] Brintzinger, Kaminsky, and Sinn in their fundamental work have been able to show that alkyl derivatives of metallocenes of Group 4 are of crucial importance for such a process.[3]

In order to understand the catalytic activity of **1**, it was necessary to examine whether a selective exchange of the fluorine atoms for alkyl groups is possible for **1**. We have now found that in the reaction of **1** with $AlMe_3$ (**2**) in the mol ratio 1:1, as expected, methyl groups are transferred from aluminum to zirconium and **3** is formed.

The resulting Me_2AlF does not form the known tetramer.[4] The single-crystal X-ray structure analysis of **3** (Fig. 1)[5] shows Me_2AlF for the first time as complex ligand; the fluorine atoms are bridging. Both Zr-F-Zr and Zr-F-Al bridges are formed (Zr–F 211.1–217.9 pm, Al–F 176.5–178.6 pm). The zirconium atoms have a distorted octahedral and the aluminum atoms a distorted tetrahedral environment.

The Zr–C bond length of the ZrMe unit in **3** (mean 228.3 pm) is comparable with those in $[(C_5H_5)_2ZrMe_2]$[6] (227.3(5), 228.0(5) pm), whereas in the $[(Me_2C_5H_3)_2ZrMe]^+$ ion,[7] the corresponding Zr–C bond is, as expected, shorter (225.2(4) pm). This trend can be explained in terms of the decrease in the electron density in the $[(Me_2C_5H_3)_2ZrMe]^+$ ion and the increase in the stength of the ZrMe bond associated with this. In the ^{19}F NMR spectrum of **3**, three signals (ratio of intensities 4:1:1) are observed, that is, the molecular structure known from the solid state is also found in solution.

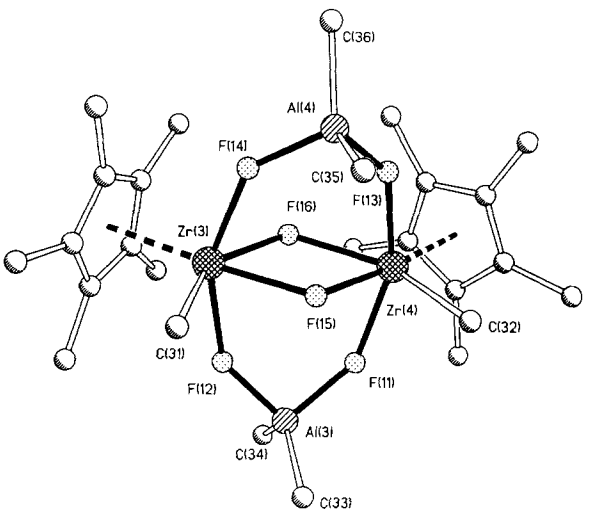

Fig. 1. Crystal structure of **3**. Selected bond lengths [pm] and angles [°]: Zr1–F2 213.9(3), Zr1–F4 211.1(3), Zr1–F6 217.9(3), Zr1–F5 214.1(3), Zr1–C12 228.3(6), Al2–F4 177.6(4), Al2–F3 178.6(4), Al2–C15 191.6(9), Al2–C16 192.1(8); F6-Zr1-F5 67.48(11), Zr1-F6-Zr2 111.67(12), Zr1-F4-Al2 140.2(2).

Remarkably, the *cis* product **3** is formed exclusively. ^1H and ^{19}F NMR measurements on **3** at 70 °C give no indication of an equilibrium with the *trans* isomer. We have also found a stereoselective substitution of this kind for the corresponding hafnium compound, which was hitherto not known for metallocenes.[8]

If **1** or **3** are allowed to react with an excess of $AlMe_3$, methane is eliminated spontaneously at room temperature in *n*-hexane, as detected by IR spectroscopy. In addition to fluorine-containing oil-like products,[9] the $Zr_3Al_6C_7$ cluster **4** is formed. The best yields of **4** (reproducible) are obtained when **1** is treated with $AlMe_3$ in the mol ratio 1:5 [Eq. (a)]. At higher

$$\underset{\mathbf{1}}{3[Cp^*ZrF_3]} + \underset{\mathbf{2}}{15\,AlMe_3} \longrightarrow \underset{\mathbf{4}}{[(Cp^*Zr)_3Al_6Me_8(CH)_5(CH_2)_2]} + 9\,Me_2AlF + 12\,CH_4 \quad \text{(a)}$$

temperatures, the formation of the cluster is accelerated at the expense of the yield; in contrast, **2** and **3** do not react within 4 h at −10 °C. However, **4** is not stable at room temperature and is converted into an insoluble solid.

The group of peaks at *m/z* 1040 (M^+–Me–2H) in the mass spectrum of **4** shows the correct distribution of isotopes. The ion with the greatest intensity is found at *m/z* 965 (M^+–6Me–2H).

Single crystals of **4** are formed from toluene. The X-ray structure analysis[10] at 153 K shows that all fluorine atoms are exchanged in **4** and a $Zr_3Al_6C_7$ cluster has formed (Fig. 2). Six metal atoms form an open cube, which is shielded by Al and C atoms. The cluster is capped by CH and CH_2 groups; some of

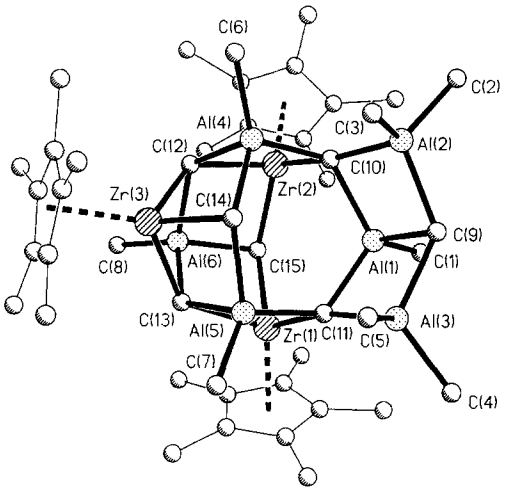

Fig. 2. Crystal structure of **4**. The H atoms are not shown. Selected bond lengths [pm] and angles [°]: Zr1–C15 217.0(7), Zr2–C15 213.9(6), Al6–C15 202.4(7), Zr1–C13 231.1(7), Zr3–C13 221.1(7), Al5–C13 216.7(7), Al6–C13 212.2(7), Zr3–C14 219.1(6), Al5–C14 211.3(7), Al4–C14 213.0(7), Al1–C10 202.8(7), Al2–C10 212.8(6), Al4–C10 200.3(7), Zr2–C10 224.1(6); C11-Zr1-C13 89.8(2), Al5-Zr1-Al1 70.34(10), Al5-C13-Al6 133.6(3), Al6-C13-Zr3 82.4(3), Al5-C13-Zr3 82.2(2), Al5-C13-Zr1 80.0(2), Al6-C13-Zr1 81.9(2), Al6-C13-Zr3 82.4(3).

the C atoms are hypervalently bound. The short metal–metal contacts are remarkable. The average Al–Zr distance (297.8 pm) is shorter than that deduced from the metal radii (303 pm).[11] In this case very long (Al1–Zr1 333.0(2), Al2–Zr2 333.7(2) pm) and very short (Zr1–Al5 288.0(2), Zr2–Al6 287.9(2), Zr3–Al4 284.6(2) pm) Al–Zr distances occur. The average Al–Al distance (268.2 pm) (Al1–Al3 268.7(3), Al1–Al2 267.8(3) pm) is comparable with that in $R_2Al-AlR_2$ ($R = CH(SiMe_3)_2$) (266.0 pm),[12] whereas the average Al–Al bond length in $[Cp^*Al]_4$[13] is 276.9 pm (in the metal 286 pm).[11] Whether the short metal–metal distances in **4** arise because of the electron deficiency, cannot be said with certainty.

As a result of the different metal–carbon bonds, the CH groups are not arranged symmetrically on the (Zr_2Al_2) faces (e.g. C12–Zr2 230.1(7), C12–Zr3 222.9(6), C12–Al6 209.8(6), C12–Al4 216.6(6) pm). The Zr–CH bond lengths lie in a wide range (213.9–231.1 pm). We do not assume that double bond contributions exist in the short Zr–C bonds. Fryzuk et al.[14] have determined a bond length of 202.4(4) pm for an isolated Zr–C double bond in [{1,3-$(SiMe_2CH_2PiPr_2)_2C_5H_3$}Zr=CHPh(Cl)]. The compound $[(C_5H_5)_2Zr(\mu\text{-}C{\equiv}CPh)(\mu\text{-}C'Ph{=}CMe)AlMe_2]$ described by Erker et al.,[15] in which the zirconium and aluminum are linked by the planar-tetracoordinate C′, has a Zr–C′ bond length of 247.0 pm. It is thus significantly longer than that in **4**; in contrast, the Al–C′ bond length is of the same order of magnitude (210.3 pm).

The crystals of **4** obtained by recrystallization from toluene are sparingly soluble in all common solvents; thus, ^{13}C NMR investigations gave no useful information and an unambiguous assignment of the signals in the high-field region of the ^1H NMR spectrum by using 2D methods is not possible.[16] Also the replacement of the Cp* group by C_5Me_4Et fails to solve the problem: the solubility of the resulting cluster analogous to **4** is not improved significantly.[8]

Experimental Procedure

3: **1** (2.00 g, 7.06 mmol) was dissolved in toluene (50 mL) and **2** (3.53 mL, 7.06 mmol, 2 M solution in *n*-hexane) was added dropwise over 0.5 min. The reaction mixture was stirred for a further 0.5 h to complete the reaction. After concentration of the solution under vacuum to a quarter of the original volume, **3** crystallized in the form of colorless crystals. Yield: 1.83 g (70%). M.p. 206 °C; ^1H NMR (C_6D_6, TMS): $\delta = -0.46$ (m, 6H, AlMe), −0.35 (m, 6H, AlMe), 0.5 (m, 3H, ZrMe), 0.54 (m, 3H, ZrMe), 1.76 (s, 30H, Cp*), 2.10 (m, 1.5H, Ph*Me*), 6.95–7.16 (m, 2.5H, *Ph*Me); ^{13}C NMR (C_6D_6, TMS): $\delta = -12.03$ (m, AlMe), −11.08 (m, AlMe), 10.76 (s, C_5Me_5), 21.37 (s, Ph*Me*), 45.17 (dd, $J = 11$ Hz, $J = 30$ Hz, ZrMe), 124.86 (C_5Me_5), 125.63 (s), 128.51 (s), 129.28 (s), 137.83 (s), (*Ph*Me); ^{19}F NMR (C_6D_6, $CFCl_3$): $\delta = -108.18$ (s, 4F, ZrFAl), −69.49 (m, 1F, ZrFZr), −32.52 (m, 1F, ZrFZr); EI-MS (70 eV): *m/z* (%): 696 (100) [$M^+ - Me$]. Correct elemental analysis.

4: **1** (1.00 g, 3.53 mmol) was suspended in *n*-hexane (60 mL) and **2** (8.85 mL, 17.70 mmol, 2 M solution in *n*-hexane) was added dropwise over 0.5 h. After the mixture had been stirred at room temperature for 18 h, no further evolution of gas was observed. The yellow solution was concentrated to a third of the original volume. This led to the precipitation of a yellow, microcrystalline solid, which was filtered off and washed with a little *n*-hexane. This crude solid was taken up in toluene (20 mL), decanted from the insoluble material, and successively concentrated (2 h). In addition to a yellow microcrystalline solid, **4** crystallized in the form of yellow crystals. Yield: 350 mg (28%). ^1H NMR ([D_8]toluene, TMS): $\delta = -1.38$ (d), −0.95 (s), −0.72 (d), −0.52 (s), −0.51 (s), −0.30 (m), −0.171 (s), −0.167 (s), 1.91 (s), 1.94 (s); EI-MS (70 eV): *m/z* (%): 1040 (4) [$M^+ - Me - 2H$], 965 (100) [$M^+ - 6Me - 2H$]. The elemental analysis gave slightly lower values for C and H than those calculated. Fluorine cannot be detected.

Synthesis and Structure of the First Dimeric Iminoalane Containing an Al_2N_2 Heterocycle**

Stephan Schulz, Ludger Häming, Regine Herbst-Irmer, Herbert W. Roesky,* and George M. Sheldrick

Dedicated to Professor M. Frederick Hawthorne on the occasion of his 65th birthday

In the last few years, compounds containing elements of Groups 13 and 15 have attracted a great deal of interest because they are potential single-source precursors for III–V systems that play an important role in semiconductor technology and optoelectronics.[1] We are especially interested in iminoalanes, which previously were only accessible through alkane eliminations, and have reported the preparation of $(MeAlNC_6F_5)_4$, an Al–N heterocubane, formed from $AlMe_3$ and $H_2NC_6F_5$.[2] Besides the heterocubanes $(RAlNR')_x$ ($x = 4$), which are apparently especially stable iminoalane derivatives,[3] compounds with higher degrees of oligomerization are also known.[4] The iminoalane $[MeAlN(2,6\text{-}iPr_2C_6H_3)]_3$ ($x = 3$) synthesized by Power et al. reveals the lowest degree of oligomerization so far. This compound has a six-membered Al_3N_3 ring and can formally be described as being "quasi-aromatic" due to its six π electrons.[5] Despite repeated efforts, iminoalanes with $x = 1$ or 2 could not be prepared. With sterically less demanding groups R′ on the nitrogen atom, products with $x > 3$ are preferred,[6] and as a rule C–H activation takes place when the substituents are larger, as a result of drastic reaction conditions required.[7]

With $(Cp^*Al)_4$ ($Cp^* = C_5Me_5$), first reported by Schnöckel et al.[8] and synthesized by our research group by an easier route,[9] it is possible to synthesize iminoalanes by oxidative addition. The driving force of this reaction is the desire of the aluminum centers to reach the oxidation state III. Due to the high reactivity of $(Cp^*Al)_4$, mild reaction conditions can be employed. By applying sterically demanding substituents on the nitrogen atom, it should be possible to prepare dimeric iminoalanes containing an Al_2N_2 ring.

The reaction of $(Cp^*Al)_4$ with $MesN_3$ ($Mes = Me_3C_6H_2$)[10] in a molar ratio of 1:4 leads to **1** in a good yield. The dimeric iminoalane $(Cp^*AlNMes)_2$ is, however, not formed during the reaction, but rather the cyclic aminoalane **1** as a result of C–H activation of the *ortho*-bonded methyl group and subsequent migration of the proton to the nitrogen atom [Eq. (a)]. This

$$0.5\ (Cp^*Al)_4 + 2\,MesN_3 \longrightarrow \underset{\mathbf{1}}{[Cp^*Al\{\mu\text{-}NH(C_6H_2\text{-}4,6\text{-}Me_2\text{-}2\text{-}CH_2)\}]_2} + 2\,N_2 \quad (a)$$

reaction has been verified by NMR and IR spectroscopic investigations. Power et al. showed that C–H activation can occur during the thermal decomposition of $[RM(Me)N(H)R']_2$ compounds (M = Al, Ga); the Ga compounds reveal a greater tendency towards C–H activation than the corresponding Al compounds.[11]

Compound **1** is a colorless, hydrolysis-sensitive compound which melts at 201 °C. The central core of **1** is a planar four-membered Al_2N_2 ring in which the Al–N bond lengths (197.0–201.3 pm) lie within the expected range. Both the aluminum and the nitrogen atoms are four-coordinate. The hydrogen on the nitrogen atom could be located in the difference electron density synthesis and was refined isotropically. The Al–C distance to the methylene group (198.8 pm) corresponds to the value for an Al–C single bond. The fourth coordination site on the aluminum atom is filled by the Cp* group.[12]

An azide for which C–H activation should be more difficult is Me_3SiN_3. The reaction of $(Cp^*Al)_4$ and Me_3SiN_3 in a molar ratio of 1:4 leads to **2** (m.p. 194 °C) in moderate yield [Eq. (b)].

$$(Cp^*Al)_4 + 4\,Me_3SiN_3 \xrightarrow{-4\,N_2} \underset{\mathbf{2}}{\text{[Me}_3\text{Si–N(Cp*)–Al(Cp*)–N(SiMe}_3\text{)–Al(Cp*)–N(SiMe}_3\text{)]}} \quad (b)$$

In the mass spectrum of **2** we could not distinguish between an Al–N heterocubane and a dimeric iminoalane. However, the X-ray crystal structure determination verified the presence of a dimeric iminoalane (Fig. 1).

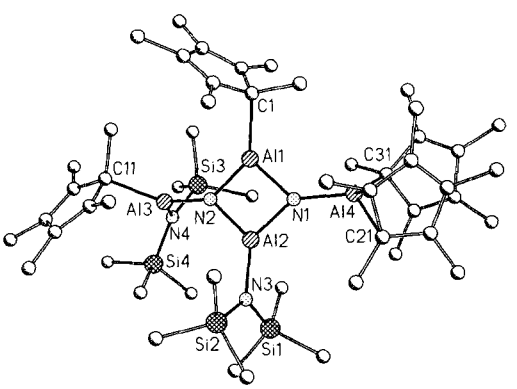

Fig. 1. The structure of **2** in the crystal. Selected bond lengths [pm] and angles [°]: Al1-N1 181.7, Al1-N2 180.3, Al2-N2 181.9, Al2-N1 180.3, N1-Al4 180.4, N2-Al3 178.1, Al3-N4 181.8, Al2-N3 179.0, Al1-C1 198.5; Al1-N1-Al2 84.3, Al1-N2-Al2 84.2, N1-Al1-N2 95.6, N1-Al2-N2 95.5, N2-Al1-C1 138.5, C1-Al1-N1 124.8, N1-Al2-N3 133.5, N3-Al2-N2 130.1, Al1-N1-Al4 132.5, Al4-N1-Al2 142.4, Al2-N2-Al3 134.3, Al3-N2-Al1 139.6.

In **2** the central core is also a four-membered, almost ideally planar Al_2N_2 ring.[13] In contrast to **1**, however, all the aluminum and nitrogen atoms are three-coordinate. Considering the six-membered Al_3N_3 ring of Power et al., **2** could be formally described as anti-aromatic because there are four π electrons available. One can envisage that **2** originates from an Al_4N_4 cube in which the top layer is broken open and the remaining Al_2N_2 ring represents the base. A silyl-group migration and a rearrangement of a Cp* group take place simultaneously.

The Al–N distances lie in the range 178.1–181.9 pm; the average bond lengths in the Al_2N_2 ring are 181.1 pm.[14] The distances are slightly longer than comparable bond lengths in $Al[N(SiMe_3)_2]_3$[15] and $[MeAlN(2,6\text{-}iPr_2C_6H_3)]_3$,[16] which also contain three-coordinate Al and N centers.[17] Higher poly(iminoalane)s with four-coordinate Al and N centers show significantly longer distances.[18] In three cases the Cp* groups in **2** are σ-bonded; one is η^2-bonded.

Apparently the steric demands of the Cp* and the $SiMe_3$ groups are too great to allow for the formation of a cubane;

thus, the dimeric iminoalane **2** is generated. By selecting appropriate groups on the azide it should be possible to prepare additional iminoalanes by this method. Perhaps even the synthesis of the first Al–N compound possessing an Al–N double bond may be achieved by oxidative addition to $(Cp^*Al)_4$.

Experimental Procedure

All the reactions were performed under nitrogen atmosphere in dried solvents.

1: $MesN_3$ (0.65 g, 1 mmol) was added to a suspension of $(Cp^*Al)_4$ (0.16 g, 0.25 mmol) in toluene (60 mL) at 25 °C. Subsequently the reaction mixture was heated to 40 °C for about 0.5 h after which time the evolution of gas ended. Over a period of two days, the solvent was condensed off from the orange-colored solution. 0.22 g (74%) of **1** was obtained as colorless crystals. M.p. 201 °C; IR (CsI): $\tilde{\nu}$[cm^{-1}] = 3320, 1305, 1259, 1203, 1068, 1025, 851, 807, 660, 579, 503, 354; ^{1}H NMR (250 MHz, C_6D_6, 25 °C, TMS): δ = 1.64 (s, 15H, C_5Me_5), 1.90 (s, 2H, CH_2), 2.14 (s, 3H, *o*-Me), 2.26 (s, 3H, *p*-Me), 3.26 (s, 1H, N-H), 6.71 (s, 1H, arene-H), 7.01 (s, 1H, arene-H); ^{13}C NMR (100 MHz, C_6D_6, 25 °C, TMS): δ = 10.48 (s, C_5Me_5), 14.20 (s, CH_2), 18.54 (s, *o*-Me), 21.08 (s, *p*-Me), 114.65 (s, C_5Me_5), 129.38 (s, *o*-C), 131.38 (s, *o*-C), 134.41 (s, *p*-C), 136.80 (s, *m*-C), 137.44 (s, *m*-C), 142.18 (s, N-C); MS (EI): *m*/*z* (%): 590 (10) [M^+], 295 (100) [M^+/2]; correct elemental analysis.

2: $(Cp^*Al)_4$ (0.32 g, 0.5 mmol) was suspended in toluene (60 mL) and Me_3SiN_3 (0.23 g, 0.5 mmol) was added. Subsequently, the reaction was heated to 70 °C at which temperature nitrogen evolution was observed. Once the reaction was complete, the mixture was stirred at 80 °C for an additional 10 min. After concentration of the solution to about 5 mL and crystallization at −78 °C, 0.17 g (34%) of **2** was obtained as colorless crystals. M.p. 194 °C; IR (CsI): $\tilde{\nu}$[cm^{-1}] = 1083, 1019, 885, 837, 803, 722, 668, 592, 370, 254; ^{1}H NMR (500 MHz, C_6D_6, 25 °C, TMS): δ = 0.09 (s, 9H, $SiMe_3$), 1.79 (s, 15H, C_5Me_5); ^{13}C NMR (125 MHz, C_6D_6, 25 °C, TMS): δ = 5.90 (s, $SiMe_3$), 13.90 (s, C_5Me_5), 122.0 (s, C_5Me_5); MS (EI): *m*/*z* (%) = 725 (30) [M^+ − 2Cp*], 363 (70) [M^+/2 − Cp*], 322 (80) [$Cp^*AlN(SiMe_3)_2$], 186 (100) [$AlN(SiMe_3)_2$]; correct elemental analysis.

[11] During thermal decomposition $[Me_2GaN(H)Mes]_2$ reacts under C–H activation [19], whereas the corresponding Al compound forms the cubane $(MeAlNMes)_4$. Only when the N atom is coordinated by the sterically more demanding ligand 2,4,6-$tBu_3C_6H_2$ does the Al compound undergo C–H activation [7].

[12] Crystal data of **1**: $C_{38}H_{52}Al_2N_2$, M_r = 590.78, triclinic, space group $P\bar{1}$, a = 1122.5(2), b = 1173.3(2) c = 1370.3(2) pm, α = 92.22(2), β = 109.57(2), γ = 101.25(2)°, V = 1.6572(5) nm^3, Z = 2, ρ_{calcd} = 1.184 Mg m^{-3}; F(000) = 640, λ = 71.073 pm, $\mu(Mo_{K\alpha})$ = 0.117 mm^{-1}. The data were collected on a STOE-Siemens-Huber diffractometer. Intensity measurements were performed by $2\theta/\omega$ scans in the range $8° \le 2\theta \le 50°$ at −120 °C on a rapidly cooled crystal of dimensions 0.30 × 0.20 × 0.15 mm in an oil drop [20]. Of the 11737 measured reflections, 5869 were independent; largest minimum and maximum in the final difference Fourier synthesis: −345 and 729 e nm^{-3}, $R1$ = 0.0733 (for 3715 reflections with $F > 4\sigma(F)$) and $wR2$ = 0.2004 (all data).

[13] The average deviation from the plane is 3.7 pm.

[14] Crystal data of **2**: $C_{52}H_{96}Al_4N_4Si_4$, M_r = 997.61, monoclinic, space group $P2_1/c$, a = 2516.7(7), b = 1942.8(5) c = 1288.5(4) pm, β = 104.50(3)°, V = 6.099(3) nm^3, Z = 4, ρ_{calcd} = 1.086 Mg m^{-3}; F(000) = 2176, λ = 71.073 pm, $\mu(Mo_{K\alpha})$ = 0.190 mm^{-1}. The data were collected on a STOE-Siemens-AED diffractometer. Intensity measurements were performed by $2\theta/\omega$ scans in the range $8° \le 2\theta \le 45°$ at −120 °C on a rapidly cooled crystal of dimensions 0.45 × 0.25 × 0.20 mm in an oil drop [20]. Of the 7405 measured reflections, 7155 were independent; largest minimum and maximum in the final difference Fourier synthesis: −245 and 237 e Å^{-3}, $R1$ = 0.0495 (for 5004 reflections with $F > 4\sigma(F)$) and $wR2$ = 0.1181 (all data). The values of $R1$ and $wR2$ are defined as $R1 = \Sigma||F_o| - |F_c||/[\Sigma|F_o|]$; $wR2 = \{[\Sigma w(F_o^2 - F_c^2)^2]/[\Sigma w(F_o^2)^2]\}^{1/2}$. The structures were solved by direct methods (SHELXS-90) [21] and refined by least-squares against F^2 (SHELX-93) [22]. The hydrogen atoms, except the hydrogen atom located on N1 in **1**, were positioned geometrically and refined by using a riding model in which the Me groups can rotate about their local axes. The hydrogen atom on N1 in **1** was refined by using distance restraints. Further details of the crystal structure investigations may be obtained from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK) on quoting the complete literature citation.

Synthesis, Crystal and Molecular Structure of Boc-Pro-ΔPhe-Ala-ΔPhe-Ala-OMe; A Pentapeptide with a Novel β-Bend Ribbon Structure**

Kanagalaghatta Ramabhatta Rajashankar, Suryanarayanarao Ramakumar, Tapas Kumar Mal, and Virander Singh Chauhan*

α,β-Dehydroamino acid residues (2,3-didehydroamino acid residues) are found in several naturally occurring peptides from microbial sources as well as in some proteins;[1] their presence in a peptide chain produces remarkable conformational consequences.[2] In addition, dehydropeptides show enhanced resistance to enzymatic degradation.[3] Thus, introduction of α,β-dehydroamino acid residues into bioactive peptide sequences has become an important tool to study structure–function relationships, and to provide analogues of peptide hormones with improved bioactivity.[4] Small peptides containing a single α,β-dehydrophenylalanine (ΔPhe) residue often have β-bend[5] structures,[2b–g] whereas helical structures are stabilized in longer peptides containing more than one ΔPhe residue.[2h–l] In

this regard the behavior of the ΔPhe residue is somewhat similar to that of α-aminoisobutyric acid (Aib), a well-studied helicogenic nonprotein amino acid residue.[6] Recently, we have observed a 3_{10}-helical conformation in a nonapeptide containing three ΔPhe residues.[2j] We report here the synthesis, X-ray crystal and molecular structure of the pentapeptide **1**, which adopts a novel flat (non-helical) β-bend ribbon conformation in contrast to the helical β-bend ribbons observed for other peptides.[7]

Boc-Pro-ΔPhe-Ala-ΔPhe-Ala-OMe **1**

The β-bend ribbon conformation is characterized by interesting hydrogen bond interactions wherein alternating 4→1 hydrogen bonds are absent.[7] This conformation was initially proposed for the $(Aib\text{-}Pro)_n$ peptide sequence on the basis of NMR data[9] and conformational energy calculations,[10] and subsequently observed in several Aib peptides with characteristic sequence.[7] Presumably because β-bend ribbons have almost the same dihedral angles as the 3_{10}-helix backbone, they have been referred to as β-bend ribbon spirals.[7b,f] The β-bend ribbon structures should be of relevance for developing models for peptaibol antibiotics and for the numerous $(Pro\text{-}X)_n$ (with X ≠ Pro) segments found in proteins.[7a,b]

Remarkably, in **1** both the crystallographically independent molecules exhibit novel β-bend ribbon conformations (Fig. 1).

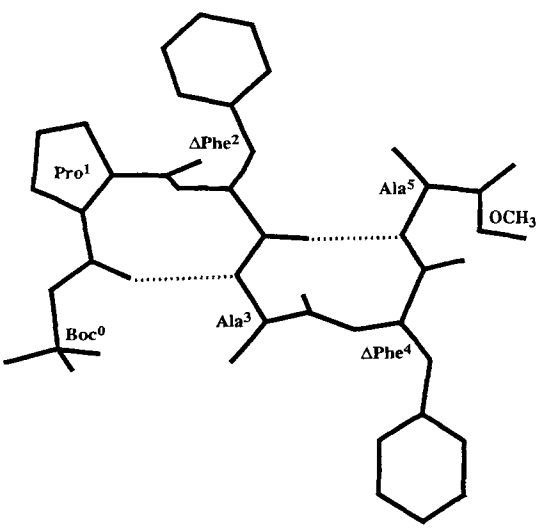

Fig. 1. Molecular structure of **1** in the crystal. Dotted lines indicate the intramolecular 4→1 hydrogen bonds.

This conformation is a consequence of two partially overlapping β-turns.[5] The $Boc^0\text{-}Pro^1\text{-}\Delta Phe^2\text{-}Ala^3$ fragment adopts a type I β-turn conformation (backbone dihedral angles $\phi_{i+1} = -64.6°$, $\psi_{i+1} = -28.5°$ and $\phi_{i+2} = -80.6°$, $\psi_{i+2} = -7.3°$) and the $\Delta Phe^2\text{-}Ala^3\text{-}\Delta Phe^4\text{-}Ala^5$ fragment adopts a type II β-turn conformation ($\phi_{i+1} = -65.8°$, $\psi_{i+1} = 129.9°$ and $\phi_{i+2} = 77.2°$, $\psi_{i+2} = 3.3°$). It should be noted that ΔPhe^2 has a negative ϕ, while ΔPhe^4 has a positive ϕ. This is not surprising in view of the achiral nature of ΔPhe. The above-mentioned β-turns are stabilized by two hydrogen bonds, N3–H···O2(Boc) and N5–H···O2′. The 4→1 hydrogen bond N4–H···O1′ is not observed, which is consistent with the hydrogen bonding features of a β-bend ribbon. However, the hydrogen bonding potential of the O1′ atom as an acceptor is satisfied by intermolecular hydrogen bonding in the two crystallographically independent molecules (Table 1).

Table 1. Intermolecular and intramolecular hydrogen bonds observed in the structure of **1** in the crystal [a].

[a] The last letter A or B in the names of the atoms refers to the two crystallographically independent molecules A and B, respectively. C1GA and C1GB represent the γ-carbon atom of the pyrrolidine ring of the Pro^1 residue.

The *trans* conformation of the tertiary urethane Boc–Pro bond in the pentapeptide deviates significantly from planarity ($\omega_0 = -162.6°$). The pyrrolidine ring of the Pro^1 residue which is characterized by $\chi_1 = -10.1°$, $\chi_2 = 7.7°$, $\chi_3 = -2.3°$, $\chi_4 = -5.0°$, and $\theta = 9.3°$, is nearly C^γ-*exo* puckered.[11] The phenyl groups of the two ΔPhe residues are almost planar with olefinic double bond (dihedral angles $\chi_2^2 = -164.5°$, $\chi_4^2 = 4.9°$).

In the β-bend ribbon structures previously reported, the backbone torsion angles are nearly 3_{10}-helical,[7] so that the overall shape of the molecules could grossly be approximated to cylinders. In contrast, in **1** the backbone torsion angles of Ala^3 deviate significantly from 3_{10}-helical values (Table 2), resulting in a relatively flat slablike structure; we designated this structure as a flat β-bend ribbon structure.

Table 2. Torsion angles averaged over the two crystallographically independent molecules of **1**.

Pro^1	−64.4 [a]	−28.5	179.3
ΔPhe^2	−80.6	−7.3	−173.4
Ala^3	−65.8	129.9	178.8
ΔPhe^4	77.2	3.3	169.8
Ala^5	−63.4	−29.6 [b]	-

[a] C5(Boc)-N1-C1A-C1′. [b] N5-C5A-C5′-O3(OMe).

The peptide molecules reported so far, possessing a β-bend ribbon conformation, invariably have at alternate positions, residues such as proline,[7b,c] *N*-methylaminoisobutyric acid (MeAib),[7d] hydroxyproline (Hyp),[7e] and α-hydroxyisobutyric acid (Hib)[7e,f] which lack the hydrogen bond donating N–H group. In these peptides, therefore, consecutive 4→1 hydrogen bonds are inherently absent at alternate positions, but an approximate 3_{10}-helical conformation is maintained due to conformationally constrained Aib residues, leading to a β-bend ribbon spiral. However, in **1**, a flat β-bend ribbon structure is observed even though the sequence allows the possibility of consecutive 4→1 hydrogen bonds.

The crystal packing of **1** as viewed down the crystallographic *b* axis is shown in Figure 2. The intermolecular hydrogen bonds are listed in Table 1. There are no head-to-tail intermolecular

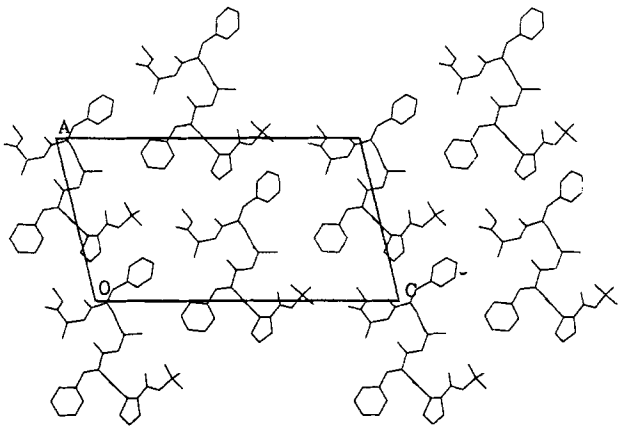

Fig. 2. Crystal packing of **1**. View down the crystallographic *b* axis.

hydrogen bonds, a frequent feature observed in some Aib peptides[6] and α,β-dehydropeptides,[2j] and no hydrogen bonds between the two crystallographically independent molecules; the *ac* plane of the crystal structure is predominantly stabilized by hydrophobic interactions. The intermolecular interactions along the *b* axis are mainly electrostatic in nature. The peptide molecules with an S-shaped backbone are stacked one above the other, along the crystallographic *b* axis and are connected by N–H···O and C–H···O types of hydrogen bonds (Table 1). We observe alternate columns along the *b* axis containing the two crystallographically independent molecules. The interface of the columns contains Boc-methyl groups and dehydrophenylalanine side chains and hence is predominantly hydrophobic. The Phe rings interact in "tilted" configurations,[12] which is in accordance with the observation made in proteins.[12] The O5′ atom does not participate in any hydrogen bond formation.

The structure of **1** now enables a comparison of ΔPhe-containing oligopeptide structures with the corresponding Aib analogues reported earlier, the N-terminal fragments (2-6) of the antibiotic alamethicin, Boc-Pro-Aib-Ala-Aib-Ala-OH[13a] and *Z*(Cl)-Pro-Aib-Ala-Aib-Ala-OMe.[13b] Both Aib peptides have a left-handed 3_{10}-helical structure. Whereas Aib is known to strongly prefer helical backbone dihedral angles, ΔPhe can be accommodated in the 'bridge' region of the conformational space, as the Ala[3]-ΔPhe[4] sequence in **1** shows.

In the crystal structures of ΔPhe-containing peptides reported so far, the ΔF-X1-ΔF-X2 fragment has always exhibited either type III or type III′ β-turn conformations[2i-l] (Table 3), leading to a helical structure, whereas in the crystal structure of **1** the same fragment, for the first time, shows a type II β-turn which is nonhelical (Table 2). Interestingly, the ΔF-X1-ΔF-X2 fragment with X1 = Leu or Val, assumes a right-handed helical conformation (Table 3), whereas, the same fragment with X1 = Ala adopts an entirely different conformation in the present case. There are several examples known, in which the peptide backbone assumes a left-handed helical conformation despite the presence of the chiral L-Ala residue.[13, 14] Thus the Ala residue, presumably, because of the less bulky side chain, appears to permit greater conformational flexibility for the peptide backbone, a result that could be made use of in fine-tuning the designed conformation.

Thus, the solid-state molecular structure of **1** shows how novel conformations such as the flat β-bend ribbon can be obtained by using ΔPhe residues. The comparison with the Aib analogues of the pentapeptide demonstrates that even though Aib and ΔPhe are achiral, conformation constraining residues, different structures may be stabilized by these residues in a given peptide sequence. The conformational variability has been elegantly described in Aib-containing peptides,[13, 15] it has also been observed to some extent in ΔPhe-containing peptides.[14] The comparison of the conformation of the dehydropentapeptide with the other dehydropeptide fragments of the type ΔF-X1-ΔF-X2, shows the role of the amino acid residues X1 and X2 in determining the overall conformation of the dehydrooligopeptide. Clearly, further studies are required to understand the influence of the dehydrophenylalanine residue on the conformation of peptides and to compare its conformation constraining behavior with that of the Aib residue.

Table 3. The conformation exhibited by the X1-ΔF segment of the ΔF-X1-ΔF-X2 fragment in crystal structures studied so far.

Experimental Procedure

Synthesis of Boc-Ala-ΔPhe-Ala-OCH_3: A solution of HCl·H-Ala-OCH_3 (0.77 g, 5.5 mM) and triethylamine (0.8 mL, 5.5 mM) in dichloromethane (10 mL) was added to a solution of Boc-Ala-ΔPhe-azlactone [2i] (1.56 g, 5 mM) in dichloromethane (10 mL) and stirred for 48 h at room temperature. After removal of solvent in vacuo, the residue was dissolved in ethyl acetate and washed with saturated $NaHCO_3$ solution, water, 5% citric acid, and saturated NaCl solution and dried over Na_2SO_4. After evaporation and crystallization from diethyl ether/petroleum ether pure tripeptide was obtained. Yield: 1.8 g (87%); m.p. 97–99 °C; R_f ($CHCl_3$/CH_3OH, 9:1) 0.85, R_f (*n*-butanol/acetic acid/H_2O, 4:1:1) 0.89. ^{1}H NMR (270 MHz, $CDCl_3$): δ = 7.76 (1H, s, NH ΔPhe), 7.43 (1H, d, NH Ala(3)), 7.4–7.3 (6H, m, aromatic protons and C^βH ΔPhe), 5.08 (1H, d, NH Ala(1)), 4.68 (1H, m, C^αH Ala(3)), 4.19 (1H, m, C^αH Ala(1)), 3.75 (3H, s, OCH_3), 1.43 (3H, d, $C^\beta H_3$ Ala(3)), 1.41 (12H, d, Boc Me_3 and $C^\beta H_3$ Ala(1)).

1: After deprotection of Boc-Ala-ΔPhe-Ala-OCH_3 with trifluoroacetic acid (TFA)/dichloromethane (1:1, v/v) at room temperature and evaporation, the oily residue was washed with ether to give TFA·H-Ala-ΔPhe-Ala-OCH_3. Boc-Pro-ΔPhe-azlactone [2i] (1.22 mg, 3.5 mM) and TFA·H-Ala-ΔPhe-Ala-OCH_3 (1.5 g, 3.5 mM) were allowed to react as described above. This led to the pure pentapeptide after recrystallization from methanol/water. Yield: 1.7 g (74%); m.p. 236–238 °C; R_f ($CHCl_3$/CH_3OH (9:1)) 0.71, R_f(*n*-butanol/acetic acid/H_2O 4:1:1) 0.93. ^{1}H NMR (270 MHz, in $CDCl_3$ with traces of $(CD_3)_2SO$): δ = 9.49 (1H, s, NH ΔPhe(2)), 8.71 (1H, s, NH ΔPhe(4)), 8.12 (1H, d, NH Ala(3)), 7.3 (1H, d, NH Ala(5)), 7.26–7.09 (12H, m, aromatic protons and 2C^βH ΔPhe(2) and ΔPhe(4)), 4.37 (1H, m, C^αH Ala(5)), 4.26 (1H, m, C^αH Ala(3)), 4.03 (1H, m, C^αH Pro(1)), 3.53 (3H, s, OCH_3), 2.09 (1H, m, C^β H Pro(1)), 1.81 (2H, m, C^γH and C^δH Pro(1)), 1.39 (3H, d, $C^\beta H_3$ Ala(5)), 1.29 (12H, d, Boc Me_3 and $C^\beta H_3$ Ala(3)).

Crystal structure analysis: Single crystals having colorless prismatic morphology were obtained by evaporation of a solution of the peptide ($C_{35}H_{43}N_5O_8$, M_r = 661.75) in methanol/acetone mixture. The crystals belong to the monoclinic space group $P2_1$ with a = 14.365(2), b = 9.931(2), c = 25.787(2) Å, β = 104.03(1)°, V = 3569 Å^3, Z = 4, ρ = 1.23 g cm^{-3}. X-ray intensity data were collected at 21 °C with an Enraf-Nonius CAD4 diffractometer with Ni-filtered $Cu_{K\alpha}$ radiation (λ = 1.5418 Å). The ω-2θ scan technique was used to collect data upto a Bragg angle of 60°. A total of 5881 unique reflections were measured, 5205 of which with $|F_o| > 3\sigma(|F_o|)$ were considered as observed and used in the structure analysis. No significant variation was observed in the intensities of three standard reflections monitored at regular intervals during the data collection, implying electronic and crystal stability. Lorentz and polarization corrections were applied to the data and no absorption corrections were made. The structure was solved by direct methods by using SHELXS86 [8] and refined by full-matrix least-squares technique with anisotropic thermal factors for all non-hydrogen atoms. All the hydrogen atoms were placed at idealized positions on the basis of the stereochemistry and they were included only in structure factor calculations. The final agreement factors are R = 0.056 and R_w = 0.069. There are two crystallographically independent molecules in the asymmetric unit (A and B). The molecular dimensions and the conformation of these two molecules are remarkably similar. Least-squares superposition of the backbone atoms of these two molecules results in an average standard devi-

ation of 0.09 Å, indicating the similarity of the two molecules. Therefore the mean values of the conformational parameters have been used in the discussions. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB21EZ (UK), on quoting the full journal citation.

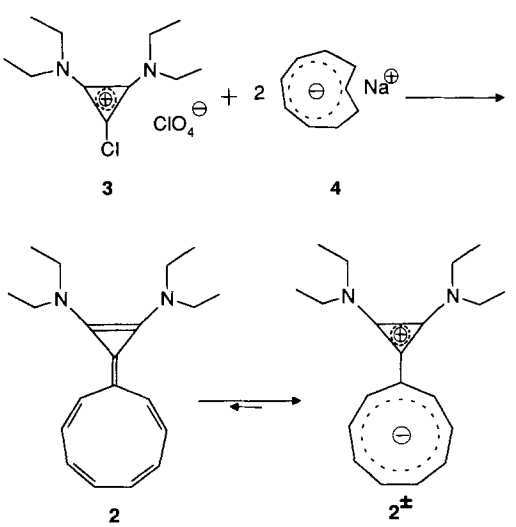
11,12-Bis(diethylamino)nonatriafulvalene, the First "Aromatic" Nonafulvene**



Shengyong Chai and Markus Neuenschwander*

According to NMR investigations, nonpolar nonafulvenes including parent **1a** ($R^1 = R^2 = H$) are olefinic compounds (characterized by strongly alternating bond lengths and a nonplanar ring).[1] As a result of the rapid equilibrium **1A** ⇄ **1B** for $R^1 = R^2$, four pairs of ring protons and four pairs of ring-C atoms are equivalent: H-1/H-8, H-2/H-7, H-3/H-6, H-4/H-5 and C-1/C-8, C-2/C-7, C-3/C-6, C-4/C-5, respectively. Furthermore, ^1H and ^{13}C NMR signals occur at $\delta = 5.4$ to 6.4 and $\delta = 115$ to 132, respectively, and do not significantly change between -100 and $+20\,^\circ C$. Remarkably different behavior is observed for the first isolated nonafulvene **1b**, whose spectra are strongly influenced by solvent polarity and temperature.[2, 3] This is explained reasonably well by an equilibrium between nonplanar olefinic **1b** and planar dipolar **1b**$^\pm$,[4] the latter being favored by polar solvents or low temperatures;[5] very similar behavior is observed for sodium nonafulvenolates.[6]

Hitherto, nonafulvenes which exist in the dipolar form **1**$^\pm$ between -100 and $20\,^\circ C$ in nonpolar solvents were unknown. The ground-state energy of **1**$^\pm$ (characterized by a planarized nine-membered ring) is expected to be considerably lower than that of the nonplanar olefinic structure **1**; thus the structure **1** should not be favored by solvent or temperature effects.

We considered several synthetic pathways to dipolar nonafulvenes;[7] one attractive plan is based on the synthesis of **2**. It is well known from calicenes (pentatriafulvalenes)[8] that a cyclopropene unit, attached to the exocyclic double bond of pentafulvenes, strongly supports or even increases the electron-releasing capacity of exocyclic substituents,[9, 10] while steric effects are

considerably reduced. In fact, reaction of 1-chloro-2,3-bis(diethylamino)cyclopropenylium perchlorate **3**[11] with two equivalents of Na-(*Z,Z,Z,E*)-cyclononatetraenide (**4**) at −60 °C in THF/CH_2Cl_2 gave pale yellow crystals of **2** (54% yield).[12]

The structure of $\mathbf{2}^{\pm}$ is in agreement with the spectroscopic and analytical results.[13] In the ^1H NMR spectrum (600 MHz, $CDCl_3$, room temperature) the signals of all the ring protons are in the range between $\delta = 7.3$ and 7.0 and are thus shifted by an average $\Delta\delta \approx 1.2$ to low field in comparison with those of nonpolar nonafulvenes.[1] Furthermore, the chemical shifts of the protons of the NEt_2 groups (q at $\delta = 3.68$ and t at $\delta = 1.39$) are very similar to those of **3**.[14] Analysis of the complex AA'BB'XX'YY'-type spectrum of the ring protons of $\mathbf{2}^{\pm}$ (Fig. 1, bottom) gives, after iterative simulation (Fig. 1, top), a set of large and nearly equal ^3J coupling constants as well as a set of surprisingly small long-range coupling constants.[15] In addition, the chemical shifts and the splitting pattern of the ring protons are virtually not influenced by changes of temperature (−50 to +50 °C) or solvents. The ^1H NMR results are convincingly explained with a dipolar cyclopropenylio cyclononatetraenide structure $\mathbf{2}^{\pm}$, which is characterized by a planarized nine-membered ring. This conclusion is supported by the ^{13}C NMR spectra: The signals of all the ring-C atoms experience an average high-field shift of $\Delta\delta = 16$ compared with those of nonpolar nonafulvenes[1] due to the negative π-charge density and moreover, do not alter their positions ($\Delta\delta = 0.9$) between −50 and +50 °C.

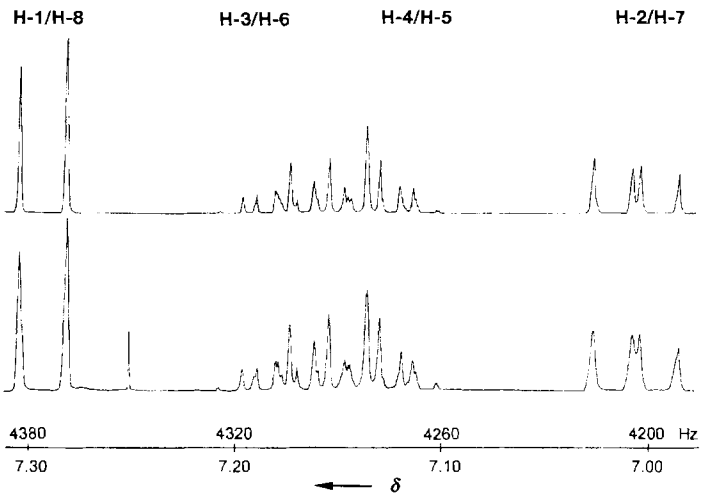

Fig. 1. Expansion of the signals of the ring protons of $\mathbf{2}^{\pm}$; bottom: experimental spectrum; top: simulation with values from [15].

For an illustrative comparison of the surprising NMR spectroscopic similarities between $\mathbf{2}^{\pm}$ and **1b**, for which a temperature-dependent equilibrium of the type $\mathbf{1b} \rightleftarrows \mathbf{1b}^{\pm}$ has been well established, the NMR data of both compounds are summarized in Figure 2.[16] At room temperature and in nonpolar solvents like $CDCl_3$, **1b** behaves like a nonplanar olefinic nonafulvene: The ^1H chemical shifts lie between $\delta = 5.4$ and 6.3[2], the vicinal ^3J coupling constants are strongly alternating,[1, 3] and the ^{13}C chemical shifts of C1 to C8 are in a fairly broad range centered around $\delta = 120$. With decreasing temperature (and increasing importance of $\mathbf{1b}^{\pm}$), ^1H NMR signals shift towards $\delta = 6.9$ to 7.2,[2] the values of the ^3J coupling constants over formal single bonds of **1b** increase dramatically,[1, 2] and the signals of C2 to C8 shift towards $\delta = 110$.[17]

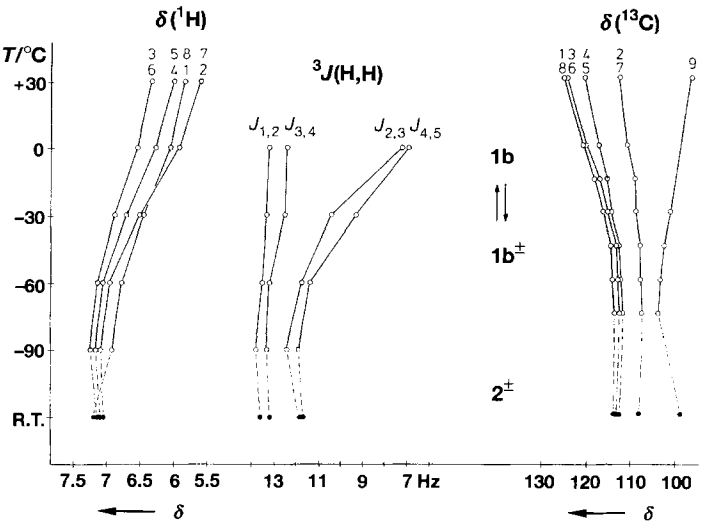

Fig. 2. NMR parameters of nonatriafulvalene **2** compared with those of 10,10-bis-(dimethylamino)nonafulvene **1b** [1–3]. R.T. = room temperature.

All the NMR spectroscopic parameters of the nonatriafulvalene **2** (Fig. 2 bottom) are virtually identical with the values of **1b** in the low-temperature range[18] (which are governed by the influence of dipolar $\mathbf{1b}^{\pm}$). The only difference is that they are not dependent on the solvent polarity or temperature. Thus it is clear that over the temperature range (from −50 to +50 °C) studied and in all the solvents used,[19] 11,12-bis(diethylamino)nonatriafulvalene **2** exists as the dipolar aromatic structure $\mathbf{2}^{\pm}$.

Experimental Procedure

A 50 mL 3-necked flask equipped with a magnetic stirring bar, a thermometer, a septum, and an Ar bubbler was flame-dried while flushed with Ar. The flask was charged with **3** (315 mg, 1 mmol), CH_2Cl_2, (8 mL), and THF (5 mL) and then cooled to −50 °C. At this temperature **4** (2 mL, 2 mmol, 1.001 M solution in THF) was added dropwise under Ar with a syringe over 20 min. The orange reaction mixture was stirred for 4 h at −40 to −50 °C. Then cooled CH_2Cl_2/pentane 1:1 (20 mL) was added. The mixture was stirred for another 10 min at −78 °C, then centrifugated for 10 min (4000 rpm) at −30 °C. The resulting solution was concentrated at −40 °C/0.1 mbar to give yellow crystals. Recrystallization from CH_2Cl_2/Et_2O (2:1) (6 mL) under Ar at −70 °C gave 161 mg (54%) of pale yellow cubic crystals of **2** [20]. Crystals and solutions of **2** are stable for days at room temperature and several hours at +50 °C under Ar, without valence isomerization; however, **2** polymerizes rapidly in the presence of O_2.

[5] Obviously ΔG between **1b** and $\mathbf{1b}^{\pm}$ is so small that solvent or temperature changes may favor either structure. For $\mathbf{1b} \rightarrow \mathbf{1b}^{\pm}$, UV measurements suggest $\Delta H^{\circ} = -6.5\ kcal\,mol^{-1}$ and $\Delta S^{\circ} = -22\ cal\,K^{-1}\,mol^{-1}$ [3].
[6] There is an equilibrium between sodium 10-methylnonafulvenolate and sodium acetylcyclononatetraenide with $\Delta H^{\circ} = -6.9\ kcal\,mol^{-1}$ and $\Delta S^{\circ} = -30\ cal\,K^{-1}\,mol^{-1}$: G. Boche, F. Heidenhain, *J. Am. Chem. Soc.* **1979**, *101*, 738; G. Boche, F. Heidenhain, W. Thiel, R. Eiben, *Chem. Ber.* **1982**, *115*, 3167.

[12] It is interesting to note that the similar reaction of **3** with the less nucleophilic Li-(*ZZZZ*)-cyclononatetraenide failed to give **2** [9].
[13] UV($CHCl_3$, 25 °C): λ_{max} (ε) = 407 (8650), 290 (12900), 255 (8590) nm; IR (KBr, 25 °C): ν = 2970m-s, 2930m, 2870w, 1915m, 1538s, 1485w, 1435w-m, 1415m-s, 1380m-s, 1360m-s, 1345m-s, 1300m-s, 1215w-m, 1190m, 1075w, 870w, 685w, 615m cm^{-1}; ^1H NMR (600 MHz, $CDCl_3$, 25 °C): δ = 7.29 (m, 2H), 7.17 (m, 2H), 7.12 (m, 2H), 7.00 (m, 2H), 3.68 (q, 8H); 1.39 (t, 12H) [14, 15]; ^{13}C NMR (100 MHz, $CDCl_3$, 0 °C): δ = 128.9s, 128.7s, 113.5d, 113.2d, 112.4d, 107.4d, 97.8s, 47.4t, 14.7q; MS: high-resolution MS of M^+: 296.2257 (calcd. $C_{18}H_{32}N$: 296.2253).
[14] ^1H NMR of **3** (300 MHz, $CDCl_3$, 25 °C, δ values): N-CH_2: 3.52 (q, 4H), 3.49 (q, 4H); N-CH_2-CH_3: 1.33 (t, 6H), 1.29 (t, 6H). Similar to **3** the N-CH_2 and N-CH_2-CH_3 groups of **2** give two multiplets due to the hindered rotation; τ_c = −25 °C for the N-CH_2 groups, $\Delta G^{\ddagger}$ = 11.5 kcal mol^{-1}. This is the only temperature-dependent process observed in the ^1H NMR spectrum of **2** between −80 and +50 °C.
[15] Results of the ^1H NMR analysis of **2** (600 MHz, $CDCl_3$, 25 °C, δ values): H-1,8: 7.29; H-2,7: 7.00; H-3,6: 7.17; H-4,5: 7.12; ^3J couplings: $J_{1,2} = J_{7,8}$ = 13.58; $J_{2,3} = J_{6,7}$ = 11.78; $J_{3,4} = J_{5,6}$ = 13.16; $J_{4,5}$ = 11.70 Hz; ^4J couplings: $J_{1,3} = J_{6,8}$ = 0.12; $J_{1,4} = 0.21$; $J_{2,4} = J_{5,7}$ = 0.15; $J_{3,5} = J_{4,6}$ = 0.15 Hz.
[16] Note that all the NMR parameters of nonpolar nonafulvenes including **1a** ($R^1 = R^2$ = H) are similar to those **1b** in $CDCl_3$ at room temperature. The only difference is that they are not influenced by solvents or temperature.
[17] C-9 of **1b** is the only ring-C atom showing an opposite trends. This is probably mainly due to the conformational changes involved with **1b** → **1b**$^{\pm}$, which are expected to have a pronounced effect on C-9 (in **1b**$^{\pm}$ the formamidinium unit is supposed to be out of the plane of the ring). Furthermore, the exocyclic "enediamine system" is expected to induce a considerable negative charge at C-9, even in the case of the olefinic stucture **1b**.
[18] Similarly, the UV spectrum of **2** ($CDCl_3$, 25 °C) is nearly identical with that of **1b** (CH_2Cl_2, −80 °C [3]).
[19] CCl_4, $CDCl_3$, [D_6]benzene, [D_8]THF, CD_2Cl_2, [D_6]acetone, CD_3CN.
[20] Several attempts at an X-ray analysis of **2** have failed so far because the compound only crystallizes as polycrystals.

Dibromine Pentoxide Br_2O_5**

Dieter Leopold and Konrad Seppelt*

Recently we synthesized pure Br_2O_3, which according to its crystal structure analysis can be described as $Br-O-BrO_2$.[1] Together with the results of the structure analysis of Br_2O by using EXAFS (*E*xtended *X*-ray *A*bsorption *F*ine *S*tructure),[2] these are the first secure structural data of bromine oxides. After the unequivocal proof of the existence of Br_2O and Br_2O_3, the question arose whether a bromine perbromate ($BrOBrO_3$) identified with the EXAFS method[3] was perhaps in fact Br_2O_3.[1] The basic difficulty of the work with bromine oxides is their thermal instability. This is the reason why in earlier literature additional bromine oxides were postulated, although only elemental analysis and sometimes Raman spectroscopy were used for their characterization, and a review also gave the impression that the syntheses are not always reproducible.[4]

In the synthesis of Br_2O_3 from bromine and ozone in $CFCl_3$ at −78 °C, we have observed a second bromine oxide. This is colorless, and thus should no longer contain an $O-Br^I$ group, and forms on longer ozonization time, therefore a higher oxygen content was to be assumed. In contrast to Br_2O_3, it is insoluble in CH_2Cl_2. In order to synthesize this compound in a pure form, we ozonized elemental bromine in CH_2Cl_2 at −78 °C. In this way the color of the solution lightens from brown (Br_2) via orange (Br_2O_3) to colorless; from the orange-colored step onwards, an initially yellow, then almost colorless powder precipitates [Eq. (a)]. This powder decomposes on warming above

$$Br_2 \xrightarrow[CH_2Cl_2,\ -78\ ^\circ C]{O_3} Br-O-BrO_2 \xrightarrow[CH_2Cl_2,\ -78\ ^\circ C]{O_3} O_2Br-O-BrO_2 \qquad (a)$$

−40 °C, occasionally with detonation. Propionitrile was found to be a suitable solvent from which this compound crystallizes out in the form of large colorless needles; an increase in weight with respect to the amount of powder used indicates the incorporation of solvent in the crystal. These needles melt at about −20 °C with decomposition.

The crystal structure analysis characterized the new oxide as Br_2O_5, which crystallizes with three molecules of propionitrile (Fig. 1). Since the four Br···N contact distances between propionitrile and Br_2O_5 are quite large (278.7(2)–290.1(2) pm), we consider Br_2O_5 in this cocrystallisate as a largely undisturbed molecule. As in Br_2O_3 it is not difficult to differentiate between terminal Br–O double bonds (160.6–161.3(2) pm) and the Br–O single bonds to the bridging oxygen atom (187.5(2), 189.6(2) pm) in Br_2O_5. The bromine atoms are pyramidally surrounded by the oxygen atoms, as to be expected for Br^V centers; the angle at the bridging oxygen atom is with 121.2(1)° likewise in the expected range. The terminal oxygen atoms at the two bromine atoms are eclipsed, the deviations from this are maximally 0.1 pm. This distinguishes Br_2O_5 from I_2O_5. The structure of the latter has been studied both as a pure substance[5] and also as a cocrystallisate $HIO_3 \cdot I_2O_5$ ("HI_3O_8"),[6] and its terminal oxygen atoms are staggered. However, the structure of I_2O_5 is dominated by intermolecular O···I interactions (up to 223 pm). The Raman spectrum of solvate-free Br_2O_5 is in agreement with the structure shown in Figure 1. The valence frequencies of the double bonds, those of the single bonds, and the deformation vibrations are significantly separated from each another. The Raman spectrum, however, differs from that described in 1976 for a Br_2O_5.[7]

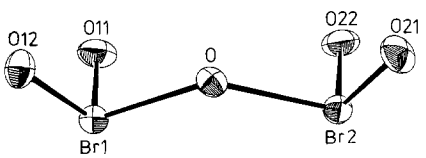

Fig. 1. Structure of the Br_2O_5 molecule in the cocrystallizate $Br_2O_5 \cdot 3C_2H_5CN$ (ORTEP plot, thermal ellipsoids at 50% probability level). Distances [pm] and angles [°]: Br1–O11 160.6(12), Br1–O12 161.1(2), Br1–O 189.6(2), Br2–O21 161.3(2), Br2–O22 160.6(2), Br2–O 187.5; O11-Br1-O12 109.9(1), O-Br1-O11 94.2(1), O-Br-O12 102.6(1), O21-Br2-O22 109.0(1), O-Br2-O21 103.3, O-Br2-O22 94.9(1), Br1-O-Br2 121.2(1)

The unambiguous existence of Br_2O_5, which is mixed with Br_2O_3 if purification is not carried out, questions once again the existence of Br_2O_4, which according to the Raman spectra should occur in two forms, $O_2Br-BrO_2$[8] and $OBr-OBrO_2$,[1b] but according to the EXAFS spectrum should have the structure $BrOBrO_3$.[3]

The structures of Br_2O, Br_2O_3, and Br_2O_5 indicate the building principles for bromine oxides: bromine in the oxidation state +1 occurs in a terminal position with a weak interaction to another bromine atom, and a bromine atom in the oxidation state +5 is pyramidally surrounded with two short and one long

bond to the coordination partners. The combination of these two building blocks leads to the least unstable compounds of the system Br/O. The relationship to chlorine is apparent in the oxidation state +1 (e.g. Cl_2O), that to iodine in the oxidation state + 5 (e.g. I_2O_5).

Experimental Procedure

After drying over silica gel, ozone prepared in the ozone generator was introduced into a solution of Br_2 (100 mg) in CH_2Cl_2 (5 mL) at −78 °C. The color of the solution lightened, and this was accompanied by the precipitation of initially an orange-colored, and later an almost colorless solid. When the solution had lost its color, it was decanted and dried under vacuum at −50 °C. Crystallization in the temperature range from −50 °C to −90 °C from C_2H_5CN gave $Br_2O_5 \cdot 3\,C_2H_5CN$ in the form of large colorless needles; the solution had a tendency towards supersaturation. Raman (solid, krypton ion laser, 647.0 nm): $\tilde{\nu}$(Br=O): 868(40), 835(15), 803(90), 774(20); $\tilde{\nu}$(Br–O): 539(30), 511(35); δ: 376(20), 351(100), 161(30), 110(30) cm^{-1}. Crystal structure analysis: $a = 1239.6(2)$, $b = 881.7(1)$, $c = 1452.8(2)$ pm, $\beta = 103.82(1)°$, $V = 1609 \times 10^6$ pm^3, −145 °C, $P2_1/n$, $Z = 4$, $\mu = 49.3$ cm^{-1}. 6988 measured reflections in the range $\theta = 2$–35°, $+h, -k, \pm l$. 6434 independent reflections, $R_{int} = 0.026$, 3617 reflections with $F > 3\sigma(F)$, $R = 0.042$, $R_w = 0.029$, 218 parameters, $W = 1.56/\sigma^2(F)$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57939.

Methylbismuth(v) Compounds**

Stephan Wallenhauer and Konrad Seppelt*

Tetraphenylbismutonium salts,[1] pentaphenylbismuth,[1] and hexaphenylbismutate[2, 3] are compounds which have been known for a long time, for which the relation between light absorption and structure could only be explained recently.[4–8] In contrast, almost nothing is known about alkylbismuth(v) compounds.[9] To our knowledge, there is only one conference report about the preparation of $Bi(C_2H_5)_3CH_3^+$ [9] as well as the detection of $Bi(CH_3)_4^+$ by β decay of $^{210}Pb(CH_3)_4$.[10] The preparation of the bromides (*E*/*Z*) $(CH_3CH{=}CH)_3BiBr_2$ with melting points of 65 and 142 °C, respectively, could not as of yet be reproduced, and this preparation is also questionable in light of the following observations.[11] This lack of knowledge is actually surprising, since the corresponding alkylantimony(v) compounds, in particular $Sb(CH_3)_5$, are prepared readily. The structure of $Sb(CH_3)_5$ was only recently determined to be unequivocally trigonal bipyramidal by an electron diffraction[12] and a single-crystal structure analysis.[13] $As(CH_3)_5$ is equally surprisingly stable, and its vibrational spectra can only be explained in terms of a trigonal bipyramidal structure.[14] Since the phenylbismuth(v) compounds are considerably more unstable than the corresponding antimony(v) compounds, the lacking knowledge on alkylbismuth(v) compounds can be explained by the expected instability. As we shall show in the following, this prediction is only partly true.

Trimethylbismuth can be methylated very easily with $CH_3OSO_2CF_3$ [Eq. (a)]. The resulting tetramethylbismutonium trifluoromethylsulfonate is a colorless compound, which is stable up to over 150 °C. It is surprising that this simple reaction was not reported earlier. According to a crystal structure analysis,[15] the $Bi(CH_3)_4^+$ ion is tetrahedral (Fig. 1a). Weak interactions to the anion and solvate molecule do not distort the structure significantly. The mean Bi–C bond length of 222 pm is

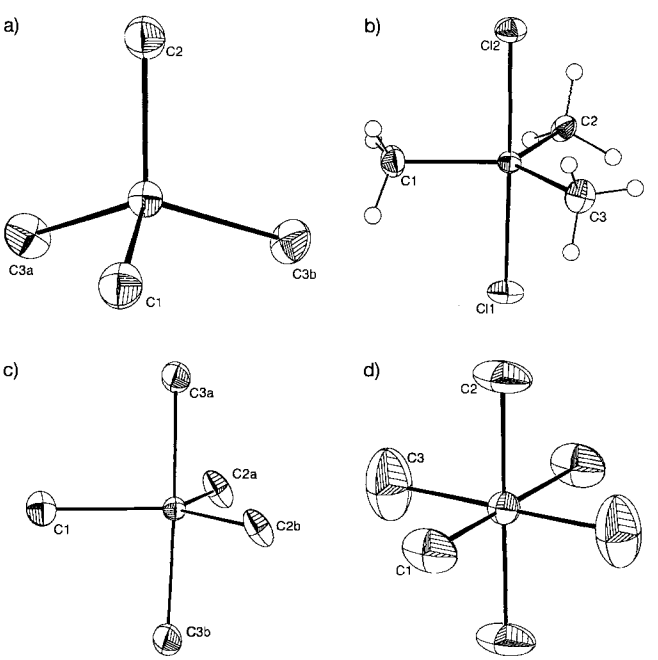

Fig. 1. Structures of the cation of $Bi(CH_3)_4^+SO_3CF_3^- \cdot CH_3CN$ (a), of $Bi(CH_3)_3Cl_2$ (b), of $Bi(CH_3)_5$ (c), and of the anion of $[Li(thf)_4]^+[Bi(CH_3)_6]^-$ (d) in the crystal (ORTEP plots; thermal ellipsoids at the 50% probability level). a) Bond lengths [pm] and angles [°] of $Bi(CH_3)_4^+$: Bi–C 222.0(10), 223.0(10), 221.0(7); C-Bi-C 112.0(4), 109.6(3), 108.9(2). b) The asymmetric unit of $Bi(CH_3)_3Cl_2$ contains one acetone molecule. Bond lengths [pm] and angles [°]: Bi–Cl 260.2(2), 261.7(2), Bi–C 218.9(7), 219.6(6), 220.7(6); Cl1-Bi-Cl2 177.8(1), C-Bi-C 117.4(2), 127.3(2), 115.3(2). The large C-Bi-C bond angle is explained by a long Bi···O contact of 323 pm to the oxygen atom of the acetone molecule. c) As in the structure of $Sb(CH_3)_5$ [13], the $Bi(CH_3)_5$ molecule here is also doubly disordered in the lattice. The second orientation is formed by a 90° rotation about the Bi-C1 axis. Only one orientation is shown for better clarity. Bond lengths [pm] and angles [°]: Bi–C1 230(2), Bi–C2 227(1), Bi–C3 228(2); C1-Bi-C2a 119.3(5), C1-Bi-C3a 89.9(5), C2a-Bi-C2b 121.4(5), C2a-Bi-C3a 90.4(6), C2a-Bi-C3b 89.9(5), C3a-Bi-C3b 179.8(8). d) Bond lengths [pm] and angles [°] of $Bi(CH_3)_6^-$: Bi–C 236(1), 233(1), 230(2); C-Bi-C 89.6(4), 90.0, 90.0, 180.0.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Graduiertenkolleg "Synthese und Strukturaufklärung niedermolekularer Verbindungen".

slightly shorter than in the isoelectronic $Pb(CH_3)_4$ (224(1) pm), and the valence force constant calculated (210 Nm^{-1}) is larger than that of tetramethylplumbane (177 Nm^{-1}).[16, 17]

Attempts to halogenate $Bi(CH_3)_3$ proved to be difficult. With Cl_2 and XeF_2, a Bi–C bond cleavage takes place; but chlorination with SO_2Cl_2 to give $Bi(CH_3)_3Cl_2$ is successful, and occurs almost quantitatively [Eq. (b)]. According to a crystal structure analysis,[15] the colorless solid is trigonal bipyramidal (Fig. 1b). This is to be expected, since all compounds known so far of this type R_3YX_2 (R = alkyl, aryl; Y = P, As, Sb, Bi; X = F, Cl, Br) have this structure, in which the halogen atoms adopt the axial-positions. $Bi(CH_3)_3Cl_2$ is, however, thermally unstable and decomposes rapidly at room temperature.

$Bi(CH_3)_3Cl_2$ is the starting material for the syntheses of $Bi(CH_3)_5$ and the anion $[Bi(CH_3)_6]^-$. The reaction with CH_3Li in diethyl ether in the ratio 1:2 at low temperatures gives a blue-violet solution, from which violet crystals of $Bi(CH_3)_5$ precipitate on cooling to $-110\,^{\circ}C$ [Eq. (c)]. According to a crystal

$$Bi(CH_3)_3Cl_2 \xrightarrow[-2\ LiCl]{+2\ CH_3Li\ /\ -95\,^{\circ}C\ /\ Et_2O} Bi(CH_3)_5 \qquad (c)$$

$$Bi(CH_3)_3Cl_2 \xrightarrow[-3\ LiCl]{+3\ CH_3Li\ /\ -78\,^{\circ}C\ /\ THF} [Li(thf)_4]^+[Bi(CH_3)_6]^- \qquad (d)$$

structure analysis[15] at $-163\,^{\circ}C$, the pentamethyl compound is isostructural, perhaps even isomorphous with $Sb(CH_3)_5$,[13] and the bismuth atom is trigonal-bipyramidally surrounded (Fig. 1c). The only noticeable difference is that in crystalline $Sb(CH_3)_5$ the axial bonds (220.9(5) pm) are about 7 pm longer than the equatorial bonds (213.5(6) and 214.5(5) pm). Similar considerations are true for gaseous $Sb(CH_3)_5$.[6]. In contrast, in $Bi(CH_3)_5$, the differences in the bond lengths ($\approx$1 pm) are smaller than the errors in the measurements. This phenomenon can be explained in terms of the reduced ligand repulsion for the larger central atom bismuth, or to put it another way, the differences in the bond lengths in trigonal-bipyramidal compounds require no other theoretical explanation.

It is surprising that $Bi(CH_3)_5$ has this trigonal-bipyramidal structure, since for pentaphenylbismuth the same deep violet color is associated with the square-pyramidal structure. Taking a relativistic correction into consideration for BiH_5, it was calculated that the HOMO–LUMO separation in trigonal-bipyramidal bismuth(V) compounds should be approximately twice as large as it should be for square pyramidal ones, because the LUMO in the latter case is more strongly Bi oriented and is therefore yet lower in energy because of the relativistic effect.[6] The +I effect of the methyl groups in $Bi(CH_3)_5$ eases the charge transfer transition, so that the absorption here also occurs in the visible region for the trigonal-bipyramidal structure. Finally, the color of $Bi(CH_3)_5$ proves that the light absorption of $Bi(C_6H_5)_5$ cannot be attributed to the presence of aromatic rings.

$Bi(CH_3)_5$ is a very unstable compound. In the crystalline state it explodes on rapid warming to room temperature, in solution it decomposes to $Bi(CH_3)_3$. Like $Sb(CH_3)_5$, it is a non-rigid compound, that is, the methyl groups are equivalent in the ^1H NMR spectrum even at $-90\,^{\circ}C$.

The reaction of $Bi(CH_3)_3Cl_2$ with an excess of CH_3Li gives $[Li(thf)_4]^+[Bi(CH_3)_6]^-$ in the form of yellow crystals at $-78\,^{\circ}C$ [Eq. (d)]. Thus, an additional example could be added to the few known compounds, in which six organic groups are bound to a main group element such as in $[Sb(C_6H_5)_6]^-$,[18] $[Bi(C_6H_5)_6]^-$,[2] and $Te(CH_3)_6$.[19] Because of its instability the $[Bi(CH_3)_6]^-$ ion could only be characterized by a crystal structure analysis;[15] the result is shown in Figure 1d. This structure investigation—like that for the isostructural (and possibly isomorphous) $[Li(thf)_4]^+[Sb(CH_3)_6]^-$[7]—proved to be more difficult by a disorder of the Li^+ ion and the THF molecules. The mean Bi–C bond length of the octahedral anion (233(1) pm) is, as expected, significantly larger than the Sb–C bond length in the likewise octahedral $[Sb(CH_3)_6]^-$ ion (224.2(6) pm (mean)).[13] Whereas $[Zr(CH_3)_6]^{2-}$[20] and $W(CH_3)_6$[21] are trigonal prisms, a circumstance which still requires a satisfactory explanation, the main group compounds $[Sb(CH_3)_6]^-$, $[Bi(CH_3)_6]^-$, and $Te(CH_3)_6$ form the expected octahedra.

Experimental Procedure

$Bi(CH_3)_4^+CF_3SO_3^-$: Under an argon atmosphere $Bi(CH_3)_3$ (1.25 g, 4.9 mmol) in CH_3CN (2 mL) was treated with methyl trifluoromethanesulfonate (0.9 g, 5.5 mmol). The mixture was stirred for 6 h at room temperature and concentrated to dryness under high vacuum. This gave 1.5 g of the salt as a colorless solid, which was recrystallized from CH_3CN/Et_2O. Raman (solid, cm^{-1}): $\tilde{\nu}$ = 3054 (m), 2180 (w), 1228 (w), 1210 (w), 1180 (m), 1030 (m), 757 (w), 574.5 (vw), 506 (vs, ν_sBiC), 475.5 (vs, ν_sBiC), 348.5 (w), 315 (w), 211 (vw, δ_eBiC), 157 (m, br, δ_sBiC); IR (solid, cm^{-1}) $\tilde{\nu}$ = 3052 (m), 2946 (m), 2855 (w), 2347 (w), 1684 (w), 1653 (w), 1636 (w), 1605 (w), 1412 (w), 1262, 1225 (s), 1203 (m), 1180 (s), 1167 (s), 1147 (s), 1030 (vs), 849 (s), 757 (m), 639 (s), 574 (m), 518 (m), 503 (s, ν_eBiC), 313 (w), 212 (m, δ_eBiC), 61 (s); NMR (90 MHz, [D$_6$]acetone, 20 °C): ^1H: δ = 2.47, ^{19}F: δ = −78.9.

$Bi(CH_3)_3Cl_2$: Freshly degassed SO_2Cl_2 (1.22 g, 9.0 mmol) at −196 °C was condensed into $Bi(CH_3)_3$ (2.3 g, 9.1 mmol) in dry Et_2O (10 mL). The mixture was stirred at −100 °C, warmed to −78 °C over 2 h, and the Et_2O and SO_2 were pumped off at 10^{-3} mbar to give 2.9 g (95%) colorless solid. NMR (90 MHz, [D$_6$]acetone, −50 °C): ^1H: δ = 3.29, $^{13}C\{^1H\}$: δ = 36.9.

$Bi(CH_3)_5$: CH_3Li (1.3 mL, ca. 1.8 M in Et_2O) was added slowly under argon to a suspension of $Bi(CH_3)_3Cl_2$ (0.3 g, 0.9 mmol) in dry Et_2O (4 mL) at −110 °C. Immediately after the addition of a few drops, the reaction mixture turned violet. After slow heating, the reaction solution was stirred for a short period at −78 °C. The finely distributed LiCl was left to settle overnight at −92 °C. The clear solution was transferred into a sealable glass ampoule with a thin Teflon tube. The volume of the solution was concentrated to a 1/5 of the original volume under the high vacuum at −85 °C. Thereafter the solution was cooled to −115 °C which led to the precipitation of a crystalline violet powder. ^1H NMR (90 MHz, [D$_8$]THF, −90 °C): δ = 1.19.

$[Bi(CH_3)_6]^-$: CH_3Li (ca. 1.8 M in Et_2O) was added to a suspension of $Bi(CH_3)_3Cl_2$ (0.5 g, 1.5 mmol) in dry THF (5 mL) at −95 °C under argon until the violet color of the reaction mixture had turned orange and remained that color. The mixture was slowly warmed to −78 °C, stirred for 30 min at this temperature and the finely distributed LiCl was left to settle out overnight at −92 °C. The resulting clear orange solution was transferred into a sealable ampoule with a thin Teflon tube. Concentration under high vacuum at −65 °C to 1/10 of the original volume and subsequent cooling to −92 °C gave yellow crystals.

Composition of Protocyanin, A Self-Assembled Supramolecular Pigment from the Blue Cornflower, *Centaurea cyanus***

Tadao Kondo,* Minoru Ueda, Hirotoshi Tamura, Kumi Yoshida, Minoru Isobe, and Toshio Goto†

Willstätter first isolated cyanin from the blue cornflower, *Centaurea cyanus*, in the early part of this century.[1, 2] In 1958 Bayer isolated a blue pigment named protocyanin from the same flower.[3, 4] Just after that, Hayashi obtained it as crystals,[5] as did Asen.[6–8] These three groups proposed protocyanin to be a metal complex, but the reported components contradicted each other, probably because of the complex properties of protocyanin. Protocyanin was described as a metalloanthocyanin analogous to another blue pigment, commelinin.[9] It is not dialyzable, migrates toward the anode on electrophoresis, and dissociates by dilution with water and then quickly decolorizes. We have already determined the complete structure of commelinin.[10] But pure protocyanin could not be obtained directly from cornflower petals since it is much less stable than commelinin. By acid dissociation of an extract, we found that the true anthocyanin and flavone components of protocyanin are succinylcyanin (Sucy, **1**) and a malonylflavone (Mafl, **2**).[11] From these components in addition to metal ions

1

2

we first prepared the true blue pigment of the cornflower. In this paper we report the exact composition of protocyanin.

Protocyanin was carefully purified from the extract of blue cornflower petals by precipitation and gel permeation chromatography (GPC). The resulting pigment shows a blue color in a buffer solution at pH 5,[12] the same as the physiological petal conditions, and exhibits a large negative Cotton effect in the visible region (Fig. 1).[13] The components of the pigment were

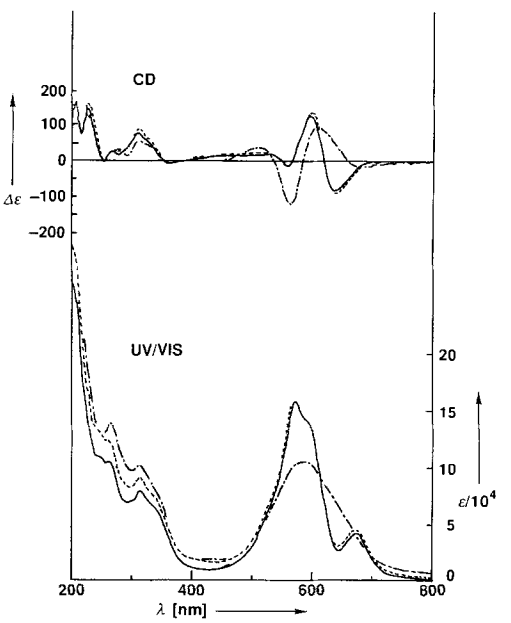

Fig. 1. UV/VIS and CD spectra of natural (——), reconstructed (- - -), and Fe_2-protocyanin (–·–·–) (5×10^{-5} M in 0.1 M acetate buffer (pH 5.0)).

analyzed by HPLC, X-ray fluorescence spectroscopy, and by measurements with inductively coupled plasma (ICP). **1**, **2**, iron, and magnesium ion were always detected, and the ratio of **1** and **2** was almost constant (ca. 1:1), though the proportion of other components changed every time. In order to obtain pure

Kuroda, Nagoya City University, for measurement of the ESR spectra and Prof. Dr. K. Endo, Showa College of Pharmaceutical Sciences, for measurement of the Mössbauer spectra.

protocyanin and determine its exact composition we tried to reconstruct it from the anthocyanin and the flavone components in the presence of various metal ions. To a solution of an equimolar mixture of **1** and **2** was added 10 equivalents of Mg^{2+}, but the color of the resulting solution was purple and differed from that of protocyanin. When 1/6 equivalent of Mohr's salt $(NH_4)_2[Fe(SO_4)_2]$ was added to the purple solution, it turned the same shade of blue as the natural pigment. The reconstructed pigment showed the same UV/VIS and CD spectra (Fig. 1) as the natural protocyanin and moves the same distance to the anode on electrophoresis. An excess of the iron(II) salt (>1/6 equiv) afforded a differently colored pigment,[14] which was also obtained by mixing **1**, **2**, and Fe^{II} ions. Reconstruction without **2** gave another blue pigment.[15] Reconstruction using iron(III) alum resulted in the same product. Therefore, all of the four components were required and sufficient for protocyanin, and no macromolecular components were involved. The ESR spectrum (X-band, 77 K) of protocyanin reconstructed using iron(II) ions displays a signal at $g = 4.26$ indicative of iron(III) ions in the high-spin state ($S = 5/2$) in a rhombic environment;[16] this finding was reconfirmed by Mössbauer spectroscopy.

The pure reconstructed protocyanin was dissociated in 10% trifluoroacetic acid (TFA) in D_2O, and its ^1H NMR spectrum was recorded. The ratio of **1** to **2** in protocyanin was determined to be 1:1, and this result was also confirmed by HPLC. Metal ions were analyzed by atomic absorption and ICP analysis.[17] The ratio of iron(III) to magnesium ions was 1:1, and the ratio of the iron(III) ions to **1** was between 1:6 and 1:8 from quantitative HPLC analysis. We succeeded in measuring the exact molecular weight of protocyanin by using electrospray ionization mass spectrometry (ESI-MS) in the negative-ion mode, which had proved very efficient for commelinin.[18] The molecular ion was observed at m/z 8508 after deconvolution (Fig. 2), and a series of peaks was observed every 22 mass units between m/z 8500 and 8600, which suggests that the carboxyl groups in protocyanin bind Na^+ ions. Therefore, the exact composition of protocyanin is established to be $[Sucy_6Mafl_6Fe^{3+}Mg^{2+}]$ ($C_{366}H_{384}O_{228}FeMg$, $M_r = 8511$). Protocyanin is a metal-complexed anthocyanin. Six molecules each of **1** and **2**, an iron(III) ion, and a magnesium ion self-assemble into a stoichiometric supramolecule. The gross structure should be similar to that of commelinin.

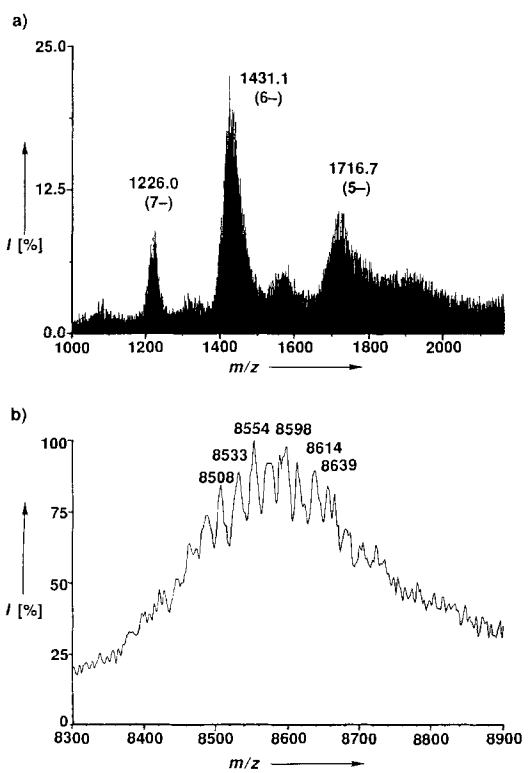

Fig. 2. a) ESI mass spectrum of protocyanin (1 mg protocyanin in 50 μL of H_2O/EtOH (1:1)); API-III PE Sciex triple-quadrupole mass spectrometer in the negative-ion mode; the potential of the interface sprayer was maintained at −105 V at a flow rate of 3 μL min^{-1}. The numbers in parentheses refer to the charge. b) Deconvoluted spectrum of a).

Experimental Procedure

Isolation of protocyanin: Fresh blue petals of *Centaurea cyanus* (3.7 kg) were frozen in liquid N_2 and pulverized, then extracted with water (1.1 L). The blue solution was filtered into EtOH immediately, and the precipitate was collected by centrifugation. The precipitate was dissolved in water then poured into EtOH two more times. The resulting pigment (544 mg) was purified by high-performance GPC (MCI-gel CQS-10, 700 × 7.0 mm, 0.1 M $NaClO_4$), and the blue eluate was passed through a Sephadex G-10 column. The blue fraction was dried in vacuo to afford protocyanin as blue powder (43 mg).—UV/VIS (0.1 M acetate buffer, pH 5.0): λ_{max} (ε) = 676 (4.31×10^4), 569 (1.60×10^5), 315 (8.16×10^4), 262 (1.08×10^5) nm; shoulders at 615 (8.85×10^4), 598 (1.37×10^5), 524 (6.00×10^4) nm. CD: $\lambda(\Delta\varepsilon)$ = 636 (−85.3), 597 (+124.6), 558 (−13.2) nm.

Reconstruction of protocyanin: **1** · TFA (20 mg, 25 μmol) and **2** · TFA (20 mg, 30 μmol) were dissolved in water and neutralized with dilute aqueous ammonia. The solution was concentrated to dryness and redissolved in 250 μL of 0.1 M acetate buffer (pH 5.0). To the purple-colored solution was added 250 μL of 0.5 M $Mg(OAc)_2$ in H_2O (250 μmol) and then 40 μL of 0.1 M Mohr's salt in H_2O (4 μmol). EtOH (1.5 mL) was added to the blue solution, which was allowed to stand at −30 °C for 30 min. After centrifugation the precipitate was collected and purified with Sephadex G-10 column chromatography to give protocyanin (23 mg).—UV/VIS (0.1 M acetate buffer, pH 5.0): λ_{max} (ε) = 676 (4.57×10^4), 569 (1.63×10^5), 315 (9.34×10^4), 262 (1.28×10^5) nm; shoulders at 615 (9.39×10^4), 598 (1.39×10^5), 524 (6.45×10^4) nm. CD: $\lambda(\Delta\varepsilon)$ = 640 (−85.5), 597 (+133.1), 558 (−15.8) nm.

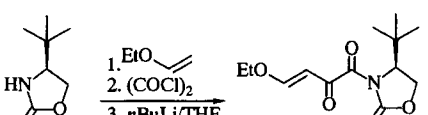
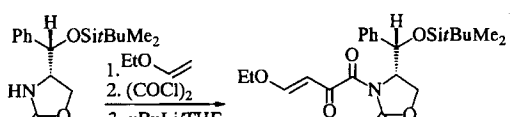
Asymmetric 1,6-Induction in Hetero-Diels–Alder Reactions of Chiral Oxabutadienes for a De Novo Synthesis of Enantiomerically Pure Carbohydrates: Lewis Acid Dependent Reversal of Facial Selectivity**

Lutz F. Tietze,* Christoph Schneider, and Andrea Montenbruck

Dedicated to Professor Christoph Rüchardt on the occasion of his 65th birthday



The inverse electron demand hetero-Diels–Alder reaction[1] of 1-oxa-1,3-butadienes with enol ethers is a powerful method for the synthesis of substituted dihydropyrans, which can be easily converted into carbohydrates in a short reaction sequence.[2] Electron-withdrawing substituents in the diene,[1] Lewis acid catalysis,[1] and high pressure[3] considerably accelerate the Diels–Alder reaction. However, problems with low *endo*/*exo* selectivity have often been encountered in these reactions. In addition, no satisfactory asymmetric induction has been achieved to date.[2h, 4] As a result, it has not been possible so far to exploit this highly convergent synthetic strategy for the de novo synthesis of enantiomerically pure carbohydrates.



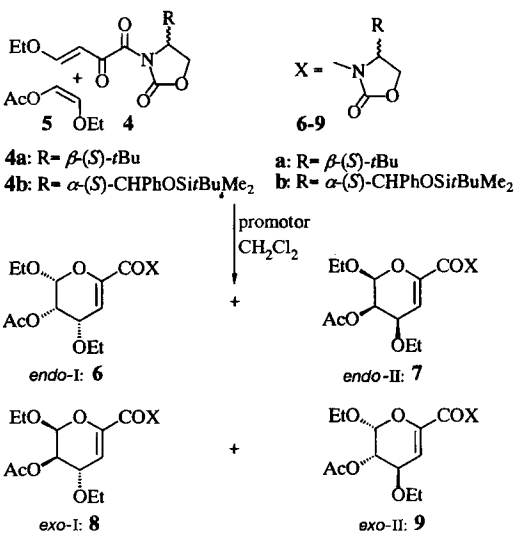
1

We recently reported on the new heterodiene **1**, which undergoes a selective hetero-Diels–Alder reaction promoted by a Lewis acid or trimethylsilyl triflate (TMS-OTf) to give either the *endo* or *exo* product, depending on the activating agent selected.[5]

We now demonstrate that a high degree of asymmetric induction can be achieved in the Diels–Alder reactions of the chiral oxabutadienes **4a** and **4b**, which are readily prepared from ethyl vinyl ether, oxalyl chloride, and the oxazolidinones **2**[6] and **3**, respectively, in a two-step procedure analogous to that used for **1**. The novel compound **3** was prepared in six steps from (1*S*,2*S*)-1-amino-2-phenylpropane-1,3-diol.[7]

2 **4a**

3 **4b**



One equivalent of the heterodiene **4a** or **4b** was allowed to react with 1.5 equivalents of Lewis acid or TMS-OTf and two equivalents of the enol ether **5** acting as dienophile at between −30 and −78 °C in dichloromethane (0.1 M) (Table 1). Separate experiments with Lewis acids and TMS-OTf confirmed that the starting materials are configurationally stable under the reaction conditions.[8]

Table 1. Results of the hetero-Diels–Alder reactions of the chiral heterodienes **4a** and **4b** with enol ether **5** in CH_2Cl_2 to yield cycloadducts **6a–9a** and **6b–9b**, respectively.

Diene	Promoter	T [°C]	Products $\Sigma_{endo}/\Sigma_{exo}$ [a] **6+7/8+9**	*endo*-I/*endo*-II [a] **6/7**	Yield [b] **6/7** [%]
4a	Me_2AlCl	−40	>50:1	60:1	84
4a	TMS-OTf	−78	>50:1	1:7.9	90
4a	$SnCl_4$	−78	1:1	50:1 (12:1) [c]	41 (37) [c]
4b	Me_2AlCl	−30	16:1 [d]	1:3.2 [d]	73
4b	TMS-OTf	−78	30:1 [d]	17:1 [d]	88
4b	TBDMS-OTf [e]	−78	17:1 [d]	23:1 [d]	81

[a] Determined by capillary gas chromatography of the crude product. [b] Isolated yield of **6** and **7**. [c] In parentheses **8a/9a**; the *endo* products **6a/7a** could be separated from the *exo* products **8a/9a** by chromatography on silica gel (ethyl acetate/petroleum ether = 1:2). [d] Determined by ^{13}C NMR spectroscopic analysis of the crude product. [e] TBDMS = Si*t*BuMe$_2$.

It is noteworthy that the Me_2AlCl- and TMS-OTf-initiated reactions of diene **4a** with **5** proceed with complete *endo* selectivity ($\Sigma_{endo}/\Sigma_{exo}$ = **(6a + 7a)/(8a + 9a)** = >50:1) and in high yield. The asymmetric induction obtained in the Me_2AlCl-promoted reaction is remarkable, especially considering the distance of the inducing and the newly formed stereogenic centers (1,6-induction) (*endo*-I/*endo*-II = **6a/7a** = 60:1; 97% *de*).[9] The highly stereoselective formation of three new stereogenic centers was thus achieved in 84% chemical yield. When TMS-OTf was used, a reversal of selectivity was observed. Although the selectivity was not as high (*endo*-I/*endo*-II = **6a/7a** = 1:7.9),[10] the major product was now the *endo*-II isomer **7a**, very minor quantities of which were formed in the reaction of **4a** and **5** in the presence of Me_2AlCl. The facial selectivity in these reactions can thus be controlled simply by varying the promotor whilst leaving the auxiliary unchanged.[11] A reduced *endo*/*exo* selectivity (1:1) was observed for the cycloaddition reaction of

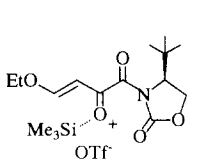
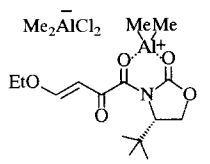
4a with **5** using $SnCl_4$ as promotor; the induced diastereoselectivity, however, was again very high (50:1 and 12:1, respectively; Table 1).[12]

As expected, formation of **7b** was favored in the Me_2AlCl-promoted reaction of the chiral oxabutadiene **4b** with **5**, whereas **6b** predominated with TMS-OTf as reagent. The *endo* selectivities were once again very high, but the induced diastereoselectivity in the reaction with Me_2AlCl was lower than for the oxabutadiene **4a**, whereas that obtained with TMS-OTf was higher. A further slight improvement in the induced diastereoselectivity was observed with TBDMS-OTf (Table 1).



The standard oxazolidinones prepared from L-valine and L-phenylalanine were also examined; they proved to be almost totally unselective in the hetero-Diels–Alder reactions.

In order to establish the absolute configuration of the cycloadducts **6**–**9**, **6a** was stereoselectively hydrogenated in the presence of Pd/C and the carboximide group reduced to a hydroxymethyl group. Acylation gave the crystalline Mosher ester **10**, which was characterized by X-ray structure analysis.[13]



10

In an effort to rationalize the course of the reaction and, in particular, the reversal of selectivity between the reactions promoted by Me_2AlCl and TMS-OTf, we developed the following model.[14] The ^{13}C NMR spectra taken on a solution of the achiral heterodiene **1** and two equivalents of TMS-OTf in dichloromethane at $-78\,^{\circ}C$ clearly show that TMS-OTf binds to the oxygen atom of the oxabutadiene moiety and not to the carbonyl groups of the imide moiety [$\Delta\delta$ (2′-CO) = 0, $\Delta\delta$ (1-CO) = 0, $\Delta\delta$ (2-CO) = 20]. Semiempirical calculations (AM1 and PM3)[15] conducted on the ground state conformations of **1** and its derivative silylated at the 2-CO group reveal that the *anti*-arrangement of the imide carbonyl groups is the more stable conformation in both cases (ΔH_f *anti*/*syn*-**1**: -7.53 and -9.20 kJ mol^{-1}, respectively; *anti*/*syn*-Me_3Si-**1**$^+$: -30.96 and -35.98 kJ mol^{-1} respectively). It is therefore to be expected that heterodiene **4a** favors conformation **A** in the transition state of the reaction promoted by TMS-OTf (non-chelate control).

4a: A

4a: B

In the case of the Diels–Alder reactions of *N*-acryloyloxazolidinones promoted by R_2AlCl, Evans et al.[6a, b] and later Castellino et al.[16] were able to show that a reactive metal-chelate complex is clearly formed in the transition state of the reaction. However, in our case low-temperature ^{13}C NMR measurements on the mixture of **1** and Me_2AlCl failed to yield any information concerning the preferred coordination site of the Lewis acid in the diene. However, by analogy with the earlier studies, we assume that conformation **B** is adopted in the transition state of the Me_2AlCl-promoted reaction (chelate control). The facial differentiations of conformations **A** and **B** are opposite. This means that attack by the enol ether **5** is preferentially directed to opposite faces of the diene, thus inducing the opposite absolute configuration in the dihydropyran unit of the cycloadduct.

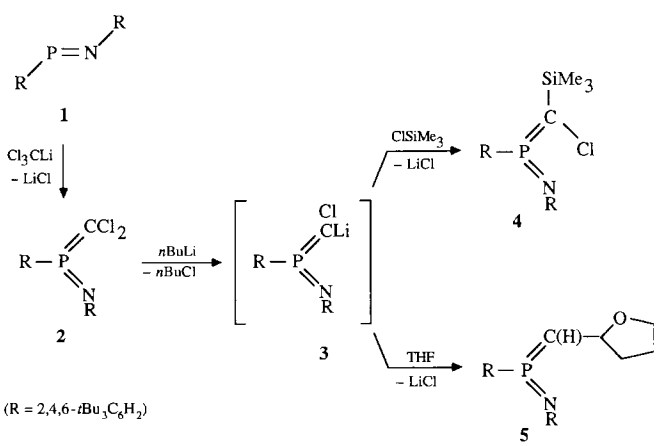
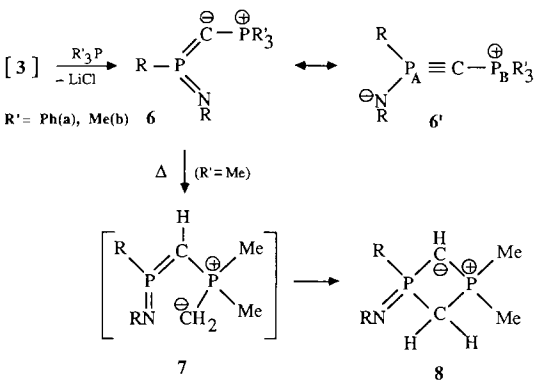
Reactions of an Iminophosphoranylidene Carbenoid**



Wolfgang Schilbach, Volker von der Gönna, Dietrich Gudat, Martin Nieger, and Edgar Niecke*

Vinylidene carbenoids **I** are of major significance as synthetic building blocks in organoelement chemistry.[1] However, little is known about this type of carbenoids with phosphorus as heteroatom (**II**–**IV**). Only for the phosphanylidene carbenoid system **II** have several experimental investigations been made.[2] Here we report on the synthesis and reactivity of an iminophosphoranylidene carbenoid of type **IV**, in which the phosphorus atom is in a trigonal-planar coordination environment.



I **II** **III** **IV**

Bis(aryl)iminophosphane[3] (**1**) reacts easily with trichloromethyllithium to give imino(dichloromethylene)phosphorane (**2**); subsequent reaction with *n*-butyllithium in THF at −105 °C results in a deepening of the color of the solution, suggestive of the formation of a carbenoid **3** as an intermediate (^{31}P NMR: $\delta = 83.2$; $J_{PLi} = 25$ Hz). This intermediate can be trapped as the thermally stable, C-silylated substitution product **4** by the subsequent addition of chlorotrimethylsilane. In the absence of an electrophile, **3** reacts with the solvent to give the imino(tetrahydrofuran-2-yl-methylene)phosphorane **5**, which can formally be regarded as an insertion product of an iminophosphorylidene carbene with tetrahydrofuran. Reaction of intermediate **3** and triphenylphosphane yields the "phosphane-adduct" phosphonio(iminophosphoranylidenemethanide) (**6a**) as a stable final product. The compound **6b** obtainable by the corresponding route with trimethylphosphane is, however, not stable in solution but isomerizes[5] by 1,3-H-shift (**7**), followed by ring closure to give the 1,2-dihydro-1,3-diphosphete **8**. Nitrogen derivatives isoelectronic to **6** and **8** are known, a *N*-silylated bis(imino)phosphorane[6] and a 1,2-dihydro-1,2,3λ^5,4λ^5-diazadiphosphete,[7] respectively.

(R = 2,4,6-*t*Bu$_3$C$_6$H$_2$)

1 **2** **3** **4** **5**

6 **6'** **7** **8**

The compositions of compounds **2**, **4**, **5**, **6a**, and **8** are confirmed by elemental analyses and mass spectra. Their constitution in solution is verified by NMR spectra and, in case of compounds **2** and **4** by X-ray structure analysis.[8] In the low-field region of the NMR spectrum the imino(methylene)-phosphoranes **2**, **4**, and **5** show the characteristic resonances for the P=C structural unit [8b] (δ (^{31}P) = 70.1 (**2**), 86.2 (**4**), 75.0 (**5**); δ (^{13}C) = 99.9 (J_{CP} = 245.9 Hz) (**2**), 93.7 (J_{CP} = 119.8 Hz) (**4**), 93.9 (J_{CP} = 184.0 Hz) (**5**)). In the phosphoranes **6a**, **b** the signal (split by the phosphonio group) for the three-coordinate phosphorus atom is shifted drastically to higher field (δ = 20.4 (**6a**), 36.8 (**6b**)); the observed shift lies in the expected range for bis(imino)phosphoranes.[9c, 10] The position of the signal of the phosphonio group and the value of $^2J_{PP}$ correspond with the values reported for carbodiphosphoranes[11] ($\delta = -12.4$, $^2J_{PP}$ = 111.8 Hz (**6a**); $\delta = -21.0$, $^2J_{PP}$ = 63.3 Hz(**6b**)). The position of the signal for the two-coordinate carbon atom (δ = 90.8 (**6a**)) at low field in comparison to carbodiphosphoranes,[12] and the relatively large coupling constants $^1J_{CP}$ (219.7 Hz [P$_A$], 162.1 Hz [P$_B$] (**6a**)) can be interpreted in terms of participation of the limiting dipolar structure **6'** and are also indicative of the formal relationship with alkylidinephosphoranes,[9d] especially the phosphonium salt [(*i*Pr$_2$N)$_2$P=C=PH(*i*Pr$_2$N)$_2$]$^+$[F$_3$CSO$_3$]$^-$.[13]

The composition and constitution of **8** can be deduced from the high-resolution mass spectrum (molecule peak) and from the results of NMR measurements. The four-membered ring structure is verified by the observation of resonance signals for one CH and one CH$_2$ unit, in which each of the carbon atoms (CH: δ = 41.7, $^1J_{CP}$ = 89, 84 Hz; CH$_2$: δ = 40.3, $^1J_{CP}$ = 60, 51 Hz) shows direct coupling to each of the two phosphorus atoms. In contrast to the NMR data obtained for **6a**, the chemical shifts for the ylidic carbon atom and for the proton bonded to it, as

well as the value of the $^2J_{PP}$ coupling constant (25.8 Hz), are quite typical. The unusual steric strain of the molecule hinders rotation of both aryl ligands, this gives rise to temperature-dependent coalescence phenomena in the ^1H and ^{13}C NMR spectra for the signals of the neighboring and non-neighboring substituents. Below temperatures of $-50\,^\circ C$ the rotation is completely "frozen" on the NMR timescale.

Figure 1 shows the structure of compound **4** in the crystal. As in all bis(ylene)phosphoranes that have been structurally investigated, the central phosphorus atom is in a trigonal-planar

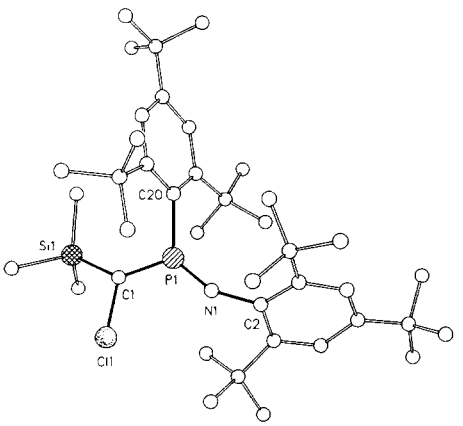

Fig. 1. Structure of imino(methylene)phosphorane **4** in the crystal. Selected bond lengths [pm] and angles [°] (in parentheses the data for **2**): P1=C 167.0(3) [165.5(5)], P1-C_{aryl} 182.5(3) [181.1(6)], P1=N 152.0(2) [152.3(3)], C_{aryl}-P1-C 108.1(1) [107.7(2)], C_{aryl}-P1-N 128.1(1) [128.9(2)], C-P1-N 122.6(1) [121.8(3)].

coordination environment (Σ 358.8°). The atoms Cl1 and Si1 are approximately coplanar with the N1-P1-C1 plane (the angle between the planes P1-C1-Cl1-Si1 and C20-P1-N1-C1 is 15°), whereas the C2 atom is positioned out-of-plane (dihedral angle C20-P1-N1-C2 −58°; C1-P1-N1-C2 137°). In contrast to those in **1**, the two aryl substituents in **4** are *Z*-configurated and orthogonal. The sterically more demanding methylene substituent ($SiMe_3$) occupies the favored *exo* position. The P1–N1 (150.0(2) pm) and P1–C1 distance (167.0(3) pm), and the C1-P1-N1 (122.6(1)°) and C2-N1-P1 angles (145.8(2)°) correspond with typical structural features found for imino(methylene)phosphoranes.[9b] All important parameters for compound **2** deviate only slightly from those of **4**.

Experimental Procedure

2: To a solution of chloroform (1.67 g, 14 mmol) in THF (50 mL) and ether (10 mL), an equimolar amount of nBuLi in n-hexane was added at −105 °C. After the mixture had been stirred for 1 h, **1** (4.3 g, 8 mmol) in ether (20 mL) was added dropwise. After warming the solution to 25 °C the volatile constituents were removed under vacuum and the remaining residue was taken up in hexane, and the insoluble material (LiCl) was separated by filtration. Compound **2** crystallized from the concentrated filtrate at −30 °C. Yield: 45%; m.p. 174–176 °C; MS (70 eV) *m/e* (%): 617 (12) [M^+], 57 (100) [tBu$^+$].

4, **5**: At −105 °C, *n*BuLi (0.63 mL, 1.6 M solution in *n*-hexane) was added to a solution of **2** (620 mg, 1 mmol) in THF (10 mL) and Et_2O (1 mL). After the mixture had been stirred for 1 h, Me_3SiCl (200 mg, 1.8 mmol) was added; the solution was then allowed to warm to room temperature. The volatile constituents were removed under vacuum, the residue was taken up in *n*-hexane, and the LiCl that had formed was filtered off. From the concentrated filtrate **4** crystallized at −30 °C as a pale yellow solid. Yield: 69%; m.p. 175–177 °C. Compound **5** is obtained in a similar fashion in the absence of Me_3SiCl. Yield: 52%. M.p. 148–150 °C.

4: NMR (without aryl) ^1H ($CDCl_3$): $\delta = -0.19$ (s, $SiMe_3$); ^{13}C ($CDCl_3$): $\delta = 93.7$ (d, $J_{CP} = 119.8$ Hz, P=C), −0.8 (d, $^3J_{CP} = 3.6$ Hz, $PCSiC_3$); MS (70 eV) *m/e* (%): 619 (2) [M^+], 57 (100) [tBu$^+$].

5: NMR (without aryl) ^1H ($CDCl_3$): $\delta = 5.26$ (ddt, $^3J_{HP} = 2.0$, $^3J_{HH} = 7.0$, 10.3 Hz, PCC*H*), 3.92 ("q", $^2J_{HH} = {}^3J_{HH} = 7.2$ Hz), 3.57 (dd, $^2J_{HP} = 32.4$, $^3J_{HH} = 10.3$ Hz, PC*H*), 2.21 (m, $OCCH_2$) 1.95 (m, $OCCH_2$); ^{13}C ($CDCl_3$): $\delta = 93.9$ (d, $J_{CP} = 184.0$ Hz, P=C), 75.2 (d, $^2P_{CP} = 1.8$ Hz, PCCO), 67.3, 34.2, 26.5 (s, C_4O framework); MS (70 eV) *m/e* (%): 619 (<1) [M^+], 100 (100) [tBu$^+$].

6, **7**: Reaction of **2** (620 mg, 1 mmol) with *n*BuLi (0.63 mL, 1.6 M in hexane) at −105 °C yielded quantitatively (^{31}P NMR control) the stable phosphorane **6a**, which, following removal of LiCl, was obtained as a pale yellow solid. In contrast, reactions with PMe_3 yielded the unstable intermediate **6b**, which isomerized to **8** during workup of the reaction solution. **6a**: Yield: 83%, m.p. 154 °C (decomp.); MS (70 eV) *m/e* (%): 809 (35) [M^+], 752 (100) [$M^+ - t$Bu$^+$]; **8**: MS (70 eV) *m/e* (%): 623 (0.4) [M^+], 566 (100) [$M^+ - t$Bu$^+$], 608 (3) [$M^+ - CH_3$]

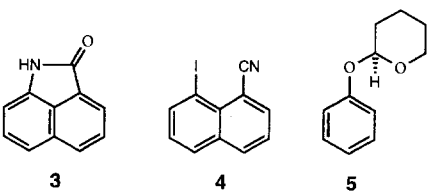
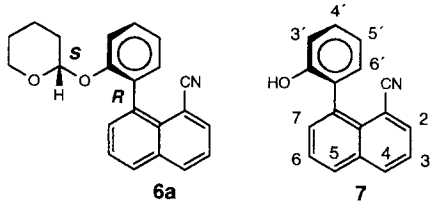
Axially Chiral Amidinium Ions with a Biaryl Skeleton: A New Class of Structure in Host–Guest Chemistry**

Stefan Lehr, Karin Schütz, Markus Bauch, and Michael W. Göbel*

As part of our search for synthetic phosphodiesterases, we reported some time ago[1] on the cationic alcohol **1**. This compound can reversibly coordinate deprotonated phosphoric acid diesters to the amidinium group and react with them in a nucleophilic substitution reaction. On account of its constitutional symmetry, **1** is achiral. We now describe a new stereochemical concept which provides access to novel, axially chiral[2] amidinium ions[3] (**2**, **14**, **15**) starting from the structural type **1** (Fig. 1). These ions are of interest as receptors and catalysts in host–guest chemistry: potential applications include their use as phase transfer catalysts[4] or—in the deprotonated form—as chiral bases.[5]

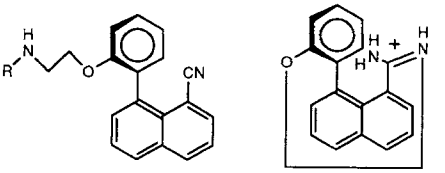


1



2

Fig. 1. Structural formula and molecular model of the axially chiral amidinium ion **2**.



The first step in the synthesis of **2** (Scheme 1) was the conversion of lactam **3** into nitrile **4**. Construction of the biaryl carbon skeleton of **2** was achieved in a palladium-catalyzed coupling of **4** with a copper reagent obtained from the *ortho*-lithiation of *rac*-**5** followed by reaction with copper(I) bromide. The two diastereomeric products formed, *rac*-**6a** ((*S**,*R**) configuration) and *rac*-**6b** ((*S**,*S**) configuration), could be hydrolyzed to give the phenol *rac*-**7** (63% from **4**). The Mitsunobu reaction[6] with *N*-Boc-aminoethanol provided *rac*-**8** (79%). Removal of the protective group gave the aminonitrile *rac*-**9**. Subsequent base-induced cyclization (and protonation) yielded the amidinium ion *rac*-**10** (isolated as the picrate). This ten-membered ring formation was achieved without any problems (78%), even in relatively concentrated solutions. We attribute the surprisingly smooth course of reaction to the fact that seven of the ten atoms in the ring were already fixed in the starting material in a conformation resembling that found in the product.

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft (Go 545/1-1), and the Graduiertenkolleg "Chemische und Biologische Synthese von Wirkstoffen". We thank Prof. Dr. G. Quinkert for his generous support.

In order to control the absolute configuration at the biaryl axis, the phenol *rac*-**7** was linked with a chiral building block, a side chain synthesized from (*S*)-alanine.[7] Again, two diastereomers were formed, the non-racemic products **11a** ((*S*,*R*) isomer) and **11b** ((*S*,*S*) isomer; total yield of 56%; unreacted phenol *rac*-**7** can be recovered). It was possible to separate **11a** and **11b**, which are interconvertible by rotation about the biaryl axis, by HPLC. A barrier to rotation of 98.3 kJ mol^{-1} (30 °C; ethyl acetate/hexane; ratio of isomers at equilibrium 1.2:1) was calculated from the rate of isomerization. The aminonitriles **12a** and **12b**, obtained by cleavage of the Boc groups, can for steric reasons only undergo the base-induced cyclization when the methyl group of the side chain becomes equatorial and the adjacent methine proton axial (see Fig. 1). This arrangement can only be achieved from the isomer **12a** with the (*S*,*R*) configuration. By raising the reaction temperature we were able to increase the rate of isomerization of **12b** to **12a** to such an extent that both compounds cyclized *stereoconvergently* to give the same amidinium picrate **2**[picrate] with the (*S*,*R*,*S*) configuration (61%).[8] The coupling constants observed in the ^{1}H NMR spectrum and the fact that the axial methylene proton shows a strong nuclear Overhauser effect to the phenyl ring provide evidence for the chair-type conformation in the ten-membered ring of **2**. The (formal) C–N double bond in the amidinium ion **2** has an (*E*) configuration. Compound **2** shows similar binding affinities towards dimethylphosphate ions[9] like cation **1**. From the mother liquor of **2**[picrate] the (*Z*) isomer **13**[picrate] could also be isolated. Conversion of **13**[picrate] to **2**[picrate] was observed on application of heat. Selected physical data for **2**, *rac*-**7**, and *rac*-**10** are given in Table 1.

above. The synthesis of derivatives of **2** tailor-made for the areas of molecular recognition and catalysis thus appears to be feasible.

The CD spectrum of the picrate salt of **2** (Fig. 3) provides a first impression of how coordination to the amidinium ion influ-

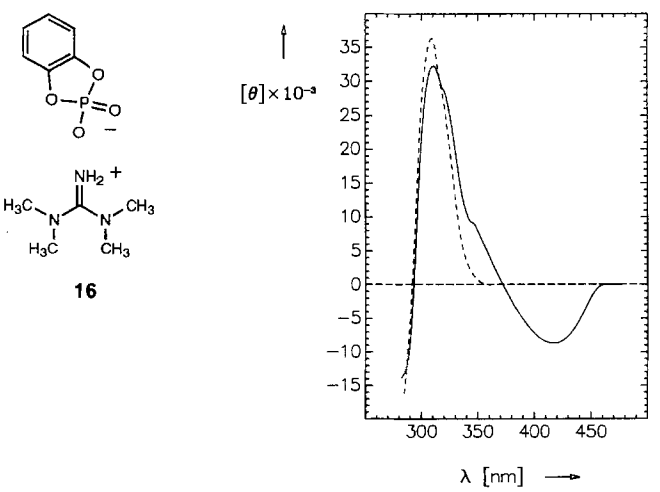

Fig. 3. CD spectrum of **2**[picrate] (50 μM in CH_2Cl_2, room temperature): — without addition, --- with addition of 20 equiv **16**.

The structural principle underlying the stereoconvergent ring closure to **2** is as clear as it is general: It should apply to many types of amino alcohol side chains and should be unaffected by the presence of further substituents, aromatic or heteroaromatic moieties attached to the phenyl ring. Indeed, the synthesis of amidinium ions **14** and **15** (isolated as their picrate salts) (Fig. 2) was achieved following an analogous procedure to that outlined

ences achiral guest molecules. Whereas no signals are recorded beyond 350 nm in the spectrum of the tetraphenylborate salt **2**[BPh_4], a pronounced band is observed at longer wavelengths in the spectrum of **2**[picrate]. The origin of this effect is a chiral disturbance of the picrate chromophore in the host–guest complex. On addition of the salt **16**, whose anion binds to the ami-

dinium ion, the long-wavelength band disappears. Our long-term goal with these investigations is to be able to enantioselectively control not only the spectroscopic behavior but also the reactivity of prochiral guest molecules.

Tunable Supramolecular Structures from a Gluconamide Containing Imidazole

Rudi J. H. Hafkamp, Martinus C. Feiters,* and Roeland J. M. Nolte*

In recent years, the interest in supramolecular structures has grown steadily. Self-assembling systems have been prepared from a variety of building blocks including surfactants,[1] polymers,[2] rodlike,[3] and disklike mesogens,[4] etc.[5] As part of our program aimed at the development of novel chiral matrices for catalytic applications, we report here on the synthesis and self-assembling properties of the *n*-octyl-D-gluconamide derivative **3**, which contains a metal-coordinating imidazole group. Our interest in gluconamides and related carbohydrates was raised by the recent studies of Fuhrhop et al. and others,[6] which indicate that these compounds can form a great variety of nanometer-sized structures in water.

Compound **3** was synthesized as shown in Scheme 1. 1,5-D-Gluconolactone was hydrolyzed and protected at its secondary hydroxyl functions in a one-step procedure.[7] The resulting product was esterified to give methyl-2,4;3,5-dimethylene-D-gluconate which was aminolyzed with octylamine to give the amide **2**. The latter compound was tosylated and subsequently converted into **3** by reaction with imidazole in an autoclave at high pressure (15 Kbar).

Scheme 1. a) Trioxane, H_2O/H^+ (74%); b) H^+/MeOH (61%); c) excess of octylamine (no additional solvent used, 77%); d) TsCl/pyridine, 0 °C (87%); e) imidazole, $CHCl_3$, 15 kbar, 50 °C (66%). R = *n*-C_8H_{17}.

Although the polarity of carbohydrate **2** is decreased due to the methylene bridges, it appears that this compound is soluble in water. However, unlike the unprotected derivative,[6a,f] it does not form well-defined aggregates, as judged by electron microscopy (EM). Apparently, the amide bond and the primary hydroxyl function in **2** cannot form hydrogen bonds leading to stable suprastructures in water. The DSC studies (DSC = differential scanning calorimetry) of an aqueous solution of **2** showed only one transition near 53 °C, which can be assigned to the disappearance of amide hydrogen bonds. No transition was observed upon cooling.[8] The thermogram of *n*-octyl-D-gluconamide shows two transitions upon heating,[9] which are attributed to the breaking of a network of intermolecular hydrogen bonds between the hydroxyl groups (at 61 °C), and between the amide hydrogen bonds (at 70 °C).[9]

Compound **3** is also soluble in water. From a titration experiment in methanol/water (95/5, v/v), it followed that the apparent pK_a value (pK_a^*) of the imidazole group is 6.28.[10] For comparison, methylimidazole and imidazole were also titrated in this medium and were found to have pK_a^* values of 7.03 and 6.96, respectively, which are comparable to their values in water (6.95 for both compounds[11]).

The copper complexation properties of **3** were investigated by UV/VIS controlled titrations. Addition of $Cu(ClO_4)_2$ to a solution of **3** in water led to the appearance of a broad band at approximately $\lambda = 620$ nm. Unfortunately, the complex $[Cu(\mathbf{3})_n]^{2+}$ was not soluble enough in water to carry out an accurate UV/VIS titration. In mixtures of organic solvents such as chloroform/methanol (1/2, v/v), clear solutions were obtained and the complexation behavior of **3** could be determined. During the titrations of **3** with $Cu(ClO_4)_2$, the λ_{max} gradually shifted from 600 to 780 nm when the ratio [Cu]/[**3**] was increased

from 1/4 to 1/1. The titrations revealed that at low copper concentrations a 4/1 ligand-to-copper complex[12] is present, whereas at high copper concentrations other complexes, for example [3]/[Cu] = 3, 2, or 1 prevail. For comparison, titrations were also carried out with the non-amphiphilic imidazole compound **4**[13] and with methylimidazole. In both water and methanol/chloroform mixtures the copper complexation curves of **3**, **4**, and *N*-methylimidazole were very similar.

4

The types of aggregates formed by **3** in water were studied by transmission electron microscopy (TEM) and scanning electron microscopy (SEM). In a NaOAc/HOAc buffer of pH 4.5, protonated **3** self-assembles to yield vesicles (100%) with diameters ranging from 160 to 780 nm (Fig. 1A).[14] In a tris(hydroxymethyl)methylamine (TRIS) buffered solution of pH 8.5 long fibers (Fig. 1B and C) and hollow tubuli are formed exclusively (Fig. 1C). The fibers can have a length/width ratio up to 500 (Fig. 1B, the diameters of these fibers are approximately 100 nm).[15] Freeze fracture experiments showed that these fibers are composed of multilayers (not shown). The hollow tubuli have diameters of approximately 3 μm. In a TRIS buffered solution, (pH 8.5), the 1:4 copper complex of amphiphile **3** forms helices (100%, Fig. 1D).[16] The diameters of these helices are approximately 330 nm; much larger than the ropelike structures formed by *N*-octyl-D-gluconamide (diameter of 27 nm).[6f]

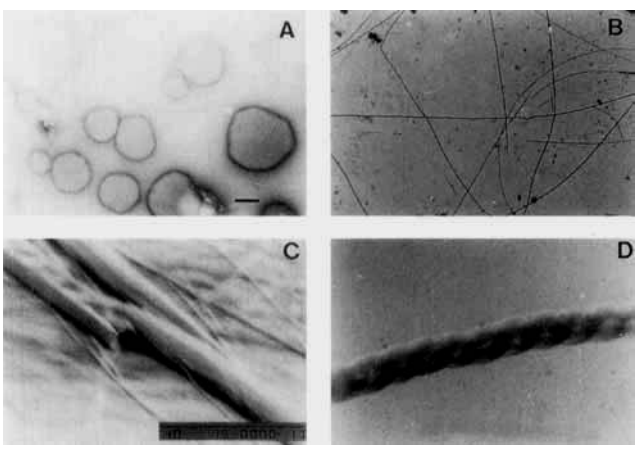

Fig. 1. A: TEM of vesicles of **3** (on a carbon-supported hydrophilic copper grid stained with 2% uranyl acetate; bar is 200 nm). B: TEM of fibers from **3** (Formvar-supported copper gid, stained with 2% uranyl acetate; bar is 5 μm). C: SEM of hollow tubuli and thin fibers of **3** (copper grid from 1B was sputtered with gold; bar is 10 μm). D: TEM of helices from the copper complex of **3** (Formvar-supported copper grid without staining, bar is 200 nm).

In conclusion, we have shown that gluconamide **3** can self assemble to give interesting supramolecular structures which can be tuned by changing the pH or by adding metal ions.

[13] This compound was synthesized from imidazole and ethylene carbonate (1,3-dioxolan-2-one) as described, cf. H. Komura, T. Yoshino, Y. Ishido, *Carbohydr. Res.* **1973**, *31*, 151–156.

[14] Vesicle samples for EM were prepared by cooling a hot clear solution of **3** in NaOAc/HOAc buffer of pH 4.5 to room temperature. Subsequently, a drop of this solution was placed on a hydrophilic formvar supported grid. The vesicles were stained with uranyl acetate (2%).

[15] For the electron micrographs a hydrophobic Formvar supported grid was used.

[16] To a hot clear solution of **3** (0.5% m/v) in TRIS buffer, 0.25 equiv of $Cu(ClO_4)_2$ was added. The turbid mixture was cooled rapidly to room temperature and allowed to stand for 30 min. No additional staining was used.

Iodine Chains in $(Me_4Sb)_3I_8$ and Discrete Triiodide Ions in Me_4AsI_3**

Ulrich Behrens, Hans Joachim Breunig,* Michael Denker, and Klaus Heinz Ebert

Polyiodides have an extensive structural chemistry,[1] and compounds with discrete iodine chains are of particular interest because of possible unusual electric behavior.[2] Iodine and iodide chains are not rare. They occur, for example, in the iodine–starch complex and in related compounds,[3] in organic metals,[4] in complexes with column structures,[5] and also in saltlike triiodides such as Bu_4NI_3.[6] The iodine chains in these compounds frequently consist of triiodide or iodide ions and iodine molecules.[7] Ordered iodine chains such as in $[Cd(NH_3)_4I_6]$ are unusual;[1] in this complex the iodine chains are not discrete, but are linked three-dimensionally by strong coordinative bonds to

the metal centers. We report here on ordered iodine chains in the golden shining crystals of the compound $(Me_4Sb)_3I_8$ (**1**) and on the structure of the triiodide Me_4AsI_3 **2** with discrete I_3 ions.

The stibonium polyiodide **1** crystallizes from solutions of Me_4SbI and iodine. The compound is air-stable and decomposes first on warming at 136 °C. We were not able to obtain the blue-black triiodide Me_4SbI_3 described by Wittig et al.[8] The results of the X-ray crystal structure analysis[15] show that linear chains of iodine atoms with only slightly alternating distances of 328.3(2) and 329.9(2) pm (Fig. 1 and 2) are present in

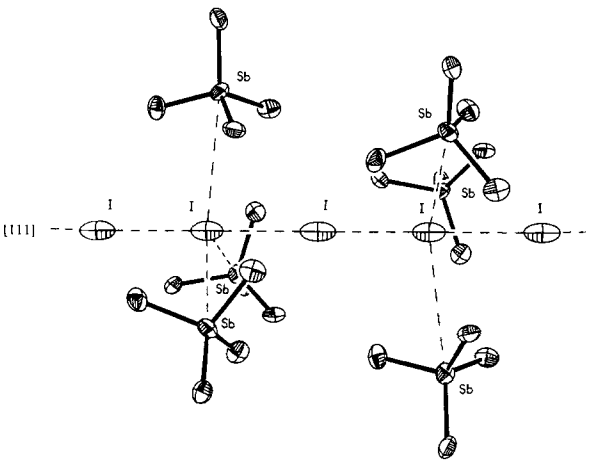

Fig. 1. Environment of a iodine chain in the crystal of **1**.

the crystal of **1**. Rotating crystal and Weissenberg measurements show no indication of a disorder or a superstructure. The iodine chains are arranged parallel to the space-diagonals of the cubic unit cell. Through antimony–iodine contact distances of 412.9(2) pm, every second iodine atom in the chain is surrounded by three stibonium ions, whose tetrahedral faces are each capped by iodine atoms. Similar contact distances and angles as in **1** are also found in the structures of Me_4SbI[9, 10] and $(Me_4Sb)_2(MeSbI_4)$.[10] The distances indicate that a weak interaction exists between every second iodine atom in the chain and the stibonium ions. The unexpected stoichiometry of **1** can be informally explained with coordination numbers.[11] The structure and properties of **1** correspond quite precisely to the criteria presented by Tebbe[1] for compounds with linear triiodide chains, which are constructed from iodine molecules and iodide ions. According to the multicenter bonding model[12, 13] alternating distances in the chain are to be expected, and the chain must be protected from the breakdown into discrete I_3 ions by additional stabilization. This stabilization is apparent from the antimony–iodine interactions. The iodine–iodine distances in the chain are greater than the values normally found in discrete triiodide ions. They correspond to the average distances in the chainlike associated triiodides. The shortest I–I distances between the chains are 570.1(2) pm.

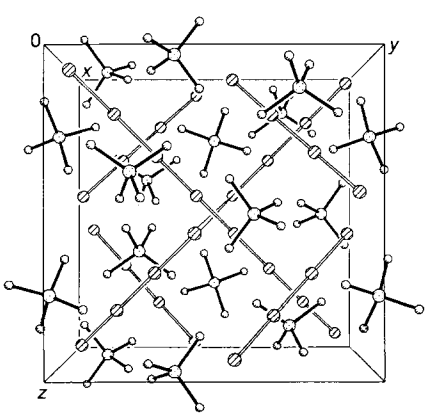

Fig. 2. Unit cell of the crystal structure of **1**. Sb: dotted spheres, I: hatched spheres, C: shaded spheres; projection along [100].

Reaction of Me_4AsI with iodine leads to the known triiodide Me_4AsI_3 **2** in the form of red-violet crystals.[14] The structure of **2** contains stacks of tetrahedral tetramethylarsonium ions, which are surrounded by discrete triiodide ions (Fig. 3). These anions are all linear; however, they differ with respect to their distances. Besides two forms of triiodide ions with equally long iodine–iodine distances of 293.0(2) or 292.3(1) pm, anions also occur with iodine–iodine distances of different lengths (294.8(2) and 290.8(2) pm). Contacts exist between the I_3 anions with iodine–iodine distances ranging from 392 to 405 pm.

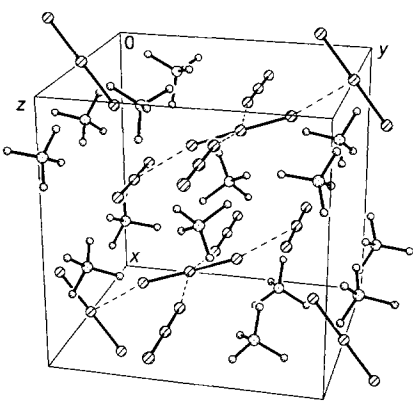

Fig. 3. Unit cell of the crystal structure of **2**. As: dotted spheres, I: hatched spheres, C: shaded spheres.

Solutions of **1** and **2** in ethanol cannot be differentiated by UV/VIS spectroscopy; the typical absorptions of triiodides (290, 357 nm) are observed for both compounds. This shows that the iodine chain in **1** is only stable in the crystal and that it breaks on dissolution with the formation of triiodide and iodide ions. A comparison of the diffuse reflectance spectra clearly shows the visually evident difference in color of **1** and **2**. In the case of **1**, a plateau with little structure covers the entire measurement range up to above 800 nm. In contrast, the absorption of **2** ends in the longwave region with a maximum at 570 nm and a sloping edge, which reaches up to about 750 nm. These results confirm the visual impression and agree qualitatively with the idea that the electron delocalization in **1** is much more extensive than that in **2**. The Raman spectra also confirm the structural differences in the solid state. The spectrum of **1** shows no lines in the expected region for the signals of iodine or of polyiodides. In contrast, for **2**, an intense signal appears at 108 cm^{-1} for the symmetric valence stretch of the triiodide ions with equally long iodine–iodine distances. A separate signal for the asymmetric valence stretch of the I_3 ions with different distances was not observed. Conductivity investigations[16] on crystals of **1** show a significant increase in the conductivity between −50 and 130 °C. The compound is a semiconductor with a band gap of 0.2 eV. At room temperature the conductivity is about 3×10^{-6} $S\,cm^{-1}$.[17]

Experimental Procedure

1: I_2 (0.2 g, 0.79 mmol) was added to Me_4SbI (0.25 g, 0.81 mmol). The mixture was vigorously stirred and dissolved in warm EtOH (5 mL). After slow cooling of the mixture to −25 °C, golden shining compact crystals of **1** were formed in the course

of 5 d. Yield: 0.32 g (67%). M.p. 136 °C (decomp); correct complete elemental analysis.

2: As for the synthesis of **1**, Me_4AsI (0.46 g, 1.76 mmol) and I_2 (0.45 g, 1.77 mmol) were mixed, dissolved in EtOH (25 mL) and cooled to −25 °C. Red-violet needle-like crystals of **2** were obtained after 2 d. Yield: 0.84 g (90%). M.p. 134 °C (ref. [14] 133 °C).

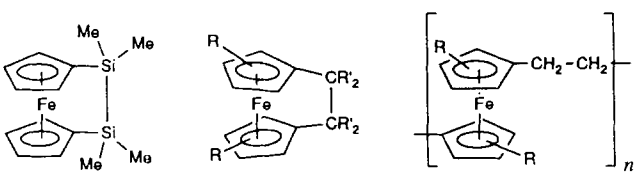
Synthesis and Ring-Opening Polymerization of Highly Strained, Ring-Tilted [2]Ruthenocenophanes**

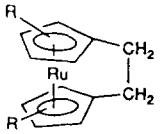
James M. Nelson, Alan J. Lough, and Ian Manners*



Dedicated to the memory of Dr. Derek S. Manners

Well-defined, soluble polymers which contain transition elements in the main chain are rare but are of considerable interest because of their unusual physical properties and potential applications.[1] As part of our work to develop new routes to these materials we have previously shown that strained [1]ferrocenophanes containing a single silicon (**1**), germanium, or phosphorus atom in the bridge undergo thermal ring-opening polymerization (ROP) to yield high molecular weight polymers (such as **2**).[2–6] These [1]ferrocenophane monomers possess strained structures in which the cyclopentadienyl ligands are significantly tilted by about 18–27° with respect to one another.[3, 7, 8]

1 **2**



[2]Ferrocenophanes such as **3** with two silicon atoms in the bridge are substantially less strained (tilt angle = 4.19(2)°) than their [1]silaferrocenophane counterparts and appear to be resistant to ROP.[3] However, [2]ferrocenophanes which possess the smaller carbon atoms in the bridge such as **4** (R = H, R′ = Me) are significantly more strained (tilt angles = 21–23°)[9] and have been found to undergo ROP at elevated temperatures to yield poly(ferrocenylethylene)s **5**.[10]

3 **4** **5**

In this paper we report on our attempts to extend this ROP approach to allow the introduction of an alternative transition metal, ruthenium, into the polymer main chain. Since a ruthenium atom is larger than an iron atom, the incorporation of the former into an [*n*]metallocenophane structure would be expected to increase the ring-tilt and provide access to more highly strained species which should be excellent candidates for ROP. In addition, based on the different electrochemical properties of ruthenocene compared to those of ferrocene, access to polymers with modified electrical characteristics would be anticipated.[11]

In contrast to [*n*]ferrocenophanes, few [*n*]ruthenocenophanes have been prepared; none with fewer than three bridging atoms.[12] We found that the reaction of $Li_2[C_5H_4CH_2]_2$ with the Ru^{II} complex *cis*-$[RuCl_2(dmso)_4]$ (dmso = dimethylsulfoxide) yielded **6a**, the first example of a [2]ruthenocenophane, as a pale yellow microcrystalline material after purification by high vacuum sublimation. The identity of this species was verified by NMR spectroscopy, mass spectrometry, and an X-ray diffraction study of a single crystal obtained from hexane at −20 °C. The molecular structure of **6a** is shown in Figure 1.[13, 14]

6

a: R = H
b: R = Me

The most dramatic structural feature of **6a** is the tilt of the virtually planar cyclopentadienyl ligands with respect to one another.

[**] This work was supported by the Petroleum Research Fund (PRF), administered by the American Chemical Society, and the Natural Science and Engineering Research Council of Canada (NSERC). We also thank Johnson Matthey PLC for a generous loan of ruthenium salts.

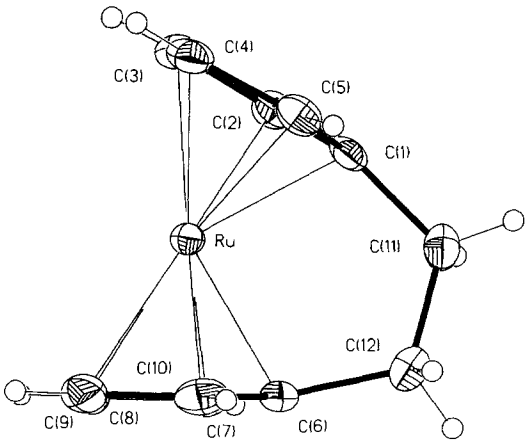

Fig. 1. Molecular structure of **6a**. Selected distances [Å] and angles [°] (estimated standard deviations in parentheses): Ru-C1 2.076(4), Ru-C2 2.156(5), Ru-C3 2.231(5), Ru-C4 2.207(6), Ru-C5 2.143(5), Ru-C6 2.073(6), Ru-C7 2.136(6), Ru-C8 2.206(6), Ru-C9 2.218(5), Ru-C10 2.146(5), C1-C11 1.523(9), C6-C12 1.525(8), C11-C12 1.549(9); C2-C1-C11 124.4(6), C5-C1-C11 127.4(5), C1-C11-C12 114.3(5), C11-C12-C6 111.5(6), C7-C6-C12 130.2(6), C10-C6-C12 121.7(6).

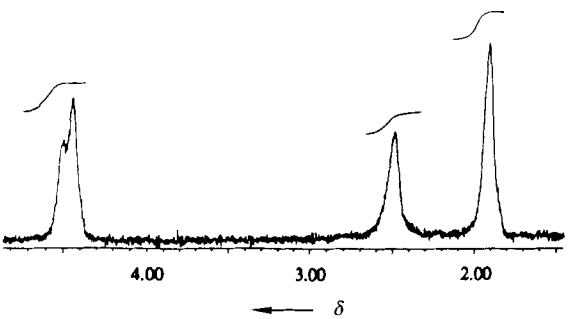
The tilt angle of 29.6(5)° is the largest found for any neutral [*n*]metallocenophane reported to date and is significantly greater than that present in **4** (R = H, R′ = Me) (23°). The degree of tilting in **6a** can also be appreciated by considering the $Cp_{centroid}$-Ru-$Cp_{centroid}$ angle which is 159.3(2)° compared to 180° in ruthenocene, 163.4(6)° for **4** (R = H, R′ = Me), and 164.74(8)° in **1**. Further evidence for a strained structure for **6a** is found in the average angle of 13.4(5)° between the planes of the cyclopentadienyl ligands and the C1–C11 and C6–C12 bonds. These angles reflect the significant distortion from planarity for C1 and C6 which is greater than that in **4** (R = H, R′ = Me), where the corresponding average angle is 9.6(11)°.[3, 9] Another interesting feature of **6a** is the angle between the C11–C12 bond and the plane defined by the centroids of the cyclopentadienyl ring and the ruthenium atom. The value is 21.3(5)°, which is also larger than the value of 18.4(1)° in **4** (R = H, R′ = Me), and indicates that the bridge in **6a** is slightly more twisted. This leads to a slight staggering of the cyclopentadienyl ligands in **6a** with an angle of 8.4(5)° between the projection of the Ru–C bonds on the mean plane of the cyclopentadienyl ligands.

The highly strained molecular framework of **6a** suggested that this species should be a good candidate for ROP. Indeed, when heated in the melt at 220 °C, samples of this material become viscous and then immobile; however, the resulting poly(ruthenocenylethylene) **7a** was insoluble in organic solvents. The soluble, white fibrous poly(ruthenocenylethylene) **7b** was prepared by the ROP of an isomeric mixture of dimethylated [2]ruthenocenophanes of the type **6b**.[15] Compound **6b** was prepared in a similar manner to **6a** using $Li_2[C_5H_3MeCH_2]_2$. A similar strategy was used previously for the preparation of soluble poly(ferrocenylethylene)s.[10] Polymer **7b** was characterized by ^{1}H NMR, ^{13}C NMR, and by gel permeation chromatography (GPC).[16] The ^{1}H NMR spectrum of **7b** (in C_6D_6), for example, showed resonances for the η-C_5H_3 ligand, CH_2 bridge, and Me protons in the correct integration ratio at about $\delta = 4.5$, 2.5, and 1.9, respectively (Fig. 2). The GPC showed that the polymer possessed a bimodal molecular weight distribution with a weight average molecular weight (M_w) of 43100 and a number average molecular weight (M_n) of 12000 for the first fraction, and $M_w = 12700$ and $M_n = 4400$ for the second.



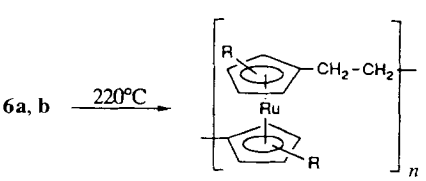


Fig. 2. ^{1}H NMR spectrum of polymer **7b**.

Detailed comparative studies of the physical properties of poly(ruthenocenylethylene)s and poly(ferrocenylethylene)s are in progress. However, even at this stage it is clear that **7b** is noticeably more resistant to oxidation than its iron analogue. This has been confirmed in preliminary cyclic voltammetry experiments which have shown that the poly(ruthenocenylethylene) **7b** possesses an irreversible oxidation wave at 0.60 V,[17] whereas the poly(ferrocenylethylene) **5** (R = Me) undergoes a reversible oxidation at −0.27 V under the same conditions.[5]

7

a : R = H
b : R = Me

Experimental Procedure

6a: A solution of $Li_2[C_5H_4CH_2]_2$ [18] (0.95 g, 5.6 mmol) in THF (40 mL) was added dropwise to a suspension of *cis*-$[RuCl_2(dmso)_4]$ [19] (2.70 g, 5.6 mmol) in the same solvent (40 mL) at −78 °C. The reaction mixture was stirred at this temperature for 3 h and was then allowed to warm to room temperature over a 12 h period. Following solvent removal in vacuo, yellow microcrystalline **6a** was isolated and purified by vacuum sublimation (80 °C, 10 mmHg). Yield 0.60 g (42%); m.p. 130 °C [13].

6b: This species was prepared similarly from $Li_2[C_5H_3MeCH_2]_2$ [10] and was purified by vacuum distillation (bp 80 °C, 10 mmHg) and was isolated as a yellow oil in 42% yield [15].

7b: Compound **6b** (0.61 g, 2.1 mmol) was placed in a sealed, evacuated Pyrex tube and heated at approximately 220 °C for 4 h. The solution gradually became more viscous and eventually immobile. Extraction with THF and precipitation into methanol produced the white fibrous poly(ruthenocenylethylene) **7b**. Yield 0.61 g (100%) [16].

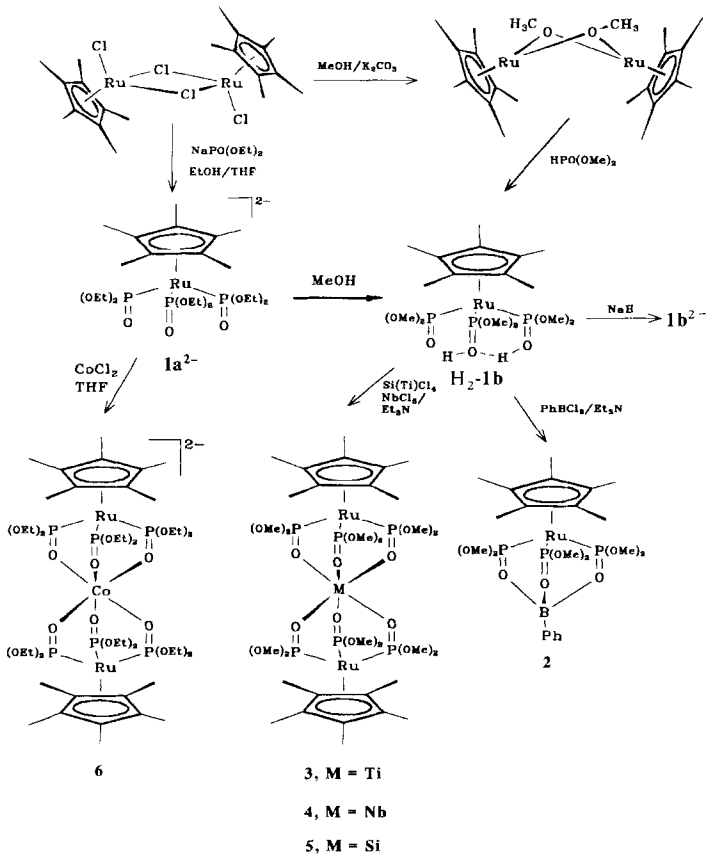
A New Oxygen Tripod Ligand and its First Complexes with p- and d-Block Elements**

Ulrich Kölle,* Thomas Rüther, Nathalie Le Narvor, Ulli Englert, and Wolfgang Kläui

The syntheses and complexation properties of the oxygen tripod ligands [(Cp, Cp*)(Co, Rh){PO(OR)$_2$}$_3$]$^-$ (Tp^l; Cp* = C_5Me_5) have been extensively investigated in recent years.[1, 2] Octahedral [(Tp^l)$_2$M] as well as half-sandwich complexes [Tp^{l}ML$_n$] are formed with s- and d-block metals, in which L may also be an organometallic ligand. To date, only Co^{III}, Rh^{III}, and Ir^{III} have been used as the "carrier" metal for the complexing tris(phosphono) unit, thereby generating a monoanionic ligand. Since the charge influences considerably the complexation properties of the hard tripod ligand, it was desirable to increase this through the use of an M^{II} carrier metal. For this purpose, Ru (possibly Os) is the only feasible option.



The syntheses of the sodium salts of the new dianionic tripod ligands Tp^{II}, [Cp*Ru^{II}{PO(OR)$_2$}$_3$]$^{2-}$ **1a**$^{2-}$ (R = Et) and **1b**$^{2-}$ (R = Me), proceeds according to Scheme 1, starting from [{Cp*RuCl$_2$}$_2$], by reaction with NaPO(OEt)$_2$ in EtOH/THF, where the alcohol serves as a reducing agent. After the reaction mixture had been evaporated to dryness, the salt Na_2-**1a** was extracted from the solid residue with pentane. The methoxy derivative H_2-**1b** is accessible by treatment of H_2-**1a** with methanol, or from the methoxide [{Cp*Ru(OMe)}$_2$] by reaction in ether with the phosphonic ester HPO(OMe)$_2$. H_2-**1b** is deprotonated by NaH. With alkoxides, an equilibrium mixture of H_2-**1b** and **1b**$^{2-}$ is generated, placing the second pK_a value for H_2-**1b** around that of MeOH.

In the ^{1}H NMR spectrum of H_2-**1b** in C_6D_6, the Cp* signal appears as a quartet (δ = 1.87, $^4J_{H,P}$ = 2.2 Hz) due to coupling to phosphorus; the POMe groups give rise to a virtual quartet (δ = 3.55, vq, $^3J_{H,P}$ = 11.2 Hz). For Na_2-**1a** in benzene, however, only three broad signals are observed for the three sorts of protons, suggesting an asymmetric mode of coordination, probably in the form of an oligomer.[3] In CD_3OD, the spectrum is similar to that of the acid, since the signals are averaged due to partial protonation of the salt. For H_2-**1b** in CD_3OD, the OCH_3 groups are exchanged slowly by OCD_3. If [{Cp*Ru(OMe)}$_2$] is treated with the phosphonic ester HPO(OEt)$_2$ or HPO(O^{i}Pr)$_2$, with workup in the presence of MeOH, only H_2-**1b** is obtained. This facile nucleophilic replacement of the OR groups is responsible for the spontaneous decomposition of H_2-**1** in solvents like water and acetonitrile. Such displacement reactions, however, provide easy access to complexes with different OR groups. In contrast, Tp^l compounds are quite stable.

Metals, nonmetals, and fragments L$_n$M may, under appropriate conditions, be complexed to Tp^{II} (Scheme 1). With $PhBCl_2$, the monotripod phenylborate complex **2** is obtained, by reaction with **1**$^{2-}$, or H_2-**1** (H_2-**1b** as an example) in the presence of Et_3N. Reaction of **1b**$^{2-}$ or H_2-**1b** with $TiCl_4$, $NbCl_5$, or $SiCl_4$

Scheme 1. Synthesis and complexation properties of the oxygen tripod ligands **1a** and **1b**.

affords the neutral bistripod complexes **3**, **4**, and **5**, respectively. The ^{1}H NMR spectrum of the paramagnetic Nb^{IV} complex **4** reveals signals which, though broadened, show virtually no paramagnetic shifting, as was found previously for paramagnetic Tp^I complexes. The Si complex **5** is characterized by a septet in the ^{29}Si NMR spectrum at $\delta = 200$ (sixfold oxygen-coordinated Si[4]), with a ^{29}Si-^{31}P coupling of 14 Hz. Reaction of Na_2-**1a** with $CoCl_2$ in THF yielded the bistripod complex of Co^{II}(**6**), as the disodium salt. Unlike the free ligand, these pentane-soluble complexes are reasonably stable to both air and moisture.

A somewhat different type of complex was formed by the direct reaction of $[\{Cp^*RuCl_2\}_2]$ with $NaOP(OEt)_2$ in THF, in the absence of a reducing agent. Partial reduction of Ru^{III} to Ru^{II}, presumably by the phosphonate, gave rise to the deep green, paramagnetic, mixed-valence monotripod complex **7**.

7

The nonmetal complexes **2** and **5** were characterized by X-ray structure analyses.[5] With **2** (Fig. 1a), bond lengths and angles are comparable to those of the analogous Tp^I complex [CpCo-$\{P(OEt)_2O\}_3BF]BF_4$.[8] In order to obtain the structure of the particularly intriguing Si compound **5**, the more crystallizable Cp^ derivative **5'** (Cp^ = η^5-C_5Me_4Et) was prepared. This crystallizes in the space group $R\bar{3}m$; the threefold rotation axis runs through Ru, Si, and the center of the disordered Cp^ rings (Fig. 1b). Disorder of the $\{P(O)(OR)_2\}_3$ belt occurs in both structures, as is observed for many such tripod complexes.[9] The Si atom is coordinated octahedrally by oxygen; a slight compression along the threefold axis (O-Si-O angles 87.1(1) and 92.9(1)°) is observed. The Si–O distance of 1.787(2) Å is comparable to those in $[Si(1,2\text{-}(O)_2C_6H_4)_3]^{2-}$ (1.813(1), 1.775(3), 1.765(3) Å)[10] and $[HN\{(CH_2)_3O\text{-}2,3\text{-}(O)_2C_6H_3\}_3Si]Cl$,[11] the only structurally characterized examples for sixfold oxygen-coordinated molecular silicon, and are also similar to those found in hexacoordinate silicates (1.73–1.80 Å).[12] This is attributed to the variable "bite" of the tripod ligand. For both **2** and **5**, the P-Ru-P and O-P-Ru angles are, characteristically, very similar, and the variation in central atom radii is compensated solely by the different O-M-O' bond angles.

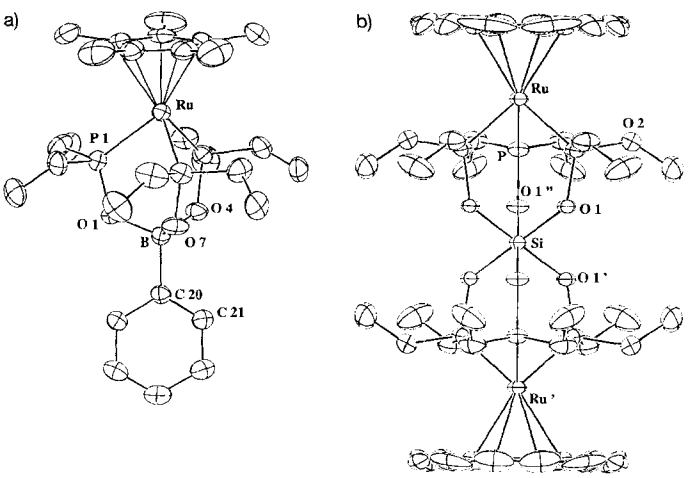

Fig. 1. a) ORTEP representation of $[Cp^*Ru\{P(O)(OMe)_2\}_3BPh]$ **2**. Selected distances [Å] and angles [°]: B-O1 1.484(6), B-O4 1.515(4), B-O7 1.456(4), B-C20 1.609(6), P-O(mean) 1.563(4), Ru-P(mean) 2.237(2), Ru-C_{Cp} 2.236–2.250(5); P-Ru-P(mean) 85.03(6), O-B-O(mean) 109.9(4). b) ORTEP representation of $[\{Cp^*\text{-}Ru[P(O)(OMe)_2]_3\}_2Si]$ **5'**. Selected distances [Å] and angles [°]: Si-O1 1.787(2), O1-P 1.545(4), O2-P 1.594(4), Ru-P 2.221(1); P-Ru-P' 86.06(5), P-O-Si 132.6(1), O1-Si-O1'' 92.9(1), O1-Si-O1' 87.6(1).

Ligand-field properties of Tp^{II} were determined from the Co^{II} complex **6**. Two absorption bands in the visible region of the spectrum, at 18620 and 17150 cm^{-1} were assigned to the transitions $^4A_{2g} \leftarrow {}^4T_{1g}$ and $^4T_{2g} \leftarrow {}^4T_{1g}$. From the ratio of wavenumbers[13] the values $Dq = 902\ cm^{-1}$ and $B = 784\ cm^{-1}$ are obtained. Thus the ligand-field strength of Tp^{II} is somewhat greater than that of Tp^I ($Dq = 825\ cm^{-1}$[12]), though less than that of water ($Dq = 981\ cm^{-1}$). The nephelauxetic parameter B is found to be significantly smaller than that of Tp^I and that of water ($B(Tp^I) = 820$, $B(H_2O) = 872\ cm^{-1}$), implying stronger covalent bonding in Tp^{II}.

The resistance of the central metal towards electrochemical redox changes is surprising. Whereas for the complexes $[(Tp^I)_2M]$, electrode reactions were measured for many d-block metals,[14, 15] the Ti^{IV} center in **3** was inert towards reduction, as was the Co^{II} center in **6** towards oxidation. The cyclic voltammogram of the Si complex **5**[15, 16] shows two almost reversible oxidation peaks ($E^1 = 0.64$, $E^2 = 0.89$ V, $\Delta E_p = 85$ mV) of equal height due to the Ru^{II}/Ru^{III} valence change of the carrier metals. This relative ease of oxidation of the ligand contrasts with the extremely redox-stable Tp^I compounds[14] and limits accordingly observable redox changes of the central metal. The potential difference of 0.25 V between the two oxidation potentials of **5** is too large for a purely electrostatic interaction over a distance of 7.74 Å (Ru ··· Ru distance in **5**) and points to some electronic coupling of the Ru atoms across the P-O-Si-O-P bridge.

The redox behavior of the Ru complex **7** provides information about the relative influence of Tp^I and Tp^{II} on the redox

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0909-0992 $ 10.00+.25/0 Angew. Chem. Int. Ed. Engl. 1994, 33, No. 9

potential of the central metal. An irreversible reduction at $E_p = -1.1$ V shows unequivocally, by comparison with **5**, that the oxidation state III must be assigned to the O-coordinated Ru. The reduction of the latter to Ru^{II}, under analogous conditions, is 0.7 V more negative than the Ru^{II}/Ru^{III} potential for the directly comparable complex [Tp^tRuCp^*].[15] Hence, relative to the Tp^t complexes, the redox potentials in $Tp^{II}M$ complexes again show a cathodic shift.

Thus, with the Tp^{II} system, a new, highly versatile oxygen tripod ligand has become available, whose doubly negative charge makes it particularly suitable for the stabilization of sixfold oxygen-coordinated elements in high oxidation states, and which may prove valuable as a model system for oxoanions of certain elements.

Experimental Procedure

H_2-**1b**: $HP(O)(OMe)_2$ (0.65 mL, 7.08 mmol) was syringed into a solution of $[\{Cp^*Ru(OMe)\}_2]$ (630 mg, 1.18 mmol) in Et_2O (60 mL). After stirring for 4 h at room temperature, the solvent was removed under vacuum, and the dark brown oily residue stirred with pentane (50 mL) and then filtered. Impurities and excess $HP(O)(OMe)_2$ were frozen out at -78 °C, and the pentane solution decanted. After evaporation to dryness, the product was obtained as a light brown powder (1.13 g, 85%).

2: To a solution of H_2-**1** (360 mg, 0.636 mmol) in pentane (20 mL) cooled to -78 °C was added by syringe $PhBCl_2$ (152 mg, 0.13 mL, 0.954 mmol) and Et_3N (206 mg, 0.26 mL, 1.908 mmol). A precipitate of Et_3NHCl formed immediately. After stirring for 2 h at room temperature, the mixture was filtered through cotton wool and washed several times with pentane. After evaporation of the combined pentane extracts to dryness, the product was obtained as a pale yellow powder.

3–**5**: To a solution of H_2-**1b** (623 mg, 1.1 mmol) in Et_2O (25 mL) cooled to -78 °C was added $SiCl_4$, $TiCl_4$, or $NbCl_5$ (1.1 mmol), respectively, and Et_3N (0.61 mL, 4.4 mmol). A precipitate of Et_3NHCl formed immediately. After stirring for 2 h at room temperature, the precipitated salt was filtered off, the solvent removed, the residue washed three times with methanol (10 mL) and dried.

6: To a solution of Na_2-**1a** (200 mg, 0.289 mmol) in THF (15 mL) was added a solution of $CoCl_2$ (19 mg, 0.15 mmol) in THF (4 mL), which caused an immediate decolorization of the blue solution. After 4 h at room temperature, the solvent was removed under vacuum and the solid residue extracted with pentane. The pentane solution was then concentrated to dryness under high vacuum to leave a gray-blue powder.

Na_2-**1a**: 90% Yield; ^{1}H NMR (C_6D_6): $\delta = 2.01$ (br. s; Cp*), 1.31 (br. t; $POCH_2CH_3$), 4.0 (br.; $POCH_2CH_3$); ^{31}P NMR: $\delta = 134.7$ (br. s); IR (KBr): $\tilde{\nu} = 1049$ (P-O-C), 1080 (P=O), 532 cm^{-1} (δ-P=O).

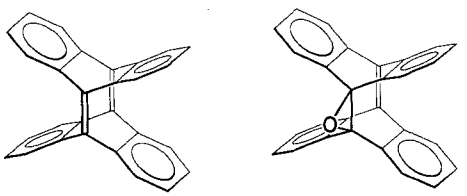
Transannular Addition of Methyllithium to 5,12:6,11-Di[1,2]benzenodibenzo[*a*,*e*]cyclooctene and Its 5,6-Epoxy Derivative



Rainer Herges,* Helfried Neumann, and Frank Hampel

Alkyllithium compounds add stereoselectively to activated double bonds in a *syn* fashion;[1–3] the corresponding ring opening of epoxides proceeds with inversion at the attacked

carbon atom, presumably assisted by coordination of Li^+ to the epoxy oxygen atom.[4, 5] In the case of 5,12:6,11-di[1,2]benzenodibenzo[*a*,*e*]cyclooctene (tetradehydrodianthracene, **1**)[6] and the epoxide **2**, direct attack is only possible from the side away from the molecular framework. The backside is shielded by a double bond which is exactly coplanar with the plane of the π orbitals (or Walsh orbitals). Thus the addition of methyllithium to **1** and **2** leads to products that would not arise from the normal reaction course[7, 8] and provides indications as to the mechanism of the reaction.

1 **2**

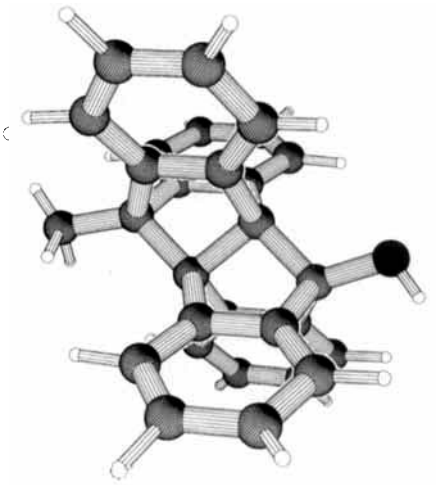
Methyllithium reacts with **1** at room temperature in THF, and after aqueous workup two products **3** and **4** are obtained. The initially formed lithium compound, formed by *syn* addition to one of the double bonds, is apparently able to react to give either **3**,[9] by formation of a transannular bond, or **4** through electrocyclic ring opening[10] (Scheme 1). The addition of lithium-complexing ligands such as [12]crown-4 and [2.2.2]cryptand favors the formation of the ring-opened product **4**.

	1	**3**	**4**
ether		53%	2%
+		32%	6%
+		30%	8%

Scheme 1. Addition of methyllithium to **1**.

Epoxide **2**, obtained by oxidation of **1** with *meta*-chloroperbenzoic acid (*m*-CPBA), also reacts with methyllithium at $-5\,^{\circ}C$ to give compound **5**, likewise a product arising from transannular addition. The structure of **5** was confirmed by X-ray crystal structure analysis (Fig. 1).[11] In addition, compound **6** was also formed, which is formally derived from a *syn* addition to the double bond. In this case too, the ratio of products could be shifted away from the transannular compound through addition of lithium complexing ligands (Scheme 2).

The unusual transannular additions of organolithium compounds[7, 8, 12] to **1** and **2** are favored by the exact coplanarity



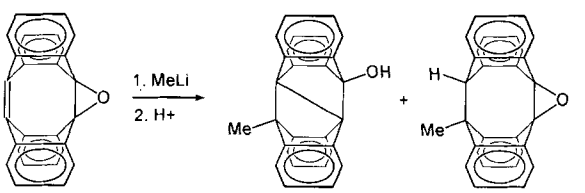


Fig. 1. Crystal structure of **5**.

and the closeness of the π orbitals of the double bonds and the π orbital of the double bond and the Walsh orbitals in the epoxide, respectively. Two possibilities exist which can explain

	2	**5**	**6**
ether		45%	6%
+		18%	22%
+		12%	25%

Scheme 2. Addition of methyllithium to **2**.

the alteration in the relative yields of the two products caused by the presence of complexing agents. These are represented in a simplified form as **A** and **B** in Scheme 3.

In the case of addition to **1**, both anionic benzylic positions (one of which is forming in the product, the other which is disappearing in the starting material) could be bridged by lithium in the transition state (transition state **A**). This coordinative stabilization of the transition state would be lost through

A **B** **C**

Scheme 3. Simplified mechanisms of the transannular addition to **1** and **2**.

increasing complexation of the lithium. The yield of **3** is reduced in favor of ring opening leading to **4**. An alternative explanation is that complexation of the double bond by a second equivalent of lithium facilitates the transannular mode of reaction (transition state **B**). Since the reaction was carried out in ether, alternative **A** is more likely.[13]

It is probable that the transannular ring opening of the epoxide proceeds by a mechanism involving transition state **C**, with the participation of a second equivalent of lithium. The "normal" ring opening of the epoxides, which is assisted by coordination of lithium at the epoxide oxygen atom, has been supported by theoretical calculations by von Schleyer et al.,[4] by isolation of the corresponding intermediate by Harder et al.,[5] and by kinetic measurements in several solvents with and without addition of complexing ligands by Chang et al.[14]

Experimental Procedure

2: **1** (1 g, 2.84 mmol) was dissolved in dichloromethane (1.2 L) and cooled to 0 °C. A solution of *m*-CPBA (581 mg, 3.37 mmol) in dichloromethane (70 mL) was then slowly added dropwise. The yellow solution was filtered through a chromatography column filled with silica gel and the eluate distilled off. The residue was suspended in dichloromethane/hexane (1:2), filtered, and washed. A white or pale yellow solid was obtained. Yield 900 mg, (86%); decomp. 276 °C, R_f value: (0.28 in dichloromethane/hexane 1:2). Purity: 80% product. According to GC and ^{13}C NMR the product contained about 10% diepoxide and 10% starting material **1**. These impurities were very difficult to separate by crystallization or chromatography; however, the impurities did not disturb the further reactions, since they were either unreactive or were converted to known products. - IR (KBr): $\tilde{\nu}[cm^{-1}] = 3060$ (w, C–H, arom.), 1450 (m, C=C, arom.), 910, (s, C–O). ^1H NMR (400 MHz, $CDCl_3$): $\delta = 7.1$ (m, 8H), 6.9 (m, 8H); ^{13}C NMR (100.6 MHz, $CDCl_3$): $\delta = 151.3$ (C=C), 146.7 (C, arom.), 139.3 (C,arom.), 126.3 (CH, arom.), 126.0 (CH, arom.), 124.1 (CH, arom.), 122.7 (CH, arom.), 72.1 (CO). MS (70 eV): *m/z* (%): 368 (100, M^+), 339 (35), 337 (27).

3 and **4**: **1** (200 mg, 0.57 mmol) was dissolved in dry THF (220 mL) under an atmosphere of nitrogen. Methyllithium (1.3 mL, 0.75 mmol, 0.58 M solution) was added at room temperature with a syringe to the stirred solution. After 15 min the solution, which had turned brown, was treated with a saturated $NaHCO_3$ solution (ca. 3 mL). This led to an almost complete loss of color. The THF was removed under vacuum to obtain a yellow solid, which was shaken with dichloromethane and water. After concentration of the organic solvent the residue was chromatographed (dichloromethane/hexane, 1:2). Two products could be isolated. **3**: Yield 111 mg (53%), white crystalline solid, decomp.: 232–236 °C, R_f value: 0.3 (dichloromethane/hexane, 1:2). - IR (KBr): $\tilde{\nu}[cm^{-1}] = 3080$ (m, C–H, arom.), 2990 (m, C–H, aliph.), 1430, 1460 (m, C=C, arom.). ^1H NMR (400 MHz, $CDCl_3$): $\delta = 7.21$ (d, $^3J = 6.71$ Hz, 2H; *o*-H, arom.), 7.08 (d, $^3J = 7.3$ Hz, 2H; *o*-H, arom.), 7.02 (d, $^3J = 7.02$ Hz, 2H; *o*-H, arom.), 6.92 (d, $^3J = 7.07$ Hz, 2H; *o*-H, arom.), 6.82 (t, $J = 7.32$ Hz, 4H; *m*-H, arom.), 6.75 (m, $J = 6.10$ Hz, 4.58 Hz, 4H; *m*-H, arom.), 4.95 (s, 1H; CH), 2.36 (s, 3H; CH_3); ^{13}C NMR (100.6 MHz, $CDCl_3$, DEPT): $\delta = 155.6$ (C, arom.), 153.5 (C arom.), 147.2 (C, arom.), 147.2 (C, arom.), 125.4 (CH, arom.), 125.2 (CH, arom.), 127.7 (CH, arom.), 124.7 (CH, arom.), 122.6 (CH, arom.), 122.3 (CH, arom.), 122.1 (CH, arom.), 119.7 (CH, arom.), 97.7 (C, aliph.), 95.0 (C, aliph.), 55.4 (CCH_3), 50.2 (CH, aliph.), 12.0 (CH_3). MS (70 eV): *m/z* (%): 368 (100, M^+), 354 (11), 353 (41), 352 (26), 351 (21), 350 (20).

4: Yield: 4.6 mg (2%), m.p. 238 °C, R_f value: 0.5 (dichloromethane/hexane, 1:2). - ^1H NMR (400 MHz, $CDCl_3$): $\delta = 8.67$ (s, 1H; 9'-H), 8.45 (d, $^3J = 9.16$ Hz, 2H; 1',8'-H), 8.14 (d, $^3J = 8.85$ Hz, 2H; 1,8-H), 7.47 (m, 4H; 2,2',7,7'-H), 7.10 (m, 4H, 4,4',6,6'-H), 3.30 (s, 1H; CH_3); ^{13}C NMR (100.6 MHz, $CDCl_3$): $\delta = 133.7$ (C), 131.8 (C), 131.3 (C), 130.9 (C), 131.5 (10-C), 130.0 (10'-C), 128.5 (9'-CH), 127.6 (9-C), 128.4 (CH), 127.0 (CH), 125.8 (CH), 125.7 (CH), 125.3 (CH), 125.2 (CH), 125.2 (CH), 124.9 (CH), 14.3 (CH_3).

5 and **6**: **2** (200 mg, 0.54 mmol) was dissolved in THF (60 mL) under nitrogen, and cooled to −5 °C with ice/salt. Methyllithium (1.24 mL, 0.72 mmol, 0.58 M solution) was added and the solution slowly darkened. The solution was stirred for a further 15 min to complete the reaction and was then quenched with a saturated $NaHCO_3$ solution until the brown solution became almost colorless. The solvent was removed under vacuum and the residue shaken with dichloromethane and water. The dichloromethane was removed under vacuum and the residue was chromatographed over silica (dichloromethane/hexane, 5:1). Two products could thus be isolated and characterized. **5**: Yield: 90 mg (43%), decomp. 280 °C, white crystalline solid, R_f value: 0.17 (dichloromethane/hexane, 5:1). - IR (KBr): $\tilde{\nu}[cm^{-1}] = 3450$ (b, O–H), 3080 (m, C–H, arom.), 2990 (m, C–H aliph.), 1430, 1460 (m, C=C, arom.). ^1H NMR (400 MHz, $CDCl_3$): $\delta = 7.26$ (d, $^3J = 7.3$ Hz, 2H; *o*-CH), 7.10 (d, $^3J = 6.4$ Hz, *o*-CH), 7.09 (d, $^3J = 4.5$ Hz, 2H; *o*-CH), 6.98 (d, $^3J = 7.3$ Hz, 2H; *o*-CH), 6.78 (m, 8H; *m*-CH), 3.17 (s, 1H; OH), 2.35 (s, 3H; CH_3); ^{13}C NMR (100.6 MHz, $CDCl_3$, DEPT): $\delta = 155.5$ (C, arom.), 153.0 (C, arom.), 146.5 (C, arom.), 145.4 (C, arom.), 125.8 (CH, arom.), 125.4 (CH, arom.), 125.0 (CH, arom.), 124.9 (CH, arom.), 122.7 (CH, arom.), 122.4 (CH, arom.), 119.8 (CH, arom.), 119.0 (CH, arom.), 96.5 (C, aliph.), 93.1 (C, aliph.), 88.4 (C–OH), 55.4 ($C-CH_3$), 12.1 (CH_3). MS (70 eV): *m/z* (%): 384 (100, M^+).

6: The fast running fractions with $R_f > 0.2$ were collected and dried under vacuum. The residue was chromatographed again with dichloromethane/hexane (1:2). The white solid obtained in this way still contained small amounts of diepoxide and **3**. Yield: 12 mg (6%), white crystalline solid, R_f value: 0.27 (dichloromethane/hexane, 1:2). - IR (KBr): $\tilde{\nu}[cm^{-1}] = 3060$ (m, C–H, arom.), 2990, 2940 (m, C–H, aliph.), 1430, 1460 (m, C=C, arom.). ^1H NMR (400 MHz, $CDCl_3$): $\delta = 7.11$ (m, 8H; CH arom.), 6.91 (m, 8H; CH arom.), 4.04 (s, 1H; CH aliph.), 2.15 (s, 3H; CH_3); ^{13}C NMR (100.6 MHz, $CDCl_3$, DEPT): $\delta = 146.3$ (C arom.), 144.0 (C arom.), 140.0 (C arom.), 139.4 (C arom.), 126.7 (CH arom.), 126.3 (CH arom.), 126.0 (CH arom.), 126.0 (CH arom.), 125.7 (CH arom.), 123.6 (CH arom.), 122.2 (CH arom.), 121.9 (CH arom.), 72.5 (CO), 71.7 (CO), 63.0 (CH, aliph.), 52.1 (CCH_3), 25.0 (CH_3). MS (70 eV): *m/z* (%): 384 (100, M^+), 368 (64), 353 (18), 352 (12), 351 (8), 350 (8), 176 (42).

The reactions with complexing agents were carried out analogously; in each case two equivalents of either crown ether or cryptand (with respect to **1** and **2**) were added to the solution before the addition of methyllithium.

C_{70} Is More Stable than C_{60}: Experimental Determination of the Heat of Formation of C_{70}**

Hans-Dieter Beckhaus, Sergej Verevkin, Christoph Rüchardt,* François Diederich,* Carlo Thilgen, Hans-Ulrich ter Meer, Holger Mohn, and Wolfgang Müller

Before the chemistry of C_{60} took the current fast development,[1] the first two years following the landmark discovery of how to prepare macroscopic amounts of fullerenes by Krätschmer and Huffman[2] were characterized mainly by investigations of the physical properties of fullerenes.[3] However, it took more than a year for a fundamental thermodynamic quantity of C_{60}—its heat of combustion –to be determined.[4–7] This time lapse was due to problems with both the production of highly pure C_{60} in sufficient quantities and the accuracy of calorimetric measurements on small samples—a procedure which is still far from trivial.

Both problems are reflected by large differences among the values published in the literature,[4–7] a fact that led us to reinvestigate the thermodynamic data in question. Reliable values for the heat of formation of the carbon spheres are of great importance not only because they provide an experimental criterion for the quality of theoretical calculations on fullerene structures, but also because they give an insight into the stability of C_{60} and of highly strained molecules in general.

Even though C_{60}, the most strained molecule known so far, is much higher in energy than the other two carbon allotropes graphite and diamond, it exhibits a surprising kinetic stability. With regard to the higher fullerenes C_n ($n \geq 70$), the question arises whether the incorporation of additional six-membered rings into a carbon network with a fixed number (12) of five-membered rings leads to a continuous increase in stability, asymptotically approaching the value of graphite.[8] The determination of the heat of combustion of C_{70} reported here provides the second experimental point on a curve describing the thermodynamic stability of fullerenes as a function of their size.

A redetermination of the heats of formation of C_{60} and C_{70} was made possible because sufficiently large quantities of highly pure samples were provided by Hoechst AG. In order to exclude any contamination by solvent molecules,"gold grade C_{60}" and "gold grade C_{70}" were both subjected to fractional sublimation using helium as the transport gas at 600 and 650 °C/atmospheric pressure, respectively, and stored under argon prior to use. Taking into account the differences in molar extinction coefficients of the two fullerenes, the composition of the C_{60} sample (99.82% C_{60} and 0.18% $C_{60}O$) and the C_{70} sample (0.44% C_{60} and 99.56% C_{70}) was determined by analytical HPLC (Fig. 1).

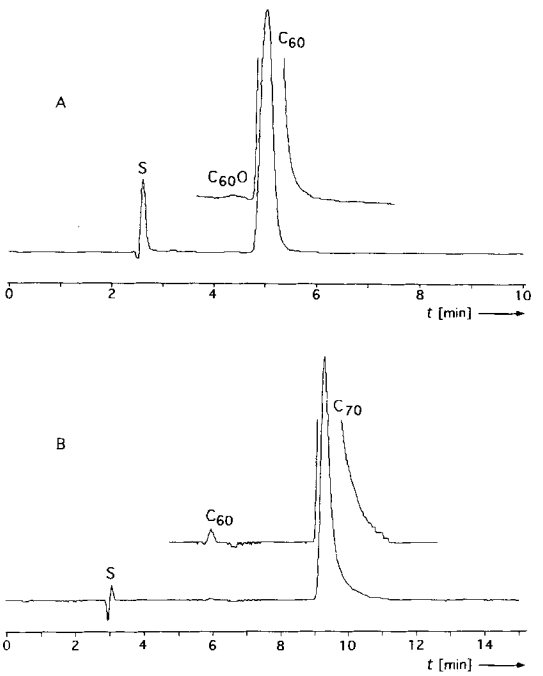

Fig. 1. HPL chromatograms of the sublimed C_{60} (A) and C_{70} (B) samples. Conditions: Vydac 201TP54 C18 reversed-phase column, 250 × 4.6 mm, acetonitrile/toluene 1/1, 1 mL min^{-1}, λ = 310 nm, S = solvent peak.

Chromatographic analysis with pure hexane as the eluent and detection at 254 nm showed that the sublimed samples did not contain any toluene from previous operations.

The heat of combustion measurements were performed in an isoperibolic aneroid microcalorimeter[9] and in a water-stirred isoperibolic macrocalorimeter[10] (Table 1). Adsorbed argon was removed from the pelletized samples by heating at 350 °C/10^{-4} bar for 2 h. The pellets were cooled under vacuum and exposed to N_2 just prior to weighing. Preliminary experiments were used to test the sample stability against oxygen, because under the experimental conditions preceding ignition (30 bar O_2, H_2O saturation), a reversible weight increase was observed. In fact, 1–2 moles of O_2 per mole of fullerene were absorbed in 0.5 h, and after 1 d of exposure, even more than 5 moles of O_2 had been absorbed per mole of C_{70}. According to analytical HPLC, however, this did not lead to a chemical transformation of the fullerenes; in particular, the amount of fullerene oxide did not increase. A control experiment using a C_{60} sample sealed in polyethylene under N_2 gave a $\Delta H_c^{\ominus}$ value within the experimental error of the measurements performed on nonsealed samples (Table 1, Experiment 2). Whereas the combustion of C_{60} was complete in each experiment, that of C_{70}, in some cases, led to the formation of traces of soot which were weighed and taken into account in the calculation.[11] The reduction to the isothermal bomb process with c_p = 0.71 (C_{60}) and 0.79 J K^{-1}g^{-1} (C_{70})

$\pm$s [b]	$\pm$17	$\pm$12
$\Delta H_f^{\ominus}$(c,C) per C atom	38.78 [c]	36.50 [d]
	$\pm$0.28	$\pm$0.17

[a] Standard deviation of the mean value. [b] Standard deviations of all measurements considered. [c] 9.269 $\pm$ 0.068 kcal mol^{-1}. [d] 8.724 $\pm$ 0.041 kcal mol^{-1}.

Since the deviations in the enthalpy of combustion caused by the impurities of 0.44% C_{60} in the C_{70} sample and 0.18% $C_{60}O$ [13] in the C_{60} sample are no larger than 0.7 kJ mol^{-1} and -0.5 kJ mol^{-1}, respectively, no corrections were made to the measured values.

The experimental results were compared to calculated standard gas phase heats of formation $\Delta H_f^{\ominus}$ (g, C) obtained with the use of the enthalpy of sublimation $\Delta H_{sub}^{\ominus}$ determined for C_{60} [14] (Table 3). Iterative MM3[16] force-field-MO calculations on both fullerenes afforded the $\Delta H_f^{\ominus}$(g, C) values given in Table 3.

The redetermination of the heat of formation $\Delta H_f^{\ominus}$ (g, C) per C atom of C_{60} using sublimed samples led to a value (10.16 kcal mol^{-1}) that is slightly higher than the one determined previously by us (10.01 kcal mol^{-1}). Both numbers are in

Table 3. Heat of formation $\Delta H_f^{\ominus}$ (g, C) per C atom of C_{60} and C_{70} [kcal mol^{-1}] [a].

[a] With $\Delta H_{sub}^{\ominus}$(c) (298 K, per C atom) = 0.93 kcal mol^{-1} [14]. ΔH_f(298 K, per C atom, graphite) = 0, ΔH_f(298 K, per C atom, diamond) = 0.4 kcal mol^{-1} (1 kcal = 4.184 kJ). [b] From the spread of the heat of combustion of the crystalline samples. [c] Hartree–Fock/double zeta plus polarization (HF/DZP) energy of MNDO structures relative to C_{60}.

relatively good agreement with the results of Kiyobayashi et al.[6] and Diogo et al.[7]. The present experimental data are best reproduced by MM3 and the incremental method, both affording values which are only slightly lower and higher, respectively. In contrast, the numbers derived from MNDO (MNDO = Modified Neglect of Differential Overlap) calculations are much higher. The difference in energy between the two fullerenes is reasonably well reflected by relative ab initio energies (LYP/DZP)(LYP = Lee–Yang–Parr/double zeta plus polarization)[19] obtained from calculations based on MNDO-approximated structures.

The $\Delta H_f^{\ominus}$ (g, C) value determined for C_{70} (9.65 kcal mol^{-1}) is lower by 0.51 kcal mol^{-1} compared to that of buckminsterfullerene. This can be interpreted as the first confirmation of the prediction stating that fullerenes show a decrease in $\Delta H_f^{\ominus}$(g, C) with increasing number of C atoms. It should not be forgotten, however, that higher fullerenes C_n with $n \geq 78$ can exist in a

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0909-0997 $ 10.00+.25/0

number of isomeric forms which may differ considerably in strain and hence in energy content.[20]

Among the theoretical methods used for the calculation of the heat of formation of C_{70}, MM3 and the incremental method give the best results (both providing values which are slightly lower than the experimental ones), whereas the number resulting from MNDO calculations is much higher. From these comparisons it can be concluded that the first two methods mentioned are best suited for the prediction of the heat of formation of higher fullerenes. Due to the lack of availability of these carbon spheres in quantities large enough for experimental measurements, knowledge about their stability will have to rely on theoretical calculations for some time.

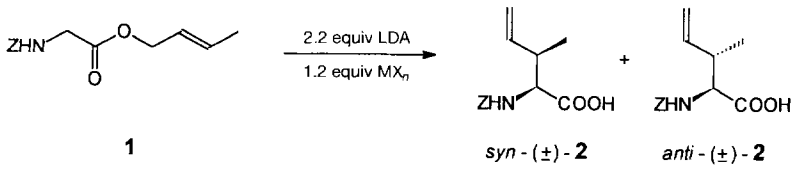
Synthesis of Unsaturated Amino Acids by [3,3]-Sigmatropic Rearrangement of Chelate-Bridged Glycine Ester Enolates**

Uli Kazmaier*

Dedicated to Professor Ulrich Schmidt on the occasion of his 70th birthday



The synthesis of γ,δ-unsaturated amino acids has received a great deal of attention for a long time. Some of these amino acids, which also occur in nature,[1] exhibit pronounced antibiotic activity, and can be used as enzyme inhibitors.[2] These unsaturated amino acids are also very interesting from a synthetic point of view, since more complex compounds can be readily constructed by functionalization of the double bond.[3] In 1975, Steglich et al. described the thermal Claisen rearrangement of *N*-benzoyl-α-amino acid allyl esters on treatment with a dehydrating agent, in which an 5-allyloxazole intermediate was formed.[4] Since the [3,3]-sigmatropic rearrangement takes place highly diastereoselectively, this elegant method found numerous applications, in particular, for the synthesis of α-alkylated amino acids.[5] In 1982, Bartlett et al. investigated the Ireland–Claisen rearrangement[6] of N-acylated glycine allyl esters in detail.[7] In the rearrangement of crotyl esters they found in some cases very high diastereoselectivities. The observed *syn* selectivity can be explained by a preferred formation of the (*E*)-lithium enolate and its chelation by the anionic acylamide group in the α-position. Similar chelate-bridged enolates have also been postulated in sigmatropic rearrangements of α-alkoxy-substituted allyl esters.[8] An interesting asymmetric boron enolate variant of the Claisen rearrangement was described by Corey and Lee in 1991.[9]

Whereas the hitherto described procedures for the Claisen rearrangement of ester enolates of α-amino acid allyl esters make use of the Ireland silylketene acetal variant,[10] we now describe a rearrangement of chelate-bridged metal enolates. Attempts to rearrange lithiated glycine allyl esters directly did not succeed, since the desired rearrangement only occurs at temperatures at which the lithium enolates decompose. However, by adding salts of chelatable metals to the lithium enolate solution, stable glycine enolate chelates are obtained which do not decompose when warmed to room temperature.[11] In fact, copper(II) and nickel(II) salts form very stable chelates with amino acids and peptides;[12] however, the corresponding enolates are not reactive enough to undergo rearrangement.

We have now investigated the influence of a number of metal salts on the yield and diastereoselectivity of the rearrangement of the *N*-benzyloxycarbonylglycine crotyl ester **1** to **2**, and have obtained interesting results (Table 1). The best results with respect to both yield and selectivity were obtained on addition of zinc(II) chloride. If a solution of the zinc enolate (No. 1) is heated from −78 °C to room temperature, the rearrangement begins at −20 °C and is complete after 3 h at room temperature. In the reaction with tetraisopropylorthotitanate (No. 5), the crotyl ester is partially split or even transesterified by titanium(IV) catalysis[13] resulting in lower yields. Otherwise, the metal enolates are clearly superior to silylketene acetals (Nos. 6 and 7) both in terms of their reactivity and selectivity.

1 *syn*-(±)-**2** *anti*-(±)-**2**

Table 1. Rearrangement of *N*-benzyloxycarbonylglycine crotyl ester **1** after deprotonation with lithium diisopropylamide (LDA) in the presence of metal salts MX_n.

No.	MX_n	Yield [%]	Diastereomer ratio *syn*-(±)-**2**:*anti*-(±)-**2**
1	$ZnCl_2$	90	95:5
2	$CoCl_2$	78	93:7
3	$MgCl_2$	85	91:9
4	$Al(OiPr)_3$	75	90:10
5	$Ti(OiPr)_4$	50	90:10
6	Me_2SiCl_2	50	85:15
7	Me_3SiCl	60	83:17

The driving force for the accelerated rearrangement of the metal enolates is probably the transformation of the high-energy ester enolate into a chelate-bridged, stabilized carboxylate. If the acidic amide proton in crotyl ester **1** is replaced by a methyl group, this chelation does not occur, and no rearrangement is observed. The same applies for *N*-phthaloyl-protected glycine allyl esters.

In view of the good results obtained with zinc(II) chloride, we used this system to carry out a detailed study into the influence of the substituents at the double bond, the olefin configuration, and the N-protective group on the yield and diastereoselectivity of the rearrangement (Scheme 1), since the selectivity for

3 (±)-**4A** (±)-**4B**

Scheme 1. $ZnCl_2$-catalyzed rearrangements of glycine ester enolates. X, R^1-R^4 see Table 2.

silylketene acetals is significantly dependent on these parameters.[7] The results are summarized in Table 2.

All substituted allyl esters **3** show high diastereoselectivities (93–96% *ds*), in which the formation of *syn* products from *trans*-substituted allyl esters (Nos. 3–5, 7–9) and *anti* products from *cis*-substituted allyl esters (Nos. 6, 10) are favored.

This can be explained in terms of a chairlike transition state like that generally postulated for [3,3]-sigmatropic rearrangements of acyclic systems.[14] The particularly high diastereoselectivity in the rearrangement of the silyloxy-substituted *cis*-allyl ester (No. 11) is remarkable. This could be caused by a stabilization of the chairlike transition state by coordination of the silyloxy substituent to the chelated zinc. This is being investigated further. Further investigations into the reasons for this remarkably high diastereoselectivity are in progress.

Table 2. Influence of the substitution, the olefin configuration, and the N-protective group of **3** on the yield and diastereoselectivity of the rearrangement to **4**.

Experimental Procedure

2: Butyllithium (20 mL, 33 mmol, 1.65 M solution in hexane) was added to a solution of diisopropylamine (5.6 mL, 40 mmol) in dry THF (30 mL) at −20 °C under argon. This was stirred for 20 min, cooled to −78 °C, and a solution of **1** (3.95 g, 15 mmol) in THF (15 mL) was added. After 5 min a solution of zinc chloride (2.32 g, 17 mmol) in THF (20 mL) was then added and slowly allowed to warm to room temperature. The clear pale yellow solution was hydrolyzed with 1 N hydrochloric acid, and the organic solvent was removed on a rotary evaporator. The residue was dissolved in ether and washed with 1 N hydrochloric acid. The ether phase was then extracted twice with 1 N sodium hydroxide. The combined aqueous phases were acidified and extracted twice with ether. After the solution had been dried with Na_2SO_4 and concentrated, 3.55 g (90%) of **2** as a white solid was obtained. Recrystallization from ether/petroleum ether gave 3.08 g (78%) of the pure diastereomer *syn*-(±)-**2**, colorless needles, melting point 81–82 °C.

Synthesis and Structural Characterization of $[\{(Et_2O)Mg\}_6(NPh)_4Br_4]$: A Magnesium–Imide Cage Species Derived from a Dimagnesylamine Solution**

Tony Hascall, Marilyn M. Olmstead, and Philip P. Power*

Dimagnesylamines (imidobis(magnesium halides)) are species in which the two hydrogen atoms from an amine are replaced by MgX moieties (X = halogen).[1] They were first prepared as long ago as 1903[2] by the reaction of a primary amine with two equivalents of Grignard reagent [Eq. (a)].

$$RNH_2 + 2R'MgX \rightarrow \underset{\text{dimagnesylamine}}{\text{"}RN(MgX)_2\text{"}} + 2R'H \qquad (a)$$

(X = halogen; R, R' = alkyl or aryl)

When these compounds are employed as synthetic reagents[3] the formula $RN(MgX)_2$ is normally used but this merely represents the formal stoichiometry required by the reaction scheme. Currently, no structural details for these interesting species are available. In this laboratory, the reactions of Grignard reagents (R'MgX) or diorganomagnesium compounds (MgR'_2) with primary amines (RNH_2) have recently been under investigation. The main objectives of this work were the establishment of the exact formulae of the products and their subsequent synthetic use as imide (NR^{2-}) transfer reagents in main group and transition metal chemistry. It has already been demonstrated that the reaction between $MgEt_2$ and H_2NPh in the presence of THF affords the new magnesium imide cage species **1** which has a

$[(thf)MgNPh]_6$ **1**

hexagonal prismatic Mg_6N_6 structural framework.[4] It is now shown that the reaction between two equivalents of the Grignard reagent EtMgBr and H_2NPh in ether solution gives the novel magnesium–imide aggregate **2**. Compound **2** (see Experimental Procedure) can be isolated from ether solution as a thermally stable, air- and moisture-sensitive, crystalline solid which turns brown upon exposure to air. The crystals are fairly soluble in ethers and slightly soluble in aromatic solvents. In [D_8]toluene at 25 °C the ^1H NMR spectrum shows that only one type of solvating ether molecule or phenyl group is present at room temperature—at least on the NMR time scale. Moreover, integration of the signals for Ph and Et_2O shows that the groups are present in a 2:3 ratio. The ^{13}C NMR spectrum also supports this view.

$[\{(Et_2O)Mg\}_6(NPh)_4Br_4]$ **2**

The stoichiometry and structure of **2** were definitively established by an X-ray crystal structure determination (Fig. 1).[5] The structure of **2** has a slightly distorted Mg_6N_4 adamantane framework composed of four nitrogen atoms (from NPh^{2-} groups) at the bridgehead positions and six ether-solvated Mg^{2+} ions. The four bromide ions, which preserve overall charge balance, are located somewhat asymmetrically[6] above the four fused six-membered Mg_3N_3 rings that form the adamantane core. An alternative view of the structure is that the four μ_3-Br^- ions describe a distorted tetrahedron which circumscribes the Mg_6N_4 cage which is itself composed of an octahedron of Mg^{2+} ions and a tetrahedron of N centers. Thus, each Mg^{2+} ion bridges an edge, and each NPh^{2-} ion caps a face in a μ_3 fashion, of the halide tetrahedron. The geometry at the magnesium centers may be described as distorted trigonal bipyramidal with the axial positions occupied by bromide ions and the equatorial sites occupied by two nitrogen atoms and an oxygen atom. The mean Mg–N and Mg–O distances are 2.041(10) and 2.026(14) Å which are close to those observed in **1**.[4] The Mg–Br distances are in the range 2.76–3.48 Å with an average length of 2.94 Å.[6] The imide nitrogen atoms have distorted tetrahedral environments, and are coordinated to three magnesium atoms and one carbon atom with an average N–C bond length of 1.46 Å.

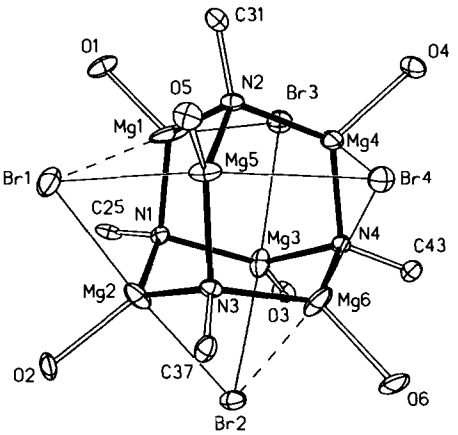

Fig. 1. Molecular structure of $[\{(Et_2O)Mg\}_6(NPh)_4Br_4]$ **2** (computer generated). For clarity, only the oxygen atoms of the ether molecules, the *ipso*-carbon atoms of the Ph substituents, and the $Mg_6N_4Br_4$ framework are shown [5, 6].

The unique formula of **2** probably arises from the disproportionation (b).

$$4RN(MgX)_2 \rightarrow Mg_6(NR)_4X_4 + 2MgX_2 \qquad (b)$$

The structure in the solid appears to closely resemble the solution species. Three crystallizations of **2** from Et_2O did not result in any change in stoichiometry. Furthermore, the addition of 1,4-dioxane (as outlined in the Experimental Procedure) is not required to induce disproportionation since **2** may be isolated by fractional crystallization from the reaction solution. In addition, the use of THF instead of ether gives **3**, which has an

$[\{(thf)Mg\}_6(NPh)_4Br_4]$ **3**

almost identical structure to **2**.[7] The significance of these structures lie in the fact that they demonstrate that the addition of two equivalents of Grignard to aniline results in a completely deprotonated nitrogen center. In this respect it resembles the reaction of $MgEt_2$ with H_2NPh which affords **1**.

Experimental Procedure

All manipulations were carried out under anaerobic and anhydrous conditions. With rapid stirring and cooling in an ice bath, the Grignard reagent EtMgBr was added as a 0.6 M solution in diethyl ether (100 mL, 60 mmol) to aniline (2.8 g, 30 mmol) in 20 mL of the same solvent. When the addition was complete, the solution was allowed to warm to room temperature and stirred for a further 2 h whereupon 1,4-dioxane (1.7 mL, 30 mmol) was added by syringe to afford a white precipitate of $MgBr_2 \cdot 2$ (1,4-dioxane). This was separated by filtration to afford a clear solution which was concentrated under reduced pressure to bring about crys-

tallization. Cooling in a freezer to −20 °C afforded the product **2** as colorless crystals. These may be recrystallized by dissolving in refluxing ether and cooling. The yield was about 70%. The crystals rapidly turned brown upon exposure to air and did not melt upon heating to 300 °C. The crystals showed evidence of desolvation and decomposition on heating above 100 °C. ^{1}H NMR: (300 MHz, 25 °C in [D$_8$]toluene: δ = 0.99 (br, 36H, $CH_3(Et_2O)$), 3.6 (br, 24H, $CH_2(Et_2O)$), 6.75 (t, 4H, *p*-H), 7.17 (m, 8H, *m*-H), 7.48 (m, 8H, *o*-H). ^{13}C{^{1}H} NMR: (75.47 MHz, [D$_8$]toluene): δ = 13.16 (s, $CH_3(Et_2O)$) 64.51 ($CH_2(Et_2O)$), 113.21 (s, *o*-C), 124.04 (s, *m*-C). IR: the IR spectrum (nujol mull) of **2** in the metal-ligand stretching region (< 600 cm^{-1}) is characterized by several medium intensity bands at 502, 428, 363, 318, and 245 cm^{-1}.

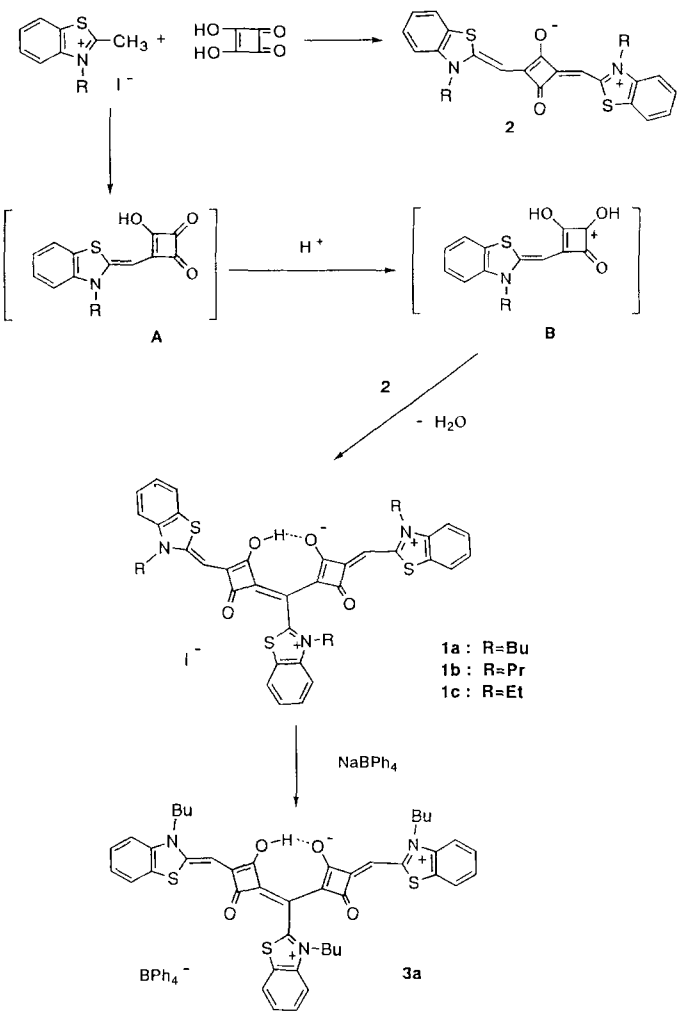
Synthesis and Structure of New Cationic Squarylium Dyes

Hiroyuki Nakazumi,* Kazuki Natsukawa, Kazuhisa Nakai, and Kakuzo Isagawa

Squarylium dyes have attracted much attention because of their potential application in xerographic photoreceptors,[1] optical recording media,[2] and organic solar cells,[3] on account of their special properties such as photoconductivity and sharp and intense absorption in the visible (VIS) or near-IR regions (NIR).[4] Generally, known squarylium dyes are 1,3- or 1,2-disubstituted squaric acid derivatives.[5] We have now prepared a hitherto unknown cationic squarylium dye (**1**) and found that it has an extended π-electron system whose two squaric acid subunits are stabilized by formation of an intramolecular hydrogen bond.

The butyl derivative **1a**[6] was prepared in 43% yield by condensation of *N*-butyl-2-methylbenzothiazolium iodide and squaric acid in refluxing butanol/benzene in the absence of a base catalyst such as quinoline. Other alkyl derivatives, **1b** and **1c**, were similarly prepared from the corresponding benzothiazolium iodides. In this reaction, the normal squarylium dye **2** was obtained as a by-product (less than 10% yield). In similar reactions of other heterocyclic compounds with squaric acid, the 2-methyl-quinolinium salt gave a cationic squarylium dye (λ_{max} 856 nm), but the 2-methylindolinium salt gave only the normal squarylium dye. Treatment of **1a** with one equivalent sodium tetraphenylborate in methanol (60 °C, 1 h) afforded the tetraphenylborate salt **3a**. The reaction of *N*-ethyl-2-methylbenzothiazolium iodide with squaric acid in the presence of quinoline was reinvestigated, and was found to yield compound **1c** (deep red squarylium dye) with an absorption maximum in the NIR spectrum (λ_{max} 796 nm), and not the proposed structure **4** previously reported.[7]



4

The preparation of squarylium dyes is usually carried out under conditions where the enamine 2-methylenebenzothiazole is formed in situ with excess of quinoline. Under such conditions, the main product was the normal squarylium dye **2**; a small amount (less than 10% yield) of the cationic dye **1** was only obtained on prolonged reaction (20 h).

In the absence of quinoline, dye **1** was formed during the early stage of the reaction as a main product (Fig. 1; reaction monitored by VIS/NIR absorption spectroscopy). Initially, the reaction of benzothiazolium iodide with squaric acid gave a mixture of intermediate **A** and the normal squarylium dye **2**. The electrophilic attack of a protonated intermediate **B**, which is easily formed in the presence of an acid, on dye **2** followed by dehydration leads to the cationic dye **1** (Scheme 1).

The X-ray structural analysis[8] of **3a** (Fig. 2) shows a planar polymethine structure, which corresponds to the chromophore

Scheme 1. Synthesis of cationic squarylium dyes **1a–c** as well as the BPh_4 salt **3a**.

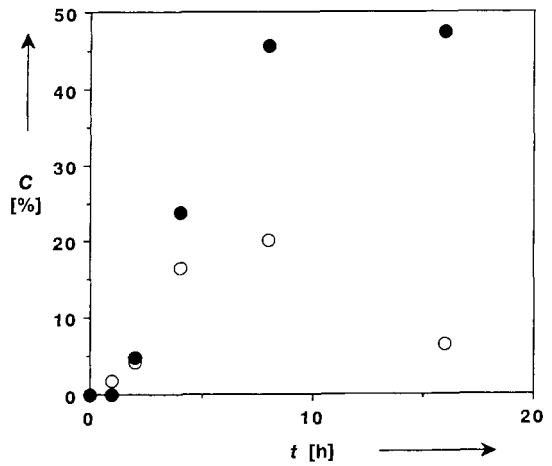

Fig. 1. Product ratios of near-IR absorbed squarylium dye **1a** (●) and blue squarylium dye **2a** (○) prepared from the reaction of squaric acid (0.5 mmol) and *N*-butyl-2-methylbenzothiazolium iodide (1.0 mmol) in the absence of quinoline (*C*: conversion of squaric acid [%] monitored by absorption at 798 and 668 nm, respectively).

in **1**; the largest deviation (0.31 Å) occurs for the O2 atom of the carbonyl group. The positive charge is delocalized over the two squaric acid units and two of the three benzothiazole rings. Two shorter C–C bonds in the cyclobutene (1.43–1.46 Å), and the other C–C as well as the C–N1 and C–N2 bond lengths (1.35–1.43 Å) are indicative of a conjugated polymethine framework in **3a**. The C–O bond (ca. 1.26 Å) in the inner carbonyl groups is longer (ca. 0.06 Å) than the others. An intramolecular hydrogen bond (1.50 Å) between the oxygen atom of the carbonyl group and the hydroxyl group (2.37 Å for O1–O3) leads to an effective delocalization of the π electrons over the polymethine subunit.

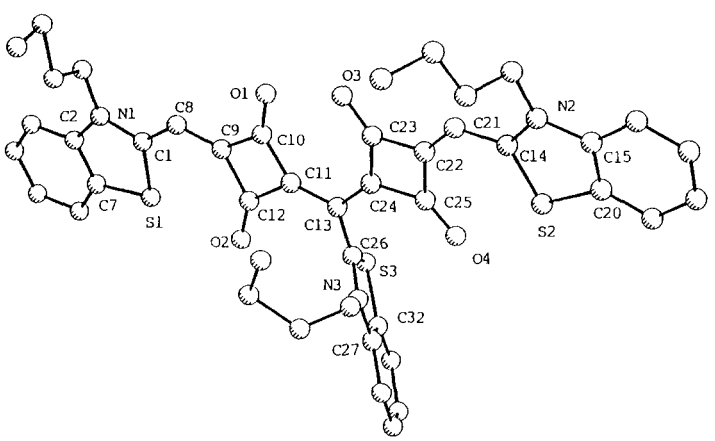

Fig. 2. X-ray crystal structure (PLUTO drawing) of **3a**. Hydrogen atoms and BPh_4^- were omitted for clarity. Selected bond lengths [Å]: N1-C1 1.36(1), N1-C2 1.40(1), C1-C8 1.38(1), S1-C1 1.72(1), S1-C7 1.75(1), C8-C9 1.39(1), C9-C10 1.43(1), C10-O1 1.27(1), C10-C11 1.43(1), C11-C12 1.49(1), C9-C12 1.50(1), C12-O2 1.20(1), C11-C13 1.41(1), C13-C24 1.41(1), N2-C15 1.41(1), N2-C14 1.35(1), S2-C14 1.72(1), S2-C20 1.75(1), C14-C21 1.42(1), C21-C22 1.34(1), C22-C23 1.47(1), C22-C25 1.48(2), C23-O3 1.26(1), C23-C24 1.43(1), C24-C25 1.50(1), C25-O4 1.20(1), C13-C24 1.41(1), C13-C26 1.43(1), S3-C26 1.68(1), S3-C32 1.74(1), N3-C26 1.32(1), N3-C27 1.38(1).

The branched benzothiazolium subunit is not conjugated with the polymethine subunit; the dihedral angle between these two units is 62.5°. The polymethine structure in **1a** or **3a** is also evident from the equivalence of two of the three *N*-butyl groups in the ^1H NMR spectrum, that is, the methylene protons of the NCH_2 group in the polymethine unit and in the branching benzothiazolium subunit of **1a** occur at $\delta = 4.2$ (4H) and 4.73 (2H), respectively. The absorption spectrum of the neutral compound **1a**–HI, which was formed by treatment with sodium hydroxide, exhibits two intense bands in the NIR spectrum ($\lambda_{max} = 845$, 799 nm)[9] for the x and the y band of a typical triarylmethane chromophore. However, the cationic dye **1** showed only a sharp and intense absorption band at 797 nm ($\lg\varepsilon = 5.44$) with a small shoulder; the squarylium dye **2** absorbs at 668 nm. Thus, the chromophore of **1** is a polymethine chromophore which is stabilized by an intramolecular hydrogen bond, and not a triarylmethane chromophore. Although the cationic dye **1** consists of three benzothiazole rings and two squaric acid subunits, the branched benzothiazolium component makes a relatively small contribution to the polymethine chromophore in the solution.

Experimental Procedure

1a: The mixture of *N*-butyl-2-methylbenzothiazolium iodide (1.32 g, 4 mmol) and squaric acid (0.23 g, 2 mmol) in butanol/benzene (4:1)(10 mL) was heated at 110 °C for 7 h. After cooling, chloroform (4 mL), ethyl acetate (3 mL), and methanol (3 mL) were added to the reaction mixture, and the solution was allowed to stand for at least 12 h. The resulting solid was then separated and washed with ethyl acetate to give a black solid, which was purified by recrystallization from CH_2Cl_2/ethyl acetate. Yield: 0.39 g (43%). Other derivatives, **1b** and **1c**, were similarly made from the corresponding *N*-alkyl-2-methylbenzothiazolium iodide in yields of 38–43%.

3a: A CH_2Cl_2 solution of **1a** (20 mL, 0.72 g, 0.8 mmol) was added dropwise to a solution of sodium tetraphenylborate in methanol (5 mL, 0.028 g, 0.8 mmol). The mixture was stirred at 60 °C for 1 h. After cooling, ethyl acetate (3 mL) was added to the reaction mixture, and the solution was allowed to stand for 20 h. The resulting solid was separated and recrystallized from CH_2Cl_2/hexane. Yield: 0.056 g (64%).

[8] **3a**: $C_{68}H_{62}N_3O_4S_3B$, $M = 1092.24$, monoclinic, space group $P2_1/a$, $a = 18.162(8)$, $b = 16.20(2)$, $c = 22.117(7)$ Å, $\beta = 107.34(3)^\circ$, $V = 6213(7)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.168$ g cm^{-3}. A total of 12975 unique data points were collected ($Mo_{K\alpha}$, $\lambda = 0.71049$ Å, $\mu = 1.60$ cm^{-1}, $2\theta < 50^\circ$) of which 4386 had $F > 4\sigma(F)$ and were used for structure refinement. These data sets were collected by using a Rigaku AFC-5R diffractometer at 296 K. An absorption correction, using the program DIFABS, was applied which resulted in transmission factors ranging from 0.88 to 1.12. The structure was solved by direct methods and refined by full-matrix least-squares method (TEXSAN, Molecular Structure Corp., USA) with anisotropic thermal parameters for non-hydrogen atoms, except for five carbon atoms of the butyl groups. Because of the disorder of the butyl group, isotropic parameters for these atoms are very large. $R = 0.076$ and $R_w = 0.100$ for 680 parameters. The minimum and maximum residual electron densities are -0.34 and 0.59 e Å^{-3}, respectively. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-58042.

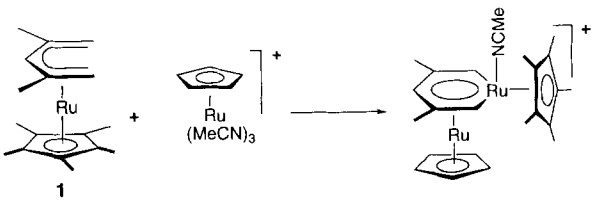
From Triple-Decker to Metallabenzene: A New Generation of Sandwich Complexes

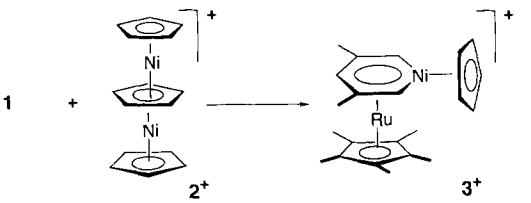
Ulrike Bertling, Ulli Englert, and Albrecht Salzer*



Dedicated to Professor Helmut Werner on the occasion of his 60th birthday

The chemistry of the metallocenes is currently experiencing a true renaissance.[1] Besides complexes with carbocyclic ligands, C_nH_n, metallocenes in which CH is substituted by isoelectronic building blocks (i.e. $C_6H_6 \rightarrow [C_5H_5BR]^-$,[2] or $C_6H_6 \rightarrow C_5H_5P$)[3] are also known. Complete exchange of the CH units leads to pure heteroatom ligands such as P_6.[4] These ligands often act as bridging ligands in triple- and poly-decker complexes. In contrast, this bonding mode has been confirmed, so far, in only two cases for the ubiquitous ligand of metal π complexes, the cyclopentadienyl anion $C_5H_5^-$.[5]

Metallacycles that are isolobal to the previously mentioned element heterocycles act only rarely as π-donor/π-acceptor ligands. The best-known examples are metallacyclopentadienes ("metalloles"), which can form as by-products or intermediates in the metal-catalyzed oligomerization of alkynes.[6] However, this reaction pathway allows only for metallacycles with an even number of C atoms.[7]



Only in recent years has it become possible to generate mono- and binuclear metallabenzenes. For example, J. Bleeke[8] succeeded in synthesizing binuclear half-sandwich complexes starting from iridabenzene and a $Mo(CO)_3$ moiety. When reacting the "half-open" metallocene **1** with $[CpRu(MeCN)_3]^+$ we obtained a binuclear complex, in which the 14e fragment $[(C_5Me_5)Ru(MeCN)]^+$ complements the pentadienyl ligand to give ruthenabenzene (Scheme 1).[9] Another diruthenium complex with an unsubstituted metallabenzene ring and Me_3Si ligands instead of MeCN has been synthesized just recently by Girolami et al. by a different route.[10]

We now have successfully synthesized the first, simple metal π complex of the composition $[(C_5R_5)_3M_2]^+$, in which the

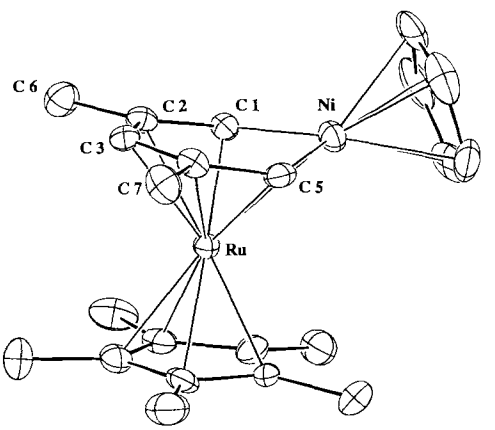
Scheme 1.

metallabenzene acts as a 6e ligand of a sandwich molecule. Reaction of **1** with the triple-decker cation $\mathbf{2}^+$ as source of the 14e fragment $[CpNi]^+$ gives the cation $\mathbf{3}^+$ (Scheme 2).

Scheme 2.

Complex $\mathbf{3}^+$, isolated as its tetrafluoroborate salt, is essentially air-stable and dissolves in polar solvents such as acetone to give cherry-red solutions without decomposition; the complex can even be purified by chromatography over aluminum oxide. Those CH units of the nickelabenzene ring bonded directly to the metal exhibit a downfield shift in the ^1H and ^{13}C NMR spectra ($\delta = 9.7$ and 167.7, respectively) characteristic for unsaturated metallacycles.[9] A triple-decker complex with a central pentadienyl ligand is conceivable as the initial reaction product that then reacts by insertion of the CpNi moiety into two terminal CH bonds, followed by reductive elimination of hydrogen to give the final product. The mass spectra of "half-open" metallocenes exhibit fragmentation patterns indicative of facile loss of H_2.[11] The thermal ring closure of pentadienyl compounds to give metallocenes by hydrogen elimination is also known.[12]

Single-crystals of **3**-BF_4 were obtained by slow diffusion of propionic anhydride and ether at $-30\,^\circ C$. A single-crystal X-ray structure analysis[13] confirms the presence of a metallabenzene sandwich complex (Fig. 1). The C_5Me_5 ring and the carbon atoms of the nickelabenzene moiety are almost coplanar



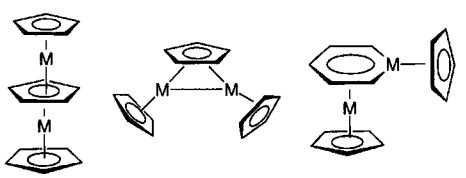


Fig. 1. Structure of $\mathbf{3}^+$ in the crystal (ORTEP). Selected bond lengths [Å]: C1–C2 1.38(1), C2–C3 1.42(1), C3–C4 1.46(1), C4–C5 1.41(1), Ru–Ni 2.554(1), Ni–C1 1.867(9), Ni–C5 1.838(9).

(6±1°). The bond lengths within the pentadienyl ligand are mostly identical and are indicative of a high degree of delocalization. The Ni–C distances in the nickelabenzene ring are very short (Ni–C1 1.867(9), Ni–C5 1.839(9) Å) and in accord with a high Ni=C bond character ($Ni-C_{alkyl} \approx 1.99$, $Ni-C_{isonitrile} \approx 1.85$, $Ni-C_{carbonyl} \approx 1.77$ Å[14]). The C-Ni-C angle of 92.4(6)° is similar to that of other heterobenzenes such as arsabenzene (As–C 1.85 Å, C-As-C 97°).[15] Arsenic and nickel have approximately the same atomic radius. The nickel atom is bent out ("upwards") of the plane of the five carbon atoms by 16.4°; this is a result of the short Ru–Ni bond length of 2.55 Å. The angle is markedly smaller than for the ruthenabenzene complex (27.2°), shown in Scheme 1, in which the Ru–Ru distance (2.67 Å) is longer. Consequently, a metallabenzene complex with two 3d metals and an even smaller M–M distance should be completely planar.

In the first publication on $[Cp_3Ni_2]^+$ ($\mathbf{2}^+$) we not only considered the triple-decker structure **I**, later proven correct, but also the structural alternative **II** (Scheme 3),[16] a type of complex

I II III

Scheme 3.

that has in the meantime been confirmed for the compounds $[(\mu\text{-}C_xH_x)Cp_2M_2]^{n+}$ ($x = 6-8$).[17–19] Cp as a ligand bridging a metal–metal bond was first introduced by H. Werner in the complexes $[(\mu\text{-}Cp)Pd_2L_2]$.[20] The metallabenzene complex described here corresponds to type **III** and is an example for the third possible structural isomer with a composition $[(C_5R_5)_3M_2]$.

The aromatic character of metallabenzenes has already been discussed by R. Hoffmann[21] and J. Bleeke.[8] Clearly metallabenzenes are in many respects similar to heteroarenes. This includes structural characteristics such as ring planarity and balanced bond order as well as similar reactivity that allows for formation of remarkably stable metal π complexes of the sandwich-type. Since the bonding mode of the nickelabenzene ligand in $\mathbf{3}^+$ can be described analogous to that of benzene in $[CpRu(C_6H_6)]^+$ the question arises whether detachment or transfer of this ligand to other complex fragments is possible. Bis(metallabenzene) complexes or even triple-decker complexes with a central metallabenzene ring are conceivable.

Experimental Procedure

Synthesis of **3**-BF_4: **1**(1.17 g, 3.5 mmol) and **2**-BF_4 (1.45 g, 3.6 mmol) were stirred in nitromethane (100 mL) for 12 h at 60 °C. After the solvent had been removed under reduced pressure, the residue was chromatographed over Al_2O_3 (activity III) with acetone as eluent. The red fraction gave 0.9 g **3**-BF_4 (48% relative to **1**). Further purification was possible by dissolution in propionic anhydride and precipitation with diethyl ether. ^{13}C NMR (125.7 MHz, CD_3NO_2, 25 °C): $\delta = 167.7$ (C1), 103.8 (C2), 101.5 (C_5Me_5), 96.4 (C_5H_5), 91.9 (C3), 21.0 (Me), 11.0 (C_5Me_5); ^1H NMR (500 MHz, CD_3NO_2, 25 °C): $\delta = 9.7$ (d, $^4J = 1.2$ Hz, 2H; CH), 5.7 (t, $^4J = 1.2$ Hz, 1H; CH), 5.68 (s, 5H; Cp), 2.2 (s, 6H; Me), 1.9 (s, 15H; C_5Me_5).

Strong, Specific Binding of Six Different DNA Sequences by a Single Conformation-Switching DNA Macrocycle**

Ethel Rubin and Eric T. Kool*

Certain nucleic-acid-binding proteins can recognize varied substrate structures by making use of multiple binding domains or by undergoing conformational changes in a specific binding domain. For example, the *Xenopus* zinc-finger protein TFIIIA recognizes a specific sequence in duplex DNA and a significantly different sequence in ribosomal RNA;[1–5] this switching of binding site is implicated in feedback-type control of gene ex-

[**] This work was supported in part by a grant from the National Institutes of Health (RO1-GM46625). E. T. K. acknowledges awards from the Young Investigator Programs of the Office of Naval Research (1992–1995), the Beckman Foundation (1992–1994), and the Army Research Office (1993–1996), and a Camille and Henry Dreyfus Teacher-Scholar Award (1993).

pression. We have recently begun to examine various approaches for the design of multifunctional DNA-recognizing molecules which can mimic this kind of multisite-binding behavior.[6] The ability to control binding in this way not only serves to mimic a complex biological function, but also may have some practical applications as well. For example, recent studies in the use of oligonucleotides as sequence-specific inhibitors of gene expression have shown that the combination of agents targeted to multiple sites can be more effective in vitro than single-site binding alone.[7–9]

We recently described the design and synthesis of a cyclic oligodeoxynucleotide molecule which can bind strongly to two separate DNA sequences by switching conformation.[6] In that earlier prototypical structure, a cyclic DNA molecule which contained separate pairs of nine-base binding domains (36 nucleotides altogether) was used to recognize two nine-base sequences by interchanging binding and bridging domains (totalling 18 nucleotides of sequence recognition by the 36 nucleotides in the cyclic compound). In order to explore the limits of this kind of multifunctional binding, we now report the synthesis and properties of a new cyclic DNA which is designed to recognize six different sequences by undergoing six conformational changes. At the same time, careful design allows the elimination of duplicated nucleotides, leading to very high economy of function: the molecule selectively recognizes 48 nucleotides of sequence although the molecule itself contains only 35 nucleotides. Several novel design principles are discussed.

The design of the DNA macrocycle **1** involves the combination of several different principles (Fig. 1). First, binding would occur by triplex formation between opposing pyrimidine domains (the Watson–Crick and Hoogsteen domains) in the circle and a complementary sequence of purines in the target molecule. This would result in stronger binding and higher sequence selectivity than is possible for simple Watson–Crick binding.[10, 11] Second, because the two pyrimidine binding domain sequences in such a circle are related by a pseudo-mirror-plane of symmetry, a pair of binding domains might bind the forward (5′ → 3′ direction) or the reverse (3′ → 5′ direction) of a given sequence by switching the roles of the Watson–Crick and Hoogsteen domains. Third, by contiguous alternating placement of three binding domain pairs, this might allow recognition of six different sequences (three in one orientation and three in the reverse). Recognition of a sequence with a given binding domain pair would then make use of the other domains as bridging loops in the complex.[6] Finally, one might achieve this multiple recognition with fewer nucleotides by eliminating those whose function is duplicated in a neighboring domain, thus overlapping the boundaries of the domains. With this approach, many of the individual nucleotides have more than one function.

Specifically, we designed and synthesized the macrocycle **1** with the ability to recognize the six eight-base sequences **2**–**7** (Fig. 1). The total sequence recognition thus encompasses 48 bases of DNA. If the pyrimidine binding domains of the circle were kept separate and incorporated contiguously into a circle, this would require a circle 48 nucleotides in size. By overlapping the ends of the required domains (Fig. 1 bottom), we eliminate the need for 13 of the nucleotides, and so the circle **1** contains only 35 nucleotides.

The structure of **1** should, in principle, retain the high sequence selectivity previously seen for this kind of circular ligand.[10] To test this selectivity, we also synthesized two sequences, **8** and **9** (sequences shown in Fig. 2), which are the same as two of the recognition sequences but with two nucleotides interchanged.

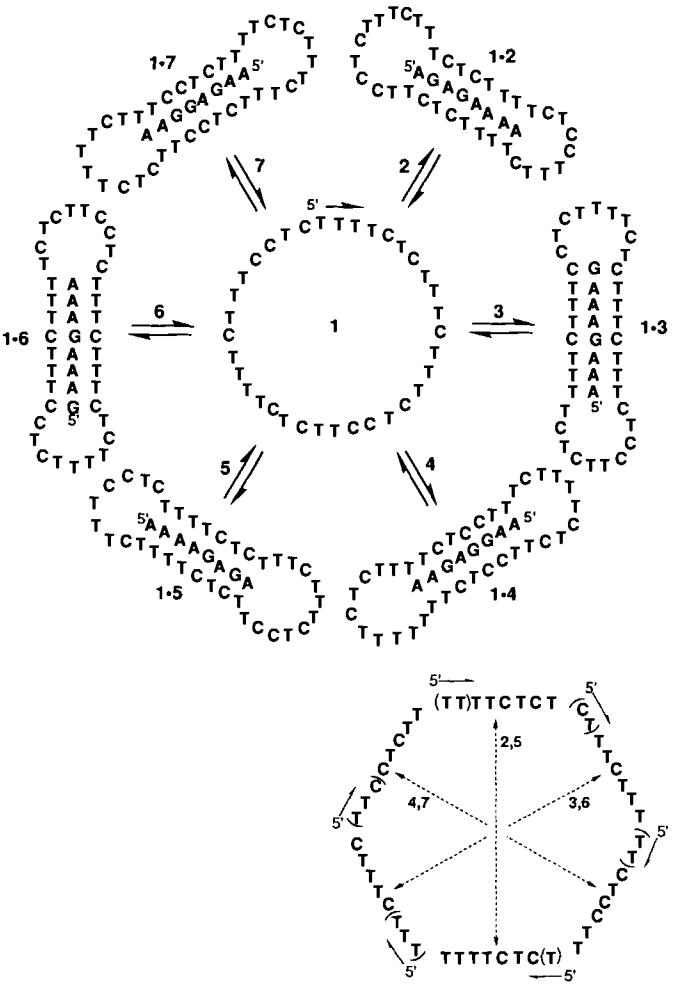

Fig. 1. Top: The sequence of circular oligodeoxynucleotide **1** (in center) and the adducts of **1** with complementary sequences **2**–**7**. Bottom: Strategies for construction of **1**. The three pairs of domains necessary for recognition by triplex formation were placed in alternating configuration such that two halves of a pair oppose one another. (The two domains in each pair are connected by an arrow.) Parentheses indicate nucleotides which are eliminated because they are repeated from the previous domain.

Binding studies of **1** with these eight purine sequences were carried out by optical monitoring of thermal denaturation of the 1:1 mixtures at pH 7.0 (100 mM NaCl, 10 mM $MgCl_2$). Melting curves reveal sharp, apparently two-state transitions at 260 nm for the complexes of **1** with **2**–**7**. As expected for such triple helical complexes,[11] the melting temperatures are considerably higher than those for simple Watson–Crick complements containing the same base pairs (see below). The melting transitions of **1** with **2**–**7** are all within the range 33–37 °C (Fig. 2 top); the hyperchromicities are 18–25%. Also consistent with this mode of binding is the finding that the stability of all six complexes are pH-dependent (data not shown), as expected for triplexes involving C · G · C triads and not duplexes.[12]

By contrast, mismatched sequences **8** and **9** are bound much more weakly than **1**, with T_m values of 18.8 and 19.6 °C, respectively, and are essentially fully dissociated at room temperature. Curve-fitting algorithms[13] allow estimates of free energy for the complexes of **1** with **2**–**9**. Under these conditions, the complexes **1** · **2**–**1** · **7** are bound with free energies ($-\Delta G^\circ_{25}$) of 10.3–12.2 kcal mol^{-1}. By comparison, the complexes of the two mismatched purine sequences (**8**, **9**) are bound much weaker to **1**,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994 0570-0833/94/0909-1005 $ 10.00+.25/0

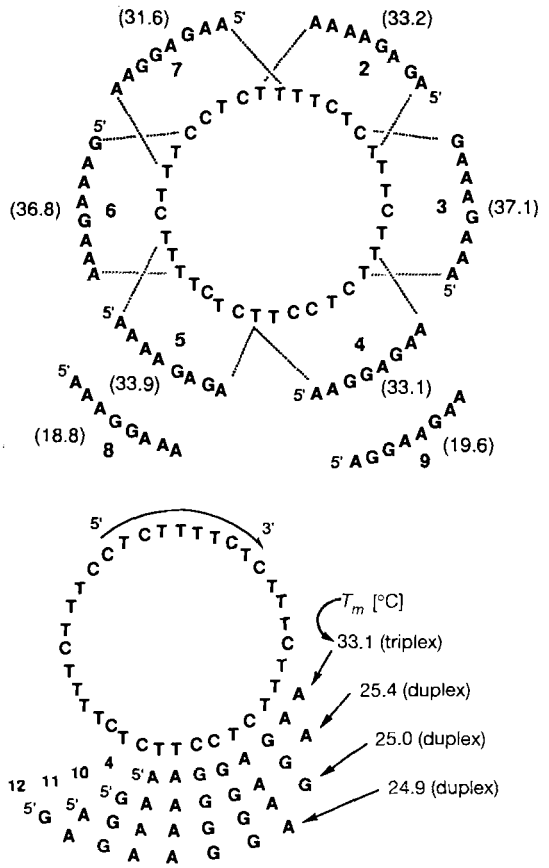

Fig. 2. Top: Melting temperatures T_m [°C] for complexes of **1** with complementary sequences **2**–**7** and mismatched sequences **8** and **9**. Bottom: The relative affinity of **1** for a triple helical complement (**4**) as compared to other Watson–Crick complements (**10**–**12**), as determined by thermal denaturation. The eight-base complements **4** and **10**–**12** are overlapping sequences related by single-nucleotide frameshifts.

with free energies of 6.5 and 6.6 kcal mol^{-1}. Thus, **1** is selective for the complementary sequences over these two mismatched sequences by three to four orders of magnitude in association constant.

A different issue of complementarity and selectivity arises from the structure of **1**. While it is designed to recognize sequences **2**–**7** by triplex formation, it is also complementary in Watson–Crick fashion to 29 additional eight-nucleotide sequences. To test whether the circle **1** binds selectively to the six intended sequences (**2**–**7**) relative to the 29 other sequences, we synthesized three purine octamers, **10**–**12**, which are fully complementary to the circle only in Watson–Crick fashion. The complementary sites for the sequences occur adjacent to the binding domain for the triplex-bound oligomer **4**, and is frameshifted by one, two, or three nucleotides, respectively (Fig. 2 bottom).

Results of these additional binding studies show that while the circle **1** is indeed complementary to the Watson–Crick complements **10**–**12**, it shows considerable selectivity instead for the intended triplex complements **2**–**7**. Thus, **10**–**12** are bound with T_m values of 24.9–25.4 °C and hypochromicity values of 0.10–0.16, while the triplex complements **2**–**7** are bound with T_m values of 33.1–37.1 °C and hypochromicity values of 0.18–0.25. The free energy of formation for these types of complex differs by 2.1–4.3 kcal mol^{-1}. The association constant for **1** · **2**–**1** · **7** is 34- to 1400-fold larger than that for **1** · **10**–**1** · **12**. The sequences which are only complementary in Watson–Crick fashion may thus be viewed as being mismatched sequences, since they are not able to form the full number of stabilizing Hoogsteen bonds that the intended six sequences can. The lower hypochromicitiy values with **1** · **10**–**1** · **12** are consistent with the Hoogsteen strand not being involved in these complexes, although we cannot rule out partial Hoogsteen-type interaction. The selectivity shown by **1** against Watson–Crick binding alone is, in fact, similar in magnitude to the amount of discrimination which a linear oligodeoxynucleotide shows against single-base mismatches.[10] It is clear, therefore, that compound **1** is readily able to distinguish between its six target sequenes and other complementary and partially complementary DNA sequences.

In summary, the results indicate that reasonably complex multifunctional behavior can be successfully designed into synthetic DNA-recognizing molecules. The design of the oligonucleotide macrocycle **1** illustrates ways to control binding properties in DNA molecules by varying more than just the simple primary sequence of nucleotide bases. In this case, the circularity, the use of opposite domains for binding, and the pseudosymmetry of the domains all allow for greater control of secondary and tertiary interactions in the final complexes than is commonly used in Watson–Crick binding. It is possible that this multisite binding might be applied to practical problems of nucleic acid recognition; for example, inhibition of gene expression by targeting more than one site in a gene, or more than one gene in an organism. Further study will be necessary to investigate these possibilities.

Experimental Procedure

Oligodeoxynucleotides **2**–**10** were synthesized by automated methods using β-cyanoethylphosphoramidite chemistry [14] on a Pharmacia LKB instrument, and were purified by preparative denaturing polyacrylamide gel electrophoresis. Quantification was done by measuring absorbance at 260 nm and calculating concentration based on extinction coefficients derived from nearest neighbor analysis [15]. For construction of compound **1**, the linear precursor 5′-dTTTTCTTTC-CTCTTTTCTCTTTCTTTCTCCTTCTCp was synthesized, along with a template for cyclization having the sequence 5′-dAGAAAAGAGAA. Cyclization was carried out with an aqueous nonenzymatic ligation reaction, with 50 μM each of linear precursor and template, 200 mM imidazole · HCl (titrated to pH 7.0 as a stock solution prior to addition to the reaction mixture), 100 mM $NiCl_2$, and 125 mM BrCN for 12 h at 23 °C, as described previously [11, 16]. Workup and isolation were as described previously [11, 17]. The conversion to circular product was about 70% (by gel analysis), and the circular product was isolated in 43% yield by excising, crushing, and elution from the peparative gel followed by dialysis to remove salts. The circular structure was confirmed by complete resistance to cleavage by a combination of T4 DNA polymerase (3′ exonuclease activity) and T4 polynucleotide kinase (3′ phosphatase activity in the absence of ATP) under conditions which cleave the linear precursor to mononucleotides. The cleavage was carried out at 37 °C (1–40 minutes) with 23 μM DNA, 58 mM tris(hydroxymethyl)aminomethane (Tris) · HCl (pH 7.6), 12 mM $MgCl_2$, 6 mM dithiothreitol, 100 μM spermidine, 100 μM EDTA, 0.5 units/μL kinase, and 0.1–0.2 units/μL polymerase. Enzymes were purchased from New England Biolabs (T4 kinase) and United States Biochemical (T4 polymerase).

Thermal denaturation studies on the 1:1 complexes were carried out at 6 μM total oligonucleotide concentration in a buffer containing 100 mM NaCl, 10 mM $MgCl_2$, and 10 mM Na-PIPES (HPIPES = 1,4-piperazinediethanesulfonic acid) at pH 7.0 in stoppered 1 cm pathlength cells. Prior to the denaturation experiment, samples were heated to 90 °C for 2 min and then allowed to cool slowly to room temperature. For the denaturation, a thermocontrolled Varian Cary 1 UV/VIS instrument was used, and temperature was increased at a rate of 0.5 K per minute under nitrogen atmosphere. The reference samples contained the identical buffer without DNA. Curve fitting was carried out as described previously [8, 10]. T_m values are obtained from the first derivative of absorbance with respect to T^{-1}, and are estimated to be accurate to within ±0.5 °C. Precision in free energy measurements is estimated to be ±10–15%.

Absorbing Free-Radical Chemistry

Half a Century of Free Radical Chemistry. By *D. H. R. Barton* and *S. I. Parekh*. Cambridge University Press, Cambridge, 1993. XI, 164 pp., hardcover £ 30.00, paperback £ 12.95.—ISBN 0-521-44005-X/0-521-44580-9

In six years time free radical chemistry will be celebrating its hundredth birthday. It was Moses Gomberg who announced the birth of the first 'free' radical, the triphenylmethyl radical, in the Journals of the American and German Chemical Societies. Before Gomberg's time, the word 'radical' belonged to the science of nomenclature, and was used to describe those parts of molecules that remained unaltered during chemical reactions. It is interesting to note that Gomberg ended his article by mentioning that his investigations were continuing, and requesting that this research topic should be left to him for a time.

Whether as a result of that statement or because the time was not yet ripe, the fact is that free radical chemistry had only a shadowy existence up to about 1940. It was only with the discoveries of the peroxide effect and, more especially, of free radical polymerization that interest in the topic was reawakened. Nowadays one cannot think of organic synthesis without including free radical chemistry, and new evidence of the importance of free radicals in processes that are vital to living organisms continues to emerge.

1940 was also the time when Derek Barton began work at Imperial College, London, on his dissertation concerning the formation of vinyl chloride during the pyrolysis of 1,2-dichloroethane. In Chapter 1 of the book reviewed here, Barton describes how this work gave him his first contact with free radicals. The first half of the book contains summaries of several lectures given by the author in 1991 as Visiting Professor at the Academia Nazionale dei Lincei in Milan. The second half consists of a new review by S. I. Parekh of the applications of the Barton reaction, discovered ten years ago, whereby free radicals with synthetic potential are generated from carboxylic acids. The first part is a valuable contribution to the history of chemistry between 1940 and 1990. It makes very enjoyable reading and is skillfully written. Derek Barton describes here how the discoveries and developments that were his contribution to free radical chemistry came about. These include the phenolate free radical coupling reaction, the preparation of alkoxy radicals from nitrites (the first 'Barton reaction') and their use in syntheses, the free radical deoxygenation reaction (Barton–McCombie reaction), and the free radical decarboxylation reaction (the third 'Barton reaction'). As one expects from this author, the chapters are written from a very personal standpoint and are enriched by many anecdotes. In Chapter 4, for example, we learn how important a role the game of bridge can have in the discovery of new reactions. The lectures reproduced here are of a quality to stand alongside Sir Derek's talk on the subject "How to Win a Nobel Prize".

The book makes absorbing reading, and (especially in its paperback form) would while away the travelling time in tram, bus, or plane in a very enjoyable way.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Review Editor, Dr. Ralf Baumann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Supramolecular Architecture. Synthetic Control in Thin Films and Solids. (ACS Symposium Series, Vol. 499.) Edited by *T. Bein*. American Chemical Society, Washington, DC, 1992. XI, 441 pp., hardcover DM 172.—ISBN 0-8412-2460-9

This book is an invaluable resource for those interested in many aspects of porous solids and thin-films synthesis—especially researchers concerned with inclusion or guest–host chemistry. The scope is broad and extremely well-rounded; the editor is to be commended on all aspects of this volume, from the quality of the authors he has attracted to the uniformity of the text, and especially for the inclusion of a very comprehensive index. This latter feature greatly enhances the utility to both the casual reader and the more dedicated user seeking specific material.

The chapters on thin-film synthesis cover self-assembled monolayers of alkanethiols on metal surfaces studied at a fundamental structural level (Whitesides et al.), while synthetic approaches and detailed characterization of self-assembled layers of metal complexes (Ru diimines, Zr phosphonates) are also described in detail. Rieke et al. describe the fascinating concept of biomimetic thin film synthesis, in which organic functionalized surfaces act as a mimic of nucleation proteins designed to direct and control mineral deposition during the formation of bone, shell, etc. in living systems. A major potential for this kind of approach is to use the directing effect of a derivatized surface to produce new materials and composites, and preliminary data are presented here. Finally, a nice review by Parkinson describes the use of scanning tunneling microscopy and atomically flat surfaces to create nanoscale surface modifications and patterning.

The increasingly fashionable area of "soft chemistry" as a new route to solid materials or new phases of known materials is covered in articles by Rouxel et al. (layered solids such as iron phosphonates) and Kaner et al. (MoS_2, ZrN). Pillared clays and related materials for use as catalysts for bromide to nitrile, thiocyanate, sulfide and ether conversions are described by Pinnavaia et al., with high activity ascribed to the stabilization of an organic/aqueous interface on the surface of the clays. Three consecutive chapters describe the use of layered and/or crystalline hosts for polyethers and polyimines to produce ionic conductor materials. The background information provided here, coupled with the authors' own work, provides a nice succinct introduction to this important area.

The remainder of the book is dedicated to three-dimensional frameworks and amorphous networks, a large fraction using zeolite host materials but also covering other microporous nets such as the $Cd(CN)_2$ system. Bein's chapter on clusters, quantum dots, and polymers is a fitting complement to the work presented by other authors on similar themes, providing a wide-ranging yet very readable account of the use of nanovessels as reaction media. Mallouk's work on self-assembled electron transport chains in zeolites is an elegant example of how these principles of zeolite inclusion chemistry can be exploited to help address the problems of photosynthesis mimics. The final two chapters on the production of sol–gel derived glasses are excellent reviews of this exciting area, not only giving background information but also conveying a fine sense of just how versatile this approach can be for the production of functional composite materials and films (e.g. enzyme derivatized materials or glasses for nonlinear optics).

In summary, this book presents a comprehensive overview written in short sections which whet the appetite for further details. It is a must for anyone even remotely interested in inclusion type phenomena, and for those seeking an introduction to the area I can think of no better way to get the feet wet.

Electrochemical and Electrocatalytic Reactions of Carbon Dioxide. Edited by *B. P. Sullivan, K. Krist* and *H. E. Guard*. Elsevier, Amsterdam, 1993. XVI, 298 pp., hardcover HFl 340.00.—ISBN 0-444-88316-9

The use of carbon dioxide as a source of carbon for chemical reactions in the laboratory or in industry is a highly topical area of research which is of great interest both environmentally and economically. Because of the thermodynamic stability of the CO_2 molecule it is necessary to supply the reaction system with energy by thermal, chemical (through an energy-rich substrate), electrical, or photochemical means. The two last-named methods have attracted growing interest in connection with the development of alternative energy sources, and therefore one especially welcomes this attempt by the editors B. P. Sullivan, K. Krist, and H. E. Guard to put together an account of the present state of research in this field. Regrettably, they have not entirely succeeded in this aim.

The book is a collection of eight review articles in which the respective authors describe their own areas of research and report results from their and other groups' work. The introductory chapter by F. R. Keene is concerned with thermodynamic aspects of the use of CO_2 as a starting material for synthetic purposes, and with the bonding of CO_2 to transition metals, but contains little that has not already been covered in previous reviews. Moreover, the detailed treatment of reactions between CO_2 and transition metal complexes seems superfluous, since the following chapter by C. Creutz is entirely devoted to this subject, giving a detailed survey of the methods of preparation, bonding characteristics, and spectroscopic properties of CO_2 complexes. Methods for detecting and identifying CO_2 adducts are also briefly discussed. However, the widening of the definition of 'CO_2 complexes' to include compounds formed by the reaction of CO_2 with a ligand is unusual and seems rather artificial. Nevertheless, that does not detract from the favorable overall impression of this useful article. Next P. C. Ford deals with the water-gas shift reaction, centered on a discussion of mechanisms. However, it is doubtful whether this topic really deserved a chapter to itself in a book with the above title. In Chapter 4 scientists at the Solar Energy Research Institute review the prospects for electrochemical energy storage based on CO_2, then in Chapter 5 F. R. Keene and B. P. Sullivan return to the topic of transition metal catalysis. Here it would have been better to change the order of the chapters, and at the same time some overlapping of subject matter between Chapter 5 and Chapters 1–3 could have been avoided (e.g., compare p. 123 with pp. 11 and 22, and p. 130 with p. 12). Chapters 6 and 7 are concerned with the electrochemical reduction of CO_2 at metal electrodes; with a total of 118 pages they form the largest part of this book of about 300 pages. Unfortunately the authors get too much immersed in detail, especially in Chapter 6, and the reader will find it difficult to discern general features among the great mass of data, which are partly collected together in tables and diagrams with insufficient accompanying text. The book ends with a brief survey of photochemical and photoelectronic systems for the reduction of CO_2, by N. S. Lewis and G. A. Shreve of Caltech. It might have been helpful to have one or two formula schemes in this article, at least in the general introduction (in 24 pages there is not a single chemical formula!). However, this complex subject is explained in a clearly understandable way, and the published data are critically evaluated.

Unfortunately the book as a whole gives the impression that neither all the authors nor the editors have taken the necessary care with their tasks. For example, a good deal of overlapping could have been avoided by better coordination. Furthermore, in the age of the computer it should have been possible to produce the articles in a more visually appealing form and to ensure some degree of uniformity. Only C. Creutz (Ch. 2) knows how to present her contribution in a really clear and neat style. In contrast, even someone with excellent eyesight will find it scarcely possible to read Chapter 7 without using a magnifying glass.

However, more disturbing than these superficial defects are the many typing errors and inaccuracies that are scattered throughout the book. Even the list of authors at the beginning has not escaped intact. Often one finds that footnotes below tables have no corresponding symbol in the table itself (e.g., pp. 39, 40), and figures and equations are often wrongly numbered and/or do not match the corresponding mention in the text (pp. 176, 177). Sometimes the notation for physical quantities is not consistent, even within a chapter (e.g., pp. 155–160: λ_{el} and λ^{el}; p. 256: M_p and m_p), and one finds incorrect chemical equations (p. 135: Eqns. 24 and 25; p. 259: Fig. 13) or mathematical equations (p. 256: Eqn. 51), even at key points in the book. Just on pages 256 and 257 there are twelve (!) errors, some quite serious. Most annoying is the authors' lack of care in compiling the lists of references for the individual chapters. Some of the errors are of a kind that the interested reader can correct—for example, wrong spellings of names (p. 287: "Cruetz"), wrong years of publication (p. 214: "198" or "19678"), or incorrect literature references (pp. 142, 154)—but vigilance is to no avail when literature references in the text give numbers higher than any contained in the bibliography (as in Chs. 3 and 4).

The shortcomings described above might be partly excused if the articles were exceptionally up-to-date, but here we come to the book's most serious weakness, as all the texts appear to have been written as early as 1989 or 1990. Only the article by C. Creutz was revised and updated at the beginning of 1991, a fact that merited a special mention at the end of her contribution. This general lack of up-to-dateness no doubt explains why, throughout the book, only the reduction of CO_2 is

discussed, with no mention of the electrochemical method for forming C–C bonds, of which there have been numerous reports since 1989.

To summarize, a critical reader with lots of patience and tenacity can extract some interesting information and many useful ideas from this book. Despite the wide-ranging importance of carbon dioxide chemistry that is referred to in the preface, the editors have produced a book that is mainly of interest to the specialist or to the newcomer who is concerned with a relatively narrow, although important, specialized area. However, the main quality that such readers expect from a monograph is up-to-dateness. The contents of this book and the amount of care taken in its preparation seem inadequate to justify the price.

Chemistry of Iron. Edited by *J. Silver*. Blackie/Chapman & Hall, London, 1993. X, 306 pp., hardcover £ 69.00.—ISBN 0-7514-0062-9

It is not without some initial bias that one approaches a book of a mere 300 pages on the chemistry of iron. One inevitably thinks of the monograph on ruthenium by Seddon and Seddon, which is at least 1000 pages longer. The editor must have anticipated such a reaction, since he states in the preface that "[The book] is not designed to be a dictionary of iron compounds." Nevertheless, it is not exactly reassuring to discover that the book consists of eight articles of greatly differing lengths, from ten pages to about a hundred. This is not to say that a book suffers from having many authors, but it is generally recognized that it is difficult under such circumstances to produce a work that is a unified whole. The combination of differences in form and common subject areas means that overlapping is often unavoidable.

After these prejudiced remarks we return to the book itself. The introductory article, written by the editor J. Silver, is a brief (25 pp.) survey of the chemistry of iron, with examples corresponding to the different oxidation states. Many aspects are only briefly touched on, and thus the level does not extend beyond that of a standard textbook. The rather glib statement that iron occurs in oxidation states up to +8 is, fortunately, qualified a few pages later. The literature references, numbering more than 120, are certainly useful. On the next 15 pages F. J. Berry sets out to introduce the reader to the industrial chemistry of iron. This topic is better covered in "Greenwood and Earnshaw", and no more need be said about this chapter. In the next article E. Sinn has attempted to treat the inorganic chemistry of iron in a mere 25 pages. The lack of success is not entirely due to the shortness of the chapter. The treatment is very superficial. I have rarely come across a text containing so many errors and inaccuracies. The olivine and perovskite structures are confused, $FeCl_2$ is claimed to crystallize in the rutile structure, the "typical" spin state of iron(III) is given as $S = 3/2$, $[Fe(CN_6]^{4-}$ is described as the "ferrocyanide" ion, the author persists in writing "marcosite", and so on. Many compounds are simply ignored: the section on binary halides contains no mention of the fluorides nor of FeI_2. Also the treatment of the subject matter is not balanced; the reason for this becomes obvious on looking through the literature citations.

The longest article (about 90 pp.) is that by P. L. Pauson on organoiron compounds. More than 300 compounds are described under clearly arranged headings, with brief notes on reaction pathways and properties. A further positive feature is the bibliography of over 400 references, including some from 1992. One may question whether a book such as this should contain a separate chapter on spectroscopic methods. However, as there is one (10 pp., B. W. Fitzsimmons), it should certainly have included a few key results obtained by Mössbauer spectroscopy to emphasize the importance of this method, especially for iron studies. The next two articles ("Biological Iron", by J. G. Leigh, G. R. Moore, and M. T. Wilson, 55 pp., and "Models for Iron Biomolecules," by A. K. Powell, 25 pp.) illustrate the fact that in such a collection some overlapping is virtually unavoidable. Apart from that, the two articles together give a very up-to-date survey of the bioinorganic chemistry of iron. The last article by R. C. Hider and S. Singh on iron chelates of clinical importance is peripheral to the book's theme, but nevertheless interesting. The authors describe various multidentate ligands of importance in therapy based on iron chelates, together with their applications, effectiveness, and side effects.

Who ought to buy this book? Although the preface mentions advanced students of all related scientific disciplines, it is too expensive to be recommended for these in its present form. Some of the articles make the book a useful addition for libraries to extend and update their coverage, but here too there is cost-cutting. I regret to say that, despite its attractive silver binding, this book is unlikely to have a glittering future.

Siegfried Pohl
Fachbereich Chemie
der Universität Oldenburg (FRG)

Photodissociation Dynamics. (Series: Cambridge Monographs on Atomic, Molecular and Chemical Physics, Vol. 1. By *R. Schinke*. Cambridge University Press, Cambridge, 1993. 417 pp., hardcover £ 50.00.—ISBN 0-521-38368-4

This book is concerned with the dynamics of photochemical processes, an area of physical chemistry which is of very wide interest. It has undergone rapid development in recent years, owing to the availability of ever more powerful laser systems, new experimental techniques, and new advances in theoretical chemistry. Schinke has written a book which succeeds well in every respect. It is intended not only for specialists with experience in this area but also for advanced students interested in this topic, who will find in it a wealth of relevant information. However, the author's aim is not to give detailed accounts of new experimental methods and results; instead the emphasis is on applying the methods of theoretical chemistry to describe photochemical dissociation processes.

Mathematical equations are limited to those that are absolutely essential, and this will undoubtedly make it much easier for many readers to digest the book. Another positive feature is that instead of reviewing all the reported work on a particular topic, the discussion of experimental and theoretical results is almost always based on a few small model systems (H_2O, H_2O_2, H_2S, ClNO, and CH_3ONO). It is entirely sensible and justifiable to limit the discussion to these model systems, especially as many of the processes described apply equally to larger systems. On the other hand, the bibliography is very extensive (over 750 references), affording easy access to the original publications.

The structure of the book is briefly as follows. A detailed introduction emphasizing the practical questions that need to be addressed is followed by a chapter on light absorption and photodissociation. The next two chapters deal with time-independent and time-dependent quantum mechanical methods, then in Chapter 5 the author turns to the classical description of photodissociation. There then follow chapters on direct and indirect

photodissociation processes and the occupancies of the different quantum states of the dissociation products, which yield important information about the dynamics of such photodissociation processes. The author devotes special attention to dissociation processes in van der Waals molecules and vibrationally excited molecules, and to nonadiabatic processes. Lastly some recent experiments using ultrashort (femtosecond) laser pulses are described.

To summarize, this is a substantial work which is of a high standard throughout. It can be recommended unreservedly, not only for theoretically orientated chemists but also for experimentalists working in the fields of photochemistry, spectroscopy, or chemical kinetics, and for advanced students who wish to become involved in this interesting area of physical chemistry.

Biocatalysts in Organic Synthesis. (Series: Studies in Organic Chemistry, Vol. 46.) By *J. Halgas*. Elsevier, Amsterdam, 1992. XIV, 334 pp., hardcover $ 180.00.—ISBN 0-444-98698-7

Biocatalytic transformations have led to important advances in asymmetric synthesis, and have now become an indispensable part of the armory of methods in this field. Introductory surveys for nonspecialists are much in demand because biological catalysts occur as a wide variety of special types with unique characteristics and can be used in diverse ways, and because the original publications are scattered throughout many journals of different disciplines. By the nature of the book Halga's this review may be seen to some extent as a postscript to other recent reviews of monographs published on this theme in 1992 (L. Poppe, L. Novák, *Selective Biocatalysis*, VCH Verlagsgesellschaft, Weinheim, **1992**; K. Faber, *Biotransformations in Organic Chemistry*, Springer, Berlin, **1992**; reviews: *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 920; H. L. Holland, *Organic Synthesis with Oxidative Enzymes*, VCH Verlagsgesellschaft, Weinheim, **1992**; review: *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 622).

The present book of nine chapters begins with three introductory discussions, first about the fundamental nature of enzymic catalysts (Ch. 1, 12 pp., nomenclature, effects of solvent, temperature, and pH, inhibition), then about the forms in which they are used (Ch. 2, 33 pp., microorganisms and isolated enzymes in both free and immobilized forms), and thirdly about the basic principles of enzymic stereoselectivity (Ch. 3, 12 pp.). The main body of the book, on synthetic applications, begins with Chapter 4 ("Substitution Reactions", 12 pp.). Here the author collects together a miscellany of reactions using enzymes of widely different types (haloperoxidases, transferases, lyases) which can be formally classed as substitutions (methylation, halogenation, transglycosidation; however, glycosyl transferases are not included, despite the fact that an index entry leads one to expect this). Chapter 5 deals with additions at C=C and C=O bonds (21 pp., Michael addition, aldol addition, formation of cyanohydrins and acyloins). Chapter 6 is the longest (97 pp.) in accordance with the preparative importance of its subject, the various aspects of the conversion of esters by hydrolytic enzymes (transesterification, hydrolysis, formation of phosphate esters). Chapter 7 (20 pp.) is devoted to the analogous reactions of amides (including hydrolysis of nitriles). Finally, the last two chapters are focused on the wide range of preparative biocatalytic redox processes, and the methods needed to regenerate cofactors. Chapter 8 (28 pp.) describes the various types of enzymic oxidations of organic compounds (alcohols, amines to carbonyls, Baeyer–Villiger, hydroxylation, dehydrogenation, oxidation at heteroatoms; also included are preparative applications of galactose oxidase, which I did not find in the pertinent monograph by Holland mentioned above). Chapter 9 (65 pp.) concentrates on reductions (mainly of C=O bonds, including reductive amination, but also reduction of C=C, NO_2, and other groups). At the end of the book is a detailed bibliography (939 references extending up to the end of 1989; interestingly, reference [9] is to a monograph that has not yet been published!), together with separate lists of recommended further reading for each chapter (important original publications and recent review articles extending up to 1992, comprising altogether an additional 121 citations). Lastly there is a six-page subject index.

It is already evident from the relative importance given to the individual chapters that Halgas, in noticeable contrast to the authors mentioned above, is especially concerned here to present the full breadth of available methods of enzymic catalysis and the individual potential for synthetic applications. On the one hand he devotes an appropriately large amount of space to the currently most important types of reactions (transesterification/hydrolysis, oxidation and reduction) and enzymes, while on the other hand, by giving a balanced broader survey of the variety of biotransformations used in organic synthesis, he undoubtedly succeeds better in providing readers with ideas for using enzymes to solve their own synthetic problems. Also very useful for beginners are the frequent cross-references to relevant technological processes, e.g., in the synthesis of amino acids.

The text is generously illustrated by formula schemes, although the formulas are unnecessarily large. This often spoils the continuity of flow schemes in relation to page breaks, especially annoying if one must turn the page to find the products of a reaction (pp. 15/16, 67/68, 199/200, 243/244, 285/286). Occasionally one wonders why trivial items (e.g., the depiction of α- and β-methyl glucoside to exemplify glycosides) are presented at the same level as more important matters.

The author's concern for variety and completeness, which is evident from the evaluations of different procedures, and from the wealth of experimental details given, may occasionally cause the reader to lose sight of the wider objective. Although some of the data are summarized in the form of tables, still more use of this form of presentation would definitely have greatly increased the usefulness of the book. Because little systematization has been brought to the varied collection of individual results and preparative details, many important facts will only become apparent after a more thorough reading, rather than allowing a rapid grasp of the salient points. Moreover, this is not helped by the fact that the index is too brief to do justice to the amount of information in the book. Although the reactions described can be well accessed by the many cross-references to the enzymes used to catalyze them, and those to the various microorganisms from which they are derived, this will only be of limited use as a searching aid to the synthetic chemist lacking relevant experience, who is primarily interested not only in reaction types but in compounds, their structural features, and specific conversions.

The book is largely free from typographical and factual errors; the few that remain are of an obvious kind which serve to entertain rather than cause problems, and one is content to overlook them. (Examples: on p. 72 di*chloro*fumaric acid supposedly splits off HF, and on p. 104 an *ee* value of 98% is given for cyclopropanol.) On the other hand it was an-

noying, especially in a fairly expensive book, to find that the review copy had printing defects on several pages, where multiple printing had produced shadow characters making the text difficult to read.

Although the material in this book by Halgas is not especially up-to-date, its particular strength lies in providing a comprehensive and detailed account of enzymic methods in organic synthesis. Thus it is suitable both as an introduction to preparative biocatalysis and as a permanent reference source for research chemists and lecturers with interests in this field.

Liquid Crystal Polymers. (Series: Speciality Polymers. Series editor: *J. M. C. Cowie.*) Edited by *N. A. Platé.* Plenum, New York, 1993. 438 pp., hardcover $ 110.00.—ISBN 0-306-44219-1

This book consists of ten chapters in which twelve Russian authors summarize the rapid developments that have occurred in the field of liquid crystal polymers in the last 15 years or so. Especially noteworthy is the very good coordination that has been achieved between the various specialists with regard to content, consistent use of symbols, and form of presentation. Each chapter has a short introduction linking it to the other authors' contributions and briefly describing the historical development. On the whole the editor has succeeded well in ensuring that the individual authors' reviews of progress in liquid crystal polymers are highly informative and critically presented. It is entirely appropriate that in this area of research the Russian literature should be given special emphasis, as much of it is not sufficiently well known in other countries. However, it must be noted less favorably that there are only sporadic references to work published from 1987 onwards. Brief descriptions of the ten chapters follow.

Chapter 1: Statistical physics of liquid crystalline order in polymeric systems (A. R. Khoklov, 38 pp., 139 refs.). Theoretical models for both rigid and flexible polymers are critically discussed with references to the original papers. Melting behavior and elastic and rheological properties are treated in rather more detail. This chapter provides the fundamental basis for the following chapters. Chapter 2: Phase equilibria in polymer systems with liquid crystalline phases (S. P. Papkov, 32 pp., 58 refs.). After a general classification of the types of phases and explanations of the meaning of thermotropic and lyotropic phases, the author concentrates mainly on the solution behavior of polymers with rigid chains. The predictions of several different models are compared. Chapter 3: Molecular structures of polymers with mesogenic groups (I. N. Shtennikova, 54 pp., 111 refs.). Different conformations are discussed, and the implications in relation to streaming birefringence and the Kerr effect are briefly considered. This is followed by a discussion of these effects as observed in lyotropic polymers and in polymers with main and side chains, from the standpoints of different theories. Chapter 4: The mesomorphic state of polymers with flexible chains (Yu. K. Godovskii and V. S. Papkov, 38 pp., 93 refs.). Various experimental results on linear polyorganosiloxanes, polyphosphazenes, and cyclolinear polyorganosiloxanes are summarized and evaluated. Chapter 5: Thermotropic liquid crystal polymers with mesogenic groups in the main chain (S. S. Skorokhodov, 30 pp., 82 refs.). Continuing the theme of Chapter 4, syntheses of polyesters, polyethers, and polyurethanes are described. Special attention is devoted to the use of texture observations to recognize the liquid-crystalline state, and to the detection of order. The effects of the previous history of the polymer on its physico-chemical properties are discussed. Chapter 6: Comb-like liquid crystal polymers (V. P. Shibaev, 57 pp., 69 refs.). V. P. Shibaev, one of the 'fathers' of polymers with liquid-crystalline side chains, discusses some of his areas of research: methods for the synthesis of polyacrylates, polymethacrylates, polyesters, and polypeptides with various liquid-crystalline side groups. Topics receiving special attention are the glass transitions of the polymers, and related discussions regarding the thermal equilibrium, the effects of chemical variations (including the degree of polymerization) on phase transition temperatures, structural aspects of the phases, and ferroelectric polymers. The survey of nematic polymers and the comparison with smectic polymers in this chapter are some of the most valuable sections of the book. Unfortunately it has only been possible to give a hint here of the start of the rapid developments in the field of elastomers that have occurred in the last few years. Chapter 7: Liquid crystal polymers of the cholesteric type (Ya. S. Freidzon and V. P. Shibaev, 52 pp., 87 refs.). By limiting the topic area to be covered, the authors have been able to give a detailed and comprehensive treatment which is well worth reading, even by specialists. Chapter 8: Structural transformations of thermotropic liquid crystal polymers in electric and magnetic fields (R. V. Talroze and N. A. Platé, 36 pp., 67 refs.). Starting from the fundamental principles, the authors deal mainly with electrooptical effects of dielectric and hydrodynamic origin, and with induced phase transformations and memory effects (information storage). This section should be especially useful to technologists with interests in this area. Chapter 9: Rheological properties of liquid crystal polymers (B. G. Kulichikhin, 44 pp., 119 refs.). The theoretical and experimental aspects of polymer solutions and melts are treated comprehensively. The author also briefly discusses some hitherto unsolved experimental problems and potential technological applications. Chapter 10: High-strength and high-modulus fibers from liquid crystal polymers (A. V. Volokhina and G. I. Kudryavtsev, 36 pp., 94 refs.). The authors discuss the technology and characterization of Aramid fibers, ultra-high-modulus fibers made from heterocyclic monomers, and lyotropic polymers, and predict a bright future for such materials.

The book can be recommended for everyone with interests in mesomorphic phases, and for those concerned with new developments in electrooptics, information storage, sensor technology, and fibers research.

Chirotechnology. Industrial Synthesis of Optically Active Compounds. By *R. A. Sheldon.* Marcel Dekker, New York, 1993. 423 pp., hardcover $ 145.00—ISBN 0-8247-9143-6

Does stereochemistry have any particular implications for the design of an industrial chemical process, and if so, what methodologies with scale-up potential are available for efficient and successful manufacturing of stereoisomers? This simple and straightforward two-fold question well reflects the tremendously increased importance and awareness of industrially related stereochemical issues over the past one or two decades. The three-dimensional concept of molecular species so brilliantly conceived in the mid-1870s and assuming a central role ever since, especially in organic

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1994* *0570-0833/94/0909-1013 $ 10.00+.25/0*

chemistry, has now definitely reached the "factory floor", driven to a large extent by the well-established fact that stereoisomers of many chiral compounds differ greatly in their properties when applied in, for example, the pharmaceutical and agrochemical areas, and thus need to be produced in high optical purity. Given this background, it is not entirely surprising to find that this "hot" topic has recently been a focus of attention in journals, books, symposia, and conferences.

It is in this context that one should view the present book entitled with the newly coined word "Chirotechnology" (introduced by Stinson in *Chem. Eng. News* **1992**, *70* (39), 46–79). The approach is comprehensive, aiming to give a broad overview of topics related to stereoisomerism. The ten chapters cover topics ranging from the early landmark discoveries and basic features in "Introduction to Optical Isomerism" via "Chirality and Biological Activity" to "Synthetic Methodology" followed by "Fermentation Processes", "The Chirality Pool", "Racemate Resolution via Crystallization", "Enzymatic Transformations", and "Catalytic Asymmetric Synthesis" up to the present state of the art, ending with about 40 pages on "Industrial Processes", and a short "Epilogue" offering an outlook at possible future developments. Unfortunately the general impression is not very favorable. Firstly, the industrial connection in the methods and processes described is rather feeble, in contrast to the expectation raised by the book's title (which is quite surprising considering that the author has a background in industry). Secondly, more emphasis should be placed on the overridingly important quality aspects (at least for pharmaceutical products), from both the chemical (e.g., residual amounts of transition metals) and optical purity points of view. Thirdly, there are many printing errors (due to the lack of proper proofreading?).

The arrangement of the contents resembles a catalogue in which many methods are presented in a rather superficial way, without enough detailed discussion and in-depth analysis on matters such as process technology and equipment characteristics, comparisons of product outputs per unit reactor volume, process safety, and environmental impact (e.g., by solvents and other waste streams). A recently published "competitor" book (Collins, Sheldrake, Crosby, eds., *Chirality in Industry*, Wiley, 1992) clearly gives a more pronounced industrial edge to the subject. Furthermore, it would be interesting to see some figures comparing the costs of attaining specified optical purities by different methods; and why not give the reader a feeling for the cost increase one would face when shifting from a racemate to a highly enantiomerically pure product? (an industrial factor of great significance indeed!). The ongoing, more or less worldwide regulatory activities in this area constituting a driving force for the industry to pursue the route to stereochemically purer and purer compounds (of course with a concomitant price increase for the final product) should be discussed in more detail than the mere page (69) devoted to the subject.

To name but a few of the flaws found throughout the book, one could mention the structure of Mosher's acid (p. 32) which besides being totally wrong also contains a pentavalent carbon (!), missing heteroatoms (p. 125: nitrogen at C-7 of cephalosporin C; p. 161: carbonyl oxygen; p. 374: penem sulfur and monobactam nitrogen), missing carbon fragments in the molecular backbone or as substituents (p. 131: a propionic acid product is depicted instead of a butyric; p. 390: a five-carbon carbohydrate product instead of one with six), mix-up of formulas (p. 147: D-sorbitol and D-mannitol should change places), the frequent usage of "propanol" for the famous beta-blocker instead of the correct spelling propranolol. In order to save space, unnecessary repetition of information should be avoided, a point which in the present case can be exemplified by a number of more or less identical reaction and formula schemes (p. 59 vs. p. 365; p. 95, Fig. 3–23 vs. p. 226, Fig. 7–12; p. 95, Fig. 3–24 vs. p. 227, Fig. 7–13). Finally, the erroneous statement on page 125 that only penicillins structurally modified at C-6 are useful in therapy ignores the important class of C-2 carboxy-substituted ampicillin pro-drugs (e.g., bacampicillin) produced on the multi-ton scale.

The literature coverage comprised of some 700 references seems to be fairly well updated through 1991; work from 1992 appears only occasionally. Again, one can complain about misspelled author names and errors in volume number and year of publication, but what is even more annoying is the lack of consistency in using both inclusive pagination and first page indication.

In conclusion then, the shortcomings pointed out above need to be corrected in a future edition before this timely book can be recommended for its intended use by chemists in academia at more advanced undergraduate or graduate stages and in industry.

Chemical Analysis of Inorganic and Organic Surfaces and Thin Films by Static Time-of-Flight Secondary Ion Mass Spectrometry (TOF-SIMS)

Alfred Benninghoven*

By using mass spectrometry to analyze the atomic and molecular secondary ions that are emitted from a solid surface when bombarded with ions, one obtains detailed information about the chemical composition of the surface. A time-of-flight mass spectrometer is especially suitable for the analysis of secondary ions because of its high transmission, high mass resolution, and ability to detect ions of different masses simultaneously. By using a finely focused primary ion beam it is also possible to analyze microareas and generate surface images with a lateral resolution of 0.1 μm or less. Static time-of-flight secondary ion mass spectrometry (TOF-SIMS) allows monolayer imaging and local analysis of monolayers with high sensitivity, a wide mass range, high mass resolution, and high lateral resolution. Besides information on elements and isotopes, the technique yields direct information on the molecular level and can also be used to analyze surface species of high molecular mass that are thermally unstable and cannot be vaporized. The method can be applied to practically all types of materials and sample forms, including insulators in particular. In this article the basic principles of TOF-SIMS are explained, and its analytical capabilities for both large-area and imaging applications are illustrated by examples. These include silicon surfaces (both uniform and structured), thermally unstable organic molecules on surfaces, synthetic polymers, and synthetically prepared molecular surface films, particles, and fibers. Emitted neutral particles can also be analyzed by post-ionization with a laser, and the possibilities of this technique are discussed.

1. Introduction

1.1. The Scientific and Technical Importance of Solid Surfaces

Many of the technically important properties of solid materials are surface properties and are essentially determined by the chemical composition and structure of the uppermost layer of atoms or molecules. Examples of such properties are adsorption behavior, chemical reactivity, frictional and wear properties, wettability, adhesion, and biocompatibility. Surfaces are therefore of central importance in nearly all areas of advanced technology, in micro- and nanoscale technologies, in microelectronics, in medical technology, and in biotechnology, as well as in chemistry, vehicle manufacture, and mechanical engineering. Accordingly, the study of the relationship between the chemical composition or structure of a surface and the resulting physical and chemical properties is a central theme of basic research.

For both technical applications and scientific studies it is essential that solid surfaces are prepared and modified in a controlled way. Methods used for the modification and structure control of surfaces include not only purely chemical processes but also various physical techniques such as irradiation with ions, electrons, and photons, and treatment by plasmas.

1.2. Surface Analysis

Effective and powerful methods for surface analysis are necessary for basic research on solid surfaces as well as for technical applications. These analytical methods must be capable of giving detailed information, particularly about the chemical composition in the region of the uppermost atomic or molecular layer, since this essentially determines the physical and chemical properties of the surface.

Selective surface sensitivity is only one of several characteristics necessary for a method to be used for the chemical analysis of surfaces. In addition, the method must be capable of detecting and distinguishing between all elements, including hydrogen, and their isotopes. Also, because of the growing importance of molecular surfaces, it should yield significant information on the molecular level. Since many surface properties can be drastically altered by minute concentrations of certain surface constituents, a surface analytical method must be highly sensitive. Surface constituents are often distributed nonhomogeneously over the surface, for example in the case of a surface

on which a lateral structure has been deliberately created, or where there are natural surface inhomogeneities such as those that occur in corrosion processes, etc. Thus, the method must also have a high lateral resolution combined with high sensitivity and should be universally applicable to surfaces of widely different materials and forms. Lastly, the analytical measurements should be capable of yielding quantitative results, if necessary with the help of external or internal standards.

The methods currently used for surface analysis of solids are nearly all based on energy or mass analysis of electrons, photons, or atomic or molecular components that are emitted from a surface when suitably stimulated.[1] Those that are most important by virtue of their breadth of applicability are Auger electron spectroscopy (AES) and X-ray photoelectron spectroscopy (XPS or ESCA). In AES, surface atoms are excited by electron bombardment so that they emit Auger electrons, which are characteristic of the element concerned. By analyzing their energies one can directly identify the excited surface atoms. In the case of XPS (or ESCA) the surface elements are identified from the energy distribution of the photoelectrons that are emitted when the surface is irradiated by X-rays.

For both techniques the depth analyzed is on the order of a few atomic layers. Both methods give quantitative results. The detection limits are about 10^{-2} of a monolayer for XPS and 10^{-3} of a monolayer for AES. Neither of these methods can be used to detect hydrogen or distinguish between isotopes. Only XPS, through the well-resolved energy distribution of the photoelectrons, yields information about the chemical environments of the emitting atoms; this allows one to detect specific functional groups but not to identify organic molecules, especially when these are large. Several other methods, such as high-resolution electron energy loss spectroscopy (HREELS) and infrared (IR) spectroscopy, also yield a certain amount of information on the molecular level by detecting functional groups, but these too are unable to identify molecules, especially larger ones.

Electron microprobe analysis and the various nanometer probe techniques, such as scanning transmission microscopy (STM) and atomic force microscopy (AFM), also fail to meet the criteria listed above for surface analytical methods. Along with other failings electron microprobe analysis has too great a depth of analysis (about 1 μm),[2] while nanometer probes yield no chemical information.[3]

With regard to the requirements demanded of a surface analytical method, mass spectrometric methods have considerable advantages. They can detect all elements, distinguish between isotopes, yield detailed information about molecules, and are extremely sensitive, even quantitative when standards are used. In principle, therefore, they offer the basis for extremely effective techniques for the analysis of solid surfaces, provided that the surface species can be converted into free ions.

1.3. Surface Mass Spectrometry

Analysis and identification by mass spectrometry is possible only for free ions in the gas phase. Thus two central problems must be solved for any kind of surface mass spectrometry: firstly, the surface constituents to be identified must be transformed into the gas phase, and secondly, these must be ionized. Furthermore, in the case of molecular surface constituents these two operations must be performed in such a way that the probability of fragmentation is acceptably low. The energy needed can in principle be supplied by heating, by applying a strong electric field, or by bombarding the surface with electrons, atomic or molecular particles, or photons. However, most of these methods of excitation are unsuitable for surface analysis. Heating a surface that is to be analyzed will in general cause large changes in its chemical constitution. The detachment and ionization of surface particles by an electric field requires extremely high field strengths which can only be produced at a pointed tip with a very small radius of curvature. The desorption of ions by electron bombardment only occurs very selectively for certain types of surface species in particular bonding situations.

In contrast, bombardment with fast ions or neutral particles,[4] or irradiation with laser light of sufficient intensity[5] results in the removal of material from any type of solid surface. Not only neutral particles but also positive and negative ions are emitted. However, controlled removal of surface material in the monolayer and submonolayer regime, with lateral resolution in the submicron range, in a way that is independent of material type, is only possible with a beam of particles, not with a laser. This is because of the different nature of the energy transfer process from the primary beam to the solid surface, and the difference in the focusing capability of ion beams, which extends down to less than 50 nm; with a laser beam it is very difficult to achieve less than 1 μm.

Alfred Benninghoven was born in 1932 in Frankfurt am Main. He studied physics and mathematics at the Universities of Cologne and Paris from 1952 to 1959. He earned his Ph. D. in physics in 1961 for his research on the flow behavior of alkali metal vapors under ultrahigh vacuum. In 1963 he habilitated at the University of Cologne for his work on the energy distribution of vaporized metal atoms. He accepted a chair for experimental physics at the University of Münster in 1972. His research is focused on the interaction of ions with solid surfaces and the development of surface analytical methods, instruments, and applications, in particular for secondary ion mass spectrometry.

All surface mass-spectrometric methods are in principle material-consuming (destructive) forms of analysis, in which one sacrifices at least those particles that are detected by the mass spectrometer. The total amount of substance available for the analysis is thus limited to the number of atoms or molecules present in the top monolayer of the area that is analyzed. For an area of 1 μm^2 this is somewhere on the order of 10^6 particles (Table 1). When one also takes into consideration that the ionization probabilities for most surface constituents are less than 10^{-4}, it is immediately obvious that for an effective surface analysis one needs a mass spectrometer that detects practically all the ions generated.

Table 1. Order of magnitude of the numbers of particles and amounts of substance in monomolecular films.

Area	1 cm^2	1 mm^2	10 μm^2	1 μm^2	0.1 μm^2
Number of particles	5×10^{14}	5×10^{12}	5×10^8	5×10^6	5×10^4
Amount of substance	1 nmol	10 pmol	1 fmol	10 amol	0.1 amol

The mass spectrum of a mixture of organic molecules—for example, of polymers—can consist of many hundreds or thousands of lines, whose distribution is at first unknown. Thus one needs a wide mass range and high mass resolution, and furthermore it is essential that all ions generated are detected. Consequently, instruments employing a magnetic sector field, and likewise quadrupole spectrometers, are less than ideal as surface mass spectrometers, because of their limited mass range, low transmission, and sequential mass scanning mode. Ion cyclotron resonance mass spectrometers have only a very limited potential for this purpose, owing to their restricted dynamic range, the requirement that the molecular ions must remain stable for a significant time, and the experimental limitations that apply as a consequence of the strong, homogeneous magnetic field required in the sample region. In contrast to these, time-of-flight mass spectrometers offer an almost ideal solution to the requirements for surface mass spectrometry.

From these considerations it can be seen that time-of-flight mass spectrometry of secondary ions generated by bombardment with primary ions is a very effective and universally applicable method for the chemical analysis of surfaces.[6, 7] During the last ten years time-of-flight secondary ion mass spectrometry (TOF-SIMS) has undergone impressive developments. The instrument technology and knowledge of secondary ion emission behavior for a wide variety of material types have now advanced to an extent that allows local monolayer analysis or monolayer imaging of nearly any kind of solid surface with high sensitivity. Detailed information on the molecular level, even for high molecular weight materials, can be obtained with high mass resolution and lateral resolution. Practically every type of material in virtually any form, including especially insulators, is accessible to this method.

In the following sections the fundamentals of time-of-flight secondary ion mass spectrometry will first be described briefly, including the process whereby secondary ions are generated and the principle of time-of-flight mass spectrometry. Then the broad scope of the analytical applications will be illustrated by discussing some typical examples.

2. Basic Principles of Time-of-Flight Secondary Ion Mass Spectrometry (TOF-SIMS)

2.1. Sputtering and the Formation of Secondary Ions

2.1.1. Interaction of Fast Ions with a Solid Surface

When fast ions hit a solid surface they penetrate into the surface region to an appreciable depth.[8] For example, when a metal surface is bombarded with a perpendicular beam of Ar^+ ions with energies in the keV range, the mean depth of penetration is a few tens of nanometers. As it penetrates into the solid the primary ion transfers its kinetic energy to the atoms of the solid in a succession of individual collisions. Through subsequent collisions some of this energy can find its way back to the surface, where it may cause surface particles to be emitted (Fig. 1)[*]. Bombardment by the primary ions not only results in these becoming embedded in the solid near its surface (ion implantation), but also induces changes in the neighborhood of the primary ion tracks. For example, the crystalline or molecular structure may be altered (radiation damage), some of the surface particles may be removed by emission (sputtering), implantation in deeper lying surface regions may occur through recoil, or molecular constituents present at the surface may undergo fragmentation.

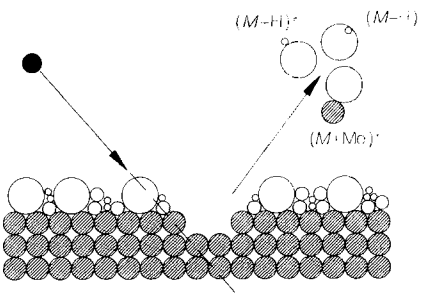

Fig. 1. Formation of secondary ions. When a metal surface Me (Ag, Au, Pt ...; hatched circles) covered by a monolayer of molecules M (white circles) is bombarded with a primary ion (black circle), secondary ions are emitted, typically including the quasi-molecular ions $(M + H)^+$, $(M - H)^-$, and $(M + Me)^+$. The neutral particles, fragment ions, and metal ions also emitted are not shown here.

In addition to these changes of the solid surface, various emission processes are observed. The emission of electrons and photons will not be discussed in detail here, since these processes yield only very limited information about the chemical composition of the emitting surface. The atomic and molecular surface constituents emitted as a result of primary ion bombardment are observed as neutral particles or as positive or negative secondary ions. These particles originate almost entirely from the uppermost layer of atoms or molecules, and therefore they yield direct information about its chemical composition. A fact of great importance for analytical applications is that even molecular surface constituents that are thermally unstable and cannot be vaporized are emitted from the surface as intact neutral particles and as positive or negative secondary ions. This phenomenon of the emission of intact molecular surface constituents, which was at first surprising, provides the basis for molecular surface analysis by SIMS.[9-11] All the surface processes initiat-

[*] In this article Me stands for metal and not for methyl.

ed by a primary ion (changes to the target and all types of emission processes) are completed within less than 10^{-12} s.

When secondary ion emission is used for surface analysis it is desirable that the information obtained should relate to the uppermost monolayer of the solid with as little modification as possible. Thus the total number of primary ions that hit the surface area to be analyzed must be low enough to ensure that the probability of a particular surface region receiving more than one primary ion is negligibly small (SIMS under "static" conditions;[11] see Section 3.1).

2.1.2. Quantitative Description of Sputtering and Secondary Ion Emission

To arrive at a quantitative description of sputtering and secondary ion emission we consider a surface constituent M (either a molecular surface constituent or an atomic species) which is present in the uppermost monolayer with a relative coverage θ(M) (see Fig. 1). The relative coverage θ(M) is the ratio of the number N of such particles present in the uppermost monolayer to the maximum number N_0 that the surface can accommodate in a complete monolayer [Eq. (1)].

$$\theta(\mathrm{M}) = \frac{N}{N_0} \tag{1}$$

The sputtering of a surface particle M can in principle be accompanied by conversion into any of a series of neutral or variously charged secondary particles X_1^q, X_2^q, ... X_i^q .... Here q denotes the charge state of the emitted secondary particle. In the case of a molecular surface constituent the series of species X_i^q will also include fragments of M. The sputtering cross section σ specifies the equivalent area of a monolayer that corresponds to the average number of particles of species M disappearing as a result of the impact of a single primary ion. The reduction of the relative coverage with time θ(M,t) caused by primary ions arriving at a constant rate of v ions per second per cm^2 is given by Equation (2) (see also Fig. 2).

$$\theta(\mathrm{M}, t) = \theta(\mathrm{M},0)^{-v\sigma t} \tag{2}$$

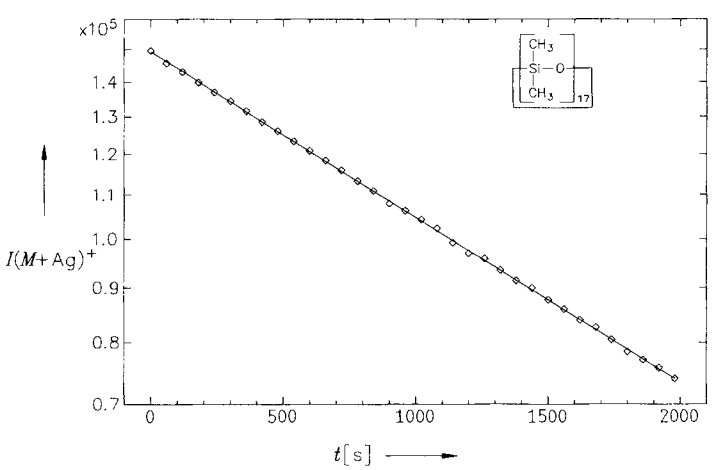

Fig. 2. Stripping of a monolayer of polydimethylsiloxane D17 (m(D17) = 1261u) from a silver substrate by a primary ion beam with a constant and uniform flux density v. The intensity I [cps] (counts per second) of the peak due to the quasi-molecular ion $(M + Ag)^+$ decays with time according to the relationship $I \propto \exp(-\sigma v t)$ [cf. Eq. (2)]. The sputtering cross section σ can be determined directly from the decay plot.

With these simplifying assumptions one can also define the following quantities:

- the sputtering yield Y_s(M), which specifies the average number of surface particles M that would disappear from a closed monolayer of particles of species M (θ(M) = 1) as a result of the impact of one primary ion;
- the secondary particle yield $Y(X_i^q)$, which specifies the average number of secondary particles of a given type X_i^q generated from a closed monolayer of particles M by the impact of one primary ion;
- the transformation probability $P(\mathrm{M} \rightarrow X_i^q)$, which is the probability that the disappearance of a surface particle M as a result of primary ion bombardment will lead to the emission of a given type of secondary particle X_i^q.

These quantities are related according to Equation (3). We

$$P(\mathrm{M} \rightarrow X_i^q) = \frac{Y(X_i^q)}{Y_s(\mathrm{M})} \tag{3}$$

also define the useful yield Y_u according to Equation (4), in which T_r is the overall transmission of the spectrometer.

$$Y_u(\mathrm{M},X_i^q) = P(\mathrm{M} \rightarrow X_i^q)T_r \tag{4}$$

2.1.3. Characteristic Features of Secondary Ion Emission

Secondary ion emission is essentially determined by the nature of the atomic and/or molecular species present at the surface. Conversely, therefore, the secondary ion spectrum enables one to draw direct conclusions about the chemical composition of the uppermost monolayer. The characteristic secondary ion emission spectra for different chemical environments have been investigated in detail for many types of materials, such as metals and semiconductors and their oxides, biopolymers, synthetic polymers, pharmaceuticals, and many other classes of organic compounds. The sputtering yields Y_s(M) for different metals have been found to be quite similar. In the case of bombardment with 10 keV Ar^+ ions, Y_s(M) is typically between 2 and 10.[8] For molecules, depending on the environment and on their nature and size, Y_s(M) can be over ten times greater than for metals. On the other hand, the secondary ion yields $Y(X_i^q)$ and the corresponding transformation probabilities $P(\mathrm{M} \rightarrow X_i^q)$ are much more strongly influenced by the chemical nature of the surface component M and its chemical environment. This matrix effect can cause considerable difficulties in quantitative surface analysis.

When the surface of a pure metal Me is bombarded with ions it emits, in addition to neutral particles, predominantly positive secondary ions Me^+. For most metals the secondary ion yields $Y(Me^+)$ are in the range 10^{-6} to 10^{-4}. $Y(Me^+)$ increases with decreasing ionization energy, and for alkali metals it can reach values approaching 1. The yields of cluster ions Me_n^+ generally fall off very rapidly with increasing n. On going from the metal to the oxide the emission of Me^+ ions is found to increase very sharply, by several orders of magnitude, but this is accompanied by only a relatively small change in the sputtering yield Y_s(Me). At the same time the emission of molecular ions with the general formula $Me_mO_n^+$ is observed. The dependence of this secondary

ion emission on the degree of oxygen coverage has been investigated in detail for many metals.[12, 13] These studies showed that the charge carried by an emitted cluster Me_mO_n is determined by its initial charge state in the oxide lattice at the surface. Thus, metal ions appear predominantly as Me^+, oxygen ions as O^-, and molecular cluster ions as negative ions in those cases where they contain more oxygen ions than metal ions. This conservation of the charge state during sputtering is also observed for other surface constituents, for example for inorganic and organic anion complexes, and has led to the proposal of a general model of "preformed" ions.[14, 15]

In the production of secondary ions from organic molecules, proton transfer and cationization (addition of a cation) both play dominant roles. In addition to the main quasi-molecular ions $(M + H)^+$, $(M - H)^-$, and $(M + \text{cation})^+$ that are formed by these processes, the secondary ion spectrum typically also shows characteristic molecular fragment peaks with quite high intensities. Cationization by Ag^+ ions is a particularly efficient process. This is the basis of a sensitive method for trace analysis of organic compounds, in which the molecules to be analyzed are sputtered from a silver surface on which they have previously been deposited as a monolayer or submonolayer (see Section 4.2).[9, 10, 16]

2.2. Time-of-Flight Secondary Ion Mass Spectrometry

2.2.1. Basic Principle

In secondary ion analysis with a time-of-flight spectrometer it is essential that the ions to be analyzed enter the flight path simultaneously or at least within the shortest possible time interval. To achieve this the area of the surface to be analyzed is bombarded with pulses of primary ions whose duration Δt_p is kept as short as possible (Fig. 3). All the secondary ions that are

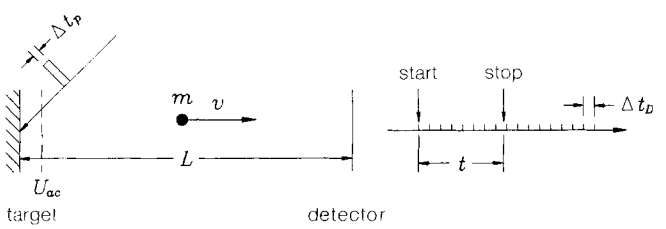

Fig. 3. Principle of a linear time-of-flight mass spectrometer (for explanation see text.)

generated almost simultaneously from one such pulse are then accelerated by passage through a fixed accelerating voltage U_{ac} before entering the flight path of length L. If we neglect the relatively small initial energy of the secondary ions, it follows that all the ions enter the flight path with the same kinetic energy. If T is the measured time of flight we then have the relationship shown in Equation (5).

$$\frac{m}{z} = \frac{2U_{ac}T^2}{L^2} \tag{5}$$

The mass resolution $\Delta m/m$ of a linear time-of-flight spectrometer as described here is limited by the primary pulse duration Δt_p, the time resolution Δt_D of the detection system, the initial energy ΔE of the emitted secondary ions, and the total flight time t, and is given by Equation (6).

$$\frac{\Delta m}{m} = \frac{\Delta E}{E} + \frac{2(\Delta t_p + \Delta t_D)}{t} \tag{6}$$

2.2.2. Practical Spectrometer Design and Performance Data

Figure 4 shows schematically the construction of a modern energy-focusing time-of-flight secondary ion mass spectrometer.[17] The instrument consists of three main components: the primary ion source, the accelerating and flight path system, and

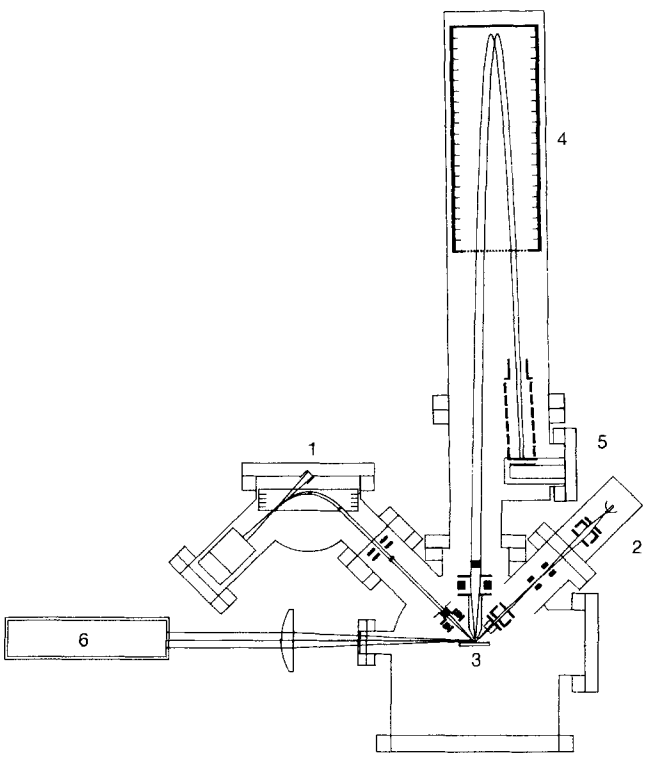

Fig. 4. Construction of a modern high-resolution time-of-flight secondary ion mass spectrometer. The system includes two primary ion sources giving different beam diameters, a pulsed, mass-separating electron impact ion source (1) and a pulsed, fine-focusing liquid metal ion source (2), as well as the target (3), a reflectron for energy focusing the mass-separated secondary ions (4), a detector (5), and a laser for post-ionization of emitted neutral particles (6).

the detector. The primary ion source produces mass-separated pulses of primary ions with a frequency of several kHz; this is achieved by pulsed 90° bending and subsequent compression of a continuous ion beam, which is generated, for example, by an electron impact ion source. This pulsed beam can then be focused by means of an ion-optic lens system to a diameter of less than 5 μm if required. If a liquid metal ion source is used instead, the pulsed ion beam can be reduced to a diameter of less than 0.1 μm.

The beam path contains several ion-optic elements: a beam extractor, an ion lens which focuses the ion beam onto the detector, and a reflectron with a retarding electric field, which has an energy-focusing function on the secondary ions and thus largely eliminates the adverse effect of their initial energy spread on the mass resolution. The detection system consists of a detec-

tor (combining a photoconverter electrode, channel plate, scintillator, and photomultiplier) and a counter giving high time resolution Δt_D [see Eq. (6)].

A spectrometer of this kind can be used in several modes. With a defocused primary ion beam one can record area-integrated secondary ion spectra, especially when high mass resolution is required. Local surface analysis can be performed by using a finely focused primary ion beam. By scanning such a focused beam over a particular area of the surface one can image the lateral distribution of mass-separated secondary ions. For nonconducting samples surface charge effects can easily be eliminated by injecting pulses of slow electrons between successive primary ion pulses.[18]

The performance of a time-of-flight secondary ion mass spectrometer is determined by the characteristics of the primary ion source, the flight path, and the detection system. The quality of the primary ion source is determined by the mass separation, the duration of the primary ion pulse, the average number of primary ions in a pulse, and the focusing of the beam. That of the secondary ion optical system and of the overall flight path is determined by the transmission efficiency and the energy focusing. Lastly, the quality of the detection system depends on its response probability, time resolution, dead time, and maximum data handling rate.[19]

3. Analytical Applications of TOF-SIMS

The main reasons for the remarkably wide range of applications of time-of-flight secondary ion mass spectrometry are its very high surface-specific sensitivity, its universal applicability to practically all types of materials and sample forms, and its ability to give direct molecular information through the emission of molecular ions. This combination of features yields information far exceeding that possible with previously available surface analytical methods.[20] There are four main modes of operation of TOF-SIMS: large-area surface analysis, surface imaging and microarea analysis, depth analysis, and trace analysis of individual substances.

3.1. Large-Area Surface Analysis

In large-area surface analysis the objective is to determine the chemical composition of the uppermost monolayer of a solid as completely as possible and with high sensitivity. For this the primary ion beam should bombard a relatively large area—between 0.01 and several mm^2. This means that the quantity of substance in the uppermost monolayer that is available for analysis and thus the number of secondary ions that can be generated is relatively large. A 1 mm^2 area of a monolayer contains around 5×10^{12} surface particles, which is on the order of 10 pmol (see Table 1). If one assumes a transformation probability of 10^{-4}, these particles can be converted into 5×10^8 analytically useful secondary ions X_i^q. It follows from this that the limit of detection should be less than 10^{-6} of a monolayer (1 ppm), which has been confirmed in practice.

To ensure that the secondary ion spectrum corresponds to the uppermost monolayer, which remains, as far as possible, unaltered by the ion bombardment, only a small fraction of this monolayer should be removed. Application of Equation (2) implies that for this "static" condition[11] the primary ion fluence vt must not be greater than several $10^{11}\,cm^{-2}$. If a value $\sigma = 10^{-12}$ is assumed for the sputtering cross section, about 90% of the analyzed surface should not be altered by the primary ion bombardment. For spectra obtained under these conditions typical recording times are on the order of one minute.

It is not only the uppermost monolayer that becomes altered or removed during ion bombardment. As the primary ions penetrate into the material they also cause severe radiation damage in the underlying layers, so that these can no longer be used for analysis, especially of molecular species. Because of this radiation damage it is not possible to determine molecular depth profiles by sputtering successive layers.

Large-area surface analysis is widely used for the characterization of virtually all types of technically important surfaces, for example in connection with their frictional, wear, corrosion, and adhesion properties, for the control of chemical and physical surface modifications, for identifying defects, for detecting and identifying trace contaminants, for the control of synthetically prepared molecular layer structures, etc.

3.2. Surface Imaging and Microarea Analysis

By reducing the diameter of the primary ion beam and scanning it over the surface region to be analyzed one can measure the lateral distribution of the secondary ion emission, and therefore that of the surface constituents responsible for the emission, with a lateral resolution determined by the beam diameter. The primary beam is positioned at a particular point on the sample surface for a short interval, and the spectrum is recorded and stored with the relevant lateral coordinates. Typical beam diameters vary from a few μm down to 50 nm. If, for example, the surface area analyzed is divided into 256×256 elements (pixels), this mode of operation requires that 65536 complete spectra must be recorded and stored. From these data one can then in principle construct an image for each secondary ion species or group of species showing the distribution on the surface. The recording time needed for such images can vary from a few seconds to several hours. By adding together all the spectra, or only those from a selected region of the imaged surface, one obtains a total spectrum. As another option, one can add together all the positive or negative secondary ions for each image point and thus obtain a total ion image. Images based on the ion-induced emission of secondary electrons can also be recorded by adding an electron detector near the sample. Total ion and electron images are especially useful for giving rapid information about the structure of a sample and for choosing the region to be analyzed or imaged.

Making the beam diameter smaller reduces the amount of substance available per image point in the uppermost monolayer, and thus also the total number of secondary ions that can be generated from the corresponding surface region. This in turn reduces the sensitivity and dynamic range for each individual image point. By subsequently adding together spectra from a sufficiently large surface region the sensitivity and dynamic range can be restored.

The equipment for surface imaging is more complex than that for large-area analysis, and the procedure is more time-consum-

ing. Nevertheless, it is indispensable for analyzing surfaces that are nonhomogeneous, whether by design or by their intrinsic nature, for example in applications in microelectronics and micromechanics, in the control of molecular surface films, and in the analysis of biological sections.

3.3. Determination of Depth Profiles

For small surface areas, for example in particle analysis, it is possible to remove many monolayers in an acceptably short time with a pulsed primary ion beam (dynamic SIMS); in this way one can determine local depth profiles. With a pulsed liquid metal ion source and a typical beam diameter of 1 μm, a primary beam flux of a few million ions per second can be achieved, giving a rate of material removal on the order of ten monolayers per second. However, because of the beam damage produced under these conditions, this dynamic mode of operation is only suitable for elemental analysis, not for molecular analysis. Greater flexibility in the determination of depth profiles is possible by using an additional sputtering ion source that operates continuously and allows rapid sputtering over a larger surface area.

3.4. Trace Analysis

SIMS can detect and identify extremely small amounts of unknown substances in the uppermost monolayer. Therefore the method can also be used for trace analysis, in particular of thermally labile organic compounds that cannot be vaporized. The substance to be analyzed is usually in the form of a solution obtained, for example, from chromatographic separation. To prepare the compound for SIMS analysis it must be applied as a monolayer or sub-monolayer onto a defined area of a suitable target. This can be achieved very simply by depositing a small quantity of the solution onto a suitable substrate with a micropipette and allowing the solvent to evaporate. If 1 μL of a 10^{-3} M solution is applied to an area of 10 mm^2 and uniformly distributed, a closed monolayer is produced. The substrate material is chosen so as to take advantage of the matrix effect, according to which the chemical environment greatly affects the secondary ion yield; by the suitable choice of substrate the yield can be optimized and stabilized. Noble metals, in particular silver, have been found to be especially good substrates.[9, 10] Firstly, they do not modify the molecules deposited on them, and secondly they give very efficient emission of cationizated molecular ions $(M + Me)^+$. This preparative technique has in practice proved to be remarkably simple, rapid, reproducible, and universally applicable. For thermally unstable organic molecules detection limits in the attomolar range (10^{-18} mol) have been achieved.[16]

The first successes in the trace analysis of nonvolatile organic compounds were obtained using quadrupole spectrometers, with consequent limitations on the accessible mass range, mass resolution, and sensitivity. By using a liquid matrix it became possible to employ sector field instruments. In this method the substance to be analyzed is incorporated into a liquid with a low vapor pressure, such as glycerol, in which it usually becomes concentrated at the liquid surface. During sputtering by ion bombardment more substance is supplied to the surface by diffusion from the bulk liquid. In this way the production of secondary ions is not confined to the uppermost monolayer, and a much greater number of substance-specific molecular ions can be generated, although a correspondingly larger quantity of the substance is consumed. This liquid SIMS technique has developed into a standard method of organic mass spectrometry, where it is called fast atom bombardment (FAB), both for historical reasons and because of the experimental details of the method.[21] However, the sensitivity that can be achieved in practice is several orders of magnitude less than that of TOF-SIMS (see Section 4.2), owing to the low transmission of sector field instruments operating at high mass resolution, and the usual sequential method of recording spectra.

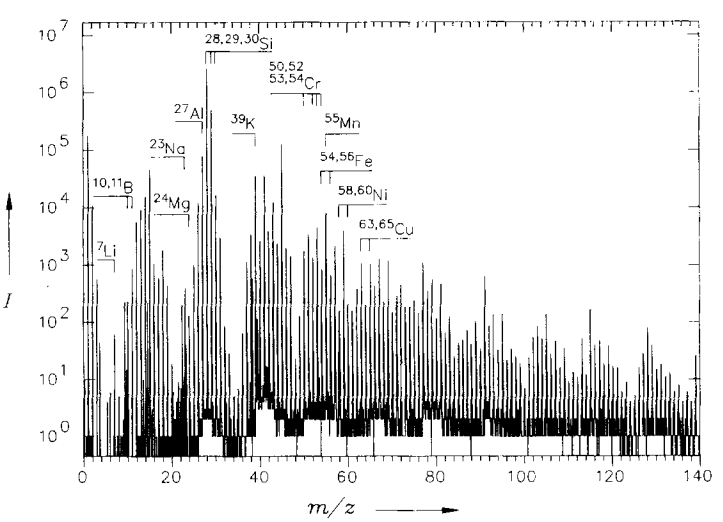
4. Examples of Applications

4.1. Surface Analysis of Homogeneous and Structured Silicon Wafers

Silicon is not only the most important material used in microelectronics, it also plays a key role in many other modern technologies, such as solar energy utilization, sensor technology, micromechanics, and nanotechnologies. Silicon surfaces have been studied in great detail with well-established surface analytical methods such as AES and XPS.[22] This section therefore concentrates on the new analytical possibilities opened up by TOF-SIMS by virtue of its high sensitivity and spatial resolution and its ability to yield information on the molecular level. Examples will be provided by analyses of silicon wafer surfaces that are contaminated, modified with molecular substances, or laterally structured.

4.1.1. Detection of Surface Contamination

The secondary ion spectra of oxide-covered silicon surfaces that have been stored in air (Fig. 5) are dominated by peaks due



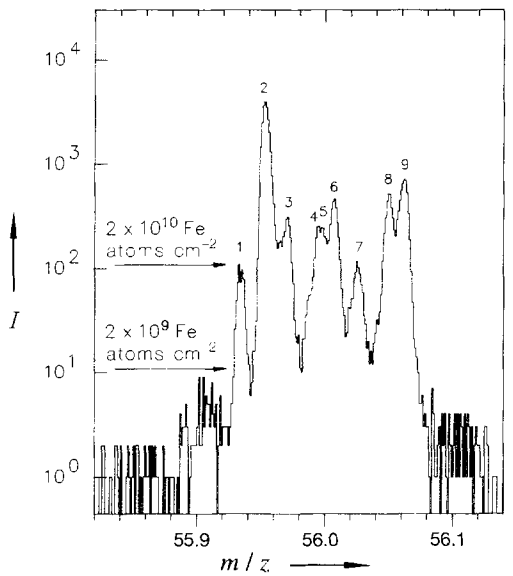


Fig. 5. Positive secondary ion spectrum in the mass range $m/z = 1$–140 for a silicon wafer stored in air. Hydrocarbon ions of the general formula $C_mH_n^+$ are found throughout the mass range. The spectrum shows an intensity range of six orders of magnitude. Additional Me^+ signals are labeled.

Peak no.	Empirical formula	Mass measured	Mass calculated
1	^{56}Fe	55.9341	55.9349
2	$^{28}Si_2$	55.9536	55.9539
3	$^{28}SiCO$	55.9707	55.9718
4	$^{28}SiCNH_2$	55.9952	55.9956
5	$^{29}SiC_2H_3$	55.9996	56.0000
6	$^{28}SiC_2H_4$	56.0074	56.0082
7	C_3NH_4	56.0252	56.0262
8	C_3NH_6	56.0499	56.0500
9	C_4H_8	56.0620	56.0626

Fig. 6. High-resolution positive secondary ion spectrum in the mass region $m/z = 56$ for the sample of Figure 5. The high mass resolution allows one to distinguish nine ion species (cf. table on the right). The positions of the maxima can be determined to an accuracy on the order of ppm, allowing identification of the molecular ions.

to $C_mH_n^+$ ions, which originate from monomolecular contamination layers. Because of the high intensity of these ions, other characteristic secondary ions of interest, such as those from metals, metal oxides, anion complexes, nitrogen-containing compounds, etc., can only be distinguished from hydrocarbon ions $C_mH_n^+$ of identical mass if lines of the same nominal mass are sufficiently separated from each other in the spectrum. Modern time-of-flight mass spectrometers are capable of the high mass resolution needed to achieve this, even in the low-mass region, as Figure 6 illustrates.[23, 24]

In the production of integrated circuit chips, contamination by metals, even at extremely low surface concentrations, can lead to high failure rates. It is therefore of great technical importance to have methods of the highest possible sensitivity for quantitatively detecting any metal contamination that might remain on a wafer surface after the various stages of cleaning and processing. For this reason the detection limits for metals that can be achieved with TOF-SIMS have been systematically investigated. With a primary beam diameter of 30 μm, limits of detectability down to 10^8 atoms per cm^2 have been achieved for metals (Table 2).[25] This corresponds to surface concentrations of less than 1 ppm. To achieve these sensitivities it is necessary to expose the silicon surface to a UV/ozone treatment before the analysis. This oxidizes the metal atoms present on the surface in a reproducible way, thus ensuring high and constant secondary ion yields (cf. Section 2.1.3)[15] and allowing the metals to be determined quantitatively with high sensitivity. With regard to sensitivity and lateral resolution, TOF-SIMS is now the most powerful method available for measuring metal contamination on semiconductor surfaces.

Table 2. Detection limits for various metals on a silicon wafer surface.

Element	Detection limit [atoms per cm^2]	Element	Detection limit [atoms per cm^2]	Element	Detection limit [atoms per cm^2]
Li	2×10^8	Al	3×10^8	Mn	4×10^9
B	2×10^8	K	2×10^{10}	Fe	2×10^9
Na	2×10^8	Ca	3×10^9	Ni	2×10^{10}
Mg	3×10^8	Cr	1×10^9	Cu	1×10^{10}

In the negative ion spectrum one finds, in addition to hydrocarbon ions $C_mH_n^-$, mainly atomic and molecular anions such as F^-, Cl^-, OH^-, CO_3^-, NO_3^-, and SO_4^-. Since the transformation probabilities for their formation are very high, the corresponding surface constituents can be detected down to levels below 1 ppm.[26] Surface constituents of higher molecular mass can also be detected with high sensitivity through their characteristic secondary ion emissions. For example, a silicon wafer surface that has undergone oxidation treatment by a CHF_3/O_2 plasma followed by inefficient cleaning emits $C_mF_n^-$ ions, which originate from plasma polymerization products left on the surface.

4.1.2. Surface Imaging

Figure 7a shows the low-mass region of the positive secondary ion spectrum of an Al/Ti/W structure on a Si test wafer, together with distribution images for ten selected secondary ions and groups of ions, and also the total ion image.[27] Each pixel corresponds to a surface area of about 1 μm^2. In addition to the ions of the main constituents Si, Al, Ti, and W, the positive ion spectrum also contains peaks due to hydrogen and oxygen compounds of these elements as well as hydrocarbon complexes. The images (Fig. 7b) give detailed information about the lateral distribution of the secondary ion emission and therefore of the corresponding surface species, for example the contamination by alkali metals (Na, K) in submonomolecular layers, and the effect of a pre-bombardment with primary ions (seen in the upper left region of the images, e.g. the aluminum image).

4.1.3. Surfaces with Molecular Modification and Lateral Structure

The chemical composition of a silicon surface, and therefore its physical and chemical properties, can be altered in controlled ways by appropriate surface treatments.[28] For example, in HF passivation the oxide layer of a silicon surface is removed, while at the same time a covering of SiH is applied, which is stable under atmospheric conditions and virtually prevents the growth of further oxide. A surface treated in this way is hydrophobic. In contrast, a high concentration of OH groups on a surface results in hydrophilic properties. The surface concentrations of SiH and SiOH can be determined directly by SIMS. The presence of the SiH complex is characterized, for example, by the production of SiH_n^+ ions ($n = 1$ to 3), whereas the SiOH complex gives $SiOH^+$ ions. Figure 8 shows the relationship between

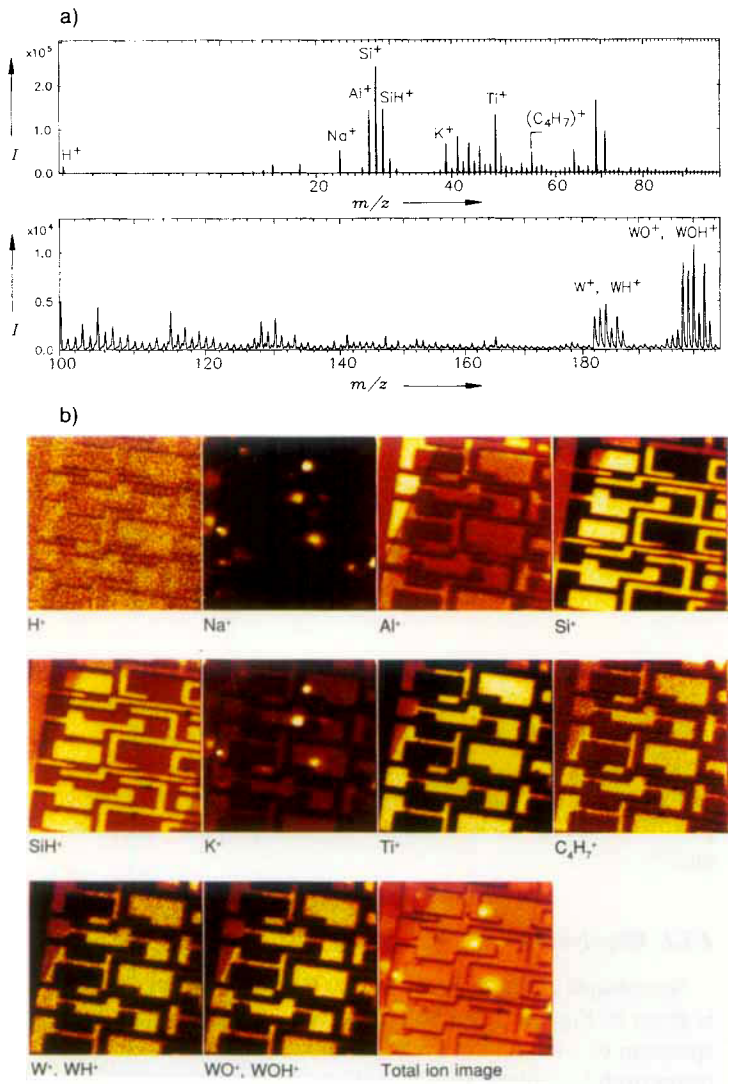

Fig. 7. a) Overall positive ion spectrum of a structured Si/Al/Ti/W test specimen, and b) images ($120 \times 120\ \mu m^2$, 128×128 pixels, 1800 pulses per pixel) showing the distribution of ten secondary ions and groups of ions. The sum image for all the secondary ions is also shown.

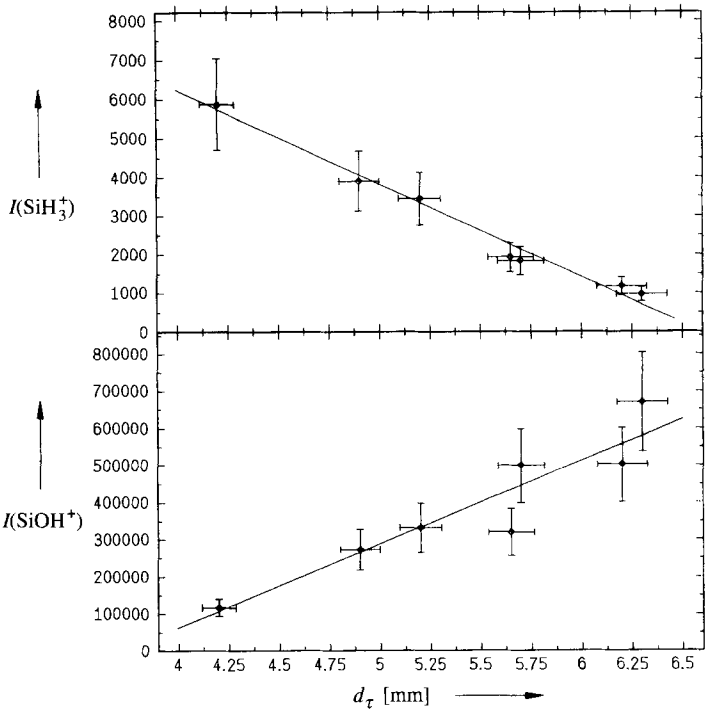

Fig. 8. Relationship between the wettability of a silicon wafer surface and the intensities of the secondary ion peaks for the SiH and SiOH complexes (SiH_3^+ and $SiOH^+$, respectively). The wettability is characterized by the diameter d_τ of a water droplet on the wafer surface.

the wettability of an HF-passivated surface and the emission of SiH_3^+ and $SiOH^+$ ions. The different concentrations of SiH and SiOH on the wafer surface were produced by exposure to UV/ozone for different lengths of time.

By chemical treatment of a silicon surface one can produce a closed monomolecular layer of trimethylsilyl groups, which emit characteristic secondary ions such as $Si(CH_3)_n^+$ $(n = 1-3)$.[29] One can produce a lateral structure in such a molecular monolayer by irradiating locally with electrons or UV light. Figure 9 shows the distribution images for various positive secondary ions emitted from a structured $Si(CH_3)_3$ monolayer.

The attachment of larger organic molecules to silicon surfaces can also be studied by secondary ion mass spectrometry. An example is the covalent linkage of various triethoxysilanes to SiOH groups,[30] and the subsequent attachment of further molecules. Various such systems have been studied in detail by TOF-SIMS, especially in connection with the development of biosensors and biocompatible surfaces.

In a similar way to studies of silicon surfaces, TOF-SIMS can be used to analyze contaminants and to investigate molecular modifications and lateral structures on the surfaces of other materials such as multielement semiconductors (e.g. GaAs), metals, and polymers.[24, 25] As an example Figure 10 shows the lateral distribution of the Ga^+ emission from a very small surface region ($3 \times 3\ \mu m^2$) of a structured GaAs test specimen.

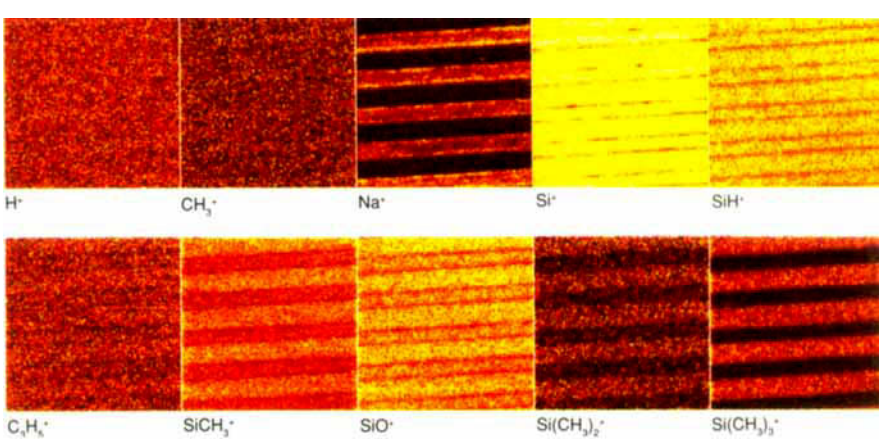

Fig. 9. TOF-SIMS images of a structured trimethylsilyl monolayer on a silicon wafer (field of view: $14 \times 14\ \mu m^2$). The lateral resolution is about 0.1 μm. Primary ion beam: 30 keV, 150 pA; pulse width: 80 us; primary ion fluence: $6.0 \times 10^{14}\ cm^{-2}$; image acquisition time: 10 min; 700 pulses per pixel.

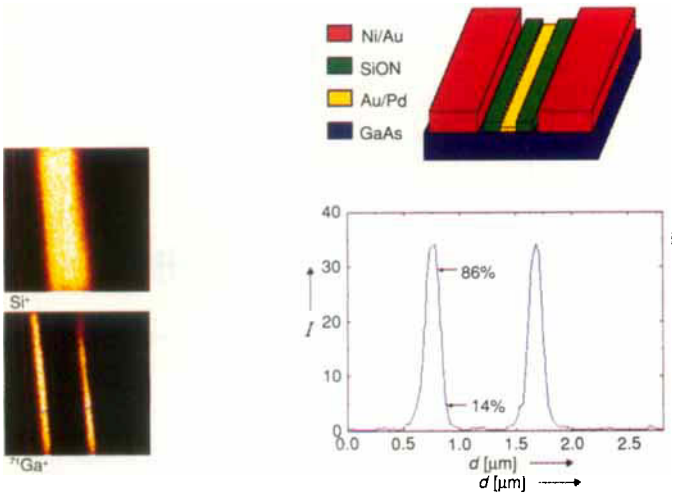

Fig. 10. Lateral distribution of the Si^+ and Ga^+ secondary ion emissions (left) from a GaAs structure (schematic representation, top right). The lateral resolution, as determined from the line scan shown (bottom right), is approximately 80 nm. Field of view: $3 \times 3\ \mu m^2$; sample consumption: 1.5 nm. In the line profile the intensity of the Ga^+ ions is plotted versus the distance coordinate d of the line scan.

Table 3. Transformation probabilities ($P(M \rightarrow X_i^q)$ [Eq. (3)] for quasi-molecular ions X_i^q.

Cmpd. class		Molecule M	Secondary ion X_i^q	Mass [u]	$P(M \rightarrow X_i^q)$
ammonium salts		crystal violet	M^+	372	1×10^{-2}
		cetylmethyl-ammonium bromide (CTAB)	CTA^+	284	5×10^{-2}
amino acids		leucine	$(M + H)^+$	132	7×10^{-4}
			$(M - COOH)^+$	86	3×10^{-4}
			$(M + Ag)^+$	240	1×10^{-3}
peptides		bradykinin	$(M + H)^+$	1060	2×10^{-4}
		gramicidin A	$(M + K)^+$	1919	1×10^{-4}
		melittin	$(M + H)^+$	2846	1×10^{-6}
polymers	mono-layer	polystyrene	$(M + Ag)^+$	1000	5×10^{-3}
			$(M + Ag)^+$	7000	5×10^{-5}
	bulk	polystyrene	$C_7H_7^+$	91	5×10^{-4}
		polydimethyl-siloxane	$Si(CH_3)_3^+$	73	1×10^{-3}
		polypropylene	$C_3H_5^+$	41	2×10^{-4}
		Teflon	CF^+	31	1×10^{-3}
		Krytox	CF_3^+	69	5×10^{-3}

4.2. Organic Molecules

A characteristic feature of the secondary ion spectrum of an organic molecule M is the appearance of the quasi-molecular ions $(M + H)^+$, $(M + \text{cation})^+$, and $(M - H)^-$ (cf. Section 2.1.3). The corresponding transformation probabilities depend on the size and structure of the molecule concerned and its chemical environment on the surface. One also often observes other quasi-molecular ions from which small functional groups have become detached, such as $(M - CH_3)^+$ or $(M - OH)^+$. Besides the above quasi-molecular ions one also finds characteristic fragment ions of various sizes in the low-mass region of both the positive and negative ion spectra. The molecular ions M^+ and M^- are found only rarely.

All the organic compounds investigated up to now, including thermally unstable compounds with masses up to several thousand u, have been found to emit quasi-molecular ions; the transformation probabilities generally decrease with increasing molecular size (Table 3). Systematic studies have been undertaken for many classes of organic compounds, including peptides, nucleotides, other biopolymers, synthetic polymers, organometallic compounds (Fig. 11),[31] inorganic anion complexes, carboxylic acids, amino acids, steroids, barbiturates, sulfonamides, and many other groups of pharmaceuticals, pesticides, dyes, surface active agents, polymer additives, etc.[20]

4.2.1. Biopolymers

An example of the analysis of a high molecular weight peptide is given in Figure 12, which shows the positive secondary ion spectrum of a mixture of cyclosporin A and D (CsA and CsD, respectively) on silver. Protonated and Ag-cationizated molecular ions are observed. The transformation probabilities $P(M \rightarrow (M + Ag)^+)$ for peptides in this mass range are typically on the order of 10^{-4}. The sensitivities achieved (cf. Fig. 13) are correspondingly high. Small fragments of cyclosporin as well as secondary ions arising from the surface contaminants are found in the mass range below 200. The molecular ion yields obtained for

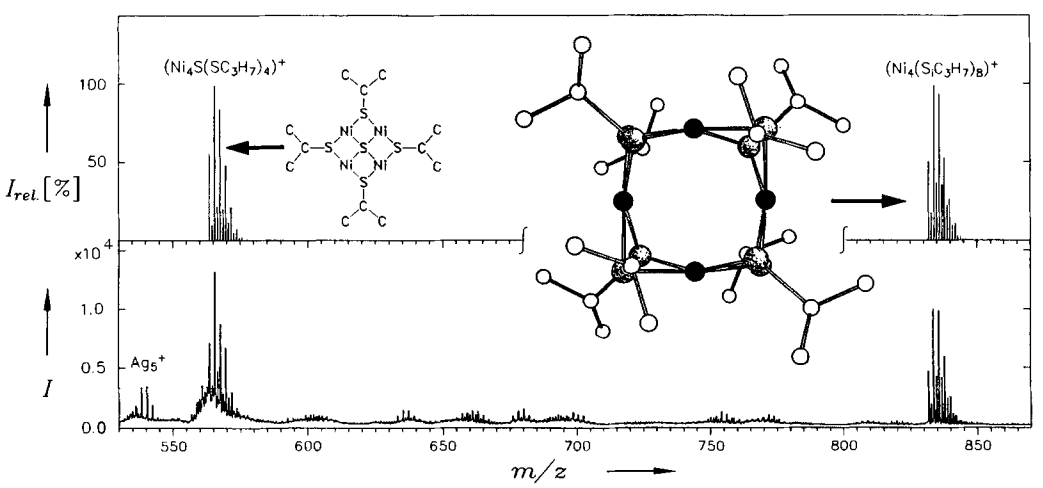

Fig. 11. Characteristic molecular ion emission from an organometallic compound. The molecular structure of the initial compound is shown (nickel: black circles; sulfur: stippled circles; carbon: white circles) together with a proposed structure for a fragment ion that is emitted with high intensity. Calculated (top) and SIMS spectrum (bottom).

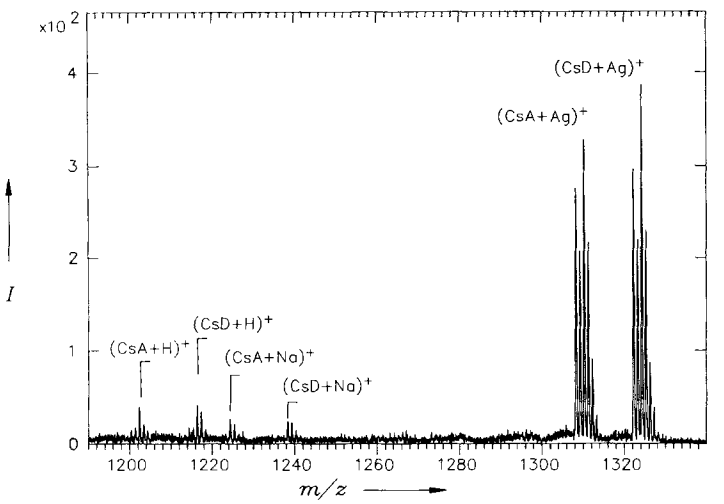

Fig. 12. Emission of protonated and cationizated quasi-molecular ions from a monolayer consisting of an equimolar mixture of cyclosporin A (CsA) and cyclosporin D (CsD). The transformation probability for the silver-cationizated molecular ion is 10^{-4}.

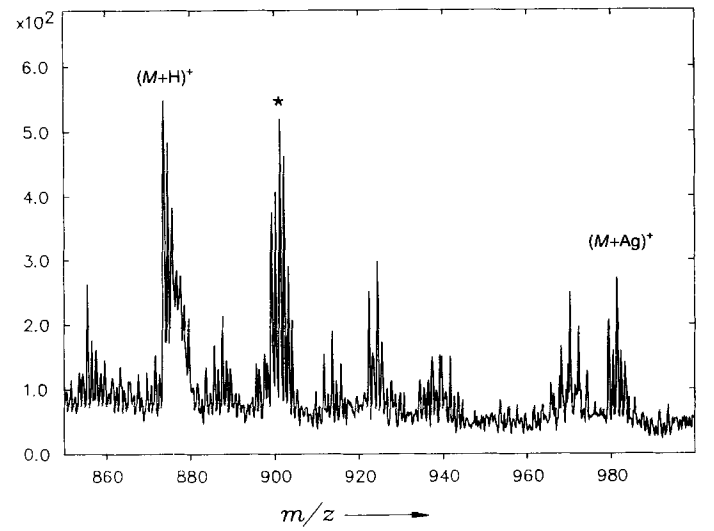

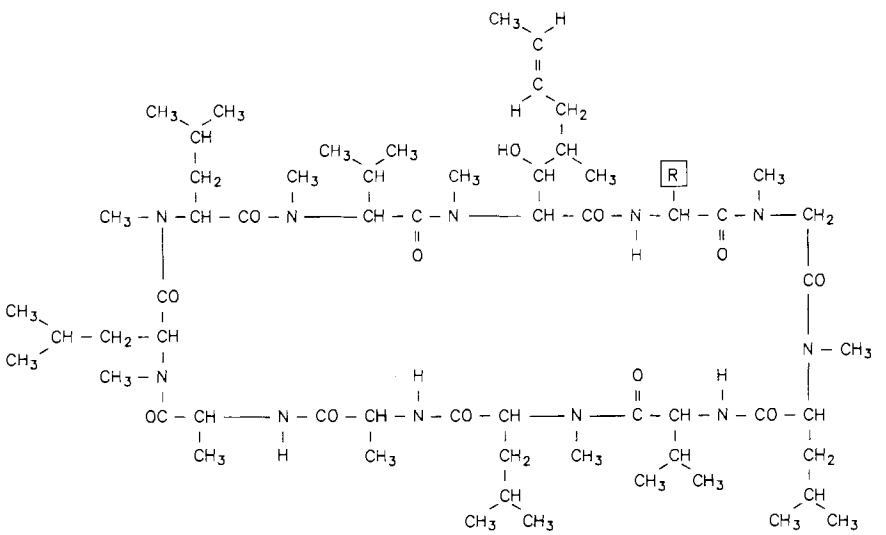

Fig. 13. Emission of $(M + H)^+$ and $(M + Ag)^+$ ions from the structurally modified peptide **1** on silver. The total amount of the peptide used for the analysis was 10^{-14} mol, and the amount in the area actually analyzed (primary ion beam diameter of 100 μm) was about 10^{-18} mol. The peak due to contaminant is marked with a star.

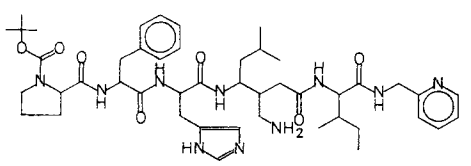
peptides, like those for all other types of organic molecules, depend on the size and primary structure of the molecule concerned and on its chemical environment.



cyclosporin A: R = CH_2–CH_3 $M = 1202$
cyclosporin D: R = $CH(CH_3)_2$ $M = 1216$

Systematic studies of the effects of these variables on the secondary ion emission of small peptides have shown that the highest molecular ion yields are usually obtained with monolayers or submonolayers on noble metal substrates, especially silver. The same applies generally to all types of organic molecules.

Reactive metal substrates greatly reduce the molecular ion yields. For peptides of higher molecular mass ($M > 3000$ u) nitrocellulose has been found to be especially suitable as a substrate. As expected, the sputtering cross sections σ increase with the mass, in other words with the size of the molecule. The σ values for peptides are typically between 10^{-13} and 10^{-12} cm^2. When the transformation probabilities are sufficiently high the distribution of molecules on a surface can be determined in detail. Figure 14 shows an example of this for cyclosporin A on a silver target.

4.2.2. Smaller Molecules

The secondary ion emission of smaller molecules ($M < 500$ u) was investigated in detail using quadrupole mass spectrometers before the development of the more powerful time-of-flight instruments,[32, 33] and therefore a large volume of results on these molecules is available. The earliest systematic studies of secondary ion emission were carried out on amino acids.[9] Since then a vast amount of data has been obtained for many other classes of compounds.[20]

1

4.2.3. Quantification with an Internal Standard

Matrix effects present a serious obstacle to quantitative analysis. Secondary ion emission will only be proportional to the area covered by a particular surface constituent if it is present in the same bonding state throughout. If a solution preparation method is used this cannot be guaranteed. However, calibration

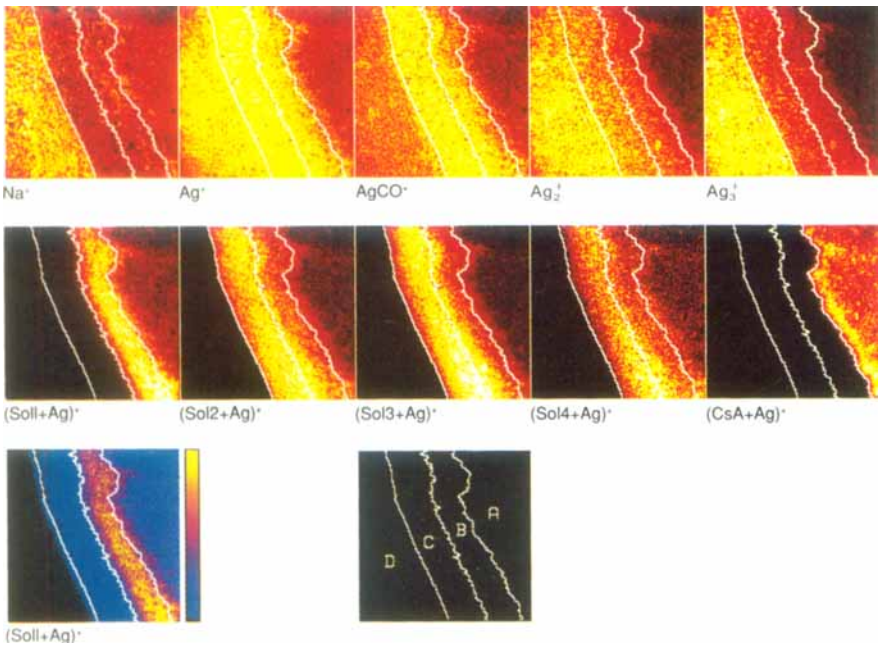


Fig. 14. Images of the edge zone ($400 \times 400\ \mu m^2$, 1800 pulses per pixel) of a Ag surface several mm in diameter on which a solution containing cyclosporin A in several different oils was deposited. These show the distribution of characteristic quasi-molecular ions from the oils (Sol 1–4) and from cyclosporin A (CsA). As the droplet evaporated the different components separated (chromatographic effect). A: $(CsA + Ag)^+$; B: Sol1; C: Sol2, Sol3, Sol4; D: uncovered silver surface.

Experience has also been obtained in quantitative analysis for cyclosporin, which is used for suppressing immune reactions following organ transplant operations. Direct quantitative detection of the therapeutically active cyclosporin A in the blood serum of patients was achieved by using cyclosporin D as a standard.[34] This differs from cyclosporin A only in having an additional CH_2 group in one of the side chains of the ten amino acids. By this method direct determination of cyclosporin A at therapeutically effective concentrations in blood serum was achieved with an accuracy of 20% (Fig. 15).

The results obtained for steroids and cyclosporin show that in many applications chemically similar molecules can be successfully used as standards for molecular SIMS. This method can be used whenever it is possible, during the preparation of the surface, to incorporate a suitable standard compound into the surface at a known concentration simultaneously with the substance to be analyzed.

is possible by introducing a suitable standard of known concentration. By directly comparing the intensities of corresponding quasi-molecular ion peaks of the analyte and the standard, whose concentration on the surface is known, one can determine the concentration of the analyte in the starting solution. The analyte and the standard must behave identically with regard to solubility and deposition on the substrate, and during evaporation of the solvent, sputtering from the surface, and ionization. When isotopically labeled molecules are employed as the standard, these preconditions are fulfilled. However, sufficiently identical behavior can also be expected if the standard used is structurally closely related to the analyte. By applying this method to steroids we have achieved analytical accuracies of about 2%.

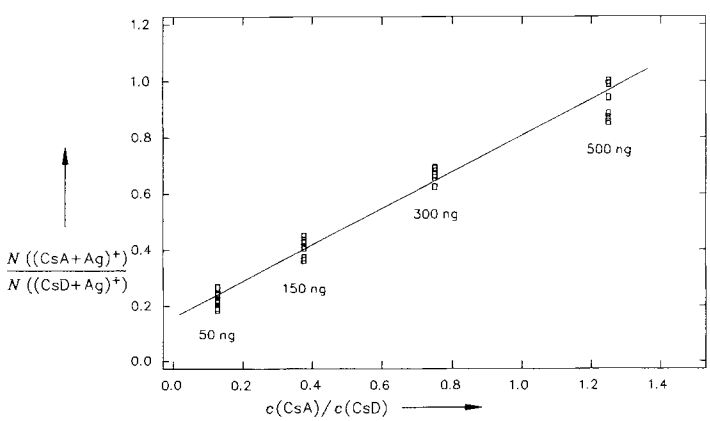

Fig. 15. Quantitative determination of cyclosporin A (50–500 ng) in 1 mL of blood serum. The concentration of the standard, cyclosporin D, was 400 ng mL^{-1}.

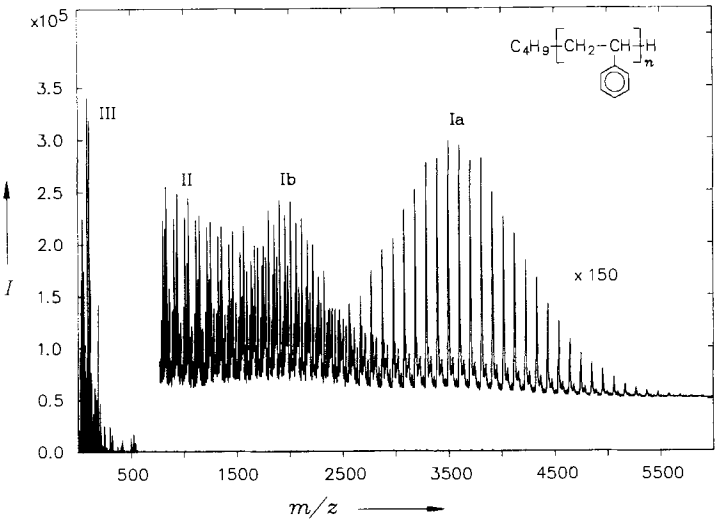
4.3. Synthetic Polymers

Synthetic polymers present a special challenge for surface analytical techniques. On the one hand, their technological importance continues to grow as new materials and surface modifications are developed by the incorporation of additives, application of chemical reactions at the surface, plasma treatments, and so on. On the other hand, however, the standard electron spectroscopic methods of AES and XPS are only of limited value for investigating the chemical composition of such surfaces, since they do not give direct information on the molecular level and are relatively insensitive.[35]

Secondary ion spectra of polymers often contain an enormous number of lines, which can extend to masses beyond $m/z = 10000$. At the same time the cross section σ for sputtering and associated radiation damage is typically quite large (up to several 10^{-12} cm^2). For these reasons the potential of secondary ion mass spectrometry for the analysis of polymers can only be fully exploited by using a time-of-flight mass spectrometer. Since the secondary ion emission behavior of polymers as monolayers on metal substrates is very different from that of bulk polymers, these two cases will be discussed separately. Polymer monolayers are prepared from suitable solutions by the method described in Section 3.4. As in the case of organic compounds, the best results are obtained when the substrate is a noble metal, usually silver. Nearly all bulk polymers are insulators, and the analysis of their surfaces by SIMS yielded reproducible and undistorted results only when the technique of pulsed charge compensation was introduced. With this technique it is very important to use only low-energy electrons (< 20 eV) so as to avoid radiation damage.

4.3.1. Polymer Monolayers on Metal Substrates

Most polymers are sufficiently soluble in appropriate solvents to allow the preparation of monolayers by the method described in Section 3.4. Figure 16 shows a typical positive secondary ion



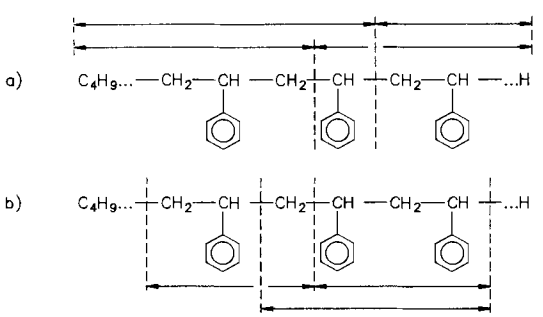


Fig. 16. The positive secondary ion spectrum of polystyrene (M_n = 3770 u) on silver (for explanation see text).

spectrum from a polymer monolayer prepared on silver by this method.[36] In this spectrum one can distinguish three regions: the oligomer region (Ia, Ib), the fragment region (II), and the fingerprint region (III).

The oligomer region arises from the silver-cationizated molecular ions $(M + Ag)^+$ (Ia) and $(M + 2Ag)^{2+}$ (Ib), which are formed by the addition of one and two silver ions, respectively, to intact oligomer molecules emitted from the surface. The fragment region (II), which overlaps with the oligomer region and extends to lower masses, is dominated by silver-cationizated fragments of the oligomers. These are formed by single or double bond cleavages during sputtering and consist of a number of monomer units, with or without one of the two end groups, depending on the position of cleavage in the molecule. The possible fragmentation modes are shown in Scheme 1. The fingerprint region, which extends from the fragment region to lower mass numbers, arises from smaller fragment ions which are emitted with quite high intensities.

Scheme 1. Fragmentation modes for polystyrene.

Systematic studies of the monolayer spectra of a wide variety of polymer types have revealed some general features of their secondary ion emission properties.[37, 38] All polymers give fingerprint spectra (III), which yield information about the mass and structure of the repeat unit and often also about the end groups.[39] The prominence of high molecular mass fragment ions (II) varies between the different polymer types; these too yield information about the repeat units and end groups. Oligomer spectra (Ia, Ib) have generally been observed only for polymers with molecular masses below 10000 u and even then not for all types of polymers; when present they give direct information about the molecular mass distribution of the polymer.

With a time-of-flight spectrometer the masses of the secondary ions can be determined with a precision of a few ppm. An example is given in Figure 17, which shows a portion of the positive ion spectrum of polydimethylsiloxane. The oligomer spectrum contains two series of peaks of different intensities. From exact mass measurements one can construct the molecular formulas for the ions of both series, leading to the conclusion that the main series arises from linear polymer molecules and the weaker series from cyclic polymer molecules.

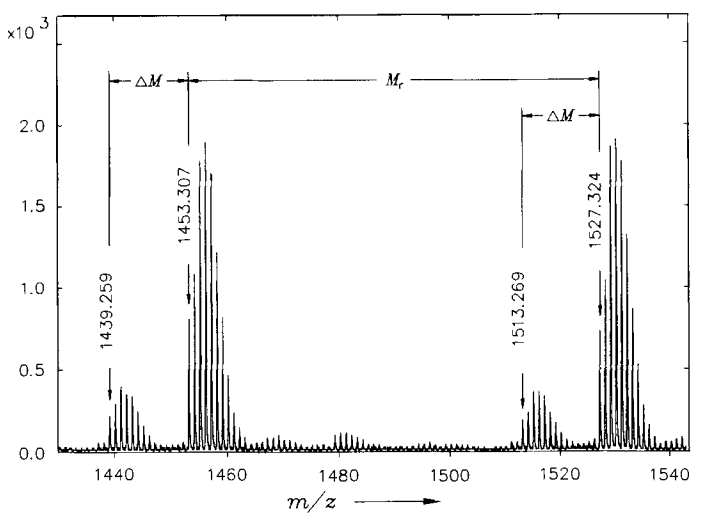

Fig. 17. Part of the high-resolution positive secondary ion spectrum of a polydimethylsiloxane monolayer on silver.

The dependence of the secondary ion emission on variables such as the molecular mass, the presence of different side groups, and the substrate material has been investigated systematically for polystyrene, poly(methyl methacrylate), poly(ethylene glycol), and perfluoroalkyl polyether (Krytox). One result of the study was that all the polymers investigated showed a linear relationship between the molecular mass and the sputtering cross section σ.[40]

As an alternative to preparation from solutions, surface films resembling monolayers have also been successfully produced by mechanically stripping relatively thick polymer films from metal substrates, or by rubbing a bulk polymer specimen against a metal surface. By using the rubbing technique one can produce films that resemble monolayers and have a similar emission

behavior, even when the starting material is insoluble (e.g. films produced by plasma polymerization).

4.3.2. Bulk Polymers

It can be assumed that when a monolayer is prepared the oligomer molecules lie flat on the surface of the substrate. Evidence for this includes the observation that covering a metal substrate with a monolayer always requires the same number of monomer units of a given polymer, regardless of its average molecular mass. Secondly, the sputtering cross section σ increases in proportion to the molecular mass, and thirdly, silver-cationized quasi-molecular ions are observed up to the high-mass region.[40] In contrast to this the molecules in the bulk polymer are more or less entangled, such that ion bombardment does not result in the emission of intact molecular ions but rather only smaller fragments. Cationization is also much less important as an ionization process.

It is in fact found that bulk polymers, with only a few exceptions, give fragment ions mainly in the low-mass region below $m/z = 500$.[41] Often the repeat unit itself is emitted as a secondary ion with high intensity. One can also obtain information about the structure of the repeat unit from the relevant fragment ions. Figure 18 shows typical fragment ion spectra in the low-mass region. The secondary ions observed can be assigned to specific molecular fragments, from which one can identify not only the monomer unit but also its characteristic side groups. The ionization of the fragments can occur through protonation, deprotonation, or charge stabilization at heteroatoms such as oxygen or halogens. If suitable cations are present, the corresponding cationizated fragment ions may also be formed. As expected, the intensities of the peaks that correspond to fragment ions containing end groups decrease as the length of the oligomer molecule increases, whereas the intensities of the peaks of fragment ions that do not contain end groups are independent of the molecular mass of the oligomer. From the ratio of the intensities of these two types of fragment ions one can estimate the average molecular mass for the oligomers, even when no intact quasi-molecular ions are found in the higher mass region.[42] Larger negative fragment ions are most often observed for polymers containing oxygen or halogen atoms, which allow for charge stabilization.

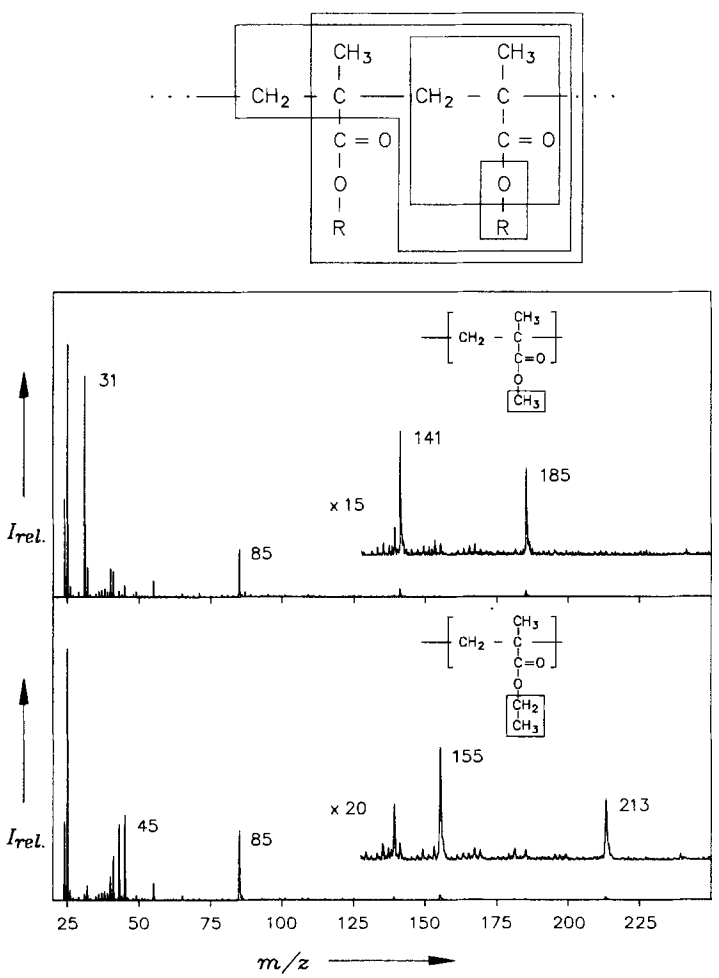

Fig. 18. Negative fragment ion spectra of the surfaces of bulk samples of poly(methyl methacrylate) (top) and poly(ethyl methacrylate) (bottom) in the fingerprint region. Fragment ions corresponding to the monomer units and to the side chains (shown above the spectra) can be identified.

Primary ion bombardment can also destroy or remove molecules of bulk polymers and is accompanied by significant radiation damage to layers below the uppermost monolayer. As a result the signal intensities of characteristic fragment ions diminish during the bombardment. The sputtering cross section for fragment ions in the low-mass region is typically several 10^{-12} cm^2. For a given type of polymer the value is independent of the average initial molecular mass. In special cases where fragment ions of higher mass are observed, the cross sections are significantly greater with values up to 10^{-11} cm^2. In certain cases the emission of characteristic secondary ions actually increases as the primary ion bombardment proceeds; this occurs when the bombardment leads to the formation of fragments that remain on the surface, which are more apt than the oligomer molecules to give rise to secondary ions. Such an increase may typically continue up to a primary ion fluence of about 10^{12} ions per cm^2 and is then followed by a reduction in the emission of the relevant fragment ions at a rate corresponding to the normal sputtering cross section. A striking example of such behavior is observed in the case of Teflon for the fragment ions $(CF_2)_n^-$.[40]

4.3.3. Modified Polymer Surfaces

In general the composition of a polymer at the surface is considerably different from that within the bulk material. For example, one often finds that additives or impurities are concentrated at the surface (Figs. 19 and 20, respectively). The surfaces of polymers are in some cases intentionally modified, for example by chemical reaction, bombardment with ions or electrons, or plasma treatment, to achieve surface properties not normally possessed by the polymer, such as adhesion properties or a degree of surface reactivity. Molecular surface modifications of these kinds can be studied in detail by SIMS. As an example, the modification of the side chain of surface molecules of poly(hydroxyethyl methacrylate) (PHEMA) by reaction with propionyl chloride can be investigated in detail by observing changes in the emission of characteristic fragments in the fingerprint spectrum (Fig. 21). In many cases, such as when oxygen is

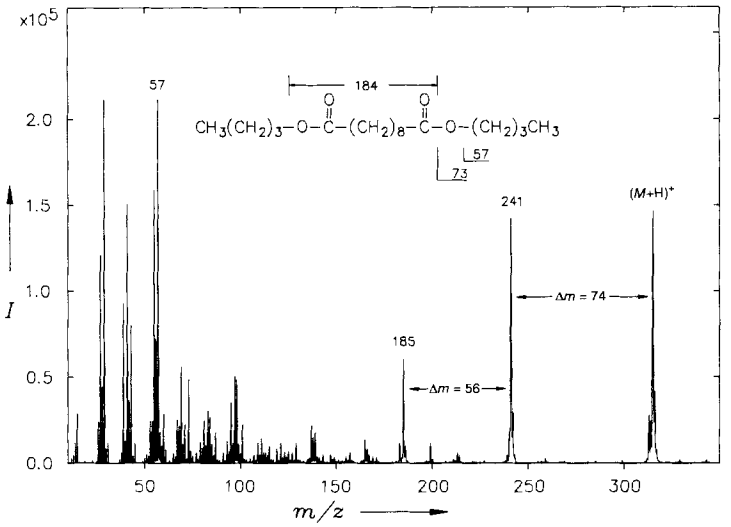

Fig. 19. Detection and identification of an additive (dibutyl sebacate) on a polyvinylchloride surface. Primary ion dose: 3×10^6, positive ion spectrum.

incorporated into the polymer surface, high mass resolution in the fingerprint region is important. For example, treatment of a polystyrene surface with an oxygen or nitrogen plasma causes

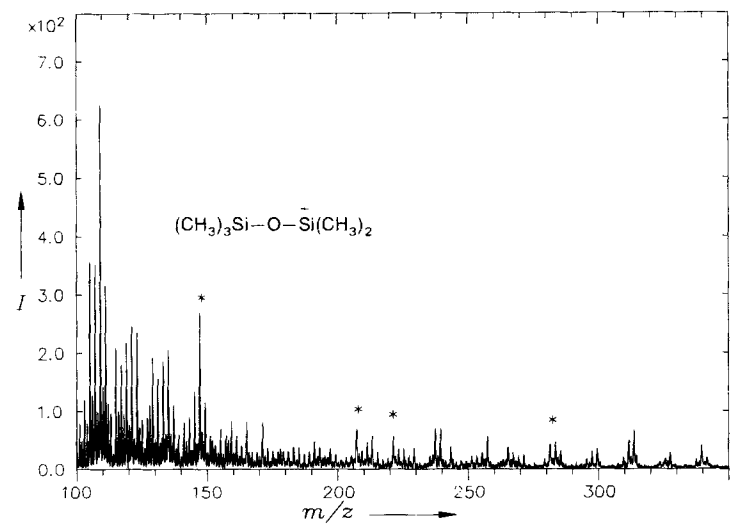

Fig. 20. Detection of silicone oil contamination on a polycarbonate surface. Peaks arising from the contamination are marked with a star.

oxygen or nitrogen to become incorporated into the molecular structure of the surface. This incorporation can be followed by observing changes in the intensities of the relevant secondary ion peaks, provided that the mass resolution is adequate for distinguishing ions of the same mass number that contain one or more atoms of oxygen or nitrogen.[43]

Surface imaging of polymers can be used to investigate the lateral distribution of specific molecular constituents. Figure 22 shows the distribution of lotader inclusions in polypropylene, and Figure 23 shows the location and identification of a particle of Teflon in an ink dot on paper.

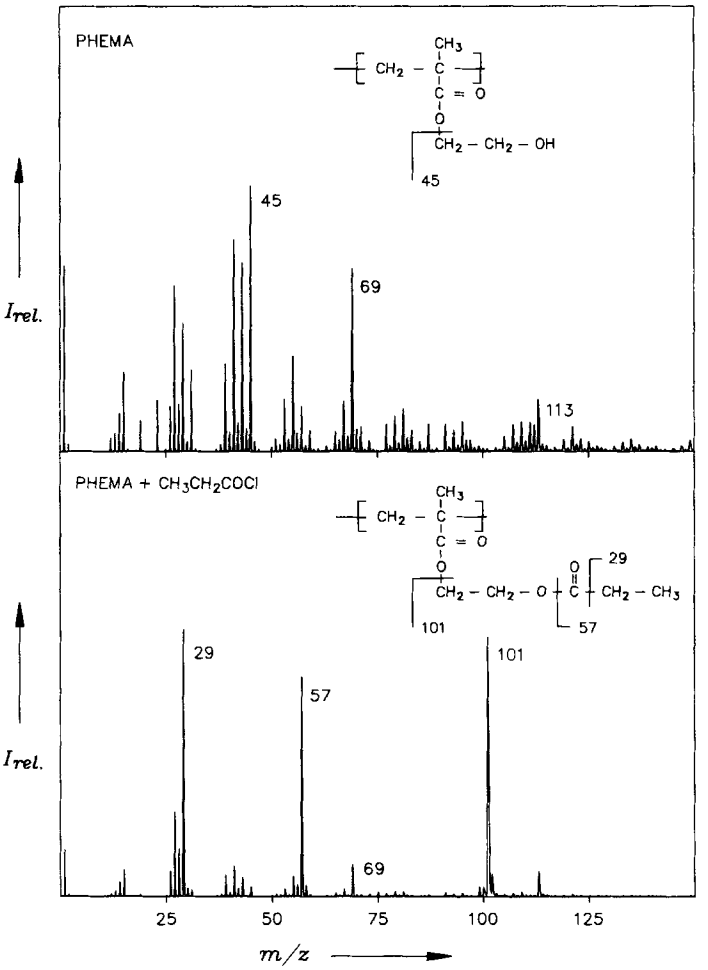

Fig. 21. Chemical modification of a polymer surface. Exposing a poly(hydroxyethyl methacrylate) (PHEMA) surface to gaseous propionyl chloride modifies the side chains, and the fingerprint spectrum then shows secondary ions characteristic of the modified side chains. Positive ion spectrum.

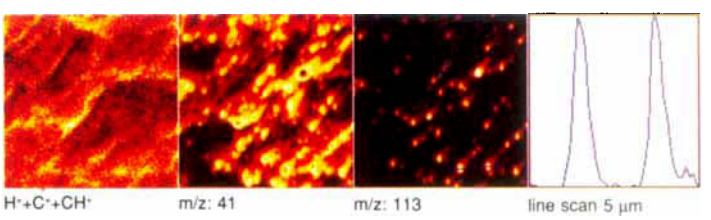
It is not possible to determine molecular depth profiles by the progressive stripping of layers by ion bombardment, owing to the severe radiation damage that would occur. However, such



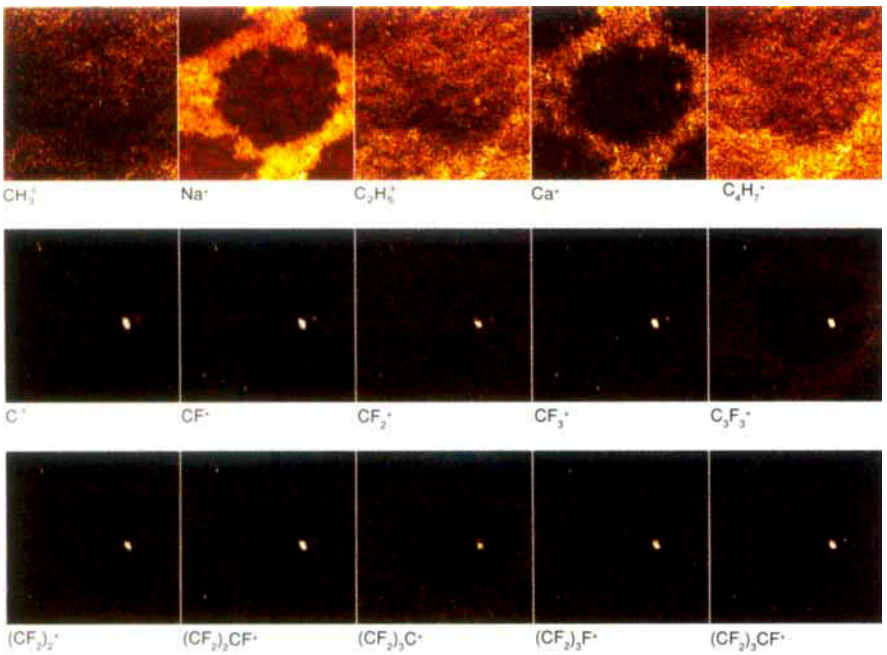


Fig. 22. Imaging of a polymer surface (15×15 µm, 200 pulses per pixel) showing lotader inclusions in polypropylene. The line scan shows that the lateral resolution is about 0.2 µm. The secondary ion with mass $m/z = 113$ is a fragment ion of the lotader. The line profile corresponds to two spots in the image recorded for $m/z = 113$.

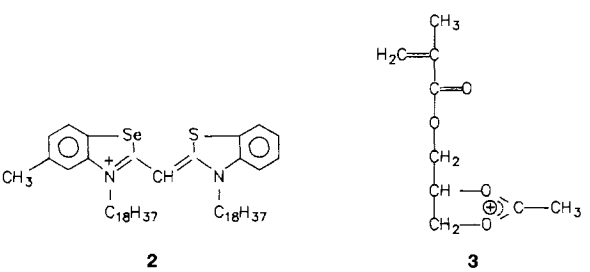
profiles can be determined indirectly by imaging suitable polymer sections in combination with image processing techniques.



ular layers, and after each step the intensities of one or more of the characteristic secondary ion peaks of the incorporated species are measured. Such experiments have been performed, for example, with a dye, **2** · ClO_4, which was incorporated into a polymethacrylate (PMA) film at high concentration (mixing ratio 1:1). This film was then covered with a gradually increasing number of layers of polyamide (PA), so that the diffusion of the dye through these layers could be measured. Figure 24 shows the sequence of intensities for the signals of the positive dye ion, its negative counterion, and a positive secondary ion (**3**) from PMA as the thickness of the overlying PA film is increased.[46] Both the counterion ClO_4^- and the PMA ion are almost completely excluded by only *one* double monolayer covering of PA. In contrast, the dye molecule itself is still easily detectable after four double monolayers are applied.

4.4. Synthetically Produced Molecular Surface Films

Synthetically produced molecular surface films are becoming increasingly important as passive coatings, as components of sensors and optoelectronic devices, as adhesion promoters, in the modification of membranes, in catalyst development, for making surfaces biocompatible, and for many other purposes. In the development and production of such film systems, and in their routine use for technical applications, an effective and reliable surface analytical method is essential for evaluating film quality (with regard to composition, uniformity, integrity, and contamination), for monitoring the stability of the films under conditions such as high temperatures or storage in aggressive environments, for following diffusion processes in heterogeneous multilayer systems, and so on. Investigations of Langmuir–Blodgett (LB) and self-assembled (SA) films, films of covalently linked amino acids and peptides on polymers, and organosilicon compounds covalently bonded to oxides have shown that for such systems TOF-SIMS gives information that cannot be obtained by any other analytical method.

4.4.1. Langmuir–Blodgett Films

Many polymers form LB films that are very stable and are therefore especially interesting for technical applications. Investigations of the secondary ion emission from such film systems have confirmed that the secondary ions are emitted from a depth of only one to two monolayers.[44, 45] SIMS is therefore an ideal method for studying phenomena such as the vertical diffusion of molecular species that are present only down to a limited depth in a multilayer system. In these experiments a film containing the substance(s) of interest is gradually covered in a stepwise progression with an increasing number of monomolec-

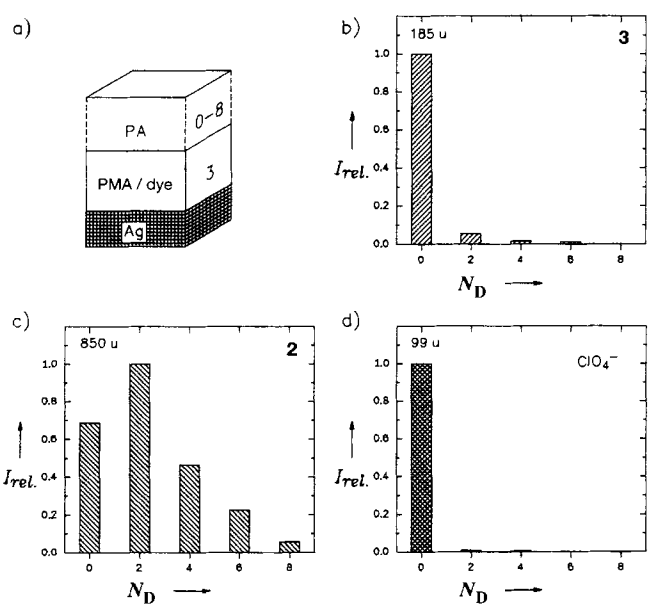


Fig. 24. Diffusion of dye ions through PA LB films of different thicknesses. a) Layer sequence with the number of double layers (the dye ion is present in the initial film in a molar ratio of 1:1). Relative intensities of b) the PMA fragment cation **3**, c) the dye ion **2**, d) the counterion. N_D = number of double layers.

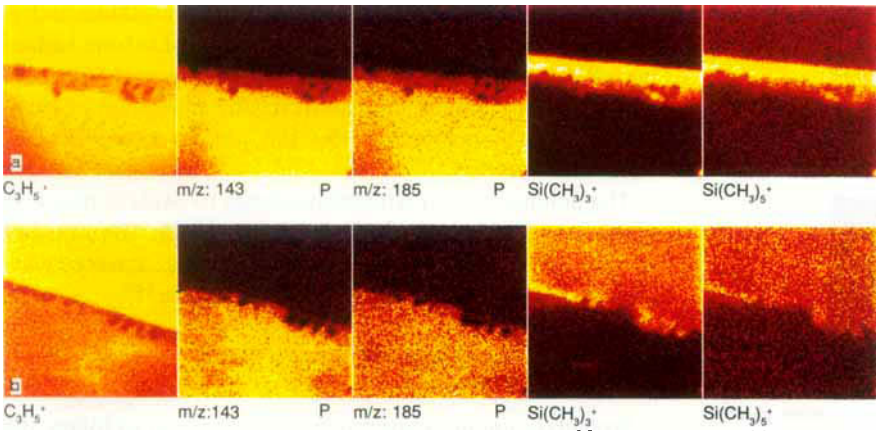

Fig. 25. Location and identification of a silicone oil impurity in a PMA LB film. Masses $m/z = 143$ and 185 correspond to secondary ions characteristic of PMA. The two rows of images (field of view $130 \times 130\ \mu m^2$) relate to different methods of preparation. In series a) the silicone oil impurity is located near the edge of the incomplete LB film, whereas in series b) it is distributed over the entire uncovered area.

Molecular contaminations that can arise, for example, in the production of LB films, can be located and diagnosed by imaging the surface region of interest. For example, it was possible to pinpoint silicone oil contamination in a PMA film by imaging the lateral distribution of the secondary ions $Si(CH_3)_3^+$ and $Si(CH_3)_5^+$ (Fig. 25).

4.4.2. *Self-Assembled Films*

Information of the same kind as for LB films can also be obtained for SA films, such as butylbenzotriazole (BBT) monolayers on metals, by using SIMS. Layers of this type are effective as corrosion inhibitors for copper and nickel. When a metal surface is treated with an aqueous solution of BBT, a closed, passivating monolayer of BBT forms. The formation of the passive layer is affected by the oxidation state of the metal surface and by any contamination that may be present. SIMS imaging of a BBT-treated copper surface yields detailed information about the surface distribution of the species present, including complex molecular species (Fig. 26).

TOF-SIMS studies have also been carried out on the adsorption of organic thiols, sulfides, and disulfides on gold substrates and have provided detailed insight into several surface reac-

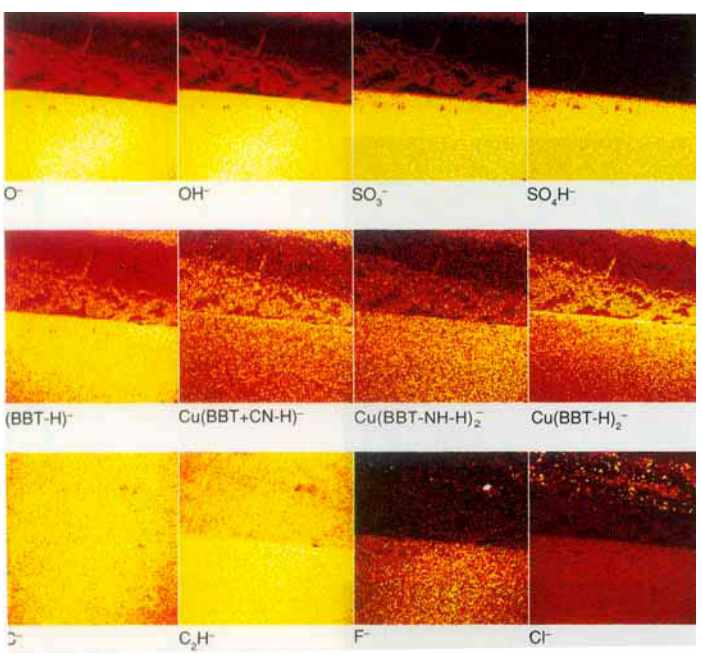

Fig. 26. A self-assembled BBT monolayer on copper. Only the lower part of the imaged area ($250 \times 250\ \mu m^2$, 1100 pulses per pixel) is covered by the BBT monolayer. The secondary ion images for the surface contaminants (F, Cl, SO_4, etc.) show their different lateral distributions. The complex behavior of the BBT molecules near the boundary between the covered and uncovered areas is also evident.

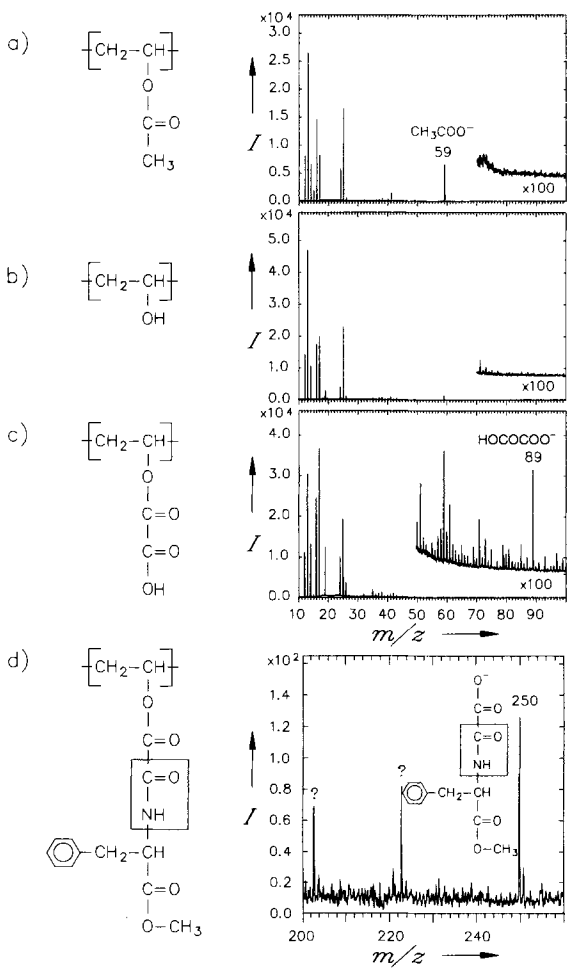

Fig. 27. Immobilization of phenylalanine on poly(vinyl acetate). The separate stages of the process can be studied and monitored by recording the characteristic secondary ion emission of the surface complexes. The spectra correspond to a) the concentration of acetate groups, b) saponification, c) addition of spacer molecules, d) attachment of amino acids.

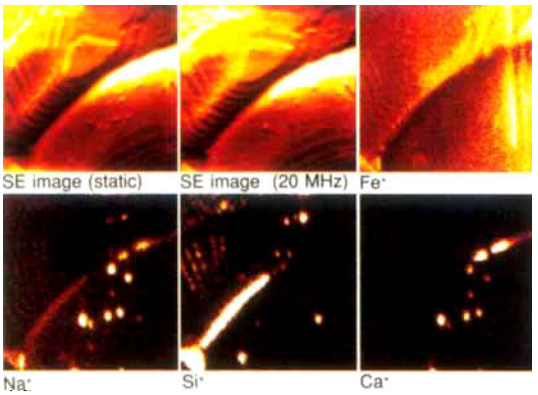

Fig. 28. Images of a $7.5 \times 7.5\ \mu m^2$ area of the surface of a dye carrier particle, obtained by recording images from the ion-induced secondary electrons and the Fe^+, Na^+, Si^+, and Ca^+ secondary ions. Primary ion beam: 140 pA.

tions. For example, SIMS spectra showed that disulfides undergo chemisorption with cleavage of the S–S bond to form surface monosulfides. SIMS has also been successfully used to investigate the most favorable conditions for the adsorption of streptavidin on a monolayer of $HS(CH_2)_{12}$-biotin with optimized stereochemistry.[47]

The bonding of methyltriethoxysilanes to oxide surfaces, in particular SiO_2, has also been studied by SIMS. The structure of the layers formed was characterized; unexpectedly, silsesquioxanes were found on the silica surface.[48]

4.4.3. Immobilized Amino Acids and Peptides on Polymer Surfaces

Secondary ion mass spectrometry can be used to follow the separate stages in the immobilization of amino acids and pep-

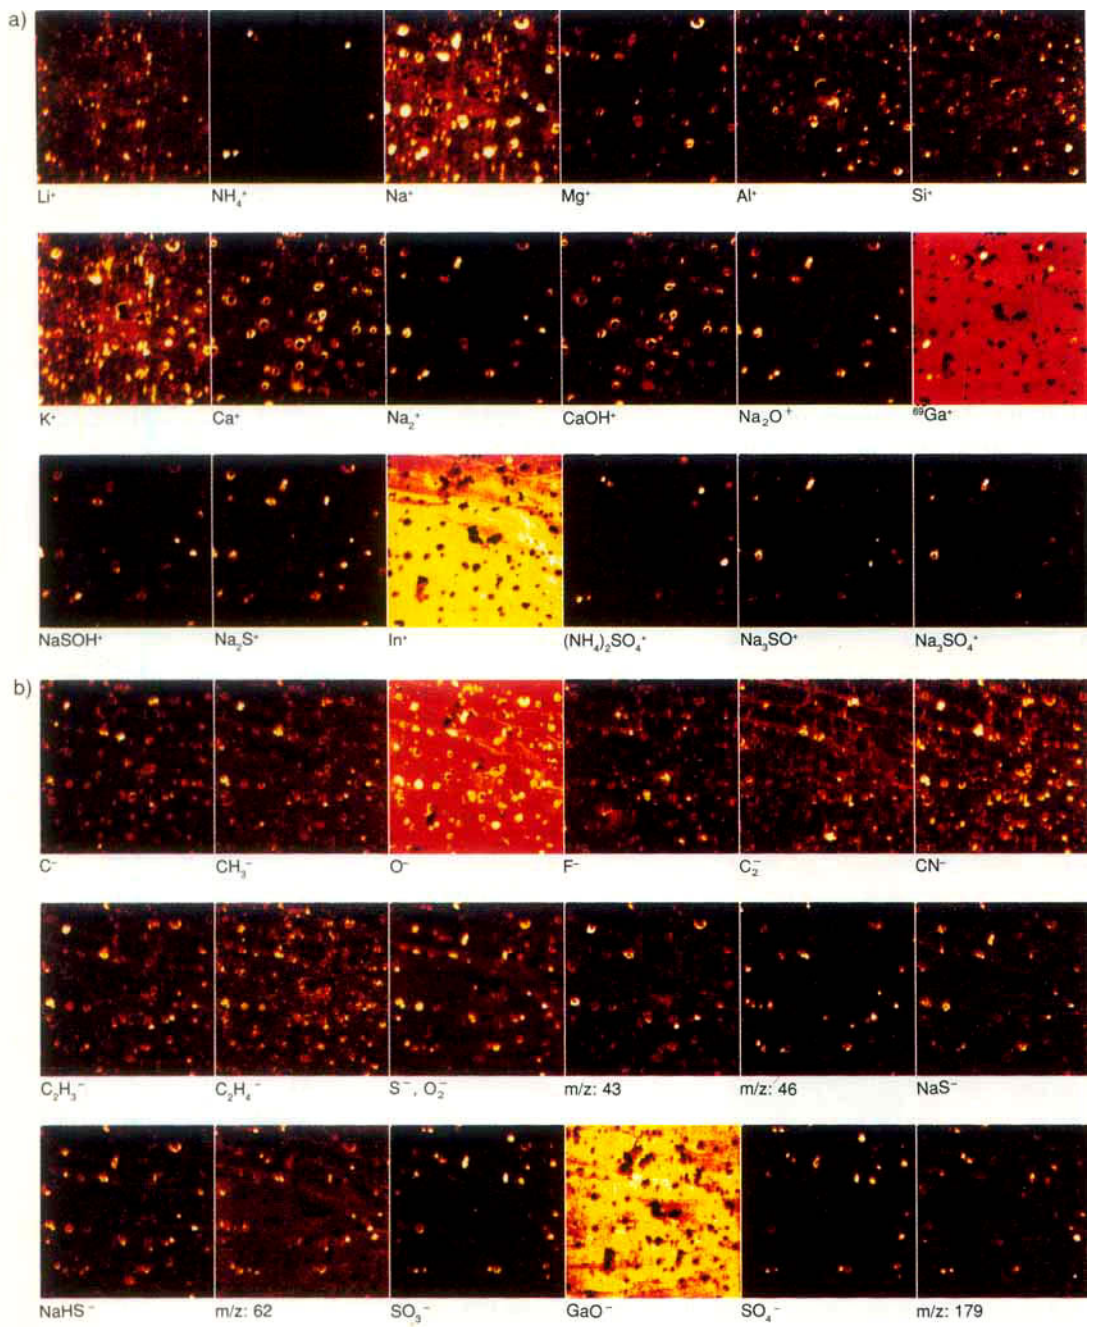

Fig. 29. a) Positive and b) negative secondary ion images of aerosol particles on an indium foil. Field of view: $120 \times 120\ \mu m^2$; 500 pulses per pixel.

tides on surfaces. In one such study the bonding of amino acids and alcohols to polymer surfaces, in particular to copolymers containing vinyl acetate, was investigated. By observing the occurrence and disappearance of characteristic secondary ion peaks it was possible to monitor changes in the concentration of acetate groups at the surface and to follow the saponification of these groups, the addition of spacer molecules, and the attachment of amino acids to these spacers (Fig. 27).[49]

4.5. Particles and Fibers

Since flat or smooth surfaces are not required for SIMS analysis, one can analyze particles and fibers down to submicron dimensions by using a focused primary ion beam. Some examples of such analyses that have been carried out on particles and fibers in recent years include determinations of the surface composition of catalysts in powder form, the elemental and isotopic composition of interplanetary dust particles, the surface composition of dye carrier materials (Fig. 28), and the origin and identity of aerosol particles (Fig. 29), as well as the investigation of polymer particles on silicon wafer surfaces (see Fig. 32), and the determination of the composition of molecular films on carbon, paper (Fig. 30), textile fibers, and hairs, and the incorporation of glass fibers into polymers. In such analyses of particles and fibers, total electron and total ion images are important aids to locating features. Digital image processing and the identification of particular types of particles by computerized comparison of spectra (cluster analysis) are also very important methods.[50] It is also possible in principle to measure depth profiles for particles and fibers, even for molecular species, by imaging sections; if necessary these can be prepared after embedding in a suitable matrix.

SIMS can be used to determine isotope ratios without appreciable distortion by matrix effects, as these affect the ionization of all isotopes of an element to the same extent. Also fluctuations of the primary ion current with time are unimportant with a time-of-flight mass spectrometer, since all secondary ions are detected almost simultaneously. Dead-time effects at high data collection rates can be corrected by suitable evaluation methods. The best accuracies currently obtained with TOF-SIMS for the determination of isotope ratios are on the order of $\pm 2 \times 10^{-3}$ (for $^{107}Ag/^{109}Ag$).[51] For determining isotope ratios with extremely small sample quantities (e.g. microscopic inclusions or interplanetary dust particles) time-of-flight mass spectrometers have a considerable advantage over sector field instruments for a given mass resolution and lateral resolution because of their simultaneous detection of all secondary ions.

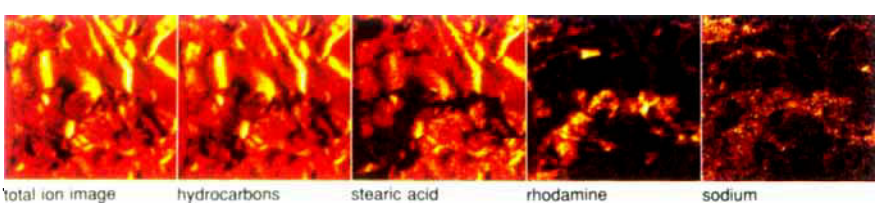

Fig. 30. Characteristic secondary ion images ($250 \times 250\ \mu m^2$; 1000 pulses per pixel) of a paper treated with a mixture of rhodamine and stearic acid.

Mesoscopic particles with dimensions in the nanometer range cannot be directly analyzed as individual particles by TOF-SIMS. However, if they are presented in the form of a sufficiently dense covering on a suitable sample support, the resulting secondary ion spectra yield valuable information about their composition and structure. For example, the negative secondary ion spectra of fullerenes can be used to directly determine the distribution of cluster sizes. For ligand-stabilized Au_{13} superclusters, secondary ions with masses up to $m/z = 150000$ have been observed, yielding important information about the structure of the clusters.[52] However, TOF-SIMS has still to be applied in a systematic way to the study of particles in this mesoscopic size range.

5. Summary and Outlook

Progress in the fundamental understanding of secondary ion emission and in its analytical applications depends critically on the close interaction between basic research, instrument development, and analytical applications. Thus, new analytical problems stimulate fundamental research on novel materials systems, often leading to further advances in knowledge about the ionization process. Analytical problems also directly influence instrument development, as has occurred, for example, in the development of surface imaging, in improvements in transmission and mass resolution, and in the development of techniques to counteract sample charging effects; all these have in turn directly benefited basic research. This review concludes with a summary of the present situation in secondary ion mass spectrometry and some likely future developments in the following three areas: fundamental knowledge (in particular of the generation of secondary ions), instrument technology, and analytical applications.

5.1. Generation of Secondary Ions

We have access to a large body of knowledge about the secondary ion emission behavior of many elements and molecules in diverse chemical environments, such as metals in different oxidation states[12, 13] and organic molecules on different substrate surfaces.[10] Well-founded propositions about secondary ion formation are drawn from these data which are valid either generally or for certain more or less narrowly defined classes of substances. This information on matters such as sputtering rates, the types of secondary ions formed, transformation probabilities, and secondary ion yields is scattered throughout the literature, and the collection and summary of such data is overdue.[52]

A number of experimental findings, including the increase of the metal ion yield by several orders of magnitude on going from a metal to its oxide, and the transformation probabilities close to 1 that are observed for alkali metals, halogens, and many anionic complexes, have led to the hypothesis of charge conservation in secondary ion emission. This states that sur-

face particles are emitted with a charge of the same sign as that which they had at the surface before emission. Such a "precursor" model is also in agreement with the general observation that protonated (deprotonated) molecular ions nearly always give positive (negative) secondary ions.

In order for a molecular ion to be emitted it must survive the sputtering process without disintegrating. This is more likely to occur if the bonding to the surface is weak. Moreover, a molecule ejected from a weakly bonding site will have less vibrational energy, such that the probability of it disintegrating later during its flight time through the spectometer is also small. As yet there is no satisfactory theoretical model to account for the emission of larger molecular secondary particles, in particular those from thermally unstable, nonvaporizable substances. This applies not only to the emission of intact molecules and fragments thereof but also to the processes by which they become ionized. Fundamental studies of precisely defined molecular surface systems of this kind are urgently needed.

5.2. Instrument Technology

The transition from sector field and quadrupole spectrometers to time-of-flight spectrometers was an important breakthrough in surface analysis by secondary ion mass spectrometry. This gave high mass resolution with a mass range that was in principle unlimited, together with a capability for precise mass measurement combined with high transmission and quasi-parallel ion counting, which thus increased the sensitivity by several orders of magnitude. These advantages opened up entirely new possibilities, both in fundamental studies and in applications to practical analytical problems. For these the development of the pulsed charge compensation technique was a very important advance. The buildup of charge on nonconducting specimens is a serious problem with all surface analysis methods such as XPS and AES. Charge compensation by pulsed injection of electrons in the target zone has practically eliminated this problem for TOF-SIMS.

The combination of a high-performance time-of-flight mass spectrometer with a finely focused pulsed ion beam allows surface imaging with a lateral resolution down to 50 nm. The mass analysis of neutral atomic and molecular particles that are emitted is a method of growing importance. With a time-of-flight mass spectrometer the post-ionization needed to make this possible can be carried out efficiently only by laser photoionization.[53] For modular TOF-SIMS instruments it is a straightforward matter to add on a laser system for this purpose (cf. Fig. 4).

During the last ten years time-of-flight secondary ion mass spectrometers have been developed to the stage of mature routine instruments. Several commercial manufacturers now offer reliable high-performance systems. Future instrument developments are likely to be directed towards reducing the time needed to record spectra and images, improving lateral resolution and mass resolution, further improving laser post-ionization facilities, and developing MS/MS techniques. One can also expect to see growth in the use of SIMS in combination with other methods such as XPS, AES, electron microscopy, scanning tunneling microscopy (STM), and atomic force microscopy (AFM).

5.3. Analytical Applications

In addition to the high sensitivity and detailed information on the molecular level possible with TOF-SIMS, an important reason for its widespread and growing use in analysis is that it is universally applicable to real samples of all kinds. Its applications now range from microelectronics through inorganic and organic chemistry, materials development, and environmental analysis to medical technology and clinical analysis. TOF-SIMS made it possible for the first time to obtain images and carry out local analysis of monolayers with high sensitivity, high lateral resolution, and high mass resolution, including measurements

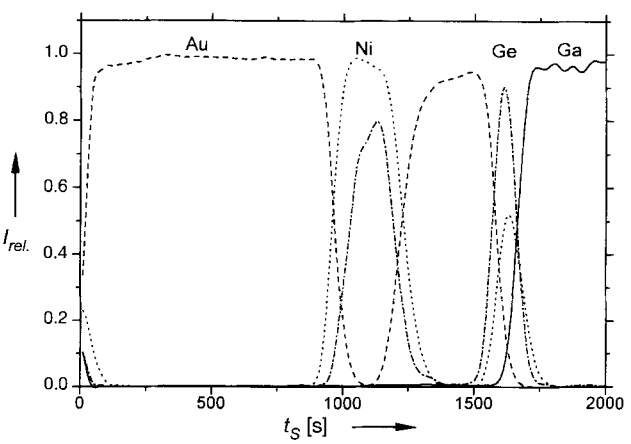

Fig. 31. Depth profile of a gold contact on a microchip, obtained by sputtering (sputter time t_s) over a 1 μm^2 area using a raster-scanned primary ion beam with a diameter of 0.1 μm. To reduce matrix effects the analysis was performed by observing neutral emitted particles after laser ionization.

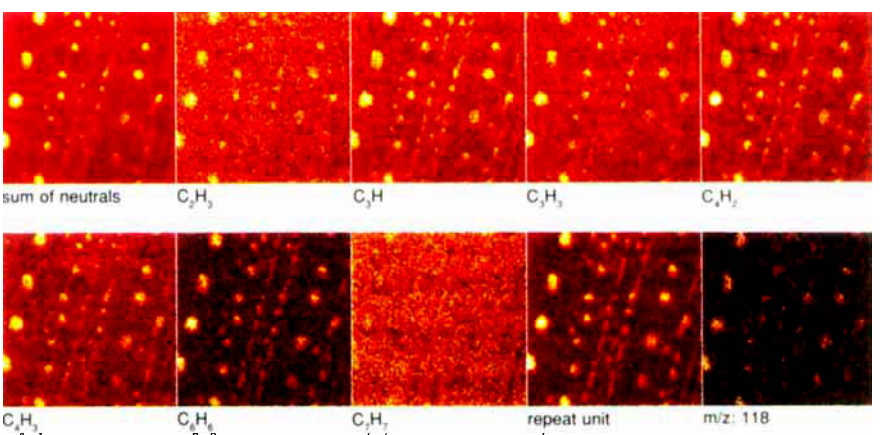

Fig. 32. Laser post-ionization of sputtered neutral particles used here to image polystyrene specks deposited from a solution onto a silicon surface. The emitted neutral particles were ionized by a UV laser before entering the mass analyzer. Field of view: 25 × 25 μm^2; primary ion fluence 10^{13} cm^{-2}; ca. 3500 primary ions per pulse; 128 × 128 pixels; 1 cycle per pixel.

in the high mass range, which gave both molecular and elemental information. The wealth of information yielded by TOF-SIMS for molecular (organic) film systems and surface modifications is particularly important, since these are being developed to replace conventional films (e.g. metals and oxides) for the production of surfaces with specific physical, chemical, and biological properties.

Quantitative SIMS analysis is greatly hindered by matrix effects, which sometimes necessitate very time-consuming comparative measurements and the use of internal or external standards. Calibrations can sometimes be made considerably more easily by measurements on post-ionized neutral particles, especially in elemental analysis (Fig. 31).[53] By using pulsed UV lasers with very short pulse durations (in the picosecond range), transformation probabilities approaching 1 have recently been achieved for metal atoms. With a lateral resolution of 0.1 μm this leads to an extrapolated detection limit of 10^{-4} of a monolayer.[54] Effective post-ionization of molecular surface species has also been achieved for a variety of types of materials (Fig. 32).[54–56]

Future work on the analytical applications of TOF-SIMS is likely to include fundamental studies (e.g. of the interaction of large molecules with precisely defined surfaces), advances in the analysis of particles (e.g. in the environment and in soil), studies of interfaces between organic and inorganic materials (e.g. metal/polymer interfaces, biocompatibility, immobilized molecular layers, lubricants), new materials (e.g. composites, molecular membranes, LB and SA films, catalysts, polymers), and technologies on the micrometer and nanometer scales (e.g. micromechanics, microelectronics, sensors). Biological specimens and sections pose an important challenge for imaging by molecular surface mass spectrometry. The prospect of obtaining molecular information from such materials opens up radically new potential applications. However, further advances in techniques are essential here, for example in the preparation of sections suitable for SIMS analysis, and in the development of "staining" methods.

Luminescent Labels—More than Just an Alternative to Radioisotopes?

Andreas Mayer* and Stephan Neuenhofer*

Chemical, chromatographic, or spectrometric methods are generally unsuitable for the detection of molecules in the nano- and subnanogram region because of their low sensitivity. The radioimmunoassay (RIA) developed by Yalow and Berson in 1959 combined the high sensitivity of radioactively labeled substances with the high specificity of immunological reactions for the first time. In this way it was possible to detect quantitatively the tiniest traces of substances in the presence of an excess of other, in some cases, similar foreign substances without prior enrichment. Immunoassays have certainly developed to become the most valuable analytical tool of in vitro diagnostics and are today routinely employed for the detection of endogenous and exogenous substances (e.g. hormones, tumor-associated proteins, bacteria, viruses, toxins, drugs, etc). The many disadvantages of radioactivity such as the required handling licenses, disposal costs, precautions necessary to prevent risks to health, short shelf-life, and limited sensitivity soon led to the search for other nonradioactive labeling methods. Encouraged by the development of light measuring techniques and the commercial availability of highly sensitive apparatus, radioactive isotopes as labels are today being replaced increasingly by enzymes, fluorophores, or luminophores. Some of the new luminescent labels have, however, not only facilitated replacement of radioisotopes, but also a breakthrough into what has until now been unattainable levels of sensitivity. The following article reviews the methods of luminescent labeling and their applications mainly in the area of immunoassays.

1. Introduction

The detection of substances with reagents which bind to the compound to be determined (analyte) is essentially dependent on three conditions if lower detection limits in the pico- to femtomolar region are to be attained and structurally similar substances are not to be measured in addition. First, the detection reagent must have a high affinity for the analyte so that even an analyte present in trace amounts is determined. Second, the binding of the detection reagent to the analyte should be highly specific; this ensures that substances similar to the analyte do not give rise to a deceptively higher concentration of the analyte, or make a time-consuming and labor-intensive prepurification necessary. Third, the reaction product from the analyte and binding reagent must be sensitive to detection, that is, emit a signal which can be quantified exactly by suitable analytical instruments.

The demands for affinity and specificity are ideally fulfilled by antibodies. This involves endogenous glycoproteins, which in organisms of higher life forms, play a decisive role within the immune system by eliminating harmful substances (bacteria, viruses, toxins etc.). In general, affinity constants of antibodies lie between 10^{10} and $10^{12}\,L\,mol^{-1}$. They are capable of recognizing the smallest structural differences at the molecular level, because only then can they distinguish reliably between exogenous and endogenous substances; confusion between the two would have fatal consequences for the host organism.

The first methods used to label detection reagents and thus make them exactly quantifiable employed radioactive isotopes, of which the ^{125}I isotope, in particular, is still in use today. The advantages of this γ emitter are its small size (minimization of steric interference), its "hard" signal, which as a result is less prone to interference, and its lower detection limit of approximately 10 amol (1 amol $= 10^{-18}$ mol).

The combination of antibody/radioactive labeling led to the introduction of radioimmunoassays at the end of the 1950s.[1] These have developed into the most important tool of in vitro diagnostics in medicine.[2] All conceivable endogenous and exogenous substances in the body fluids (e.g. blood or serum) taken from a patient are routinely determined quantitatively by radioimmunoassays. Of considerable importance for routine applicability is that despite the complex composition of the serum medium under investigation, in general, further purifica-

tion steps are not necessary because of the high specificity of the detection reagent "antibody".

Besides the advantages of radioactive labeling there are also, however, a number of disadvantages: The handling of radioactive materials is regulated (official license) and is, thus, limited. The half-life of 60 days for ^{125}I isotope is too short to guarantee a longer shelf-life for labeled reagents. Limited signal emission during measurement due to the natural half-life prevents the high detection sensitivity required for some applications.

In order to overcome these disadvantages the search for nonradioactive labeling methods (nonisotopic methods) in immunodiagnostics had already begun long ago.[3] At the beginning of the 1970s the use of enzymes as labels was described,[4] and in the meantime a large number of stable enzyme labels have become available. In combination with chromogenic or luminogenic substrates, detection of the signal is attributed to the measurement of light as absorption or emission. Emitted light instead of radioactive radiation is also employed in luminogenic direct labeling for the quantification of the analyte concentration. Since the number of photons from samples of luminescent-labeled molecules can be higher than the number of radiation quanta emitted from radioisotopes,[5] initially fluorescence detection seemed to have a good chance of a wide application in nonradioactive labeling;[5, 6] for example, detection of a single fluorescent-labeled protein molecule was successful.[7, 8] However, because of certain disadvantages associated with the first fluorescent label a signifcant replacement of the radioactive label was not forthcoming. This was only achieved by further development of luminescent labels and luminogenic enzyme substrates.[9–15] Luminescent labels not only dispense with having to handle radioactivity but they also allow more precise diagnostic results on account of enhanced sensitivity, and open up new areas of application.

In 1985 the radioimmunoassay (RIA) dominated the German immunoassay market (83% share) with the greatest turnover in the indication fields endocrinology (thyroid gland, fertility) and tumor diagnosis (Fig. 1). The tendency towards the use of methods with nonisotopically labeled compounds is shown in the statistics for 1991; the RIA share of the market has sunk considerably to 55%.[16] The market share of nonradioactive methods comprises luminescence techniques (e.g. fluorescence immunoassay (FIA), chemiluminescence immunoassay (CIA)), enzyme immunoassay (EIA), and other methods such as nephelometry. A further increase in the market share for methods that work without isotopically labeled compounds is to be expected in the future.

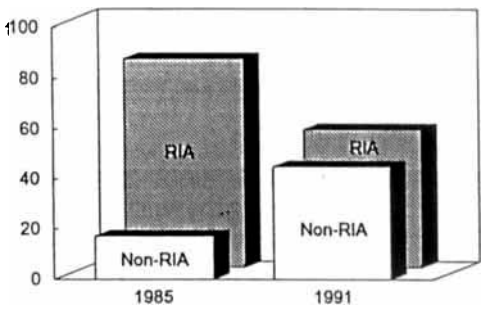

Fig. 1. Market share of radioactive (RIA) and nonradioactive immunoassays (non-RIA).

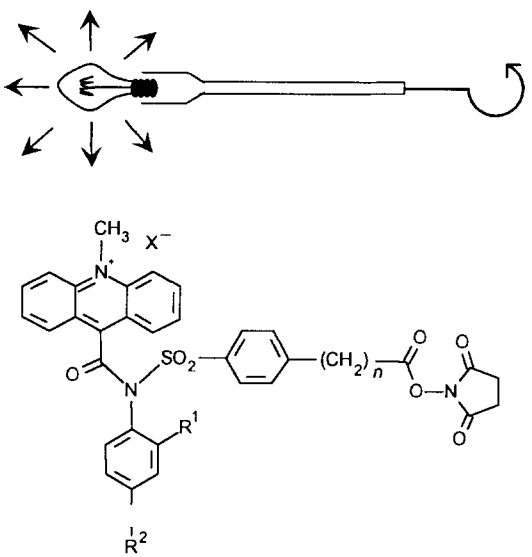
This review article deals in the broadest sense with luminescent labels and their application. After a definition of the term "label" in Section 2 luminescent processes are presented in a simplified energy-level diagram in Section 3. Section 4 describes the enzyme labels in combination with chromogenic and luminogenic substrates. In Section 5 labels for luminescent direct labeling with special consideration of the underlying mechanisms of chemiluminescent labeling are discussed. Section 6 presents several examples of applications in medicine; further important areas of application are in environmental and food analysis.[17g–h, 18k–p] In addition to the literature already mentioned, the theme of luminescent labels, nonradioactive immunoassays, and gene probes is referred to in several recent books[17] and review articles.[18]

Andreas Mayer, born 1960 in Aschaffenburg, studied chemistry at the Universität Würzburg and received his doctorate under the supervision of H. Quast for work on dicyanosemibullvalenes. In 1989 he entered the main laboratory of the Hoechst AG and strengthened the team working on the development of chemiluminescent labels for diagnostic applications. The main emphasis of his work so far has been the synthesis of functional dyes for applications in the area of diagnostics and information technology.

Stephan Neuenhofer, born 1955 in Mayen/Eifel, studied chemistry and pharmacy in Bonn. After completing his diploma in chemistry (1982) he moved into biochemistry and received his doctorate in 1985 with K. Sandhoff on the topic of gangliosides (Lysogangliosides—Synthesis, Detection in Pathological Brain Tissue and Applications in Biochemical Studies). For his dissertation he received the Edmund-Ter-Meer-Preis. In 1987 he received his approbation as a pharmacist. In August 1987 he began working in the research and development department at the Hoechst AG. His area of interests comprises luminogenic labeling substances, immunoassays, and diagnostic systems as well as their transfer to production. He moved to Behringwerke AG in October 1993 where he has continued with these avenues of research.



A. Mayer S. Neuenhofer

2. The Label

2.1. Definition and General Structure

A label is a molecule capable of emitting a signal, which is used for labeling proteins and other molecules. It contains, apart from the signal-generating group (fluorescer; more specifically, label), another reactive group (anchor group) which facilitates the covalent bonding to the molecule to be labeled. Between these two groups there is usually a spacer which is supposed to prevent, or at least make difficult, undesirable steric interactions between the signal-generating group of the molecule and the labeled substance. In this way any influences on the immunological reaction ought to be excluded. The schematic structure of a label as well as the chemical formula of a chemiluminescent label from the

Scheme 1. Schematic representation of a luminescent label (top) with the three components: signal-generating unit (fluorescer), spacer, and anchor group as well as a concrete example from the *N*-methylacridinium-9-(*N*-sulfonyl)carboxamide class of compounds (bottom).

class of *N*-methylacridinium-9-(*N*-sulfonyl)carboxamides is shown in Scheme 1. A substance labeled in this way is designated as a tracer.

2.2. Luminescent Labels

2.2.1. *Definitions of Terms*

The term luminescence[19] serves as the generic term for most light emission processes such as fluorescence, phosphorescence, chemiluminescence, electroluminescence etc. Exceptions are, for example, glow emission and coherent scattering processes. In practice, three categories are often used, namely luminescence, fluorescence, and phosphorescence. Luminescence serves as the generic term for chemi- and bioluminescence.

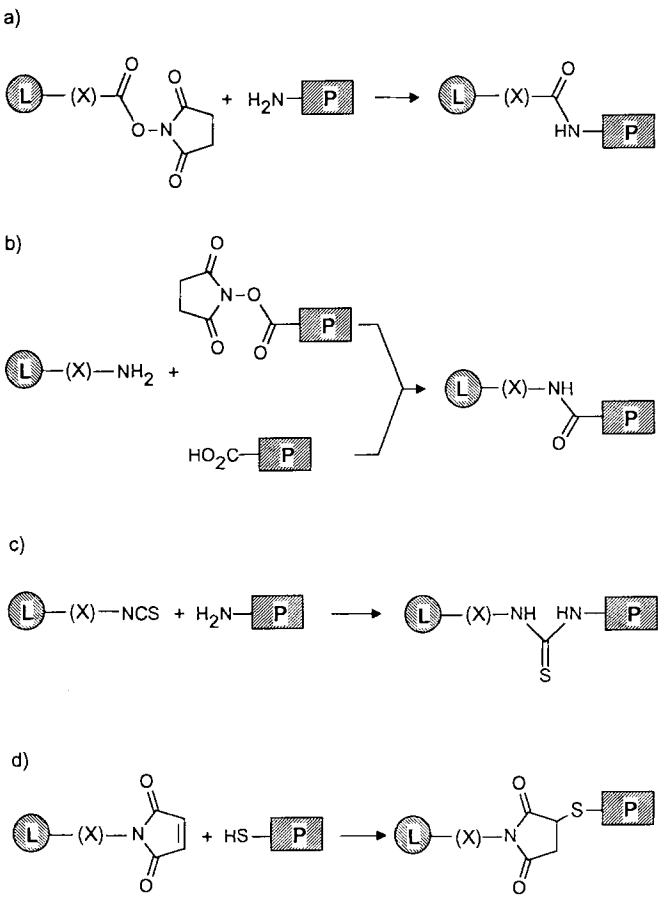
2.2.2. *Requirements for the Suitability as a Luminescent Label*

The suitability of a compound as a luminescent label has certain conditions which must be fulfilled:[20]

Coupling to the compound to be analyzed (analyte) must be simple and quite gentle. A large palette of reactive groups is available for this purpose.

The luminescent properties of the label should not change significantly after the coupling.

The properties of the labeled substance must not be altered significantly by the labeling. The whole spectrum of characteristics must be taken into consideration, for example physico-chemical properties such as solubility and immunological properties. For the duration of the immunoassay, the immunological reactivity, in particular, must remain sufficiently high.



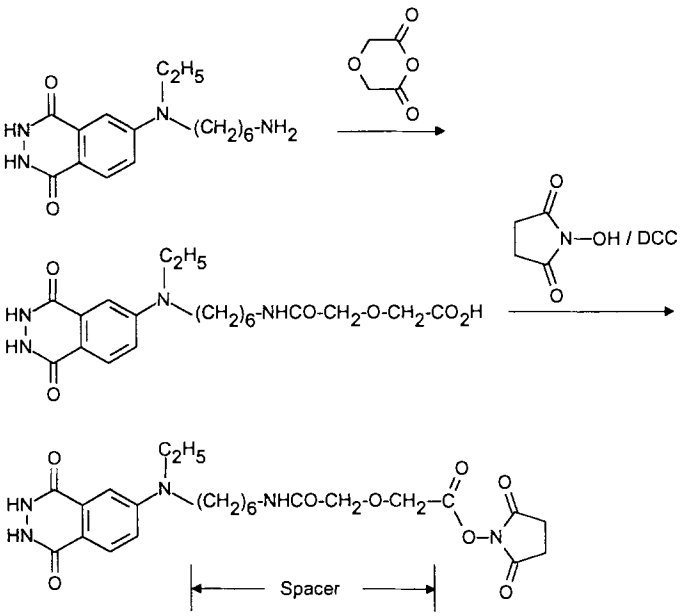
Of course, these general requirements, with the exception of the second point, are also applicable to other labels. The extent to which these points are fulfilled greatly depends on the details of each system and differs from case to case. For instance, small molecules (molecular weight <2 kD) are altered more significantly than large proteins when labeled with a marker of similar size. Proteins, however, are often more sensitive under the labeling conditions; for example, syntheses cannot be carried out in organic solvents. Nevertheless, for most, the conditions to yield suitable conjugates are established by chemical modification of the signal-generating group and/or of the spacer and by choice of the optimal reactive group.

2.2.3. *The Signal-Generating Group*

Fundamentally all luminescent compounds can be considered to be signal-generating groups if they exhibit a sufficient quantum yield in aqueous solutions, are stable enough under the conditions employed, and can be functionalized synthetically in such a way that a reactive group can be bound and the properties can be modified, for example, to increase the solubility in water or to change emission characteristics such as wavelength and decay time. Variability is a prerequisite for the broadest possible application of the label. The most important fluorescent and chemiluminescent labels are considered in more detail in Section 5.[7a, 21]

2.2.4. *The Reactive Group*

As mentioned previously, the reactive or anchor group is used to bind the label to the substance to be labeled. Since coupling to biological material such as proteins, antibodies, hormones etc. is frequently necessary, the formation of an acid amide bond between activated carboxyl groups and amino groups is quite common. Many processes for this are known in peptide chemistry which proceed in aqueous solution under mild conditions.[22, 23] However, only a few reactions have achieved practical significance for labeling processes. Some of the most important coupling reactions are summarized in Scheme 2. Many luminescent labels have an *N*-hydroxysuccinimide (NHS) ester as the reactive group (Scheme 2a).[21, 25] This reactive group has several advantages:[22, 24] it can be readily synthesized from carboxylic acid derivatives;[26] corresponding labels can be purified to a high degree, for example, by HPLC; thus, labeling can be carried out

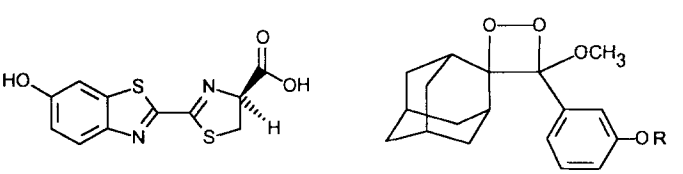


Scheme 2. Important labeling processes; L = label, P = protein, X = spacer.

in a defined and reproducible way. With the exclusion of moisture it is possible to store the label over longer periods of time without the reversal of the coupling activity.[24, 27, 28] The coupling reaction of the succinimide with amino groups proceeds under mild conditions (room temperature) in aqueous solutions; in contrast, alcohols do not react with NHS esters under these conditions.[27] As a variation of this reaction the label can also contain a primary amino functionality as the reactive group for coupling with an NHS ester functionality on the protein (Scheme 2b). The conversion can also be achieved with free carboxyl groups, for example, of proteins, following carbodiimide or "mixed anhydride" methods.[22, 23, 25] Recently acridinium ester labels with imido ester reactive groups were described.[29] Particularly in the case of fluorescent labels, in addition to the the methods already mentioned the isothiocyanate group is often used for coupling with amino groups of proteins to form thiourea derivatives (Scheme 2c).[30] The method shown in Scheme 2d for the coupling by thiol addition to maleic imido groups is well known in peptide chemistry. This reaction is also employed in luminescent labeling[21] and plays a particularly important role in the coupling of enzyme labels to proteins.[31]

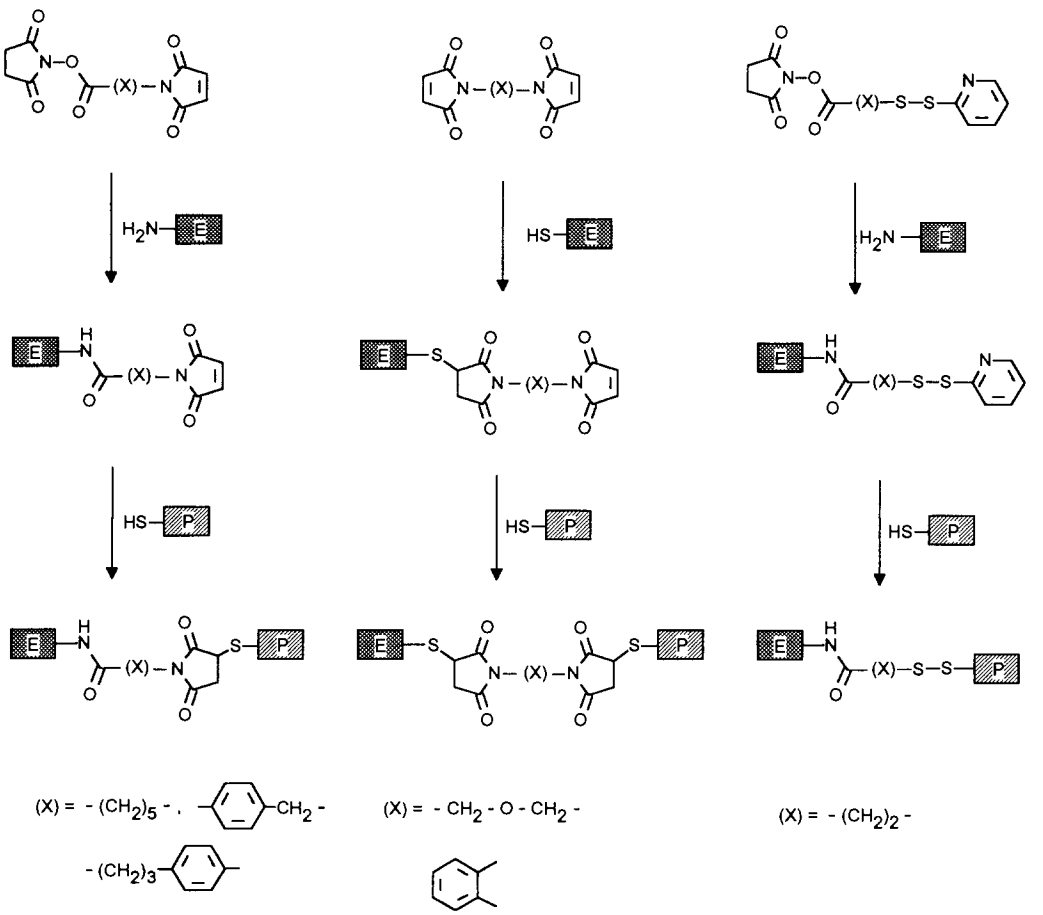
2.2.5. *The Spacer*

Usually simple, short alkyl chains or groups which contain aromatic and aliphatic groups (cf. Scheme 1) are employed as



Scheme 3. Synthesis method for a spacer with an NHS reactive group as illustrated by an example of an isoluminol label; DCC = dicyclohexylcarbodiimide.

spacer. An example of the conversion of an amino group of an isoluminol label to give an NHS ester is shown in Scheme 3.[32] By using a spacer of the type shown, which contains several acid amide groups and ether bridges as hydrophilic units, the solubility of immunoconjugates in water can be improved.[33]



2.3. Enzyme Labels

As a result of their practical significance chromogens and luminogens are also dealt with in this article; these are employed as substrates for the enzyme label (Section 4). The reaction of luciferin derivatives (naturally occurring bioluminescent compounds) with their respective luciferase (enzyme which catalyzes the bioluminescent reaction) leads to luminescent reactions with the highest known quantum yields. The leader in this field is the luciferin (Scheme 4)/luciferase system of the North American

Scheme 4. Firefly luciferin (left) and a stable dioxetane derivative (right).

firefly (*Photinus Pyralis*) with quantum yields around 0.9 Einstein mol^{-1}.[11, 15] Since the end of the 1980s important biogenic luciferases have been genetically engineered and are thus now considered for routine applications.[15] High quantum yields are also obtained by enzyme labels with stable dioxetanes (Scheme 4) as luminogenic substrates. The enzymes often employed are alkaline phosphatase and β-galactosidase (the residue R is phosphate and β-galactose, respectively). Such enzymatic systems are dealt with in more detail in Section 4.

Scheme 5. Bifunctional coupling reagents for labeling of enzymes; E = enzyme, P = protein (e.g. antibody), X = spacer.

Since, in general, enzyme labels are not obtainable as stable universally applicable labels, several methods for enzyme labeling should be addressed. The coupling of enzymes to antibodies or fragments of antibodies is often achieved by bifunctional coupling reagents. Some examples are shown in Scheme 5. The reactions are analogous to the methods already mentioned in Section 2.2.4, and details can be obtained from the references cited in the literature.[24, 31] Coupling methods that exploit the strong noncovalent bonding of the biotin/(strept-)avidin system can only be referred to here.[34]

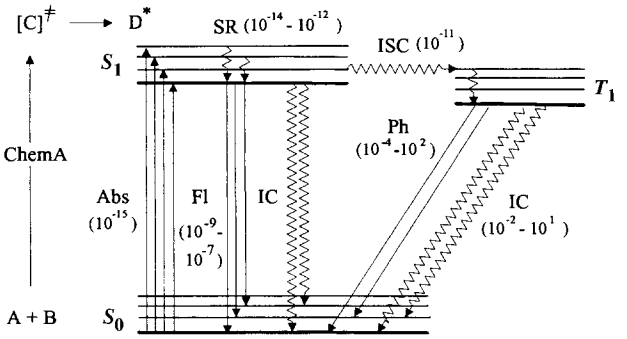
3. Electromagnetic Radiation as the Measured Signal

3.1. Comparison of Light and Radioactive Radiation

A considerable disadvantage in the use of radioactive isotopes is the necessity to undertake extensive safety precautions against high-energy β- or γ radiation (up to 10^{18} kJ mol^{-1}). Since luminescent labels emit light which is not dangerous—mostly in the visible region of the electromagnetic spectrum ($E \approx$ 200 kJ mol^{-1})—safety measures for the protection from high-energy radiation are no longer required. Furthermore, the specific activity that can be achieved with radioisotopes has an upper limit set by the radiolytic decomposition of the labeled material. Labeling with the isotope ^{125}I is usually limited to one atom per molecule.[21, 35] In addition, the half-life of the radioisotope, which, for example, is only 59.7 days for the frequently used ^{125}I, limits the storability of the labeled material and detection limits. Moreover, radioisotopes emit radiation continuously even when a signal is not necessary for measurement. For the actual measurement, which normally lasts about a minute, only a tiny fraction of the available signal, can be used. An advantage, however, is that a repeat measurement is possible at any time. Luminescent labels, which have a considerably longer lifetime, emit all the available light within a very short space of time once the light reaction has been triggered. In addition, the activity of the tracer can be enhanced further mainly by multiple labelings; in this way the sensitivity of detection is increased. Repeat measurements on the same sample are, however, not possible, at least in the application of chemiluminescent labels with rapid light emission.

3.2. Photophysical Processes

In the simplified energy-level diagram in Figure 2 the most important photophysical processes are summarized with their typical lifetimes τ [s].[36] The radiative transitions shown can be used for the production of detection signals. Since radiationless deactivation leads to less efficiency, especially in long-lived phosphorescence processes in solution, phosphorescence detection plays a minor role for luminescent labels. Finally, the quantification in enzyme systems with chromogenic substrates (cf. Sec-



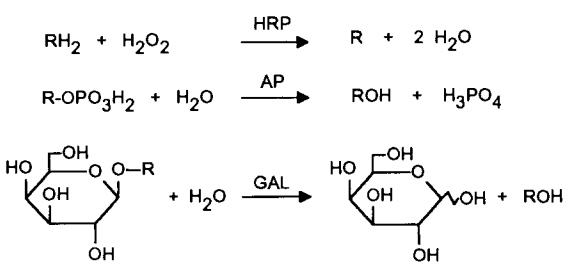


Fig. 2. Simplified energy-level diagram with some photophysical processes. Lifetime τ [s] is given in parentheses; Abs = absorption, Fl = fluorescence, Ph = phosphorescence, SR = vibrational relaxation, ChemA = chemical excitation, IC = internal conversion, ISC = intersystem crossing; straight lines represent radiative processes and wavy lines radiationless processes.

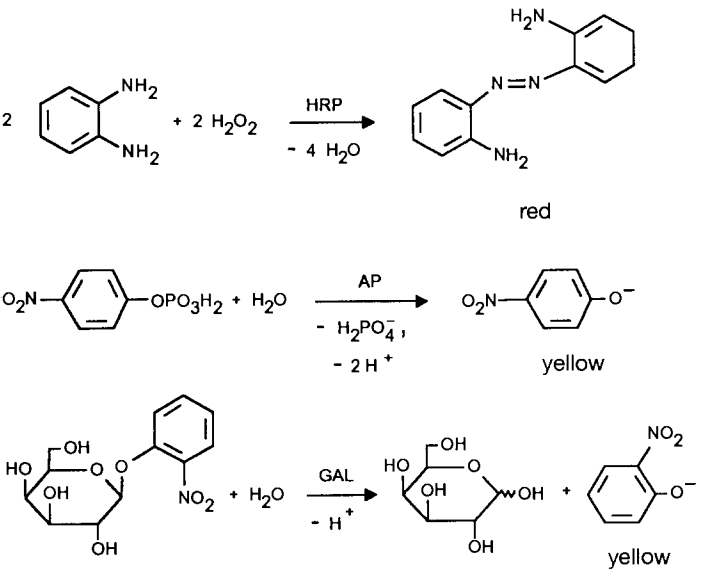
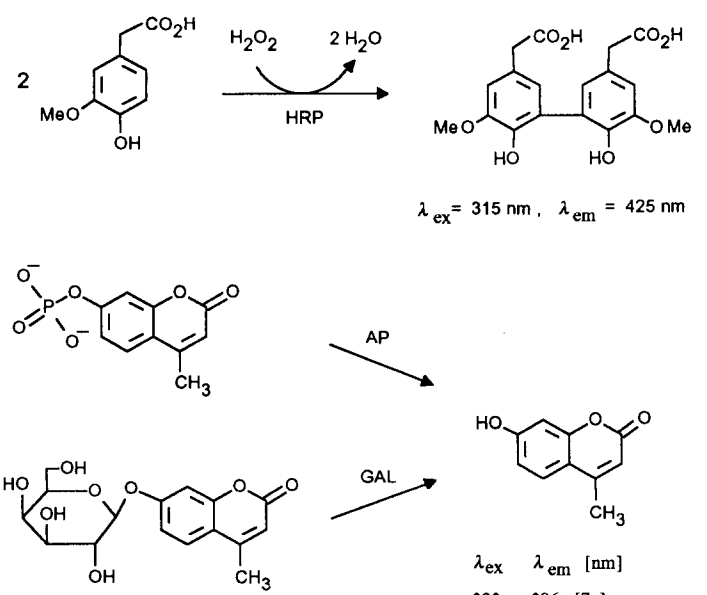
tion 4) is ascribable to absorption measurements. Photoexcitation and evaluation of the fluorescence provide the basis for fluorescent labeling (cf. Section 5.1). The production of excited singlet states (S_1) by chemical reactions is necessary for chemiluminescence detection. The difference in energy between the S_1 and S_0 states for emissions in the visible region lies between 167 (red light) and 293 kJ mol^{-1} (violet light).[11,37] For the effective use of the principles mentioned, in each case, sufficient quantum yields are also a prerequisite. Further details are given for each individual luminophore (see Section 5).

4. Enzyme Labels

The use of enzymes as labels presented the first alternative to radioactive labeling.[38] The basic idea is very promising, because no signal-generating compounds are used, but molecules (enzymes) which produce a lot of signal-generating species. In this way an effective signal amplification mechanism is built in right from the outset.



The three most important enzymes that are used as labels are horseradish peroxidase (HRP), alkaline phosphotase (AP), and β-D-galactosidase (GAL). The reactions catalyzed by these enzymes are summarized in Scheme 6. HRP is the smallest enzyme

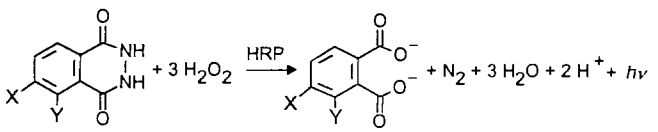


Scheme 6. General representation of the reactions catalyzed by the three most important enzyme labels HRP, AP, and GAL.

of the three with a molecular weight of approximately 40 kD (AP approx. 100 kD, GAL approx. 500 kD) and as a result presents the fewest steric problems. HRP is, however, sensitive towards antimicrobial agents (azide, Thiomersal) frequently employed. AP has the highest catalytic activity; however, it is inhibited by phosphate (product inhibition) and ethylenediaminetetraacetic acid (edta; chelates Zn^{2+} and Mg^{2+} ions which are necessary for enzyme activity).

The oldest enzyme substrates to be employed in analytical methods are the chromogens. These are colorless and are only transformed into colored products by an enzymatic reaction. These products can be quantified photometrically; Scheme 7 shows examples.

Scheme 7. Examples of chromogenic substrates. Apart from *o*-phenylenediamine, 3,3',5,5'-tetramethylbenzidine (TMB) and 2,2'-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) are often employed. Instead of 4-nitrophenylphosphate, 1-napthylphosphate and 5-bromo-4-chloro-3-indolylphosphate are often employed. In addition to 2- or 4-nitrophenyl-β-D-galactopyranoside, chlorophenol red-β-galactopyranoside and 5-bromo-4-chloro-3-indolyl-β-galactopyranoside are often employed.

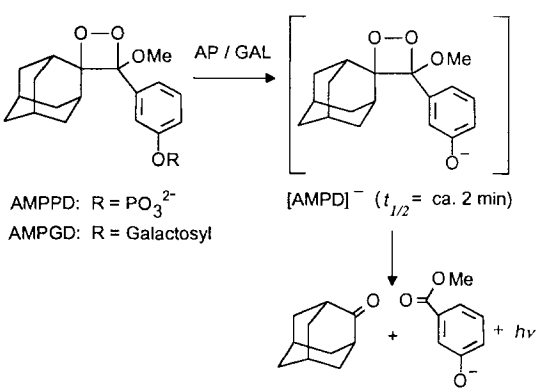


λ_{ex}	λ_{em} [nm]	
323	386	[7a]
380	450	[6]
360	447	[44]

Scheme 8. Examples of fluorogenic substrates. λ_{ex} = excitation wavelength, λ_{em} = emission wavelength.

The most important fluorogenic substrates of the peroxidases contain the same structural element[39, 40, 43] *p*-HO–C_6H_4-C-, whereas in the case of AP and GAL,[41–43] 4-methylumbelliferyl compounds are preferred (Scheme 8).

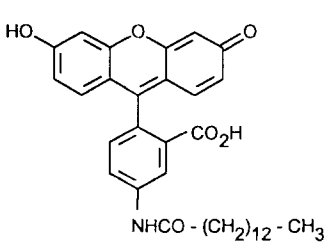
The chemiluminescent arylhydrazides luminol and isoluminol[45] (Scheme 9) are known substrates for HRP. The quantum



Luminol: X = H, Y = NH_2
Isoluminol: X = NH_2, Y = H

Scheme 9. HRP-catalyzed oxidation of luminol and isoluminol.

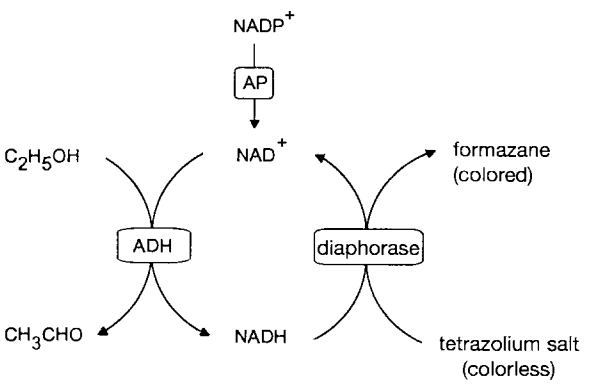
yields of the oxidation of these arylhydrazides, that is, the percentage of the molecules of the starting material which at the end of the reaction afford a photon-emitting final product, is approximately 1%. The light intensity can be drastically increased (up to a factor of 1000!) by so-called enhancers such as 6-hydroxybenzothiazole derivatives or *para*-substituted phenols in comparison to a non-enhanced reaction.[46] The underlying mechanism of this enhanced chemiluminescence is not completely understood. The most probable explanation is that one or more of the oxidation steps to generate luminol radicals during the complex reaction pathway of the enzymatic oxidation is accelerated.[46k]



Dioxetane derivatives are the most important chemiluminogenic substrates for AP and GAL[47] (Scheme 10). Also in the

AMPPD: R = PO_3^{2-}
AMPGD: R = Galactosyl

[AMPD]$^-$ ($t_{1/2}$ = ca. 2 min)



Scheme 10. Adamantylmethoxy(phosphoryloxyphenyl)dioxetane (AMPPD) and adamantylmethoxy(galactopyranosyloxyphenyl)dioxetane (AMPGD) as enzyme substrates. This reaction is catalyzed by AP and GAL.

Scheme 11. Example [5-(*N*-tetradecanoylamino fluorescein)] of a fluorescent tenside.

reactions catalyzed by AP and GAL, the chemiluminescence can be enhanced; for this purpose fluorescent tensides are particularly effective (Scheme 11). Together with normal tenside molecules (e.g. cetyltrimethylammonium bromide) they form micelles into which the substrate diffuses immediately after enzymatic cleavage of the phosphate or galactoside residue. Decomposition of the dioxetane derivative in the micelle leads to an effective transfer of energy to the fluorophore groups of the tenside molecules. This results in a considerable increase in the quantum yield[47j] (Φ_{CL} = approx. 0.005 Einstein per mol; for comparison: Φ_{CL} in tenside-free aqueous buffer solution is ca. 10^{-5} Einstein per mol). According to the literature, as few as 600 different enzyme molecules have so far been detected by employing dioxetane derivatives.[47e]

In the detection systems described previously the signal-generating group forms immediately in the reaction catalyzed by the enzyme label. There is also, however, a series of detection systems in which the signal-generating group is formed only in a subsequent reaction. In analogy to enzyme-catalyzed reactions, considerable increases in the sensitivity can often be achieved by such coupling reactions. In the detection system of Self,[48a] the enzyme label AP catalyzes the formation of NAD^+ from $NADP^+$. The NAD^+ formed catalyzes a specific redox cycle from which a colored substance is produced (Scheme 12).

Scheme 12. Example of a signal amplification: The NAD formed from AP acts as a catalyst in a subsequent redox cycle. ADH = alcohol dehydrogenase.

The lower detection limit for the enzyme label AP with this method was given as 0.01 amol,[48b] and in a more recent publication[48c] even 0.6 zmol (1 zeptomol = 10^{-21} mol); values which would have been inconceivable for direct formation of a dye.

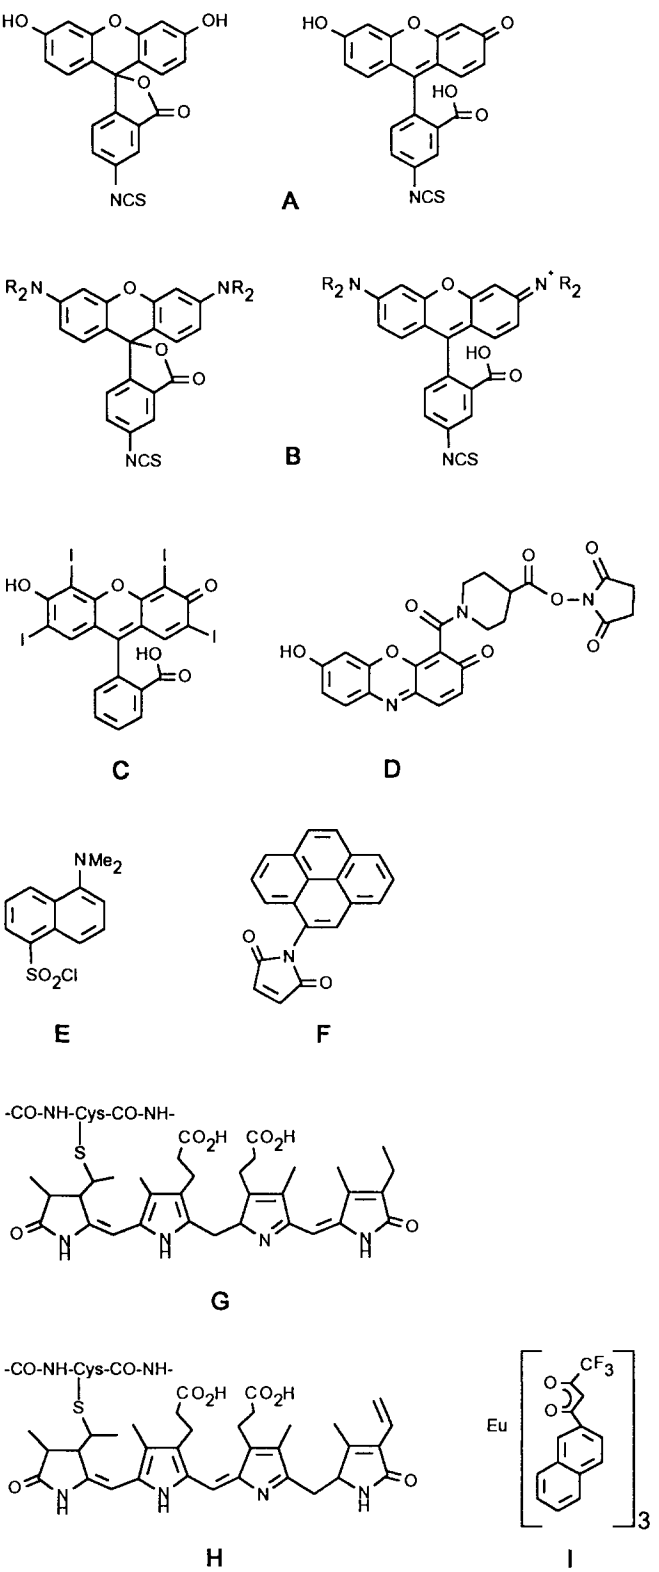
Another method for the highly sensitive detection of AP was described by Christopoulos and Diamandis.[49] AP catalyzes formation of 5-fluorosalicylic acid from 5-fluorosalicylic phosphate. In a subsequent reaction 5-fluorosalicylic acid forms a strongly fluorescing ternary complex with Tb^{3+} and edta the concentration of which can be quantified by time-resolved fluorescence measurements (cf. Section 5.1.4). The lower detection limit was quoted as being 0.6 amol AP per 50 μL sample volume. In the detection system of A. Baret et al.[50] xanthine oxidase is used as the enzyme label. In the presence of oxygen, it oxidizes hypoxanthine to xanthine and uric acid with formation of superoxide radical anions ($O_2^{\cdot-}$). Additional reactive oxygen species (H_2O_2, $^1O_2$, $OH^{\cdot}$) that form in subsequent reactions are suitable for the chemiluminescent oxidation of luminol.

5. Luminescent Labels

5.1. Fluorescent Labeling

Fluorescent labels have been used for a wide range of applications in biology, biomedicine, and analytic methods for a long time.[30] Applications worthy of mention are fluorescence detection with HPLC after precolumn or postcolumn derivatization,[51] flow cytometry,[52] fluorescence microscopy,[53] DNA analysis,[54] and the use as labels in immunoassays, which will be covered in more detail here (see Section 5.1.1). Labeling is usually achieved by the formation of a covalent bond between label—as described, in general, in Section 2—and target substance. Fluorescent dyes without a reactive group can be employed for some purposes. They are only bonded associatively and as a result can accumulate, for example, in cells. A review of fluorochromes that are applied in medicine and biology as well as their spectral data can be found in reference [36].

5.1.1. Special Requirements of Fluorescent Labels for Immunoassays



Besides the previously mentioned general requirements for luminescent labels, fluorescent labels for the use in immunoassays should fulfill a few additional conditions which can be derived directly from measured data. In principle, fluorescence measurements of the highest sensitivity are indeed possible,[6, 7, 55] but, in practice, the sensitivity of fluorescent immunoassays (FIAs) is, however, drastically limited by background fluorescence, light scattering and quenching effects. The intrinsic fluorescence of serum components is mainly responsible for the background signal[6, 7] which covers a broad wavelength region. Serum proteins are excited, for example, at 280 nm and emit at 320–350 nm. Other components such as NADH and bilirubin are excited between 330 and 360 nm and 450 and 460 nm, respectively, and fluoresce in the range 430–470 nm and 515 nm, respectively.[7c] The detection limit for immunoconjugates of a fluorescent label with bovine serum albumin or immunoglobulin G (IgG) is on average 10 to 50 times worse in serum than in buffer solution.[6a] Many solid phase materials, for example polystyrene, likewise yield a blank reading. Light scattering is a problem, particularly, in solutions which contain proteins or colloidally dispersed substances. In addition to Rayleigh and Tyndall scattering at the same frequency as the excitation beam, Raman scattering also occurs with a frequency usually shifted by approximately 50 nm. Fluorescence quenching can often result from the smallest changes in the environment of the fluorophore (pH, polarity, oxidation level, proximity of heavy atoms or other absorbing groups). If, for example, a protein is multiply labeled, two fluorophores can become so close that self-quenching of the signal takes place if the absorption and emission spectra overlap.

In order to minimize the influences mentioned the following properties of fluorescent labels are desirable:[56] a) longest possible wavelength emission (500–700 nm), b) large Stoke's shift of > 50 nm, c) long fluorescence lifetime of $\tau > 20$ ns.

A sufficiently long lifetime is particularly significant in applying the principle of fluorescence polarization transfer (cf. Section 5.1.3). Fluorescence lifetimes $\tau > 100$ ns facilitate a significant improvement of the signal-to-noise ratio and thus of the sensitivity, since measurement can only take place after decay of background fluorescence and light scattering. This principle is applied in time-resolved fluorescence measurements which are explained in more detail in Section 5.1.4.

5.1.2. Labels for Direct Fluorescent Labeling

The first compound used for fluorescent labeling of biological material by Coons et al. in 1941 was anthracene isocyanate for the labeling of bacterial proteins.[57] The same group introduced fluoroscein isothiocyanate (FITC, **A**, Scheme 13) as a more ef-

Scheme 13. Selected fluorescent labels **A**–**I**. See Table 1.

fective label soon afterwards.[58] Although judging from its spectral data this xanthene dye (cf. Table 1) does not completely fulfil the above-mentioned requirements for fluorescent labels,

Table 1. Spectral data of selected fluorescent labels **A**–**I**.

	$\lambda_{abs,exc}$ [nm]	λ_{em} [nm]	ε [L mol^{-1} cm^{-1}]	τ [ns]	θ

[a] Unclear literature values: 12300 [6a,b]; 10300 [7a]. b) fl = fluorescence; ph = phosphorescence. c) Most phycobiliproteins afford θ values up to 0.98.

FITC has become the fluorochrome of choice in most applications.[5, 10] Despite the large number of fluorescent labels which have been developed since, FITC still remains the most commonly used in fluorescence immunoassays, possibly due to a high quantum yield and stability. Similar properties are exhibited by rhodamines **B** which belong to the same class of dyes (Scheme 13). Both dyes can exist in the two isomeric forms shown, a spirolactone and quinoid structure.

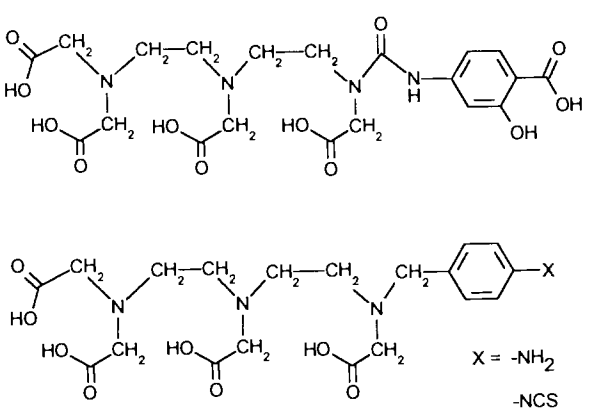
Efforts to obtain fluorescent labels that can be excited in the longwave region and also emit revealed, for example, that derivatives of the phenoxazin dye resorufin were successful to a certain extent. In the synthesis of fluorescent labels, suitably functionalized resorufins are obtained, for example, from nitroresorcin and 2,6-dihydroxybenzoic acid after reduction of the initially formed resazurine (resorufin-*N*-oxide). Apart from the derivative **D** shown in Scheme 13 which has a succinimidoyl ester as the reactive group, labels based on resorufin with other reactive groups are also known. Compared to fluorescein, resorufin is less affected by the background fluorescence of serum.[59] A longwave shift of excitation and emission wavelengths is also possible with phycobiliproteins,[60] which are obtained from different kinds of red and green algae. The structures of the two prosthetic groups are given in Scheme 13 (**G**, **H**). The compounds exhibit very high molar extinction coefficients and high quantum yields (> 0.8).[61] Not all phycobiliproteins couple with the protein at the A-ring. The substances, which have, in the meantime, become commercially available, were first employed in fluorescence microscopy and flow cytometry, thereafter as labels in immunoassays. When, for example, fluorescein was replaced by phycoerythrin in a sandwich immunoassay, a significant increase in sensitivity (factor 2–10) was achieved; however, this was below that expected from the spectral data.[61, 62] The size of the label and the difficulty in coupling are unfavorable. Since the phycobiliproteins show a broad excitation and emission band, a parallel determination of several parameters is conceivable by the use of different labels with non-overlapping emission bands. This was confirmed in preliminary experiments.

5.1.3. Fluorescence Polarization

The principle of fluorescence polarization,[63] known for a long time, was first employed in the antigen–antibody reaction in 1961.[64] Fluorescence polarization immunoassay is based on the following principle: if a fluorescing compound in solution is excited by polarized light, the observed emission is also polarized. The degree of this polarization depends upon the rotation relaxation time and, thus, on the size of the molecule. If a small (M: 1–10 kD) fluorescent-labeled fast-rotating molecule is bound to an antibody ($M \approx 160$ kD), the result is an increase in the rotating relaxation time of the slowly tumbling immunocomplex and thus also the polarization of the fluorescence. With this principle one can differentiate between unbound labeled antigen and immunocomplex. The method is, however, not suitable for large antigens, since the rotation hardly changes on formation of the immunocomplex. A more exact derivation of the measurement principles is given in reference [63]. The fluorophores mentioned already can be used as labels, although substances with longer fluorescence lifetimes would be more advantageous. In most cases fluorescein isothiocyanate **A** is employed. Accordingly, the sensitivity is limited by factors mentioned already.

Since no separation step is necessary with this principle (homogeneous immunoassay), determinations can be carried out relatively easily provided that sensitivity in the picomolar region is not required. Fluorescence polarization immunoassay is widely used particularly in the area of drug analysis.[59, 63] This method can also be employed in environmental analysis, for example, in the determination of polychlorinated biphenyls (PCBs). Fluorescein derivatives are used as labels.[65]

5.1.4. Time-Resolved Fluorescence



It has already been mentioned that the limiting background fluorescence and the scattering effects can be excluded by the use of labels with very long fluorescence lifetimes and by taking measurements only when the background signal is no longer present. Generally, the lifetime of the unspecific background signal is less than 10 ns. For an interference-free measurement of a specific signal, labels are required whose lifetimes are at least 10 times the decay time of the background.[6a] Suitable organic fluorophores with lifetimes $\tau > 50$ ns are, however, very rare. Pyrene derivatives such as **F** in Scheme 13 exhibit lifetimes of approximately 100 ns, which, however, were shown to be insufficient.[66] The lifetimes of phoshorescence processes are considerably longer. The principle applicability of phosphorescent labels, such as erythrosin derivatives in oxygen-free solutions, could indeed be shown[67] but no progress with phosphores

cence was achieved due to its low quantum yields and high expenditure.

It was not until complexes with rare-earth metal ions, primarily europium(III), were employed as labels that prospects of attaining a drastic improvement in the sensitivity of fluorescence immunoassays by time-resolved measurements and developing more sensitive fluorescent alternatives to RIA were realized.[6, 66] The use of europium trisdiketonates was proposed by Wieder[7b] in 1978 and developed further by other groups.[68]

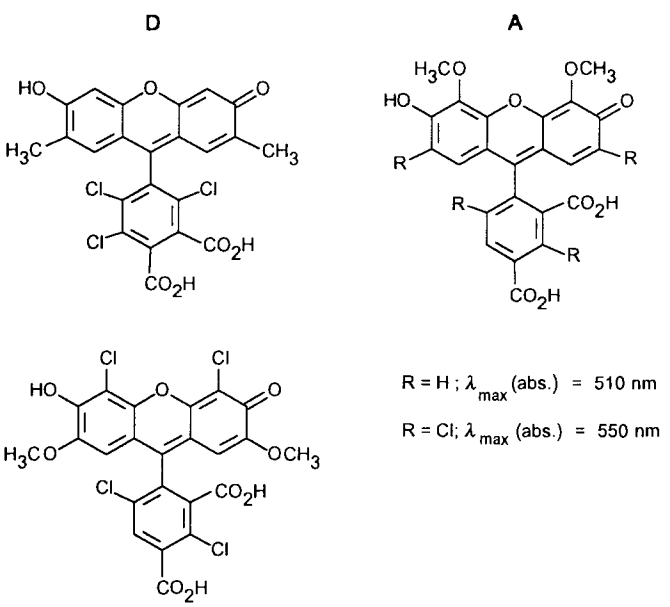
The chelate complexes of europium(III), terbium(III), samarium(III), and dysprosium(III) are distinguished by unique fluorescent properties (cf. **I** in Scheme 13 and Table 1). Apart from extremely long lifetimes of about 1 μs to 1 ms, a very large Stoke's shift (>200 nm) and sharp emission lines impart the complexes with a high sensitivity (10^{-14} mol L^{-1}).[6, 66] The reason for the observed lifetimes lies in the excitation/emission mechanism. After excitation of the ligand to the S_1 state and intersystem crossing to an energetically suitable triplet state of the ligand, an effective energy transfer to the resonance state of the metal ion occurs, which then gives rise to a sharp emission characteristic of metal ions.[6, 66, 69]

The fluorescent properties of chelates of rare-earth metals alone still do not produce an efficient label for immunoassays. What is essential, also in aqueous buffer solution, is a stable binding to antigens and antibodies. Due to their high stability and solubility in water, polyaminopolycarboxylate chelates, chiefly derivatives of ethylenediaminetetraacetic acid (edta) or diethylenetriaminepentaacetic acid are used for most applications. The use of diazo- and isothiocyanatophenylethylenediaminetriacetate for coordination to europium(III) and terbium(III) has been described.[66, 70] Likewise, mixtures of ethylenediaminetriacetic acid, terbium(III), and 5-sulfosalicylic acid,[7b, 71] mixtures of an edta derivative, europium(III), and a β-diketone[7b, 72] as well as diethylenetriaminetetraacetic acid derivatives with different trivalent lanthanides[7b, 66, 70, 73] were employed for the labeling (Scheme 14).

Scheme 14. Ligands for the coordination of lanthanide ions.

Since many of the very stable lanthanide chelate complexes do not fluorescence with these ligands, a dissociation step must be carried out prior to detection.[74] Furthermore, once the immune reaction is complete, a so-called enhancement solution is added after washing, which leads to the dissociation of the chelate complex and to the formation of fluorescent complexes [DELFIA system (*D*issociation *E*nhanced *L*anthanide *F*luorescence *I*mmuno-*A*ssay)]. The 1,3-diketones β-naphthoyltrifluoroacetone and pivaloyltrifluoroacetone are commonly employed.

The use of chelate complexes with trivalent lanthanide ions facilitated not only the development of highly sensitive immunoassays by time-resolved measurement, but also the simultaneous determination of several parameters, since Eu^{III}, Tb^{III}, Sm^{III}, and Dy^{III} complexes emit at considerably different wavelengths and have different fluorescence lifetimes. Several double determinations have been described;[73, 75] Eu^{III}/Tb^{III} chelates[76] or Eu^{III}/Sm^{III}[76] complexes were used as label pairs. In simultaneous determinations of two parameters from each, the dissociation/enhancement principle was employed. A simultaneous and highly sensitive determination of more than two lanthanide labels is, however, not possible with the simple enhancement solutions.



Simultaneous multianalyte determinations are gaining interest,[78] since with the four lanthanide ions mentioned and specially developed enhancement solutions, so-called *co*fluorescence-based *e*nhancement *s*olutions (CFES),[79] four parameters could be determined simultaneously by using time-resolved fluorescence measurements.[73] The enhancement solutions formed in this way consist of a dissociation element, pivaloyltrifluoroacetone and Y^{III}, as well as an element, 1,10-phenanthroline which enhances the fluorescence. Europium(III) and terbium(III) chelates with macrobicyclic ligands that contain α,α′-bipyridine or 1,10-phenanthroline units were already described earlier as efficient luminophores which act as molecular light transformers.[79d]

5.1.5. *Fluorescence Energy Transfer*

In the application of fluorescent labels for immunoassays, the principle of fluorescence-polarization, which facilitated development of homogeneous immunoassays, has already been mentioned. Another method, in which no separation of the unbound labeled molecules from the immunocomplexes is necessary, uses fluorescence energy transfers.[6b, 80] In this case an energy transfer from an electronically excited fluorophore (donor) to a neighboring acceptor dye molecule (quencher) occurs by dipole–dipole coupling. According to Förster[81] the efficiency of the energy transfer is indirectly proportional to the power 6 of the distance. With Förster's theory distance measurements in molecules, for example, can be obtained,[82] and for efficient energy transfer distances must not be greater than 10 nm. This condition is fulfilled in many antigen–antibody complexes. If, for example, the antigen is labeled with the donor and a specific antibody is labeled with the acceptor, quenching of fluorescence (of the donor) occurs in the immunocomplex. In a mixture of labeled and unlabeled antigens the fluorescence signal increases with the quantity of the unlabeled analyte to be determined.

The requirements for the fluorescent labels (donors) that should be employed in energy-transfer immunoassays are the same as those for fluorescent labels already mentioned. Furthermore, the choice of the donor–acceptor pair must be such that the emission spectrum of the donor and the absorption spectrum of the acceptor overlap well. In the beginning the use of the donor–acceptor pair fluorescein isothiocyanate/tetramethyl-

rhodamine isothiocyanate was described.[80b] Since interference from background signals such as background fluorescence from serum are particularly large in homogeneous immunoassay, standard labels such as fluorescein isothiocyanate, umbelliferones, or dansyl chloride certainly are of little significance. For the latter, in addition, the high sensitivity for background effects is disadvantageous. The same can be said for rhodamines such as tetramethylrhodamine. Due to higher absorption and emission wavenumbers, phycobiliproteins and lanthanide chelates are better suited as donors. With the latter, particularly in conjunction with time-resolved measurements, the development of more sensitive fluorescence energy-transfer immunoassays is possible. Also substituted fluoresceins with absorption and emission wavelengths greater than 500 nm (cf. Scheme 15) were used as donors.[80, 83]

Scheme 15. Fluorescein derivatives employed in fluorescent energy transfers; D = donor molecules, A = acceptor molecules.

The energy acceptors (quencher labels) should ideally fulfill the following conditions:[80a] a) high extinction coefficient of the emission wavelength of donor; b) no fluorescence during excitation in the absorption maxima of donor; c) good solubility in water in order to facilitate multiple labeling with the quencher (greater quenching effect); d) the smallest possible background interference in the absorption spectrum.

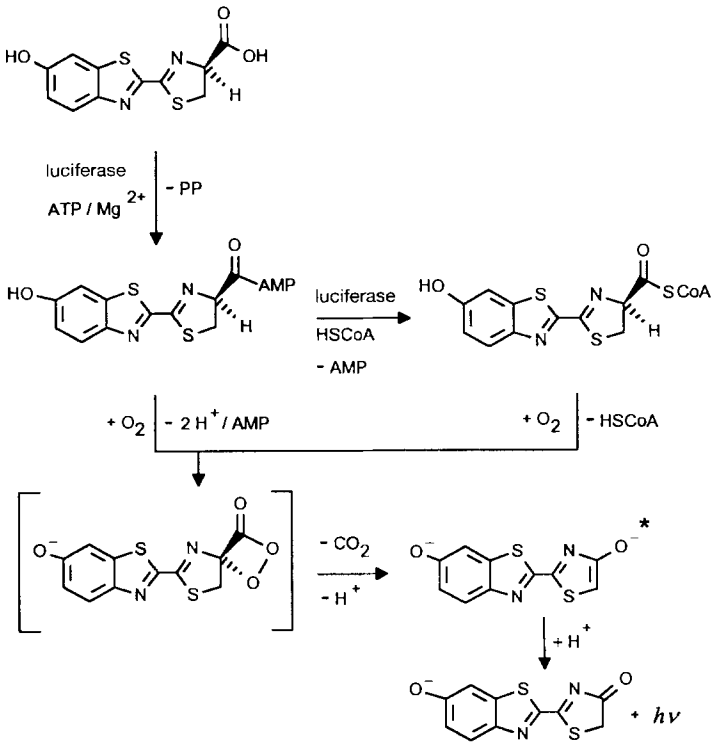
Since frequently used acceptors such as tetramethylrhodamines do not fulfill these requirements, new non-fluorescent fluorescein derivatives were described which form effective pairs with the donors in Scheme 15.[80, 84]

Fluorescent labeling and the principle of fluorescent energy transfers have recently also found application in the development of biosensors.[85] Detection can be based on the quenching of emission from the donor, new emission from the acceptor, or on the ratio of both emission wavelengths. One biosensor principle based on Langmuir–Blodgett films and fluorescence energy transfer with a cumarin derivative as donor and tetramethylrhodamine as acceptor was recently described.[86]

5.2. Chemiluminescent Labeling

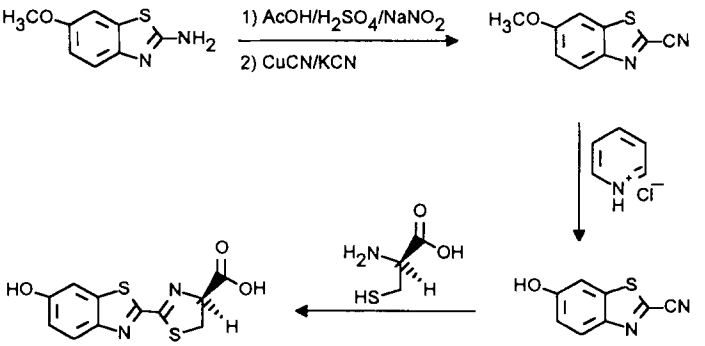
A considerable difference between chemiluminescent detection systems and fluorescent labels is that former do not require the irradiation of the excitation light. With these chemiluminescent systems, in particular, in working with serum, the problems with high background signals, which are mainly responsible for the limited sensitivity of many methods with fluorescence detection, are prevented. However, in several chemiluminescent labels, complex systems comprising oxidation reagents, signal enhancer additives, and catalysts can likewise lead to an unacceptable high background signal, which, of course, has an adverse effect on sensitivity.[87] In the case of chemiluminescence detection in analysis systems, which above all are applied in medical diagnostics, compounds mainly from the following categories are employed:[9, 10–15, 17] luciferins in combination with the corresponding luciferases, cyclic arylhydrazides, acridinium derivatives, stable dioxetanes, and oxalic acid derivatives.

5.2.1. *Bioluminescence*



The luciferin/luciferase system of the North American firefly

One of the most well-known and most studied light systems in nature "operates" in the North American firefly (*Photinus Pyralus*). Although the mechanism of bioluminescence has been studied for more than 30 years, and the benzothiazole derivative luciferin became available synthetically and was structurally determined at the beginning of the 1960s, not all the details of the bioluminescence reaction have been elucidated. Since a more detailed description of this and other bioluminescent systems would go beyond the framework of this review article only the latest developments are described briefly.



As had been assumed for a long time[88a, b] and to a large extent proven at the end of the 1970s,[88c] the specific luciferase of the firefly catalyzes the oxidation of luciferin in the presence of ATP and magnesium ions (Scheme 16). Initially a complex is formed from the acyl-AMP species of luciferin and luciferase. In the presence of oxygen oxidation ensues to give excited oxyluciferin which returns to the ground state by emitting a photon.[15, 89, 90] In vivo the yellow-green emission (λ_{max} = 565 nm) of the dianion was observed and in vitro an additional red emission (λ_{max} = 615 nm) of the monoanion which was pH-dependent.[88b, 90, 91] The oxidation proceeds presumably via a dioxetanone intermediate[11, 87, 92] which decarboxylates to furnish excited oxyluciferin.

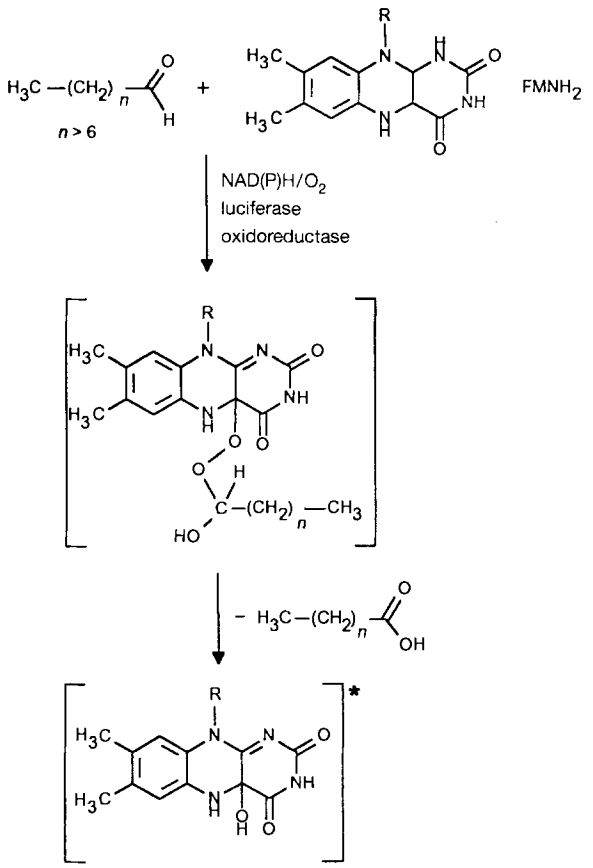
To what extent one can view the often proposed dioxetanone as an intermediate or rather as a transition state is, as in the luminescent systems previously mentioned, still unclear. Instead of the dioxetanone intermediates in the oxidation of luciferins, acridiniumcarboxylic acid derivatives, and oxalic acid esters, the direct formation of excited products by charge-transfer can also be assumed during the decomposition of peroxide intermediates.[93] The mechanistic details cannot be emphasized within the framework of this review and interested readers should refer to the references [11, 87, 92, 93].

All in all, the light reaction of the firefly appears to be elucidated. However, the assumption, first made at the end of the 1950s,[94] that Coenzyme A also plays a role in the light reaction

Scheme 16. Chemistry of the light reaction of the firefly; PP = pyrophosphate; ATP = adenosine triphosphate, AMP = adenosine monophosphate, CoASH = coenzyme A.

Scheme 17. Key step in the synthesis of the firefly luciferin.

has been comfirmed in the past few years.[89, 95] Addition of the coenzyme may further improve the applicability of the firefly luciferin/luciferase system in the near future, since the intensity and duration of the light emission can be increased. The limiting factor for this method until now, in addition to the limited hydrolytic stability of luciferin and the sensitivity of luciferase, was, above all, the poor availability of the enzyme which could be extracted from fireflys. In the meantime the situation has fundamentally changed since the *Photinus Pyralis* luciferase, a protein with a molecular weight of 62 kD, can be expressed in bacteria, for example *E. coli*, by genetic engineering methods.[15, 89, 96, 97] The availability of genetically engineered luciferase and synthetic luciferin has now increased the expectation that this system, which with a quantum yield of up to 0.88 Einstein per mol is the most efficient of all known bio- and chemiluminescence systems, will be more widely applied than previously.



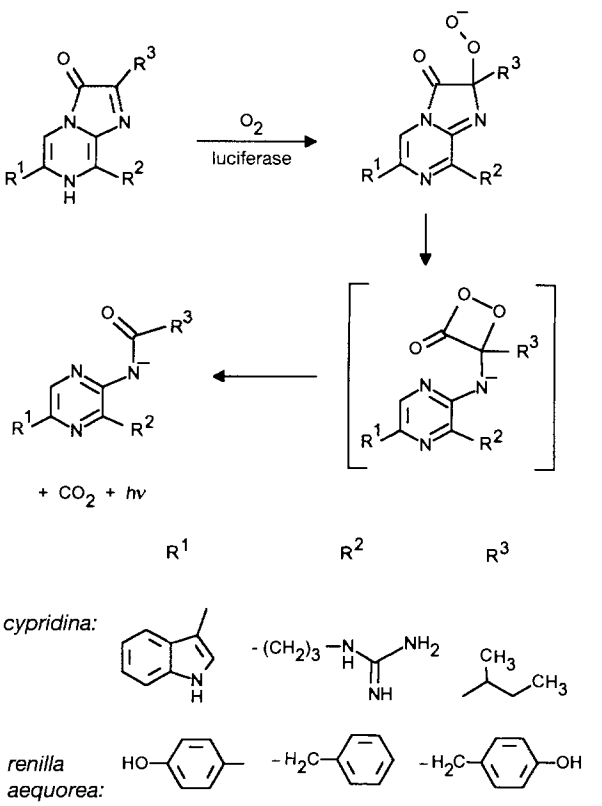
In the last thirty years essentially three synthetic pathways for the construction of firefly luciferin have been described, all of which proceed via the key intermediate 6-methoxybenzothiazole-2-carbonitrile (Scheme 17).[91, 98] The routes differ in the synthesis of the intermediate. Recently a new synthesis[99] has been published in which 6-methoxybenzothiazole-2-carbonitrile is obtained in one step by Sandmeyer cyanation of the commercially available 2-amino-6-methoxybenzothiazole (Scheme 17). The remainder of the synthetic pathway is already well-known: cleavage of the methyl ether and condensation with D-cysteine furnish the luciferin. In reference [99], earlier syntheses are also summarized. The oldest and until now most important application of the firefly luciferin/luciferase system is derived from the ATP-dependence of the bioluminescence reaction. Hence, a sensitive ATP determination can be carried out by using this system. ATP assays[100] are of interest above all in the screening for microorganisms in clinical microbiology in the areas of hygiene and nutrition.[101] A more recent application of steadily increasing significance is the use of the firefly luciferase gene as a reporter gene for the quantification of the gene expression in cells.[89, 102] Here a measurement of the light emission is made after addition of luciferin.

The use of luciferin derivatives,[103] which themselves are not substrates for luciferase, as substrates in enzyme immunoassays offers additional applications. After the luciferin has been released light emission is determined in the presence of luciferase.[103] In this way derivatives in which the phenolic hydroxyl group has been functionalized, such as D-luciferin-*O*-sulfate and -*O*-phosphate, can be cleaved by sulfatases or phosphatases. If the carboxyl group of the luciferin can be functionalized (methyl ester and phenylalanine and arginine amides have been described), the luciferin is released by carboxyesterases or carboxypeptidases.[103] Luciferin-*O*-phosphate as substrate for alkaline phosphatase, in comparison to the chromogenic substrate *p*-nitrophenylphospate, facilitates a sixty-fold increase in sensitivity.[103a] In addition, D-luciferin-β-D-galactopyranoside as substrate for β-galactosidase was described.[104]

Bacterial luciferin derivatives/luciferases

In luminous bacteria such as *Photobacterium fischeri* and *Photobacterium phosphoreum*, light production ensues from the oxidation of long-chain aldehydes in the presence of reduced flavin mononucleotide ($FMNH_2$), oxidoreductase, and bacterial luciferase.[15, 90, 97, 105] The intermediate is assumed to be a peroxide formed from a long-chain aldehyde and a flavin building block (Scheme 18). Depending on the bacterium, light emission occurs in the blue-green to yellow region of the spectrum with quantum yields of up to 0.3. The emitter is presumably a hydroxy derivative of FMN.[11, 15, 105] In vitro blue light (λ_{max} = 492 nm) is emitted.[15, 105c] As with the firefly luciferase, several bacterial luciferases can be obtained by genetic engineering.[97]

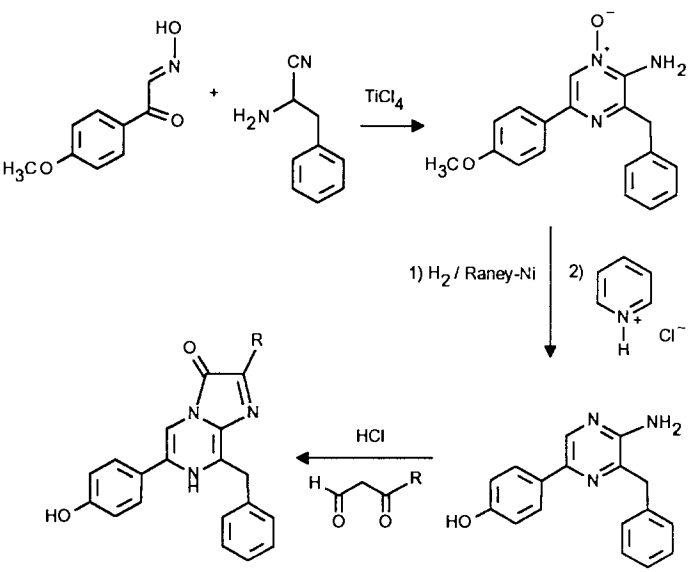
The bioluminescence of bacterial luciferases can, in principle, be used to determine all the components that participate in the luminescence reaction, that is, NADH, NADPH, FMN, $FMNH_2$, long-chain aldehydes, and oxygen.[105d] The possibility of determining the concentration of the extremely unstable $FMNH_2$ is theoretical. The use of bacterial luciferases is indeed still less widespread. The bioluminescent determination of long-



Scheme 18. Bacterial light systems.

chain aldehydes[106] and trace analysis of oxygen[105c] have some significance. A further field of application is in homogeneous DNA hybridization assays.[15, 107] The system for the bioluminescent determination of Papilloma viruses serves as an example.[107]

Luciferin derivatives with imidazopyrazine building blocks and photoproteins



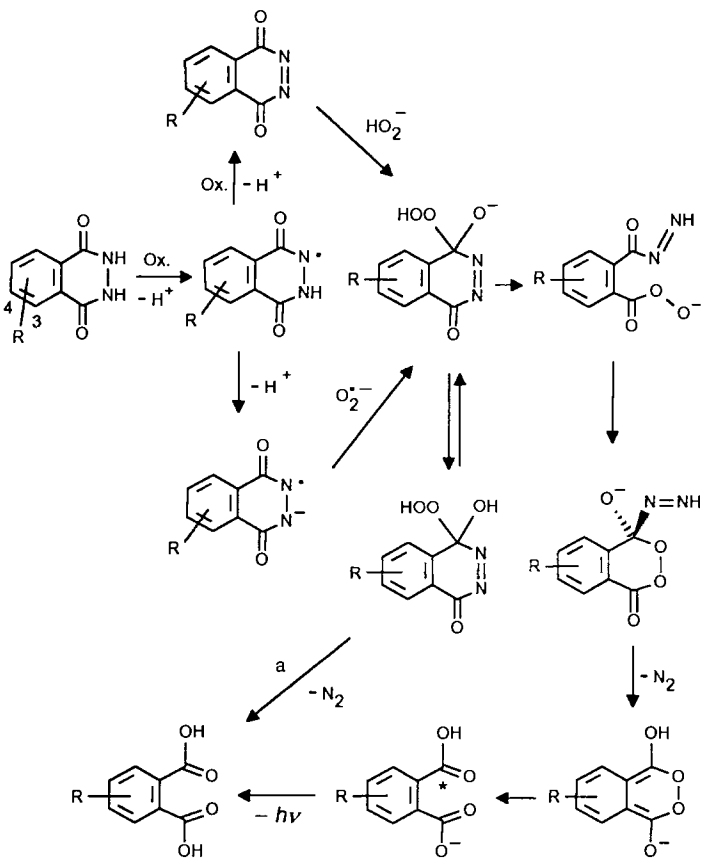
Bioluminescence occurs particularly frequently in marine life such as in crabs, jellyfish, mussels, sponges, fungi, and many fish.[9, 92b, 108] The luciferins of the mussel crab *Cypridina hilgendorfii*, sea pansy *Renilla reniformis*, and of the jellyfish *Aequorea aequorea* show a structural similarity (Scheme 19) which infers a common biosynthetic pathway.[92b] The luminescence mechanism is thought to consist of a catalytic oxygenation followed by ring closure to give an α-peroxylactone. This intermediate decomposes with the formation of the emitter and carbon dioxide (Scheme 19). One should refer to the relevant discussions of the theories concerning the firefly luminescence mechanism in specialist literature.

The photoprotein Aequorin, which was obtained from the jelly fish *Aequorea victoria* in 1962, has aroused particular interest in recent years.[109] It consists of a complex of apoaequorin, coelenterazine (cf. Scheme 19), and molecular oxygen. Addition of calcium or strontium ions to the complex triggers light emission.[110a] One assumes that the binding of calcium ions to the protein induces the decomposition of the resulting oxygenated

Scheme 19. Structures of some imidazolpyrazine luciferin derivatives and an outline of the peroxylactone mechanism.

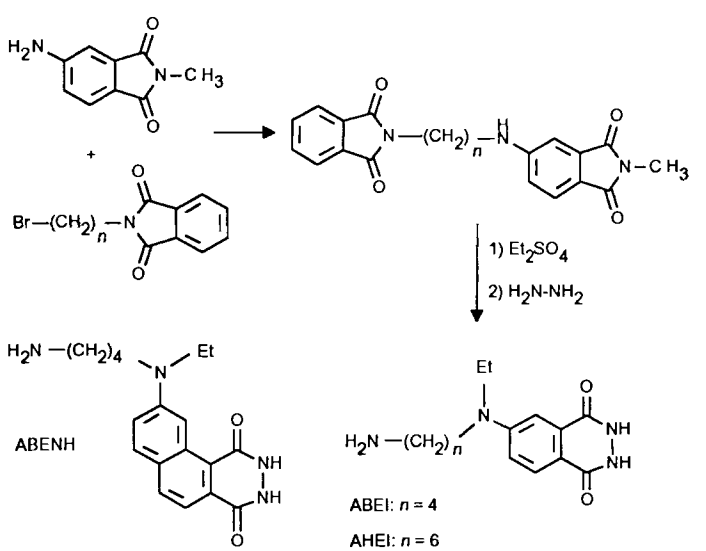
chromophore. An additional luciferase is not necessary. The emitter was postulated to be the protein-bound anion of the chromophore (cf. Scheme 19).[110b] The active photoprotein is regenerated by incubation of the apoprotein with the coelentarazine in the presence of oxygen, ethylenediaminetetraacetate, and mercaptoethanol.[110c] In the meantime the apoprotein has become accessible by expression in *E. coli*.[111] The synthesis of the coelenterazine was described long ago,[112a, b] and in addi-

Scheme 20. Synthetic route for the construction of coelenterazines. R = CH_3, C_6H_5, $(CH_2)_nC_6H_5$ ($n = 1-3$), $CH_2C_6H_4OH$.



tion the synthesis of some systems with a modified structure was reported.[112c] The synthetic route is summarized in Scheme 20.

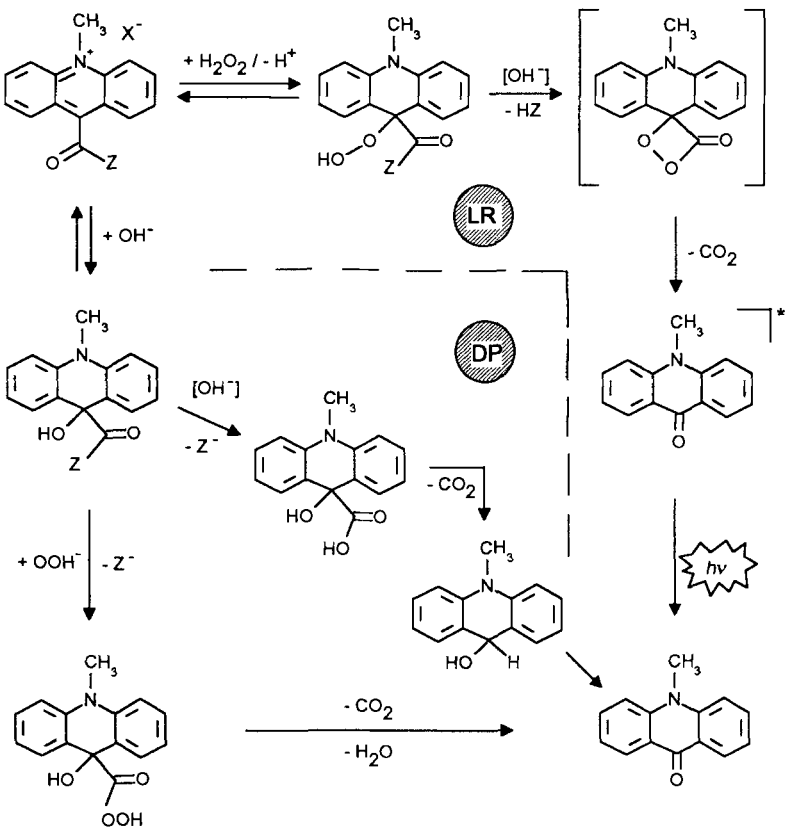
Aequorin can be used as a bioluminescent label after biotinylation. The triggering of light emission results from addition of calcium chloride solution. The label can also be detected in the attomol region. This label facilitated, for example, the development of a highly sensitive assay for salmonella determination. With regard to the sensitivity the test was shown to be clearly superior to other ELISA tests (see Section 3.1.2), even those with alkaline phosphotase as label and with chemiluminescent dioxetane AMPPD as substrate.[113a, b] In addition, the use of Aequorin in DNA and protein diagnostics[113c] and in the determination of serum glycoproteins has been described.[113d]



5.2.2. *Cyclic Arylhydrazides*

The chemiluminescence of luminol (3-aminophthalic hydrazide) was observed in 1928 in the form of blue light which was emitted during the oxidation with an alkaline solution of hexacyanoferrate(III) in the presence of hydrogen peroxide.[114] Luminol and carboxylic acid hydrazides have since been extensively studied. A wealth of reagents and catalysts can be employed in the oxidations of luminol and its derivatives. In organic, aprotic solvents, chemiluminescent reactions can be triggered by oxygen in the presence of a strong base. In aqueous solutions hydrogen peroxide is usually employed in the presence of catalysts such as peroxidases, hemin, and cobalt(II) salts.[105] Horseradish peroxidase (HRP)/H_2O_2 is frequently employed. In the course of time, different reaction mechanisms have been discussed.[45v] A simplified reaction mechanism, which is only applicable for a one-electron oxidation and which affords the free luminol radical, is given in Scheme 21. According to a more recent review article it is suggested that the mechanism should be divided into two steps, formation of the key intermediate, an α-hydroxyhydroperoxide, and its decomposition to the excited emitter. Whilst the formation of the hydroperoxide depends considerably on exact reaction conditions, decomposition of the key intermediate is only influenced by pH. Under these conditions the emitter appears to be the monoanion of aminophthalic acid. With other reagents, for example DMSO/base, the dianion of aminophthalic acid functions as the emitter. Intermediates in other proposed mechanisms are azaquinones, endoperoxides, and other peroxidic intermediates.[115b]

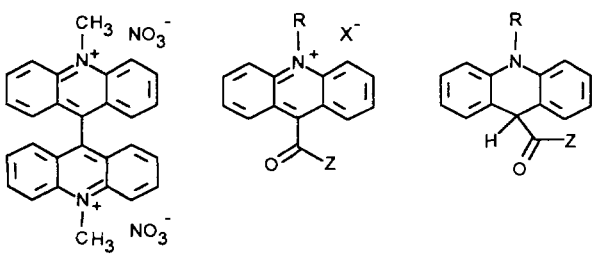
One of the oldest applications of luminol, which is still important today, is forensic blood analysis.[116] The application of luminol as a substrate for peroxidases in enzyme immunoassay has already been mentioned. Coupling reactions are necessary for the synthesis of labels for chemiluminescent direct labeling. The study of the chemiluminescent properties of luminol and isoluminol derivatives[117] had revealed that isoluminol only has approximately 10% of the quantum yield of luminol. Since, however, the chemiluminescent quantum yield of luminol decreases significantly[25, 37, 115, 117] if the primary 3-amino group is substituted, isoluminol derivatives, which are not sensitive with regard to substitution of the amino group, or the even more advantageous naphthalenedicarboxylic acid hydrazides which exhibit higher light yields,[21, 117b] were as a rule employed in the synthesis of arylhydrazide labels. The first label based on luminol, diazoluminol,[118] clearly showed the disadvantages outlined and the quantum yield decreased to 1% of that of luminol. Considerable improvements were brought about by isoluminol derivatives in which the coupling group was introduced via the amino functionality.[117b] The structure and the synthesis of some important arylhydrazide labels are summarized in Scheme 22.



Scheme 21. Simplified mechanism of the chemiluminescence reaction of phthalic hydrazides. Ox = oxidising agent which affords the free luminol radical, for example, HRP. R = 3-NH_2: luminol; R = 4-NH_2: isoluminol. Since the regiochemistry of most processes is unclear, the position of the R residue remains open. a = dark.

Scheme 22. Synthesis and structures of some arylhydrazide labels.

4-Amino-*N*-methylphthalic imide served as the starting material, which was successively alkylated with *N*-(bromoalkyl)phthalic imides and diethylsulfate. The subsequent hydrazinolysis of the bisphthalic imide furnished the frequently used phthalic hydrazide labels ABEI and AHEI (*N*-aminobutyl- or *N*-aminohexyl-*N*-ethylisoluminol), which contain an amino functionality as the coupling group. The phthalic hydrazide label ABENH (*N*-aminobutyl-*N*-ethylnaphthylhydrazide) was obtained by a similar method. The starting material was dimethyl 7-amino-1,2-naphthalenedicarboxylate.[117b] Derivatives of these three labels which contain other reactive groups (isothiocyanate, N-hydroxysuccinimide ester) are also known. Conversion of AHEI to a derivative with a *N*-hydroxysuccinimide-reactive ester was shown previously in Scheme 3.

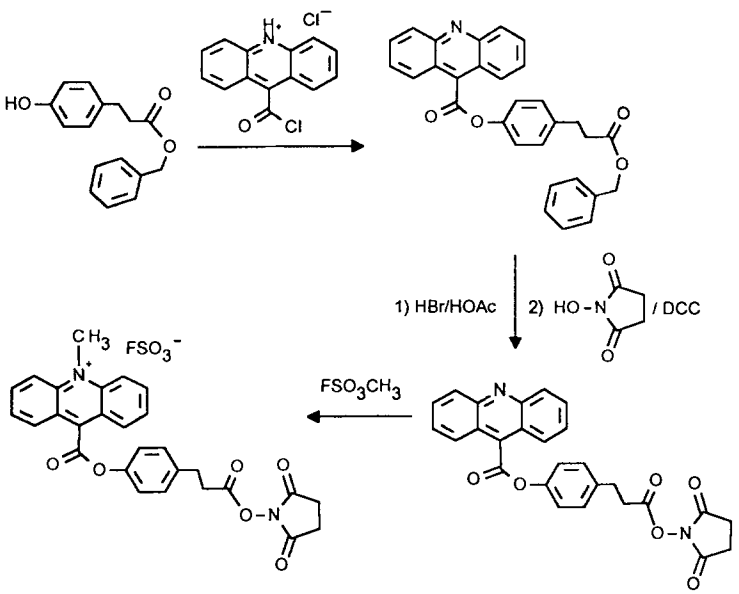


Arylhydrazide labels have and are finding broad application in immunoassays for chemiluminescent labeling of small and large molecules.[119] A distinct disadvantage is the considerable loss of the luminscencent quantum yield of the label after the coupling. Furthermore, these labels are prone to interference since many components catalyze the luminescent reaction. In addition, the reagents which trigger light emission give rise to a large background signal which decreases the sensitivity.[25]

Scheme 24. Chemiluminescence mechanism and pseudo-base equilibrium of 9-acridiniumcarboxylic acid derivatives; DP = dark process, LR = light reaction.

5.2.3. *Acridinium Compounds*

The chemiluminescence of lucigenin [9,9′-bis-(*N*-methylacridinium nitrate); Scheme 23] was reported in 1935.[120] But it was

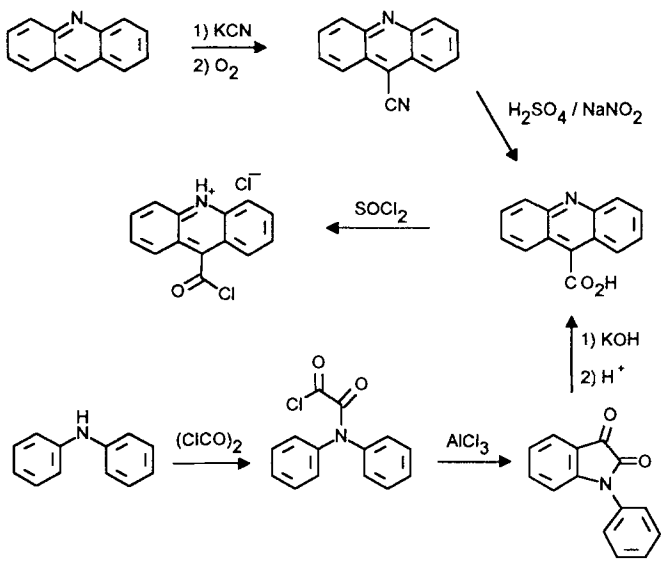


Scheme 23. Examples of chemiluminescent acridinium compounds and acridanes; Z = leaving group.

not until around thirty years later that studies led to other chemiluminescent acridinium compounds. These are specifically, 9-chlorocarbonylacridine hydrochloride,[121] 9-carboxy-10-methylacridinium chloride,[121] and 9-cyano-10-methylacridinium nitrate.[122] Today 9-acridiniumcarboxylic acid derivatives and acridanes are among the best-studied examples of chemiluminescent compounds. No additional reagents, apart from hydrogen peroxide and base, are necessary for the chemiluminescence of acridiniumcarboxylic acid derivatives. Quantum yields of up to approximately 0.05 can be attained with aryl esters;[111] higher still are the light yields which can be attained with acridane aryl esters. The latter exhibit efficient chemiluminescence after treatment with a base in the presence of oxygen.[123] Only the acridiniumcarboxylic acid derivatives that have been more important for the development of luminescent labels will be considered in more detail below. The mechanism of their chemiluminescence shown in Scheme 24 can be considered to be elucidated as far as possible.

First of all, addition of hydrogen peroxide takes place at the electrophilic C-9 position of the acridinium unit. In the case of aryl esters—the leaving group Z then stands for phenolate—the corresponding hydroperoxides could be isolated and characterized.[123] After the addition of hydroxide spontaneous chemiluminescence resulted, usually as intense light flashes. A dioxetanone is often proposed as intermediate, which decomposes to give carbon dioxide and electronically excited *N*-methylacridone, the emitter. The transition to the ground state ensues by emission of a photon at a wavelength of approximately 430 nm. According to more recent studies,[93b] however, no dioxetanone seems to appear as a discrete intermediate. The final product of the light reaction, *N*-methylacridone, can also be formed by other pathways in dark reactions. An important prerequisite for degradation in the dark is the well-known[124] pH-dependant pseudo-base equilibrium of acridinium compounds.[125] The reactions, which for the phenyl ester were studied more accurately in a flow system,[126] are integrated into Scheme 24. It is immediately clear that both the light reaction and the dark process are dependent, for instance, on the properties of the leaving group Z. Other important factors include the peroxide concentration

and the pH value.[126, 127] McCapra et al. showed that for effective chemiluminescence the pK value of the conjugate acid of the leaving group should be less than 12—the pK value of hydrogen peroxide.[108e] Since a good label should exhibit a high chemiluminescent yield in addition to a high stability in the labeled reagent, the discovery of suitable compounds can be equated to a fine balancing act, ending in a compromise between light yield and stability.

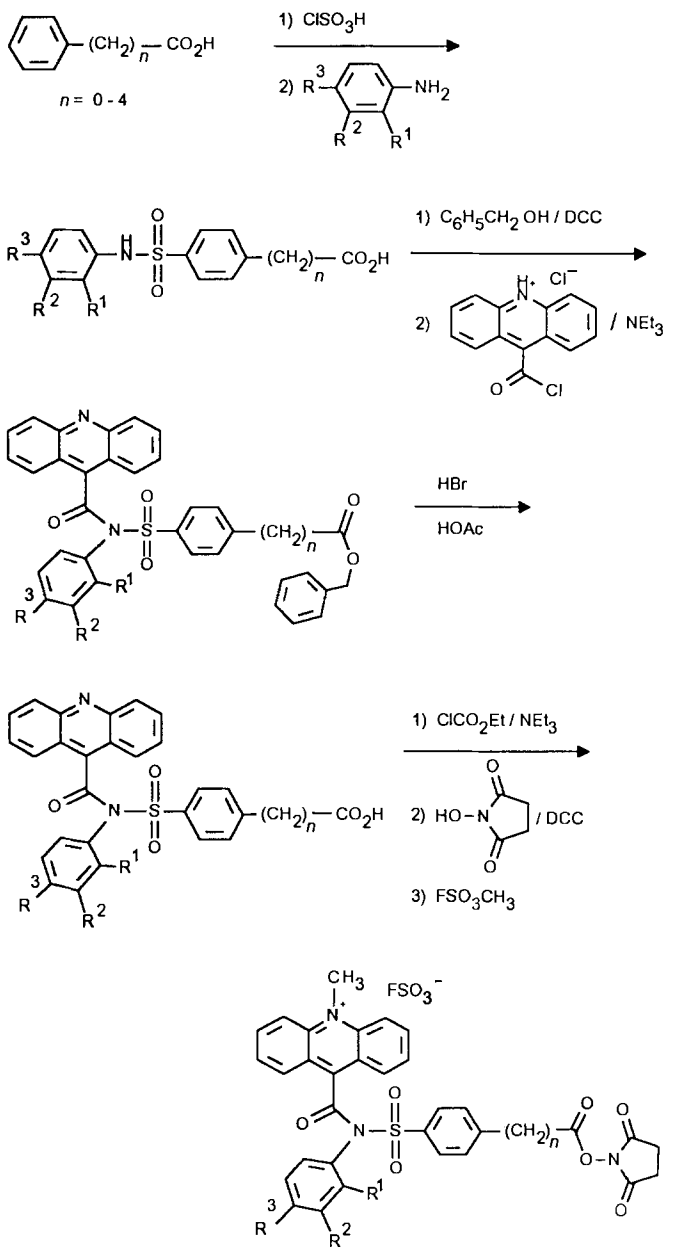


The first attempts to use 9-acridiniumcarboxylate as a label in immunoassays were reported at the beginning of the 1980s. In this an attempt was made to couple aryl esters, which contained free carboxyl groups, to proteins, after activation of the carboxyl groups. These labeling experiments had only limited success.[128] It was not until a phenyl N-methylacridinium-9-carboxylate, containing a hydroxysuccinimide ester on the phenyl group as the reactive group for coupling to proteins, was used that successful labelings could be carried out.[126, 129] The synthesis of this prototype of a chemiluminescent label based on a 9-acridiniumcarboxylic acid derivative,[25, 126, 128–130] the so-called Woodhead label, is summarized in Scheme 25.

Scheme 25. Synthesis of an acridinium ester label.

An important precursor for this and other labels discussed later was 9-acridinecarboxylic acid, whose synthesis is shown in Scheme 26. One reaction route starts from acridine and proceeds via 9-cyanoacridine to give the carboxylic acid.[131] In another synthetic method 9-acridinecarboxylic acid is formed from diphenylamine, which is acylated with oxalyl chloride and is cyclized by using aluminum trichloride to give the N-phenylisatine.[132] The synthesis of substituted acridinecarboxylic acids from substituted N-arylisatines has also been described;[133] however, it appears to work only on a very small scale.

Since the acridinium ester label mentioned was not sufficiently stable for development of commercial chemiluminescence immunoassays[134, 135] (hydrolysis of the ester bond (cf. degradation in the dark in Scheme 24) results in a too rapid a decrease of activity in conjugates), different research groups have been



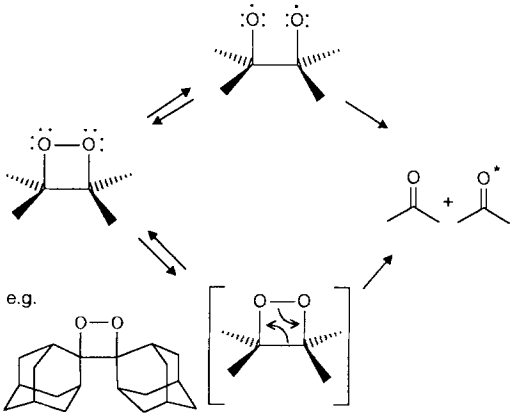
Scheme 26. Possible synthetic routes to 9-acridinecarboxylic acid.

looking for more stable labels based on acridiniumcarboxylic acid. One solution to the problem involved the steric shielding of the ester bond and the C-9 position of the acridine unit, for example, by methyl groups in the 2,6-position of the aryl ring.[134] In addition, other 9-acridiniumcarboxylic acid-(2,6-substituted)aryl esters were described.[136] Here the reactive group can also be bound through a spacer to the acridinium system. To complete the picture one should not forget to mention that aryl N-methylphenanthridinium-6-carboxylates have been described as chemiluminescent labels.[136, 137]

Other research groups have attempted to improve the properties of the acridiniumcarboxylic acid derivatives in comparison to those of the aryl esters, by varying the leaving groups. Thiol esters, indeed, brought about progress in as far as the light yield is concerned, but not, however, as regards to hydrolytic stability.[138] A significant improvement of the stability and very good chemiluminescence quantum yields were achieved when N-sulfonylamide anion was used as the leaving group instead of phenoxide.[138–141] In this class of compounds the spectrum of properties can be influenced much more specifically than for the acridinium ester labels by tailored variations in the structures. For instance, the solubility in water (an important parameter) can be significantly improved by the introduction of suitable substituents.[139, 142] The synthesis of N-methylacridinium-9-(N-sulfonyl)carboxamide labels is summarized in Scheme 27.

In addition, the hydrolysis behavior and the kinetics of emission can be varied to a certain extent.[142, 143] Although phenols and sulfonamides have similar pK values, labels with the latter are usually considerably more stable. This may be attributed to a combination of steric shielding effects and electronic stabilization,[127, 143] through which the dark reaction pathways described are minimized. It is assumed that in N-sulfonylcarboxamides there is an increased bond order of the C–N bond in comparison to the ester C–O bond. This is also evident from the frequencies of the carbonyl stretching vibration in the IR spectrum.[143]

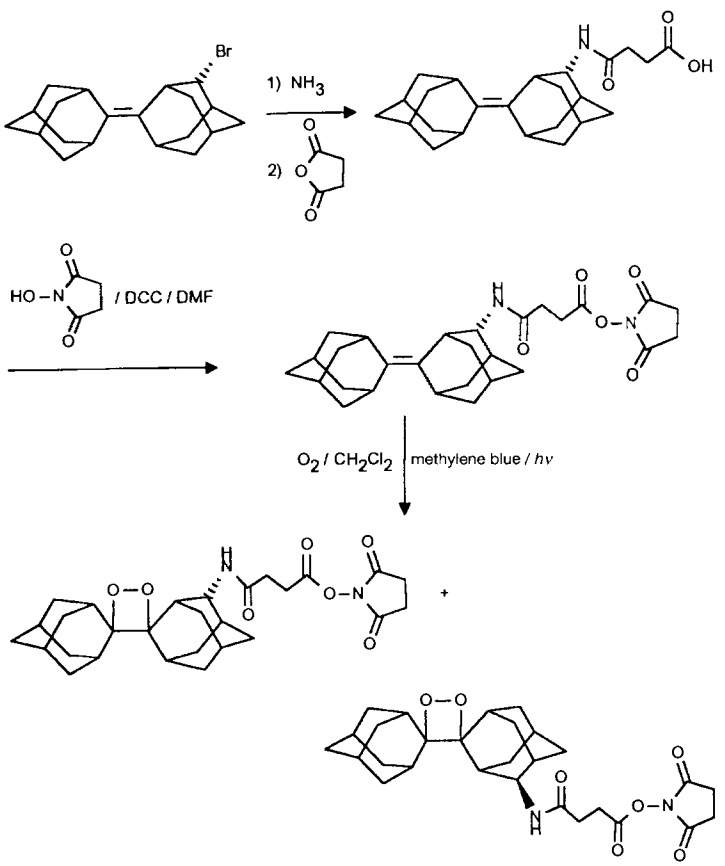
Labels based on 9-acridiniumcarboxylic esters and acridinium-9-(N-sulfonyl)carboxamides have, in the meantime, found



Scheme 27. Synthesis of acridinium-9-(*N*-sulfonyl)carboxamide labels.

broad application in commerical immunoassays (see Section 6).[119c, 144] Up until now only a few applications for other acridinium derivatives have been described. For example, lucigenin can be used in micellular chemiluminescence assays for the determination of reductants (ascorbic acid, uric acid, glucose, and fructose).[145] The micelles are necessary to improve the solubility of lucigenin.

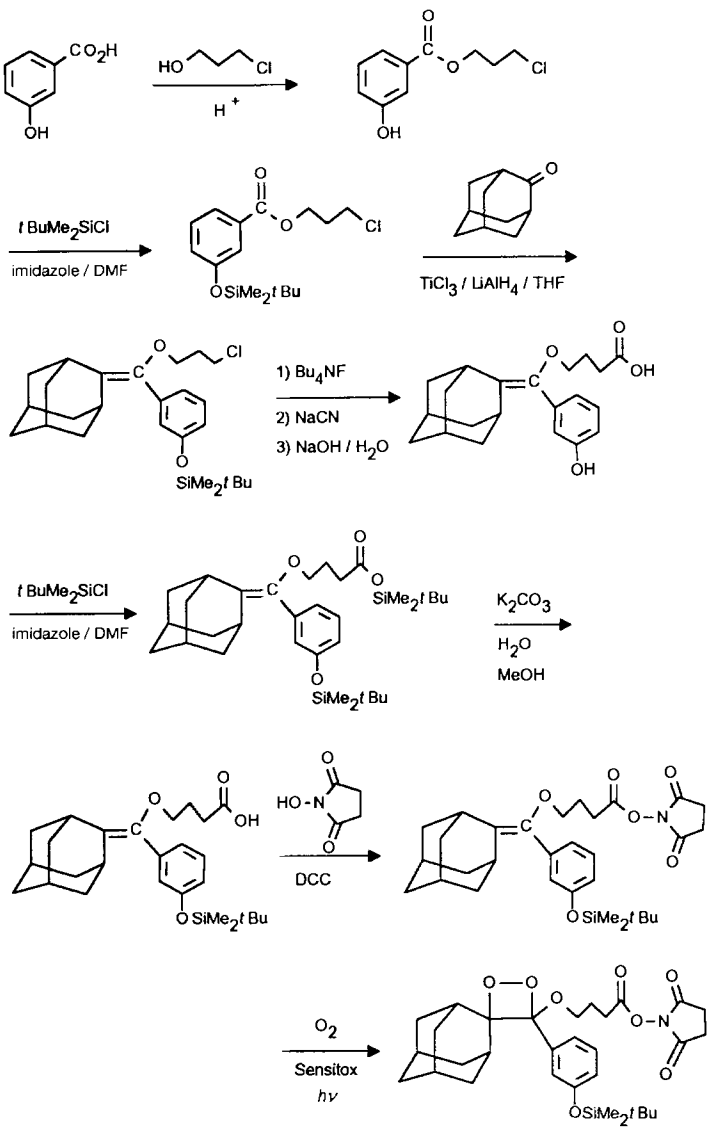
5.2.4. *Dioxetanes*



Dioxetanes have for a long time been regarded as merely having curiosity value in the laboratory. Use of the extremely unstable compounds in reagents for diagnostics was not considered. It was not until after adamantylideneadamantane-1,2-dioxetane (an extremely stable compound due to the steric shielding prepared by W. Adam et al.[146] in 1972) became known that the development of dioxetane labels really took off. Light emission could only be triggered thermally for stable dioxetanes of the type mentioned which exhibit a half-life of greater than 20 years at room temperature. In the thermolysis two molecules of adamantone are formed, partly in the S_1 state and partly in the T_1 state (Scheme 28). In principle, cleavage can occur according

Scheme 28. Simplified representation of the decomposition reaction of dioxetanes.

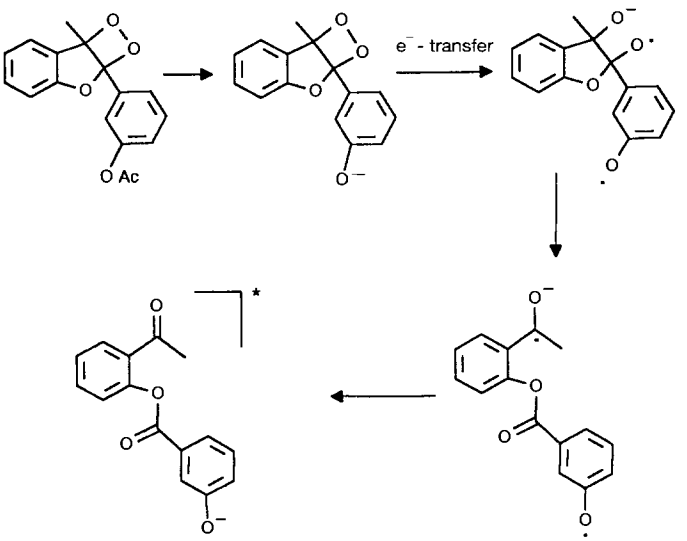
to a diradical or a concerted mechanism.[87] A stepwise pathway, involving homolysis of the O–O bond and formation of a diradical, has been proposed for the decomposition of the stable dioxetanes.[147] The light emission results from the deactivation of the S_1 excited species. Dioxetanes, which, in addition to the steric stabilization by only one adamantyl group, still contain a substituent of low oxidation potential, mostly aryloxy, undergo a different decomposition mechanism. This decomposition route is triggered by cleavage of the O–O bond and by an electron transfer from the oxidizable group into the antibonding orbital of the peroxide bond (CIEEL mechanism, *c*hemically *i*nitiated *e*lectron *e*xchange *l*uminescence).[92e, 148–155] This mechanism for the dioxetanes mentioned which are substrates for enzyme labels is discussed in Section 4.



Functionalized adamantylideneadamantanes that contain a reactive group bound to a spacer have been described as a label for thermochemilunescent immunoassays[156] (Hummelen et al., 1986). The synthesis of one such label is given in Scheme 29. The starting material is adamantylideneadamantane, which can be obtained in two steps from adamantanone.[157] In the last step of the synthesis, sensitized (methylene blue) photooxygenation, a mixture (ca. 1:1) of two dioxetane isomers results, which was used in this form in the labeling experiments. The overall yield of the seven-step synthesis, starting from adamantanone is 50%. The triggering of luminescence results from heating the sample adsorbed onto aluminum oxide for a short time at 240 °C. An apparatus for measuring thermochemiluminescence has also been described.[156] Since the efficiency of the direct chemiluminescence of adamantylideneadamantane-1,2-dioxetane is 1×10^{-4} (6×10^{19} photons per mol)[158] under optimal conditions (only 1% of that of luminol), an increase in the energy transfer to a good fluorescent dye is necessary. Bovine serum albumin conjugates with the dioxetane label and 9,10-diphenylanthracene, which, in turn, have been used as labels in

Scheme 29. Synthesis of a thermochemiluminescent dioxetane label. DMF = dimethylformamide.

*f*luorescence *a*mplified *t*hermochemiluminescence *im*muno*a*ssay (FATIMA), have been described. The first assays, for example, for the tumor marker CEA have been described, but the thermochemiluminescence principle appears to be altogether too costly for wider commercial use. The search was then started for model compounds for thermally somewhat less stable dioxetane labels, which could be activated at approximately 150 °C.[159] For example, 9-xanthenylideneadamantane decomposes at around 100 °C (Hummelen et al., 1988). The light emitted from this compound corresponds to the emission from adamantone. Other monoadamantyldioxetane derivatives of the xanthene, naphthalene, and phenyl series, which can be triggered enzymatically and chemically and in which the olefinic starting material contains a methoxy substituent to facilitate dioxetane synthesis, have been described (Schaap et al., 1987).[47c, 47d] Shortly afterwards AMPPD, already mentioned in Section 4, was reported. In contrast to the above-mentioned thermal decomposition, the emitter in the CIEEL decomposition of adamantylidenearyloxy-1,2-dioxetanes, which can be triggered enzymatically or chemically (cf. Scheme 10), is chiefly an excited aryloxy anion.

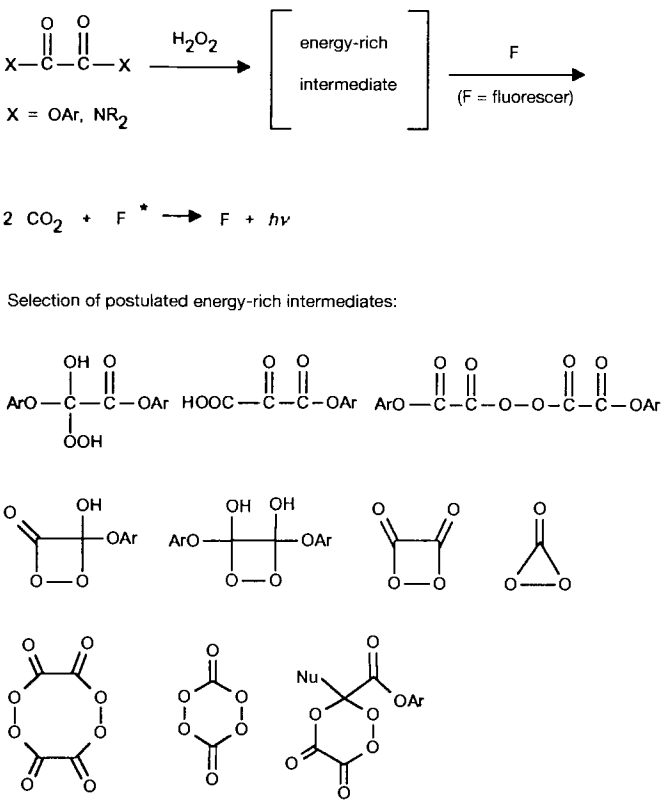


Thus, in less than twenty years since their discovery, dioxetanes have developed from merely being laboratory curiosities to being stable derivatives employed worldwide in immunolgical and biochemical analysis. The development has not yet reached an end. Until a short time ago the 1,2-dioxetanes, which can be triggered enzymatically or chemically, were not known as classical labels with a reactive group for coupling to molecules to be labeled, however, recently also such dioxetane labels for direct labeling methods were introduced.[14, 47p, 160] The synthesis of a selected label is outlined in Scheme 30. Apart from the silyloxy

Scheme 30. Dioxetane labels for chemiluminescent direct labeling which can be triggered chemically. Sensitox = polymer-supported Rose Bengal.

group shown which can be cleaved to trigger luminescence, other substituents can also be employed, for example, phosphate and galactosyl groups. In addition to the hydroxysuccinimide esters shown other common reactive groups should also be considered. A label with a biotin anchor and its use for labeling proteins and antibodies has also been described.[47p] Further applications of this relatively new label are as yet unknown, but judging from the high quantum yields (0.20–0.25 in DMSO)[14] they will presumably not be long in coming.

Finally in this section on dioxetanes another new class of relatively stable dioxetanes should be mentioned namely, phenyl-substituted benzofuran-1,2-dioxetanes.[14, 92e, f] These give quantum yields (up to 4×10^{-6}) similar to those of the enzyme substrates described earlier. The acetoxy-substituted



Scheme 31. Structure and decomposition of a benzofurandioxetane.

compound shown in Scheme 31 decomposes, presumably base-induced, according to the CIEEL mechanism. For analogous siloxy-substituted compounds decomposition can, as with similar adamantyl systems, be triggered by fluoride ions.[192f]

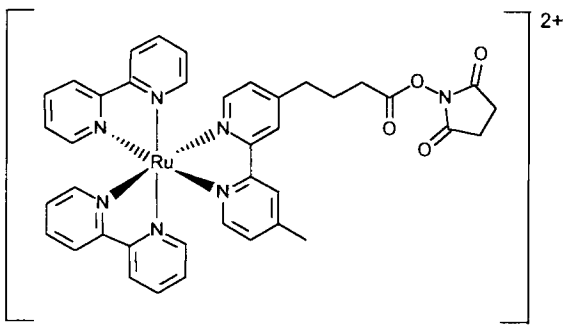
5.2.5. Oxalic Acid Derivatives

Oxalic acid derivatives such as oxalyl chloride,[161,162] certain oxalic acid anhydrides,[163] diaryl esters,[164] and oxamides[165] are among the synthetic molecules which exhibit the highest chemiluminescence quantum yields (up to 0.5).[11] Intense luminescence is observed in the presence of a fluorescent dye during the oxidation of oxalic acid derivatives with hydrogen peroxide. Despite extensive studies the complete mechanism of peroxyoxalate chemiluminescence is still not fully understood. A dioxetanedione is often proposed as the energy-rich intermediate which forms the oxalic acid derivative by reaction with hydrogen peroxide (Scheme 32). However, according to the results of more recent work, this highly strained intermediate is not formed;[93b] a large number of possible intermediates is shown in Scheme 32.[14,166–169] As has already been considered in other mechanisms, reaction pathways involving electron transfer or energy transfer are discussed.[14] Finally, either excited carbon dioxide is formed which activates the fluorescent dye by energy transfer, or a charge-transfer complex is formed which decomposes to give CO_2 and a fluorescent dye molecule in the excited state. The luminescence of these systems is relatively long lasting and the emission color can be controlled by choice of dye. The best known application of this are the Cyalume light sticks.[170]

Oxalic acid esters or oxamides cannot be considered for the development of luminescent labels for diagnostic purposes because the solubility of the oxalates and fluorescent dyes requires the use of organic solvents; the compounds are hydrolyzed quickly in aqueous solutions.[11] However, oxalates are employed in chemiluminescence detectors in HPLC or flow injection analysis.[14,171] The appropriate systems allow, inter alia, analysis of environmental toxins, drugs, amino acids, fatty acids, and amines with detection sensitivities ranging from the nanogramm

Scheme 32. Mechanism of chemiluminescence for oxalic acid derivatives.

into the attomol region. Another interesting area of application of oxalate chemiluminescence in diagnostics is the quantitative determination of oxalic acid in urine with detection limits as low as 10 nmol L^{-1}. For this purpose the oxalic acid present is treated with carbodiimide in the presence of hydrogen peroxide and a fluorescent dye. The light emission measured is proportional to the concentration of oxalic acid.[172,173] Even the determination of porphyrins in urine is possible with this method. In this case a fluorescent dye is not necessary because the porphyrins themselves act as sensitizers.[174]



5.2.6. Electrochemiluminescence

The triggering of chemiluminescence by electrochemical processes has been known for a long time but has only gained practical significance in recent years.[175] Radicals produced electrochemically play a significant role in these processes and the electrochemical excitation of luminol/hydrogen peroxide mixtures has been studied in detail.[176] Luminescence is observed with potentials greater than 0.5 V. A mechanism similar to the one presented in Scheme 21 is assumed for potentials of up to 0.7 V. Diazaquinone produced electrochemically reacts with hydrogen peroxide. At higher potentials (1.2 V) the reaction is considerably more complex since the amino group of luminol is involved in oxidation processes.[176] An electrochemical detector based on this system can be used for the determination of hydrogen peroxide.

In addition, the electrochemical processes of acridinium compounds have been investigated.[177] Whilst lucigenin is reduced at −0.3 V and gives rise to luminescence in a subsequent reaction of the radical, acridinium esters show no activity in the range +1

to −1 V. However, the luminescent reaction of the acridinium esters can be initiated electrochemically by hydrogen peroxide produced from oxygen. This principle facilitated development of detectors for labeled analytes without the need for additional reagents. Lysin labeled with the first acidinium ester described earlier could be detected with a sensitivity of 10 fmol.[177]

The chemiluminescence of ruthenium(III) chelate complexes has been known for a long time,[178a, 175a] likewise the electrochemically generated luminescence from trisbipyridineruthenium(II) chelates.[178b] However, the labeling of haptens, proteins, and nucleic acids with ruthenium(II) chelates was only described recently.[179a] The ruthenium complex, which is shown in Scheme 33, uses a hydroxysuccinimide ester sub-

Scheme 33. Structure of an electrochemiluminescent label based on a [tris(bipyridine)]ruthenium chelate.

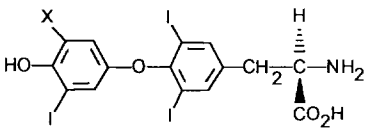
stituent as the reactive group. The advantages of the label cited are high stability, relatively low molecular weight, high solubility in water, and high sensitivity—the detection limit of the label is 200 fmol L^{-1}. Multiple labeling of proteins and oligonucleotides are possible without being detrimental to immune reactivity, solubility, or ability of the conjugate to hybridize. In the electrochemical reaction $[Ru(bpy)_3]^{2+}$ (bpy = bipyridine) is first oxidized to $[Ru(bpy)_3]^{3+}$ on the electrode surface. Simultaneously, the tripropylamine (TPA) present in a large excess is likewise oxidized to a radical cation $TPA^{\cdot+}$ which spontaneously cleaves a proton. In the reaction of the strong oxidizing reagent $[Ru(bpy)_3]^{3+}$ with the radical $TPA^{\cdot}$, a strong reducing agent, a $[Ru(bpy)_3]^{2+}$ complex is formed in the electronically excited state which returns to the ground state by emission of a photon at 620 nm. The ruthenium(II) complex can re-enter the cyclic process, which automatically causes amplification of the signal.

In addition to an electrochemiluminescent analyser,[179b] immunoassays,[179a] and genetic probe tests[179a, 180] with the, in the meantime, commercially available ruthenium label have been described. The available data is insufficient to evaluate the suitability of electrochemiluminescent detection in diagnostic practice.

6. Applications

6.1. Immunoassays

6.1.1. Introduction



When Yalow and Berson developed the first radioimmunoassay for the in vitro determination of insulin in 1959,[1] they surely could not have envisaged that their method in this or in some other form would become the most important analytical tool of medicinal in vitro diagnostics. It is difficult to overlook the wealth of substances, whose concentrations are today routinely determined in clinical laboratories with immunoassays. A number of these analytes are listed in Table 2 according to diagnostic indications.

Table 2. Some analytes which are routinely determined by immunoassay in different diagnostic areas.

Diseases of the thyroid gland	*Gastrointestinal tract*
TSH (thyroid stimulating hormone, thyrotropin)	calcitonin
T3 (triiodothyronine)	C-peptide
FT3 (free T3, i.e. not bound to binding protein)	gastrin
T4 (tetraiodothyronine)	insulin
FT4 (free T4, i.e. not bound to binding protein)	anti-insulin antibody
TBG (thyroxine binding globulin)	pepsinogen
Tg (thyreoglobulin)	trypsin
Anti-Tg (autoantibody against Tg)	trysin neonatal
TPO (thyroidal peroxidase)	vitamin D
Anti-TPO (autoantibody against TPO)	
TRAK (autoantibody against the TSH receptor)	*Hypertonia and nephrology*
	aldosterone
Tumour growth controls	androstendione
AFP (α-fetoprotein)	angiotensin I (renin)
CA 50 (CA = cancer antigen)	cortisol
CA 125	DHEA (dehyroepiandrosterone)
CA 15-3	17 α-OH-progesterone
CA 19-9	
CA 72-4	*Cardiology*
CA 754	digoxin
calcitonin	myoglobin
CEA (carcinoembryonic antigen)	
cyfra 21-1	*Connective tissue diseases*
ferritin	laminin
HCG (human choriongonadotropin)	NC1 (N-terminal collagen I)
β_2-microglobulin	PIIIP (procollagen-III-peptide)
NCAM (neural cell adhesion molecule)	7S-collagen
NSE (neuron specific enolase)	
osteocalcin	*Infectious diseases*
PAP (prostatic acid phosphatase)	HBsAg (hepatitis B surface antigen)
prolactin	HSV antigens
PSA (prostatic specific antigen)	p24 antigen (HIV antigen)
SCC (squamous cell carcinoma antigen)	rotavirus antigen
TATI (tumor-associated trypsin inhibitor)	antibodies against:
Tg (thyreoglobulin)	– FSME virus
TPA (tissue polypeptide antigen)	– HBsAg
	– HIV1
Pregnancy	– HIV2
AFP (α-fetoprotein)	– HSV
estriol	– measles virus
HCG (human choriongonadotropin)	– rotavirus
progesterone	– rubella virus
	– toxoplasma gondii
Sexual functions	– varicella Zoster
FSH (follicle stimulating hormone, follitropin)	*Inflammatory processes*
LH (luteinizing hormone, lutropin)	α-antitrypsin
progesterone	CRP (C reactive protein)
17α-OH-progesterone	α_1-macroglobulin
prolactin	α_2-acid glycoprotein (Orosomucoid)
testosterone	

The success of immunological assays is owed primarily to their high specificity and sensitivity; antibodies, which are employed in immunoassays as detection reagents, can "recognize" at the molecular level smallest structural differences (much cited "lock-and-key" principle). For example, an antibody raised

against the thyroid hormone thyroxin binds with high affinity (equilibrium constants usually are of the order of 10^{10}–10^{12} L mol^{-1}), whereas triiodothyronine which differs by only one iodine atom is not recognized (Scheme 34).

Scheme 34. Structure of the thyroid hormones T3 (X = H, 3,3'5-triiodo-L-thyronine) and T4 (X = I, 3,3',5,5'-tetraiodo-L-thyronine, L-thyroxine).

As a result of this impressive specificity practically all substances with a molecular weight of greater than 100 D even in complicated liquids such as serum can be determined exactly without prior separation of similar substances. Modern labels can even be traced into the attomolar range (1 amol = 10^{-18} mol). Thus, by labeling antibodies with such labels, the substances to be analyzed can be quantified exactly to the femtomolar range (1 fmol = 10^{-15} mol). A current listing of almost 500 literature references can be found in "Bioluminescence and Chemiluminescence Literature - Immunoassays and Blotting Assays" by O. Nozaki et al.[181]

6.1.2 Categories

Immunoassays can be divided into different groups.

Group I: Competitive immunoassays with analyte tracer:

This group concerns assays in which the detection reagents are an antibody specifically directed against the substance to be determined and an analyte derivative which carries the label (analyte derivative tracer, usually abbreviated to analyte tracer). The analyte tracer should not be too structurally different from the analyte (which under the circumstances only exists in the presence of the label) that it no longer is recognized by the antibody. Furthermore, immunoassays of this group are competitive assays, that is the analyte and analyte tracer compete for a small number of antibody binding sites in an equilibrium reaction (Fig. 3a). The lower the concentration of the analyte-sample to be analyzed, the more antibody–analyte tracer complexes can form as a result. The analyte concentration of an unknown sample can be determined exactly by using a calibration curve drawn up from samples of known concentration (Fig. 3b). As is apparent from Figure 3a, selective measurement of the signal emitted from the antibody–analyte tracer complex requires prior separation of uncomplexed analyte tracer. Separations of this kind are dealt with in Section 6.1.3.

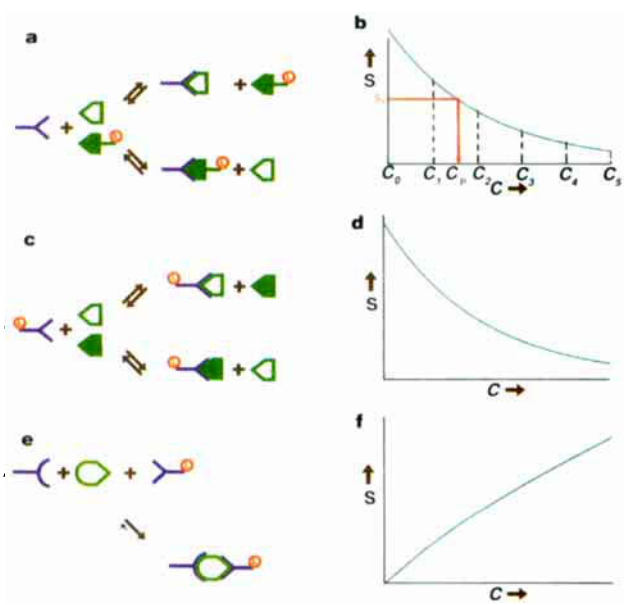


Fig. 3. Principle of the three most important immunoassay methods (left) with the corresponding calibration curves (right). Left: blue = antibody, green = analyte (open) and analyte derivative (closed), red = label. Right: c = concentration, P = unknown sample, S = signal emitted by the antibody–analyte tracer complex (a,b), antibody tracer–analyte derivative complex (c,d) and from the sandwich complex (e,f). This and other schematic representations of an antibody do not take into account the existence of several binding sites (in the case of the IgG antibody: two).

Group II: Competitive immunoassays with antibody tracer:

As in Group I this is also a competitive process. The only difference is that of the two detection reagents (antibody, analyte derivative) it is not the analyte derivative that carries the label but the antibody (antibody tracer also called tracer antibody). As can be seen from Figure 3c, the concentration of the analyte to be determined correlates with the concentration of the antibody tracer-analyte derivative complex after adjusting the equilibrium (Fig. 3d). For the separation of the two labeled complexes which is also necessary in this case see Section 6.1.3.

Group III: Sandwich assays:

Instead of the analyte derivative in competitive assays, in this case a second antibody is the detection reagent. The label is situated on one of the two antibodies. Both antibodies bind to the analyte at different sites (epitopes) and thus form a sandwich complex. An excess of the two antibodies is employed in order to shift the equilibrium in favor of the sandwich complex (Fig. 3e). The favorable equilibrium position in this type of assay due to the excess of reagent leads to a considerably higher sensitivity of detection. Whilst, for example, a competitive assay for the determination of the thyroid hormone thyrotropin is capable of detecting an analyte concentration of about 1–2 fmol mL^{-1}, the lower detection limit in the case of a comparable sandwich assay is about 0.1–0.2 fmol mL^{-1}. The sandwich strategy achieved its breakthrough when it became possible to obtain pure uniform antibodies in virtually any quantity. (Monoclonal antibodies, Nobel Prize, 1984 for Köhler and Milstein).[182, 183]

About the only disadvantage is the limited applicability of this type of assay: small analytes (M < approx. 5 kD) are excluded, since two antibodies cannot bind simultaneously for steric reasons. In the case where the analyte is an antibody (cf. listing in Section 6.1.1; indication: infectious diseases), the sandwich assay can be applied in a slightly modified form: an antigen plays the part of one of the two detection antibodies, thus, for example, a virus particle, against which the analyte antibody is directed. In this case, the resulting sandwich complex consists of antigen, analyte antibody, and detection antibody; the antigen corresponding to its complementary structure binds to the recognition site of the analyte antibody and is, thus, responsible for the specificity of the detection. For the detection antibody it suffices if this is directed against the structure element of the analyte antibody, although this is standard for all

antibodies of the same animal (in this case human) species (Fc portion). The latter presupposes, of course, that the antibodies present in the patient's blood, which are directed against completely different antigens, do not "capture" a significant fraction of the detection anti body. In practice such complications can be easily avoided by the choice of a corresponding high concentration of the detection antibody or by a so-called two-step performance of the assay. The separation of the sandwich complex and excess tracer, also necessary in this case prior to the measurement, is dealt with in Section 6.1.3.

The individual variations within these groups (cold and hot preincubation, one-step and two-step performance, double antibody method) as well as immunoassays which work without a tracer[118a] cannot be dealt with here.

Definitions of Terms:

In scarcely any other area is there such a confusion of terms and abbreviations as in the field of immunoassays. The most well-known expression is the "radioimmunoasssay" (RIA). Unfortunately it is often used for two different circumstances. First, it stands for competitive immunoassays with a radioactive analyte tracer, that is, for the assay type described in Group I, and second it is often employed as the generic term for all immunoassays with a radioactive label. The same can also be said for the enzyme immunoassay (EIA), fluorescence immunoassay (FIA), and luminescence or chemiluminescence immunoassay (LIA and CIA, respectively) which are distinguished from RIA only by the type of label used. A similar ambiguity exists with the acronym ELISA (*e*nzyme-*l*inked *i*mmuno*s*orbent *a*ssay). This term is reserved by some authors for the excess reagent assay (Group III) with the enzyme label and by others is employed quite generally for all immunoassays with enzyme label.

Just as XIA (RIA, EIA, FIA, LIA, CIA) designates specifically assays of Group I, Group II does not have a generally accepted abbreviation. However, in this case one often comes across the expression SPALT (*s*olid *p*hase *a*ntigen *l*uminescence *t*echnique). This describes an assay of Group II with luminogenic label, for which a particular but frequently used technique for separating excess antibody tracer is employed (see Section 6.1.3).

A synonym for sandwich assay (Group III) is the expression 2-site IXMA; this stands for "immuno-x....metric assay" (for example: IRMA: immunoradiometric assay; ILMA: immunoluminometric assay). The expression immunometric means that, in contrast to the competitive assays, one is dealing with an assay with excess reagent. Unfortunately the designation is also not uniform in this case. Hence, Group II, despite its competitive nature, is still designated with the expression "1-site IXMA". Strictly speaking the 1-site IXMA is, however, a very rare type of assay, which uses the same detection reagents as Group II (analyte derivative and antibody tracer), however, uses the antibody tracer in excess, and does not measure the complex formed from the analyte derivative and antibody tracer, but the complex formed from the analyte and antibody tracer.

6.1.3. Separation Methods

As already mentioned the selective measurement of labeled immune complexes necessitate a prior separation of the unbound analyte tracer (in the case of Group I), of antibody tracer not bound to the analyte derivative (Group II), or of unbound antibody tracer (Group III).

The first separation methods involved really difficult purification steps, for example chromatography or electrophoresis. Considerably more manageable, but today regarded as being antiquated, are the methods in which the immune complexes are precipitated by addition of salts or organic solvents, or the unbound analyte tracer is adsorbed on addition of activated charcoal or ion exchange resin. The requisite centrifugation step renders these methods as being no longer able to compete today.

Modern methods usually employ a solid phase. In the simplest case this is a small tube made of synthetic material, whose inner wall is coated with one of the detection reagents (coated tubes). At the same time these tubes serve as the reaction vessel for the immunological detection reaction. The separation immediately prior to measurement is reduced to just merely decanting off or removal of the reaction solution by suction (Fig. 4).

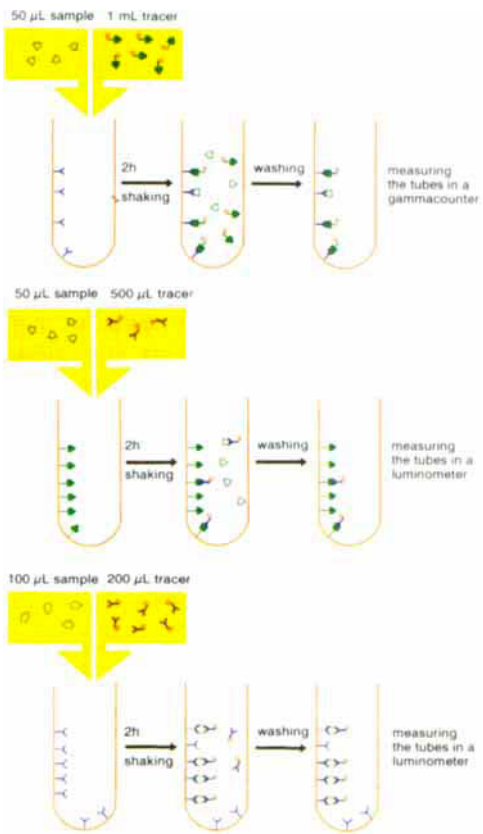

Fig. 4. Examples of commercial immunoassays performed with a coated tube: RIA-gnost T3 (top), a RIA and BeriLux T3 (middle), a SPALT assay for determination of triiodothyronine (T3) and BeriLux TSH (bottom), a 2-site ILMA for the determination of thyroid stimulating hormone (TSH) in serum.

The coating of the solid phase proceeds in the most simple case by direct adsorption of the detection reagent; the solid phase is kept in contact with a solution of the detection reagent for several hours. Under suitable conditions the adsorptive binding is so strong that the immobilized reagent cannot be dissolved by washing the solid phase. Binding can also result through an anchor protein, which adsorbs particularly well onto

the solid phase to which the detection reagent is covalently bonded by bifunctional reagents.[24] Often an antibody, which recognizes a structural element that is common to all antibodies of another animal species, is attached to the solid phase. For instance, antibodies which are directed against the Fc portion of mouse antibodies can be produced in rabbit. In this way antibodies can be anchored onto the solid phase which are less suitable for a direct adsorption. More of these universal solid phases are based on the high affinity binding between biotin and avidin (strept-)avidin[34] as well as between fluorescein and anti-fluorescein antibodies[184] (Fig. 5).

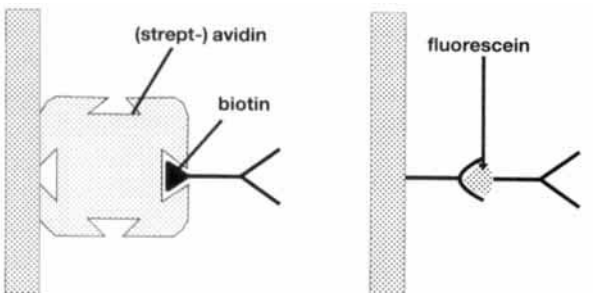

Fig. 5. The binding of a detection reagent (in this case an antibody) to a solid support can be achieved by means of the (strept-)avidin/biotin system (left): The biotinylated antibody is supported by the (strept-)avidin adsorbed onto the solid support. A similar anchoring method is based on the strong bonding between fluorescein groups and antibodies directed against fluorescein (right).

Instead of coated tubes other coated solid phases can also be employed (synthetic spheres, magnetic particles, and membranes). These can also (cf, Fig. 4) participate directly in the immune reaction or merely have a separation function. In the latter case the immune reaction occurs in a homogeneous liquid phase (which has certain advantages with regards to the rate of reaction), and the separation function of the solid phase is only "switched on" once the reaction is completed (Fig. 6).

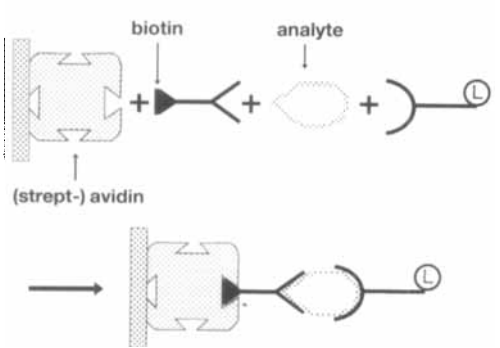

Fig. 6. After completion of the reaction between antibody labeled with either FITC or biotin, analyte, and analyte tracer in the liquid phase, the solid support coated with (strept-)avidin or anti-fluorescein antibodies, respectively, is added, and the sandwich complex is attached to the solid support.

With the OPUS system[185] separation is accomplished without further operation steps. The whole immune reaction takes place in a test module which is about the size of two sugar cubes. An essential component is a transparent polyester film, on the surface of which are three agarose layers. Complexes of the antibody and fluorescent-labeled analyte derivative are embedded in the lower layer (1 μm thick). The serum sample is applied to the top layer (10 μm thick). The analyte molecules contained in the sample diffuse into the lower layer, where they—depending on their concentration—displace more or less tracer molecules from the antibody binding sites. Additional reagents such as aqueous solutions are not necessary here. Whereas antibodies are not able to leave the lower layer because of their size, the unbound tracer molecules are free to diffuse into the two upper layers. The antibody–tracer complexes which remain in the lowest layer are quantified by fluorescence detection. The light source and detector are situated below the test module. The middle agarose layer (10 μm thick) acts as an optical filter due to its iron oxide content and prevents measurement of released tracer molecules which have diffused from the lower layer.

In the purely homogeneous assays there is no separation step because they are based on a changing signal in the formation of the immune complex. The first assay of this type was presented by Rubenstein and Ullman in 1971.[186a] This EMIT method (*e*nzyme-*m*odulated *i*mmunoassay *t*echnology) involves EIA; enzymatic activity of the enzyme label is inhibited by the binding of antibodies (Fig. 7). Another example of a homogeneous assay which employs chemiluminescence energy transfer is shown in Figure 8. Disadvantages of these, at first glance, particularly elegant homogeneous assays are lower sensitivity of detection and a more pronounced susceptibility to interference.

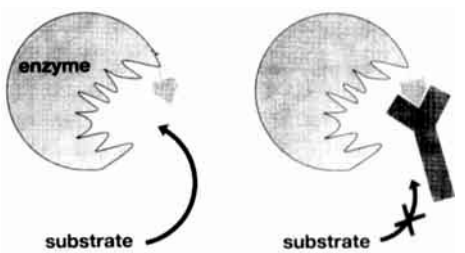

Fig. 7. In the EMIT method an antibody bound to the analyte tracer (analyte derivative labeled with the enzyme) prevents the catalytic conversion of the substrate (e.g. a chromogen) by the enzyme, for example, by steric hindrance at the active site.

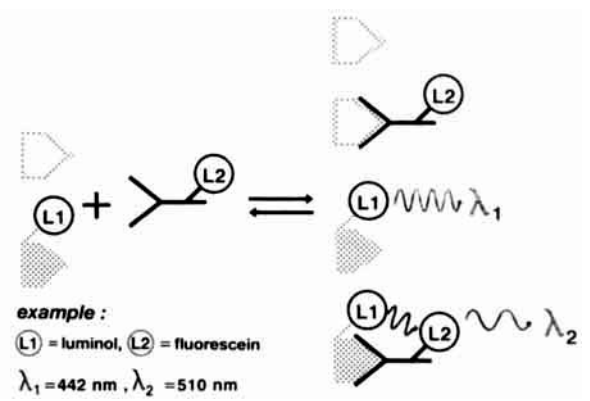

Fig. 8. Example of a homogeneous LIA: The energy transfer across the small distance between the two labels L1 and L2 results in an electronic excitation of L2. The intensity of the light emitted from L2 therefore correlates to the analyte concentration.

6.2. Gene Probes

Whereas analytes in immunological determination methods are after all products of genetic information, nucleic acid sequences are the information itself. The qualitative and quantitative determination at this "primary level" is increasingly gaining significance.

The most important application at present is in the detection of pathogenic organisms (bacteria, viruses).[187] A particular advantage is that not only active viral infections, but also latent ones, are ascertainable by detection of the nucleic acid sequences. Thus, for example, infections with the AIDS virus can be detected already in the incubation phase of seronegative patients. In addition, the control of blood supplies for HIV, HTLV-I, Hepatitis B, etc. is much safer with the detection of the corresponding nucleic acid sequences than with an immunological test.

A series of hereditary diseases, such as diabetes mellitus, Lesch–Nyhan syndrome, phenylketonuria, and sickle cell anemia, can be detected reliably by tracing the mutated genes,[188] likewise the activation of different oncogenes which are involved in the formation of tumors.[189] In forensic medicine the detection of nucleic acid sequences is employed for solving cases involving sexual crimes or in tests for paternity suits.[190]

In contrast to immunoassays no antibodies are employed as direct detection reagents, but relatively short, mostly synthetic nucleic acid sequences (so-called gene probes) which are complementary to part of the analyte (so-called target sequence) (Fig. 9). These hybridize with the target sequence, that is, they

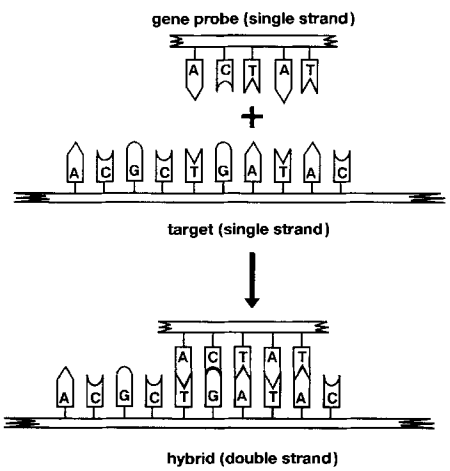

Fig. 9. The affinity of two nucleic acid strands arises from complementary base pairs: adenine (A) bonds to thymine (T) or uracil (U), and cytosine (C) to guanine (G). The gene probes employed are usually chains of 15–30 nucleotides.

bind with it to form a double strand which is held together by hydrogen bonding.

In the Southern–Blot method,[191] named after its founder, the DNA, on which presumably the sequence to be determined lies, is initially cut into defined fragments by restriction enzymes. These are separated by electrophoresis and the bands on the electrophoresis gel are transferred to a suitable carrier (e.g. nitrocellulose), whilst maintaining the relative positions of the bands. The individual DNA fragments (double-stranded) are denatured (that is, they are split into single strands) by heating, in order to make them accessible to a hybridization with the labeled gene probe. One of the advantages of this method is that different probes can be employed simultaneously to trace several nucleic acid sequences.

The visualization of the fragments hybridized with the probes can be accomplished, for example, by applying a photographic film. The exposure times are greatly dependent on the label employed. For the ^{32}P isotope used almost exlusively earlier, it was not unusual to have to wait for several weeks. By employing more modern luminogenic labels the exposure times can be drastically reduced. Methods that use fluorescent labels dispense with need for photographic film and, moreover, there is the advantage that different colored light signals can be received by employing different labels simultaneously. This can make the distinction of DNA fragments which exhibit similar electrophoresis profiles considerably easier.

In analogy to immunoassays there are also corresponding gene probe tests. The pendant of a 2-site IXMA[192] is shown in Figure 10. An analogue of the competitive immunoassay is the

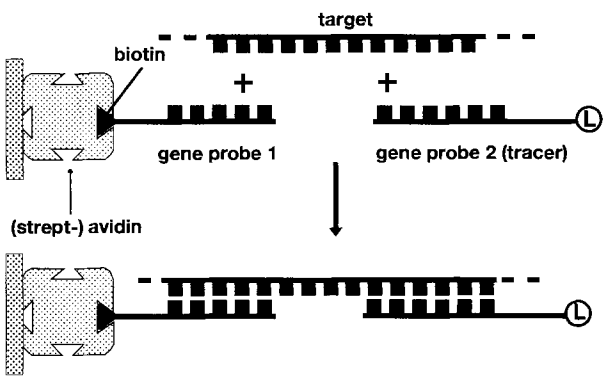

Fig. 10. The counterpart corresponding to the 2-site IXMA on gene probe site.

strand displacement assay[193] (Fig. 11). The only difference, in principle, to the XIA presented in Section 6.1.2. (Group I) is that the labeled gene probe (corresponds to the analyte tracer in XIA) and the target sequence (analyte) do not compete at the same time for the probe bound to the solid phase (corresponds to the antibody in XIA), but that the tracer gains a lead in time (principle of hot incubation; not an unusual experimental variable in XIA).

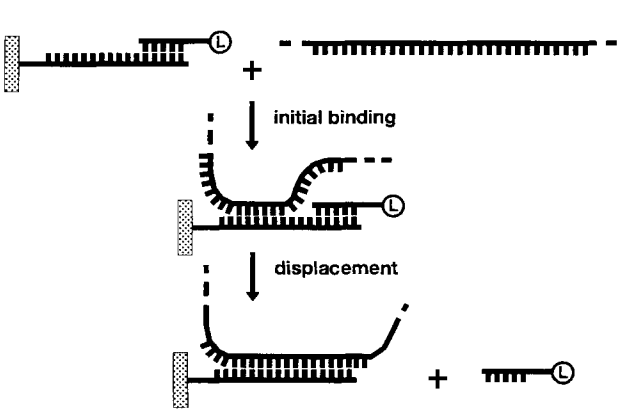

Fig. 11. Principle of the strand displacement assay.

The transfer of techniques from the field of immunoassays has also led to homogeneous gene probe test. In kissing probes (Fig. 12), two labeled probes bind to the target so closely to each other that an interaction is effected between the labels. Thus, only the changes in the signal occurring in this way can be viewed as highly specific.

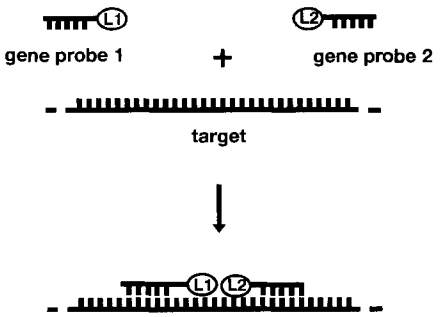

Fig. 12. Principle of the "kissing probes".

The acridinium label is able to intercalate double-stranded DNA and therefore is protected against attack from nucleophilic reagents. In this way it is possible to distinguish between single-stranded and double-stranded bound labels. This has been of use in the "hybridization protection assay".[194]

A revolutionary step for enhancing the sensitivity of gene probe tests was achieved by the PCR methods (polymerase chain reaction).[195] K. B. Mullis received the Nobel prize for the development of this method in 1993. The basic idea is original and at the same time simple. Whereas almost all attempts to improve the lower detection limit were directed at increasing the signal intensity and reducing the background signal, that is, to have the tracer in sight, with the PCR method, the target sequence is selectively replicated(!) and moreover quite simply. First, the target sequence present as a DNA double strand is cleaved into two single strands by denaturing with heat. The two single strands were then hybridized with complementary oligonucleotides and these were subsequently enzymatically

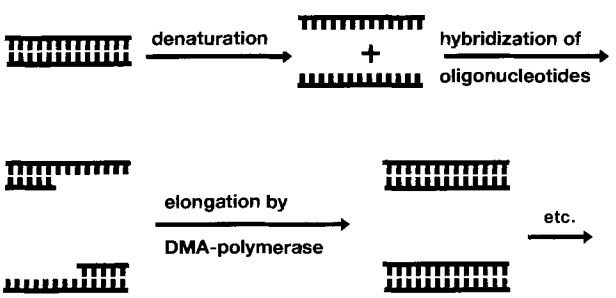

Fig. 13. PCR method.

elongated at the 3'-end with deoxynucleotide triphosphates. This process is repeated several times (Fig. 13) and after 20 cycles the target sequence is amplified by 100 000-fold.

7. Outlook

Even if a γ source which radiates continually for months to emit a signal often only required for a few seconds is everything but modern, there is much to be said, not only on ecological grounds, for the replacement of radioactive labels. With the labeling alternatives available today radioactive labels have, as far as detection sensitivity is concerned, been partly superseded. Why is it then that RIA did not die out long ago? A considerable advantage of RIA is tied up with one of its greatest disadvantages—as seen from an ecological standpoint—the emission of energy-rich radiation. In the thirty years of experience in the field of RIA this method has proved to be extraordinarily "robust". Thus, for example, in the case of the radioactive label the tracer is not influenced by its direct surroundings ("matrix effects") except for in the rarest of cases. Furthermore, the signal is not affected either in terms of its absolute value or in terms of its constancy by most external factors. In addition, the labeling of small analyte derivatives by an isotope inevitably results in fewer changes in properties compared to the introduction of a sterically demanding label. Thus, replacement of radioactive methods will understandably not occur overnight, but is more of a gradual process which is sustained by a steady increase in experience in dealing with nonradioactive labels and the synthesis of more effective labels. Since the most efficient luminescent labels and luminogenic enzyme substrates have only been available for a few years, one can expect an acceleration of this hitherto slow replacement of radioisotopes in the years to come.

We thank all our colleagues for helpful discussions during the drafting and correction of this manuscript as well as Mr. R. Kaske for providing marketing data and Mrs. J. Bruchmann and Mrs. N. Laloi for support during the preparation of the manuscript. Our special thanks go to Mr. A. Kraft for preparing the figures in Section 6.

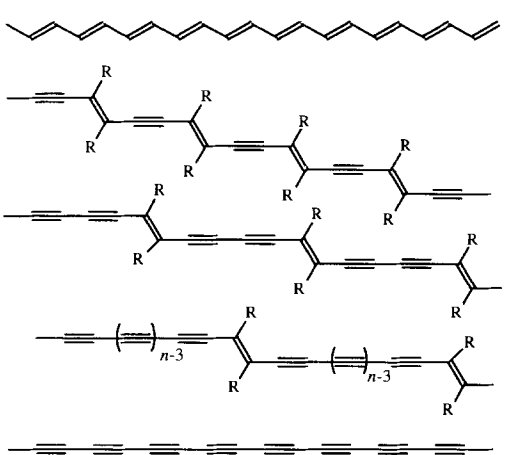
Polyynes—Fascinating Monomers for the Construction of Carbon Networks?**

Uwe H. F. Bunz*

The synthesis of novel carbon modifications and their precursors is currently an area of intensive activity.[1, 2] The discovery of the fullerenes[3] by Krätschmer, Smalley, and Kroto and the all-carbon rings (cyclo[*n*]carbons) by Diederich et al.[4] have fueled interest in this field. Related work has resulted in the synthesis of carbon-rich compounds such as polyethynylenarylene dendrimers by Moore et al.,[5] pericyclynes by Scott et al.,[6] and compounds with a perethynylated π perimeter by Vollhardt et al.[7] (**6**) and by our own research group[8] (**4**, **5**). Molecules **1**–**6** are a selection of monomers reported in the past few years that could be used potentially in the construction of carbon networks.[9]

1 **2** **3**



4 **5** **6**

A common feature in the efforts directed towards the preparation of carbon-rich systems is the use of the C–C triple bond as a functional group and linking unit. The alkyne group is the only easily preparable all-carbon building block; terminal alkyne functions can be linked to sp^2-C-Hal molecules readily and in high yields,[10] and are amenable to copper-catalyzed, oxidative Hay or Eglington[11] coupling reactions. Thus, the acetylene function is indispensable not only in the construction of carbon-rich structures but also in the synthesis of larger rings and three-dimensional cages. The relative rigidity and linearity of the C≡C fragment is a further advantage in the synthesis of rigid and uniformly shaped structures.

Strategy for the Construction of Carbon Networks: The stepwise construction of networks, in other words the transformation of appropriate monomers into successively larger oligomers, is the most promising approach. In this way the solubility and stability of the larger systems can be estimated from the properties of smaller molecules. If necessary the monomers can be modified to improve the desired properties of the anticipated network (structural uniformity, solubility, stability).

Linear Systems

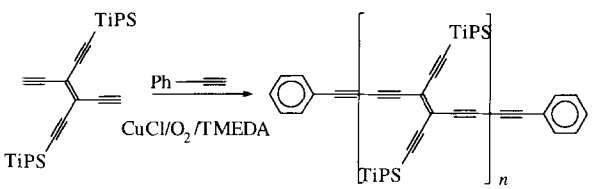
The simplest carbon modification conceivable is the polyyne carbon rod **11** with alternating single and triple bonds; this material is referred to in the literature as carbyne or chaoite.[1] Segments of this allotrope with up to 16 conjugated triple bonds were synthesized by Eastmond, Walton, et al. a number of years ago.[12] The stability of these polyynes relies on the bulky triethylsilyl end groups, which effectively prevent the polymerization of the carbon rods. In a recent study Grösser and Hirsch[13] examined the reaction of carbon vapor in the presence of cyanogen under the standard conditions for fullerene synthesis. The authors had intended to generate heteroatom-substituted fullerenes but instead obtained the previously unknown dicyanopolyynes NC–$(C{\equiv}C)_n$–CN ($n = 3$–7).

7 polyacetylene

8 polydiacetylene

9 polytriacetylene

10 poly-*n*-acetylene



11 carbyne

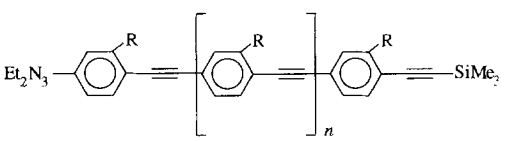
The insertion of alkene units between the alkyne functions in carbyne **11** can be envisioned to lead to polydiacetylenes **8**,[14a] polytriacetylenes **9**, and poly-*n*-acetylenes **10** in general. Although **11** is likely to polymerize in condensed phase owing to the lack of steric hindrance, it should be possible to synthesize stable hybrid forms intermediate between **7** and **11**. Bulky substituents on the alkene units should be particularly effective in ensuring the stability and solubility of **9** and **10**.

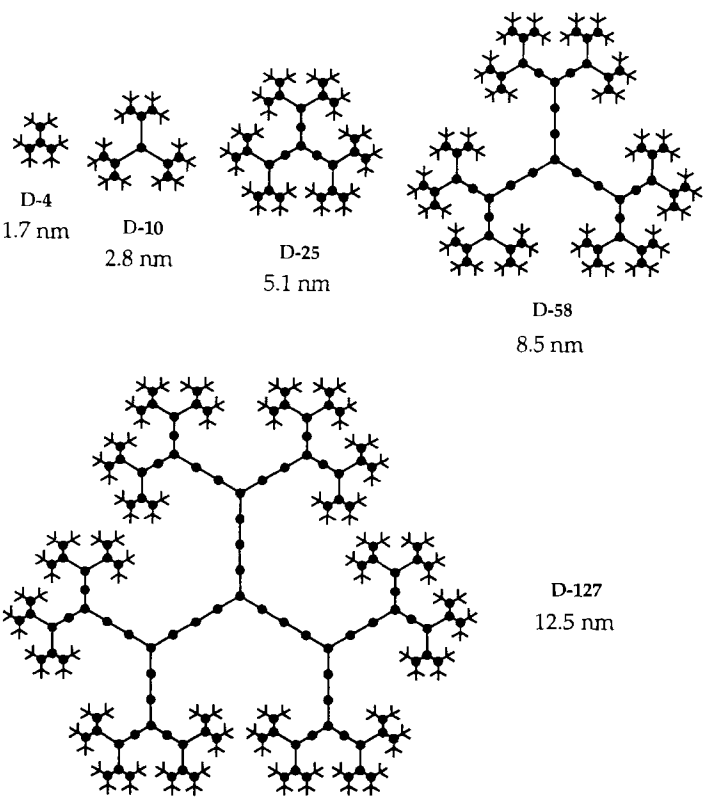


Whereas structures of type **8** were prepared in 1969 by Wegner[14b] by topochemical reaction of appropriate diynes, nothing has been reported on the synthesis of polytriacetylene **9**; the topotactical polymerization of triynes to give **9** has not been successful.[14c] The higher homologue **10** has not been investigated. However, sections of a polytriacetylene structure were recently synthesized by Diederich et al.:[15] Hay coupling of tetrayne **12** (TiPS = triisopropylsilyl) and phenylacetylene produced oligomers **13** ($n = 1-6$). The particular advantage of this

12 **13**

approach is the good solubility and stability of **13** provided by the triisopropylsilyl groups, and the fact that after cleavage of the silyl protecting groups further cross-linking is possible, at least in principle. Calculations conducted by Baughman and Galvao[16] indicate that a three-dimensional carbon network constructed by the cross-linking of **8** should have unusual mechanical properties (auxetes).

Further motivation for the synthesis of oligomers **13** (nanostructures) lies in their potential use as molecular wires in molecular electronics and microlithography: Tour et al.[17] synthesized oligomeric *p*-phenylenethynylenes, which were intended for such applications, by following a strategy developed by Moore et al.[18] Due to solubilizing substituents, chains **14** (R = ethyl, ethylheptyl) with up to 16 phenylethynyl units could be construct-

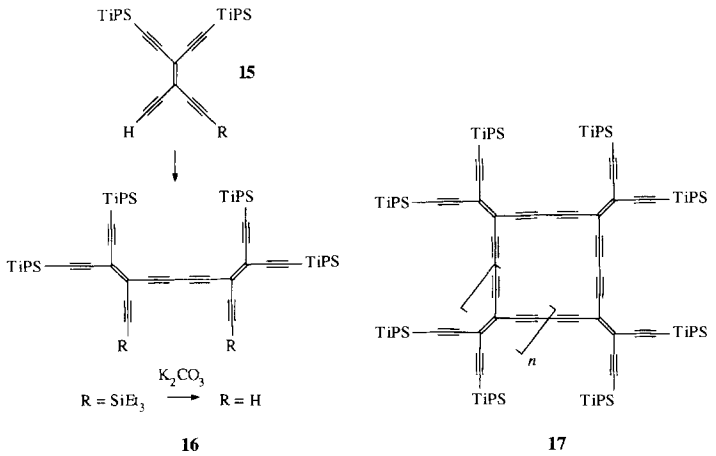


14, $n = 2, 6, 14$

ed as monodisperse particles. The roughly 128 Å long hexadecamer was readily soluble owing to its occurrence as a mixture of diastereomers and the presence of the ethylheptyl group. When the ethylheptyl group was replaced by an ethyl group, even the octameric phenylenethynylene was practically insoluble.

Two-Dimensional Systems

The synthesis of cascade molecules[19] is an established area of research. Molecules with high molecular weights can be obtained in only a few steps by nonlinear growth with high structural control. Recently, Moore et al. reported on the synthesis of the hitherto largest phenylenethynylene dendrimer (Scheme 1).[5] Owing to their rigid components, these molecules have a structurally uniform molecular framework. In the synthesis of classic dendrimers constructed of identical monomeric units growth is halted after several generations, as the spatial demand of the subsequent generation is greater than the volume available. To prepare higher generation dendrimers Moore and Xu used extended monomers of the next generation, which circumvented steric interference. This strategy should allow the synthesis of dendrimers of almost any generation.

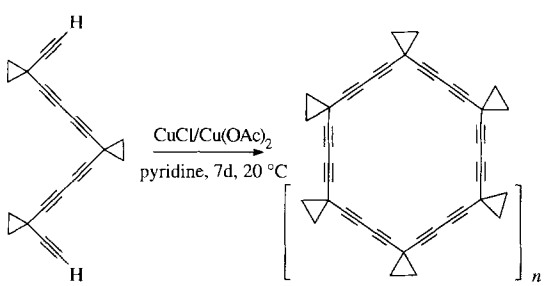


Scheme 1. Dendrimers synthesized by Moore and Xu. ⅄ 1,3,5-substituted benzene ring; —●— : 1,4-substituted phenylene unit; ⋋⋌ 1,3-di-*tert*-butylphenyl unit; — : C≡C unit.

In similar dendrimers, the tetra- and pentaethynyl-substituted organometallic compounds **4** and **5**,[8] respectively, which we prepared from the corresponding iodides, and hexaethynylbenzene (**6**),[7b] generated in 1986 by Vollhardt et al., could also serve as initiator cores.

Rings

The oxidative coupling of diynes under either Hay or Eglington conditions was highlighted by the research of Eglington[11a] and Sondheimer.[11d] Depending on the structure of the monomer,

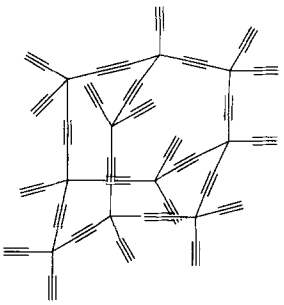


this reaction provides varying amounts of cyclized products with butadiyne units. This reaction has been known and employed for many years, but it still provides fascinating new compounds. Two attractive examples were prepared by Diederich et al.[20] and de Meijere et al.[21] The Diederich group reported on the synthesis of expanded radialenes,[22] which allows access to a new class of cross-conjugated macrocycles. The synthetic approach to **17** is shown in Scheme 2. Attempts to cyclize the

15,16 a (R = SiEt$_3$), **b** (R = H) **a** (n = 1), **b** (n = 2), **c** (n = 3)

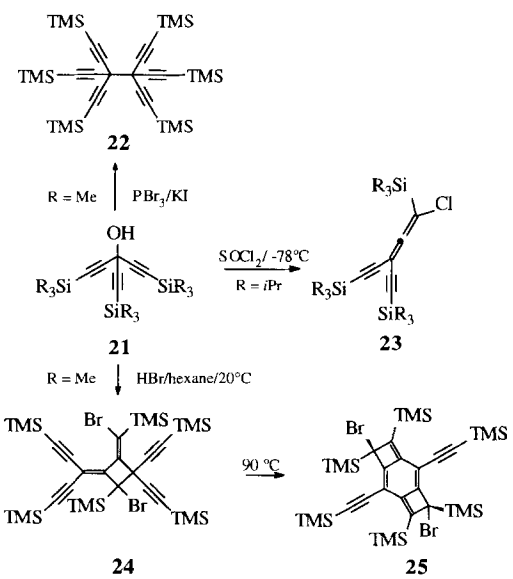
Scheme 2. Synthesis of radialenes **17**.

doubly deprotected monomer **15b** by coupling reactions were unsuccessful and gave only acyclic oligomers. However, reaction of dimer **16b** furnished cycles **17a–c**. A novel family of pericyclynes[6] was synthesized by de Meijere et al. The cyclization of trimer **18** under modified Eglington conditions led to three products, two of which were identified unequivocally as the cyclic dimer **19a** and trimer **19b**. The rigid structure and the



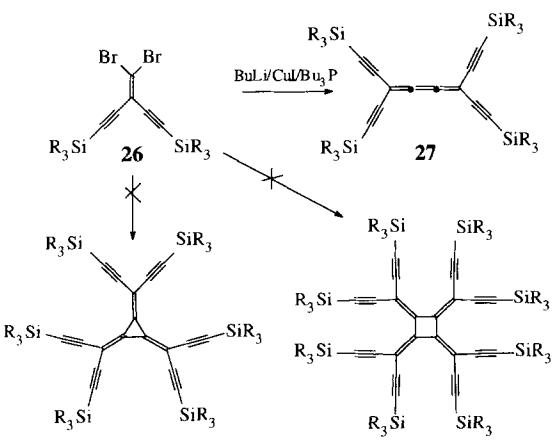
18 **19**
a (n = 1), **b** (n = 2)

electronic interaction between the cyclopropane and butadiyne units is evident in the X-ray structure analysis of **19a**.



Three-Dimensional Networks

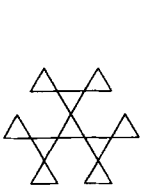
The synthesis of "nonnatural", structurally uniform, three-dimensional carbon networks presents a tremendous challenge and has recently been the focus of intensive research. Hexaethynylbenzene (**6**) synthesized by Vollhardt et al.[7] is a potential building block of supergraphite (graphyne[23]). Tetraethynylmethane **1**, which was postulated by Alberts and Wynberg[24] and prepared recently by Feldman, Kraebel, and Parvez,[25] is a potential monomer for the construction of "superdiamond" **20** (Dutch diamond[23]); here an alkyne unit is inserted between each carbon atom in the diamond lattice (cf. ref.[1]). "Expanded methane" **1** is the smallest member of a new type of "superalkanes" in which an alkyne unit is inserted in every C–H and C–C bond. These structures should be kinetically stable and not explosive (vide infra), since the alkyne units are not conjugated. As a number of research groups were unsuccessful in the synthesis of **1**, Feldman's ten-step "total synthesis" is particularly noteworthy. In contrast to the tetrakis(trimethylsilyl)-protected derivative, unsubstituted **1** is very sensitive towards hydrolysis and decomposes quickly to give a brown oil. Remarkably, the higher homologue tetrapropargylmethane **2**, which we prepared,[26] was unchanged after several weeks at room temperature in air.



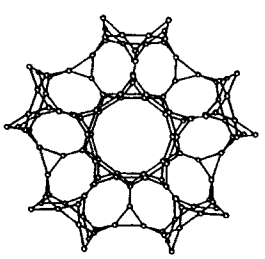
20

Until recently, triethynylmethanol **21**, synthesized by Alberts and Wynberg, was considered to be a possible precursor in the

synthesis of **1**; however, attempts to trap the cation, generated from the reaction of **21** with a Lewis acid, with a metal acetylide were unsuccessful.[27] Attempted halogenation of the OH group in **21** also did not give the desired result. Depending on the combination of reagent and silyl protecting group, completely different products were obtained. The reaction of the trimethylsilyl (TMS)-protected alcohol **21** with a mixture of PBr_3 and KI gave hexaethynylethane **22**,[23] whereas treatment with HBr/CuBr at 20 °C led to cyclobutane **24**. The latter rearranged upon heating to give the surprisingly stable *para*-quinodimethane **25**. On the other hand, when the more sterically hindered TiPS derivative



21b was treated with $SOCl_2$ at $-78\,^{\circ}C$, chloroallene **23** was isolated, which did not spontaneously dimerize because of the efficient steric hindrance of the silyl groups. Related and equally promising monomers for the construction of exotic carbon nets include tetraethynylbutatriene **3**, derivatives of which were obtained recently by Diederich et al.[28] by carbenoid dimerization according to the method of Iyoda et al.[29] (Scheme 3). Under



Scheme 3. Synthesis of tetraethynylbutatrienes **27**, R = Me, *i*Pr.

these reaction conditions [3]- and/or [4]radialenes **28** and **29**, respectively, would be expected; however, the steric demand of the TMS and TiPS substituents in these compounds may prevent reactions beyond the dimerization of the intermediate carbenoid, which is formed from **26**, to give **27**. The attempted dimerization of tetraethynylbutatriene **27** with triphenylphosphane catalysis to provide **29** also failed and resulted instead in the hydrogenation of the central double bond in **27**.

One approach to the synthesis of sections of a carbon network without triple bonds was published recently by de Meijere et al.[30] The perspirocyclopropanated [3]rotane **30** obtained is a section of a network type composed exclusively of spirocyclopropane units. A higher oligomer in this series is [80]triangulane **31**, which is an attractive, though not easily achievable, synthetic target.

30

31

The construction of carbon networks is still in its infancy, yet important advances in the synthesis of small sections of such structures are currently being made. The monomers themselves with their unusual structures often display fascinating chemistry. The most difficult problem to be overcome in the synthesis of two- and three-dimensional networks is the rapid drop in the solubility of the higher homologues. Currently, structurally uniform all-carbon networks can be the generated and studied only by computer.[1, 14, 31] This will hopefully change in the future.

Homoleptic Noble Metal Carbonyl Cations**

Lothar Weber*

Homoleptic neutral carbonyl complexes of the noble metals silver, gold, palladium, and platinum have so far only been detected in noble gas and CO matrices at $T \leq 15$ K, and they decompose well below the temperature of liquid nitrogen.[1-3] Thus, it is surprising that after more than a century of metal carbonyl chemistry, thermally stable salts with $[M(CO)_2]^+$ (M = Ag, Au) and $[M(CO)_4]^{2+}$ ions (M = Pd, Pt) were isolated. This is even more remarkable since homoleptic and well-defined stable metal carbonyl cations are rare in comparison to the large number of neutral and anionic metal carbonyls, and since so far they have been limited to the octahedral cations $[M(CO)_6]^+$ (M = Mn, Te, Re).[4-6]

Preparation

In comparison with classic methods the syntheses of noble metal carbonyl cations are unusual. Whereas $[Ag(CO)_2][B(OTeF_5)_4]$ crystallizes from solutions of $Ag[B(OTeF_5)_4]$ in 1,1,2-trichlorotrifluoroethane under about 0.5 bar CO at $T \leq -15\,^\circ C$[7] [Eq. (a)], the considerably more stable $[Au(CO)_2]^+$ salts form in strongly ionizing protic acids or are produced in Lewis acids such as SbF_5. Metallic gold is oxidized by UF_6 in liquid HF in the presence of CO to give $[Au(CO)_2][UF_6]$[8] [Eq. (b)].

$$Ag[B(OTeF_5)_4] \xrightarrow[\leq -15\,^\circ C]{CO} [Ag(CO)_2][B(OTeF_5)_4] \quad (a)$$

$$Au + 2CO + UF_6 \xrightarrow[HF\ liq.]{} [Au(CO)_2][UF_6] \quad (b)$$

The reductive carbonylation of $Au(SO_3F)_3$ in fluorosulfonic acid leads via $[Au(CO)_2]^+$(solv.) to solid $[Au(CO)SO_3F]$, which is carbonylated in pure SbF_5 under solvolysis to give colorless, crystalline $[Au(CO)_2][Sb_2F_{11}]$ with a melting point of 156 °C (decomp.)[9] [Eqs. (c)–(e)].

$$Au(SO_3F)_3 + 3CO \xrightarrow[HSO_3F]{25\,^\circ C} [Au(CO)_2]^+ + CO_2 + S_2O_5F_2 + [SO_3F]^- \quad (c)$$

$$[Au(CO)_2]^+ + [SO_3F]^- \xrightarrow[HSO_3F]{\Delta} [Au(CO)SO_3F] + CO \quad (d)$$

$$[Au(CO)SO_3F] + CO + 4SbF_5 \xrightarrow{SbF_5} [Au(CO)_2][Sb_2F_{11}] + Sb_2F_9(SO_3F) \quad (e)$$

The same strategy has proved to be successful for the preparation of $[Pd(CO)_4][Sb_2F_{11}]_2$ (m.p. 155 °C, decomp.) and $[Pt(CO)_4][Sb_2F_{11}]_2$ (m.p. 200 °C, decomp.)[10] [Eq. (f)]. The necessary starting materials for this reaction *cis*-$[M(CO)_2(SO_3F)_2]$, (M = Pd, Pt) form during the reductive carbonylation of solid

$$[M(CO)_2(SO_3F)_2] + 8SbF_5 + 2CO \xrightarrow[\approx 0.5\ \ 0.6\ bar\ CO]{80\,^\circ C} [M(CO)_4][Sb_2F_{11}]_2 + 2Sb_2F_9(SO_3F) \quad (f)$$

$Pd^{II}[Pd^{IV}(SO_3F)_6]$ and of $Pt(SO_3F)_4$ in HSO_3F, respectively, at 80 °C. If the carbonylation of the latter is carried out at 25 °C, $[Pt(CO)_4][Pt(SO_3F)_6]$ can be isolated as a yellow solid with a melting point of 140 °C (decomp.).[11]

The familiar range of existence (with regard to the metal) of "classic" carbonyl compounds is finally left with the first mercury carbonyl cations $[Hg(CO)_2]^{2+}$ and $[Hg_2(CO)_2]^{2+}$. In this case, too, the solvolysis processes of the corresponding mercury fluorosulfonates in SbF_5 at CO pressures of 0.7–0.9 bar are successful. The colorless salts $[Hg(CO)_2][Sb_2F_{11}]_2$ [m.p. 160 °C, decomp.; Eq. (g)] and $[Hg_2(CO)_2][Sb_2F_{11}]_2$ are formed in almost quantitative yield.[12]

$$Hg(SO_3F)_2 + 8SbF_5 + 2CO \xrightarrow[100\,^\circ C,\ 1\,h]{SbF_5} [Hg(CO)_2][Sb_2F_{11}]_2 + 2Sb_2F_9(SO_3F) \quad (g)$$

Properties

With the exception of $[Ag(CO)_2][B(OTeF_5)_4]$, which decomposes above −15 °C with evolution of CO to give $Ag[B(OTeF_5)_4]$, and $[Hg_2(CO)_2][Sb_2F_{11}]_2$ (the CO decomposition partial pressure at 20 °C is 8 mbar), the salts with noble metal carbonyl cations discussed here are thermally surprisingly stable with melting points between 140 and 200 °C. Without doubt their existence is coupled to the presence of anions with extremely low nucleophilicity such as $[Sb_2F_{11}]^-$ or $[Pt(SO_3F)_6]^{2-}$. The synthesis of derivatives such as $[Au(CO)SO_3F]$ and *cis*-$[M(CO)_2(SO_3F)_2]$ (M = Pd, Pt) from solutions of $[Au(CO)_2]^+$(solv.) and $[M(CO)_4]^{2+}$(solv.) in HSO_3F indicates the substitution lability of these species. In acetonitrile $[Au(CO)_2][Sb_2F_{11}]$ reacts immediately to give $[Au(NCMe)_2][SbF_6]$ [Eq. (h)], whereas the salt is soluble in liquid SO_2 and magic acid (SbF_5/HSO_3F) without decomposition.[9] The mercury carbonyls are only soluble in

$$[Au(CO)_2][Sb_2F_{11}] \xrightarrow[-2CO]{MeCN} [Au(NCMe)_2][SbF_6] \quad (h)$$

magic acid without elimination of CO. In the main, the chemical reactivity of noble metal carbonyl salts has still to be investigated.

Bonding and Structures

Carbon monoxide is the prototype of a very weak donor but excellent acceptor ligand. The synergetic interplay of σ-donor

bonding (from occupied 5σ molecular orbital of CO into an empty metal orbital of the σ type) and π-backbonding (from occupied metal d-orbitals into the 2π CO orbitals) is essential for the stability of the classic transition metal carbonyls. The CO valence frequencies in the vibration spectra of the noble metal carbonyl cations (2200–2289 cm^{-1}) are measured relative to the absorption of CO gas (2143 cm^{-1}) at considerably higher wavenumbers (Table 1).[13] The force constants (19.5–21.0 × 10^2 Nm^{-1}) derived herefrom almost reach the value calculated for the HCO^+ ion (21.3 × 10^2 Nm^{-1}) and thus emphasize that the π-backbonding does not play a significant role in the compounds discussed here. The increase of the CO bond order by coordination to a metal cation can be easily explained by the MO scheme of CO: the highest occupied molecular orbital (5σ) of the free CO ligand has antibonding character, which is reduced by bonding to the metal atom.[14]

Table 1. CO vibration frequencies [cm^{-1}], force constants f [10^2 Nm^{-1}], and ^{13}C NMR data [Hz] of binary metal carbonyl cations, CO, and HCO^+.

Species	IR	Raman		NMR	
	$\tilde{\nu}$(CO)	$\tilde{\nu}$(CO)	f(CO)	$\delta(^{13}C)$	$^1J(M-^{13}C)$
CO	2143		18.6	184	
HCO^+	2184		21.3		
$[Ag(CO)_2]^+$	2200		19.5	174	221
$[Au(CO)_2]^+$	2217	2254	20.1	174	
$[Pd(CO)_4]^{2+}$	2248	2278, 2263	20.6		
$[Pt(CO)_4]^{2+}$	2244	2289, 2267	20.6	140	1576
$[Hg(CO)_2]^{2+}$	2278	2281	21.0	169	5220
$[Hg_2(CO)_2]^{2+}$	2247	2248	20.4	189	3350
$[Mn(CO)_6]^+$	2096				
$[Re(CO)_6]^+$	2081				

Whereas in the classic metal carbonyls the ^{13}C NMR resonance signals for the CO ligands are measured in the range $184 \lesssim \delta \lesssim 223$[15] ($\delta^{13}C(CO)g = 184$),[10] the corresponding resonance signals in the cations introduced here generally occur at considerably higher field ($-44 \lesssim \Delta\delta^{13}C \lesssim 5$). These results, too, are in good agreement with the thermal stability of such compounds, which in the main results from the σ-donor bond and which is strengthened by polar contributions and by relativistic effects.

This supports theoretical studies on the structures and bonding energies of linear silver and gold carbonyl cations as well as the cyano complexes isoelectronic to these. It was shown that the metal–ligand bonds are primarily electrostatic in nature and in addition covalent contributions occur through σ-bonds, and at the same time negligible π-backbonding takes place. The greater stability of the corresponding cyano complexes is attributed to the strong σ-donor capability of the CN^- ion.[16] In a similar way to the linear compounds $[M(CO)_2]^+$, $[M(CN)_2]^-$ (M = Ag, Au), $[Hg(CO)_2]^{2+}$, and $Hg(CN)_2$, the square-planar $[M(CO)_4]^{2+}$ and $[M(CN)_4]^{2-}$ ions are also isoelectronic and, in contrast to the classic carbonyl complexes, no longer obey the 18e rule.

Outlook

Stable salts with noble metal carbonyl cations teach us that our view of the transition metal–CO interaction needs revising. Furthermore, once again the fundamental question must be raised at which point the uncritical usage of a familiar and, in general, useful concept leads to preconceived ideas which are an obstacle to further innovation, since in view of the easy access to, in part, considerably stable mercury carbonyl compounds, it is surprising that such "post transition metal carbonyls" were not isolated earlier. The more than 100-year-old chemistry of the metal carbonyls has not lost any of its fascination and still holds further surprises in store.

The Pressure Effect in Pericyclic Rearrangements: the Cope Rearrangement, Electrocyclization, and the Intramolecular Diels–Alder Reaction**

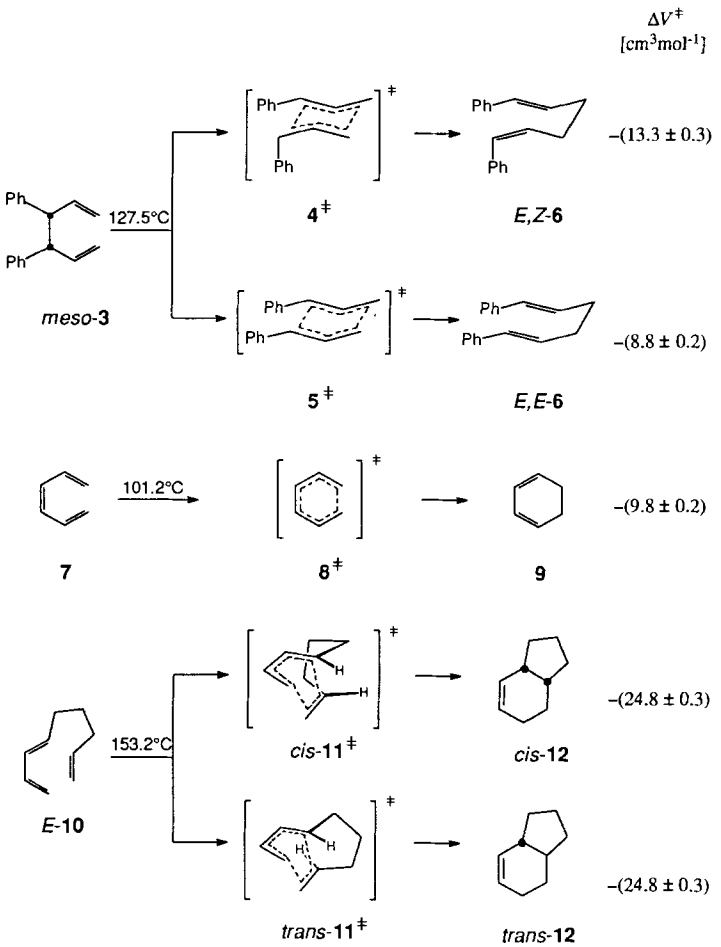
Matthias K. Diedrich, Dirk Hochstrate, Frank-Gerrit Klärner,* and Bernd Zimny

Many Diels–Alder reactions are accelerated under high pressure, and this effect is frequently employed in synthetic work. The activation volumes, which can be determined from the dependence of the reaction rate on pressure, are usually very small ($\Delta V^{\neq}$ in the range of -25 to $-45\ cm^3\,mol^{-1}$). Sometimes they are even smaller (i.e., more negative) than the reaction volumes (ΔV_R in the range -30 to $-40\ cm^3\,mol^{-1}$; $(\Delta V^{\neq}/\Delta V_R \geq 1)$.[1] Accordingly, the transition states[2] have volumes similar to, or in some cases smaller than, the products. Competing one-step, pericyclic cycloadditions and multistep cycloadditions that take place via diradical intermediates show relatively large differences in their activation volumes ($\Delta\Delta V^{\neq} \approx 10\ cm^3\,mol^{-1}$), which, at high pressure, has the effect of increased selectivity in favor of pericyclic reactions.[3] Examples are the dimerization of chloroprene,[4] 1,3-cyclohexadiene,[5] and 1,3-butadiene.[3b, 6] The preference for pericyclic reactions under high pressure is because the cyclic transition states—like the ground states—exhibit larger packing coefficients η than the transition states for the corresponding multistep reactions. The packing coefficients of transition states and ground states are defined as the ratio of the van der Waals volumes[7] to the partial molar volumes ($\eta = V_W^{\neq}/V^{\neq}$).

In the reorganization processes mentioned in the title, new interactions occur in the pericyclic transition states. The investigation of the pressure dependence reported here demonstrates a simple relationship between the number of new interactions in the transition state and the size of the activation volume.

On the basis of stereochemical and kinetic investigations, most Cope rearrangements of 1,5-hexadiene derivatives are regarded as pericyclic processes.[8] The van der Waals volumes *calculated* for the parent 1,5-hexadiene (**1**) and the pericyclic transition state $\mathbf{2}^{\neq}$ [9] (Scheme 1) are approximately the same. This is understandable since in the symmetrical transition state $\mathbf{2}^{\neq}$ the bond breaking and making have proceeded to the same extent so that the effects of the two processes on the van der Waals volumes compensate, and no great overall effect of pressure on the Cope rearrangement is to be expected. If it is assumed that, by analogy with the one- and multistep cycloaddition reactions already mentioned, the transition states here also exhibit larger packing coefficients because of their cyclic geometry, the activation volumes ought to be negative, and the Cope rearrangement should be accelerated under pressure. The activation volume can be estimated at approximately $-12\ cm^3\,mol^{-1}$ if the packing coefficient for the transition state is replaced by that for cyclohexene ($\eta = 0.5829$)[3, 7] (Scheme 1). In fact, negative activation volumes of the expected size are found for the Cope rearrangements of 4-cyano-4-ethoxycarbonyl-5-ethyl-1,5-heptadiene[10] and 3-hydroxy-3,5-dimethyl-1,5-hexadiene.[11] However, the compounds are highly polar, so the negative activation volumes could also be due to causes such as electrostriction effects rather than the interactions in the transition state, mentioned above.

	1	**2**$^{\neq}$	**1**
V_w	63.9	62.8	$\Delta V_w^{\neq} = -1.1$
V	119.4	107.7	$\Delta V^{\neq} = -11.7$



Scheme 1. All volumes are given in $cm^3\,mol^{-1}$. The structural parameters necessary for the calculation of the van der Waals volumes for $\mathbf{2}^{\neq}$ were taken from ab initio calculations [9]. The partial molar volumes for $\mathbf{2}^{\neq}$ were calculated from the equation $V(\mathbf{2}^{\neq}) = V_w(\mathbf{2}^{\neq})/\eta$(cyclohexene).

Because of this we investigated the pressure and temperature dependence of the Cope rearrangement of a pure hydrocarbon, *meso*-3,4-diphenyl-1,5-hexadiene (*meso*-**3**),[12] which reacts at 1 bar and 127.5 °C to form (*E,Z*)- and (*E,E*)-1,6-diphenylhexadienes [(*E,Z*)- and (*E,E*)-**6**] in the ratio of 60.5:39.5. When the pressure was raised an acceleration was observed for both reaction paths as well as an increased selectivity in favor of (*E,Z*)-**6** (127.5 °C, 4.3 kbar:(*E,Z*)-**6**:(*E,E*)-**6** = 73:27). From the pressure dependence of the rate constants (Table 1)[13] the negative activation volumes shown in Scheme 2 were derived. These lie within the order of magnitude expected for the formation of a new ring in the transition state. Dissociation of *meso*-**3** into two 1-phenylallyl radicals (with subsequent recombination to (*E,Z*)-**6** and/or (*E,E*)-**6**) can be excluded, since in this case positive activation volumes, and therefore a pressure-induced retardation, would be expected. On the other hand the pressure effect by itself does not allow a distinction between a pericyclic and a diradical reaction course. In the potential reaction of *meso*-**3** via an intermediate 2,3-diphenylcyclohexa-1,4-diyl, an additional ring is formed in the transition state, just as in the case of the corresponding pericyclic reaction, so both processes should have negative activation volumes of a similar order of magnitude.[14] Thermochemical estimates[15] for the competitive paths from *meso*-**3** to (*E,Z*)-**6** and (*E,E*)-**6**, however, suggest pericyclic processes. A possible explanation for the difference of $\Delta\Delta V^{\neq} = -4.5\ cm^3\,mol^{-1}$ in the activation volumes for competitive reactions is the also volume-reducing, higher steric hindrance[1c] in the chairlike transition state $\mathbf{4}^{\neq}$ compared with that of the boatlike transition state $\mathbf{5}^{\neq}$, caused by the axial position of one phenyl group in $\mathbf{4}^{\neq}$. The concept presented elucidates why the

Scheme 2. Cope rearrangement of *meso*-**3**, electrocyclization of **7**, and intramolecular Diels–Alder reaction of (*E*)-**10**, and the activation volumes for each of the rearrangements.

degenerate Cope rearrangement in bullvalene, investigated with pressure- and temperature-dependent NMR spectroscopy, shows no significant pressure effect and has an activation volume of virtually zero (19.8 °C: $\Delta V^{\neq} = -0.5\,cm^3\,mol^{-1}$).[16] As a result of the fixed stereochemistry of the bullvalene skeleton, no new interactions in the sense discussed here appear in the transition state.

In the transition state of the electrocyclization of (*Z*)-1,3,5-hexatriene (**7**) to 1,3-cyclohexadiene (**9**),[17] a new interaction develops analogously to that of the Cope rearrangement of *meso*-**3** already discussed. The conversion of **7** to **9** is accelerated by an increase in pressure. The activation volume derived from the pressure dependence of the rate constants[13] at 101.2 °C (Table 1) is $\Delta V^{\neq} = -9.8\,cm^3\,mol^{-1}$ and thereby corresponds to that of the Cope rearrangement in acyclic hexadiene derivatives.

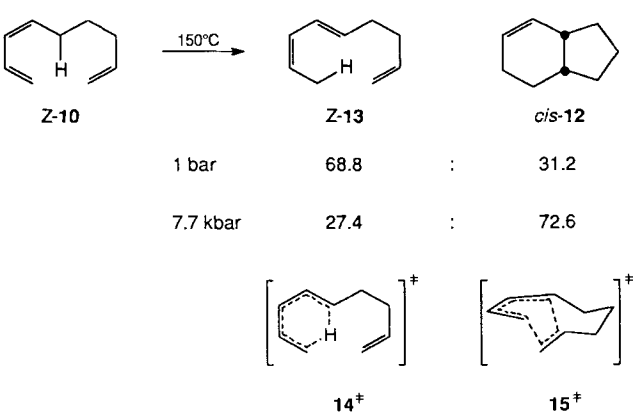
In intramolecular Diels–Alder reactions, bicyclic products are formed from acyclic starting materials. For such reactions examples of relatively large pressure-induced accelerations, which are also useful for preparative purposes, are found in the literature.[18] These compounds, without exception, bear polar groups and are not, therefore, very suitable for the foregoing analysis. We have investigated the pressure and temperature dependence of the intramolecular Diels–Alder reaction of (*E*)-1,3,8-nonatriene to form *cis*- and *trans*-bicyclo[4.3.0]non-2-ene (*cis*- and *trans*-**12**)[19] and determined that the product ratio (at 153.2 °C

Table 1. Pressure dependence of the rate constants k for the pericyclic reactions investigated.

p [bar]	1	230	510	810	990	1540	2750	4340	5850
k(*meso*-**3** → (*E,Z*)-**6**) [a]	1.24	1.21	1.37	1.53	1.62	1.84	2.36	3.03	3.71
k(*meso*-**3** → (*E,E*)-**6**) [a]	0.812	0.693	0.762	0.828	0.879	0.989	1.08	1.11	1.17
p [bar]	1	500	1000	1500	2000	3000	4000	5000	6000
k(**7** → **9**) [b]	0.813	0.946	1.14	1.26	1.45	1.94	2.50	3.17	3.87
p [bar]	1	210	400	800	1100	1600	3100	4600	
k((*E*)-**10** → *cis*-**12**) [c]	0.290	0.757	0.893	1.15	1.36	1.81	3.68	6.13	
k((*E*)-**10** → *trans*-**12**) [c]	0.0951	0.253	0.314	0.388	0.449	0.601	1.28	2.06	

[a] $[10^{-5}\,s^{-1}]$ at 127.5 °C in *n*-hexane. [b] $[10^{-5}\,s^{-1}]$ at 101.2 °C in toluene. [c] $[10^{-5}\,s^{-1}]$ at 153.2 °C in *n*-hexane.

cis-**12**:*trans*-**12** = 74.8:25.2) is not noticeably pressure-dependent. From the temperature dependence of the rate constants, measured at nine points between 195 and 280 °C, the Arrhenius equations (a) and (b) can be derived, which allow the calculation of the activation parameters[20] shown.



$$k((E)\text{-}\mathbf{10} \rightarrow \textit{cis}\text{-}\mathbf{12}) = 9.12 \times 10^7\,s^{-1} \times \exp[-(26.32 \pm 0.10)\,kcal\,mol^{-1}/RT] \quad (a)$$

238 °C: $\Delta H^{\neq} = (25.30 \pm 0.09)\,kcal\,mol^{-1}$; $\Delta S^{\neq} = -(25.18 \pm 0.19)\,cal\,mol^{-1}\,K^{-1}$

$$k((E)\text{-}\mathbf{10} \rightarrow \textit{trans}\text{-}\mathbf{12}) = 1.70 \times 10^8\,s^{-1} \exp[-(27.79 \pm 0.09)\,kcal\,mol^{-1}/RT] \quad (b)$$

238 °C: $\Delta H^{\neq} = (26.77 \pm 0.09)\,kcal\,mol^{-1}$; $\Delta S^{\neq} = -(23.93 \pm 0.17)\,cal\,mol^{-1}\,K^{-1}$

The activation volumes are determined from the pressure dependence of the rate constants in solution at 153.2 °C (Table 1) to be $\Delta V^{\neq} = -24.8\,cm^3\,mol^{-1}$ for both reactions and are twice as large as that of the Cope rearrangement and the electrocyclization. From this it can be extrapolated that each additional five- or six-membered ring formed in the transition state contributes about -10 to $-12\,cm^3\,mol^{-1}$ to the activation volume. The activation volume therefore yields important information about transition state geometries.

Scheme 3. Thermolysis of (*Z*)-**10** to (*Z*)-**13** or *cis*-**12**. The product ratios at 1 bar and 7.7 kbar are shown.

A particularly instructive example is the thermolysis of (*Z*)-1,3,8-nonatriene [(*Z*)-**10**],[21] in which an intramolecular Diels–Alder reaction leading to *cis*-**12** competes with a sigmatropic [1,5]-hydrogen shift leading to (1,5*E*,7*Z*)-nonatriene (**13**, Scheme 3). The use of high pressure here enables a reversal of the selectivity. At 150 °C and 1 bar the 1,5-hydrogen shift is preferred to the monocyclic transition state **14**‡. At 7.7 bar, on the other hand, the intramolecular Diels–Alder reaction is preferred to the bicyclic transition state **15**‡.

[13] The rate of the rearrangements described here were determined at various pressures in a 7 kbar autoclave that could be held at a constant temperature (±0.2 °C). Samples of about 100 µL were removed from the compressed solutions (about 10 mL) by means of a precise dispensing valve and were analyzed by HPLC or GC.

[14] The investigation of the pressure effect in the rearrangement of 2,5-diphenylhexa-1,5-diene, for which a 1,4-diphenylcyclohexa-1,4-diyl intermediate is assumed [8], is under way.

[15] a) The following Arhenius equations were calculated from the temperature dependence of the rate constants k, measured in hexane at five temperatures between 133 and 174 °C: k(*meso*-**3** → (*E,Z*)-**6**) = $4.68 \times 10^{10}\ s^{-1} \exp[-(28.54 \pm 0.33)\ kcal\,mol^{-1}/RT^{-1}]$, from which the following parameters were derived (153.2 °C): $\Delta H^{\ddagger} = (27.69 \pm 0.33)\ kcal\,mol^{-1}$; $\Delta S^{\ddagger} = -(12.43 \pm 0.71)\ cal\,mol^{-1}\,K^{-1}$. k(*meso*-**3** → (*E,E*)-**6**) = $1.58 \times 10^{11}\ s^{-1} \exp[-(29.85 \pm 0.30)\ kcal\,mol^{-1}/RT]$, from which the following parameters were derived (153.2 °C): $\Delta H^{\ddagger} = (29.01 \pm 0.30)\ kcal\,mol^{-1}$; $\Delta S^{\ddagger} = -(9.99 \pm 0.70)\ cal\,mol^{-1}\,K^{-1}$. The activation enthalpies of the rearrangements of *meso*-**3** to (*E,Z*)-**6** and (*E,E*)-**6** are, respectively, 3.7 and 5.0 kcal mol^{-1} larger than those of the Cope rearrangement of *rac*-**3** to (*E,E*)-**6** ($\Delta H^{\ddagger} = 24.0\ kcal\,mol^{-1}$; $\Delta S^{\ddagger} = -12.4\ cal\,mol^{-1}\,K^{-1}$) [12], a fact that is certainly due to steric effects in the *cis*-configured transition state. From the activation enthalpies and the enthalpies of formation calculated with the force field MM2ERW for *meso*-**3** and *rac*-**3** (ΔH_f = 73.8 and 73.5 kcal mol^{-1} respectively)[8], the enthalpies of formation of the transition states for the reactions *meso*-**3** → (*E,Z*)-**6** (ΔH_f° = 101.5 kcal mol^{-1}), *meso*-**3** → (*E,E*)-**6** (ΔH_f° = 102.8 kcal mol^{-1}) and *rac*-**3** → (*E,E*)-**6** (ΔH_f = 97.5 kcal mol^{-1}) could be calculated. The enthalpies of formation thus obtained for the transition states are, without exception, 12 to 17 kcal mol^{-1} lower than the enthalpies of formation, also calculated with the MM2ERW force field, for the potential diradical intermediates *cis*- and *trans*-2,3-diphenylcyclohexa-1,4-diyl (*cis*-chair: ΔH_f° = 118.2 kcal mol^{-1}; twisted *cis*-boat (twist-boat [8]): ΔH_f° = 120.1 kcal mol^{-1}; *trans*-chair: ΔH_f° = 113.8 kcal mol^{-1}) or those of the free radicals resulting from the homolysis of the C-3–C-4 bond (2 × 1-phenylallyl: $\Delta H_f^{\circ} = 2 \times 57.2 = 114.4\ kcal\,mol^{-1}$) [8]. It is, therefore, unlikely that a diradical rearrangement *meso*-**3** → (*E,E*)-**6** occurs as proposed by one of the referees. b) W. von E. Doering, W. R. Roth, R. Breuckmann, L. Figge, H.-W. [20] From the activation enthalpies of the reactions (*E*)-**10** → *cis*-**12** and (*E*)-**10** → *trans*-**12** as well as the enthalpy of formation calculated with the force field MM2ERW [15b, c] for (*E*)-**10** (ΔH_f° = 25.9 kcal mol^{-1}), enthalpies of formation for the transition states were calculated: ΔH_f° = 51.7 and 53.0 kcal mol^{-1} respectively. Comparison with the enthalpy of formation of the energetically favored, potential diradical intermediate cyclonon-2-ene-1,6-diyl (ΔH_f° = 67.6 kcal mol^{-1}) also calculated with the MM2ERW force field yielded values of about −16 and −15 kcal mol^{-1} for the transition state resonance energy (TS-RE, energy of concert); thus the two intramolecular Diels–Alder reactions certainly take place by pericyclic processes.

[21] From a mixture of (*Z*)- and (*E*)-**10**, (about 1:1) prepared in a Wittig reaction of (2-propenylidene)triphenylphosphorane [22] and 5-hexenal [23], isomerically pure (*Z*)-**10** was obtained by allowing the (*E*)-**10** to react with maleic anhydride in a selective Diels–Alder reaction and separating the unconverted (*Z*)-**10** from the adduct by column chromatography.

Polymorphism and C=N–N=C Conformational Isomers of Azines: X-ray Crystal and Ab Initio Structures of Two Rotational Isomers of Methyl (*para*-Tolyl) Ketone Azine**

Grace Shiahuy Chen, Mitchell Anthamatten, Charles L. Barnes, and Rainer Glaser*

Azines are important substrates for crisscross additions and their organometallic variants,[2, 3] they react as the "ene" component in [3+2] additions,[4] and they are becoming increasingly important for C–C bond forming reactions.[5] Azines also are receiving increasing attention for their biological,[6] chemical,[7] and physical properties.[8] The characterization of the electronic structure of azines is fundamental to the understanding and the advancement of their chemistry. We have been studying the stereochemistry and stereoelectronics of azines in a systematic fashion,[1] and we report here on the rotamers of methyl (*para*-tolyl) ketone azine, **I**.

Compound **I** was prepared from methyl (*para*-tolyl) ketone and hydrazine hydrate in acidic ethanol.[9] Yellow single

Samples of about 100 µL were removed from the compressed solutions (about 10 mL) by means of a precise dispensing valve and were analyzed by HPLC or GC.

[14] The investigation of the pressure effect in the rearrangement of 2,5-diphenylhexa-1,5-diene, for which a 1,4-diphenylcyclohexa-1,4-diyl intermediate is assumed [8], is under way.

[15] a) The following Arhenius equations were calculated from the temperature dependence of the rate constants k, measured in hexane at five temperatures between 133 and 174 °C: k(*meso*-**3** → (*E,Z*)-**6**) = $4.68 \times 10^{10}\ s^{-1} \exp[-(28.54 \pm 0.33)\ kcal\,mol^{-1}/RT^{-1}]$, from which the following parameters were derived (153.2 °C): $\Delta H^{\ddagger} = (27.69 \pm 0.33)\ kcal\,mol^{-1}$; $\Delta S^{\ddagger} = -(12.43 \pm 0.71)\ cal\,mol^{-1}\,K^{-1}$. k(*meso*-**3** → (*E,E*)-**6**) = $1.58 \times 10^{11}\ s^{-1} \exp[-(29.85 \pm 0.30)\ kcal\,mol^{-1}/RT]$, from which the following parameters were derived (153.2 °C): $\Delta H^{\ddagger} = (29.01 \pm 0.30)\ kcal\,mol^{-1}$; $\Delta S^{\ddagger} = -(9.99 \pm 0.70)\ cal\,mol^{-1}\,K^{-1}$. The activation enthalpies of the rearrangements of *meso*-**3** to (*E,Z*)-**6** and (*E,E*)-**6** are, respectively, 3.7 and 5.0 kcal mol^{-1} larger than those of the Cope rearrangement of *rac*-**3** to (*E,E*)-**6** ($\Delta H^{\ddagger} = 24.0\ kcal\,mol^{-1}$; $\Delta S^{\ddagger} = -12.4\ cal\,mol^{-1}\,K^{-1}$) [12], a fact that is certainly due to steric effects in the *cis*-configured transition state. From the activation enthalpies and the enthalpies of formation calculated with the force field MM2ERW for *meso*-**3** and *rac*-**3** (ΔH_f = 73.8 and 73.5 kcal mol^{-1} respectively)[8], the enthalpies of formation of the transition states for the reactions *meso*-**3** → (*E,Z*)-**6** (ΔH_f° = 101.5 kcal mol^{-1}), *meso*-**3** → (*E,E*)-**6** (ΔH_f° = 102.8 kcal mol^{-1}) and *rac*-**3** → (*E,E*)-**6** (ΔH_f = 97.5 kcal mol^{-1}) could be calculated. The enthalpies of formation thus obtained for the transition states are, without exception, 12 to 17 kcal mol^{-1} lower than the enthalpies of formation, also calculated with the MM2ERW force field, for the potential diradical intermediates *cis*- and *trans*-2,3-diphenylcyclohexa-1,4-diyl (*cis*-chair: ΔH_f° = 118.2 kcal mol^{-1}; twisted *cis*-boat (twist-boat [8]): ΔH_f° = 120.1 kcal mol^{-1}; *trans*-chair: ΔH_f° = 113.8 kcal mol^{-1}) or those of the free radicals resulting from the homolysis of the C-3–C-4 bond (2 × 1-phenylallyl: $\Delta H_f^{\circ} = 2 \times 57.2 = 114.4\ kcal\,mol^{-1}$) [8]. It is, therefore, unlikely that a diradical rearrangement *meso*-**3** → (*E,E*)-**6** occurs as proposed by one of the referees. b) W. von E. Doering, W. R. Roth, R. Breuckmann, L. Figge, H.-W. [20] From the activation enthalpies of the reactions (*E*)-**10** → *cis*-**12** and (*E*)-**10** → *trans*-**12** as well as the enthalpy of formation calculated with the force field MM2ERW [15b, c] for (*E*)-**10** (ΔH_f° = 25.9 kcal mol^{-1}), enthalpies of formation for the transition states were calculated: ΔH_f° = 51.7 and 53.0 kcal mol^{-1} respectively. Comparison with the enthalpy of formation of the energetically favored, potential diradical intermediate cyclonon-2-ene-1,6-diyl (ΔH_f° = 67.6 kcal mol^{-1}) also calculated with the MM2ERW force field yielded values of about −16 and −15 kcal mol^{-1} for the transition state resonance energy (TS-RE, energy of concert); thus the two intramolecular Diels–Alder reactions certainly take place by pericyclic processes.

[21] From a mixture of (*Z*)- and (*E*)-**10**, (about 1:1) prepared in a Wittig reaction of (2-propenylidene)triphenylphosphorane [22] and 5-hexenal [23], isomerically pure (*Z*)-**10** was obtained by allowing the (*E*)-**10** to react with maleic anhydride in a selective Diels–Alder reaction and separating the unconverted (*Z*)-**10** from the adduct by column chromatography.

Polymorphism and C=N–N=C Conformational Isomers of Azines: X-ray Crystal and Ab Initio Structures of Two Rotational Isomers of Methyl (*para*-Tolyl) Ketone Azine**

Grace Shiahuy Chen, Mitchell Anthamatten, Charles L. Barnes, and Rainer Glaser*

Azines are important substrates for crisscross additions and their organometallic variants,[2, 3] they react as the "ene" component in [3+2] additions,[4] and they are becoming increasingly important for C–C bond forming reactions.[5] Azines also are receiving increasing attention for their biological,[6] chemical,[7] and physical properties.[8] The characterization of the electronic structure of azines is fundamental to the understanding and the advancement of their chemistry. We have been studying the stereochemistry and stereoelectronics of azines in a systematic fashion,[1] and we report here on the rotamers of methyl (*para*-tolyl) ketone azine, **I**.

Compound **I** was prepared from methyl (*para*-tolyl) ketone and hydrazine hydrate in acidic ethanol.[9] Yellow single

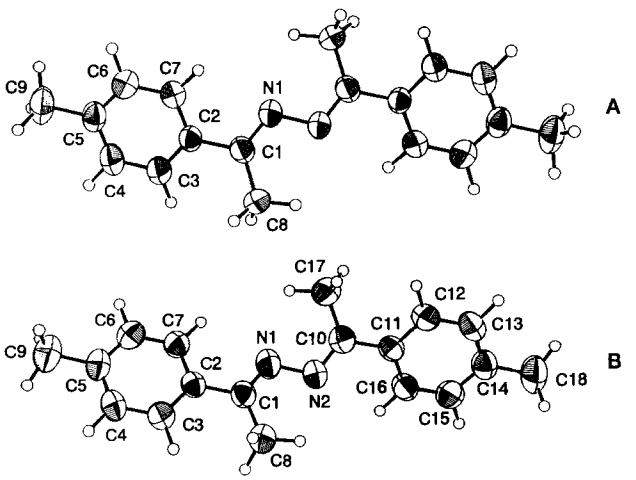
[**] Stereochemistry and Stereoelectronics of Azines, Part 3. This research was supported by the Petroleum Research Fund of the American Chemical Society, the Research Board of the University of Missouri, and the National Science Foundation, and is part of the projected Ph.D. dissertation of G. S. Chen. – Parts 1 and 2: [1].

crystals[10] suitable for X-ray crystallography were formed from a solution of **I** in methylene chloride by vapor diffusion of *n*-hexane. **I** cocrystallizes in two monoclinic racemic modifications,[11] space groups $P2_1/n$ and $P2_1/c$. The two independent molecules **A** and **B** are shown in Figure 1. Both assume the (*E*,*E*) configuration in which the large groups attached to the C=N bonds are *trans*. In general, the configurations of azines are governed by steric factors and result in "*trans*–*trans* structures" which, depending on the priorities of the attached groups, are (*E*,*E*)[12] or (*Z*,*Z*) configured.[1a, 13] The stereochemistry of the azines with regard to the N–N single bond is the focus of the present study.



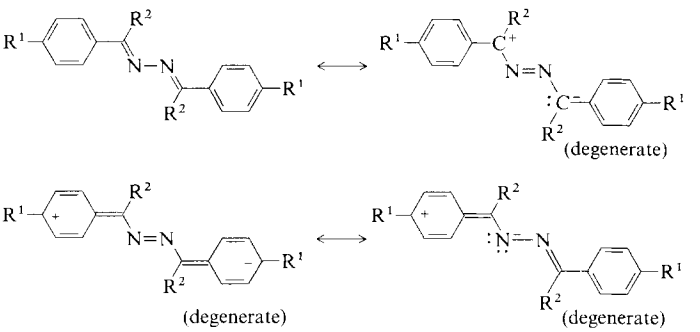


Fig. 1. ORTEPII drawings of the azines **A** (top) and **B** (bottom) with the numbering scheme.

The crystal structures of azines reported previously all show either N–N s-*trans* or *gauche* conformations, and only two cases are known in which *both* conformations occur in polymorphous crystals.[14] In the case of **I** molecule **A** exhibits a *trans* conformation with a C-N-N-C torsion angle τ of 180°, while **B** shows a *gauche* conformation with $\tau = 142.8°$. Similarly, for the azine of 3-acetyl-4-(2-chlorophenyl)-4-hydroxy-2-methoxycrotonic acid lactone, **II**,[15] the *trans* and *gauche* conformers crystallize in different modifications. Our study is of particular significance, as **I** contains phenyl substituents and allows for the first experimental examination of conjugation effects in azines as a function of the N–N conformation. The importance of such solid-state studies has been emphasized by the recent studies by the research groups led by Brock, Grützmacher, and Gompper.[16]

Molecule **A** has a center of inversion, and the phenyl rings are twisted out of the best molecular plane by $\theta_1 = \theta_2 = 23.7°$ (see Table 1 for a definition of the angles). These phenyl conformations would allow for only attenuated conjugation with the azine fragment even though the N–N s-*trans* conformation is best suited for conjugation through the entire azine system (Scheme 1). The C–N bond lengths are 1.279 Å, similar to that in formaldoxime (1.276 Å).[17] The N–N bond lengths of 1.405 Å in **A** are shorter than the generally accepted N–N single bond length of 1.47 Å,[18] but this shortening is expected for N–N bonds between sp^2-hybridized N atoms and cannot be interpreted as an indication of conjugation. Such hybridization effects are also found for the C–C bonds between the azine C and the aromatic C atom; the bond lengths of 1.482 Å agree with the normal $C_{sp^2}-C_{sp^2}$ single bond length of 1.48 Å.[19]

Scheme 1. Is conjugation with the azine fragment (top) or within the Ar-C-N fragment (bottom) important? Not all resonance forms are shown, and only one form is shown for degenerate structures $R^1 = R^2 = CH_3$.

Thus, neither the C–N and N–N bonds nor the C_{ipso}–C bonds show clear structural indications of phenyl conjugation. This result supports the conclusion we made previously by comparative analysis of related phenyl-substituted azines.[1a, 20]

The N–N and C–N bonds in **A** and **B** differ by no more than 0.002 Å, which leads us to the important conclusion that they are essentially independent of the conformation. Thus, conjugation within the azine functional group cannot be significant for **I**.

In **B** one phenyl ring is twisted only slightly ($\theta_1 = 0.5°$), while the torsion angle of the other is more significant ($\theta_2 = 19.9°$). Structure **B** gives us the unique opportunity of examining the possibility of partial conjugation over the fragment Ar–C–N (Scheme 1, bottom) with experimental data. Surprisingly, the C–N bond in the fragment with the N-C-C_{ipso}-C_{ortho} dihedral angle of 0.5° is 0.005 Å *shorter* than that in the fragment with the more marked torsion angle (19.9°). Moreover, the C–C_{ipso} bond in the first fragment is 0.012 Å *longer* than the analogous bond in the second. The latter C–C_{ipso} bond is virtually identical to those in **A**. These structural data provide strong evidence against significant conjugative interactions in the fragment Ar–C–N. We have shown for Ph(HOOC)C=N–N=CH_2[1a] that the barrier to rotation about the Ph–C bond is less than 5 kcal mol^{-1}, and the present analysis corroborates the conclusions of the theoretical study.

Based on the *gauche* preference of formaldazine, according to CNDO/2 calculations, Ishida et al. concluded that *gauche*-**II** would be thermodynamically preferred over *trans*-**II**. However, higher level ab initio studies of the N–N rotational profile of formaldazine[21] show that the *gauche*-**II** structure is over 2 kcal mol^{-1} less stable than *trans*-**II**. Hence, Ishida's conclusion requires revision. We have investigated the energetic preferences of **I** with all-electron ab initio calculations at the RHF/6-31G* level.[22] We completely optimized **I** (C_1) at the RHF/3-21G level, and the de facto D_{2h}-symmetric N–N s-*trans* structure **1** resulted (Fig. 2 and Table 1). Since no *gauche* conformer exists on the potential energy surface, a model for the *gauche* structure, **2**, was obtained by optimizing **I** with the single constraint of $\tau = 142.8$ (τ angle in **B**). The s-*trans* structure **1** is

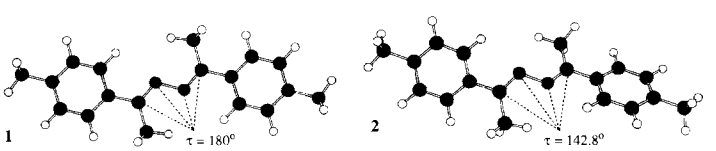

Fig. 2. RHF/3-21G-optimized structures of methyl (*para*-methylphenyl) ketone azine **I**. The planar N–N s-*trans* structure **1** is the minimum; the *gauche* structure **2** was obtained with the constraint C-N-N-C = 142.8°.

[a] Lengths in Å and angles in degrees. The standard deviations given in parentheses refer to the last digit(s). [b] Structures **1** (optimized in C_1 symmetry, de facto D_{2h} symmetry) and **2** (optimized in C_1 symmetry with C-N-N-C fixed to 142.8°) calculated at the RHF/3-21G level. [c] For atom numbering see Fig. 1. [d] Total and relative energies in Hartrees and kcal mol^{-1}, respectively. Vibrational zero-point energy for the minimum **1** is 227.21 kcal mol^{-1} (RHF/3-21G). [e] Symmetry equivalent to another structural parameter.

preferred over structure **2** by 0.36 kcal mol^{-1} at the RHF/6-31G*//RHF/3-21G level. This theoretical result demonstrates in a compelling fashion that the activation energy required for τ variations between the N–N s-*trans* and *gauche* structures is very small. Hence, small differences in packing interactions in polymorphous crystals suffice to overcome the intrinsic *trans* preference, and solid-state structures with *gauche* molecules also are realized.

Molecule **1** is inversion symmetric and planar, and **2** is C_2-symmetric with azine-phenyl and azine-methyl group twists of 9.7° and 2.2°, respectively. The N–N bonds are about 0.025 Å longer than in the solid-state *trans* and *gauche* conformers, while the C–N bonds are shorter by 0.011 Å.[23] The C–C_{ipso} bond lengths in the gas phase are the same as the corresponding bond in the fragment with $\theta_1 = 0.5°$ in **B** and slightly longer than the others. As was found for the solid-state structures, the important conclusion here is that the conformation dependence of the main structural parameters is minor: for **1** and **2**, all bond lengths are almost the same and the angles differ by less than 1°.

The ^{1}H, ^{13}C, and ^{15}N NMR spectra recorded for **I** show the presence of one isomer in solution. Similarly, the two modifications of **II** give the same ^{1}H NMR spectrum. Therefore, either one centrosymmetric isomer exists in solution or *gauche* enantiomers are found in a fast equilibrium. Our ab initio results favor the former alternative.

Sinha suggested, "there is thus no doubt that ... an excited [diradical] structure ... must also contribute ..." to the ground state of benzaldazine.[24] If the diradical resonance form (Scheme 2) were to contribute to the ground states of phenyl-substituted azines, one would predict that its importance would increase if radical-stabilizing groups were placed in the *para* positions. We examined this prediction by comparison of **1** to the *trans* conformer of unsubstituted methyl phenyl ketone azine[1b] and found that the lengths of the calculated C–N, N–N, and C_{ipso}–C bonds of two D_{2h} structures *are the same.*

Scheme 2. Diradical resonance forms for aryl-substituted azines as suggested by Sinha.

Our analysis thus demonstrates that the resonance form suggested by Sinha plays no major role for the ground state, although other resonance forms may be important for the description of electronically excited states and in discussions of the UV/VIS spectroscopic properties of azines.

Experimental Procedure

Hydrazine hydrate (8 mmol) was added dropwise to a solution of methyl (*para*-tolyl) ketone (10 mmol) in 5 mL of ethanol, and 1 drop of concentrated HCl was then added. The solution was refluxed for 40 min and yellow crystals formed after cooling. M.p. 134–135 °C; ^{1}H NMR (500 MHz, $CDCl_3$): δ = 2.29 (s, 6H; CH_3), 2.38 (s, 6H; CH_3), 7.21 (d, J = 8.1 Hz, 4H; ArH), 7.80 (d, J = 8.1 Hz, 4H; ArH); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 14.8, 21.3, 126.6, 129.0, 135.7, 139.6, 157.6; ^{15}N NMR (51 MHz, CD_2Cl_2): δ = 29.6 [25].

Isolation of RNA Aptamers for Biological Cofactors by In Vitro Selection**

Petra Burgstaller and Michael Famulok*

In vitro selection enables the simultaneous screening of a large number ($\geq 10^{15}$) of different DNA or RNA sequences for certain functionalities. In vitro selection experiments encompass a number of sequential steps, in which the first is always the synthesis of a library of random DNA sequences. After amplification of the DNA by polymerase chain reaction (PCR), an RNA pool is produced by transcription in vitro. Those RNAs (aptamers) that specifically bind to the target molecule are selected from this RNA pool, for example, by affinity chromatography.[1, 2] Such specific ligand-binding nucleic acids not only can have use as potential lead structures for protein inhibitors,[3] but can also help to increase our understanding of the biochemically important recognition processes that involve the interaction of RNA with substrates such as nucleotides, proteins, peptides, amino acids, metal ions, and antibiotics. Furthermore, detailed knowledge of this kind could facilitate the development of new ribozymes.

We report here on the isolation of RNA motifs that bind to the flavin portion of flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN). In addition, selection experiments were performed in order to isolate RNA aptamers for nicotinamide adenine dinucleotide (NAD^+) and nicotinamide mononucleotide (NMN^+) (Scheme 1).

Scheme 1. The FMN, NAD^+, and NMN^+ ligands employed in the selection, and 7,8-dimethylalloxazine which was employed for investigating the binding specificity.

For the selections we used a pool of ^{32}P-labeled RNA 113-mers with a complexity of 10^{15} different sequences which consisted of a random sequence of 74 nucleotides flanked by two defined primer binding sites. By means of affinity chromatography with agarose derivatized with the given cofactor, those RNA sequences were enriched that were bound to agarose and eluted with a solution containing the appropriate ligand (Scheme 2, Table 1).

After six cycles significant amounts of the RNA were bound to the FMN and NAD^+ columns. Binding to the FAD matrix could be detected after four cycles, whereas enrichment of

Scheme 2. a) The design of the DNA library for the synthesis of the RNA pools employed. The framed sequence is the T7-promoter, the underlined sequences the restriction sites for the subsequent cloning. b) A schematic representation of the in vitro selection cycle. The RNA was loaded onto the preselection column (0.5 mL adipic acid dihydrazide agarose) and eluted from the column with 1.0 mL of a buffer solution (250 mM NaCl; 50 mM tris-HCL, pH 7.6; 5 mM $MgCl_2$). Nonbinding RNAs were separated by washing with five column volumes of the buffer solution. Bound RNAs were eluted with a buffer solution of the ligand and then treated with reverse transcriptase (50 mM Tris-HCl, pH 8.3; 75 mM KCl; 3 mM $MgCl_2$; 10 mM dithiothreitol (DTT), 0.3% TWEEN 100; 0.4 mM of one of the deoxynucleotide triphosphates dATP, TTP, dGTP, dCTP; 1 μM primer M20.106; 40 U Superscript reverse transcriptase; 45 min reaction at 42 °C). The cDNA was amplified with PCR (10 mM tris-HCL, pH 8.3; 50 mM KCl; 0.01% gelatine; 1.5 mM $MgCl_2$; 0.3% TWEEN 100; 0.2 mM one of the deoxynucleotide triphosphates dATP, TTP, dGTP, dCTP; 3.0 μM primer M38.27; 3.0 μM primer M20.106; 2.5 U 100 μL^{-1} TAQ DNA polymerase; conditions of cycle: 94 °C - 1 min, 55 °C - 2 min, 72 °C - 2 min), the PCR-DNA is transcribed (40 mM tris-HCL, pH 7.9; 6.8 mM spermidine; 22 mM $MgCl_2$; 0.01% Triton X-100; 5 mM of the nucleotide triphosphates ATP, UTP, GTP, CTP; 10 mM DTT; 50 U T7 RNA polymerase; 1–2 μCi α-^{32}P-GTP; reaction for 16 h at 37 °C). The selection cycle can now be repeated with the enriched RNA pool.

NMN^+ was not evident after eight cycles of selection/amplification. The FMN-, FAD-, and NAD^+-selected RNA pools from the last of the respective cycles listed in Table 1 were treated with reverse transcriptase and the cDNA amplified with PCR and cloned. We sequenced 17 clones from the FMN-, 14 from the FAD-, and 16 from the NAD^+-selected RNA pools (Scheme 3).

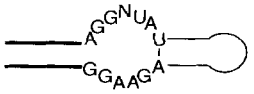

Table 1. Bound fraction [%] of RNA used in the selection cycle. The values represent the fraction of bound RNA that was eluted from the column with the corresponding ligand in the buffer solution; the column was previously washed with five column volumes of buffer solution.

Selection cycle	FMN	FAD	NAD^+	NMN^+
1	0.09	0.11	0.13	0.07
2	1.74	1.20	0.75	0.10
3	1.31	0.14	0.27	0.55
4	0.23	11.09	0.95	0.11
5	0.48	21.38	1.63	0.17
6	33.03		16.07	1.44
7	38.60		36.40	0.12
8				0.33

Thirteen of the FMN-binding RNAs contained two conserved regions with the sequences AGGNUAU and AGAAGG (the sequence of the clone FMN-2 occurred three times). Both consensus sequences are flanked by variable nucleotides, which pair together to form a defined secondary structure. The monoclonal RNAs of the FMN-2, FMN-7, FMN-12, and FMN-15 sequences all have affinity for FMN. By means of analytical affinity chromatography[4] we determined the dissociation constant K_d for the FMN-2 aptamer/FMN complex. The specificity of this RNA was quantified by elution with 7,8-dimethylalloxazine (**1**), FAD, ATP, and GTP. Based on the conserved secondary structure we constructed an RNA sequence of 35 bases (35FMN-2 = 5′-GGCGUGUAGGAUAUCGUGUUCGAGAAGGACACGCC-3′). For the binding of 35FMN-2 and FMN-2 to FMN a K_d of around 0.5 μM was measured. The ribose moiety of FMN was not recognized by the aptamers, as both FMN-2 and 35FMN-2 bind to **1**. Both of these aptamers show very low affinity for adenosine triphosphate (ATP) and do not bind to guanosine triphosphate (GTP) at all. As expected, they bind to FAD with similar values of K_d as for binding to FMN (Table 2).

Four of the fourteen FAD-binding RNAs were identical to the FMN-2 clone. The FAD-3 clone can form the same secondary structure. In comparison to all the other sequences that form this motif, the two consensus sequences are in reversed
